One- and Three-Letter Symbols for the Amino Acids^a

A	Ala	Alanine
B	Asx	Asparagine or aspartic acid
C	Cys	Cysteine
D	Asp	Aspartic acid
E	Glu	Glutamic acid
F	Phe	Phenylalanine
G	Gly	Glycine
H	His	Histidine
I	Ile	Isoleucine
K	Lys	Lysine
L	Leu	Leucine
M	Met	Methionine
N	Asn	Asparagine
P	Pro	Proline
Q	Gln	Glutamine
R	Arg	Arginine
S	Ser	Serine
T	Thr	Threonine
V	Val	Valine
W	Trp	Tryptophan
Y	Tyr	Tyrosine
Z	Glx	Glutamine or glutamic acid

^aThe one-letter symbol for an undetermined or nonstandard amino acid is X.

Thermodynamic Constants and Conversion Factors

Joule (J)

$$1 \text{ J} = 1 \text{ kg}\cdot\text{m}^2\cdot\text{s}^{-2} \quad 1 \text{ J} = 1 \text{ C}\cdot\text{V} \text{ (coulomb volt)}$$

$$1 \text{ J} = 1 \text{ N}\cdot\text{m} \text{ (newton meter)}$$

Calorie (cal)

$$1 \text{ cal heats } 1 \text{ g of H}_2\text{O from } 14.5 \text{ to } 15.5^\circ\text{C}$$

$$1 \text{ cal} = 4.184 \text{ J}$$

Large calorie (Cal)

$$1 \text{ Cal} = 1 \text{ kcal} \quad 1 \text{ Cal} = 4184 \text{ J}$$

Avogadro's number (N)

$$N = 6.0221 \times 10^{23} \text{ molecules}\cdot\text{mol}^{-1}$$

Coulomb (C)

$$1 \text{ C} = 6.241 \times 10^{18} \text{ electron charges}$$

Faraday (F)

$$1 \text{ F} = N \text{ electron charges}$$

$$1 \text{ F} = 96,485 \text{ C}\cdot\text{mol}^{-1} = 96,485 \text{ J}\cdot\text{V}^{-1}\cdot\text{mol}^{-1}$$

Kelvin temperature scale (K)

$$0 \text{ K} = \text{absolute zero} \quad 273.15 \text{ K} = 0^\circ\text{C}$$

Boltzmann constant (k_B)

$$k_B = 1.3807 \times 10^{-23} \text{ J}\cdot\text{K}^{-1}$$

Gas constant (R)

$$R = Nk_B \quad R = 1.9872 \text{ cal}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$$

$$R = 8.3145 \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1} \quad R = 0.08206 \text{ L}\cdot\text{atm}\cdot\text{K}^{-1}\cdot\text{mol}^{-1}$$

The Standard Genetic Code

First Position (5' end)	Second Position				Third Position (3' end)
	U	C	A	G	
U	UUU Phe	UCU Ser	UAU Tyr	UGU Cys	U
	UUC Phe	UCC Ser	UAC Tyr	UGC Cys	C
	UUA Leu	UCA Ser	UAA Stop	UGA Stop	A
	UUG Leu	UCG Ser	UAG Stop	UGG Trp	G
C	CUU Leu	CCU Pro	CAU His	CGU Arg	U
	CUC Leu	CCC Pro	CAC His	CGC Arg	C
	CUA Leu	CCA Pro	CAA Gln	CGA Arg	A
	CUG Leu	CCG Pro	CAG Gln	CGG Arg	G
A	AUU Ile	ACU Thr	AAU Asn	AGU Ser	U
	AUC Ile	ACC Thr	AAC Asn	AGC Ser	C
	AUA Ile	ACA Thr	AAA Lys	AGA Arg	A
	AUG Met ^a	ACG Thr	AAG Lys	AGG Arg	G
G	GUU Val	GCU Ala	GAU Asp	GGU Gly	U
	GUC Val	GCC Ala	GAC Asp	GGC Gly	C
	GUA Val	GCA Ala	GAA Glu	GGA Gly	A
	GUG Val	GCG Ala	GAG Glu	GGG Gly	G

^aAUG forms part of the initiation signal as well as coding for internal Met residues.

In memory of Alexander Rich (1924-2015), a trailblazing molecular biologist and a mentor to numerous eminent scientists

Vice President & Director: Petra Recter
Development Editor: Joan Kalkut
Associate Development Editor: Alyson Rentrop
Senior Marketing Manager: Kristine Ruff
Senior Production Editor: Elizabeth Swain
Senior Designers: Maddy Lesure and Tom Nery
Cover Designer: Tom Nery
Product Designer: Sean Hickey
Senior Product Designer: Geraldine Osnato
Photo Editor: Billy Ray

Cover molecular art credits (left to right): Bacteriorhodopsin, based on an X-ray structure determined by Nikolaus Grigorieff and Richard Henderson, MRC Laboratory of Molecular Biology, Cambridge, U.K. Glutamine synthetase, based on an X-ray structure determined by David Eisenberg, UCLA. The KcsA K⁺ channel based on an X-ray structure determined by Roderick MacKinnon, Rockefeller University.

This book was typeset in 10.5/12 STIX at Aptara and printed and bound at Quad Versailles. The cover was printed by Quad Versailles.

Founded in 1807, John Wiley & Sons, Inc. has been a valued source of knowledge and understanding for more than 200 years, helping people around the world meet their needs and fulfill their aspirations. Our company is built on a foundation of principles that include responsibility to the communities we serve and where we live and work. In 2008, we launched a Corporate Citizenship Initiative, a global effort to address the environmental, social, economic, and ethical challenges we face in our business. Among the issues we are addressing are carbon impact, paper specifications and procurement, ethical conduct within our business and among our vendors, and community and charitable support. For more information, please visit our website: www.wiley.com/go/citizenship.

The paper in this book was manufactured by a mill whose forest management programs include sustained yield-harvesting of its timberlands. Sustained yield harvesting principles ensure that the number of trees cut each year does not exceed the amount of new growth.

This book is printed on acid-free paper.

ABOUT THE AUTHORS

Donald Voet received his B.S. in Chemistry from the California Institute of Technology in 1960, a Ph.D. in Chemistry from Harvard University in 1966 under the direction of William Lipscomb, and then did his postdoctoral research in the Biology Department at MIT with Alexander Rich. Upon completion of his postdoc in 1969, Don became a faculty member in the Chemistry Department at the University of Pennsylvania, where he taught a variety of biochemistry courses as well as general chemistry and X-ray crystallography. Don's research has focused on the X-ray crystallography of molecules of biological interest. He has been a visiting scholar at Oxford University, U.K., the University of California at San Diego, and the Weizmann Institute of Science in Israel. Don is the coauthor of four previous editions of *Fundamentals of Biochemistry* (first published in 1999) as well as four editions of *Biochemistry*, a more advanced textbook (first published in 1990). Together with Judith G. Voet, Don was Co-Editor-in-Chief of the journal *Biochemistry and Molecular Biology Education* from 2000 to 2014. He has been a member of the Education Committee of the International Union of Biochemistry and Molecular Biology (IUBMB) and continues to be an invited speaker at numerous national and international venues. He, together with Judith G. Voet, received the 2012 award for Exemplary Contributions to Education from the American Society for Biochemistry and Molecular Biology (ASBMB). His hobbies include backpacking, scuba diving, skiing, travel, photography, and writing biochemistry textbooks.

Judith (“Judy”) Voet was educated in the New York City public schools, received her B.S. in Chemistry from Antioch College, and her Ph.D. in Biochemistry from Brandeis University under the direction of Robert H. Abeles. She did postdoctoral research at the University of Pennsylvania, Haverford College, and the Fox Chase Cancer Center. Judy's main area of research involves enzyme reaction mechanisms and inhibition. She taught biochemistry at the University of Delaware before moving to Swarthmore College, where she taught biochemistry, introductory chemistry, and instrumental methods for 26 years, reaching the position of James

H. Hammons Professor of Chemistry and Biochemistry and twice serving as department chair before going on “permanent sabbatical leave.” Judy has been a visiting scholar at Oxford University, U.K., University of California, San Diego, University of Pennsylvania, and the Weizmann Institute of Science, Israel. She is a coauthor of four previous editions of *Fundamentals of Biochemistry* and four editions of the more advanced text, *Biochemistry*. Judy was Co-Editor-in-Chief of the journal *Biochemistry and Molecular Biology Education* from 2000 to 2014. She has been a National Councilor for the American Chemical Society (ACS) Biochemistry Division, a member of the Education and Professional Development Committee of the American Society for Biochemistry and Molecular Biology (ASBMB), and a member of the Education Committee of the International Union of Biochemistry and Molecular Biology (IUBMB). She, together with Donald Voet, received the 2012 award for Exemplary Contributions to Education from the ASBMB. Her hobbies include hiking, backpacking, scuba diving, tap dancing, and playing the Gyl (an African xylophone).

Charlotte Pratt received her B.S. in Biology from the University of Notre Dame and her Ph.D. in Biochemistry from Duke University under the direction of Salvatore Pizzo. Although she originally intended to be a marine biologist, she discovered that biochemistry offered the most compelling answers to many questions about biological structure–function relationships and the molecular basis for human health and disease. She conducted postdoctoral research in the Center for Thrombosis and Hemostasis at the University of North Carolina at Chapel Hill. She has taught at the University of Washington and currently teaches and supervises undergraduate researchers at Seattle Pacific University. Developing new teaching materials for the classroom and student laboratory is a long-term interest. In addition to working as an editor of several biochemistry textbooks, she has co-authored *Essential Biochemistry* and previous editions of *Fundamentals of Biochemistry*. When not teaching or writing, she enjoys hiking and gardening.

BRIEF CONTENTS

PART I INTRODUCTION

- 1 Introduction to the Chemistry of Life 1
- 2 Water 23

PART II BIOMOLECULES

- 3 Nucleotides, Nucleic Acids, and Genetic Information 42
- 4 Amino Acids 80
- 5 Proteins: Primary Structure 97
- 6 Proteins: Three-Dimensional Structure 131
- 7 Protein Function: Myoglobin and Hemoglobin, Muscle Contraction, and Antibodies 180
- 8 Carbohydrates 221
- 9 Lipids and Biological Membranes 245
- 10 Membrane Transport 293

PART III ENZYMES

- 11 Enzymatic Catalysis 322
- 12 Enzyme Kinetics, Inhibition, and Control 361
- 13 Biochemical Signaling 402

PART IV METABOLISM

- 14 Introduction to Metabolism 442
- 15 Glucose Catabolism 478
- 16 Glycogen Metabolism and Gluconeogenesis 523
- 17 Citric Acid Cycle 558
- 18 Electron Transport and Oxidative Phosphorylation 588
- 19 Photosynthesis: **Can be found at www.wiley.com/college/voet and in WileyPLUS Learning Space**
- 20 Lipid Metabolism 664
- 21 Amino Acid Metabolism 718
- 22 Mammalian Fuel Metabolism: Integration and Regulation 773

PART V GENE EXPRESSION AND REPLICATION

- 23 Nucleotide Metabolism 802
- 24 Nucleic Acid Structure 831
- 25 DNA Replication, Repair, and Recombination 879
- 26 Transcription and RNA Processing 938
- 27 Protein Synthesis 982
- 28 Regulation of Gene Expression 1033

Solutions: **Can be found at www.wiley.com/college/voet and in WileyPLUS Learning Space** **WPLS**

Glossary G-1

Index I-1

CONTENTS

Preface xv

Acknowledgments xix

PART I INTRODUCTION

1 Introduction to the Chemistry of Life 1

1 The Origin of Life 2

- A. Biological Molecules Arose from Inanimate Substances 2
- B. Complex Self-Replicating Systems Evolved from Simple Molecules 3

2 Cellular Architecture 5

- A. Cells Carry Out Metabolic Reactions 6
- B. There Are Two Types of Cells: Prokaryotes and Eukaryotes 7
- C. Molecular Data Reveal Three Evolutionary Domains of Organisms 9
- D. Organisms Continue to Evolve 10

3 Thermodynamics 11

- A. The First Law of Thermodynamics States That Energy Is Conserved 11
- B. The Second Law of Thermodynamics States That Entropy Tends to Increase 13
- C. The Free Energy Change Determines the Spontaneity of a Process 14
- D. Free Energy Changes Can Be Calculated from Reactant and Product Concentrations 16
- E. Life Achieves Homeostasis While Obeying the Laws of Thermodynamics 18

BOX 1-1 Pathways of Discovery **Lynn Margulis and the Theory of Endosymbiosis** 10

BOX 1-2 Perspectives in Biochemistry **Biochemical Conventions** 12

2 Water 23

1 Physical Properties of Water 24

- A. Water Is a Polar Molecule 24
- B. Hydrophilic Substances Dissolve in Water 27
- C. The Hydrophobic Effect Causes Nonpolar Substances to Aggregate in Water 27
- D. Water Moves by Osmosis and Solutes Move by Diffusion 29

2 Chemical Properties of Water 31

- A. Water Ionizes to Form H⁺ and OH⁻ 32
- B. Acids and Bases Alter the pH 33
- C. Buffers Resist Changes in pH 36

BOX 2-1 Perspectives in Biochemistry **The Consequences of Ocean Acidification** 34

BOX 2-2 Biochemistry in Health and Disease **The Blood Buffering System** 38

PART II BIOMOLECULES

3 Nucleotides, Nucleic Acids, and Genetic Information 42

1 Nucleotides 43

2 Introduction to Nucleic Acid Structure 46

- A. Nucleic Acids Are Polymers of Nucleotides 46

- B. DNA Forms a Double Helix 47
- C. RNA Is a Single-Stranded Nucleic Acid 50

3 Overview of Nucleic Acid Function 50

- A. DNA Carries Genetic Information 51
- B. Genes Direct Protein Synthesis 51

4 Nucleic Acid Sequencing 53

- A. Restriction Endonucleases Cleave DNA at Specific Sequences 54
- B. Electrophoresis Separates Nucleic Acids According to Size 56
- C. Traditional DNA Sequencing Uses the Chain-Terminator Method 57
- D. Next-Generation Sequencing Technologies Are Massively Parallel 59
- E. Entire Genomes Have Been Sequenced 62
- F. Evolution Results from Sequence Mutations 63

5 Manipulating DNA 66

- A. Cloned DNA Is an Amplified Copy 66
- B. DNA Libraries Are Collections of Cloned DNA 70
- C. DNA Is Amplified by the Polymerase Chain Reaction 71
- D. Recombinant DNA Technology Has Numerous Practical Applications 72

BOX 3-1 Pathways to Discovery **Francis Collins and the Gene for Cystic Fibrosis** 61

BOX 3-2 Perspectives in Biochemistry **DNA Fingerprinting** 73

BOX 3-3 Perspectives in Biochemistry **Ethical Aspects of Recombinant DNA Technology** 75

4 Amino Acids 80

1 Amino Acid Structure 81

- A. Amino Acids Are Dipolar Ions 84
- B. Peptide Bonds Link Amino Acids 84
- C. Amino Acid Side Chains Are Nonpolar, Polar, or Charged 84
- D. The pK Values of Ionizable Groups Depend on Nearby Groups 86
- E. Amino Acid Names Are Abbreviated 87

2 Stereochemistry 88

3 Amino Acid Derivatives 91

- A. Protein Side Chains May Be Modified 92
- B. Some Amino Acids Are Biologically Active 92

BOX 4-1 Pathways to Discovery **William C. Rose and the Discovery of Threonine** 81

BOX 4-2 Perspectives in Biochemistry **The RS System** 90

BOX 4-3 Perspectives in Biochemistry **Green Fluorescent Protein** 93

5 Proteins: Primary Structure 97

1 Polypeptide Diversity 98

2 Protein Purification and Analysis 99

- A. Purifying a Protein Requires a Strategy 100
- B. Salting Out Separates Proteins by Their Solubility 102
- C. Chromatography Involves Interaction with Mobile and Stationary Phases 103
- D. Electrophoresis Separates Molecules According to Charge and Size 106
- E. Ultracentrifugation Separates Macromolecules by Mass 108

3 Protein Sequencing 110

- A. The First Step Is to Separate Subunits 110
- B. The Polypeptide Chains Are Cleaved 114

- C. Edman Degradation Removes a Peptide's N-Terminal Amino Acid Residue 114
- D. Peptides Can Be Sequenced by Mass Spectrometry 117
- E. Reconstructed Protein Sequences Are Stored in Databases 118

4 Protein Evolution 119

- A. Protein Sequences Reveal Evolutionary Relationships 120
- B. Proteins Evolve by the Duplication of Genes or Gene Segments 122

BOX 5-1 Pathways of Discovery Frederick Sanger and Protein Sequencing 112

6 Proteins: Three-Dimensional Structure 131

1 Secondary Structure 132

- A. The Planar Peptide Group Limits Polypeptide Conformations 132
- B. The Most Common Regular Secondary Structures Are the α Helix and the β Sheet 135
- C. Fibrous Proteins Have Repeating Secondary Structures 140
- D. Most Proteins Include Nonrepetitive Structure 144

2 Tertiary Structure 145

- A. Protein Structures Are Determined by X-Ray Crystallography, Nuclear Magnetic Resonance, and Cryo-Electron Microscopy 145
- B. Side Chain Location Varies with Polarity 149
- C. Tertiary Structures Contain Combinations of Secondary Structure 150
- D. Structure Is Conserved More Than Sequence 154
- E. Structural Bioinformatics Provides Tools for Storing, Visualizing, and Comparing Protein Structural Information 155

3 Quaternary Structure and Symmetry 158

4 Protein Stability 160

- A. Proteins Are Stabilized by Several Forces 160
- B. Proteins Can Undergo Denaturation and Renaturation 162
- C. Proteins Are Dynamic 164

5 Protein Folding 165

- A. Proteins Follow Folding Pathways 165
- B. Molecular Chaperones Assist Protein Folding 168
- C. Many Diseases Are Caused by Protein Misfolding 173

BOX 6-1 Pathways of Discovery Linus Pauling and Structural Biochemistry 136

BOX 6-2 Biochemistry in Health and Disease Collagen Diseases 143

BOX 6-3 Perspectives in Biochemistry Thermostable Proteins 162

BOX 6-4 Perspectives in Biochemistry Protein Structure Prediction and Protein Design 167

7 Protein Function: Myoglobin and Hemoglobin, Muscle Contraction, and Antibodies 180

1 Oxygen Binding to Myoglobin and Hemoglobin 181

- A. Myoglobin Is a Monomeric Oxygen-Binding Protein 181
- B. Hemoglobin Is a Tetramer with Two Conformations 185
- C. Oxygen Binds Cooperatively to Hemoglobin 187
- D. Hemoglobin's Two Conformations Exhibit Different Affinities for Oxygen 190
- E. Mutations May Alter Hemoglobin's Structure and Function 197

2 Muscle Contraction 200

- A. Muscle Consists of Interdigitated Thick and Thin Filaments 201
- B. Muscle Contraction Occurs when Myosin Heads Walk Up Thin Filaments 208
- C. Actin Forms Microfilaments in Nonmuscle Cells 210

3 Antibodies 212

- A. Antibodies Have Constant and Variable Regions 212
- B. Antibodies Recognize a Huge Variety of Antigens 214

BOX 7-1 Perspectives in Biochemistry Other Oxygen-Transport Proteins 185

BOX 7-2 Pathways of Discovery Max Perutz and the Structure and Function of Hemoglobin 186

BOX 7-3 Biochemistry in Health and Disease High-Altitude Adaptation 195

BOX 7-4 Pathways of Discovery Hugh Huxley and the Sliding Filament Model 203

BOX 7-5 Perspectives in Biochemistry Monoclonal Antibodies 216

8 Carbohydrates 221

1 Monosaccharides 222

- A. Monosaccharides Are Aldoses or Ketoses 222
- B. Monosaccharides Vary in Configuration and Conformation 223
- C. Sugars Can Be Modified and Covalently Linked 225

2 Polysaccharides 228

- A. Lactose and Sucrose Are Disaccharides 228
- B. Cellulose and Chitin Are Structural Polysaccharides 230
- C. Starch and Glycogen Are Storage Polysaccharides 231
- D. Glycosaminoglycans Form Highly Hydrated Gels 232

3 Glycoproteins 234

- A. Proteoglycans Contain Glycosaminoglycans 235
- B. Bacterial Cell Walls Are Made of Peptidoglycan 235
- C. Many Eukaryotic Proteins Are Glycosylated 238
- D. Oligosaccharides May Determine Glycoprotein Structure, Function, and Recognition 240

BOX 8-1 Biochemistry in Health and Disease Lactose Intolerance 228

BOX 8-2 Perspectives in Biochemistry Artificial Sweeteners 229

BOX 8-3 Biochemistry in Health and Disease Peptidoglycan-Specific Antibiotics 238

9 Lipids and Biological Membranes 245

1 Lipid Classification 246

- A. The Properties of Fatty Acids Depend on Their Hydrocarbon Chains 246
- B. Triacylglycerols Contain Three Esterified Fatty Acids 248
- C. Glycerophospholipids Are Amphiphilic 249
- D. Sphingolipids Are Amino Alcohol Derivatives 252
- E. Steroids Contain Four Fused Rings 254
- F. Other Lipids Perform a Variety of Metabolic Roles 256

2 Lipid Bilayers 259

- A. Bilayer Formation Is Driven by the Hydrophobic Effect 259
- B. Lipid Bilayers Have Fluidlike Properties 260

3 Membrane Proteins 262

- A. Integral Membrane Proteins Interact with Hydrophobic Lipids 262
- B. Lipid-Linked Proteins Are Anchored to the Bilayer 267
- C. Peripheral Proteins Associate Loosely with Membranes 268

4 Membrane Structure and Assembly 269

- A. The Fluid Mosaic Model Accounts for Lateral Diffusion 269
- B. The Membrane Skeleton Helps Define Cell Shape 271
- C. Membrane Lipids Are Distributed Asymmetrically 274
- D. The Secretory Pathway Generates Secreted and Transmembrane Proteins 276
- E. Intracellular Vesicles Transport Proteins 280
- F. Proteins Mediate Vesicle Fusion 284

BOX 9-1 Biochemistry in Health and Disease Lung Surfactant 251

BOX 9-2 Pathways of Discovery Richard Henderson and the Structure of Bacteriorhodopsin 265

BOX 9-3 Biochemistry in Health and Disease Tetanus and Botulinum Toxins Specifically Cleave SNAREs 286

10 Membrane Transport 293

1 Thermodynamics of Transport 294

2 Passive-Mediated Transport 295

- A. Ionophores Carry Ions across Membranes 295
- B. Porins Contain β Barrels 297
- C. Ion Channels Are Highly Selective 297
- D. Aquaporins Mediate the Transmembrane Movement of Water 304
- E. Transport Proteins Alternate between Two Conformations 305

3 Active Transport 309

- A. The $(\text{Na}^+-\text{K}^+)\text{-ATPase}$ Transports Ions in Opposite Directions 310
- B. The $\text{Ca}^{2+}\text{-ATPase}$ Pumps Ca^{2+} Out of the Cytosol 312
- C. ABC Transporters Are Responsible for Drug Resistance 314
- D. Active Transport May Be Driven by Ion Gradients 315

BOX 10-1 Perspectives in Biochemistry Gap Junctions 306

BOX 10-2 Perspectives in Biochemistry Differentiating Mediated and Nonmediated Transport 308

BOX 10-3 Biochemistry in Health and Disease The Action of Cardiac Glycosides 312

PART III ENZYMES

11 Enzymatic Catalysis 322

1 General Properties of Enzymes 323

- A. Enzymes Are Classified by the Type of Reaction They Catalyze 324
- B. Enzymes Act on Specific Substrates 324
- C. Some Enzymes Require Cofactors 326

2 Activation Energy and the Reaction Coordinate 327

3 Catalytic Mechanisms 330

- A. Acid–Base Catalysis Occurs by Proton Transfer 330
- B. Covalent Catalysis Usually Requires a Nucleophile 334
- C. Metal Ion Cofactors Act as Catalysts 335
- D. Catalysis Can Occur through Proximity and Orientation Effects 336
- E. Enzymes Catalyze Reactions by Preferentially Binding the Transition State 338

4 Lysozyme 339

- A. Lysozyme's Catalytic Site Was Identified through Model Building 340
- B. The Lysozyme Reaction Proceeds via a Covalent Intermediate 342

5 Serine Proteases 345

- A. Active Site Residues Were Identified by Chemical Labeling 345
- B. X-Ray Structures Provide Information about Catalysis, Substrate Specificity, and Evolution 346
- C. Serine Proteases Use Several Catalytic Mechanisms 350
- D. Zymogens Are Inactive Enzyme Precursors 355

BOX 11-1 Perspectives in Biochemistry Drawing Reaction Mechanisms 331

BOX 11-2 Perspectives in Biochemistry Effects of pH on Enzyme Activity 332

BOX 11-3 Biochemistry in Health and Disease Nerve Poisons 346

BOX 11-4 Biochemistry in Health and Disease The Blood Coagulation Cascade 356

12 Enzyme Kinetics, Inhibition, and Control 361

1 Reaction Kinetics 362

- A. Chemical Kinetics Is Described by Rate Equations 362
- B. Enzyme Kinetics Often Follows the Michaelis–Menten Equation 364
- C. Kinetic Data Can Provide Values of V_{max} and K_M 369
- D. Bisubstrate Reactions Follow One of Several Rate Equations 372

2 Enzyme Inhibition 374

- A. Competitive Inhibition Involves Inhibitor Binding at an Enzyme's Substrate Binding Site 374

- B. Uncompetitive Inhibition Involves Inhibitor Binding to the Enzyme–Substrate Complex 380
- C. Mixed Inhibition Involves Inhibitor Binding to Both the Free Enzyme and the Enzyme–Substrate Complex 381

3 Control of Enzyme Activity 382

- A. Allosteric Control Involves Binding at a Site Other than the Active Site 383
- B. Control by Covalent Modification Usually Involves Protein Phosphorylation 387

4 Drug Design 391

- A. Drug Discovery Employs a Variety of Techniques 392
- B. A Drug's Bioavailability Depends on How It Is Absorbed and Transported in the Body 393
- C. Clinical Trials Test for Efficacy and Safety 393
- D. Cytochromes P450 Are Often Implicated in Adverse Drug Reactions 395

BOX 12-1 Pathways of Discovery J.B.S. Haldane and Enzyme Action 366

BOX 12-2 Perspectives in Biochemistry Kinetics and Transition State Theory 369

BOX 12-3 Biochemistry in Health and Disease HIV Enzyme Inhibitors 376

13 Biochemical Signaling 402

1 Hormones 403

- A. Pancreatic Islet Hormones Control Fuel Metabolism 404
- B. Epinephrine and Norepinephrine Prepare the Body for Action 405
- C. Steroid Hormones Regulate a Wide Variety of Metabolic and Sexual Processes 406
- D. Growth Hormone Binds to Receptors in Muscle, Bone, and Cartilage 407

2 Receptor Tyrosine Kinases 408

- A. Receptor Tyrosine Kinases Transmit Signals across the Cell Membrane 409
- B. Kinase Cascades Relay Signals to the Nucleus 412
- C. Some Receptors Are Associated with Nonreceptor Tyrosine Kinases 417
- D. Protein Phosphatases Are Signaling Proteins in Their Own Right 420

3 Heterotrimeric G Proteins 423

- A. G-Protein–Coupled Receptors Contain Seven Transmembrane Helices 424
- B. Heterotrimeric G Proteins Dissociate on Activation 426
- C. Adenylate Cyclase Synthesizes cAMP to Activate Protein Kinase A 427
- D. Phosphodiesterases Limit Second Messenger Activity 432

4 The Phosphoinositide Pathway 432

- A. Ligand Binding Results in the Cytoplasmic Release of the Second Messengers IP_3 and Ca^{2+} 433
- B. Calmodulin Is a Ca^{2+} -Activated Switch 434
- C. DAG Is a Lipid-Soluble Second Messenger That Activates Protein Kinase C 436
- D. Epilog: Complex Systems Have Emergent Properties 437

BOX 13-1 Pathways of Discovery Rosalyn Yalow and the Radioimmunoassay (RIA) 404

BOX 13-2 Perspectives in Biochemistry Receptor–Ligand Binding Can Be Quantitated 410

BOX 13-3 Biochemistry in Health and Disease Oncogenes and Cancer 416

BOX 13-4 Biochemistry in Health and Disease Drugs and Toxins That Affect Cell Signaling 431

PART IV METABOLISM

14 Introduction to Metabolism 442

1 Overview of Metabolism 443

- A. Nutrition Involves Food Intake and Use 443

- B. Vitamins and Minerals Assist Metabolic Reactions 444
- C. Metabolic Pathways Consist of Series of Enzymatic Reactions 445
- D. Thermodynamics Dictates the Direction and Regulatory Capacity of Metabolic Pathways 449
- E. Metabolic Flux Must Be Controlled 450

2 “High-Energy” Compounds 452

- A. ATP Has a High Phosphoryl Group-Transfer Potential 454
- B. Coupled Reactions Drive Endergonic Processes 455
- C. Some Other Phosphorylated Compounds Have High Phosphoryl Group-Transfer Potentials 457
- D. Thioesters Are Energy-Rich Compounds 460

3 Oxidation–Reduction Reactions 462

- A. NAD⁺ and FAD Are Electron Carriers 462
- B. The Nernst Equation Describes Oxidation–Reduction Reactions 463
- C. Spontaneity Can Be Determined by Measuring Reduction Potential Differences 465

4 Experimental Approaches to the Study of Metabolism 468

- A. Labeled Metabolites Can Be Traced 468
- B. Studying Metabolic Pathways Often Involves Perturbing the System 470
- C. Systems Biology Has Entered the Study of Metabolism 471

BOX 14-1 Perspectives in Biochemistry Oxidation States of Carbon 447

BOX 14-2 Pathways of Discovery Fritz Lipmann and “High-Energy” Compounds 453

BOX 14-3 Perspectives in Biochemistry ATP and ΔG 455

15 Glucose Catabolism 478

1 Overview of Glycolysis 479

2 The Reactions of Glycolysis 481

- A. Hexokinase Uses the First ATP 482
- B. Phosphoglucose Isomerase Converts Glucose-6-Phosphate to Fructose-6-Phosphate 482
- C. Phosphofruktokinase Uses the Second ATP 484
- D. Aldolase Converts a 6-Carbon Compound to Two 3-Carbon Compounds 484
- E. Triose Phosphate Isomerase Interconverts Dihydroxyacetone Phosphate and Glyceraldehyde-3-Phosphate 485
- F. Glyceraldehyde-3-Phosphate Dehydrogenase Forms the First “High-Energy” Intermediate 489
- G. Phosphoglycerate Kinase Generates the First ATP 491
- H. Phosphoglycerate Mutase Interconverts 3-Phosphoglycerate and 2-Phosphoglycerate 492
- I. Enolase Forms the Second “High-Energy” Intermediate 493
- J. Pyruvate Kinase Generates the Second ATP 494

3 Fermentation: The Anaerobic Fate of Pyruvate 497

- A. Homolactic Fermentation Converts Pyruvate to Lactate 498
- B. Alcoholic Fermentation Converts Pyruvate to Ethanol and CO₂ 498
- C. Fermentation Is Energetically Favorable 501

4 Regulation of Glycolysis 502

- A. Phosphofruktokinase Is the Major Flux-Controlling Enzyme of Glycolysis in Muscle 503
- B. Substrate Cycling Fine-Tunes Flux Control 506

5 Metabolism of Hexoses Other than Glucose 508

- A. Fructose Is Converted to Fructose-6-Phosphate or Glyceraldehyde-3-Phosphate 508
- B. Galactose Is Converted to Glucose-6-Phosphate 510
- C. Mannose Is Converted to Fructose-6-Phosphate 512

6 The Pentose Phosphate Pathway 512

- A. Oxidative Reactions Produce NADPH in Stage 1 514
- B. Isomerization and Epimerization of Ribulose-5-Phosphate Occur in Stage 2 515

- C. Stage 3 Involves Carbon–Carbon Bond Cleavage and Formation 515
- D. The Pentose Phosphate Pathway Must Be Regulated 518

BOX 15-1 Pathways of Discovery Otto Warburg and Studies of Metabolism 479

BOX 15-2 Perspectives in Biochemistry Synthesis of 2,3-Bisphosphoglycerate in Erythrocytes and Its Effect on the Oxygen Carrying Capacity of the Blood 494

BOX 15-3 Perspectives in Biochemistry Glycolytic ATP Production in Muscle 502

BOX 15-4 Biochemistry in Health and Disease Glucose-6-Phosphate Dehydrogenase Deficiency 518

16 Glycogen Metabolism and Gluconeogenesis 523

1 Glycogen Breakdown 524

- A. Glycogen Phosphorylase Degrades Glycogen to Glucose-1-Phosphate 525
- B. Glycogen Debranching Enzyme Acts as a Glucosyltransferase 528
- C. Phosphoglucomutase Interconverts Glucose-1-Phosphate and Glucose-6-Phosphate 529

2 Glycogen Synthesis 532

- A. UDP–Glucose Pyrophosphorylase Activates Glucosyl Units 532
- B. Glycogen Synthase Extends Glycogen Chains 533
- C. Glycogen Branching Enzyme Transfers Seven-Residue Glycogen Segments 535

3 Control of Glycogen Metabolism 536

- A. Glycogen Phosphorylase and Glycogen Synthase Are under Allosteric Control 536
- B. Glycogen Phosphorylase and Glycogen Synthase Undergo Control by Covalent Modification 536
- C. Glycogen Metabolism Is Subject to Hormonal Control 542

4 Gluconeogenesis 544

- A. Pyruvate Is Converted to Phosphoenolpyruvate in Two Steps 545
- B. Hydrolytic Reactions Bypass Irreversible Glycolytic Reactions 549
- C. Gluconeogenesis and Glycolysis Are Independently Regulated 549

5 Other Carbohydrate Biosynthetic Pathways 551

BOX 16-1 Pathways of Discovery Carl and Gerty Cori and Glucose Metabolism 526

BOX 16-2 Biochemistry in Health and Disease Glycogen Storage Diseases 530

BOX 16-3 Perspectives in Biochemistry Optimizing Glycogen Structure 537

BOX 16-4 Perspectives in Biochemistry Lactose Synthesis 552

17 Citric Acid Cycle 558

1 Overview of the Citric Acid Cycle 559

2 Synthesis of Acetyl-Coenzyme A 562

- A. Pyruvate Dehydrogenase Is a Multienzyme Complex 562
- B. The Pyruvate Dehydrogenase Complex Catalyzes Five Reactions 564

3 Enzymes of the Citric Acid Cycle 568

- A. Citrate Synthase Joins an Acetyl Group to Oxaloacetate 568
- B. Aconitase Interconverts Citrate and Isocitrate 570
- C. NAD⁺-Dependent Isocitrate Dehydrogenase Releases CO₂ 571
- D. α -Ketoglutarate Dehydrogenase Resembles Pyruvate Dehydrogenase 572
- E. Succinyl-CoA Synthetase Produces GTP 572
- F. Succinate Dehydrogenase Generates FADH₂ 574
- G. Fumarase Produces Malate 574
- H. Malate Dehydrogenase Regenerates Oxaloacetate 574

4 Regulation of the Citric Acid Cycle 575

- A. Pyruvate Dehydrogenase Is Regulated by Product Inhibition and Covalent Modification 576

- B. Three Enzymes Control the Rate of the Citric Acid Cycle 577
- 5 Reactions Related to the Citric Acid Cycle** 579
- A. Other Pathways Use Citric Acid Cycle Intermediates 580
 - B. Some Reactions Replenish Citric Acid Cycle Intermediates 581
 - C. The Glyoxylate Cycle Shares Some Steps with the Citric Acid Cycle 582

BOX 17-1 Pathways of Discovery Hans Krebs and the Citric Acid Cycle 561

BOX 17-2 Biochemistry in Health and Disease Arsenic Poisoning 568

BOX 17-3 Perspectives in Biochemistry Evolution of the Citric Acid Cycle 582

18 Electron Transport and Oxidative Phosphorylation 588

1 The Mitochondrion 589

- A. Mitochondria Contain a Highly Folded Inner Membrane 590
- B. Ions and Metabolites Enter Mitochondria via Transporters 591

2 Electron Transport 593

- A. Electron Transport Is an Exergonic Process 593
- B. Electron Carriers Operate in Sequence 594
- C. Complex I Accepts Electrons from NADH 597
- D. Complex II Contributes Electrons to Coenzyme Q 601
- E. Complex III Translocates Protons via the Q Cycle 602
- F. Complex IV Reduces Oxygen to Water 607

3 Oxidative Phosphorylation 609

- A. The Chemiosmotic Theory Links Electron Transport to ATP Synthesis 610
- B. ATP Synthase Is Driven by the Flow of Protons 613
- C. The P/O Ratio Relates the Amount of ATP Synthesized to the Amount of Oxygen Reduced 618
- D. Oxidative Phosphorylation Can Be Uncoupled from Electron Transport 619

4 Control of Oxidative Metabolism 620

- A. The Rate of Oxidative Phosphorylation Depends on the ATP and NADH Concentrations 622
- B. Aerobic Metabolism Has Some Disadvantages 623

BOX 18-1 Perspectives in Biochemistry Cytochromes Are Electron-Transport Heme Proteins 602

BOX 18-2 Pathways of Discovery Peter Mitchell and the Chemiosmotic Theory 611

BOX 18-3 Perspectives in Biochemistry Bacterial Electron Transport and Oxidative Phosphorylation 612

BOX 18-4 Perspectives in Biochemistry Uncoupling in Brown Adipose Tissue Generates Heat 621

BOX 18-5 Biochemistry in Health and Disease Oxygen Deprivation in Heart Attack and Stroke 625

19 Photosynthesis 630

1 Chloroplasts 631

- A. The Light Reactions Take Place in the Thylakoid Membrane 631
- B. Pigment Molecules Absorb Light 632

2 The Light Reactions 635

- A. Light Energy Is Transformed to Chemical Energy 635
- B. Electron Transport in Photosynthetic Bacteria Follows a Circular Path 637
- C. Two-Center Electron Transport Is a Linear Pathway That Produces O₂ and NADPH 639
- D. The Proton Gradient Drives ATP Synthesis by Photophosphorylation 650

3 The Dark Reactions 651

- A. The Calvin Cycle Fixes CO₂ 651
- B. Calvin Cycle Products Are Converted to Starch, Sucrose, and Cellulose 655

- C. The Calvin Cycle Is Controlled Indirectly by Light 656

- D. Photorespiration Competes with Photosynthesis 658

BOX 19-1 Perspectives in Biochemistry Segregation of PSI and PSII 649

CHAPTER 19 can be found at www.wiley.com/college/voet and in WileyPLUS Learning Space **WPLS**

20 Lipid Metabolism 664

1 Lipid Digestion, Absorption, and Transport 664

- A. Triacylglycerols Are Digested before They Are Absorbed 665
- B. Lipids Are Transported as Lipoproteins 667

2 Fatty Acid Oxidation 671

- A. Fatty Acids Are Activated by Their Attachment to Coenzyme A 672
- B. Carnitine Carries Acyl Groups across the Mitochondrial Membrane 672
- C. β Oxidation Degrades Fatty Acids to Acetyl-CoA 674
- D. Oxidation of Unsaturated Fatty Acids Requires Additional Enzymes 676
- E. Oxidation of Odd-Chain Fatty Acids Yields Propionyl-CoA 678
- F. Peroxisomal β Oxidation Differs from Mitochondrial β Oxidation 684

3 Ketone Bodies 685

4 Fatty Acid Biosynthesis 686

- A. Mitochondrial Acetyl-CoA Must Be Transported into the Cytosol 687
- B. Acetyl-CoA Carboxylase Produces Malonyl-CoA 688
- C. Fatty Acid Synthase Catalyzes Seven Reactions 689
- D. Fatty Acids May Be Elongated and Desaturated 695
- E. Fatty Acids Are Esterified to Form Triacylglycerols 696

5 Regulation of Fatty Acid Metabolism 697

6 Synthesis of Other Lipids 700

- A. Glycerophospholipids Are Built from Intermediates of Triacylglycerol Synthesis 700
- B. Sphingolipids Are Built from Palmitoyl-CoA and Serine 703
- C. C₂₀ Fatty Acids Are the Precursors of Prostaglandins 704

7 Cholesterol Metabolism 706

- A. Cholesterol Is Synthesized from Acetyl-CoA 707
- B. HMG-CoA Reductase Controls the Rate of Cholesterol Synthesis 710
- C. Abnormal Cholesterol Transport Leads to Atherosclerosis 713

BOX 20-1 Biochemistry in Health and Disease Vitamin B₁₂ Deficiency 680

BOX 20-2 Pathways of Discovery Dorothy Crowfoot Hodgkin and the Structure of Vitamin B₁₂ 680

BOX 20-3 Perspectives in Biochemistry Polyketide Synthesis 694

BOX 20-4 Biochemistry in Health and Disease Sphingolipid Degradation and Lipid Storage Diseases 706

21 Amino Acid Metabolism 718

1 Protein Degradation 719

- A. Lysosomes Degrade Many Proteins 719
- B. Ubiquitin Marks Proteins for Degradation 720
- C. The Proteasome Unfolds and Hydrolyzes Ubiquitinated Polypeptides 721

2 Amino Acid Deamination 724

- A. Transaminases Use PLP to Transfer Amino Groups 725
- B. Glutamate Can Be Oxidatively Deaminated 728

3 The Urea Cycle 728

- A. Five Enzymes Carry Out the Urea Cycle 729
- B. The Urea Cycle Is Regulated by Substrate Availability 732

4 Breakdown of Amino Acids 733

- A. Alanine, Cysteine, Glycine, Serine, and Threonine Are Degraded to Pyruvate 734
- B. Asparagine and Aspartate Are Degraded to Oxaloacetate 736

- C. Arginine, Glutamate, Glutamine, Histidine, and Proline Are Degraded to α -Ketoglutarate 737
- D. Methionine, Threonine, Isoleucine, and Valine Are Degraded to Succinyl-CoA 738
- E. Leucine and Lysine Are Degraded Only to Acetyl-CoA and/or Acetoacetate 743
- F. Tryptophan Is Degraded to Alanine and Acetoacetate 744
- G. Phenylalanine and Tyrosine Are Degraded to Fumarate and Acetoacetate 745

5 Amino Acid Biosynthesis 746

- A. Nonessential Amino Acids Are Synthesized from Common Metabolites 748
- B. Plants and Microorganisms Synthesize the Essential Amino Acids 752

6 Other Products of Amino Acid Metabolism 758

- A. Heme Is Synthesized from Glycine and Succinyl-CoA 758
- B. Amino Acids Are Precursors of Physiologically Active Amines 762
- C. Nitric Oxide Is Derived from Arginine 763

7 Nitrogen Fixation 764

- A. Nitrogenase Reduces N_2 to NH_3 764
- B. Fixed Nitrogen Is Assimilated into Biological Molecules 768

BOX 21-1 Biochemistry in Health and Disease Homocysteine, a Marker of Disease 740

BOX 21-2 Biochemistry in Health and Disease Phenylketonuria and Alcaptonuria Result from Defects in Phenylalanine Degradation 746

BOX 21-3 Biochemistry in Health and Disease The Porphyrins 760

22 Mammalian Fuel Metabolism: Integration and Regulation 773

1 Organ Specialization 774

- A. The Brain Requires a Steady Supply of Glucose 775
- B. Muscle Utilizes Glucose, Fatty Acids, and Ketone Bodies 776
- C. Adipose Tissue Stores and Releases Fatty Acids and Hormones 778
- D. Liver Is the Body's Central Metabolic Clearinghouse 778
- E. Kidney Filters Wastes and Maintains Blood pH 780
- F. Blood Transports Metabolites in Interorgan Metabolic Pathways 780

2 Hormonal Control of Fuel Metabolism 781

- A. Insulin Release Is Triggered by Glucose 782
- B. Glucagon and Catecholamines Counter the Effects of Insulin 783

3 Metabolic Homeostasis: The Regulation of Energy Metabolism, Appetite, and Body Weight 786

- A. AMP-Dependent Protein Kinase Is the Cell's Fuel Gauge 786
- B. Adipocytes and Other Tissues Help Regulate Fuel Metabolism and Appetite 788
- C. Energy Expenditure Can Be Controlled by Adaptive Thermogenesis 789

4 Disturbances in Fuel Metabolism 790

- A. Starvation Leads to Metabolic Adjustments 790
- B. Diabetes Mellitus Is Characterized by High Blood Glucose Levels 792
- C. Obesity Is Usually Caused by Excessive Food Intake 795
- D. Cancer Metabolism 796

BOX 22-1 Biochemistry in Health and Disease The Intestinal Microbiome 777

BOX 22-2 Pathways of Discovery Frederick Banting and Charles Best and the Discovery of Insulin 794

PART V GENE EXPRESSION AND REPLICATION

23 Nucleotide Metabolism 802

1 Synthesis of Purine Ribonucleotides 802

- A. Purine Synthesis Yields Inosine Monophosphate 803

- B. IMP Is Converted to Adenine and Guanine Ribonucleotides 806
- C. Purine Nucleotide Biosynthesis Is Regulated at Several Steps 807
- D. Purines Can Be Salvaged 808

2 Synthesis of Pyrimidine Ribonucleotides 809

- A. UMP Is Synthesized in Six Steps 809
- B. UMP Is Converted to UTP and CTP 811
- C. Pyrimidine Nucleotide Biosynthesis Is Regulated at ATCase or Carbamoyl Phosphate Synthetase II 811

3 Formation of Deoxyribonucleotides 812

- A. Ribonucleotide Reductase Converts Ribonucleotides to Deoxyribonucleotides 812
- B. dUMP Is Methylated to Form Thymine 817

4 Nucleotide Degradation 820

- A. Purine Catabolism Yields Uric Acid 822
- B. Some Animals Degrade Uric Acid 825
- C. Pyrimidines Are Broken Down to Malonyl-CoA and Methylmalonyl-CoA 827

BOX 23-1 Biochemistry in Health and Disease Inhibition of Thymidylate Synthesis in Cancer Therapy 821

BOX 23-2 Pathways of Discovery Gertrude Elion and Purine Derivatives 826

24 Nucleic Acid Structure 831

1 The DNA Helix 832

- A. DNA Can Adopt Different Conformations 832
- B. DNA Has Limited Flexibility 838
- C. DNA Can Be Supercoiled 840
- D. Topoisomerases Alter DNA Supercoiling 842

2 Forces Stabilizing Nucleic Acid Structures 848

- A. Nucleic Acids Are Stabilized by Base Pairing, Stacking, and Ionic Interactions 849
- B. DNA Can Undergo Denaturation and Renaturation 850
- C. RNA Structures Are Highly Variable 852

3 Fractionation of Nucleic Acids 856

- A. Nucleic Acids Can Be Purified by Chromatography 856
- B. Electrophoresis Separates Nucleic Acids by Size 857

4 DNA-Protein Interactions 859

- A. Restriction Endonucleases Distort DNA on Binding 860
- B. Prokaryotic Repressors Often Include a DNA-Binding Helix 861
- C. Eukaryotic Transcription Factors May Include Zinc Fingers or Leucine Zippers 864

5 Eukaryotic Chromosome Structure 868

- A. DNA Coils around Histones to Form Nucleosomes 868
- B. Chromatin Forms Higher-Order Structures 870

BOX 24-1 Pathways of Discovery Rosalind Franklin and the Structure of DNA 833

BOX 24-2 Biochemistry in Health and Disease Inhibitors of Topoisomerases as Antibiotics and Anticancer Chemotherapeutic Agents 848

BOX 24-3 Perspectives in Biochemistry The RNA World 854

25 DNA Replication, Repair, and Recombination 879

1 Overview of DNA Replication 880

2 Prokaryotic DNA Replication 882

- A. DNA Polymerases Add the Correctly Paired Nucleotides 883
- B. Replication Initiation Requires Helicase and Primase 889

- C. The Leading and Lagging Strands Are Synthesized Simultaneously 891
- D. Replication Terminates at Specific Sites 895
- E. DNA Is Replicated with High Fidelity 897

3 Eukaryotic DNA Replication 898

- A. Eukaryotes Use Several DNA Polymerases 898
- B. Eukaryotic DNA Is Replicated from Multiple Origins 900
- C. Telomerase Extends Chromosome Ends 902

4 DNA Damage 904

- A. Environmental and Chemical Agents Generate Mutations 905
- B. Many Mutagens Are Carcinogens 907

5 DNA Repair 909

- A. Some Damage Can Be Directly Reversed 909
- B. Base Excision Repair Requires a Glycosylase 910
- C. Nucleotide Excision Repair Removes a Segment of a DNA Strand 912
- D. Mismatch Repair Corrects Replication Errors 913
- E. Some DNA Repair Mechanisms Introduce Errors 914

6 Recombination 916

- A. Homologous Recombination Involves Several Protein Complexes 916
- B. DNA Can Be Repaired by Recombination 922
- C. CRISPR–Cas9, a System for Editing and Regulating Genomes 925
- D. Transposition Rearranges Segments of DNA 929

BOX 25-1 Pathways of Discovery **Arthur Kornberg and DNA Polymerase I** 883

BOX 25-2 Perspectives in Biochemistry **Reverse Transcriptase** 900

BOX 25-3 Biochemistry in Health and Disease **Telomerase, Aging, and Cancer** 905

BOX 25-4 Perspectives in Biochemistry **DNA Methylation** 908

BOX 25-5 Perspectives in Biochemistry **Why Doesn't DNA Contain Uracil?** 911

26 Transcription and RNA Processing 938

1 Prokaryotic RNA Transcription 939

- A. RNA Polymerase Resembles Other Polymerases 939
- B. Transcription Is Initiated at a Promoter 942
- C. The RNA Chain Grows from the 5' to 3' End 943
- D. Transcription Terminates at Specific Sites 946

2 Transcription in Eukaryotes 948

- A. Eukaryotes Have Several RNA Polymerases 949
- B. Each Polymerase Recognizes a Different Type of Promoter 954
- C. Transcription Factors Are Required to Initiate Transcription 956

3 Posttranscriptional Processing 961

- A. Messenger RNAs Undergo 5' Capping and Addition of a 3' Tail 962
- B. Splicing Removes Introns from Eukaryotic Genes 963
- C. Ribosomal RNA Precursors May Be Cleaved, Modified, and Spliced 973
- D. Transfer RNAs Are Processed by Nucleotide Removal, Addition, and Modification 977

BOX 26-1 Perspectives in Biochemistry **Collisions between DNA Polymerase and RNA Polymerase** 945

BOX 26-2 Biochemistry in Health and Disease **Inhibitors of Transcription** 950

BOX 26-3 Pathways of Discovery **Richard Roberts and Phillip Sharp and the Discovery of Introns** 964

27 Protein Synthesis 982

1 The Genetic Code 983

- A. Codons Are Triplets That Are Read Sequentially 983
- B. The Genetic Code Was Systematically Deciphered 984
- C. The Genetic Code Is Degenerate and Nonrandom 986

2 Transfer RNA and Its Aminoacylation 988

- A. All tRNAs Have Similar Structures 988
- B. Aminoacyl-tRNA Synthetases Attach Amino Acids to tRNAs 990
- C. Most tRNAs Recognize More than One Codon 994

3 Ribosomes 996

- A. The Prokaryotic Ribosome Consists of Two Subunits 997
- B. The Eukaryotic Ribosome Contains a Buried Prokaryotic Ribosome 1002

4 Translation 1004

- A. Chain Initiation Requires an Initiator tRNA and Initiation Factors 1006
- B. The Ribosome Decodes the mRNA, Catalyzes Peptide Bond Formation, Then Moves to the Next Codon 1011
- C. Release Factors Terminate Translation 1023

5 Posttranslational Processing 1024

- A. Ribosome-Associated Chaperones Help Proteins Fold 1025
- B. Newly Synthesized Proteins May Be Covalently Modified 1026

BOX 27-1 Perspectives in Biochemistry **Evolution of the Genetic Code** 986

BOX 27-2 Perspectives in Biochemistry **Expanding the Genetic Code** 996

BOX 27-3 Biochemistry in Health and Disease **The Effects of Antibiotics on Protein Synthesis** 1020

28 Regulation of Gene Expression 1033

1 Genome Organization 1034

- A. Gene Number Varies among Organisms 1034
- B. Some Genes Occur in Clusters 1037
- C. Eukaryotic Genomes Contain Repetitive DNA Sequences 1039

2 Regulation of Prokaryotic Gene Expression 1043

- A. The *lac* Operon Is Controlled by a Repressor 1043
- B. Catabolite-Repressed Operons Can Be Activated 1046
- C. Attenuation Regulates Transcription Termination 1048
- D. Riboswitches Are Metabolite-Sensing RNAs 1050

3 Regulation of Eukaryotic Gene Expression 1052

- A. Chromatin Structure Influences Gene Expression 1052
- B. Eukaryotes Contain Multiple Transcriptional Activators 1063
- C. Posttranscriptional Control Mechanisms 1069
- D. Antibody Diversity Results from Somatic Recombination and Hypermutation 1076

4 The Cell Cycle, Cancer, Apoptosis, and Development 1080

- A. Progress through the Cell Cycle Is Tightly Regulated 1080
- B. Tumor Suppressors Prevent Cancer 1082
- C. Apoptosis Is an Orderly Process 1085
- D. Development Has a Molecular Basis 1089

SOLUTIONS can be found at www.wiley.com/college/voet and in WileyPLUS Learning Space **WPLS**

An easy way to help students learn, collaborate, and grow.

Designed to engage today's student, WileyPLUS Learning Space will transform any course into a vibrant, collaborative learning community.

Identify which students are struggling early in the semester.

Educators assess the real-time engagement and performance of each student to inform teaching decisions. Students always know what they need to work on.

Facilitate student engagement both in and outside of class.

Educators can quickly organize learning activities, manage student collaboration, and customize their course.

Measure outcomes to promote continuous improvement.

With visual reports, it's easy for both students and educators to gauge problem areas and act on what's most important.

WileyPLUS Learning Space

In WileyPLUS Learning Space students can...

Visualize molecular processes

Guided Explorations: A set of self-contained presentations, many with narration, employ extensive animated computer graphics to enhance student understanding of key topics.

Animated Figures: A set of figures from the text, illustrating various concepts, techniques, and processes, are presented as brief animations to facilitate learning.

Animated Process Diagrams: The many Process Diagrams in the text have each been broken down into discrete steps that students can navigate at their desired pace.

These resources are intended to enrich the learning process for students, especially those who rely heavily on visual information. Whereas some resources, particularly the Animated Figures and Animated Process Diagrams, are brief and could easily be incorporated into an instructor's classroom lecture, all the resources are ideal for student self-study, allowing students to proceed at their own pace or back up and review as needed. All the media resources are keyed to specific figures or sections of the text, so students can explore molecular structures and processes as they work through a chapter.

Solve problems using real data, using the same analytical tools the experts use

Sample Calculation Videos: Students come to biochemistry with different levels of math skills. These embedded videos, created by Charlotte Pratt, walk students through the Sample Calculations provided for key equations throughout the text.

Brief Bioinformatics Exercises: A series of 74 short, assessable, and content-specific bioinformatics projects (at least two per chapter) by Rakesh Mogul, Cal Poly Pomona. They introduce students to the rich variety of biochemical information and software tools available over the Internet and show them how to mine this information, thereby illuminating the connections between theory and applied biochemistry and stimulating student interest and proficiency in the subject.

Extended Bioinformatics Projects: A set of 12 newly updated exercises by Paul Craig, Rochester Institute of Technology, covering the contents and uses of databases related to nucleic acids, protein sequences, protein structures, enzyme inhibition, and other topics. The exercises use real data sets, pose specific questions, and prompt students to obtain information from online databases and to access the software tools for analyzing such data.

Case Studies: A set of 33 case studies by Kathleen Cornely, Providence College, using problem-based learning to promote understanding of biochemical concepts. Each case presents data from the literature and asks questions that require students to apply principles to novel situations, often involving topics from multiple chapters in the textbook.

In WileyPLUS Learning Space instructors can...

Assign a robust variety of practice and assessment questions

Test Bank: Over 1400 questions in a variety of question types (multiple choice, matching, fill in the blank, and short answer) by Marilee Benore, University of Michigan-Dearborn and Robert Kane, Baylor University, and revised by Amy Stockert, Ohio Northern University and Peter van der Geer, San Diego State University. Each question is keyed to the relevant section in the text and is rated by difficulty level. (Tests can be created and administered online or with test-generator software.)

Exercises: Over 1000 conceptually based questions by Rachel Milner and Adrienne Wright, University of Alberta, which can be sorted by chapter and/or topic and can be assigned as graded homework or additional practice.

Practice Questions: Quizzes, by Steven Vik, Southern Methodist University, to accompany each chapter, consisting of multiple-choice, true/false, and fill-in-the-blank questions, with instant feedback to help students master concepts.

Prelecture Questions: Multiple-choice questions that can be assigned prior to lecture to help students prepare for class.

Discussion Questions: Embedded within the WileyPLUS Learning Space eText, these thought-provoking questions serve as a point of departure for student discussion and engagement with the content.

Access instructors' resources

PowerPoint Slides contain all images and tables in the text, optimized for viewing onscreen.

Interactive Protein PowerPoints contain text images of a wide variety of proteins. Each slide includes a molecular structure and PDB code from the text that links students and instructors to the specific protein in the Protein Data Bank website (<http://www.rcsb.org/pdb/home/home.do>) The website provides a host of information about the 3D structures of large biological molecules, including proteins and nucleic acids.

Classroom Response Questions ("Clicker Questions"), by Rachel Milner and Adrienne Wright, University of Alberta, are interactive questions designed for classroom response systems to facilitate classroom participation and discussion. These questions can also be used by instructors as prelecture questions that help gauge students' knowledge of overall concepts, while addressing common misconceptions.

PREFACE

Biochemistry is no longer a specialty subject but is part of the core of knowledge for modern biologists and chemists. In addition, familiarity with biochemical principles has become an increasingly valuable component of medical education. In revising this textbook, we asked, “Can we provide students with a solid foundation in biochemistry, along with the problem-solving skills to use what they know? We concluded that it is more important than ever to meet the expectations of a standard biochemistry curriculum, to connect biological chemistry to its chemical roots, and to explore the ways that biochemistry can explain human health and disease. We also wanted to provide students with opportunities to develop the practical skills that they will need to meet the scientific and clinical challenges of the future. This revised version of *Fundamentals of Biochemistry* continues to focus on basic principles while taking advantage of new tools for fostering student understanding. Because we believe that students learn through constant questioning, this edition features expanded problem sets, additional questions within the text, and extensive online resources for assessment. As in previous editions, we have strived to provide our students with a textbook that is complete, clearly written, and relevant.

New for the Fifth Edition

The fifth edition of *Fundamentals of Biochemistry* includes significant changes and updates to the contents. In recognition of the tremendous advances in biochemistry, we have added new information about prion diseases, trans fats, membrane transporters, signal transduction pathways, mitochondrial respiratory complexes, photosynthesis, nitrogen fixation, nucleotide synthesis, chromatin structure, and the machinery of DNA replication, transcription, and protein synthesis. New experimental approaches for studying complex systems are introduced, including next generation DNA sequencing techniques, cryo-electron microscopy, metabolomics, genome editing with the CRISPR–Cas9 system, and the role of noncoding RNAs in gene regulation. Notes on a variety of human diseases and pharmacological effectors have been expanded to reflect recent research findings.

Pedagogy

As in the previous four editions of *Fundamentals of Biochemistry*, we have given significant thought to the pedagogy within the text and have concentrated on fine-tuning and adding new elements to promote student learning. Pedagogical enhancements in this fifth edition include the following:

- **Gateway Concepts.** Short statements placed in the margin to summarize some of the general concepts that underpin modern biochemistry, such as Evolution, Macromolecular Structure/Function, Matter/Energy Transformation, and Homeostasis. These reminders help students develop a richer understanding as they place new information in the context of what they have encountered in other coursework.

GATEWAY CONCEPT Free Energy Change

You can think of the free energy change (ΔG) for a reaction in terms of an urge or a force pushing the reactants toward equilibrium. The larger the free energy change, the farther the reaction is from equilibrium and the stronger is the tendency for the reaction to proceed. At equilibrium, of course, the reactants undergo no net change and $\Delta G = 0$.

GATEWAY CONCEPT The Steady State

Although many reactions are near equilibrium, an entire metabolic pathway—and the cell’s metabolism as a whole—never reaches equilibrium. This is because materials and energy are constantly entering and leaving the system, which is in a steady state. Metabolic pathways proceed, as if trying to reach equilibrium (Le Châtelier’s principle), but they cannot get there because new reactants keep arriving and products do not accumulate.

- **Sample Calculation Videos within WileyPLUS Learning Space.** Students come to biochemistry with different levels of math skills. These embedded videos, created by Charlotte Pratt, walk students through the Sample Calculations provided for key equations throughout the text.
- **Animated Process Diagrams in WileyPLUS Learning Space.** The many Process Diagrams in the text have each been broken down into discrete steps that students can navigate at their desired pace.
- **Brief Bioinformatics Exercises in WileyPLUS Learning Space.** A series of 74 short, assessable, and content-specific bioinformatics projects (at least two per chapter) by Rakesh Mogul, Cal Poly Pomona. They introduce students to the rich variety of biochemical information available over the Internet and show them how to mine this information, thereby illuminating the connections between theory and applied biochemistry and stimulating student interest and proficiency in the subject.
- **Focus on evolution.** An evolutionary tree icon marks passages in the text that illuminate examples of evolution at the biochemical level.
- **Reorganized and Expanded Problem Sets.** End-of-chapter problems are now divided into two categories so that students and instructors can better assess lower- and higher-order engagement: **Exercises** allow students to check their basic understanding of concepts and apply them in straightforward problem solving. **Challenge Questions** require more advanced skills and/or the ability to make connections between topics. The fifth edition contains nearly 1000 problems, an increase of 26% over the previous edition. Most of the problems are arranged as successive pairs that address the same or related topics. Complete solutions to the odd-numbered problems are included in an appendix for quick feedback. (www.wiley.com/college/voet). Complete solutions to both odd- and even-numbered problems are available in the *Student Companion to Accompany Fundamentals of Biochemistry, Fifth Edition*.

Artwork

Students’ ability to understand and interpret biochemical diagrams, illustrations, and processes plays a significant role in their understanding both the big picture and details of biochemistry. In addition to designing new illustrations and redesigning existing figures to enhance clarity, we have continued to address the needs of visual learners by using several unique features to help students use the visuals in concert with the text:

- **Figure Questions.** To further underscore the importance of students’ ability to interpret various images and data, we have added questions at the ends of figure captions that encourage students to more fully engage the material and test their understanding of the process being illustrated.

FIG. 11-7 Effect of a catalyst on the transition state diagram of a reaction. Here $\Delta\Delta G_{\text{cat}}^{\ddagger} = \Delta G_{\text{uncat}}^{\ddagger} - \Delta G_{\text{cat}}^{\ddagger}$.

? Does the catalyst affect $\Delta G_{\text{reaction}}$?

- **Molecular Graphics.** Numerous figures have been replaced with state-of-the-art molecular graphics. The new figures are more detailed, clearer, and easier to interpret, and in many cases, reflect recent refinements in molecular visualization technology that have led to higher-resolution macromolecular models or have revealed new mechanistic features.

FIG. 13-4 X-Ray structure of the insulin receptor ectodomain. One of its $\alpha\beta$ protomers is shown in ribbon form with its six domains successively colored in rainbow order with the N-terminal domain blue and the C-terminal domain red. The other protomer is represented by its identically colored surface diagram. The β subunits consist of most of the orange and all of the red domains. The protein is viewed with the plasma membrane below and its twofold axis vertical. In the intact receptor, a single transmembrane helix connects each β subunit to its C-terminal cytoplasmic PTK domain. [Based on an X-ray structure by Michael Weiss, Case Western Reserve University; and Michael Lawrence, Walter and Eliza Hall Institute of Medical Research, Victoria, Australia. PDBid 3LOH.]

- **Media Assets.** WileyPLUS Learning Space plays a key role in students' ability to understand and manipulate structural images. Guided Explorations, Animated Figures, and Animated Process Diagrams employ extensive animations and three-dimensional structures so that students can interact with the materials at their own pace, making them ideal for independent study.

Traditional Pedagogical Strengths

Successful pedagogical elements from prior editions of *Fundamentals of Biochemistry* have been retained. Among these are:

- **Key concepts** at the beginning of each section that prompt students to recognize the important "takeaways" or concepts in each section, providing the scaffolding for understanding by better defining these important points.
- **Checkpoint** questions, a robust set of study questions that appear at the end of every section for students to check their mastery of the section's key concepts. Separate answers are not provided, encouraging students to look back over the chapter to reinforce their understanding, a process that helps develop confidence and student-centered learning.
- **Key sentences** printed in italics to assist with quick visual identification.
- **Overview figures** for many metabolic processes.
- **Detailed enzyme mechanism figures** throughout the text.

- **Process Diagrams.** These visually distinct illustrations highlight important biochemical processes and integrate descriptive text into the figure, appealing to visual learners. By following information in the form of a story, students are more likely to grasp the key principles and less likely to simply memorize random details.

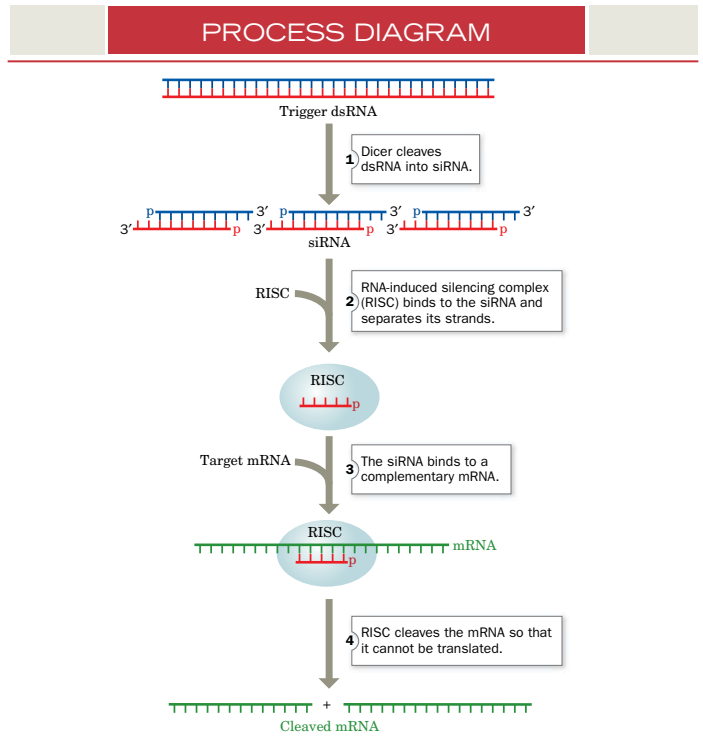

FIG. 28-37 A mechanism of RNA interference. ATP is required for Dicer-catalyzed cleavage of RNA and for RISC-associated helicase unwinding of double-stranded RNA. Depending on the species, the mRNA may not be completely degraded. **WPLS** See the Animated Process Diagrams.

? Explain why RNAi is a mechanism for "silencing" genes.

- **PDB identification codes** in the figure legend for each molecular structure so that students can easily access the structures online and explore them on their own.
- **Reviews of chemical principles** that underlie biochemical phenomena, including thermodynamics and equilibria, chemical kinetics, and oxidation–reduction reactions.
- **Sample calculations** that demonstrate how students can apply key equations to real data.

SAMPLE CALCULATION 10-1

Show that $\Delta G < 0$ when Ca^{2+} ions move from the endoplasmic reticulum (where $[\text{Ca}^{2+}] = 1 \text{ mM}$) to the cytosol (where $[\text{Ca}^{2+}] = 0.1 \mu\text{M}$). Assume $\Delta\psi = 0$.

The cytosol is *in* and the endoplasmic reticulum is *out*.

$$\begin{aligned}\Delta G &= RT \ln \frac{[\text{Ca}^{2+}]_{\text{in}}}{[\text{Ca}^{2+}]_{\text{out}}} = RT \ln \frac{10^{-7}}{10^{-3}} \\ &= RT(-9.2)\end{aligned}$$

Hence, ΔG is negative.

WPLS See Sample Calculation Videos.

- **Boxes to highlight topics** that link students to areas beyond basic biochemistry, such as ocean acidification (Box 2-1), production of complex molecules via polyketide synthesis (Box 20-3), and the intestinal microbiome (Box 22-1).

Biochemistry in Health and Disease essays highlight the importance of biochemistry in the clinic by focusing on the molecular mechanisms of diseases and their treatment.

Perspectives in Biochemistry provide enrichment material that would otherwise interrupt the flow of the text. Instead, the material is set aside so that students can appreciate some of the experimental methods and practical applications of biochemistry.

Pathways of Discovery profile pioneers in various fields, giving students a glimpse of the personalities and scientific challenges that have shaped modern biochemistry.

- **Caduceus symbols** to highlight relevant in-text discussions of medical, health, or drug-related topics. These include common diseases such as diabetes and neurodegenerative diseases as well as lesser known topics that reveal interesting aspects of biochemistry.
- **Expanded chapter summaries** grouped by major section headings, again guiding students to focus on the most important points within each section.
- **More to Explore guides** consisting of a set of questions at the end of each chapter that either extend the material presented in the text or prompt students to reach further and discover topics not covered in the textbook. In addition, WileyPLUS Learning Space offers over 1,000 concept-based questions that can be assigned and automatically graded, providing students with additional valuable practice opportunities.
- **Boldfaced Key terms.**
- **List of key terms** at the end of each chapter, with the **page numbers** where the terms are first defined.
- Comprehensive **glossary containing over 1200 terms.**
- List of **references** for each chapter, selected for their relevance and user-friendliness.

Organization

As in the fourth edition, the text begins with two introductory chapters that discuss the origin of life, evolution, thermodynamics, the properties of water, and acid–base chemistry. Nucleotides and nucleic acids are covered in Chapter 3, since an understanding of the structures and functions of these molecules supports the subsequent study of protein evolution and metabolism.

Four chapters (4 through 7) explore amino acid chemistry, methods for analyzing protein structure and sequence, secondary through quaternary protein structure, protein folding and stability, and structure–function relationships in hemoglobin, muscle proteins, and antibodies. Chapter 8 (Carbohydrates), Chapter 9 (Lipids and Biological Membranes), and Chapter 10 (Membrane Transport) round out the coverage of the basic molecules of life.

The next three chapters examine proteins in action, introducing students first to enzyme mechanisms (Chapter 11), then shepherding them through discussions of enzyme kinetics, the effects of inhibitors, and enzyme regulation (Chapter 12). These themes are continued in Chapter 13, which describes the components of signal transduction pathways.

Metabolism is covered in a series of chapters, beginning with an introductory chapter (Chapter 14) that provides an overview of metabolic

pathways, the thermodynamics of “high-energy” compounds, and redox chemistry. Central metabolic pathways are presented in detail (e.g., glycolysis, glycogen metabolism, and the citric acid cycle in Chapters 15–17) so that students can appreciate how individual enzymes catalyze reactions and work in concert to perform complicated biochemical tasks. Chapters 18 (Electron Transport and Oxidative Phosphorylation) and 19 (Photosynthesis) complete a sequence that emphasizes energy-acquiring pathways. Not all pathways are covered in full detail, particularly those related to lipids (Chapter 20), amino acids (Chapter 21), and nucleotides (Chapter 23). Instead, key enzymatic reactions are highlighted for their interesting chemistry or regulatory importance. Chapter 22, on the integration of metabolism, discusses organ specialization and metabolic regulation in mammals.

Six chapters describe the biochemistry of nucleic acids, starting with their metabolism (Chapter 23) and the structure of DNA and its interactions with proteins (Chapter 24). Chapters 25–27 cover the processes of DNA replication, transcription, and translation, highlighting the functions of the RNA and protein molecules that carry out these processes. Chapter 28 deals with a variety of mechanisms for regulating gene expression, including the histone code and the roles of transcription factors and their relevance to cancer and development.

Additional Support

Student Companion to Fundamentals of Biochemistry, 5th Edition

ISBN 978 111 926793 5

This enhanced study resource by Akif Uzman, University of Houston-Downtown, Jerry Johnson, University of Houston-Downtown, William Widger, University of Houston, Joseph Eichberg, University of Houston, Donald Voet, Judith Voet, and Charlotte Pratt, is designed to help students master basic concepts and hone their analytical skills. Each chapter contains a summary, a review of essential concepts, and additional problems. The fifth edition features *Behind the Equations* sections and *Calculation Analogies* that provide connections between key equations in the text and their applications. The authors have also included new categories of questions for the student:

- *Graphical analysis questions*, which focus on quantitative principles and challenge students to apply their knowledge.
- *Play It Forward questions* that draw specifically on knowledge obtained in previous chapters.

The Student Companion contains complete solutions to all of the end of chapter problems in the text.

Customize your own course with Wiley Custom Select

Create a textbook with precisely the content you want in a simple, three-step online process that brings your students a cost-efficient alternative to a traditional textbook. Select from an extensive collection of content at customselect.wiley.com, upload your own materials as well, and select from multiple delivery formats—full-color or black-and-white print with a variety of binding options, or eBook. Preview the full text online, get an instant price quote, and submit your order. We’ll take it from there.

ACKNOWLEDGMENTS

This textbook is the result of the dedicated effort of many individuals, several of whom deserve special mention: Foremost is our editor, Joan Kalkut, who kept us informed, organized, and on schedule. Madelyn Lesure designed the book's typography and Tom Nery created the cover. Billy Ray acquired many of the photographs in the textbook and kept track of all of them. Deborah Wenger, our copy editor, put the final polish on the manuscript and eliminated grammatical and typographical errors. Elizabeth Swain, our Production Editor skillfully managed the production of the textbook. Kristine Ruff spearheaded the marketing campaign. Special thanks to Aly Rentrop, Associate Development Editor, and Amanda Rillo, Editorial Program Assistant.

Geraldine Osnato, Senior Product Designer and Sean Hickey, Product Designer developed the *WileyPLUS* Learning Space course.

The atomic coordinates of many of the proteins and nucleic acids that we have drawn for use in this textbook were obtained from the Protein Data Bank (PDB) maintained by the Research Collaboratory for Structural Bioinformatics (RCSB). We created the drawings using the molecular graphics programs PyMOL by Warren DeLano; RIBBONS by Mike Carson; and GRASP by Anthony Nicholls, Kim Sharp, and Barry Honig.

CHAPTER 1

Introduction to the Chemistry of Life

Chapter Contents

1 The Origin of Life

- A Biological Molecules Arose from Inanimate Substances
- B Complex Self-Replicating Systems Evolved from Simple Molecules

2 Cellular Architecture

- A Cells Carry Out Metabolic Reactions
- B There Are Two Types of Cells: Prokaryotes and Eukaryotes
- C Molecular Data Reveal Three Evolutionary Domains of Organisms
- D Organisms Continue to Evolve

3 Thermodynamics

- A The First Law of Thermodynamics States That Energy Is Conserved
- B The Second Law of Thermodynamics States That Entropy Tends to Increase
- C The Free Energy Change Determines the Spontaneity of a Process
- D Free Energy Changes Can Be Calculated from Reactant and Product Concentrations
- E Life Achieves Homeostasis While Obeying the Laws of Thermodynamics

M. I. Walker/Science Source Images

The structures that make up this *Paramecium* cell, and the processes that occur within it, can be explained in chemical terms. All cells contain similar types of macromolecules and undergo similar chemical reactions to acquire energy, grow, communicate, and reproduce.

Biochemistry is, literally, the study of the chemistry of life. Although it overlaps other disciplines, including cell biology, genetics, immunology, microbiology, pharmacology, and physiology, biochemistry is largely concerned with a limited number of issues:

1. What are the chemical and three-dimensional structures of biological molecules?
2. How do biological molecules interact with one another?
3. How does the cell synthesize and degrade biological molecules?
4. How is energy conserved and used by the cell?
5. What are the mechanisms for organizing biological molecules and coordinating their activities?
6. How is genetic information stored, transmitted, and expressed?

Biochemistry, like other modern sciences, relies on sophisticated instruments to dissect the architecture and operation of systems that are inaccessible to the human senses. In addition to the chemist's tools for separating, quantifying, and otherwise analyzing biological materials, biochemists take advantage of the uniquely biological aspects of their subject by examining the evolutionary histories of organisms, metabolic systems, and individual molecules. In addition to its obvious implications for human health, biochemistry reveals the workings of the natural world, allowing us to understand and appreciate the unique and mysterious condition that we call life. In this introductory chapter, we will review some aspects of chemistry and biology—including the basics of evolution, the different types of cells, and the elementary principles of thermodynamics—to help put biochemistry in context and to introduce some of the themes that recur throughout this book.

1 The Origin of Life

KEY CONCEPTS

- Biological molecules are constructed from a limited number of elements.
- Certain functional groups and linkages characterize different types of biomolecules.
- During chemical evolution, simple compounds condensed to form more complex molecules and polymers.
- Self-replicating molecules were subject to natural selection.

Certain biochemical features are common to all organisms: the way hereditary information is encoded and expressed, for example, and the way biological molecules are built and broken down for energy. The underlying genetic and biochemical unity of modern organisms implies that they are descended from a single ancestor. Although it is impossible to describe exactly how life first arose, paleontological and laboratory studies have provided some insights about the origin of life.

A Biological Molecules Arose from Inanimate Substances

Living matter consists of a relatively small number of elements (**Table 1-1**). For example, C, H, O, N, P, Ca, and S account for ~97% of the dry weight of the human body (humans and most other organisms are ~70% water). Living organisms may also contain trace amounts of many other elements, including B, F, Al, Si, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, As, Se, Br, Mo, Cd, I, and W, although not every organism makes use of each of these substances.

The earliest known fossil evidence of life is ~3.5 billion years old (**Fig. 1-1**). The preceding **prebiotic era**, which began with the formation of the earth ~4.6 billion years ago, left no direct record, but scientists can experimentally duplicate the sorts of chemical reactions that might have given rise to living organisms during that billion-year period.

The atmosphere of the early earth probably consisted of small, simple compounds such as H₂O, N₂, CO₂, and smaller amounts of CH₄ and NH₃. In the 1920s, Alexander Oparin and J. B. S. Haldane independently suggested that ultraviolet radiation from the sun or lightning discharges caused the molecules of the primordial atmosphere to react to form simple **organic** (carbon-containing) **compounds**. This process was replicated in 1953 by Stanley Miller and Harold Urey, who subjected a mixture of H₂O, CH₄, NH₃, and H₂ to an electric discharge for about a week. The resulting solution contained water-soluble organic compounds, including several amino acids (which are components of proteins) and other biochemically significant compounds.

The assumptions behind the Miller–Urey experiment, principally the composition of the gas used as a starting material, have been challenged by some

TABLE 1-1 Most Abundant Elements in the Human Body^a

Element	Dry Weight (%)
C	61.7
N	11.0
O	9.3
H	5.7
Ca	5.0
P	3.3
K	1.3
S	1.0
Cl	0.7
Na	0.7
Mg	0.3

FIG. 1-1 Microfossil of filamentous bacterial cells. This fossil (shown with an interpretive drawing) is from ~3.4-billion-year-old rock from Western Australia.

scientists who have suggested that the first biological molecules were generated in a quite different way: in the dark and under water. Hydrothermal vents in the ocean floor, which emit solutions of metal sulfides at temperatures as high as 400°C (Fig. 1-2), may have provided conditions suitable for the formation of amino acids and other small organic molecules from simple compounds present in seawater.

Whatever their actual origin, the early organic molecules became the precursors of an enormous variety of biological molecules. These can be classified in various ways, depending on their composition and chemical reactivity. A familiarity with organic chemistry is useful for recognizing the **functional groups** (reactive portions) of molecules as well as the **linkages** (bonding arrangements) among them, since these features ultimately determine the biological activity of the molecules. Some of the common functional groups and linkages in biological molecules are shown in Table 1-2.

B Complex Self-Replicating Systems Evolved from Simple Molecules

During a period of chemical evolution, the prebiotic era, simple organic molecules condensed to form more complex molecules or combined end-to-end as **polymers** of repeating units. In a **condensation reaction**, the elements of water are lost. The rate of condensation of simple compounds to form a stable polymer must therefore be greater than the rate of **hydrolysis** (splitting by adding the elements of water; Fig. 1-3). In this prebiotic environment, minerals such as clays may have catalyzed polymerization reactions and sequestered the reaction products from water. The size and composition of prebiotic macromolecules would have been limited by the availability of small molecular starting materials, the efficiency with which they could be joined, and their resistance to degradation. The major biological polymers and their individual units (**monomers**) are given in Table 1-3.

Obviously, *combining different monomers and their various functional groups into a single large molecule increases the chemical versatility of that molecule*, allowing it to perform chemical feats beyond the reach of simpler molecules. (This principle of emergent properties can be expressed as “the whole is greater than the sum of its parts.”) Separate macromolecules with **complementary arrangements** (reciprocal pairing) of functional groups can associate with each other (Fig. 1-4), giving rise to more complex molecular assemblies with an even greater range of functional possibilities.

Specific pairing between complementary functional groups permits one member of a pair to determine the identity and orientation of the other member. *Such complementarity makes it possible for a macromolecule to replicate, or copy itself, by directing the assembly of a new molecule from smaller complementary units.* Replication of a simple polymer with intramolecular complementarity is

FIG. 1-3 Reaction of a carboxylic acid with an amine. The elements of water are released during condensation. In the reverse process—hydrolysis—water is added to cleave the amide bond. In living systems, condensation reactions are not freely reversible.

FIG. 1-2 A hydrothermal vent. Such ocean-floor formations are known as “black smokers” because the metal sulfides dissolved in the superheated water they emit precipitate on encountering the much cooler ocean water.

GATEWAY CONCEPT Functional Groups

Different classes of biological molecules are characterized by different types of functional groups and linkages. A biological molecule may contain multiple functional groups.

FIG. 1-4 Association of complementary molecules. The positively charged amino group interacts electrostatically with the negatively charged carboxylate group.

TABLE 1-2 Common Functional Groups and Linkages in Biochemistry

Compound Name	Structure ^a	Functional Group or Linkage
Amine ^b	RNH_2 or $\text{R}\overset{+}{\text{N}}\text{H}_3$ R_2NH or $\text{R}_2\overset{+}{\text{N}}\text{H}_2$ R_3N or $\text{R}_3\overset{+}{\text{N}}\text{H}$	$-\text{N}<$ or $\overset{+}{\text{N}}$ (amino group)
Alcohol	ROH	$-\text{OH}$ (hydroxyl group)
Thiol	RSH	$-\text{SH}$ (sulfhydryl group)
Ether	ROR	$-\text{O}-$ (ether linkage)
Aldehyde	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{H}$	$-\overset{\text{O}}{\parallel}{\text{C}}-$ (carbonyl group)
Ketone	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{R}$	$-\overset{\text{O}}{\parallel}{\text{C}}-$ (carbonyl group)
Carboxylic acid ^b	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{OH}$ or $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}^-$	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{OH}$ (carboxyl group) or $-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}^-$ (carboxylate group)
Ester	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{OR}$	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{O}-$ (ester linkage) $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-$ (acyl group) ^c
Thioester	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{SR}$	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{S}-$ (thioester linkage) $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-$ (acyl group) ^c
Amide	$\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{NH}_2$ $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{NHR}$ $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-\text{NR}_2$	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{N}<$ (amido group) $\text{R}-\overset{\text{O}}{\parallel}{\text{C}}-$ (acyl group) ^c
Imine (Schiff base) ^b	$\text{R}=\text{NH}$ or $\text{R}=\overset{+}{\text{N}}\text{H}_2$ $\text{R}=\text{NR}$ or $\text{R}=\overset{+}{\text{N}}\text{HR}$	$>\text{C}=\text{N}-$ or $>\text{C}=\overset{+}{\text{N}}<$ (imino group)
Disulfide	$\text{R}-\text{S}-\text{S}-\text{R}$	$-\text{S}-\text{S}-$ (disulfide linkage)
Phosphate ester ^b	$\text{R}-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{OH})\text{O}^-$	$-\overset{\text{O}}{\parallel}{\text{P}}(\text{OH})\text{O}^-$ (phosphoryl group)
Diphosphate ester ^b	$\text{R}-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{OH})\text{O}^-$	$-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{OH})\text{O}^-$ (phosphoanhydride group)
Phosphate diester ^b	$\text{R}-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{O}-\text{R}$	$-\text{O}-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{O}-$ (phosphodiester linkage)

^aR represents any carbon-containing group. In a molecule with more than one R group, the groups may be the same or different.

^bUnder physiological conditions, these groups are ionized and hence bear a positive or negative charge.

^cIf attached to an atom other than carbon.

? Cover the Structure column and draw the structure for each compound listed on the left. Do the same for each functional group or linkage.

TABLE 1-3 Major Biological Polymers and Their Component Monomers

Polymer	Monomer
Protein (polypeptide)	Amino acid
Nucleic acid (polynucleotide)	Nucleotide
Polysaccharide (complex carbohydrate)	Monosaccharide (simple carbohydrate)

FIG. 1-5 Replication through complementarity. In this simple case, a polymer serves as a template for the assembly of a complementary molecule, which, because of intramolecular complementarity, is an exact copy of the original.

? Distinguish the covalent bonds from the noncovalent interactions in this polymer.

illustrated in **Fig. 1-5**. A similar phenomenon is central to the function of DNA, where the sequence of bases on one strand (e.g., A-C-G-T) absolutely specifies the sequence of bases on the strand to which it is paired (T-G-C-A). When DNA replicates, the two strands separate and direct the synthesis of complementary daughter strands. Complementarity is also the basis for transcribing DNA into RNA and for translating RNA into protein.

A critical moment in chemical evolution was the transition from systems of randomly generated molecules to systems in which molecules were organized and specifically replicated. Once macromolecules gained the ability to self-perpetuate, the primordial environment would have become enriched in molecules that were best able to survive and multiply. The first replicating systems were no doubt somewhat sloppy, with progeny molecules imperfectly complementary to their parents. Over time, **natural selection**, the competitive process by which reproductive preference is given to the better adapted, would have favored molecules that made more accurate copies of themselves.

CHECKPOINT

- Which four elements occur in virtually all biological molecules?
- Summarize the major stages of chemical evolution.
- Practice drawing a simple condensation and hydrolysis reaction.
- Explain why complementarity would have been necessary for the development of self-replicating molecules.

2 Cellular Architecture

KEY CONCEPTS

- Compartmentation of cells promotes efficiency by maintaining high local concentrations of reactants.
- Metabolic pathways evolved to synthesize molecules and generate energy.
- The simplest cells are prokaryotes.
- Eukaryotes are characterized by numerous membrane-bounded organelles, including a nucleus.
- The phylogenetic tree of life includes three domains: bacteria, archaea, and eukarya.
- Evolution occurs as natural selection acts on randomly occurring genetic variations among individuals.

The types of systems described so far would have had to compete with all the other components of the primordial earth for the available resources. A selective advantage would have accrued to a system that was sequestered and protected by boundaries of some sort. How these boundaries first arose, or even what they were made from, is obscure. One theory is that membranous **vesicles** (fluid-filled sacs) first attached to and then enclosed self-replicating systems. These vesicles would have become the first cells.

A Cells Carry Out Metabolic Reactions

The advantages of **compartmentation** are several. In addition to receiving some protection from adverse environmental forces, an enclosed system can maintain high local concentrations of components that would otherwise diffuse away. More concentrated substances can react more readily, leading to increased efficiency in polymerization and other types of chemical reactions.

A membrane-bounded compartment that protected its contents would gradually become quite different in composition from its surroundings. Modern cells contain high concentrations of ions, small molecules, and large molecular aggregates that are found only in traces—if at all—outside the cell. For example, a cell of the bacterium *Escherichia coli* (*E. coli*) contains millions of molecules, representing some 3000 to 6000 different compounds (Fig. 1-6). A typical animal cell may contain 100,000 different types of molecules.

Early cells depended on the environment to supply building materials. As some of the essential components in the prebiotic soup became scarce, natural selection favored organisms that developed **metabolic pathways**, mechanisms for synthesizing the required compounds from simpler but more abundant **precursors**. The first metabolic reactions may have used metal or clay **catalysts** (a catalyst is a substance that promotes a chemical reaction without itself undergoing a net change). In fact, metal ions are still at the heart of many chemical reactions in modern cells. Some catalysts may also have arisen from polymeric molecules that had the appropriate functional groups.

In general, biosynthetic reactions require energy; hence the first cellular reactions also needed an energy source. The eventual depletion of preexisting energy-rich substances in the prebiotic environment would have favored the development of energy-producing metabolic pathways. For example, photosynthesis evolved relatively early to take advantage of a practically inexhaustible energy supply, the sun. However, the accumulation of O_2 generated from H_2O

FIG. 1-6 Cross-section through an *E. coli* cell.

The cytoplasm is packed with macromolecules. At this magnification ($\sim 1,000,000\times$), individual atoms are too small to resolve. The green structures on the right include the inner and outer membrane components along with a portion of a flagellum. Inside the cell, various proteins are shown in blue, and ribosomes are purple. The gold and orange structures represent DNA and DNA-binding proteins, respectively. In a living cell, the remaining spaces would be crowded with water and small molecules. [From Goodsell, D.S., *The Machinery of Life* (2nd ed.), Springer (2009). Reproduced with permission.]

by photosynthesis (the modern atmosphere is 21% O₂) presented an additional challenge to organisms adapted to life in an oxygen-poor atmosphere. Metabolic refinements eventually permitted organisms not only to avoid oxidative damage but also to use O₂ for oxidative metabolism, a much more efficient form of energy metabolism than anaerobic metabolism. Vestiges of ancient life can be seen in the anaerobic metabolism of certain modern organisms.

Early organisms that developed metabolic strategies to synthesize biological molecules, conserve and utilize energy in a controlled fashion, and replicate within a protective compartment were able to propagate in an ever-widening range of habitats. Adaptation of cells to different external conditions ultimately led to the present diversity of species. Specialization of individual cells also made it possible for groups of differentiated cells to work together in multicellular organisms.

B There Are Two Types of Cells: Prokaryotes and Eukaryotes

All modern organisms are based on the same morphological unit, the cell. There are two major classifications of cells: the **eukaryotes** (Greek: *eu*, good or true + *karyon*, kernel or nut), which have a membrane-enclosed **nucleus** encapsulating their DNA; and the **prokaryotes** (Greek: *pro*, before), which lack a nucleus. *Prokaryotes, comprising the various types of bacteria, have relatively simple structures and are almost all unicellular (although they may form filaments or colonies of independent cells). Eukaryotes, which are multicellular as well as unicellular, are vastly more complex than prokaryotes. (Viruses are much simpler entities than cells and are not classified as living because they lack the metabolic apparatus to reproduce outside their host cells.)*

Prokaryotes are the most numerous and widespread organisms on the earth. This is because their varied and often highly adaptable metabolisms suit them to an enormous variety of habitats. Prokaryotes range in size from 1 to 10 μm and have one of three basic shapes (Fig. 1-7): spheroidal (cocci), rodlike (bacilli), and helically coiled (spirilla). Except for an outer cell membrane, which in most cases is surrounded by a protective cell wall, nearly all prokaryotes lack cellular membranes. However, the prokaryotic **cytoplasm** (cell contents) is by no means a homogeneous soup. Different metabolic functions are carried out in different regions of the cytoplasm (Fig. 1-6). The best characterized prokaryote is *Escherichia coli*, a 2 μm by 1 μm rodlike bacterium that inhabits the mammalian colon.

FIG. 1-7 Scale drawings of some prokaryotic cells.

FIG. 1-8 Diagram of a typical animal cell with electron micrographs of its organelles. Membrane-bounded organelles include the nucleus, endoplasmic reticulum, lysosome, peroxisome (not pictured), mitochondrion, vacuole, and Golgi apparatus. The nucleus contains chromatin (a complex of DNA and protein) and the nucleolus (the site of ribosome synthesis). The rough endoplasmic reticulum is studded with ribosomes; the smooth endoplasmic reticulum is not. A pair of centrioles help organize cytoskeletal elements. A typical plant cell differs mainly by the presence of an outer cell wall and

chloroplasts in the cytosol. [Smooth endoplasmic reticulum © Dennis Kunkel Microscopy, Inc./Phototake; rough endoplasmic reticulum © Pietro M. Motta & Tomonori Naguro/Photo Researchers, Inc.; nucleus © Tektoff-RM, CNRI/Photo Researchers; mitochondrion © CNRI/Photo Researchers; Golgi apparatus © Secchi-Lecaque/Roussel-UCLAF/CNRI/Photo Researchers; lysosome © Biophoto Associates/Photo Researchers.]

? With the labels covered, name the parts of this eukaryotic cell.

Eukaryotic cells are generally 10 to 100 μm in diameter and thus have a thousand to a million times the volume of typical prokaryotes. It is not size, however, but a profusion of membrane-enclosed **organelles** that best characterizes eukaryotic cells (**Fig. 1-8**). In addition to a nucleus, eukaryotes have an **endoplasmic reticulum**, the site of synthesis of many cellular components, some of which are subsequently modified in the **Golgi apparatus**. The bulk of aerobic metabolism takes place in **mitochondria** in almost all eukaryotes, and photosynthetic cells contain **chloroplasts**, which convert the energy of the sun's rays to chemical energy. Other organelles, such as **lysosomes** and **peroxisomes**, perform specialized functions. **Vacuoles**, which are more prominent in plant than in animal cells, usually function as storage depots. The **cytosol** (the cytoplasm minus its membrane-bounded organelles) is organized by the **cytoskeleton**, an extensive array of filaments that also gives the cell its shape and the ability to move.

The various organelles that compartmentalize eukaryotic cells represent a level of complexity that is largely lacking in prokaryotic cells. Nevertheless, prokaryotes are more efficient than eukaryotes in many respects. Prokaryotes have exploited the advantages of simplicity and miniaturization. Their rapid growth rates permit them to occupy ecological niches in which there may be drastic fluctuations of the available nutrients. In contrast, the complexity of eukaryotes, which renders them larger and more slowly growing than prokaryotes, gives them the competitive advantage in stable environments with limited resources. It is therefore erroneous to consider prokaryotes as evolutionarily primitive compared to eukaryotes. Both types of organisms are well adapted to their respective lifestyles.

C Molecular Data Reveal Three Evolutionary Domains of Organisms

🌿 The practice of lumping all prokaryotes in a single category based on what they lack—a nucleus—obscures their metabolic diversity and evolutionary history. Conversely, the remarkable morphological diversity of eukaryotic organisms (consider the anatomical differences among, say, an amoeba, an oak tree, and a human being) masks their fundamental similarity at the cellular level. Traditional taxonomic schemes (**taxonomy** is the science of biological classification), which are based on gross morphology, have proved inadequate to describe the actual relationships between organisms as revealed by their evolutionary history (**phylogeny**).

Biological classification schemes based on reproductive or developmental strategies more accurately reflect evolutionary history than those based solely on adult morphology. However, *phylogenetic relationships are best deduced by comparing polymeric molecules—RNA, DNA, or protein—from different organisms*. For example, analysis of RNA led Carl Woese to group all organisms into three domains (**Fig. 1-9**). The **archaea** (also known as **archaeobacteria**) are a group of prokaryotes that are as distantly related to other prokaryotes (the **bacteria**, sometimes called **eubacteria**) as both groups are to eukaryotes (**eukarya**). The archaea include some unusual organisms: the **methanogens** (which produce CH_4), the **halobacteria** (which thrive in concentrated brine solutions), and certain **thermophiles** (which inhabit hot springs). The pattern of branches in Woese's diagram indicates the divergence of different types of organisms (each branch point represents a common ancestor). The three-domain scheme also shows that animals, plants, and fungi constitute only a small portion of all life-forms. Such phylogenetic trees supplement the fossil record, which provides a patchy record of life prior to about 600 million years before the present (multicellular organisms arose about 700–900 million years ago).

It is unlikely that eukaryotes are descended from a single prokaryote, because the differences among eubacteria, archaea, and eukaryotes are so profound. Instead, eukaryotes probably evolved from the association of archaeobacterial and eubacterial cells. The eukaryotic genetic material includes features that suggest an archaeobacterial origin. In addition, the mitochondria and chloroplasts of modern eukaryotic cells resemble eubacteria in size and shape, and both types of organelles contain their own genetic material and protein synthetic machinery. Evidently, as Lynn Margulis proposed, mitochondria and chloroplasts evolved from free-living eubacteria that formed **symbiotic** (mutually beneficial) relationships with a primordial eukaryotic cell (Box 1-1). In fact, certain eukaryotes that lack mitochondria or chloroplasts permanently harbor symbiotic bacteria.

FIG. 1-9 Phylogenetic tree showing the three domains of organisms. The branches indicate the pattern of divergence from a common ancestor. The archaea are prokaryotes, like eubacteria, but share many features with eukaryotes. [After Wheelis, M.L., Kandler, O., and Woese, C.R., *Proc. Natl. Acad. Sci.* **89**, 2931 (1992).]

Lynn Margulis (1938–2011) After growing up in Chicago and enrolling in the University of Chicago at age 16, Lynn Margulis intended to be a writer. Her interest in biology was sparked by a required science course for which she read Gregor Mendel's accounts of his experiments with the genetics of pea plants. Margulis continued her studies at the University of Wisconsin–

Berkeley, earning a doctorate in 1963. Her careful consideration of cellular structures led her to hypothesize that eukaryotic cells originated from a series of endosymbiotic events involving multiple prokaryotes. The term *endo* (Greek: within) refers to an arrangement in which one cell comes to reside inside another. This idea was considered outrageous at the time (1967), but many of Margulis's ideas have since become widely accepted.

Endosymbiosis as an explanation for the origin of mitochondria had been proposed by Ivan Wallin in 1927, who noted the similarity between mitochondria and bacteria in size, shape, and cytological staining. Wallin's hypothesis was rejected as being too fantastic and was ignored until it was taken up again by Margulis. By the 1960s, much more was known about mitochondria (and chloroplasts), including the facts that they contained DNA and reproduced by division. Margulis did not focus all her attention on the origin of individual organelles but instead sought to explain the origin of the entire eukaryotic cell, which also includes centrioles, another possible bacterial relic. Her paper, "On the origin of mitosing cells," was initially rejected by several journals before being accepted by the *Journal of Theoretical Biology*. The notion that a complex eukaryotic cell could arise from a consortium of mutually dependent prokaryotic cells was incompatible with the prevailing view that evolution occurred as a series of small steps. Evolutionary theory of the time had no room for the dramatic amalgamation of cells—and their genetic material—that Margulis had proposed. Nevertheless, the outspoken Margulis persisted, and by the time she published

Symbiosis in Cell Evolution in 1981, much of the biological community had come on board to agree with her.

Two main tenets of Margulis's theory, that mitochondria are the descendants of oxygen-respiring bacteria and that chloroplasts were originally photosynthetic bacteria, are now almost universally accepted. The idea that the eukaryotic cytoplasm is the remnant of an archaeobacterial cell is still questioned by some biologists. Margulis was in the process of collecting evidence to support a fourth idea, that cilia and flagella and some sensory structures such as the light-sensing cells of the eye are descendants of free-living spirochete bacteria. Margulis's original prediction that organelles such as mitochondria could be isolated and cultured has not been fulfilled. However, there is ample evidence for the transfer of genetic material between organelles and the nucleus, consistent with Margulis's theory of endosymbiosis. In fact, current theories of evolution include the movement of genetic material among organisms, as predicted by Margulis, in addition to small random mutations as agents of change.

Perhaps as an extension of her work on bacterial endosymbiosis, Margulis came to recognize that the interactions among many different types of organisms as well as their interactions with their physical environment constitute a single self-regulating system. This notion is part of the Gaia hypothesis proposed by James Lovelock, which views the entire earth as one living entity (Gaia was a Greek earth goddess). However, Margulis had no patience with those who sought to build a modern mythology based on Gaia. She was adamant about the importance of using scientific tools and reasoning to discover the truth and was irritated by the popular belief that humans are the center of life on earth. Margulis understood that human survival depends on our relationships with waste-recycling, water-purifying, and oxygen-producing bacteria, with whom we have been evolving, sometimes endosymbiotically, for billions of years.

Sagan, L., On the origin of mitosing cells, *J. Theor. Biol.* **14**, 255–274 (1967).

D Organisms Continue to Evolve

 The natural selection that guided prebiotic evolution continues to direct the evolution of organisms. Richard Dawkins has likened evolution to a blind watchmaker capable of producing intricacy by accident, although such an image fails to convey the vast expanse of time and the incremental, trial-and-error manner in which complex organisms emerge. Small **mutations** (changes in an individual's genetic material) arise at random as the result of chemical damage or inherent errors in the DNA replication process. *A mutation that increases the chances of survival of the individual increases the likelihood that the mutation will be passed on to the next generation.* Beneficial mutations tend to spread rapidly through a population; deleterious changes tend to die along with the organisms that harbor them.

The theory of evolution by natural selection, which was first articulated by Charles Darwin in the 1860s, has been confirmed through observation and experimentation. It is therefore useful to highlight several important—and often misunderstood—principles of evolution:

- 1. Evolution is not directed toward a particular goal.** It proceeds by random changes that may affect the ability of an organism to reproduce under the prevailing conditions. An organism that is well adapted to its environment may fare better or worse when conditions change.

- Variation among individuals** allows organisms to adapt to unexpected changes. This is one reason that genetically homogeneous populations (e.g., a corn crop) are so susceptible to a single challenge (e.g., a fungal blight). A more heterogeneous population is more likely to include individuals that can resist the adversity and recover.
- The past determines the future.** New structures and metabolic functions emerge from preexisting elements. For example, insect wings did not erupt spontaneously but appear to have developed gradually from small heat-exchange structures.
- Evolution is ongoing,** although it does not proceed exclusively toward complexity. An anthropocentric view places human beings at the pinnacle of an evolutionary scheme, but a quick survey of life's diversity reveals that simpler species have not died out or stopped evolving.

CHECKPOINT

- Explain the selective advantages of compartmentation and metabolic pathways.
- Discuss the differences between prokaryotes and eukaryotes.
- Make a list of the major eukaryotic organelles and their functions.
- Explain why a taxonomy based on molecular sequences is more accurate than one based on morphology.
- Which of the three domains are prokaryotic? Which domain is most similar to eukaryotes?
- Explain how individual variations allow evolution to occur.
- Why is evolutionary change constrained by its past but impossible to predict?

3 Thermodynamics

KEY CONCEPTS

- Energy must be conserved, but it can take different forms.
- In most biochemical systems, enthalpy is equivalent to heat.
- Entropy, a measure of a system's disorder, tends to increase.
- The free energy change for a process is determined by its changes in both enthalpy and entropy.
- A spontaneous process occurs with a decrease in free energy.
- The free energy change for a reaction can be calculated from the temperature and the concentrations and stoichiometry of the reactants and products.
- Biochemists define standard state conditions as a temperature of 25°C, a pressure of 1 atm, and a pH of 7.0.
- Organisms are nonequilibrium, open systems that constantly exchange matter and energy with their surroundings while maintaining homeostasis.
- Enzymes increase the rate at which a reaction approaches equilibrium.

The normal activities of living organisms—moving, growing, reproducing—demand an almost constant input of energy. Even at rest, organisms devote a considerable portion of their biochemical apparatus to the acquisition and utilization of energy. The study of energy and its effects on matter falls under the purview of **thermodynamics** (Greek: *therme*, heat + *dynamis*, power). Although living systems present some practical challenges to thermodynamic analysis, *life obeys the laws of thermodynamics*. Understanding thermodynamics is important not only for describing a particular process—such as a biochemical reaction—in terms that can be quantified, but also for predicting whether that process *can* actually occur; that is, whether the process is **spontaneous**. To begin, we will review the fundamental laws of thermodynamics. We will then turn our attention to free energy and how it relates to chemical reactions. Finally, we will look at how biological systems deal with the laws of thermodynamics.

A The First Law of Thermodynamics States That Energy Is Conserved

In thermodynamics, a **system** is defined as the part of the universe that is of interest, such as a reaction vessel or an organism; the rest of the universe is known as the **surroundings**. The system has a certain amount of **energy, U** . *The first law of thermodynamics states that energy is conserved*; it can be neither created nor destroyed. However, when the system undergoes a change, some of its energy can be used to perform work. The energy change of the system is defined as the

difference between the **heat** (q) absorbed by the system from the surroundings and **work** (w) done by the system on the surroundings:

$$\Delta U = U_{\text{final}} - U_{\text{initial}} = q - w \quad [1-1]$$

where the upper case Greek letter Δ (delta) indicates change. Heat is a reflection of random molecular motion, whereas work, which is defined as force times the distance moved under its influence, is associated with organized motion. Force may assume many different forms, including the gravitational force exerted by one mass on another, the expansional force exerted by a gas, the tensional force exerted by a spring or muscle fiber, the electrical force of one charge on another, and the dissipative forces of friction and viscosity. Because energy can be used to perform different kinds of work, it is sometimes useful to speak of energy taking different forms, such as mechanical energy, electrical energy, or chemical energy—all of which are relevant to biological systems.

Most biological processes take place at constant pressure. Under such conditions, the work done by the expansion of a gas (pressure–volume work) is $P\Delta V$. Consequently it is useful to define a new thermodynamic quantity, the **enthalpy** (Greek: *enthalpein*, to warm in), symbolized H :

$$H = U + PV \quad [1-2]$$

Then, when the system undergoes a change at constant pressure,

$$\Delta H = \Delta U + P\Delta V = q_p - w + P\Delta V \quad [1-3]$$

where q_p is defined as the heat at constant pressure. Since we already know that in this system $w = P\Delta V$,

$$\Delta H = q_p - P\Delta V + P\Delta V = q_p \quad [1-4]$$

In other words, the change in enthalpy at constant pressure is equivalent to heat. Moreover, the volume changes in most biochemical reactions are insignificant ($P\Delta V \approx 0$), so the differences between their ΔU and ΔH values are negligible, and hence the energy change for the reacting system is equivalent to its enthalpy change. Enthalpy, like energy, heat, and work, is given units of joules. Some commonly used units and biochemical constants and other conventions are given in Box 1-2.

Thermodynamics is useful for indicating the spontaneity of a process. A **spontaneous process** occurs without the input of additional energy from outside

Box 1-2 Perspectives in Biochemistry Biochemical Conventions

Modern biochemistry generally uses Système International (SI) units, including meters (m), kilograms (kg), and seconds (s) and their derived units, for various thermodynamic and other measurements. The following lists the commonly used biochemical units, some useful biochemical constants, and a few conversion factors.

Units

Energy, heat, work	joule (J)	$\text{kg} \cdot \text{m}^2 \cdot \text{s}^{-2}$ or $\text{C} \cdot \text{V}$
Electric potential	volt (V)	$\text{J} \cdot \text{C}^{-1}$

Prefixes for units

mega (M)	10^6	nano (n)	10^{-9}
kilo (k)	10^3	pico (p)	10^{-12}
milli (m)	10^{-3}	femto (f)	10^{-15}
micro (μ)	10^{-6}	atto (a)	10^{-18}

Conversions

angstrom (\AA)	10^{-10} m
calorie (cal)	4.184 J
kelvin (K)	degrees Celsius ($^{\circ}\text{C}$) + 273.15

Constants

Avogadro's number (N)	6.0221×10^{23} molecules $\cdot \text{mol}^{-1}$
Coulomb (C)	6.241×10^{18} electron charges
Faraday (F)	96,485 C $\cdot \text{mol}^{-1}$ or 96,485 J $\cdot \text{V}^{-1} \cdot \text{mol}^{-1}$
Gas constant (R)	8.3145 J $\cdot \text{K}^{-1} \cdot \text{mol}^{-1}$
Boltzmann constant (k_B)	1.3807×10^{-23} J $\cdot \text{K}^{-1}$ (R/N)
Planck's constant (h)	6.6261×10^{-34} J $\cdot \text{s}$

Throughout this text, molecular masses of particles are expressed in units of **daltons (D)**, which are defined as 1/12th the mass of a ^{12}C atom ($1000 \text{ D} = 1$ **kilodalton, kD**). Biochemists also use **molecular weight**, a dimensionless quantity defined as the ratio of the particle mass to 1/12th the mass of a ^{12}C atom, which is symbolized M_r (for relative molecular mass).

the system (although keep in mind that thermodynamic spontaneity has nothing to do with how quickly a process occurs). The first law of thermodynamics, however, cannot by itself determine whether a process is spontaneous. Consider two objects of different temperatures that are brought together. Heat flows spontaneously from the warmer object to the cooler one, never vice versa, yet either process would be consistent with the first law of thermodynamics since the aggregate energy of the two objects does not change. Therefore, an additional criterion of spontaneity is needed.

B The Second Law of Thermodynamics States That Entropy Tends to Increase

According to the second law of thermodynamics, spontaneous processes are characterized by the conversion of order to disorder. In this context, disorder is defined as the number of energetically equivalent ways, W , of arranging the components of a system. Note that there are more ways of arranging a disordered system than a more ordered system. To make this concept concrete, consider a system consisting of two bulbs of equal volume, one of which contains molecules of an ideal gas (Fig. 1-10). When the stopcock connecting the bulbs is opened, the molecules become randomly but equally distributed between the two bulbs (each gas molecule has a 50% probability of being in the left bulb and hence there are 2^N equivalent ways of randomly distributing them between the two bulbs, where N is the number of gas molecules; note that even when N is as small as 100, 2^N is an astronomically large number). The equal number of gas molecules in each bulb is not the result of any law of motion; it is because the probabilities of all other distributions of the molecules are so overwhelmingly small. Thus, the probability of all the molecules in the system spontaneously rushing into the left bulb (the initial condition, in which $W = 1$) is nil, even though the energy and enthalpy of that arrangement are exactly the same as those of the evenly distributed molecules. By the same token, the mechanical energy (work) of a swimmer jumping into a pool heats the water (increases the random motion of its molecules), but the reverse process, a swimmer being ejected from the water by the organized motion of her surrounding water molecules, has never been observed, even though this process does not violate any law of motion.

Since W is usually inconveniently large, the degree of randomness of a system is better indicated by its **entropy** (Greek: *en*, in + *tropē*, turning), symbolized S :

$$S = k_B \ln W \quad [1-5]$$

where k_B is the **Boltzmann constant**. The units of S are $\text{J} \cdot \text{K}^{-1}$ (absolute temperature, in units of kelvins, is a factor because entropy varies with temperature; e.g., a system becomes more disordered as its temperature rises). The most probable arrangement of a system is the one that maximizes W , and hence S . Thus, if a spontaneous process, such as the one shown in Fig. 1-10, has overall energy and enthalpy changes (ΔU and ΔH) of zero, its entropy change (ΔS) must be greater than zero; that is, the number of equivalent ways of arranging the final state must be greater than the number of ways of arranging the initial state. Furthermore, because

$$\Delta S_{\text{system}} + \Delta S_{\text{surroundings}} = \Delta S_{\text{universe}} > 0 \quad [1-6]$$

all processes increase the entropy—that is, the disorder—of the universe.

In chemical and biological systems, it is impractical, if not impossible, to determine the entropy of a system by counting all the equivalent arrangements of its components (W). However, there is an entirely equivalent expression for entropy that applies to the constant-temperature conditions typical of biological systems: for a spontaneous process,

$$\Delta S \geq \frac{q}{T} \quad [1-7]$$

Thus, the entropy change in a process can be experimentally determined from measurements of heat and temperature.

FIG. 1-10 Illustration of entropy. In (a), a gas occupies the leftmost of two equal-sized bulbs and hence the entropy is low. When the stopcock is opened (b), the entropy increases as the gas molecules diffuse back and forth between the bulbs and eventually become distributed evenly, half in each bulb.

? Does the total heat content of this system change when the stopcock is opened?

C The Free Energy Change Determines the Spontaneity of a Process

The spontaneity of a process cannot be predicted from a knowledge of the system's entropy change alone. For example, a mixture of 2 mol of H₂ and 1 mol of O₂, when sparked, reacts (explodes) to form 2 mol of H₂O. Yet two water molecules, each of whose three atoms are constrained to stay together, are more ordered than are the three diatomic molecules from which they formed. Thus, this spontaneous reaction occurs with a decrease in the system's entropy.

What, then, is the thermodynamic criterion for a spontaneous process? Equations 1-4 and 1-7 indicate that at constant temperature and pressure,

$$\Delta S \geq \frac{q_r}{T} = \frac{\Delta H}{T} \quad [1-8]$$

Thus,

$$\Delta H - T\Delta S \leq 0 \quad [1-9]$$

This is the true criterion for spontaneity as formulated, in 1878, by J. Willard Gibbs. He defined the **Gibbs free energy** (**G**, usually called just **free energy**) as

$$G = H - TS \quad [1-10]$$

The change in free energy for a process is ΔG . Consequently, spontaneous processes at constant temperature and pressure have

$$\boxed{\Delta G = \Delta H - T\Delta S < 0} \quad [1-11]$$

Processes in which ΔG is negative are said to be **exergonic** (Greek: *ergon*, work). Processes that are not spontaneous have positive ΔG values ($\Delta G > 0$) and are said to be **endergonic**; they must be driven by the input of free energy. If a process is exergonic, the reverse of that process is endergonic and vice versa. Thus, the ΔG value for a process indicates whether the process can occur spontaneously in the direction written (see Sample Calculation 1-1). Processes at **equilibrium**, those in which the forward and reverse reactions are exactly balanced, are characterized by $\Delta G = 0$. Processes that occur with $\Delta G \approx 0$, so the system, in effect, remains at equilibrium throughout the process, are said to be **reversible**. Processes that occur with $\Delta G \neq 0$ are said to be **irreversible**. An irreversible process with $\Delta G < 0$ is said to be **favorable** or to occur spontaneously, whereas an irreversible process with $\Delta G > 0$ is said to be **unfavorable**.

A process that is accompanied by an increase in enthalpy ($\Delta H > 0$), which opposes the process, can nevertheless proceed spontaneously if the entropy change is sufficiently positive ($\Delta S > 0$; **Table 1-4**). Conversely, a process that is accompanied by a decrease in entropy ($\Delta S < 0$) can proceed if its enthalpy change is sufficiently negative ($\Delta H < 0$). It is important to emphasize that *a large negative value of ΔG does not ensure that a process such as a chemical reaction*

TABLE 1-4 Variation of Reaction Spontaneity (Sign of ΔG) with the Signs of ΔH and ΔS

ΔH	ΔS	$\Delta G = \Delta H - T\Delta S$
-	+	The reaction is both enthalpically favored (exothermic) and entropically favored. It is spontaneous (exergonic) at all temperatures.
-	-	The reaction is enthalpically favored but entropically opposed. It is spontaneous only at temperatures <i>below</i> $T = \Delta H/\Delta S$.
+	+	The reaction is enthalpically opposed (endothermic) but entropically favored. It is spontaneous only at temperatures <i>above</i> $T = \Delta H/\Delta S$.
+	-	The reaction is both enthalpically and entropically opposed. It is nonspontaneous (endergonic) at all temperatures.

SAMPLE CALCULATION 1-1

The enthalpy and entropy of the initial and final states of a reacting system are shown in the table.

	H ($\text{J} \cdot \text{mol}^{-1}$)	S ($\text{J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$)
Initial state (before reaction)	54,000	22
Final state (after reaction)	60,000	43

- Calculate the change in enthalpy and change in entropy for the reaction.
- Calculate the change in free energy for the reaction when the temperature is 4°C . Is the reaction spontaneous?
- Is the reaction spontaneous at 37°C ?

$$\begin{aligned} \text{a. } \Delta H &= H_{\text{final}} - H_{\text{initial}} = 60,000 \text{ J} \cdot \text{mol}^{-1} - 54,000 \text{ J} \cdot \text{mol}^{-1} = 6000 \text{ J} \cdot \text{mol}^{-1} \\ \Delta S &= S_{\text{final}} - S_{\text{initial}} = \Delta S = 43 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1} - 22 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1} \\ &= 21 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1} \end{aligned}$$

- First, convert temperature from $^\circ\text{C}$ to K: $4 + 273 = 277 \text{ K}$. Then use Eq. 1-11.

$$\begin{aligned} \Delta G &= \Delta H - T\Delta S \\ \Delta G &= (6000 \text{ J} \cdot \text{mol}^{-1}) - (277 \text{ K})(21 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}) \\ &= 6000 \text{ J} \cdot \text{mol}^{-1} - 5820 \text{ J} \cdot \text{mol}^{-1} = 180 \text{ J} \cdot \text{mol}^{-1} \end{aligned}$$

The value for ΔG is greater than zero, so this is an endergonic (nonspontaneous) reaction at 4°C .

- Convert temperature from $^\circ\text{C}$ to K: $37 + 273 = 310 \text{ K}$.

$$\begin{aligned} \Delta G &= \Delta H - T\Delta S \\ \Delta G &= (6000 \text{ J} \cdot \text{mol}^{-1}) - (310 \text{ K})(21 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}) \\ &= 6000 \text{ J} \cdot \text{mol}^{-1} - 6510 \text{ J} \cdot \text{mol}^{-1} = -510 \text{ J} \cdot \text{mol}^{-1} \end{aligned}$$

The value for ΔG is less than zero, so the reaction is spontaneous (exergonic) at 37°C .

WPLS See Sample Calculation Videos.

will proceed at a measurable rate. The rate depends on the detailed mechanism of the reaction, which is independent of ΔG (Section 11-2).

Free energy, as well as energy, enthalpy, and entropy, are **state functions**. In other words, their values depend only on the current state or properties of the system, not on how the system reached that state. Therefore, *thermodynamic measurements can be made by considering only the initial and final states of the system and ignoring all the stepwise changes in enthalpy and entropy that occur in between*. For example, it is impossible to directly measure the energy change for the reaction of glucose with O_2 *in vivo* (in a living organism) because of the numerous other simultaneously occurring chemical reactions. However, because ΔG depends on only the initial and final states, the combustion of glucose can be analyzed in any convenient apparatus, using the same starting materials (glucose and O_2) and end products (CO_2 and H_2O) that occur *in vivo*. A system may undergo an irreversible cyclic process that returns it to its initial state and hence, for this system, $\Delta G = 0$. However, this process must be accompanied by an increase in the entropy (disordering) of the surroundings so that for the universe, $\Delta G < 0$.

Note that heat (q) and work (w) are not state functions. This is because, as Eq. 1-1 indicates, they are interchangeable forms of energy and hence the change in both these quantities varies with the pathway taken in changing the state of a system. It is therefore invalid to refer to the heat content or the work content of a system (in the same way that it is invalid to describe the money in your bank account as consisting only of a fixed number of pennies and dimes).

D Free Energy Changes Can Be Calculated from Reactant and Product Concentrations

The entropy (disorder) of a substance increases with its volume. For example, a collection of gas molecules, in occupying all of the volume available to it, maximizes its entropy (assumes its most disordered arrangement). Similarly, dissolved molecules become uniformly distributed throughout their solution volume. Entropy is therefore a function of concentration.

If entropy varies with concentration, so must free energy. Thus, *the free energy change of a chemical reaction depends on the concentrations of both its reacting substances (reactants) and its reaction products*. This phenomenon has great significance because many biochemical reactions operate spontaneously in either direction depending on the relative concentrations of their reactants and products.

Equilibrium Constants Are Related to ΔG . Only changes in free energy, enthalpy, and entropy (ΔG , ΔH , and ΔS) can be measured, not their absolute values (G , H , and S). To compare these changes for different substances, it is therefore necessary to express their values relative to some **standard state** (likewise, we refer the elevations of geographic locations to sea level, which is arbitrarily assigned the height of zero). We discuss standard state conventions below.

The relationship between the concentration and the free energy of a substance A is approximately

$$\bar{G}_A = \bar{G}_A^\circ + RT \ln[A] \quad [1-12]$$

where \bar{G}_A is known as the **partial molar free energy** or the **chemical potential** of A (the bar indicates the quantity per mole), \bar{G}_A° is the partial molar free energy of A in its standard state, R is the gas constant, and $[A]$ is the molar concentration of A. Thus, for the general reaction

the free energy change is

$$\Delta G = c\bar{G}_C + d\bar{G}_D - a\bar{G}_A - b\bar{G}_B \quad [1-13]$$

and

$$\Delta G^\circ = c\bar{G}_C^\circ + d\bar{G}_D^\circ - a\bar{G}_A^\circ - b\bar{G}_B^\circ \quad [1-14]$$

because free energies are additive and the free energy change of a reaction is the sum of the free energies of the products less those of the reactants. Substituting these relationships into Eq. 1-12 yields

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad [1-15]$$

where ΔG° is the free energy change of the reaction when all of its reactants and products are in their standard states (see below). Thus, the expression for the free energy change of a reaction consists of two parts: (1) a constant term whose value depends only on the reaction taking place and (2) a variable term that depends on the concentrations of the reactants and the products, the stoichiometry of the reaction, and the temperature.

For a reaction at equilibrium, there is no *net* change (the rates of the forward and reverse reactions are equal) because the free energy change of the forward reaction exactly balances that of the reverse reaction. Consequently, $\Delta G = 0$, so Eq. 1-15 becomes

$$\boxed{\Delta G^\circ = -RT \ln K_{\text{eq}}} \quad [1-16]$$

where K_{eq} is the familiar **equilibrium constant** of the reaction:

$$K_{\text{eq}} = \frac{[\text{C}]_{\text{eq}}^c [\text{D}]_{\text{eq}}^d}{[\text{A}]_{\text{eq}}^a [\text{B}]_{\text{eq}}^b} = e^{-\Delta G^\circ/RT} \quad [1-17]$$

The subscript “eq” denotes reactant and product concentrations at equilibrium. (The equilibrium condition is usually clear from the context of the situation, so equilibrium concentrations are usually expressed without this subscript.) *The equilibrium constant of a reaction can therefore be calculated from standard free energy data and vice versa* (see Sample Calculation 1-2). The actual free energy change for a reaction can be calculated from the standard free energy change (ΔG°) and the actual concentrations of the reactants and products (see Sample Calculation 1-3).

SAMPLE CALCULATION 1-3

Using the data provided in Sample Calculation 1-2, what is the actual free energy change for the reaction $\text{A} \rightarrow \text{B}$ at 37°C when $[\text{A}] = 10.0 \text{ mM}$ and $[\text{B}] = 0.100 \text{ mM}$?

Use Equation 1-15 and remember that the units for concentration are moles per liter.

$$\Delta G = \Delta G^\circ + RT \ln \frac{[\text{B}]}{[\text{A}]}$$

$$\begin{aligned} \Delta G &= -15,000 \text{ J} \cdot \text{mol}^{-1} + (8.314 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1})(37 + 273 \text{ K}) \ln(0.0001/0.01) \\ &= -15,000 \text{ J} \cdot \text{mol}^{-1} - 11,900 \text{ J} \cdot \text{mol}^{-1} \\ &= -26,900 \text{ J} \cdot \text{mol}^{-1} \end{aligned}$$

WPLS See Sample Calculation Videos.

SAMPLE CALCULATION 1-2

The standard free energy change for the reaction $\text{A} \rightarrow \text{B}$ is $-15.0 \text{ kJ} \cdot \text{mol}^{-1}$. What is the equilibrium constant for the reaction at 25°C ?

Since ΔG° is known, Eq. 1-17 can be used to calculate K_{eq} . The absolute temperature is $25 + 273 = 298 \text{ K}$.

$$\begin{aligned} K_{\text{eq}} &= e^{-\Delta G^\circ/RT} \\ &= e^{-(-15,000 \text{ J} \cdot \text{mol}^{-1})/(8.314 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1})(298 \text{ K})} \\ &= e^{6.05} \\ &= 426 \end{aligned}$$

WPLS See Sample Calculation Videos.

Equations 1-15 through 1-17 indicate that when the reactants in a process are in excess of their equilibrium concentrations, the net reaction will proceed in the forward direction until the excess reactants have been converted to products and equilibrium is attained. Conversely, when products are in excess, the net reaction proceeds in the reverse direction. Thus, as **Le Châtelier's principle** states, *any deviation from equilibrium stimulates a process that tends to restore the system to equilibrium*. In cells, many metabolic reactions are freely reversible ($\Delta G \approx 0$), and the direction of the reaction can shift as reactants and products are added to or removed from the cell. Some metabolic reactions, however, are irreversible; they proceed in only one direction (that with $\Delta G < 0$), which permits the cell to maintain reactant and product concentrations far from their equilibrium values.

K Depends on Temperature. The manner in which the equilibrium constant varies with temperature can be seen by substituting Eq. 1-11 into Eq. 1-16 and rearranging:

$$\ln K_{\text{eq}} = \frac{-\Delta H^\circ}{R} \left(\frac{1}{T} \right) + \frac{\Delta S^\circ}{R} \quad [1-18]$$

where H° and S° represent enthalpy and entropy in the standard state. Equation 1-18 has the form $y = mx + b$, the equation for a straight line. A plot of $\ln K_{\text{eq}}$ versus $1/T$, known as a **van't Hoff plot**, permits the values of ΔH° and ΔS° (and hence ΔG°) to be determined from measurements of K_{eq} at two (or more) different temperatures. This method is often more practical than directly measuring ΔH and ΔS by calorimetry (which measures the heat, q_p , of a process).

Biochemists Have Defined Standard-State Conventions. According to the convention used in physical chemistry, a solute is in its standard state when the

temperature is 25°C, the pressure is 1 atm, and the solute has an **activity** of 1 (activity of a substance is its concentration corrected for its nonideal behavior at concentrations higher than infinite dilution).

The concentrations of reactants and products in most biochemical reactions are usually so low (on the order of millimolar or less) that their activities are closely approximated by their molar concentrations. Furthermore, because biochemical reactions occur near neutral pH, biochemists have adopted a somewhat different **biochemical standard-state** convention:

1. The activity of pure water is assigned a value of 1, even though its concentration is 55.5 M. This procedure simplifies the free energy expressions for reactions in dilute solutions involving water as a reactant, because the $[\text{H}_2\text{O}]$ term can then be ignored. In essence, the $[\text{H}_2\text{O}]$ term is incorporated into the value of the equilibrium constant.
2. The hydrogen ion (H^+) activity is assigned a value of 1 at the physiologically relevant pH of 7. Thus, the biochemical standard state is pH 7.0 (neutral pH, where $[\text{H}^+] = 10^{-7} \text{ M}$) rather than pH 0 ($[\text{H}^+] = 1 \text{ M}$), the physical chemical standard state, where many biological substances are unstable.
3. The standard state of a substance that can undergo an acid–base reaction is defined in terms of the total concentration of its naturally occurring ion mixture at pH 7. In contrast, the physical chemistry convention refers to a pure species, whether or not it actually exists at pH 0. The advantage of the biochemistry convention is that the total concentration of a substance with multiple ionization states, such as most biological molecules, is usually easier to measure than the concentration of one of its ionic species. *Because the ionic composition of an acid or base varies with pH, however, the standard free energies calculated according to the biochemical convention are valid only at pH 7.*

GATEWAY CONCEPT The Direction of a Reaction

The free energy change for a reaction, which depends on the reactant and product concentrations as well as the standard free energy change for that reaction, determines whether the process occurs in the forward or reverse direction. Adding products or removing reactants can cause the reaction to proceed in the opposite direction.

Under the biochemistry convention, the standard free energy changes of reactions are customarily symbolized by $\Delta G^{\circ'}$ to distinguish them from physical chemistry standard free energy changes, ΔG° . If a reaction includes neither H_2O , H^+ , nor an ionizable species, then its $\Delta G^{\circ'} = \Delta G^{\circ}$.

E Life Achieves Homeostasis While Obeying the Laws of Thermodynamics

At one time, many scientists believed that life, with its inherent complexity and order, somehow evaded the laws of thermodynamics. However, elaborate measurements on living animals are consistent with the conservation of energy predicted by the first law. Unfortunately, experimental verification of the second law is not practicable, since it requires dismantling an organism to its component molecules, which would result in its irreversible death. Consequently, it is possible to assert only that the entropy of living matter is less than that of the products to which it decays. *Life persists, however, because a system (a living organism) can be ordered at the expense of disordering its surroundings to an even greater extent.* In other words, the total entropy of the system plus its surroundings increases, as required by the second law. Living organisms achieve order by disordering (breaking down) the nutrients they consume. Thus, *the entropy content of food is as important as its energy content.*

Living Organisms Are Open Systems. Classical thermodynamics applies primarily to reversible processes in **isolated systems** (which cannot exchange matter or energy with their surroundings) or in **closed systems** (which can exchange only energy). An isolated system inevitably reaches equilibrium. For example, if

FIG. 1-11 Energy flow in the biosphere.

Plants use the sun's radiant energy to synthesize carbohydrates in a process that uses CO_2 and H_2O . Plants or the animals that eat them eventually metabolize the carbohydrates to release their stored free energy and thereby return CO_2 and H_2O to the environment.

its reactants are in excess, the forward reaction will proceed faster than the reverse reaction until equilibrium is attained ($\Delta G = 0$), at which point the forward and reverse reactions exactly balance each other. In contrast, **open systems**, which exchange both matter and energy with their surroundings, can reach equilibrium only after the flow of matter and energy has stopped.

Living organisms, which take up nutrients, release waste products, and generate work and heat, are open systems and therefore can never be at equilibrium. They continuously ingest high-enthalpy, low-entropy nutrients, which they convert to low-enthalpy, high-entropy waste products. The free energy released in this process powers the cellular activities that produce and maintain the high degree of organization characteristic of life. If this process is interrupted, the system ultimately reaches equilibrium, which for living things is synonymous with death. An example of energy flow in an open system is illustrated in **Fig. 1-11**. Through photosynthesis, plants convert radiant energy from the sun, the primary energy source for life on the earth, to the chemical energy of carbohydrates and other organic substances. The plants, or the animals that eat them, then metabolize these substances to power such functions as the synthesis of biomolecules, the maintenance of intracellular ion concentrations, and cellular movements.

Living Things Maintain a Non-Equilibrium Steady State. Even in a system that is not at equilibrium, matter and energy flow according to the laws of thermodynamics. For example, materials tend to move from areas of high concentration to areas of low concentration. This is why blood takes up O_2 in the lungs, where O_2 is abundant, and releases it to the tissues, where O_2 is scarce.

Living systems are characterized by being in a non-equilibrium **steady state**. This means that all flows in the system are constant so that the system maintains **homeostasis** (does not change with time). An example of metabolic homeostasis is the hormonal maintenance of mammalian blood glucose levels within rigid limits during feast or famine (Section 22-2). Energy flow in the biosphere (Fig. 1-11) is an example of an open system in a non-equilibrium steady state. Slight perturbations from the steady state give rise to changes in flows that restore the system to the steady state (global warming may now be threatening the homeostasis of the biosphere). In all living systems, energy flow is exclusively “downhill” ($\Delta G < 0$). In addition, nature is inherently dissipative, so the recovery

CHECKPOINT

- Summarize the relationship between energy (U), heat (q), and work (w).
- Restate the first and second laws of thermodynamics.
- Use the analogy of a china cabinet to describe a system with low entropy or high entropy.
- Explain why changes in both enthalpy (ΔH) and entropy (ΔS) determine the spontaneity of a process.
- What is the relationship between the rate of a process and its thermodynamic spontaneity?
- What is the free energy change for a reaction at equilibrium?
- Write the equation showing the relationship between ΔG° and K_{eq} .
- Write the equation showing the relationship between ΔG , ΔG° , and the concentrations of the reactants and products.
- Explain how biochemists define the standard state of a solute. Why do biochemists and chemists use different conventions?
- Explain how organisms avoid reaching equilibrium while maintaining a non-equilibrium steady state.
- How do enzymes affect the rate and free energy change of a reaction?

of free energy from a biochemical process is never total and some energy is always lost to the surroundings.

Enzymes Catalyze Biochemical Reactions. Nearly all the molecular components of an organism can potentially react with one another, and many of these reactions are thermodynamically favored (spontaneous). However, only a subset of all possible reactions actually occur to a significant extent in a living organism. As we shall see (Section 11-2), the rate of a particular reaction depends not on the free energy difference between the initial and final states but on the actual path through which the reactants are transformed to products. Living organisms take advantage of **catalysts**, substances that increase the rate at which the reaction approaches equilibrium without affecting the reaction's ΔG and without themselves undergoing a net change. Biological catalysts are referred to as **enzymes**, most of which are proteins (RNA catalysts are also called **ribozymes**).

Enzymes accelerate biochemical reactions by physically interacting with the reactants and products to provide a more favorable pathway for the transformation of one to the other. Enzymes increase the rates of reactions by increasing the likelihood that the reactants can interact productively. Enzymes cannot, however, promote reactions whose ΔG values are positive.

A multitude of enzymes mediate the flow of energy in every cell. As free energy is harvested, stored, or used to perform cellular work, it may be transferred to other molecules. Although it is tempting to think of free energy as something that is stored in chemical bonds, chemical energy can be transformed into heat, electrical work, osmotic work, or mechanical work, according to the needs of the organism and the biochemical machinery with which it has been equipped through evolution.

Summary

1 The Origin of Life

- A model for the origin of life proposes that organisms ultimately arose from simple organic molecules that polymerized to form more complex molecules capable of replicating themselves.

2 Cellular Architecture

- Compartmentation gave rise to cells that developed metabolic reactions for synthesizing biological molecules and generating energy.
- All cells are either prokaryotic or eukaryotic. Eukaryotic cells contain a variety of membrane-bounded organelles.
- Phylogenetic evidence groups organisms into three domains: archaea, bacteria, and eukarya.
- Natural selection determines the evolution of species.

3 Thermodynamics

- The first law of thermodynamics (energy is conserved) and the second law (spontaneous processes increase the disorder of the universe) apply to biochemical processes. The spontaneity of a process is determined by its free energy change ($\Delta G = \Delta H - T\Delta S$): Spontaneous reactions have $\Delta G < 0$ and nonspontaneous reactions have $\Delta G > 0$.
- The equilibrium constant for a process is related to the standard free energy change for that process.
- Living organisms are open systems that maintain a non-equilibrium steady state (homeostasis).

Problems

EXERCISES

- Which of the functional groups in Table 1-3 give a molecule a positive charge? Which give a molecule a negative charge?
- Identify the circled functional groups and linkages in the compound below.

- Which reactions tend to be characterized by an increase in entropy: condensation or hydrolysis reactions?
- The bacterium *Thiomargarita namibiensis*—at about 0.1 to 0.3 mm in diameter—is visible to the human eye. How does its size compare to the size of typical prokaryotic cells? How does it compare to the size of typical eukaryotic cells?
- According to molecular sequence data, to which prokaryotic group are eukaryotes more closely related?
- (a) Which has greater entropy, liquid water at 0°C or ice at 0°C?
(b) How does the entropy of ice at -5°C differ, if at all, from its entropy at -50°C?

- Does entropy increase or decrease in the following processes?

Urea

3-Phosphoglycerate

2-Phosphoglycerate

- Can a process occur if the entropy of the system decreases and the enthalpy increases?
- Label the following statements true or false:
 - A reaction is said to be spontaneous when it can proceed in either the forward or reverse direction.
 - A spontaneous process always happens very quickly.
 - A nonspontaneous reaction will proceed spontaneously in the reverse direction.
 - A spontaneous process can occur with a large decrease in entropy.
- Consider a reaction with $\Delta H = 15\text{ kJ}$ and $\Delta S = 50\text{ J} \cdot \text{K}^{-1}$. Is the reaction spontaneous (a) at 10°C, (b) at 80°C?
- For the reaction $A \rightarrow B$ at 298 K, the change in enthalpy is $-7\text{ kJ} \cdot \text{mol}^{-1}$ and the change in entropy is $-25\text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$. Is the reaction spontaneous? If not, should the temperature be increased or decreased to make the reaction spontaneous?
- When the reaction $A + B \rightleftharpoons C$ is at equilibrium, the concentrations of reactants are as follows: $[A] = 2\text{ mM}$, $[B] = 3\text{ mM}$, and $[C] = 9\text{ mM}$. What is the standard free energy change for the reaction?
- Calculate ΔG° for the reaction $A + B \rightleftharpoons C + D$ at 25°C when the equilibrium concentrations are $[A] = 10\text{ }\mu\text{M}$, $[B] = 15\text{ }\mu\text{M}$, $[C] = 3\text{ }\mu\text{M}$, and $[D] = 5\text{ }\mu\text{M}$. Is the reaction exergonic or endergonic under standard conditions?
- Calculate the equilibrium constant for the reaction

$$\text{glucose-1-phosphate} + H_2O \rightarrow \text{glucose} + H_2PO_4^-$$
 at pH 7.0 and 25°C ($\Delta G^\circ = -20.9\text{ kJ} \cdot \text{mol}^{-1}$).
- ΔG° for the isomerization reaction

$$\text{glucose-1-phosphate (G1P)} \rightleftharpoons \text{glucose-6-phosphate (G6P)}$$
 is $-7.1\text{ kJ} \cdot \text{mol}^{-1}$. Calculate the equilibrium ratio of $[G1P]$ to $[G6P]$ at 25°C.

CHALLENGE QUESTIONS

16. Why is the cell membrane not an absolute barrier between the cytoplasm and the external environment?
17. Most of the volume of *T. namibiensis* cells (see Problem 4) is occupied by a large central vacuole. Why were scientists surprised to discover a bacterial cell containing a vacuole?
18. A spheroidal bacterium with a diameter of 1 μm contains two molecules of a particular protein. What is the molar concentration of the protein?
19. How many glucose molecules does the cell in Problem 18 contain when its internal glucose concentration is 1.0 mM?
20. For the conversion of reactant A to product B, the change in enthalpy is $7 \text{ kJ} \cdot \text{mol}^{-1}$ and the change in entropy is $20 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$. Above what temperature does the reaction become spontaneous?
21. The equilibrium constant for the reaction $\text{Q} \rightarrow \text{R}$ is 25.
- If 50 μM of Q is mixed with 50 μM of R, which way will the reaction proceed to generate more Q or more R?
 - Calculate the equilibrium concentrations of Q and R.
22. At 10°C , K_{eq} for a reaction is 100. At 30°C , $K_{\text{eq}} = 10$. Does enthalpy increase or decrease during the reaction?

23. Two biochemical reactions have the same $K_{\text{eq}} = 5 \times 10^8$ at temperature $T_1 = 298 \text{ K}$. However, Reaction 1 has $\Delta H^\circ = -28 \text{ kJ} \cdot \text{mol}^{-1}$ and Reaction 2 has $\Delta H^\circ = +28 \text{ kJ} \cdot \text{mol}^{-1}$. The two reactions utilize the same reactants. Your lab partner has proposed that you can get more of the reactants to proceed via Reaction 2 rather than Reaction 1 by lowering the temperature of the reaction. Will this strategy work? Why or why not? How much would the temperature have to be raised or lowered in order to change the value of K_2/K_1 from 1 to 10?

Water on a leaf's surface forms tiny spheres due to the cohesion of water molecules, the result of hydrogen bonding between water molecules. Such weak interactions also play a central role in the structures and functions of biological molecules.

Any study of the chemistry of life must include a study of water. Biological molecules and the reactions they undergo can be best understood in the context of their aqueous environment. Not only are organisms made mostly of water (about 70% of the mass of the human body is water), they are surrounded by water on this, the “blue planet.” Aside from its sheer abundance, water is central to biochemistry for the following reasons:

1. Nearly all biological molecules assume their shapes (and therefore their functions) in response to the physical and chemical properties of the surrounding water.
2. The medium for the majority of biochemical reactions is water. Reactants and products of metabolic reactions, nutrients as well as waste products, depend on water for transport within and between cells.
3. Water itself actively participates in many chemical reactions that support life. Frequently, the ionic components of water, the H^+ and OH^- ions, are the true reactants. In fact, the reactivity of many functional groups on biological molecules depends on the relative concentrations of H^+ and OH^- in the surrounding medium.

All organisms require water, from the marine creatures who spend their entire lives in an aqueous environment to terrestrial organisms that must guard their watery interiors with protective skins. Not surprisingly, living organisms can be found wherever there is liquid water—in hydrothermal vents as hot as 121°C and in the cracks and crevices between rocks hundreds of meters beneath the surface of the earth. Organisms that survive desiccation do so only by becoming dormant, as seeds or spores.

An examination of water from a biochemical point of view requires a look at the physical properties of water, its powers as a solvent, and its chemical behavior—that is, the nature of aqueous acids and bases.

1 Physical Properties of Water

KEY CONCEPTS

- Water molecules, which are polar, can form hydrogen bonds with other molecules.
- In ice, water molecules are hydrogen bonded in a crystalline array, but in liquid water, hydrogen bonds rapidly break and re-form in irregular networks.
- The attractive forces acting on biological molecules include ionic interactions, hydrogen bonds, and van der Waals interactions.
- Polar and ionic substances can dissolve in water.
- The hydrophobic effect explains the exclusion of nonpolar groups as a way to maximize the entropy of water molecules.
- Amphiphilic substances form micelles or bilayers that hide their hydrophobic groups while exposing their hydrophilic groups to water.
- Molecules diffuse across membranes that are permeable to them from regions of higher concentration to regions of lower concentration.
- During dialysis, solutes diffuse across a semipermeable membrane from regions of higher concentration to regions of lower concentration.

FIG. 2-1 Structure of the water molecule.

(a) The shaded area represents the van der Waals envelope, the effective “surface” of the molecule. (b) The oxygen atom’s sp^3 hybrid orbitals are arranged tetrahedrally. Two orbitals contain nonbonding electron pairs.

? Identify the electron-rich and electron-poor regions of the water molecule.

The colorless, odorless, and tasteless nature of water belies its fundamental importance to living organisms. Despite its bland appearance to our senses, water is anything but inert. Its physical properties—unique among molecules of similar size—give it unparalleled strength as a solvent, and yet its limitations as a solvent also have important implications for the structures and functions of biological molecules.

A Water Is a Polar Molecule

A water molecule consists of two hydrogen atoms covalently bonded to an oxygen atom. The O—H bond distance is 0.958 \AA ($1 \text{ \AA} = 10^{-10} \text{ m}$), and the angle formed by the three atoms is 104.5° (Fig. 2-1). The hydrogen atoms are not arranged linearly, because the oxygen atom’s four sp^3 hybrid orbitals extend roughly toward the corners of a tetrahedron. Hydrogen atoms occupy two corners of the tetrahedron, and the nonbonding electron pairs of the oxygen atom occupy the other two corners (in a perfectly tetrahedral molecule, such as methane, CH_4 , the bond angles are 109.5° ; the deviation of water’s bond angle from an exact tetrahedral angle is due to the greater repulsion between the electron pairs in water’s lone pair orbitals relative to those between the less closely held electron pairs forming its C—H bonds).

Water Molecules Form Hydrogen Bonds. The angular geometry of the water molecule has enormous implications for living systems. Water is a **polar molecule**: the oxygen atom with its unshared electrons carries a partial negative charge (δ^-) of $-0.66e$, and the hydrogen atoms each carry a partial positive charge (δ^+) of $+0.33e$, where e is the charge of the electron. Electrostatic attractions between the dipoles of water molecules are crucial to the properties of water itself and to its role as a biochemical solvent. Neighboring water molecules tend to orient themselves so that the O—H bond of one water molecule (the positive end) points toward one of the electron pairs of the other water molecule (the negative end). The resulting directional intermolecular association is known as a **hydrogen bond** (Fig. 2-2).

*In general, a hydrogen bond can be represented as $D-H \cdots A$, where $D-H$ is a weakly acidic “donor” group such as O—H or N—H, and A is a weakly basic, lone pair-bearing, “acceptor” atom such as O or N. Hydrogen bonds are structurally characterized by an $H \cdots A$ distance that is at least 0.5 \AA shorter than the calculated **van der Waals distance** (the distance of closest approach between two nonbonded atoms). In water, for example, the $O \cdots H$ hydrogen bond distance is $\sim 1.8 \text{ \AA}$, versus 2.6 \AA for the corresponding van der Waals distance. C—H groups, for the most part, do not participate in hydrogen bonds due to their lack of polarity (C and H atoms have nearly equal electronegativities).*

FIG. 2-2 A hydrogen bond between two water molecules. The hydrogen bond is represented by a dotted line. The strength of the interaction is maximal when the O—H covalent bond of one molecule points directly toward the lone-pair electron cloud of the other.

FIG. 2-3 The structure of ice. Each water molecule interacts tetrahedrally with four other water molecules. Oxygen atoms are red and hydrogen atoms are white. Hydrogen bonds are represented by dashed lines. [After Pauling, L., *The Nature of the Chemical Bond* (3rd ed.), p. 465, Cornell University Press (1960).]

? Expand this ice crystal by drawing additional water molecules with the appropriate hydrogen bonds.

A single water molecule contains two hydrogen atoms that can be “donated” and two unshared electron pairs that can act as “acceptors,” so each molecule can participate in a maximum of four hydrogen bonds with other water molecules. Although the energy required to break an individual hydrogen bond ($\sim 20 \text{ kJ} \cdot \text{mol}^{-1}$) is relatively small (e.g., the energy required to break an O—H covalent bond is $460 \text{ kJ} \cdot \text{mol}^{-1}$), the sheer number of hydrogen bonds in a sample of water is the key to its remarkable properties.

Ice Is a Crystal of Hydrogen-Bonded Water Molecules. The structure of ice provides a striking example of the cumulative strength of many hydrogen bonds. X-Ray and neutron diffraction studies have established that water molecules in ice are arranged in an unusually open structure. Each water molecule is tetrahedrally surrounded by four nearest neighbors to which it is hydrogen bonded (**Fig. 2-3**). As a consequence of its open structure, water is one of the very few substances that expands on freezing (at 0°C , liquid water has a density of $1.00 \text{ g} \cdot \text{mL}^{-1}$, whereas ice has a density of $0.92 \text{ g} \cdot \text{mL}^{-1}$).

The expansion of water on freezing has overwhelming consequences for life on the earth. Suppose that water contracted on freezing—that is, became more dense rather than less dense. Ice would then sink to the bottoms of lakes and oceans rather than float. This ice would be insulated from the sun so that oceans, with the exception of a thin surface layer of liquid in warm weather, would be permanently frozen solid (the water at great depths, even in tropical oceans, is close to 4°C , its temperature of maximum density). Thus, the earth would be locked in a permanent ice age and life might never have arisen.

The melting of ice represents the collapse of the tetrahedral orientation of hydrogen-bonded water molecules, although hydrogen bonds between water molecules persist in the liquid state. In fact, liquid water is only 15% less hydrogen bonded than ice. [Water’s enthalpy of sublimation (ΔH for converting a solid to a gas) is $47 \text{ kJ} \cdot \text{mol}^{-1}$, of which only $\sim 6 \text{ kJ} \cdot \text{mol}^{-1}$ is attributable to the kinetic energy of gaseous water molecules. Thus, water’s $6 \text{ kJ} \cdot \text{mol}^{-1}$ enthalpy of fusion (ΔH for converting a solid to a liquid) is $(6 \times 100)/(47 - 6) = 15\%$ of the energy required to break all of water’s intermolecular hydrogen bonds (gaseous water molecules at 1 atm are too far apart to have significant intermolecular interactions).] Moreover, the boiling point of water (100°C) is 264°C higher than that of methane (-164°C), a substance with nearly the same molecular mass as H_2O but which is incapable of hydrogen bonding (substances with similar intermolecular associations and equal molecular masses should have similar boiling points). These and other phenomena, such as water’s high surface tension, reflect the extraordinarily large internal cohesiveness of liquid water resulting from its intermolecular hydrogen bonding.

The Structure of Liquid Water Is Irregular. Because each molecule of liquid water reorients about once every 10^{-12} s , very few experimental techniques can explore the instantaneous arrangement of these water molecules. Theoretical considerations and spectroscopic evidence suggest that molecules in liquid water are, on average, each hydrogen bonded to 3.4 nearest neighbors, much as they are in ice. These hydrogen bonds are distorted, however, so the networks of linked molecules are irregular and varied. For example, three- to seven-membered rings of hydrogen-bonded molecules commonly occur in liquid water (**Fig. 2-4**), in contrast to the six-membered rings characteristic of ice (**Fig. 2-3**). Moreover, these networks continually break up and re-form every $2 \times 10^{-11} \text{ s}$ or so. *Liquid*

GATEWAY CONCEPT Molecular Behavior

When we describe the properties of a substance, such as water or another molecule, we are really describing the average behavior of a large population of molecules. Most biochemical methods cannot assess the behavior of an individual molecule.

FIG. 2-4 Rings of water molecules. These models, containing three, four, or five molecules, are based on theoretical predictions and spectroscopic data. [After Liu, K., Cruzan, J.D., and Saykally, R.J., *Science* **271**, 929 (1996).]

water therefore consists of rapidly fluctuating, three-dimensional networks (clusters) of hydrogen-bonded H_2O molecules. Because ΔH for the melting and sublimation of ice are both positive quantities and $\Delta G = \Delta H - T\Delta S$ must be negative for a spontaneous process (Section 1-3C), it is the increase in ΔS —that is, the disordering of its water molecules—that drives these processes.

Hydrogen Bonds and Other Weak Interactions Influence Biological Molecules.

Biochemists are concerned not just with the strong covalent bonds that define chemical structure, but also with the weak forces that act under relatively mild physical conditions. The structures of most biological molecules are determined by the collective influence of many individually weak noncovalent interactions. The weak electrostatic forces of biochemical interest include ionic interactions, hydrogen bonds, and van der Waals forces.

The energy of association of two electric charges, q_1 and q_2 , that are immersed in a medium of **dielectric constant** D and separated by the distance r , is given by **Coulomb's law**:

$$U = \frac{kq_1q_2}{Dr} \quad [2-1]$$

where $k = 9.0 \times 10^9 \text{ J} \cdot \text{m} \cdot \text{C}^{-2}$ is a proportionality constant. The dielectric constant varies with the polarity of the medium; it is 1 (by definition) in a vacuum, in the range 1.5 to 3 in hydrocarbons, and 78.5 in liquid water. In general, the energy of association of two charged groups (the energy required to completely separate them in the medium of interest) is less than the energy of a covalent bond but greater than the energy of a hydrogen bond (Table 2-1).

The noncovalent associations between neutral molecules, collectively known as **van der Waals forces**, arise from electrostatic interactions among permanent or induced dipoles (the hydrogen bond is a special kind of dipolar interaction). Interactions among permanent dipoles such as carbonyl groups (Fig. 2-5a) are much weaker than ionic interactions. Moreover, their energies vary with r^{-3} , so they rapidly attenuate with distance. A permanent dipole also induces a dipole moment in a neighboring group by electrostatically distorting its electron distribution (Fig. 2-5b). Such dipole-induced dipole interactions are generally much weaker than dipole-dipole interactions.

At any instant, nonpolar molecules have a small, randomly oriented dipole moment resulting from the rapid fluctuating motion of their electrons. This transient dipole moment can polarize the electrons in a neighboring group (Fig. 2-5c),

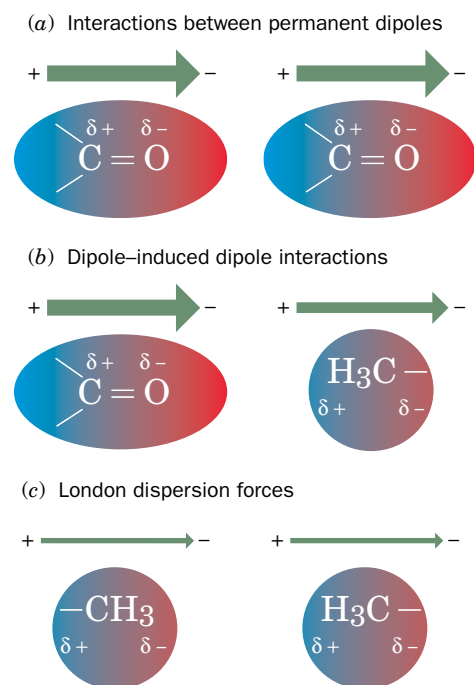

FIG. 2-5 Dipole-dipole interactions. The strength of each dipole is indicated by the thickness of the accompanying arrow. (a) Interactions between permanent dipoles. (b) Dipole-induced dipole interactions. (c) London dispersion forces.

TABLE 2-1 Bond Energies in Biomolecules

Type of Bond	Example	Typical Bond Energy (kJ · mol ⁻¹)
Covalent	O—H	460
	C—H	414
	C—C	348
Noncovalent		
Ionic interaction	—COO ⁻ ··· ⁺ H ₃ N—	86
van der Waals forces		
Hydrogen bond	—O—H···O<	20
Dipole-dipole interaction	>C=O···<C=O	9.3
London dispersion forces	$\begin{array}{c} \text{H} & & \text{H} \\ & & \\ -\text{C}-\text{H} \cdots \text{H}-\text{C}- \\ & & \\ \text{H} & & \text{H} \end{array}$	0.3

so that the groups are attracted to each other. These so-called **London dispersion forces** are extremely weak and fall off so rapidly with distance (as r^{-6}) that they are significant only for groups in close contact. They are, nevertheless, extremely important in determining the structures of biological molecules, whose interiors contain many closely packed groups (note that London dispersion forces occur between all atoms, in contrast to the other types of noncovalent interactions, which occur only among atoms with differing electronegativities).

B Hydrophilic Substances Dissolve in Water

Solubility depends on the ability of a solvent to interact with a solute more strongly than solute particles interact with each other. Water is said to be the “universal solvent.” Although this statement cannot literally be true, water certainly dissolves more types of substances, and in greater amounts, than any other solvent. In particular, the polar character of water makes it an excellent solvent for polar and ionic materials, which are said to be **hydrophilic** (Greek: *hydro*, water + *philos*, loving). On the other hand, nonpolar substances are virtually insoluble in water (“oil and water don’t mix”) and are consequently described as **hydrophobic** (Greek: *phobos*, fear). Nonpolar substances, however, are soluble in nonpolar solvents such as CCl_4 and hexane. This information is summarized by another maxim, “like dissolves like.”

Why do salts such as NaCl dissolve in water? Polar solvents, such as water, which have high dielectric constants, weaken the attractive forces between oppositely charged ions (such as Na^+ and Cl^-) and can therefore hold the ions apart. (In nonpolar solvents, which have low dielectric constants, ions of opposite charge attract each other so strongly that they coalesce to form a solid salt.) An ion immersed in a polar solvent such as water attracts the oppositely charged ends of the solvent dipoles (Fig. 2-6). The ion is thereby surrounded by one or more concentric shells of oriented solvent molecules, which essentially spreads the ionic charge over a much larger volume. Such ions are said to be **solvated** or, when water is the solvent, to be **hydrated**.

The water molecules in the hydration shell around an ion move more slowly than water molecules that are not involved in solvating the ion. In bulk water, the energetic cost of breaking a hydrogen bond is low because another hydrogen bond is likely to be forming at the same time. The cost is higher for the relatively ordered water molecules of the hydration shell. The energetics of solvation also play a role in chemical reactions, since a reacting group must shed its **waters of hydration** (the molecules in its hydration shell) in order to closely approach another group.

The bond dipoles of uncharged polar molecules make them soluble in aqueous solutions for the same reasons that ionic substances are water soluble. The solubilities of polar and ionic substances are enhanced when they carry functional groups, such as hydroxyl (OH), carbonyl ($\text{C}=\text{O}$), carboxylate (COO^-), or ammonium (NH_3^+) groups, that can form hydrogen bonds with water, as illustrated in Fig. 2-7. Indeed, water-soluble biomolecules such as proteins, nucleic acids, and carbohydrates bristle with just such groups. In contrast, nonpolar substances, such as methane or other hydrocarbons, lack hydrogen-bonding donor and acceptor groups.

C The Hydrophobic Effect Causes Nonpolar Substances to Aggregate in Water

When a nonpolar substance is added to an aqueous solution, it does not dissolve but instead is excluded by the water. *The tendency of water to minimize its contacts*

FIG. 2-7 Hydrogen bonding by functional groups. Water forms hydrogen bonds with (a) hydroxyl groups, (b) keto groups, (c) carboxylate ions, and (d) ammonium ions.

? Identify the hydrogen bond donors and acceptors.

GATEWAY CONCEPT Intermolecular Interactions

In biological systems, covalent bonds hold atoms together in molecules, but noncovalent forces—such as ionic interactions, hydrogen bonds, and other van der Waals interactions—determine how those molecules can “recognize” or interact with one another.

FIG. 2-6 Solvation of ions. The dipoles of the surrounding water molecules are oriented according to the charge of the ion. Only one layer of solvent molecules is shown. However, this figure is an exaggeration; the rapid fluctuations of the water molecules in solution results in only their partial ordering around their associated ion.

TABLE 2-2 Thermodynamic Changes for Transferring Hydrocarbons from Water to Nonpolar Solvents at 25°C

Process	ΔH (kJ · mol ⁻¹)	$-T\Delta S$ (kJ · mol ⁻¹)	ΔG (kJ · mol ⁻¹)
CH ₄ in H ₂ O \rightleftharpoons CH ₄ in C ₆ H ₆	11.7	-22.6	-10.9
CH ₄ in H ₂ O \rightleftharpoons CH ₄ in CCl ₄	10.5	-22.6	-12.1
C ₂ H ₆ in H ₂ O \rightleftharpoons C ₂ H ₆ in benzene	9.2	-25.1	-15.9

with hydrophobic molecules is termed the **hydrophobic effect**. As we shall see, many large molecules and molecular aggregates, such as proteins, nucleic acids, and cellular membranes, assume their shapes at least partially in response to the hydrophobic effect.

Consider the thermodynamics of transferring a nonpolar molecule from an aqueous solution to a nonpolar solvent. In all cases, the free energy change is negative, which indicates that such transfers are spontaneous processes (Table 2-2). Interestingly, these transfer processes are either endothermic (positive ΔH) or isothermic ($\Delta H = 0$); that is, it is enthalpically more or approximately equally favorable for nonpolar molecules to dissolve in water as in nonpolar media. In contrast, the entropy change (expressed as $-T\Delta S$) is large and negative in all cases. Clearly, the transfer of a hydrocarbon from an aqueous medium to a nonpolar medium is entropically driven (i.e., the free energy change is mostly due to an entropy change).

Entropy, or “randomness,” is a measure of the order of a system (Section 1-3B). If entropy increases when a nonpolar molecule leaves an aqueous solution, entropy must decrease when the molecule enters water. This decrease in entropy when a nonpolar molecule is solvated by water is an experimental observation, not a theoretical conclusion, yet the entropy changes are too large to reflect only the changes in the conformations of the hydrocarbons. Thus the entropy changes must arise mainly from some sort of ordering of the water itself. What is the nature of this ordering?

The extensive hydrogen-bonding network of liquid water molecules is disturbed when a nonpolar group intrudes. A nonpolar group can neither accept nor donate hydrogen bonds, so the water molecules at the surface of the cavity occupied by the nonpolar group cannot hydrogen bond to other molecules in their usual fashion. To fully exploit their hydrogen-bonding capacity, these surface water molecules must orient themselves to form a hydrogen-bonded network enclosing the cavity (Fig. 2-8). This orientation constitutes an ordering of the water structure since the number of ways that water molecules can form hydrogen bonds around the surface of a nonpolar group is fewer than the number of ways they can form hydrogen bonds in bulk water. The water molecules can still form the same number of hydrogen bonds, but they must give up some of their rotational and translational freedom to do so.

Unfortunately, the ever-fluctuating nature of liquid water’s basic structure has not yet allowed a detailed description of this ordering process. One model proposes that water forms transient ice-like hydrogen-bonded “cages” around the nonpolar groups such as that drawn in Fig. 2-8. The water molecules of the cages

FIG. 2-8 Orientation of water molecules around a nonpolar solute. To maximize their number of hydrogen bonds, water molecules form a “cage” around the solute. Dotted lines represent hydrogen bonds.

are tetrahedrally hydrogen bonded to other water molecules, such that the ordering of water molecules extends several layers beyond the first hydration shell of the nonpolar solute.

The unfavorable free energy of hydration of a nonpolar substance caused by its ordering of the surrounding water molecules has the net result that the nonpolar substance tends to be excluded from the aqueous phase. This is because the surface area of a cavity containing an aggregate of nonpolar molecules is less than the sum of the surface areas of the cavities that each of these molecules would individually occupy (Fig. 2-9). The aggregation of the nonpolar groups thereby minimizes the surface area of the cavity and therefore maximizes the entropy of the entire system. In this sense, the nonpolar groups are squeezed out of the aqueous phase.

Amphiphiles Form Micelles and Bilayers. Most biological molecules have both polar (or charged) and nonpolar segments and are therefore simultaneously hydrophilic and hydrophobic. Such molecules, for example, fatty acid ions (soaps; Fig. 2-10), are said to be **amphiphilic** or **amphipathic** (Greek: *amphi*, both; *pathos*, suffering). How do amphiphiles interact with an aqueous solvent? Water tends to hydrate the hydrophilic portion of an amphiphile, but it also tends to exclude the hydrophobic portion. Amphiphiles consequently tend to form structurally ordered aggregates. For example, **micelles** are globules of up to several thousand amphiphilic molecules arranged so that the hydrophilic groups at the globule surface can interact with the aqueous solvent while the hydrophobic groups associate at the center, away from the solvent (Fig. 2-11a). Of course, the model presented in Fig. 2-11a is an oversimplification, since it is geometrically impossible for all the hydrophobic groups to occupy the center of the micelle. Instead, the amphipathic molecules pack in a more disorganized fashion that buries most of the hydrophobic groups and leaves the polar groups exposed (Fig. 2-12).

Alternatively, amphiphilic molecules may arrange themselves to form **bilayered** sheets or vesicles in which the polar groups face the aqueous phase (Fig. 2-11b). In both micelles and bilayers, the aggregate is stabilized by the hydrophobic effect, the tendency of water to exclude hydrophobic groups.

The consequences of the hydrophobic effect are often called hydrophobic forces or hydrophobic “bonds.” However, the term *bond* implies a discrete directional relationship between two entities. The hydrophobic effect acts indirectly on nonpolar groups and lacks directionality. Despite the temptation to attribute some mutual attraction to a collection of nonpolar groups excluded from water, their exclusion is largely a function of the entropy of the surrounding water molecules, not some “hydrophobic force” among them (the London dispersion forces between the nonpolar groups are relatively weak).

D Water Moves by Osmosis and Solutes Move by Diffusion

The fluid inside cells and surrounding cells in multicellular organisms is full of dissolved substances ranging from small inorganic ions to huge molecular aggregates. The concentrations of these solutes affect water’s **colligative properties**,

Palmitate (C₁₅H₃₁COO[−])

Oleate (C₁₇H₃₃COO[−])

FIG. 2-10 Fatty acid anions (soaps). Palmitate and oleate are amphiphilic compounds; each has a polar carboxylate group and a long nonpolar hydrocarbon chain.

FIG. 2-9 Aggregation of nonpolar molecules in water. (a) The individual hydration of dispersed nonpolar molecules (brown) decreases the entropy of the system because their hydrating water molecules (dark blue) are not as free to interact with other water molecules as they do in the absence of the nonpolar molecules. (b) Aggregation of the nonpolar molecules increases the entropy of the system, since the number of water molecules required to hydrate the aggregated solutes is less than the number of water molecules required to hydrate the dispersed solute molecules. This increase in entropy accounts for the spontaneous aggregation of nonpolar substances in water.

? Explain why it is inappropriate to describe the aggregation of nonpolar substances as being the result of “hydrophobic bonds.”

FIG. 2-11 Structures of micelles and bilayers. In aqueous solution, the polar head groups of amphipathic molecules are hydrated while the nonpolar tails aggregate by exclusion from water. (a) A micelle is a spheroidal aggregate. (b) A bilayer is an extended planar aggregate.

FIG. 2-12 Model of a micelle. Twenty molecules of octyl glucoside (an eight-carbon chain with a sugar head group) are shown in space-filling form in this computer-generated model. The polar O atoms of the glucoside groups are red and C atoms are gray. H atoms have been omitted for clarity. Computer simulations indicate that such micelles have an irregular, rapidly fluctuating structure (unlike the symmetric aggregate pictured in Fig. 2-11a) such that portions of the hydrophobic tails are exposed on the micelle surface at any given instant. [Courtesy of Michael Garavito and Shelagh Ferguson-Miller, Michigan State University.]

the physical properties that depend on the concentration of dissolved substances rather than on their chemical features. For example, solutes depress the freezing point and elevate the boiling point of water by making it more difficult for water molecules to crystallize as ice or to escape from solution into the gas phase.

Osmotic pressure is also a colligative property. When a solution is separated from pure water by a semipermeable membrane that permits the passage of water molecules but not solutes, water moves into the solution due to its tendency to equalize its concentration on both sides of the membrane. **Osmosis** is the net movement of solvent across the membrane from a region of high concentration (here, pure water) to a region of relatively low concentration (water containing dissolved solute).

The **osmotic pressure** of a solution is the pressure that must be applied to the solution to equalize the flow of water across the membrane in both directions (the added pressure forces more water from the solution through the membrane); it is proportional to the concentration of the solute (**Fig. 2-13**). For a 1 M solution, the osmotic pressure is 22.4 atm. Consider the implications of osmotic pressure for living cells, which are essentially semipermeable sacs of aqueous solution. To minimize the osmotic influx of water, which would burst the relatively weak cell membrane, many animal cells are surrounded by a solution of similar osmotic pressure (so there is no net flow of water). Another strategy, used by most plants and bacteria, is to enclose the cell with a rigid cell wall that can withstand the osmotic pressure generated within.

When an aqueous solution is separated from pure water by a membrane that is permeable to both water and solutes, solutes move out of the solution even as water moves in. The molecules move randomly, or **diffuse**, until the concentration of the solute is the same on both sides of the membrane. At this point, equilibrium is established; that is, there is no further *net* flow of water or solute (i.e., molecules continue to move through the membrane, but at the same rate in both directions). Note that the tendency for solutes to diffuse from an area of high concentration to an area of low concentration (i.e., down a concentration gradient) is analogous to the net transport of gas molecules from a region of high pressure to one of low pressure (**Fig. 1-10**); both processes are thermodynamically favored because they result in an increase in entropy.

FIG. 2-13 Osmotic pressure. (a) A water-permeable membrane separates a tube of concentrated solution from pure water. (b) As water moves into the solution by osmosis, the height of the solution in the tube increases. (c) The pressure that prevents the influx of water is the osmotic pressure (22.4 atm for a 1 M solution).

FIG. 2-14 Dialysis. (a) A concentrated solution is separated from a large volume of solvent by a dialysis membrane (shown here as a tube knotted at both ends). Only small molecules can diffuse through the pores in the membrane. (b) At equilibrium, the concentrations of small molecules are nearly the same on either side of the membrane, whereas the macromolecules remain inside the dialysis bag.

? Draw arrows in Part (a) to indicate the direction of diffusion of water molecules and small solutes.

Diffusion of solutes is the basis for the laboratory technique of **dialysis**. In this process, solutes smaller than the pore size of the dialysis membrane exchange freely between the sample and the bulk solution until equilibrium is reached (Fig. 2-14). Larger substances cannot cross the membrane and remain where they are. Dialysis is particularly useful for separating large molecules, such as proteins or nucleic acids, from smaller molecules. Because small solutes (and water) move freely between the sample and the surrounding medium, dialysis can be repeated several times to replace the sample medium with another solution.

 Individuals with kidney failure are kept alive by a dialysis procedure in which the blood is pumped through a machine containing a semipermeable membrane. As blood flows along one side of the membrane, a fluid called the dialysate flows in the opposite direction on the other side. This countercurrent arrangement maximizes the concentration differences between the two solutions so that waste materials such as urea and creatinine (present at high concentration in the blood) will efficiently diffuse through the membrane into the dialysate (where their concentrations are low). Excess water can also be eliminated, as it moves into the dialysate by osmosis. The “cleansed” blood is then returned to the patient. Some challenges of clinical dialysis are the requirement for ultrapure water to prepare the dialysate and the need to monitor the patient’s salt and water balance over the long term.

CHECKPOINT

- Sketch a diagram of a water molecule and indicate the ends that bear partial positive and negative charges.
- Compare the structures of ice and water with respect to the number and geometry of hydrogen bonds.
- Which of the functional groups listed in Table 1-2 can function as hydrogen bond donors? As hydrogen bond acceptors?
- Describe the nature and relative strength of covalent bonds, ionic interactions, and van der Waals interactions (hydrogen bonds, dipole–dipole interactions, and London dispersion forces).
- What is the relationship between polarity and hydrophobicity?
- Explain why polar substances dissolve in water while nonpolar substances do not.
- What is the role of entropy in the hydrophobic effect?
- Explain why amphiphiles form micelles or bilayers in water.
- How does osmosis differ from diffusion? Which process occurs during dialysis?
- Describe the osmotic challenges facing a cell placed in pure water or in a high-salt solution.

2 Chemical Properties of Water

KEY CONCEPTS

- A water molecule dissociates to form H^+ and OH^- ions, with a dissociation constant of 10^{-14} .
- The acidity of a solution is expressed as a pH value, where $\text{pH} = -\log [\text{H}^+]$.
- An acid is a compound that can donate a proton, and a base is a compound that can accept a proton.
- A dissociation constant varies with the strength of an acid.
- The Henderson–Hasselbalch equation relates the pH of a solution of a weak acid to its pK and the concentrations of the acid and its conjugate base.
- A titration curve demonstrates that if the concentrations of an acid and its conjugate base are close, the solution is buffered against changes in pH when acid or base is added.
- Many biological molecules contain ionizable groups so that they are sensitive to changes in pH.

FIG. 2-15 Proton jumping. Proton jumps occur more rapidly than direct molecular migration, accounting for the observed high ionic mobilities of hydronium ions (and hydroxide ions) in aqueous solutions.

? Draw a similar diagram to show how a hydroxide ion jumps.

Water is not just a passive component of the cell or its extracellular environment. By virtue of its physical properties, water defines the solubilities of other substances. Similarly, water's chemical properties determine the behavior of other molecules in solution.

A Water Ionizes to Form H^+ and OH^-

Water is a neutral molecule with a very slight tendency to ionize. We express this ionization as

There is actually no such thing as a free proton (H^+) in solution. Rather, the proton is associated with a water molecule as a **hydronium ion**, H_3O^+ . The association of a proton with a cluster of water molecules also gives rise to structures with the formulas H_5O_2^+ , H_7O_3^+ , and so on. For simplicity, however, we often represent these ions by H^+ . The other product of water's ionization is the **hydroxide ion**, OH^- .

The proton of a hydronium ion can jump rapidly to another water molecule and then to another (Fig. 2-15). For this reason, the mobilities of H^+ and OH^- ions in solution are much higher than for other ions, which must move through the bulk water carrying their waters of hydration. **Proton jumping** is also responsible for the observation that acid–base reactions are among the fastest reactions that take place in aqueous solution.

The ionization (dissociation) of water is described by an equilibrium expression in which the concentration of the parent substance is in the denominator and the concentrations of the dissociated products are in the numerator:

$$K = \frac{[\text{H}^+][\text{OH}^-]}{[\text{H}_2\text{O}]} \quad [2-2]$$

K is the **dissociation constant** (here and throughout this text, quantities in square brackets symbolize the molar concentrations of the indicated substances, which in many cases are only negligibly different from their activities; Section 1-3D). Because the concentration of the undissociated H_2O ($[\text{H}_2\text{O}]$) is so much larger than the concentrations of its component ions, it can be considered constant ($[\text{H}_2\text{O}] = 1000 \text{ g} \cdot \text{L}^{-1} / 18.015 \text{ g} \cdot \text{mol}^{-1} = 55.5 \text{ M}$). It can therefore be incorporated into K to yield an expression for the ionization of water,

$$K_w = [\text{H}^+][\text{OH}^-] \quad [2-3]$$

The value of K_w , the ionization constant of water, is 10^{-14} M^2 at 25°C .

Pure water must contain equimolar amounts of H^+ and OH^- , so $[\text{H}^+] = [\text{OH}^-] = (K_w)^{1/2} = 10^{-7} \text{ M}$. Since $[\text{H}^+]$ and $[\text{OH}^-]$ are reciprocally related by Eq. 2-3, when $[\text{H}^+]$ is greater than 10^{-7} M , $[\text{OH}^-]$ must be correspondingly less and vice versa. Solutions with $[\text{H}^+] = 10^{-7} \text{ M}$ are said to be **neutral**, those with $[\text{H}^+] > 10^{-7} \text{ M}$ are said to be **acidic**, and those with $[\text{H}^+] < 10^{-7} \text{ M}$ are said to be **basic**. Most physiological solutions have hydrogen ion concentrations near neutrality. For example, human blood is normally slightly basic, with $[\text{H}^+] = 4.0 \times 10^{-8} \text{ M}$.

The values of $[\text{H}^+]$ for most solutions are inconveniently small and thus difficult to compare. A more practical quantity, which was devised in 1909 by Søren Sørensen, is known as the **pH**:

$$\text{pH} = -\log[\text{H}^+] = \log \frac{1}{[\text{H}^+]} \quad [2-4]$$

The higher the pH, the lower is the H^+ concentration; the lower the pH, the higher is the H^+ concentration (Fig. 2-16). The pH of pure water is 7.0, whereas acidic solutions have $\text{pH} < 7.0$ and basic solutions have $\text{pH} > 7.0$

FIG. 2-16 Relationship of pH and the concentrations of H^+ and OH^- in water. Because the product of $[H^+]$ and $[OH^-]$ is a constant (10^{-14}), $[H^+]$ and $[OH^-]$ are reciprocally related. Solutions with relatively more H^+ are acidic ($pH < 7$), solutions with relatively more OH^- are basic ($pH > 7$), and solutions in which $[H^+] = [OH^-] = 10^{-7}$ M are neutral ($pH = 7$). Note the logarithmic scale for ion concentration.

(see Sample Calculation 2-1). Note that solutions that differ by one pH unit differ in $[H^+]$ by a factor of 10. The pH values of some common substances are given in **Table 2-3**.

B Acids and Bases Alter the pH

H^+ and OH^- ions derived from water are fundamental to the biochemical reactions we will encounter later in this book. Biological molecules, such as proteins and nucleic acids, have numerous functional groups that act as acids or bases—for example, carboxyl and amino groups. These molecules influence the pH of the surrounding aqueous medium, and their structures and reactivities are in turn influenced by the ambient pH. An appreciation of acid–base chemistry is therefore essential for understanding the chemical context of many biological processes. Box 2-1 describes the effect of ocean acidification on marine life.

An Acid Can Donate a Proton. According to a definition formulated in 1923 by Johannes Brønsted and Thomas Lowry, an *acid* is a substance that can donate a proton, and a *base* is a substance that can accept a proton. Under the Brønsted–Lowry definition, an acid–base reaction can be written as

An acid (HA) reacts with a base (H_2O) to form the **conjugate base** of the acid (A^-) and the **conjugate acid** of the base (H_3O^+). Accordingly, the acetate ion (CH_3COO^-) is the conjugate base of acetic acid (CH_3COOH), and the ammonium ion (NH_4^+) is the conjugate acid of ammonia (NH_3). The acid–base reaction is frequently abbreviated

with the participation of H_2O implied. An alternative expression for a basic substance B is

TABLE 2-3 pH Values of Some Common Substances

Substance	pH
1 M NaOH	14
Household ammonia	12
Seawater	8
Blood	7.4
Milk	7
Saliva	6.6
Tomato juice	4.4
Vinegar	3
Gastric juice	1.5
1 M HCl	0

SAMPLE CALCULATION 2-1

1.0×10^{-4} mole of H^+ (as HCl) is added to 1.0 liter of pure water. Determine the final pH of the solution.

Pure water has a pH of 7, so its $[H^+] = 10^{-7}$ M. The added H^+ has a concentration of 1.0×10^{-4} M, which overwhelms the $[H^+]$ already present. The total $[H^+]$ is therefore 1.0×10^{-4} M, so that the pH is equal to $-\log[H^+] = -\log(1.0 \times 10^{-4}) = 4$.

WPLS See Sample Calculation Videos.

GATEWAY CONCEPT Acid–Base Chemistry

An acid can function as an acid (proton donor) only if a base (proton acceptor) is present, and vice versa. The acid must have a conjugate base, and the base must have a conjugate acid. If a reactant appears to be missing from an equilibrium expression, assume that it is water or its conjugate ions H_3O^+ or OH^- .

Box 2-1 Perspectives in Biochemistry The Consequences of Ocean Acidification

The human-generated increase in atmospheric carbon dioxide that is contributing to climate change through global warming is also affecting the chemistry of the world's oceans. Atmospheric CO_2 dissolves in water and reacts with it to generate carbonic acid, which rapidly dissociates to form protons and bicarbonate:

The addition of hydrogen ions from CO_2 -derived carbonic acid therefore leads to a decrease in the pH. Currently, the earth's oceans are slightly basic, with a pH of approximately 8.0. It has been estimated that over the next 100 years, the ocean pH could drop to about 7.8. Although the oceans act as a CO_2 "sink" that helps mitigate the increase in atmospheric CO_2 , the increase in acidity in the marine environment represents an enormous challenge to organisms that must adapt to the new conditions.

A variety of marine organisms, including mollusks, many corals, and some plankton, use dissolved carbonate ions to construct protective shells of calcium carbonate (CaCO_3). However, carbonate ions can combine with H^+ to form bicarbonate:

Consequently, the increase in ocean acidity could decrease the availability of carbonate and thereby slow the growth of shell-building organisms. In fact, experiments have shown that calcification is reduced in organisms such as sea urchins and corals under acidic conditions. It is also possible that ocean acidification could dissolve existing carbonate-based coral reefs, which are species-rich ecosystems and important components of marine food chains.

Interestingly, not all shell-building organisms respond to high levels of CO_2 in the same way. Experiments with coccolithophores (single-celled

STEVE GSCHMEISSNER / Photolibrary

eukaryotes that are encased in calcium carbonate plates; see photo) indicate that at least under some conditions, increased CO_2 leads to increased bicarbonate that actually contributes to increased calcification:

These results suggest that the impact of increased CO_2 on marine organisms may not be a simple matter of decreased pH but may be a more complicated function of the relative amounts of all the carbon species, which include dissolved CO_2 , HCO_3^- , and CO_3^{2-} .

The Strength of an Acid Is Specified by Its Dissociation Constant. The equilibrium constant for an acid–base reaction is expressed as a dissociation constant with the concentrations of the “reactants” in the denominator and the concentrations of the “products” in the numerator:

$$K = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}][\text{H}_2\text{O}]} \quad [2-5]$$

However, since in dilute aqueous solution the term $[\text{H}_2\text{O}] = 55.5 \text{ M}$ is essentially constant, it is customarily combined with the dissociation constant, which then takes the form

$$K_a = K[\text{H}_2\text{O}] = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} \quad [2-6]$$

For brevity, however, we will henceforth omit the subscript “a.”

The dissociation constants of some common acids are listed in [Table 2-4](#). Because acid dissociation constants, like $[\text{H}^+]$ values, can be cumbersome to work with, they are transformed to **pK** values by the formula

$$\text{pK} = -\log K \quad [2-7]$$

which is analogous to Eq. 2-4.

Acids can be classified according to their relative strengths, that is, their tendencies to transfer a proton to water. The acids listed in Table 2-4 are known as **weak acids** because they are only partially ionized in aqueous solution ($K < 1$). Many of the so-called mineral acids, such as HClO_4 , HNO_3 , and HCl , are **strong acids** ($K \gg 1$). Since strong acids rapidly transfer all their protons to H_2O , *the*

TABLE 2-4 Dissociation Constants and pK Values at 25°C of Some Acids

Acid	K	pK
Oxalic acid	5.37×10^{-2}	1.27 (pK ₁)

? Which of the substances listed here is the strongest acid?

strongest acid that can stably exist in aqueous solutions is H₃O⁺. Likewise, there can be no stronger base in aqueous solutions than OH⁻. Virtually all the acid–base reactions that occur in biological systems involve H₃O⁺ (and OH⁻) and weak acids (and their conjugate bases).

The pH of a Solution Is Determined by the Relative Concentrations of Weak Acids and Bases. The relationship between the pH of a solution and the concentrations of a weak acid and its conjugate base is easily derived. Equation 2-6 can be rearranged to

$$[\text{H}^+] = K \frac{[\text{HA}]}{[\text{A}^-]} \quad [2-8]$$

Taking the negative log of each term (and letting $\text{pH} = -\log[\text{H}^+]$; Eq. 2-4) gives

$$\text{pH} = -\log K + \log \frac{[\text{A}^-]}{[\text{HA}]} \quad [2-9]$$

Substituting pK for $-\log K$ (Eq. 2-7) yields

$$\boxed{\text{pH} = \text{pK} + \log \frac{[\text{A}^-]}{[\text{HA}]}} \quad [2-10]$$

SAMPLE CALCULATION 2-2

Calculate the pH of a 2.0 L solution containing 10 mL of 5 M acetic acid and 10 mL of 1 M sodium acetate.

First, calculate the concentrations of the acid and conjugate base, expressing all concentrations in units of moles per liter.

$$\text{Acetic acid: } (0.01 \text{ L})(5 \text{ M})/(2.0 \text{ L}) = 0.025 \text{ M}$$

$$\text{Sodium acetate: } (0.01 \text{ L})(1 \text{ M})/(2.0 \text{ L}) = 0.005 \text{ M}$$

Substitute the concentrations of the acid and conjugate base into the Henderson–Hasselbalch equation. Find the pK for acetic acid in Table 2-4.

$$\text{pH} = \text{pK} + \log([\text{acetate}]/[\text{acetic acid}])$$

$$\text{pH} = 4.76 + \log(0.005/0.025)$$

$$\text{pH} = 4.76 - 0.70$$

$$\text{pH} = 4.06$$

WPLS See Sample Calculation Videos.

This relationship is known as the **Henderson–Hasselbalch equation**. When the molar concentrations of an acid (HA) and its conjugate base (A^-) are equal, $\log([A^-]/[HA]) = \log 1 = 0$, and the pH of the solution is numerically equivalent to the pK of the acid. The Henderson–Hasselbalch equation is invaluable for calculating, for example, the pH of a solution containing known quantities of a weak acid and its conjugate base (see Sample Calculation 2-2). However, since the Henderson–Hasselbalch equation does not account for the ionization of water itself, it is not useful for calculating the pH of solutions of strong acids or bases. For example, in a 1 M solution of a strong acid, $[H^+] = 1 \text{ M}$ and the pH is 0. In a 1 M solution of a strong base, $[OH^-] = 1 \text{ M}$, so $[H^+] = [OH^-]/K_w = 1 \times 10^{-14} \text{ M}$ and the pH is 14.

C Buffers Resist Changes in pH

Adding a 0.01-mL droplet of 1 M HCl to 1 L of pure water changes the pH of the water from 7 to 5, which represents a 100-fold increase in $[H^+]$. Such a huge change in pH would be intolerable to most biological systems, since even small changes in pH can dramatically affect the structures and functions of biological molecules. Maintaining a relatively constant pH is therefore of paramount importance for living systems. To understand how this is possible, consider the titration of a weak acid with a strong base.

Figure 2-17 shows how the pH values of solutions of acetic acid, $H_2PO_4^-$, and ammonium ion (NH_4^+) vary as OH^- is added. **Titration curves** such as these can

FIG. 2-17 Titration curves for acetic acid, phosphate, and ammonia. At the starting point, the acid form predominates. As strong base (e.g., NaOH) is added, the acid is converted to its conjugate base. At the midpoint of the titration, where $\text{pH} = \text{pK}$, the concentrations of the acid and the conjugate base are equal. At the end point (equivalence point), the conjugate base predominates, and the total amount of OH^- that has been added is equivalent to the amount of acid that was present at the starting point. The shaded bands indicate the pH ranges over which the corresponding solution can effectively function as a buffer. **WPLS** See the Animated Figures.

? What is the approximate pK of each acid?

be constructed from experimental observation or by using the Henderson–Hasselbalch equation to calculate points along the curve (see Sample Calculation 2-3). When OH^- reacts with HA , the products are A^- and water:

Several details about the titration curves in Fig. 2-17 should be noted:

1. The curves have similar shapes but are shifted vertically along the pH axis.
2. The pH at the midpoint of each titration is numerically equivalent to the $\text{p}K$ of its corresponding acid; at this point, $[\text{HA}] = [\text{A}^-]$.
3. The slope of each titration curve is much lower near its midpoint than near its wings. This indicates that *when $[\text{HA}] \approx [\text{A}^-]$, the pH of the solution is relatively insensitive to the addition of strong base or strong acid*. Such a solution, which is known as an acid–base **buffer**, resists pH changes because small amounts of added H^+ or OH^- react with A^- or HA , respectively, without greatly changing the value of $\log([\text{A}^-]/[\text{HA}])$.

Substances that can lose more than one proton, or undergo more than one ionization, such as H_3PO_4 or H_2CO_3 , are known as **polyprotic acids**. The titration curves of such molecules, as illustrated in Fig. 2-18 for H_3PO_4 , are more complicated than the titration curves of monoprotic acids such as acetic acid. A polyprotic acid has multiple $\text{p}K$ values, one for each ionization step. H_3PO_4 , for example, has three dissociation constants because the ionic charge resulting

FIG. 2-18 Titration of a polyprotic acid. The first and second equivalence points for titration of H_3PO_4 occur at the steepest parts of the curve. The pH at the midpoint of each stage provides the $\text{p}K$ value of the corresponding ionization. **WPLS See the Animated Figures.**

? Sketch the titration curve for the diprotic acid succinic acid and label the midpoints and equivalence points.

SAMPLE CALCULATION 2-3

Calculate the pH of a 1 L solution containing 0.100 M formic acid and 0.100 M sodium formate before and after the addition of 1.00 mL of 5.00 M NaOH. How much would the pH change if the NaOH were added to 1.00 L of pure water?

According to Table 2-4, the $\text{p}K$ for formic acid is 3.75. Since $[\text{formate}] = [\text{formic acid}]$, the $\log([\text{A}^-]/[\text{HA}])$ term of the Henderson–Hasselbalch equation is 0 and $\text{pH} = \text{p}K = 3.75$. The addition of 1.00 mL of NaOH does not significantly change the volume of the solution, so the $[\text{NaOH}]$ is $(0.00100 \text{ L})(5.00 \text{ M})/(1.00 \text{ L}) = 0.00500 \text{ M}$.

Since NaOH is a strong base, it completely dissociates, and $[\text{OH}^-] = [\text{NaOH}] = 0.00500 \text{ M}$. This OH^- reacts with formic acid to produce formate and H_2O . Consequently, the concentration of formic acid decreases and the concentration of formate increases by 0.00500 M.

The new formic acid concentration is $0.100 \text{ M} - 0.00500 \text{ M} = 0.095 \text{ M}$, and the new formate concentration is $0.100 \text{ M} + 0.00500 \text{ M} = 0.105 \text{ M}$. Substituting these values into the Henderson–Hasselbalch equation gives

$$\begin{aligned} \text{pH} &= \text{p}K + \log([\text{formate}]/[\text{formic acid}]) \\ \text{pH} &= 3.75 + \log(0.105/0.095) \\ \text{pH} &= 3.75 + 0.044 \\ \text{pH} &= 3.79 \end{aligned}$$

In the absence of the formic acid buffering system, the $[\text{H}^+]$ and therefore the pH can be calculated directly from K_w . Since $K_w = [\text{H}^+][\text{OH}^-] = 10^{-14}$,

$$\begin{aligned} [\text{H}^+] &= \frac{10^{-14}}{[\text{OH}^-]} = \frac{10^{-14}}{(0.005)} = 2 \times 10^{-12} \text{ M} \\ \text{pH} &= -\log[\text{H}^+] = -\log(2 \times 10^{-12}) = 11.7 \end{aligned}$$

WPLS See Sample Calculation Videos.

Bicarbonate is the most significant buffer compound in human blood; other buffering agents, including proteins and organic acids, are present at much lower concentrations. The buffering capacity of blood depends primarily on two equilibria: (1) between gaseous CO_2 dissolved in the blood and carbonic acid formed by the reaction

and (2) between carbonic acid and bicarbonate formed by the dissociation of H^+ :

The overall pK for these two sequential reactions is 6.35. (The further dissociation of HCO_3^- to CO_3^{2-} , $pK = 10.33$, is not significant at physiological pH.)

When the pH of the blood falls due to metabolic production of H^+ , the bicarbonate–carbonic acid equilibrium shifts toward more carbonic acid. At the same time, carbonic acid loses water to become CO_2 , which is then expired in the lungs as gaseous CO_2 . Conversely, when the blood pH rises, relatively more HCO_3^- forms. Breathing is adjusted so that increased amounts of CO_2 in the lungs can be reintroduced into

the blood for conversion to carbonic acid. In this manner, a near-constant hydrogen ion concentration can be maintained. The kidneys also play a role in acid–base balance by excreting HCO_3^- and NH_4^+ .

Disturbances in the blood buffer system can lead to conditions known as **acidosis**, with a pH as low as 7.1, or **alkalosis**, with a pH as high as 7.6 – both of which, in extreme cases, can be fatal. For example, obstructive lung diseases that prevent efficient expiration of CO_2 can cause respiratory acidosis. Hyperventilation accelerates the loss of CO_2 and causes respiratory alkalosis. Overproduction of organic acids due to dietary precursors, sudden surges in lactic acid levels during extreme exertion, or uncontrolled **diabetes** (Section 22-4B), can lead to acidosis.

Acid–base imbalances are best alleviated by correcting the underlying physiological problem. In the short term, acidosis is commonly treated by administering NaHCO_3 intravenously. Alkalosis is more difficult to treat. Metabolic alkalosis sometimes responds to KCl or NaCl (the additional Cl^- helps minimize the secretion of H^+ by the kidneys), and respiratory alkalosis can be ameliorated by breathing an atmosphere enriched in CO_2 .

from one proton dissociation electrostatically inhibits further proton dissociation, thereby increasing the corresponding pK values. Similarly, a molecule with more than one ionizable group has a discrete pK value for each group. In a biomolecule that contains numerous ionizable groups with different pK values, the many dissociation events may yield a titration curve without any clear “plateaus.”

Biological fluids, both intracellular and extracellular, are heavily buffered. For example, the pH of the blood in healthy individuals is closely controlled at $\text{pH } 7.4 \pm 0.05$ (see Box 2-2). The phosphate and bicarbonate ions in most biological fluids are important buffering agents because they have pK s in this range (Table 2-4). Moreover, many biological molecules, such as proteins and some lipids, as well as numerous small organic molecules, bear multiple acid–base groups that are effective buffer components in the physiological pH range.

The concept that the properties of biological molecules vary with the acidity of the solution in which they are dissolved was not fully appreciated before the twentieth century. Many early biochemical experiments were undertaken without controlling the acidity of the sample, so the results were often poorly reproducible. Nowadays, biochemical preparations are routinely buffered to simulate the properties of naturally occurring biological fluids. A number of synthetic compounds have been developed for use as buffers; some of these are included in Table 2-4. The **buffering capacity** of these weak acids (their ability to resist pH changes on addition of acid or base) is maximal when $\text{pH} = pK$. It is helpful to remember that a weak acid is in its useful buffer range within one pH unit of its pK (e.g., the shaded regions of Fig. 2-17). Above this range, where the ratio $[\text{A}^-]/[\text{HA}] > 10$, the pH of the solution changes rapidly with added strong base. A buffer is similarly impotent with the addition of strong acid when its pK exceeds the pH by more than one unit.

In the laboratory, the desired pH of the buffered solution determines which buffering compound is selected. Typically, the acid form of the compound and one of its soluble salts are dissolved in the (nearly equal) molar ratio necessary to provide the desired pH and, with the aid of a pH meter, the resulting solution is fine-tuned by titration with strong acid or base (see Sample Calculation 2-4).

SAMPLE CALCULATION 2-4

How many milliliters of a 2.0 M solution of boric acid must be added to 600 mL of a solution of 10 mM sodium borate in order for the pH to be 9.45?

Rearrange the Henderson–Hasselbalch equation to isolate the $[A^-]/[HA]$ term:

$$\text{pH} = \text{p}K + \log \frac{[A^-]}{[HA]}$$

$$\log \frac{[A^-]}{[HA]} = \text{pH} - \text{p}K$$

$$\frac{[A^-]}{[HA]} = \log^{(\text{pH} - \text{p}K)}$$

Substitute the known $\text{p}K$ (from Table 2-4) and the desired pH:

$$\frac{[A^-]}{[HA]} = 10^{(9.45 - 9.24)} = 10^{0.21} = 1.62$$

The starting solution contains $(0.6 \text{ L})(0.01 \text{ mol} \cdot \text{L}^{-1}) = 0.006$ mole of borate (A^-). The amount of boric acid (HA) needed is $0.006 \text{ mol}/1.62 = 0.0037$ mol. Since the stock boric acid is 2.0 M, the volume of boric acid to be added is $(0.0037 \text{ mol})/(2.0 \text{ mol} \cdot \text{L}^{-1}) = 0.0019 \text{ L}$, or 1.9 mL.

WPLS See Sample Calculation Videos.

CHECKPOINT

- What are the products of water's ionization? How are their concentrations related?
- Predict the pH of a sample of water if K_w were 10^{-10} or 10^{-20} .
- Describe how to calculate pH from the concentration of H^+ or OH^- .
- Define *acid* and *base*.
- What is the relationship between the strength of an acid and its $\text{p}K$ value?
- Explain why it is more complicated to calculate the pH of a solution of weak acid or base than to calculate the pH of a solution of strong acid or base.
- Be able to sketch a titration curve, and label its parts, for a monoprotic and a polyprotic acid.
- What must a buffer solution include in order to resist changes in pH on addition of acid or base?
- Why is it important to maintain biological molecules in a buffered solution?

Summary

1 Physical Properties of Water

- Water is essential for all living organisms.
- Water molecules can each form four hydrogen bonds with other molecules because they have two H atoms that can be donated and two unshared electron pairs that can act as acceptors.
- Liquid water is an irregular network of water molecules that each form up to four hydrogen bonds with neighboring water molecules.
- Hydrophilic substances such as ions and polar molecules dissolve readily in water.
- The hydrophobic effect is the entropically driven tendency of water to minimize its contacts with nonpolar substances.
- Water molecules move through semipermeable membranes from regions of high concentration to regions of low concentration by osmosis; solutes move from regions of high concentration to regions of low concentration by diffusion.

2 Chemical Properties of Water

- Water ionizes to H^+ (which represents the hydronium ion, H_3O^+) and OH^- .
- The concentration of H^+ in solutions is expressed as a pH value; in acidic solutions $\text{pH} < 7$, in basic solutions $\text{pH} > 7$, and in neutral solutions $\text{pH} = 7$.
- Acids can donate protons and bases can accept protons. The strength of an acid is expressed as its $\text{p}K$; the stronger the acid, the lower its $\text{p}K$.
- The Henderson–Hasselbalch equation relates the pH of a solution to the $\text{p}K$ and concentrations of an acid and its conjugate base.
- Buffered solutions resist changes in pH within about one pH unit of the $\text{p}K$ of the buffering species.

EXERCISES

1. Identify the potential hydrogen bond donors and acceptors in the following molecules:

2. Rank the water solubility of the following compounds:

3. Approximately how many molecules of H_2O are in one spoonful of water, assuming that the spoon holds about 18 mL?

4. An *E. coli* cell contains about 2.6×10^8 ions, which constitute about 1% of the mass of the cell, and each ion has an average molecular mass of 40 g.

- (a) What is the approximate mass of the cell?
- (b) The same cell contains about 2×10^8 carbohydrate molecules, which have an average molecular mass of $150 \text{ g} \cdot \text{mol}^{-1}$. Approximately what percentage of the cell's mass is carbohydrate?
- (c) The molecular mass of *E. coli* DNA is about $5.6 \times 10^9 \text{ g} \cdot \text{mol}^{-1}$, and it accounts for about 0.6% of the cell's mass. How many DNA molecules does the cell contain?

5. Where would the following substances partition in water containing palmitic acid micelles? (a) $^+\text{H}_3\text{N}-\text{CH}_2-\text{COO}^-$, (b) $^+\text{H}_3\text{N}-(\text{CH}_2)_{11}-\text{COO}^-$.

6. Where would the following substances partition in water containing palmitic acid micelles? (a) $\text{H}_3\text{C}-(\text{CH}_2)_{11}-\text{COO}^-$, (b) $\text{H}_3\text{C}-(\text{CH}_2)_{11}-\text{CH}_3$

7. Describe what happens when a dialysis bag containing pure water is suspended in a beaker of seawater. What would happen if the dialysis membrane were permeable to water but not solutes?

8. A red blood cell has an internal salt concentration of $\sim 150 \text{ mM}$. The cell is placed in a beaker of 500 mM salt. (a) Assuming the cell membrane is permeable to water but not to ions, describe what will happen to the cell in terms of osmosis. (b) If the membrane were permeable to ions, in which direction would solutes diffuse: into or out of the cell?

9. Draw the structures of the conjugate bases of the following acids:

10. Draw the structures of the conjugate bases of the following acids:

11. Indicate the ionic species of ammonia that predominates at pH 4, 8, and 11.

12. Indicate the ionic species of phosphoric acid that predominates at pH 4, 8, and 11.

13. Calculate the pH of a 200 mL solution of pure water to which has been added 50 mL of 1 mM HCl.

14. Calculate the pH of a 1 L solution containing (a) 10 mL of 5 M NaOH, (b) 10 mL of 100 mM glycine and 20 mL of 5 M HCl, and (c) 10 mL of 2 M acetic acid and 5 g of sodium acetate (formula weight $82 \text{ g} \cdot \text{mol}^{-1}$).

15. A solution is made by mixing 50 mL of 2.0 M K_2HPO_4 and 25 mL of 2.0 M KH_2PO_4 . The solution is diluted to a final volume of 200 mL. What is the pH of the final solution?

16. What is the $\text{p}K$ of the weak acid HA if a solution containing 0.1 M HA and 0.2 M A^- has a pH of 6.5?

17. (a) At any instant, how many water molecules are ionized in 1 L of pure water at pH 7.0? (b) Express this number as a percentage of the total water molecules.

18. (a) Would phosphoric acid or succinic acid be a better buffer at pH 5?

(b) Would ammonia or piperidine be a better buffer at pH 9?

(c) Would HEPES or Tris be a better buffer at pH 7.5?

CHALLENGE QUESTIONS

19. Use Coulomb's law (Equation 2-1) to explain why a salt crystal such as NaCl remains intact in benzene (C_6H_6) but dissociates into ions in water.

20. Calculate the standard free energy change for the dissociation of HEPES.

21. Certain C—H groups can form weak hydrogen bonds. Why would such a group be more likely to be a hydrogen bond donor group when the C is next to N?

22. Explain why water forms nearly spherical droplets on the surface of a freshly waxed car. Why doesn't water bead on a clean windshield?

23. Many foods must be refrigerated to prevent spoiling (microbial growth). Explain why honey (which is $\sim 82\%$ carbohydrate by weight) resists microbial growth even at room temperature.

24. You have a 5 mL sample of a protein in 0.5 M NaCl. You place the protein/salt sample inside dialysis tubing (see Fig. 2-14) and place the bag in a large beaker of distilled water. If your goal is to remove as much NaCl from the sample as possible, which would be more effective: (1) placing the dialysis bag in 4 L of distilled water for 12 h, or (2) placing the bag in 1 L of distilled water for 6 h and then in another 1 L of fresh distilled water for another 6 h?

25. Patients with kidney failure frequently develop metabolic acidosis. If such patients undergo dialysis, the dialysate includes sodium bicarbonate at a concentration higher than that of the blood. Explain why this would benefit the patient.

26. The kidneys function to eliminate ammonia from the blood. Based on ammonia's $\text{p}K$ value, what is the molecular form that predominates in the blood? Could this molecule easily diffuse through the hydrophobic lipid membrane of a kidney cell? Explain.

27. Marble is composed largely of calcium carbonate (CaCO_3). Spilling tomato juice on a slab of marble etches (eats away) the surface. Explain what happens in chemical terms.

28. Rapidly growing *Burkholderia* bacteria normally produce ammonia as a waste product. The accumulation of ammonia kills mutant bacteria that are unable to also produce oxalic acid. Explain how the normal *Burkholderia* cells are able to avoid death.

29. How many grams of sodium succinate (formula weight $140 \text{ g} \cdot \text{mol}^{-1}$) and disodium succinate (formula weight $162 \text{ g} \cdot \text{mol}^{-1}$) must be added to 1 L of water to produce a solution with pH 6.0 and a total solute concentration of 50 mM?

30. Estimate the volume of a solution of 5 M NaOH that must be added to adjust the pH from 4 to 9 in 100 mL of a 100 mM solution of phosphoric acid.

31. You need a buffer at pH 7.5 for use in purifying a protein at 4°C . You have chosen Tris, pK 8.08, $\Delta H^\circ = 50 \text{ kJ} \cdot \text{mol}^{-1}$. You carefully make up 0.01 M Tris buffer, pH 7.5 at 25°C , and store it in the cold to equilibrate it to the temperature of the purification. When you measure the pH of the temperature-equilibrated buffer it has increased to 8.1. What is the explanation for this increase? How can you avoid this problem?

32. Glycine hydrochloride ($\text{Cl}^- \text{H}_3\text{N}^+ \text{CH}_2\text{COOH}$) is a diprotic acid that contains a carboxylic acid group and an ammonium group and is therefore called an amino acid. It is often used in biochemical buffers.

(a) Which proton would you expect to dissociate at a lower pH, the proton of the carboxylic acid group or the ammonium group?

(b) Write the chemical equations describing the dissociation of the first and second protons of $\text{Cl}^- \text{H}_3\text{N}^+ \text{CH}_2\text{COOH}$.

(c) A solution containing 0.01 M $\text{Cl}^- \text{H}_3\text{N}^+ \text{CH}_2\text{COOH}$ and 0.02 M of the monodissociated species has $\text{pH} = 2.65$. What is the pK of this dissociation?

(d) In analogy with Figure 2-18, sketch the titration curve of this diprotic acid.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Structure and Solubility

Exercise 2 Amino Acids, Ionization, and pK Values

CASE STUDY www.wiley.com/college/voet

Case 1 Acute Aspirin Overdose: Relationship to the Blood Buffering System

Focus concept: The carbonic acid–bicarbonate buffering system responds to an overdose of aspirin.

Prerequisite: Chapter 2

- Principles of acids and bases, including pK and the Henderson–Hasselbalch equation.
- The carbonic acid–bicarbonate blood buffering system.

MORE TO EXPLORE Compare and contrast the strategies for eliminating waste nitrogen (as ammonia) and carbon dioxide in (a) a terrestrial mammal, (b) a freshwater fish, and (c) a saltwater fish. Be sure to consider osmotic effects as well as acid–base balance.

CHAPTER 3

Nucleotides, Nucleic Acids, and Genetic Information

Chapter Contents

1 Nucleotides

2 Introduction to Nucleic Acid Structure

- A Nucleic Acids Are Polymers of Nucleotides
- B DNA Forms a Double Helix
- C RNA Is a Single-Stranded Nucleic Acid

3 Overview of Nucleic Acid Function

- A DNA Carries Genetic Information
- B Genes Direct Protein Synthesis

4 Nucleic Acid Sequencing

- A Restriction Endonucleases Cleave DNA at Specific Sequences
- B Electrophoresis Separates Nucleic Acids According to Size
- C Traditional DNA Sequencing Uses the Chain-Terminator Method
- D Next-Generation Sequencing Technologies Are Massively Parallel
- E Entire Genomes Have Been Sequenced
- F Evolution Results from Sequence Mutations

5 Manipulating DNA

- A Cloned DNA Is an Amplified Copy
- B DNA Libraries Are Collections of Cloned DNA
- C DNA Is Amplified by the Polymerase Chain Reaction
- D Recombinant DNA Technology Has Numerous Practical Applications

Families of genes shared by five different species of grains are depicted by overlapping shapes. By identifying the genes in samples of DNA, researchers can focus on the genetic features that have a common purpose or provide some unique function to an organism.

Despite obvious differences in lifestyle and macroscopic appearance, organisms exhibit striking similarity at the molecular level. The structures and metabolic activities of all cells rely on a common set of molecules that includes amino acids, carbohydrates, lipids, and nucleotides, as well as their polymeric forms. Each type of compound can be described in terms of its chemical makeup, its interactions with other molecules, and its physiological function. We begin our survey of biomolecules with a discussion of the **nucleotides** and their polymers, the **nucleic acids**.

Nucleotides are involved in nearly every facet of cellular life. Specifically, they participate in oxidation–reduction reactions, energy transfer, intracellular signaling, and biosynthetic reactions. Their polymers, the nucleic acids DNA and RNA, are the primary players in the storage and decoding of genetic information. Nucleotides and nucleic acids also perform structural and catalytic roles in cells. No other class of molecules participates in such varied functions or in so many functions that are essential for life.

It is becoming increasingly clear that the appearance of nucleotides permitted the evolution of organisms that could harvest and store energy from their surroundings and, most importantly, could make copies of themselves. Although the chemical and biological details of early life-forms are the subject of speculation, it is incontrovertible that life as we know it is inextricably linked to the chemistry of nucleotides and nucleic acids.

In this chapter, we briefly examine the structures of nucleotides and the nucleic acids DNA and RNA. We also consider how the chemistry of these molecules allows them to carry biological information in the form of a sequence of nucleotides. This information is expressed by the transcription of a segment of DNA to yield RNA, which is then translated to form protein. Because a cell's structure and function ultimately depend on its genetic makeup, we discuss how genomic sequences provide information about evolution, metabolism, and disease. Finally,

we consider some of the techniques used in manipulating DNA in the laboratory. In later chapters, we will examine in greater detail the participation of nucleotides and nucleic acids in metabolic processes. Chapter 24 includes additional information about nucleic acid structures, DNA's interactions with proteins, and DNA packaging in cells, as a prelude to several chapters discussing the roles of nucleic acids in the storage and expression of genetic information.

1 Nucleotides

KEY CONCEPTS

- The nitrogenous bases of nucleotides include two types of purines and three types of pyrimidines.
- A nucleotide consists of a nitrogenous base, a ribose or deoxyribose sugar, and one or more phosphate groups.
- DNA contains adenine, guanine, cytosine, and thymine deoxyribonucleotides, whereas RNA contains adenine, guanine, cytosine, and uracil ribonucleotides.

Nucleotides are ubiquitous molecules with considerable structural diversity. *There are eight common varieties of nucleotides, each composed of a nitrogenous base linked to a sugar to which at least one phosphate group is also attached.* The bases of nucleotides are planar, aromatic, heterocyclic molecules that are structural derivatives of either **purine** or **pyrimidine** (although they are not synthesized *in vivo* from either of these organic compounds).

The most common purines are **adenine (A)** and **guanine (G)**, and the major pyrimidines are **cytosine (C)**, **uracil (U)**, and **thymine (T)**. The purines form bonds to a five-carbon sugar (a pentose) via their N9 atoms, whereas pyrimidines do so through their N1 atoms (**Table 3-1**).

In **ribonucleotides**, the pentose is **ribose**, while in **deoxyribonucleotides** (or just **deoxynucleotides**), the sugar is **2'-deoxyribose** (i.e., the carbon at position 2' lacks a hydroxyl group).

Note that the “primed” numbers refer to the atoms of the pentose; “unprimed” numbers refer to the atoms of the nitrogenous base.

In a ribonucleotide or a deoxyribonucleotide, one or more phosphate groups are bonded to atom C3' or atom C5' of the pentose to form a 3'-nucleotide or a 5'-nucleotide, respectively (**Fig. 3-1**). When the phosphate group is absent, the compound is known as a **nucleoside**. A 5'-nucleotide can therefore be called a nucleoside-5'-phosphate. Nucleotides most commonly contain one to three

FIG. 3-1 Chemical structures of nucleotides. (a) A 5'-ribonucleotide and (b) a 3'-deoxynucleotide. The purine or pyrimidine base is linked to C1' of the pentose and at least one phosphate (red) is also attached. A nucleoside consists only of a base and a pentose.

? Compare the net charge on a nucleoside and a nucleotide.

TABLE 3-1 Names and Abbreviations of Nucleic Acid Bases, Nucleosides, and Nucleotides

Base Formula	Base (X = H)	Nucleoside (X = ribose ^a)	Nucleotide ^b (X = ribose phosphate ^a)
	Adenine Ade A	Adenosine Ado A	Adenylic acid Adenosine monophosphate AMP
	Guanine Gua G	Guanosine Guo G	Guanylic acid Guanosine monophosphate GMP
	Cytosine Cyt C	Cytidine Cyd C	Cytidylic acid Cytidine monophosphate CMP
	Uracil Ura U	Uridine Urd U	Uridylic acid Uridine monophosphate UMP
	Thymine Thy T	Deoxythymidine dThd dT	Deoxythymidylic acid Deoxythymidine monophosphate dTMP

^aThe presence of a 2'-deoxyribose unit in place of ribose, as occurs in DNA, is implied by the prefixes "deoxy" or "d." For example, the deoxynucleoside of adenine is deoxyadenosine, or dA. However, for thymine-containing residues, which rarely occur in RNA, the prefix is redundant and may be dropped. The presence of a ribose unit may be explicitly implied by the prefix "ribo."

^bThe position of the phosphate group in a nucleotide may be explicitly specified as in, for example, 3'-AMP and 5'-GMP.

? Without looking at the table, give the name of each base and its corresponding nucleoside.

phosphate groups at the C5' position and are called nucleoside monophosphates, diphosphates, and triphosphates.

The structures, names, and abbreviations of the common bases, nucleosides, and nucleotides are given in Table 3-1. Ribonucleotides are components of **RNA (ribonucleic acid)**, whereas deoxynucleotides are components of **DNA (deoxyribonucleic acid)**. Adenine, guanine, and cytosine occur in both ribonucleotides and deoxynucleotides (accounting for six of the eight common nucleotides), but uracil occurs primarily in ribonucleotides and thymine occurs in deoxynucleotides. Free nucleotides, which are anionic, are almost always associated with the counterion Mg^{2+} in cells.

Nucleotides Participate in Metabolic Reactions. The bulk of the nucleotides in any cell are found in polymeric forms, as either DNA or RNA, whose primary functions are information storage and transfer. However, free nucleotides and nucleotide derivatives perform an enormous variety of metabolic functions not related to the management of genetic information.

Perhaps the best known nucleotide is **adenosine triphosphate (ATP)**, a nucleotide containing adenine, ribose, and a triphosphate group. ATP is often mistakenly referred to as an energy-storage molecule, but it is more accurately termed an energy carrier or energy transfer agent. The process of photosynthesis or the breakdown of metabolic fuels such as carbohydrates and fatty acids leads to the formation of ATP from **adenosine diphosphate (ADP)**:

ATP diffuses throughout the cell to provide energy for other cellular work, such as biosynthetic reactions, ion transport, and cell movement. The chemical potential energy of ATP is made available when it transfers one (or two) of its phosphate groups to another molecule. This process can be represented by the reverse of the preceding reaction, namely, the hydrolysis of ATP to ADP. (As we will see in later chapters, the interconversion of ATP and ADP in the cell is not freely reversible, and free phosphate groups are seldom released directly from ATP.) The degree to which ATP participates in routine cellular activities is illustrated by calculations indicating that while the concentration of cellular ATP is relatively moderate (~ 5 mM), humans typically recycle their own weight of ATP each day.

Nucleotide derivatives participate in a wide variety of metabolic processes. For example, starch synthesis in plants proceeds by repeated additions of glucose units donated by ADP–glucose (Fig. 3-2). Other nucleotide derivatives, as we will see in later chapters, carry groups that undergo oxidation–reduction reactions. The attached group, which may be a small molecule such as glucose (Fig. 3-2) or even another nucleotide, is typically linked to the nucleotide through a mono- or diphosphate group.

CHECKPOINT

- Identify the purines and pyrimidines commonly found in nucleic acids.
- Practice drawing the structures of adenine, adenosine, and adenylate.
- Describe the chemical differences between a ribonucleoside triphosphate and a deoxyribonucleoside monophosphate.

FIG. 3-2 ADP–glucose. In this nucleotide derivative, glucose (*blue*) is attached to adenosine (*black*) by a diphosphate group (*red*).

? Indicate the bonds that formed as a result of condensation reactions.

2 Introduction to Nucleic Acid Structure

KEY CONCEPTS

- Phosphodiester bonds link nucleotide residues in DNA and RNA.
- In the DNA double helix, two antiparallel polynucleotide strands wind around each other, interacting via hydrogen bonding between bases in opposite strands.
- RNA molecules are usually single-stranded and may form intramolecular base pairs.

Nucleotides can be joined to each other to form the polymers that are familiar to us as RNA and DNA. In this section, we describe the general features of these nucleic acids. Nucleic acid structure is considered further in Chapter 24.

A Nucleic Acids Are Polymers of Nucleotides

The nucleic acids are chains of nucleotides whose phosphates bridge the 3' and 5' positions of neighboring ribose units (Fig. 3-3). The phosphates of these **polynucleotides** are acidic, so at physiological pH, nucleic acids are polyanions. The linkage between individual nucleotides is known as a **phosphodiester bond**, so named because the phosphate is esterified to two ribose units. Each nucleotide that has been incorporated into the polynucleotide is known as a **nucleotide residue**. The terminal residue whose C5' is not linked to another nucleotide is called the **5' end**, and the terminal residue whose C3' is not linked to another nucleotide is called the **3' end**. By convention, the sequence of nucleotide residues in a nucleic acid is written, left to right, from the 5' end to the 3' end.

FIG. 3-4 Tautomeric forms of bases. Some of the possible tautomeric forms of (a) thymine and (b) guanine are shown. Cytosine and adenine can undergo similar proton shifts.

? Draw the tautomers of adenine and cytosine.

The properties of a polymer such as a nucleic acid may be very different from the properties of the individual units, or **monomers**, before polymerization. As the size of the polymer increases from **dimer**, **trimer**, **tetramer**, and so on through **oligomer** (Greek: *oligo*, few), physical properties such as charge and solubility may change. In addition, a *polymer of nonidentical residues has a property that its component monomers lack—namely, it contains information in the form of its sequence of residues.*

Chargaff's Rules Describe the Base Composition of DNA. Although there appear to be no rules governing the nucleotide composition of typical RNA molecules, DNA has equal numbers of adenine and thymine residues ($A = T$) and equal numbers of guanine and cytosine residues ($G = C$). These relationships, known as **Chargaff's rules**, were discovered in the late 1940s by Erwin Chargaff, who devised the first reliable quantitative methods for the compositional analysis of DNA.

DNA's base composition varies widely among different organisms. It ranges from ~25 to 75 mol % $G + C$ in different species of bacteria. However, it is more or less constant among related species; for example, in mammals $G + C$ ranges from 39 to 46%. The significance of Chargaff's rules was not immediately appreciated, but we now know that the structural basis for the rules derives from DNA's double-stranded nature.

B DNA Forms a Double Helix

The determination of the structure of DNA by James Watson and Francis Crick in 1953 is often said to mark the birth of modern molecular biology. The **Watson–Crick structure** of DNA not only provided a model of what is arguably the central molecule of life, but it also suggested the molecular mechanism of heredity. Watson and Crick's accomplishment, which is ranked as one of science's major intellectual achievements, was based in part on two pieces of evidence in addition to Chargaff's rules: the correct tautomeric forms of the bases and indications that DNA is a helical molecule.

The purine and pyrimidine bases of nucleic acids can assume different tautomeric forms (**tautomers** are readily interconverted isomers that differ only in hydrogen positions; Fig. 3-4). X-Ray, nuclear magnetic resonance (NMR), and spectroscopic investigations have firmly established that the nucleic acid bases are overwhelmingly in the keto tautomeric forms shown in Fig. 3-3. In 1953, however, this was not generally appreciated. Information about the dominant tautomeric forms was provided by Jerry Donohue, an officemate of Watson and Crick and an expert on the X-ray structures of small organic molecules.

Evidence that DNA is a helical molecule was provided by an X-ray diffraction photograph of a DNA fiber taken by Rosalind Franklin (Fig. 3-5). The appearance of the photograph enabled Crick, an X-ray crystallographer by training, to deduce (a) that DNA is a helical molecule and (b) that its planar aromatic bases form a stack that is parallel to the fiber axis.

Courtesy of Maurice Wilkins, King's College, London.

FIG. 3-5 An X-ray diffraction photograph of a vertically oriented DNA fiber. This photograph, taken by Rosalind Franklin, provided key evidence for the elucidation of the Watson–Crick structure. The central X-shaped pattern indicates a helix, whereas the heavy black arcs at the top and bottom of the diffraction pattern reveal the spacing of the stacked bases (3.4 Å).

FIG. 3-6 Three-dimensional structure of DNA.

The repeating helix is based on the structure of the self-complementary dodecamer d(CGCGAATTCGCG) determined by Richard Dickerson and Horace Drew. The view in this ball-and-stick model is perpendicular to the helix axis. The sugar-phosphate backbones (*blue, with green ribbon outlines*) wind around the periphery of the molecule. The bases (*red*) form hydrogen-bonded pairs that occupy the core. H atoms have been omitted for clarity. The two strands run in opposite directions. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

**FIG. 3-7 Diagrams of left- and right-handed helices.**

In each case, the fingers curl in the direction the helix turns when the thumb points in the direction the helix rises. Note that the handedness is retained when the helices are turned upside down.

The limited structural information, along with Chargaff's rules, provided few clues to the structure of DNA; Watson and Crick's model sprang mostly from their imaginations and model-building studies. Once the Watson–Crick model had been published, however, its basic simplicity combined with its obvious biological relevance led to its rapid acceptance. Later investigations have confirmed the general validity of the Watson–Crick model, although its details have been modified.

The Watson–Crick model of DNA has the following major features (**Fig. 3-6**):

1. Two polynucleotide chains wind around a common axis to form a **double helix**.
2. The two strands of DNA are **antiparallel** (run in opposite directions), but each forms a right-handed helix. (The difference between a right-handed and a left-handed helix is shown in **Fig. 3-7**.)

FIG. 3-8 Complementary base pairing in DNA. Adenine in one strand pairs with thymine in the other strand by forming specific hydrogen bonds (*dashed lines*). Similarly, guanine pairs with cytosine. This base pairing between polynucleotide chains is responsible for the double-stranded nature of DNA.

? Indicate the 5' → 3' sequence of the strand that would be complementary to the nucleic acid shown in Fig. 3-3a.

- The bases occupy the core of the helix and sugar–phosphate chains run along the periphery, thereby minimizing the repulsions between charged phosphate groups. The surface of the double helix contains two grooves of unequal width: the **major** and **minor grooves**.
- Each base is hydrogen bonded to a base in the opposite strand to form a planar **base pair**. The Watson–Crick structure can accommodate only two types of base pairs. Each adenine residue must pair with a thymine residue and vice versa, and each guanine residue must pair with a cytosine residue and vice versa (**Fig. 3-8**). These hydrogen-bonding interactions, a phenomenon known as **complementary base pairing**, result in the specific association of the two chains of the double helix.

The Watson–Crick structure can accommodate any sequence of bases on one polynucleotide strand if the opposite strand has the complementary base sequence. This immediately accounts for Chargaff's rules. More importantly, it suggests that *each DNA strand can act as a **template** for the synthesis of its complementary strand and hence that hereditary information is encoded in the sequence of bases on either strand.*

Most DNA Molecules Are Large. The extremely large size of DNA molecules is in keeping with their role as the repository of a cell's genetic information. Of course, an organism's **genome**, its unique DNA content, may be allocated among several **chromosomes** (Greek: *chromos*, color + *soma*, body), each of which contains a separate DNA molecule. Note that many organisms are **diploid**; that is, they contain two equivalent sets of chromosomes, one from each parent. Their content of unique (**haploid**) DNA is half their total DNA. For example, humans are diploid organisms that carry 46 chromosomes per cell; their haploid number is therefore 23.

Because of their great lengths, DNA molecules are described in terms of the number of base pairs (**bp**) or thousands of base pairs (**kilobase pairs**, or **kb**). Naturally occurring DNAs vary in length from ~5 kb in small DNA-containing viruses to well over 250,000 kb in the largest mammalian chromosomes. Although DNA molecules are long and relatively stiff, they are not completely rigid. We will see in Chapter 24 that the DNA double helix forms coils and loops when it is packaged inside the cell. Furthermore, depending on the nucleotide

GATEWAY CONCEPT Noncovalent Interactions

The sequence of nucleotides in a polynucleotide chain is determined by covalent bonds, but hydrogen bonds, which are much weaker, allow one chain to interact with another via base pairing.

FIG. 3-9 Formation of a stem-loop structure. Base pairing between complementary sequences within an RNA strand allows the polynucleotide to fold back on itself.

sequence, DNA may adopt slightly different helical conformations. Finally, in the presence of other cellular components, the DNA may bend sharply or the two strands may partially unwind.

CHECKPOINT

- Using Fig. 3-3a as a guide, draw the complete structure of a nucleoside triphosphate before and after it becomes incorporated into a polynucleotide chain. Draw the structure that would result if the newly formed phosphodiester bond were hydrolyzed.
- Explain the structural basis for Chargaff's rules.
- Using a three-dimensional computer model of the DNA molecule (such as shown in Interactive Exercise 1), identify each of the following structural features: the 3' and 5' end of each strand, the atoms that make up the sugar-phosphate backbone, the major and minor grooves, the bases in several base pairs, and the atoms that participate in hydrogen bonding in A · T and G · C base pairs.
- List the structural differences between DNA and RNA.

C RNA Is a Single-Stranded Nucleic Acid

Single-stranded DNA is rare, occurring mainly as the hereditary material of certain viruses. In contrast, RNA occurs primarily as single strands, which usually form compact structures rather than loose extended chains (double-stranded RNA is the hereditary material of certain viruses). An RNA strand—which is identical to a DNA strand except for the presence of 2'-OH groups and the substitution of uracil for thymine—can base-pair with a complementary strand of RNA or DNA. As expected, A pairs with U (or T in DNA), and G with C. Base pairing often occurs intramolecularly, giving rise to **stem-loop** structures (Fig. 3-9) or, when loops interact with each other, to more complex structures.

The intricate structures that can potentially be adopted by single-stranded RNA molecules provide additional evidence that RNA can do more than just store and transmit genetic information. Numerous investigations have found that certain RNA molecules can specifically bind small organic molecules and can catalyze reactions involving those molecules. These findings provide substantial support for theories that *many of the processes essential for life began through the chemical versatility of small polynucleotides* (a situation known as the **RNA world**). We will further explore RNA structure and function in Section 24-2C.

3 Overview of Nucleic Acid Function

KEY CONCEPTS

- DNA carries genetic information in the form of its sequence of nucleotides.
- The nucleotide sequence of DNA is transcribed into the nucleotide sequence of messenger RNA, which is then translated into a protein, a sequence of amino acids.

DNA is the carrier of genetic information in all cells and in many viruses. Yet a period of over 75 years passed from the time the laws of inheritance were discovered by Gregor Mendel until the biological role of DNA was elucidated. Even now, many details of how genetic information is expressed and transmitted to future generations remain unclear.

From Avery, O. T., MacLeod, C. M., and McCarty, M. *J. Exp. Med.* **79**, 153 (1944). Copyright © 1944 by Rockefeller University Press.

FIG. 3-10 Transformed pneumococci. The large colonies are virulent pneumococci that resulted from the transformation of nonpathogenic pneumococci (smaller colonies) by DNA extracted from the virulent strain. We now know that this DNA contained a gene that was defective in the nonpathogenic strain.

Mendel's work with garden peas led him to postulate that each trait in an individual plant is determined by a pair of factors (which we now call **genes**), one inherited from each parent. But Mendel's theory of inheritance, reported in 1866, was almost universally ignored by his contemporaries, whose knowledge of anatomy and physiology provided no basis for its understanding. Eventually, genes were hypothesized to be part of chromosomes, and the pace of genetic research accelerated greatly.

A DNA Carries Genetic Information

Until the 1940s, it was generally assumed that genes were made of protein, since proteins were the only biochemical entities that, at the time, seemed complex enough to serve as agents of inheritance. Nucleic acids, which had first been isolated in 1869 by Friedrich Miescher, were believed to have monotonously repeating nucleotide sequences and were therefore unlikely candidates for transmitting genetic information.

It took the efforts of Oswald Avery, Colin MacLeod, and Maclyn McCarty to demonstrate that DNA carries genetic information. Their experiments, completed in 1944, showed that DNA—not protein—extracted from a virulent (pathogenic) strain of the bacterium *Diplococcus pneumoniae* was the substance that **transformed** (permanently changed) a nonpathogenic strain of the organism to the virulent strain (**Fig. 3-10**). Avery's discovery was initially greeted with skepticism, but it influenced Erwin Chargaff, whose rules (Section 3-2A) led to subsequent models of the structure and function of DNA.

The double-stranded, or duplex, nature of DNA facilitates its **replication**. When a cell divides, each DNA strand acts as a template for the assembly of its complementary strand (**Fig. 3-11**). Consequently, every progeny cell contains a complete DNA molecule (or a complete set of DNA molecules in organisms whose genomes contain more than one chromosome). Each DNA molecule consists of one parental strand and one daughter strand. Daughter strands are synthesized by the stepwise polymerization of nucleotides that specifically pair with bases on the parental strands. The mechanism of replication, while straightforward in principle, is exceedingly complex in the cell, requiring a multitude of cellular factors to proceed with fidelity and efficiency, as we will see in Chapter 25.

B Genes Direct Protein Synthesis

The question of how sequences of nucleotides control the characteristics of organisms took some time to be answered. In experiments with the mold *Neurospora crassa* in the 1940s, George Beadle and Edward Tatum found that *there is a specific connection between genes and enzymes: the one gene—one enzyme theory*. Beadle and Tatum showed that certain mutant varieties of *Neurospora*

FIG. 3-11 DNA replication. Each strand of parental DNA (*blue*) acts as a template for the synthesis of a complementary daughter strand (*red*). Thus, the resulting double-stranded molecules are identical.

? What types of bonds or interactions form during DNA replication?

FIG. 3-12 Transcription and translation. One strand of DNA directs the synthesis of messenger RNA (mRNA). The base sequence of the transcribed RNA is complementary to that of the DNA strand. The message is translated when transfer RNA (tRNA) molecules align with the mRNA by complementary base pairing between three-nucleotide segments known as **codons**. Each tRNA carries a specific amino acid. These amino acids are covalently joined to form a protein. Thus, the sequence of bases in DNA specifies the sequence of amino acids in a protein.

? What might happen if a mutation changed one of the nucleotides in the DNA?

that were generated by irradiation with X-rays required additional nutrients in order to grow. Presumably, the offspring of the radiation-damaged cells lacked the specific enzymes necessary to synthesize those nutrients.

The link between DNA and enzymes (nearly all of which are proteins) is RNA. *The DNA of a gene is **transcribed** to produce an RNA molecule that is complementary to the DNA. The RNA sequence is then **translated** into the corresponding sequence of amino acids to form a protein (Fig. 3-12).* These transfers of biological information are summarized in the so-called **central dogma of molecular biology** formulated by Crick in 1958.

WileyPLUS Learning Space

See **Guided Exploration**
Overview of transcription and translation

In this diagram, the arrows represent the flow of genetic information: DNA directs its own replication to produce new DNA molecules; the DNA is transcribed into RNA; and the RNA is translated into proteins.

Just as the daughter strands of DNA are synthesized from free deoxynucleoside triphosphates that pair with bases in the parent DNA strand, RNA strands are synthesized from free ribonucleoside triphosphates that pair with the complementary bases in one DNA strand of a gene (transcription is described in greater detail in Chapter 26). The RNA that corresponds to a protein-coding gene (called **messenger RNA**, or **mRNA**) makes its way to a **ribosome**, an organelle that is itself composed largely of RNA (**ribosomal RNA**, or **rRNA**). At the ribosome, each set of three nucleotides in the mRNA pairs with three complementary nucleotides in a small RNA molecule called

FIG. 3-13 Translation. tRNA molecules with their attached amino acids bind to complementary three-nucleotide sequences (codons) on mRNA. The ribosome facilitates the alignment of the tRNA and the mRNA, and it catalyzes the joining of amino acids to produce a protein chain. When a new amino acid is added, the preceding tRNA is ejected, and the ribosome proceeds along the mRNA.

a **transfer RNA**, or **tRNA** (Fig. 3-13). Attached to each tRNA molecule is its corresponding amino acid. The ribosome catalyzes the joining of amino acids, which are the monomeric units of proteins (protein synthesis is described in detail in Chapter 27). Amino acids are added to the growing protein chain according to the order in which the tRNA molecules bind to the mRNA. Since the nucleotide sequence of the mRNA in turn reflects the sequences of nucleotides in the gene, DNA directs the synthesis of proteins. It follows that alterations to the genetic material of an organism (**mutations**) may manifest themselves as proteins with altered structures and functions.

Using techniques that are described in the following sections and in other parts of this book, researchers can compile a catalog of all the information encoded in an organism's DNA. The study of the genome's size, organization, and gene content is known as **genomics**. By analogy, **transcriptomics** refers to the study of **gene expression**, which focuses on the set of mRNA molecules, or **transcriptome**, that is transcribed from DNA under any particular set of circumstances. Finally, **proteomics** is the study of the proteins (the **proteome**) produced as a result of transcription and translation. Although an organism's genome remains essentially unchanged throughout its lifetime, its transcriptome and proteome may vary greatly among different types of tissues, developmental stages, and environmental conditions.

GATEWAY CONCEPT The Central Dogma

Although we sometimes think of a cell's nucleus as a sort of command center, it does not broadcast information to the rest of the cell. Instead, as the central dogma reminds us, genetic information in the form of DNA is relatively inert and is simply copied—via replication or transcription.

CHECKPOINT

- Explain why the double-stranded nature of DNA is relevant for copying and transmitting genetic information when a cell divides.
- Summarize the steps of the central dogma. What role does RNA play in each?

4 Nucleic Acid Sequencing

KEY CONCEPTS

- In the laboratory, nucleic acids can be cut at specific sequences by restriction enzymes.
- Nucleic acid fragments are separated by size using electrophoresis.
- In the chain-termination method, DNA polymerase generates DNA fragments that are randomly terminated. The identities of the terminator nucleotides of successive fragments reveal the original DNA sequence.
- The human genome contains ~21,000 genes, corresponding to about 1.2% of its 3 billion nucleotides.
- Sequence differences reveal evolutionary changes.

Much of our current understanding of protein structure and function rests squarely on information gleaned not from the proteins themselves, but indirectly from their genes. *The ability to determine the sequence of nucleotides in nucleic acids*

FIG. 3-14 Determining the sequence of an oligonucleotide using nonspecific enzymes. The oligonucleotide is partially digested with snake venom phosphodiesterase, which breaks the phosphodiester bonds between nucleotide residues, starting at the 3' end of the oligonucleotide. The result is a mixture of fragments of all lengths, which are then separated. Comparing the base composition of a pair of fragments that differ in length by one nucleotide establishes the identity of the 3'-terminal nucleotide in the larger fragment. Analysis of each pair of fragments reveals the sequence of the original oligonucleotide.

has made it possible to deduce the amino acid sequences of their encoded proteins and, to some extent, the structures and functions of those proteins. Nucleic acid sequencing has also revealed information about the regulation of genes. Certain portions of genes that are not actually transcribed into RNA nevertheless influence how often a gene is transcribed and translated—that is, **expressed**. Moreover, efforts to elucidate the sequences in hitherto unmapped regions of DNA have led to the discovery of new genes and new regulatory elements. *Once in hand, a nucleic acid sequence can be duplicated, modified, and expressed, making it possible to study proteins that could not otherwise be obtained in useful quantities.* In this section, we describe how nucleic acids are sequenced and what information the sequences may reveal. In the following section, we discuss the manipulation of purified nucleic acid sequences for various purposes.

The overall strategy for sequencing any polymer of nonidentical units is

1. Cleave the polymer into fragments that are small enough to be fully sequenced.
2. Determine the sequence of residues in each fragment.
3. Determine the order of the fragments in the original polymer by aligning fragments that contain overlapping sequences.

The first efforts to sequence RNA used nonspecific enzymes to generate relatively small fragments whose nucleotide composition was then determined by partial digestion with an enzyme that selectively removed nucleotides from one end or the other (Fig. 3-14). Sequencing RNA in this manner was tedious and time-consuming. Using such methods, it took Robert Holley 7 years to determine the sequence of a 76-residue tRNA molecule.

After 1975, dramatic progress was made in nucleic acid sequencing technology. The advances were made possible by the discovery of enzymes that could cleave DNA at specific sites and by the development of rapid sequencing techniques for DNA. Because most specific DNA sequences are normally present in a genome in only a single copy, most sequencing projects take advantage of methods to amplify segments of DNA by cloning or copying them (Section 3-5).

A Restriction Endonucleases Cleave DNA at Specific Sequences

Many bacteria are able to resist infection by **bacteriophages** (viruses that are specific for bacteria) by virtue of a **restriction–modification system**. The bacterium modifies certain nucleotides in specific sequences of its own DNA by adding a methyl ($-\text{CH}_3$) group in a reaction catalyzed by a **modification methylase**. A **restriction endonuclease**, which recognizes the same nucleotide sequence as does the methylase, cleaves any DNA that has not been modified on at least one of its two strands. (An **endonuclease** cleaves a nucleic acid within the polynucleotide strand; an **exonuclease** cleaves a nucleic acid by removing one of its terminal residues.) This system destroys foreign (phage) DNA containing a recognition site that has not been modified by methylation. The host DNA is always at least half methylated, because although the daughter strand is not methylated until shortly after it is synthesized, the parental strand to which it is paired is already modified (and thus protects both strands of the DNA from cleavage by the restriction enzyme).

Type II restriction endonucleases are particularly useful in the laboratory. These enzymes cleave DNA within the four- to eight-base sequence that is recognized by their corresponding modification methylase. (Type I and Type III restriction endonucleases cleave DNA at sites other than their recognition sequences.) More than 11,000 Type II restriction enzymes with more than 270 different recognition sequences have been characterized. Some of the more widely used restriction enzymes are listed in Table 3-2. A restriction enzyme is named by the first letter of the genus and the first two letters of the species of the

TABLE 3-2 Recognition and Cleavage Sites of Some Restriction Enzymes

Enzyme	Recognition Sequence ^a	Microorganism

bacterium that produced it, followed by its serotype or strain designation, if any, and a roman numeral if the bacterium contains more than one type of restriction enzyme. For example, EcoRI is produced by *E. coli* strain RY13.

Interestingly, most Type II restriction endonucleases recognize and cleave palindromic DNA sequences. A **palindrome** is a word or phrase that reads the same forward or backward. Two examples are “refer” and “Madam, I’m Adam.” In a palindromic DNA segment, the sequence of nucleotides is the same in each strand, and the segment is said to have twofold symmetry (Fig. 3-15). Most restriction enzymes cleave the two strands of DNA at positions that are staggered, producing DNA fragments with complementary single-strand extensions. Restriction fragments with such **sticky ends** can

FIG. 3-15 Restriction sites. The recognition sequences for Type II restriction endonucleases are palindromes, sequences with a twofold axis of symmetry. (a) Recognition site for EcoRI, which generates DNA fragments with sticky ends. (b) Recognition site for EcoRV, which generates blunt-ended fragments.

FIG. 3-16 Apparatus for gel electrophoresis. Samples are applied in slots at the top of the gel and electrophoresed in parallel lanes. Negatively charged molecules such as DNA migrate through the gel matrix toward the anode in response to an applied electric field. Because smaller molecules move faster, the molecules in each lane are separated according to size. Following electrophoresis, the separated molecules may be visualized by staining or fluorescence.

? What would happen if the sample contained positively charged molecules?

associate by base pairing with other restriction fragments generated by the same restriction enzyme. Some restriction endonucleases cleave the two strands of DNA at the symmetry axis to yield restriction fragments with fully base-paired **blunt ends**.

B Electrophoresis Separates Nucleic Acids According to Size

Treating a DNA molecule with a restriction endonuclease produces a series of precisely defined fragments that can be separated according to size. **Gel electrophoresis** is commonly used for the separation. In principle, a charged molecule moves in an electric field with a velocity proportional to its overall charge density, size, and shape. For molecules with a relatively homogeneous composition (such as nucleic acids), shape and charge density are constant, so the velocity depends primarily on size. Electrophoresis is carried out in a gel-like matrix, usually made from **agarose** (carbohydrate polymers that form a loose mesh) or **polyacrylamide** (a more rigid cross-linked synthetic polymer). The gel is typically held between two glass plates (Fig. 3-16) or inside a narrow capillary tube (Section 5-2D). The molecules to be separated are applied to one end of the gel, and the molecules move through the pores in the matrix under the influence of an electric field. Smaller molecules move more rapidly through the gel and therefore migrate farther in a given time.

Following electrophoresis, the separated molecules may be visualized in the gel by an appropriate technique, such as addition of a stain that binds tightly to the DNA, by radioactive labeling, or by their fluorescence. Depending on the dimensions of the gel and the visualization technique used, samples containing less than a nanogram of material can be separated and detected by gel electrophoresis. Several samples can be electrophoresed simultaneously. For example, the fragments obtained by digesting a DNA sample with different restriction endonucleases can be visualized side by side (Fig. 3-17). The

FIG. 3-17 Electrophoretogram of restriction digests. The plasmid pAgK84 has been digested with (A) BamHI, (B) PstI, (C) BglIII, (D) HaeIII, (E) HincII, (F) SacI, (G) XbaI, and (H) HpaI. Lane I contains bacteriophage λ digested with HindIII as a standard since these fragments have known sizes. The restriction fragments in each lane are made visible by fluorescence against a black background.

sizes of the various fragments can be determined by comparing their electrophoretic mobilities to the mobilities of fragments of known size.

C Traditional DNA Sequencing Uses the Chain-Terminator Method

Until recent years, the most widely used technique for sequencing DNA was the **chain-terminator method**, which was devised by Frederick Sanger. The first step in this procedure is to obtain single polynucleotide strands. Complementary DNA strands can be separated by heating, which breaks the hydrogen bonds between bases. Next, polynucleotide fragments that terminate at positions corresponding to each of the four nucleotides are generated. Finally, the fragments are separated and detected.

DNA Polymerase Copies a Template Strand. The chain-terminator method (also called the **dideoxy method**) uses an *E. coli* enzyme to make complementary copies of the single-stranded DNA being sequenced. The enzyme is a fragment of **DNA polymerase I**, one of the enzymes that participates in replication of bacterial DNA (Section 25-2A). Using the single DNA strand as a template, DNA polymerase I assembles the four deoxynucleoside triphosphates (**dNTPs**), dATP, dCTP, dGTP, and dTTP, into a complementary polynucleotide chain that it elongates in the 5' → 3' direction (Fig. 3-18).

DNA polymerase I can sequentially add deoxynucleotides only to the 3' end of a polynucleotide that is base-paired to the template strand. Replication is initiated in the presence of a short polynucleotide (a **primer**) that is complementary to the 3' end of the template DNA, and thus becomes the 5' end of the new strand. If the DNA being sequenced is a restriction fragment, as it usually is, it begins and ends with a restriction site. The primer can therefore be a short DNA segment with the sequence of this restriction site.

WileyPLUS Learning Space

See Guided Exploration

DNA sequence determination by the chain-terminator method

FIG. 3-18 Action of DNA polymerase I. Using a single DNA strand as a template, the enzyme elongates the primer by stepwise addition of complementary nucleotides. Incoming nucleotides pair with bases on the template strand and are joined to the growing polynucleotide strand

in the 5' → 3' direction. The polymerase-catalyzed reaction requires a free 3'-OH group on the growing strand. **Pyrophosphate** ($O_3P-O-PO_3^{4-}$; PP_i) is released with each nucleotide addition.

? List the substrates and products of the DNA polymerase reaction.

DNA Synthesis Terminates after Specific Bases. In the chain-terminator technique (Fig. 3-19), the DNA to be sequenced is incubated with DNA polymerase I, a suitable primer, and the four dNTP substrates (reactants in enzymatic reactions) for the polymerization reaction. The key component of the reaction mixture is a small amount of a **2',3'-dideoxynucleoside triphosphate (ddNTP)**,

which lacks the 3'-OH group of deoxynucleotides. *When the dideoxy analog is incorporated into the growing polynucleotide in place of the corresponding normal nucleotide, chain growth is terminated because addition of the next nucleotide requires a free 3'-OH group.*

By using only a small amount of the ddNTP, a series of truncated chains is generated, each of which ends with the dideoxy analog at one of the positions occupied by the corresponding base. Each ddNTP bears a different fluorescent “tag” so that the products of the polymerase reaction can be readily detected. Gel electrophoresis separates the newly synthesized DNA segments, which differ in size by one nucleotide. Thus, the sequence of the replicated strand can be directly read from the gel. Note that the sequence obtained by the chain-terminator method is complementary to the DNA strand being sequenced.

The most advanced sequencing devices that employ the chain-terminator method identify each DNA fragment as it exits the bottom of a capillary

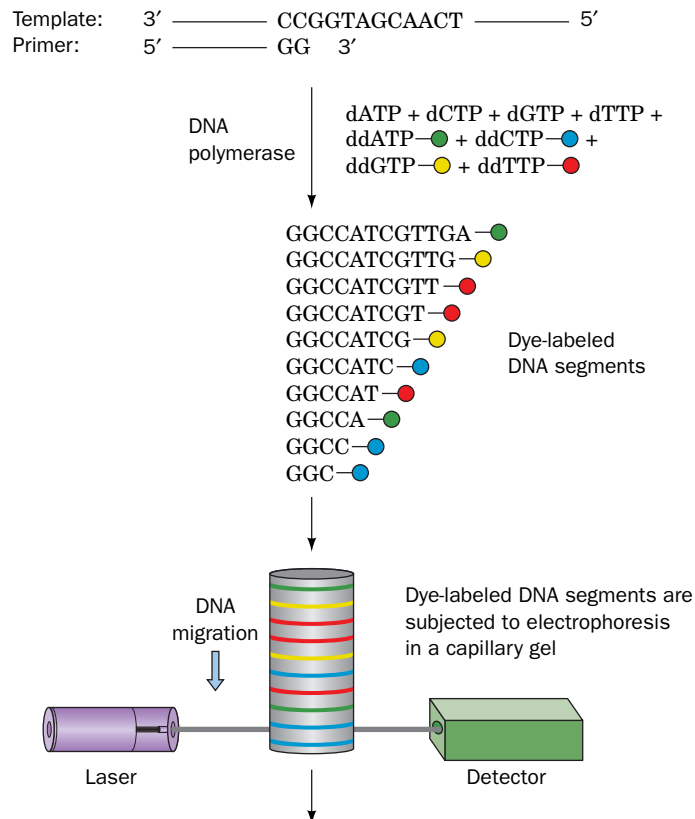

FIG. 3-19 Automated DNA sequencing by the chain-terminator method. The reaction mixture includes the single-stranded DNA to be sequenced (the template), a primer, the four deoxynucleotide triphosphates (represented as dATP, etc.), and small amounts of the four fluorescently labeled dideoxynucleoside triphosphates (ddATP, etc.). DNA polymerase extends the primer until a chain-terminating dideoxy nucleotide is added, generating a set of DNA fragments that differ by one nucleotide. The mixture is subjected to gel electrophoresis in a capillary tube, which separates the fragments according to size. As each polynucleotide passes the detector, its 3'-terminal nucleotide is identified according to its laser-stimulated fluorescence.

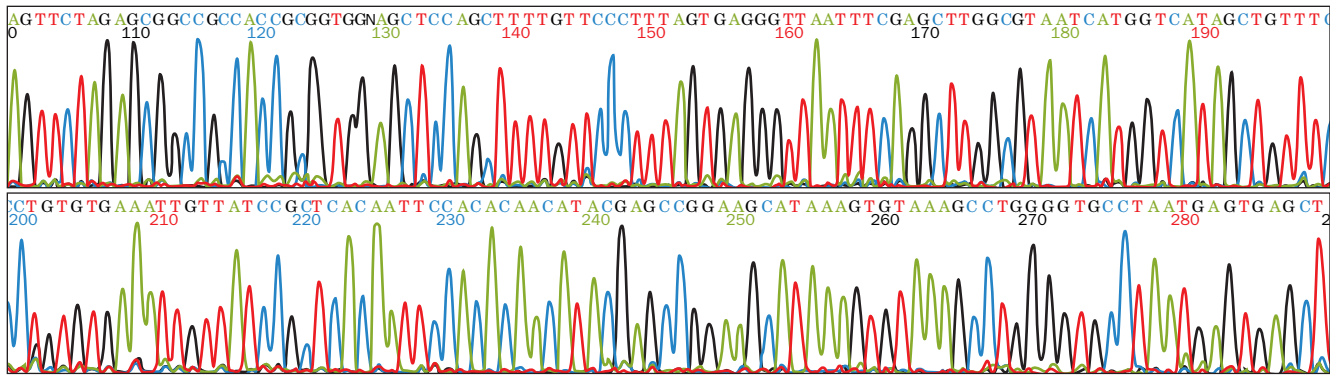

FIG. 3-20 DNA sequence data. Each of the four colored curves represents the electrophoretic pattern of fragments containing one of the dideoxynucleotides: Green, red, black, and blue peaks correspond to fragments ending in ddATP, ddTTP, ddGTP, and ddCTP, respectively. The 3'-terminal base of each oligonucleotide, identified by the fluorescence of

its gel band, is indicated by a single letter (A, T, G, or C). This portion of the readout corresponds to nucleotides 100–290 of the DNA segment being sequenced. [Courtesy of Mark Adams, The Institute for Genomic Research, Rockville, Maryland.]

electrophoresis tube, so the sequence data take the form of a series of peaks (Fig. 3-20). Sample preparation and data analysis are fully automated, and sequences of DNA (called **reads**) of up to 1000 nucleotides can be obtained from a single reaction mixture before cumulative errors reduce the confidence of identification to unacceptable levels. Moreover, these systems contain arrays of up to 384 capillary tubes and hence can simultaneously sequence as many as 384 DNA segments.

The many reads that have been sequenced must be correctly assembled into the far longer strand of DNA from which they originated. This is done by comparing reads with overlapping sequences as is schematically indicated in Fig. 3-21. The overlapping sets of DNA fragments are generated by separately cleaving the DNA with at least two restriction endonucleases that have different sequence specificities. Alternatively, fragments may be generated by subjecting a solution of the stiff double-stranded DNA to high-frequency sound waves, a process called **sonication**, thereby mechanically breaking (shearing) the DNA at random sites. For even relatively small chromosomes (the *E. coli* genome has 4600 kb; the average human chromosome has ~125,000 kb), assembly is a highly computationally intensive process. In addition, the chain-terminator method has an error rate of ~0.1% (which would lead to ~125,000 mistakes in a 125,000-kb chromosome). To minimize these errors, the DNA must be independently sequenced multiple times—normally with at least a 10-fold redundancy.

D Next-Generation Sequencing Technologies Are Massively Parallel

The value of DNA sequence information, particularly the enormous datasets obtained by sequencing entire genomes, has fostered the development of so-called

FIG. 3-21 The order of the sequenced fragments in their DNA of origin is determined by matching the sequences of overlapping sets of fragments. Thus, the 3' end of fragment 1 is identical to the 5' end of fragment 2, whose 3' end is identical to the 5' end of fragment 3, etc.

next-generation sequencing technologies that offer various trade-offs among cost, speed, and accuracy. Like the chain-terminator method, many of the newer methods take advantage of the ability of a DNA template strand to direct the synthesis of its complementary copy (a procedure known as **sequencing by synthesis**). But in addition, these methods can simultaneously determine hundreds of thousands to billions of different reads; that is, they carry out massively parallel sequencing reactions. Two of the several DNA sequencing technologies that are in use are described below.

In **pyrosequencing** (which employs instrumentation made by 454 Life Sciences, Inc. and hence is also known as **454 sequencing**), segments of the DNA to be sequenced are immobilized on the surfaces of microscopic plastic beads under dilution conditions such that no more than one DNA molecule is attached to a bead. The DNA on each bead is then replicated (amplified) many-fold by a variant of the process described in Section 3-5C, and the beads are deposited in wells in a fiber-optic slide that can hold only one bead per well. A primer and DNA polymerase are added, and then a dNTP is introduced. If DNA polymerase adds that nucleotide to the growing DNA strand, pyrophosphate (PP_i) is released and undergoes a chemical reaction sequence involving the firefly enzyme **luciferase**, which generates a flash of light. Solutions of each of the four dNTPs are successively washed across the immobilized DNA template, and a detector records whether light is produced in the presence of a particular dNTP. By multiply repeating this process, the sequence of nucleotides complementary to the template strand can be deduced. Pyrosequencing can accurately determine reads of up to 700 nucleotides, somewhat shorter than the reads determined by chain-terminator sequencing. Each fiber-optic slide contains numerous wells so that as many as ~ 1 million templates can be sequenced simultaneously. Consequently, the pyrosequencing system is ~ 1000 -fold faster than the most advanced chain-terminator sequencing systems.

In **Illumina sequencing** (using instrumentation produced by Illumina, Inc.), which is also a sequencing-by-synthesis method, numerous DNA segments are attached to a glass plate and amplified in place to form clusters of millions of identical DNA molecules. To determine their sequences, a solution containing the four dNTPs that are each linked to a different fluorescent group and chemically blocked at their 3' positions is flowed over the plate so that only a single nucleotide is added, by DNA polymerase, to each primer strand. The unreacted dNTPs are then washed away and the fluorescent groups that are linked to the primer strands are excited by a laser and identified according to their color of fluorescence by a digital camera (**Fig. 3-22**). The fluorescent and 3'-blocking groups are then chemically removed and the synthesis-and-identification cycle is repeated. The Illumina system can accurately determine reads of 30 to 300 nucleotides, significantly shorter than those of the chain-terminator and pyrosequencing methods, but it can determine up to 3 billion reads per run.

FIG. 3-22 Schematic diagram of six successive cycles from an Illumina DNA sequencing device. The different nucleotide derivatives (C, A, T, and G) each fluoresce with a different color. [Reprinted by permission from Macmillan Publishers Ltd: *Nature Reviews Genetics*, Vol. 11, No. 1, 31-46, Copyright (2009).]

Several other high-throughput DNA-sequencing technologies are in use or under development. Perhaps the most intriguing of these methods are those in which a single strand of DNA is electrophoretically driven through a nanopore (molecular-sized pore) in a membrane, and its sequence is divulged by the minute changes in the electrical properties of the pore as different bases pass through it. Such a single-molecule technique, if it could be made sufficiently reliable, would reveal the sequence of a DNA strand within seconds or minutes (rather than the hours or days required by the foregoing methods) and would have reads of unlimited length. Moreover, it would not require the DNA to be amplified before it is sequenced, it would eliminate the need for expensive enzymes and reagents, and its long reads would greatly reduce the computational effort required to assemble the reads into chromosomes.

Databases Store Nucleotide Sequences. The results of sequencing projects, large and small, are customarily deposited in online databases such as GenBank (see Bioinformatics Project 1). As of mid-2015, ~1.2 trillion nucleotides representing nearly 450 million sequences had been recorded, numbers that are doubling every ~18 months.

Nucleic acid sequencing has become so routine that directly determining a protein's amino acid sequence (Section 5-3) is far more time-consuming than determining the base sequence of its corresponding gene. In fact, nucleic acid sequencing is invaluable for studying genes whose products have not yet been identified. If the gene can be sequenced, the probable function of its protein product may be deduced by comparing the base sequence to those of genes whose products are already characterized (see Box 3-1).

Box 3-1 Pathways to Discovery

Francis Collins and the Gene for Cystic Fibrosis

Francis S. Collins (1950–) By the mid-twentieth century, the molecular bases of several human diseases were appreciated. For example, sickle-cell anemia (Section 7-1E) was known to be caused by an abnormal hemoglobin protein. Studies of sickle-cell hemoglobin eventually revealed the underlying genetic defect, a mutation in a hemoglobin gene. It therefore seemed possible to trace other diseases to defective genes. But for many genetic diseases, even those with well-characterized symptoms,

no defective protein had yet been identified. One such disease was cystic fibrosis, which is characterized mainly by the secretion of thick mucus that obstructs the airways and creates an ideal environment for bacterial growth. Cystic fibrosis is the most common inherited disease in individuals of northern European descent, striking about 1 in 2500 newborns and leading to death by early adulthood due to irreversible lung damage. It was believed that identifying the molecular defect in cystic fibrosis would lead to better understanding of the disease and to the ability to design more effective treatments.

Enter Francis Collins, who began his career by earning a doctorate in physical chemistry but then enrolled in medical school to take part in the molecular biology revolution. As a physician-scientist, Collins developed methods for analyzing large stretches of DNA in order to home in on specific genes, including the one that, when mutated, causes cystic fibrosis. By analyzing the DNA of individuals with the disease (who had two copies of the defective gene) and of family members who were asymptomatic carriers (with one normal and one defective copy of the gene), Collins and his team localized the cystic fibrosis gene to the

long arm of chromosome 7. They gradually closed in on a DNA segment that appears to be present in a number of mammalian species, which suggests that the segment contains an essential gene. The cystic fibrosis gene was finally identified in 1989. Collins had demonstrated the feasibility of identifying a genetic defect in the absence of other molecular information.

Once the cystic fibrosis gene was in hand, it was a relatively straightforward process to deduce the probable structure and function of the encoded protein, which turned out to be a membrane channel for chloride ions. When functioning normally, the protein helps regulate the ionic composition and viscosity of extracellular secretions. Discovery of the cystic fibrosis gene also made it possible to design tests to identify carriers so that they could take advantage of genetic counseling.

Throughout Collins' work on the cystic fibrosis gene and during subsequent hunts for the genes that cause neurofibromatosis and Huntington's disease, he was mindful of the ethical implications of the new science of molecular genetics. Collins has been a strong advocate for protecting the privacy of genetic information. At the same time, he recognizes the potential therapeutic use of such information. In his tenure as director of the human genome project, he was committed to making the results freely and immediately accessible, as a service to researchers and the individuals who might benefit from new therapies based on molecular genetics. He is presently the Director of the National Institutes of Health (NIH).

E Entire Genomes Have Been Sequenced

The advent of large-scale sequencing techniques brought to fruition the dream of sequencing entire genomes. However, the major technical hurdle in sequencing all the DNA in an organism's genome is not the DNA sequencing itself but, rather, assembling the tens of thousands to tens of millions of reads into their correct order in a chromosome. To do so required the development of automated sequencing protocols and mathematically sophisticated computer algorithms.

The first complete genome sequence to be determined, that of the bacterium *Haemophilus influenzae*, was reported in 1995 by Craig Venter. By mid-2015, the complete genome sequences of over 33,000 prokaryotes had been reported (with many more being determined) as well as those of over 2200 eukaryotes, including humans, animals, plants, fungi, human pathogens, and laboratory organisms (Table 3-3). The genomes of several extinct organisms have even been sequenced, including those of Neanderthals, our closest relative, and the woolly mammoth.

In **metagenomic sequencing**, the DNA sequences of multiple organisms are analyzed as a single dataset. This approach is used to characterize complex interdependent microbial communities, such as those in marine environments, soils, and the digestive tracts of animals. Many of the species in these communities

TABLE 3-3 Some Sequenced Genomes

Organism	Genome Size (kb)	Number of Chromosomes
<i>Mycoplasma genitalium</i> (human parasite)	580	1
<i>Rickettsia prowazekii</i> (putative relative of mitochondria)	1,112	1
<i>Haemophilus influenzae</i> (human pathogen)	1,830	1
<i>Escherichia coli</i> (human symbiont)	4,639	1
<i>Saccharomyces cerevisiae</i> (baker's yeast)	12,070	16
<i>Plasmodium falciparum</i> (protozoan that causes malaria)	23,000	14
<i>Caenorhabditis elegans</i> (nematode)	97,000	6
<i>Arabidopsis thaliana</i> (dicotyledonous plant)	119,200	5
<i>Drosophila melanogaster</i> (fruit fly)	180,000	4
<i>Oryza sativa</i> (rice)	389,000	12
<i>Danio rerio</i> (zebra fish)	1,700,000	25
<i>Gallus gallus</i> (chicken)	1,200,000	40
<i>Mus musculus</i> (mouse)	2,500,000	20
<i>Homo sapiens</i>	3,038,000	23

? What is the relationship, if any, between genome size and chromosome number?

cannot be individually cultured and sequenced (it is estimated that only ~1% of existing microorganisms have been cultured in the laboratory). Metagenomic sequence data reveal the overall gene number and an estimate of the collective metabolic capabilities of the community. For example, over 3 million genes have been identified in metagenomic analyses of the microorganisms that inhabit the human gut, representing up to 1000 bacterial species. This so-called **microbiome**, which typically consists of ~100 trillion cells (far more cells than comprise the human body), aids in digestion in that it breaks down certain carbohydrates that humans cannot otherwise digest, supplies certain vitamins, and promotes immune system development. While most humans share a common core set of about 60 gut microorganisms, significant differences appear to correlate with metabolic variables such as body mass. Atypical gut microbiomes are also associated with certain diseases such as **inflammatory bowel diseases**.

The Human Genome Contains Relatively Few Genes. The determination of the 3-billion-nucleotide human genome sequence was a gargantuan undertaking involving hundreds of scientists working in two groups, one led by Venter and the other by Francis Collins (Box 3-1), Eric Lander, and John Sulston, and costing \$300 million. After 13 years of intense effort, the “rough draft” of the human genome sequence was reported in early 2001 and the “finished” sequence, covering ~99% of the genome, was reported in 2004. This stunning achievement is revolutionizing the way both biochemistry and medicine are viewed and practiced, although it is likely to require many years of further effort before its full significance is understood. Nevertheless, numerous important conclusions can already be drawn, including these:

1. About half the human genome consists of repeating sequences of various types.
2. At least 80% of the genome is transcribed to RNA.
3. Only ~1.2% of the genome encodes protein.
4. The human genome appears to contain only ~21,000 protein-encoding genes [also known as **open reading frames (ORFs)**] rather than the 35,000 to 140,000 ORFs that had previously been predicted. This compares with the ~6000 ORFs in yeast, ~13,000 in *Drosophila*, ~19,000 in *C. elegans*, and ~26,000 in *Arabidopsis* (although these numbers will almost certainly change as our ability to recognize ORFs improves).
5. Only a small fraction of human proteins are unique to vertebrates; most occur in other if not all life-forms.
6. Two randomly selected human genomes differ, on average, by only 1 nucleotide per 1000; that is, any two people are likely to be ~99.9% genetically identical.

The obviously greater complexity of humans (vertebrates) relative to invertebrate forms of life is unlikely to be due to the not-much-larger numbers of ORFs that vertebrates encode. Rather, it appears that vertebrate proteins themselves are more complex than those of invertebrates; that is, vertebrate proteins tend to have more domains (modules) than invertebrate proteins, and these modules are more often selectively expressed through **alternative gene splicing** (a phenomenon in which a given gene transcript can be processed in multiple ways to yield different proteins when translated; Section 26-3B). In fact, most vertebrate genes encode several different although similar proteins.

F Evolution Results from Sequence Mutations

One of the richest rewards of nucleic acid sequencing technology is the information it provides about the mechanisms of evolution. The chemical and physical properties of DNA, such as its regular three-dimensional shape and the elegant process of replication, may leave the impression that genetic information is

relatively static. In fact, *DNA is a dynamic molecule, subject to changes that alter genetic information*. For example, the mispairing of bases during DNA replication can introduce single-nucleotide errors known as **point mutations** in the daughter strand. Mutations also result from DNA damage by chemicals or radiation. More extensive alterations in genetic information are caused by faulty **recombination** (exchange of DNA between chromosomes) and the **transposition** of genes within or between chromosomes and, in some cases, from one organism to another. All these alterations to DNA provide the raw material for natural selection. When a mutated gene is transcribed and the messenger RNA is subsequently translated, the resulting protein may have properties that confer some advantage to the individual. As a beneficial change is passed from generation to generation, it may become part of the standard genetic makeup of the species. Of course, many changes occur as a species evolves, not all of them simple and not all of them gradual.

Phylogenetic relationships can be revealed by comparing the sequences of similar genes in different organisms. The number of nucleotide differences between the corresponding genes in two species roughly indicates the degree to which the species have diverged through evolution. The regrouping of prokaryotes into archaea and bacteria (Section 1-2C) according to rRNA sequences present in all organisms illustrates the impact of sequence analysis.

Nucleic acid sequencing also reveals that species differing in **phenotype** (physical characteristics) are nonetheless remarkably similar at the molecular level. For example, humans and chimpanzees share nearly 99% of their DNA. Studies of corn (maize) and its putative ancestor, teosinte, suggest that the plants differ in only a handful of genes governing kernel development (teosinte kernels are encased by an inedible shell; **Fig. 3-23**).

Small mutations in DNA are apparently responsible for relatively large evolutionary leaps. This is perhaps not so surprising when the nature of genetic information is considered. A mutation in a gene segment that does not encode protein might interfere with the binding of cellular factors that influence the timing of transcription. A mutation in a gene encoding an RNA might interfere with the binding of factors that affect the efficiency of translation. Even a minor rearrangement of genes could disrupt an entire developmental process, resulting in the appearance of a novel species. Notwithstanding the high probability that most sudden changes would lead to diminished individual fitness or the inability to reproduce, the capacity for sudden changes in genetic information is consistent with the fossil record. Ironically, the discontinuities in the fossil record that are probably caused in part by sudden genetic changes once fueled the adversaries of Charles Darwin's theory of evolution by natural selection.

FIG. 3-23 Maize and teosinte. Despite the large differences in phenotype—maize (*bottom*) has hundreds of easily chewed kernels, whereas teosinte (*top*) has only a few hard, inedible kernels—the plants differ in only a few genes. The ancestor of maize is believed to be a mutant form of teosinte in which the kernels were more exposed. [(*top*) Courtesy John Doebley, University of Wisconsin; (*bottom*) Marek Mnich/Stockphoto.]

Sequence Variations Can Be Linked to Human Diseases. Over 5000 mutations have been linked to various human diseases, yet monogenetic diseases, such as cystic fibrosis (see Box 3-1), are relatively rare. Most diseases result from interactions among multiple genes and from environmental factors. Nevertheless, advances in genomics are clearly leading to a better understanding of how genetic information impacts human health and susceptibility to illness. Two areas of notable success are the screening of newborn infants for treatable genetic diseases and the identification of adults who are carriers for a recessive genetic disorder; that is, they have a normal phenotype but bear one copy of the defective gene, which may be passed to their children. Clinical tests are available to detect several hundred such single-gene defects (**Table 3-4**). Preliminary results suggest that as more parents become aware of their carrier status, fewer children with the disease are being born.

Next-generation sequencing technologies have made it possible to sequence a complete human genome in a few days at a cost of about \$1000, quantities that are expected to be significantly reduced over the next few years. However, the 50- to 300-nucleotide reads generated by the Illumina sequencing system are too short to confidently assemble them into large chromosomes. Rather, by comparing these relatively short reads to a human genome of known sequence, a process called **resequencing**, sequence differences between the chromosomes of different individuals are readily determined. This has permitted the complete sequencing, by mid-2015, of tens of thousands of human genomes, a number that is increasing rapidly.

Most of the differences among the various human genomes are due to **single-nucleotide polymorphisms (SNPs)**, pronounced “snips”; instances where the DNA sequence differs among individuals at one nucleotide position). However, insertions and deletions of single nucleotides and tracts of DNA also occur. Around 10 million SNPs have been cataloged.

From studies involving tissue samples from thousands of subjects with and without certain complex diseases, such as cancers and type 2 diabetes, researchers have identified numerous SNPs that are associated with increased risk for these conditions. An ongoing challenge for this work is that each genetic variant associated with a disease typically increases risk for the disease by only a few percent, so an individual’s likelihood of developing a particular disease appears to be a complicated function of which variants are present. Moreover, only a small fraction (estimated to be 5–20%) of disease risk factors have been identified. Hence, although several commercial enterprises offer partial genome-sequencing services to individuals, until genetic information can be reliably translated into effective disease-prevention or treatment regimens, the practical value of “personal genomics” is quite limited.

TABLE 3-4 Some Genetic Diseases with Carrier Screening Tests

Disease	Symptoms
Ataxia telangiectasia	Loss of motor control, immunodeficiency, increased risk of cancer
Beta thalassemia	Severe anemia, slow growth
Galactosemia	Mental disability, organ damage
Niemann–Pick disease	Loss of intellectual and motor skills, accumulation of lipid
Tay–Sachs disease	Loss of intellectual and motor skills, death by age 3
Usher syndrome	Deafness and progressive loss of vision
Breast, ovarian, and prostate cancers	Uncontrolled proliferation of cancer cells

CHECKPOINT

- Explain how restriction enzymes generate either sticky ends or blunt ends.
- Why do the smallest fragments of DNA move the farthest during electrophoresis?
- List all the components and explain their purpose in the reaction mixture used for the dideoxy DNA sequencing method.
- Describe the methodology behind next-generation sequencing techniques.
- Summarize what is known about the size and gene content of the human genome.
- Explain how evolution results from mutations in DNA.

In addition to greatly expanding our knowledge of human biology and disease processes, comparisons of multiple human genome sequences have provided unprecedented insights as to how humans evolved and their patterns of migration. For example, Neanderthals (also called Neandertals) were a subspecies of hominid living in Europe and the Middle East that became extinct around 40,000 years ago. DNA fragments recovered from Neanderthal bones permitted Svante Pääbo to determine their genome sequence. This revealed that the genomes of present-day Europeans and Asians, but not Africans, are 1–4% Neanderthal in content, which is genetically equivalent to having roughly one Neanderthal great-great-great-grandparent. Apparently, modern humans migrated out of Africa through the Middle East on the way to populating the rest of the world (fossil evidence indicates that Neanderthals occupied Europe and the Middle East at least 230,000 years ago, whereas modern humans migrated out of Africa around 100,000 years ago). In 2010, the genomic analysis of a 41,000-year-old finger bone found in the Denisova Cave in Siberia revealed the existence of a second extinct hominid subspecies, named Denisovans. They also interbred with modern humans—although, curiously, only with the ancestors of populations presently occupying Island Southeast Asia and Oceania.

5 Manipulating DNA

KEY CONCEPTS

- Segments of DNA can be cloned, or reproduced, in a host organism.
- A DNA library is a collection of cloned DNA segments that can be screened to find a particular gene.
- The polymerase chain reaction amplifies a DNA segment by repeatedly synthesizing complementary strands.
- Recombinant DNA technology can be used to manipulate genes for protein expression or for the production of transgenic organisms.

Along with nucleic acid sequencing, techniques for manipulating DNA *in vitro* and *in vivo* (in the test tube and in living systems) have produced dramatic advances in biochemistry, cell biology, and genetics. In many cases, this **recombinant DNA technology** has made it possible to purify specific DNA sequences and to prepare them in quantities sufficient for study. Consider the problem of isolating a unique 1000-bp length of chromosomal DNA from *E. coli*. A 10-L culture of cells grown at a density of $\sim 10^{10}$ cells \cdot mL⁻¹ contains only ~ 0.1 mg of the desired DNA, which would be all but impossible to separate from the rest of the DNA using classical separation techniques (Sections 5-2 and 24-3). *Recombinant DNA technology, also called molecular cloning or genetic engineering, makes it possible to isolate, amplify, and modify specific DNA sequences.*

A Cloned DNA Is an Amplified Copy

The following approach is used to obtain and amplify a segment of DNA:

1. A fragment of DNA of the appropriate size is generated by a restriction enzyme, by PCR (Section 3-5C), or by chemical synthesis.
2. The fragment is incorporated into another DNA molecule known as a **vector**, which contains the sequences necessary to direct DNA replication.
3. The vector—with the DNA of interest—is introduced into cells, in which it is replicated.
4. Cells containing the desired DNA are identified, or selected.

Cloning refers to the production of multiple identical organisms derived from a single ancestor. The term **clone** refers to the collection of cells that contain the

FIG. 3-24 The plasmid pUC18. As shown in this diagram, the circular plasmid contains multiple restriction sites, including a **polylinker** sequence that contains 13 restriction sites that are not present elsewhere on the plasmid. The three genes expressed by the plasmid are *amp^R*, which confers resistance to the antibiotic **ampicillin**; *lacZ*, which encodes the enzyme **β -galactosidase**; and *lacI*, which encodes a factor that controls the transcription of *lacZ* (as described in Section 28-2A).

? Which restriction enzymes could you use to insert a gene without affecting the host cell's resistance to ampicillin?

vector carrying the DNA of interest or to the DNA itself. In a suitable host organism, such as *E. coli* or yeast, large amounts of the inserted DNA can be produced.

Cloned DNA can be purified and sequenced (Section 3-4). Alternatively, if a cloned gene is flanked by the properly positioned regulatory sequences for RNA and protein synthesis, the host may also produce large quantities of the RNA and protein specified by that gene. Thus, cloning provides materials (nucleic acids and proteins) for other studies and also provides a means for studying gene expression under controlled conditions.

Cloning Vectors Carry Foreign DNA. A variety of small, autonomously replicating DNA molecules are used as cloning vectors. **Plasmids** are circular DNA molecules of 1 to 200 kb found in bacteria or yeast cells. Plasmids can be considered molecular parasites, but in many instances they benefit their host by providing functions, such as resistance to antibiotics, that the host lacks.

Some types of plasmids are present in one or a few copies per cell and replicate only when the bacterial chromosome replicates. However, the plasmids used for cloning are typically present in hundreds of copies per cell and can be induced to replicate until the cell contains two or three thousand copies (representing about half of the cell's total DNA). The plasmids that have been constructed for laboratory use are relatively small, replicate easily, carry genes specifying resistance to one or more antibiotics, and contain a number of conveniently located restriction endonuclease sites into which foreign DNA can be inserted. Plasmid vectors can be used to clone DNA segments of no more than ~ 10 kb. The *E. coli* plasmid designated **pUC18** (Fig. 3-24) is a representative cloning vector ("pUC" stands for plasmid-Universal Cloning).

Bacteriophage λ (Fig. 3-25) is an alternative cloning vector that can accommodate DNA inserts up to 16 kb. The central third of the 48.5-kb phage genome is not required for infection and can therefore be replaced by foreign DNAs of similar size. The resulting **recombinant**, or **chimera** (named after the mythological monster with a lion's head, goat's body, and serpent's tail), is packaged into phage particles that can then be introduced into the host cells. One advantage of using phage vectors is that the recombinant DNA is produced in large amounts in easily purified form. **Baculoviruses**, which infect insect cells, are similarly used for cloning in cultures of insect cells.

Much larger DNA segments—up to several hundred kilobase pairs—can be cloned in large vectors known as **bacterial artificial chromosomes (BACs)** or **yeast artificial chromosomes (YACs)**. YACs are linear DNA molecules that contain all the chromosomal structures required for normal replication and segregation during yeast cell division. BACs, which replicate in *E. coli*, are derived from circular plasmids that normally replicate long regions of DNA and are maintained at the level of approximately one copy per cell (properties similar to those of actual chromosomes).

FIG. 3-25 Bacteriophage λ . During phage infection, DNA contained in the "head" of the phage particle enters the bacterial cell, where it is replicated ~ 100 times and packaged to form progeny phage.

Courtesy of Michael Wurtz/University of Basel, Switzerland/Science Source Images

Ligase Joins Two DNA Segments. A DNA segment to be cloned is often obtained through the action of restriction endonucleases. Most restriction enzymes cleave DNA to yield sticky ends (Section 3-4A). Therefore, as Janet Mertz and Ron Davis first demonstrated in 1972, *a restriction fragment can be inserted into a cut made in a cloning vector by the same restriction enzyme* (Fig. 3-26). The complementary ends of the two DNAs form base pairs (**anneal**) and the sugar-phosphate backbones are covalently **ligated**, or spliced together, through the action of an enzyme named **DNA ligase**. (A ligase produced by a bacteriophage can also join blunt-ended restriction fragments.) A great advantage of using a restriction enzyme to construct a recombinant DNA molecule is that the DNA insert can later be precisely excised from the cloned vector by cleaving it with the same restriction enzyme.

Selection Detects the Presence of a Cloned DNA. The expression of a chimeric plasmid in a bacterial host was first demonstrated in 1973 by Herbert Boyer and Stanley Cohen. A host bacterium can take up a plasmid when the two are mixed together, but the vector becomes permanently established in its bacterial host (transformation) with an efficiency of only ~0.1%. However, a single transformed cell can multiply without limit, producing large quantities of recombinant DNA. Bacterial cells are typically plated on a semisolid growth medium at a low enough density that discrete colonies, each arising from a single cell, are visible.

It is essential to select only those host organisms that have been transformed and that contain a properly constructed vector. In the case of plasmid transformation, selection can be accomplished through the use of antibiotics and/or chromogenic (color-producing) substances. For example, the *lacZ* gene in the pUC18 plasmid (see Fig. 3-24) encodes the enzyme β -galactosidase, which cleaves the colorless compound **X-gal** to a blue product:

Cells of *E. coli* that have been transformed by an unmodified pUC18 plasmid form blue colonies. However, if the plasmid contains a foreign DNA insert in its polylinker region, the colonies are colorless because the insert interrupts the protein-coding sequence of the *lacZ* gene and no functional β -galactosidase is produced. Bacteria that have failed to take up any plasmid are also colorless due to the absence of β -galactosidase, but these cells can be excluded by adding the

PROCESS DIAGRAM

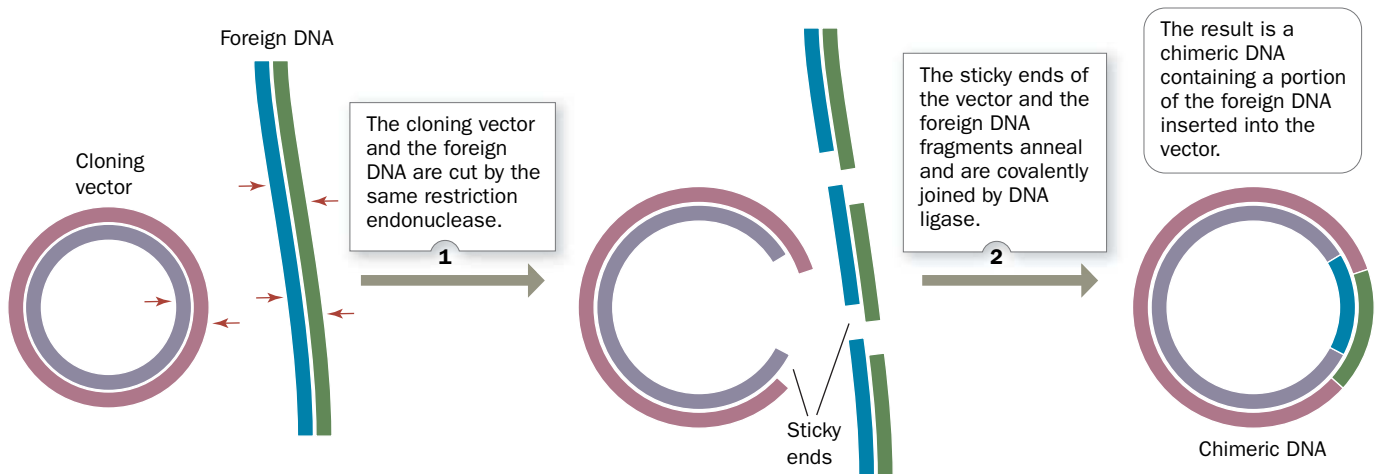

FIG. 3-26 Construction of a recombinant DNA molecule. **WPLS** See the Animated Process Diagrams.

? Would this method work if you used a restriction enzyme that produced blunt-ended DNA fragments?

antibiotic ampicillin to the growth medium (the plasmid includes the gene *amp^R*, which confers ampicillin resistance). Thus, successfully transformed cells form colorless colonies in the presence of ampicillin. Genes such as *amp^R* are known as **selectable markers**.

Genetically engineered bacteriophage λ vectors contain restriction sites that flank the dispensable central third of the phage genome. This segment can be replaced by foreign DNA, but the chimeric DNA is packaged in phage particles only if its length is from 75 to 105% of the 48.5-kb wild-type λ genome (Fig. 3-27). Consequently, λ phage vectors that have failed to acquire a foreign DNA insert are unable to propagate because they are too short to form infectious phage particles.

PROCESS DIAGRAM

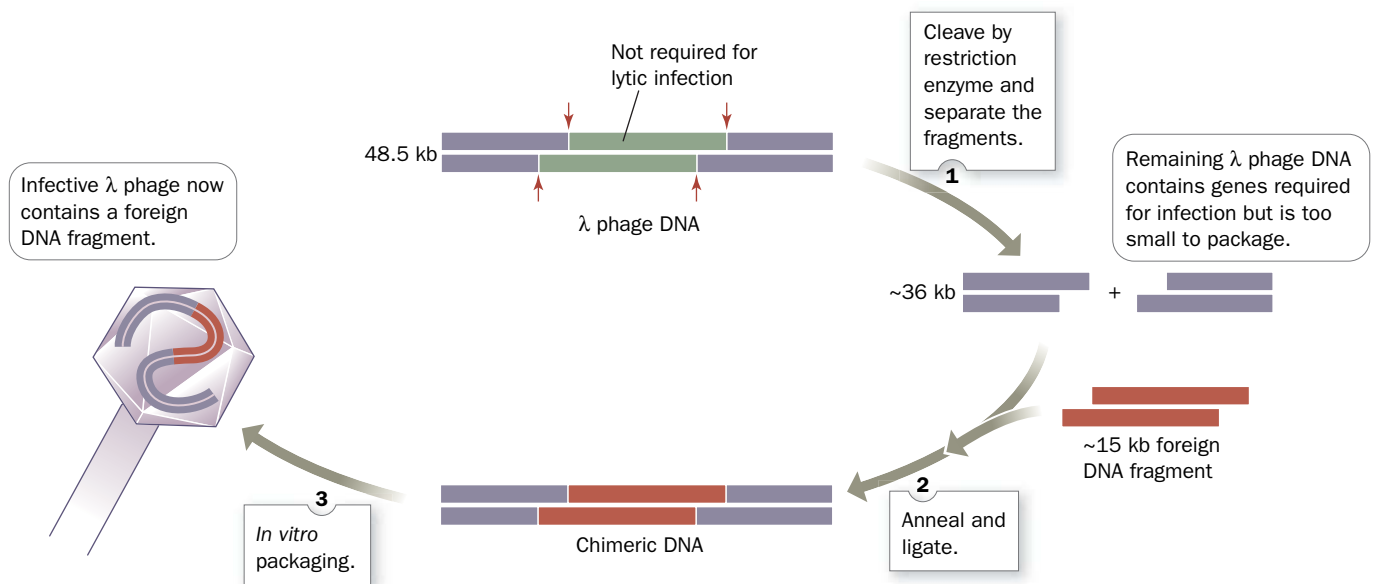

FIG. 3-27 Cloning with bacteriophage λ . Removal of a nonessential portion of the phage genome allows a segment of foreign DNA to be inserted. The DNA insert can be packaged into an infectious phage particle only if the insert DNA has the appropriate size. **WPLS** See the Animated Process Diagrams.

Of course, the production of infectious phage particles results not in a growing bacterial colony but in a **plaque**, a region of lysed bacterial cells, on a culture plate containing a “lawn” of the host bacteria. The recombinant DNA—now much amplified—can be recovered from the phage particles in the plaque.

B DNA Libraries Are Collections of Cloned DNA

To clone a particular DNA fragment, it must first be obtained in relatively pure form. The magnitude of this task can be appreciated by considering that, for example, a 1-kb fragment of human DNA represents only 0.00003% of the 3 billion-bp human genome. Of course, identifying a particular DNA fragment requires knowing something about its nucleotide sequence or its protein product. In practice, it is usually more difficult to identify a particular DNA fragment from an organism and then clone it than it is to clone all the organism’s DNA that might contain the DNA of interest and then identify the clones containing the desired sequence.

A Genomic Library Includes All of an Organism’s DNA. The cloned set of all DNA fragments from a particular organism is known as its **genomic library**. Genomic libraries are generated by a procedure known as **shotgun cloning**. The chromosomal DNA of the organism is isolated, cleaved to fragments of cloneable size, and inserted into a cloning vector. The DNA is usually fragmented by partial rather than exhaustive restriction digestion so that the genomic library contains intact representatives of all the organism’s genes, including those that contain restriction sites. DNA in solution can also be sheared into randomly-sized fragments by sonication (Section 3-4C).

Given the large size of a genome relative to a gene, the shotgun cloning method is subject to the laws of probability. The number of randomly generated fragments that must be cloned to ensure a high probability that a desired sequence is represented at least once in the genomic library is calculated as follows: The probability P that a set of N clones contains a fragment that constitutes a fraction f , in bp, of the organism’s genome is

$$P = 1 - (1 - f)^N \quad [3-1]$$

Consequently,

$$N = \log(1 - P)/\log(1 - f) \quad [3-2]$$

Thus, for P to equal 0.99 for fragments averaging 10 kb in length, $N = 2116$ for the 4600-kb *E. coli* chromosome (see Sample Calculation 3-1). The use of BAC- or YAC-based genomic libraries with their large fragment lengths therefore greatly reduces the effort necessary to obtain a given gene segment from a large genome. After a BAC- or YAC-based clone containing the desired DNA has been identified (see below), its large DNA insert can be further fragmented and cloned again (**subcloned**) to isolate the target DNA.

A cDNA Library Represents Expressed Sequences. A different type of DNA library contains only the expressed sequences from a particular cell type. Such a **cDNA library** is constructed by isolating all the cell’s mRNAs and then copying them to DNA using a specialized type of DNA polymerase known as **reverse transcriptase** because it synthesizes DNA using RNA templates (Box 25-2). The **complementary DNA (cDNA)** molecules are then inserted into cloning vectors to form a cDNA library. A cDNA library can also be used to construct a **DNA microarray (DNA chip)**, in which each different cDNA is immobilized at a specific position on a slide. A DNA chip can be used for detecting the presence of mRNA in a biological sample (the mRNA, if present, will bind to its complementary cDNA; Section 14-4C). The DNA corresponding to a complete set of a cell’s mRNAs is known as its **exome** (as opposed to its **transcriptome**, which corresponds to all of a cell’s RNAs). The human exome represents only ~1% of its genome (~30,000 kb), but harbors ~85% of its disease-causing mutations.

SAMPLE CALCULATION 3-1

How many clones must be obtained from *Drosophila* to be 99% sure that they include a particular 10-kb fragment?

Use Equation 3-2 and the size of the *Drosophila* genome given in Table 3-3. Here, $f = 10 \text{ kb}/180,000 \text{ kb} = 5.56 \times 10^{-5}$.

$$\begin{aligned} N &= \log(1 - P)/\log(1 - f) \\ &= \log(1 - 0.99)/\log(1 - 5.56 \times 10^{-5}) \\ &= -2/(-2.413 \times 10^{-5}) \\ &= 83,000 \end{aligned}$$

WPLS See Sample Calculation Videos.

FIG. 3-28 Colony (*in situ*) hybridization. Colonies are transferred from a “master” culture plate by replica plating. Clones containing the DNA of interest are identified by the ability to bind a specific probe. Here, binding is detected by laying X-ray film over the dried filter. Since the colonies on the master plate and on the filter have the same spatial distribution, positive colonies are easily retrieved. **WPLS** See the Animated Process Diagrams.

Consequently, several hundred thousand human exomes have been sequenced, mainly in efforts to characterize genetic diseases.

A Library Is Screened for the Gene of Interest. Once the requisite number of clones is obtained, the genomic library must be **screened** for the presence of the desired gene. This can be done by a process known as **colony** or ***in situ* hybridization** (Latin: *in situ*, in position; Fig. 3-28). The cloned yeast colonies, bacterial colonies, or phage plaques to be tested are transferred, by replica plating, from a master plate to a nitrocellulose filter (replica plating is also used to transfer colonies to plates containing different growth media). Next, the filter is treated with NaOH, which lyses the cells or phages and separates the DNA into single strands, which preferentially bind to the nitrocellulose. The filter is then dried to fix the DNA in place and incubated with a labeled **probe**. The probe is a short segment of DNA or RNA whose sequence is complementary to a portion of the DNA of interest. After washing away unbound probe, the presence of the probe on the nitrocellulose is detected by a technique appropriate for the label used (e.g., exposure to X-ray film for a radioactive probe, a process known as **autoradiography**, or illumination with an appropriate wavelength for a fluorescent probe). Only colonies or plaques containing the desired gene bind the probe and are thereby detected. The corresponding clones can then be retrieved from the master plate. Using this technique, a human genomic library of ~1 million clones can be readily screened for the presence of one particular DNA segment.

Choosing a probe for a gene whose sequence is not known requires some artistry. The corresponding mRNA can be used as a probe if it is available in sufficient quantities to be isolated. Alternatively, if the amino acid sequence of the protein encoded by the gene is known, the probe may be a mixture of the various synthetic oligonucleotides that are complementary to a segment of the gene’s inferred base sequence. Several disease-related genes have been isolated using probes specific for nearby markers, such as repeated DNA sequences, that were already known to be genetically linked to the disease genes.

C DNA Is Amplified by the Polymerase Chain Reaction

Although molecular cloning techniques are indispensable to modern biochemical research, the **polymerase chain reaction (PCR)** is often a faster and more convenient method for amplifying a specific DNA. Segments of up to 6 kb can be amplified by this technique, which was devised by Kary Mullis in 1985. *In PCR*, a DNA sample is separated into single strands and incubated with DNA polymerase, dNTPs, and two oligonucleotide primers whose sequences flank the DNA segment of interest. The primers direct the DNA polymerase to synthesize complementary strands of the target DNA (Fig. 3-29). Multiple cycles of this process, each doubling the amount of the target DNA, geometrically amplify the DNA starting from as little as a single gene copy. In each cycle, the two strands of the duplex DNA are separated by heating, then the reaction mixture is cooled to allow the primers to anneal to their complementary segments on the DNA. Next, the DNA polymerase directs the synthesis of the complementary strands. The use of a heat-stable DNA polymerase, such as **Taq polymerase** isolated from *Thermus aquaticus*, a bacterium that thrives at 75°C, eliminates the need to add fresh enzyme after each round of heating (heat inactivates most enzymes). Hence, in the presence of sufficient quantities of primers and dNTPs, PCR is carried out simply by cyclically varying the temperature.

PROCESS DIAGRAM

PROCESS DIAGRAM

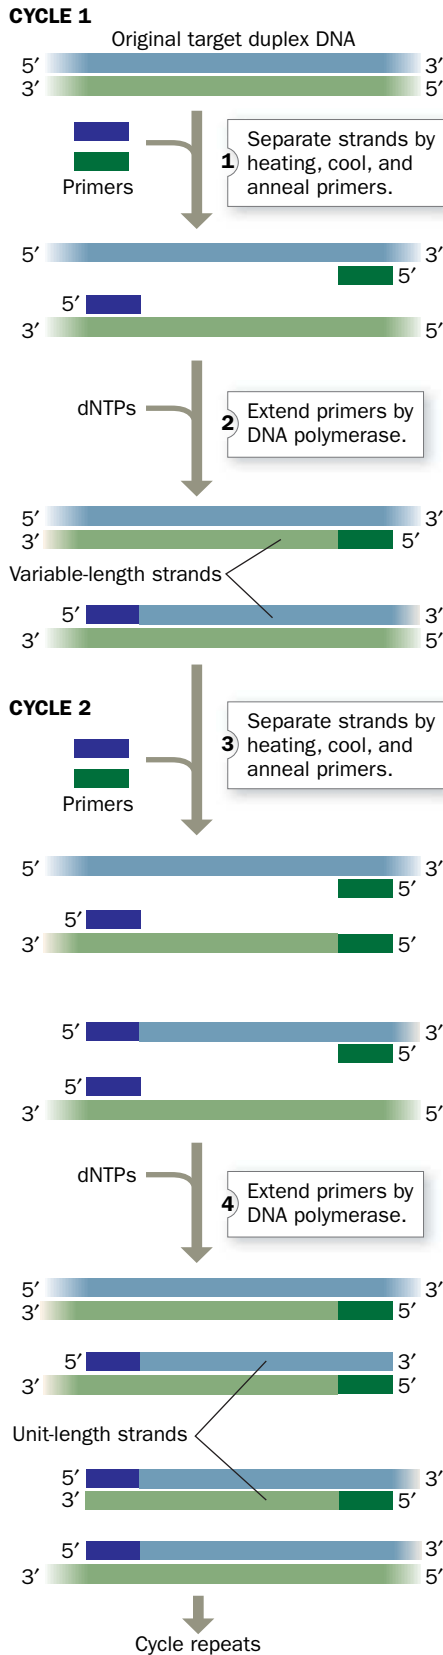

FIG. 3-29 The polymerase chain reaction (PCR). The number of “unit-length” strands doubles with every cycle after the second cycle. By choosing primers specific for each end of a gene, the gene can be amplified over a millionfold. **WPLS** See the Animated Process Diagrams.

? Why is a heat-stable polymerase used for PCR?

WileyPLUS Learning Space

See Guided Exploration

PCR and site-directed mutagenesis

Twenty cycles of PCR increase the amount of the target sequence around a millionfold ($\sim 2^{20}$) with high specificity. Indeed, PCR can amplify a target DNA present only once in a sample of 10^5 cells, so this method can be used without prior DNA purification. The amplified DNA can then be sequenced or cloned.

PCR amplification has become an indispensable tool. Clinically, it is used to diagnose infectious diseases and to detect rare pathological events such as mutations leading to cancer. Forensically, the DNA from a single hair or sperm can be amplified by PCR so it can be used to identify the donor (Box 3-2). Traditional ABO blood-type analysis requires a coin-sized drop of blood; PCR is effective on pinhead-sized samples of biological fluids. Courts now consider DNA sequences as unambiguous identifiers of individuals, as are fingerprints, because the chance of two individuals sharing extended sequences of DNA is typically one in a million or more. In a few cases, PCR has dramatically restored justice to convicts who were released from prison on the basis of PCR results that proved their innocence—even many years after the crime-scene evidence had been collected.

D Recombinant DNA Technology Has Numerous Practical Applications

The ability to manipulate DNA sequences allows genes to be altered and expressed to obtain proteins with improved functional properties or to correct genetic defects.

Cloned Genes Can Be Expressed. The production of large quantities of scarce or novel proteins is relatively straightforward only for bacterial proteins: A cloned gene must be inserted into an **expression vector**, a plasmid that contains properly positioned transcriptional and translational control sequences. The production of a protein of interest may reach 30% of the host’s total cellular protein. Such genetically engineered organisms are called **overproducers**. Bacterial cells often sequester large amounts of useless and possibly toxic (to the bacterium) protein as insoluble inclusions, which sometimes simplifies the task of purifying the protein.

Bacteria can produce eukaryotic proteins only if the recombinant DNA that carries the protein-coding sequence also includes bacterial transcriptional and translational control sequences. Synthesis of eukaryotic proteins in bacteria also presents other problems. For example, many eukaryotic genes are large and contain stretches of nucleotides (**introns**) that are transcribed and excised before translation (Section 26-3A); bacteria lack the machinery to excise the introns. In addition, many eukaryotic proteins are posttranslationally modified by the addition of carbohydrates or by other reactions. These problems can be overcome by using expression vectors that propagate in eukaryotic hosts, such as yeast or cultured insect or animal cells.

Table 3-5 lists some recombinant proteins produced for medical and agricultural use. In many cases, purification of these proteins directly from human or

Box 3-2 Perspectives in Biochemistry DNA Fingerprinting

Forensic DNA testing takes advantage of DNA sequence variations or **polymorphisms** that occur among individuals. Many genetic polymorphisms have no functional consequences because they occur in regions of the DNA that contain many repetitions but do not encode genes (although if they are located near a “disease” gene, they can be used to track and identify the gene). Modern **DNA fingerprinting** methods examine these noncoding repetitive DNA sequences in samples that have been amplified by PCR.

Tandemly repeated DNA sequences occur throughout the human genome and include **short tandem repeats (STRs)**, which contain variable numbers of repeating segments of two to seven base pairs. The most popular STR sites for forensic use contain tetranucleotide repeats. The number of repeats at any one site on the DNA varies between individuals, even within a family. Each different number of repeats at a site is called an **allele**, and each individual can have two alleles, one from each parent (see figure above).

Since PCR is the first step of the fingerprinting process, only a tiny amount (~1 ng) of DNA is needed. The region of DNA containing the STR is amplified by PCR using primers that are complementary to the unique (nonrepeating) sequences flanking the repeats.

The amplified products are separated by electrophoresis and detected by the fluorescent tag on their primers. An STR allele is small enough (~500 bp) that DNA fragments differing by a four-base repeat can be readily differentiated. The allele designation for each STR site is generally the number of times a repeated unit is present. STR sites that have been selected for forensic use generally have 7 to 30 different alleles.

In the example shown at right, the upper trace shows the fluorescence of the electrophoretogram of reference standards (the set of all possible alleles, each identified by the number of repeat units, from 13 to 23). The lower trace corresponds to the sample being tested, which contains two alleles, one with 16 repeats and one with 18 repeats. Several STR sites can be analyzed simultaneously by using the appropriate primers and tagging them with different fluorescent dyes.

The probability of two individuals having matching DNA fingerprints depends on the number of STR sites examined and the number of alleles at each site. For example, if a pair of alleles at one site

occurs in the population with a frequency of 10% (1/10), and a pair of alleles at a second site occurs with a frequency of 5% (1/20), then the probability that the DNA fingerprints from two individuals would match at both sites is 1 in 200 (1/10 × 1/20; the probabilities of independent events are multiplied). By examining multiple STR sites, the probability of obtaining matching fingerprints by chance becomes exceedingly small.

animal tissues is unfeasible on ethical or practical grounds. Expression systems permit large-scale, efficient preparation of the proteins while minimizing the risk of contamination by viruses or other pathogens from tissue samples.

Site-Directed Mutagenesis Alters a Gene's Nucleotide Sequence. After isolating a gene, it is possible to modify the nucleotide sequence to alter the amino acid sequence of the encoded protein. **Site-directed mutagenesis**, a technique pioneered by Michael Smith, *mimics the natural process*

TABLE 3-5 Some Proteins Produced by Genetic Engineering

Protein	Use
Human insulin	Treatment of diabetes
Human growth hormone	Treatment of some endocrine disorders
Erythropoietin	Stimulation of red blood cell production
Colony-stimulating factors	Production and activation of white blood cells
Coagulation factors IX and X	Treatment of blood-clotting disorders (hemophilia)
Tissue-type plasminogen activator	Lysis of blood clots after heart attack and stroke
Bovine growth hormone	Production of milk in cows
Hepatitis B surface antigen	Vaccination against hepatitis B

FIG. 3-30 Site-directed mutagenesis. The altered gene can be inserted into a suitable cloning vector to be amplified, expressed, or used to generate a mutant organism. **WPLS** See the Animated Process Diagrams.

of evolution and allows predictions about the structural and functional roles of particular amino acids in a protein to be rigorously tested in the laboratory.

Synthetic oligonucleotides are required to specifically alter genes through site-directed mutagenesis. An oligonucleotide whose sequence is identical to a portion of the gene of interest except for the desired base changes is used to direct replication of the gene. The oligonucleotide hybridizes to the corresponding **wild-type** (naturally occurring) sequence if there are no more than a few mismatched base pairs. Extension of the oligonucleotide, called a primer, by DNA polymerase yields the desired altered gene (**Fig. 3-30**). The altered gene can then be inserted into an appropriate vector. A mutagenized primer can also be used to generate altered genes by PCR.

Transgenic Organisms Contain Foreign Genes. For many purposes it is preferable to tailor an intact organism rather than just a protein—true genetic engineering. Multicellular organisms expressing a gene from another organism are said to be **transgenic**, and the transplanted foreign gene is called a **transgene**.

For the change to be permanent—that is, heritable—a transgene must be stably integrated into the organism's germ cells. For mice, this is accomplished by microinjecting cloned DNA encoding the desired altered characteristics into a fertilized egg and implanting it into the uterus of a foster mother. A well-known example of a transgenic mouse contains extra copies of a growth hormone gene (**Fig. 3-31**).

FIG. 3-31 Transgenic mouse. The gigantic mouse on the left was grown from a fertilized ovum that had been microinjected with DNA containing the rat growth hormone gene. He is nearly twice the weight of his normal littermate on the right.

Courtesy of Ralph Brinster, University of Pennsylvania.

Transgenic farm animals have also been developed. In many cases, the genes of such animals have been tailored to allow the animals to grow faster on less food or to be resistant to particular diseases. Some transgenic farm animals have been engineered to secrete pharmaceutically useful proteins into their milk (a process called “pharming”). Harvesting such a substance from milk is much more cost-effective than producing the same substance in bacterial cultures.

One of the most successful transgenic organisms is corn (maize) that has been genetically modified to produce a protein that is toxic to plant-eating insects (but harmless to vertebrates). The toxin is synthesized by the soil microbe *Bacillus thuringiensis*. The toxin gene has been cloned into corn to confer protection against the European corn borer, a commercially significant pest that spends much of its life cycle inside the corn plant, where it is largely inaccessible to chemical insecticides. The use of “Bt corn,” which is now widely planted in the United States, has greatly reduced the need for such toxic substances.

Transgenic plants have also been engineered for better nutrition. For example, researchers have developed a strain of rice with foreign genes that encode enzymes necessary to synthesize **β -carotene** (an orange pigment that is the precursor of **vitamin A**) and a gene for the iron-storage protein **ferritin**. The genetically modified rice, which is named “golden rice” (Fig. 3-32), should help alleviate vitamin A deficiencies (which afflict some 400 million people) and iron deficiencies (an estimated 30% of the world’s population suffers from iron deficiency). Other transgenic plants include freeze-tolerant strawberries; slow-ripening tomatoes; rapidly maturing fruit trees; crop plants resistant to drought, high salinity, pathogenic viruses, or herbicides (so that herbicides can be used to eliminate weeds without killing the crop plant); and plants that produce large amounts of biofuels.

There is currently a widely held popular suspicion, particularly in Europe, that genetically modified or “GM” foods are somehow harmful. However, extensive research, as well as considerable consumer experience, has failed to reveal any deleterious consequences of consuming GM foods (see Box 3-3).

Transgenic organisms have greatly enhanced our understanding of gene expression. Animals that have been engineered to contain a defective gene or that lack a gene entirely (a so-called **gene knockout**) also serve as experimental models for human diseases.

Genetic Defects Can Be Corrected. **Gene therapy** is the transfer of new genetic material to the cells of an individual to produce a therapeutic effect. Although the

Box 3-3 Perspectives in Biochemistry

Ethical Aspects of Recombinant DNA Technology

In the early 1970s, when genetic engineering was first discussed, little was known about the safety of the proposed experiments. After considerable debate, during which there was a moratorium on such experiments, regulations for recombinant DNA research were drawn up. The rules prohibit obviously dangerous experiments (e.g., introducing the gene for diphtheria toxin into *E. coli*, which would convert this human symbiont into a deadly pathogen). Other precautions limit the risk of accidentally releasing potentially harmful organisms into the environment. For example, many vectors must be cloned in host organisms with special nutrient requirements. These organisms are unlikely to survive outside the laboratory.

The proven value of recombinant DNA technology has silenced nearly all its early opponents. Certainly, it would not have been possible to study some pathogens, such as the virus that causes AIDS, without cloning. The lack of recombinant-induced genetic catastrophes so far does not guarantee that recombinant organisms won’t ever adversely affect the environment. Nevertheless, the techniques used by genetic engineers mimic those used in nature—that is, mutation and selection—so natural and man-made organisms are fundamentally similar. In any case, people have been breeding plants and animals for several millen-

nia already, and for many of the same purposes that guide experiments with recombinant DNA.

There are other ethical considerations to be faced as new genetic engineering techniques become available. Bacterially produced human growth hormone is now routinely prescribed to increase the stature of abnormally short children. However, should athletes be permitted to use this protein, as some reportedly have, to increase their size and strength? Few would dispute the use of gene therapy, if it can be developed, to cure such genetic defects as sickle-cell anemia (Section 7-1E) and Lesch-Nyhan syndrome (Section 23-1D). If, however, it becomes possible to alter complex (i.e., multigene) traits such as athletic ability and intelligence, which changes would be considered desirable and who would decide whether to make them? Should gene therapy be used only to correct an individual’s defects, or should it also be used to alter genes in the individual’s germ cells so succeeding generations would not inherit the defect? When it becomes easy to determine an individual’s genetic makeup, should this information be used in evaluating applicants for educational and employment opportunities or for health insurance? These conundrums have led to the creation of a branch of philosophy, named **bioethics**, designed to deal with them.

CHECKPOINT

- Summarize the steps required to amplify a given segment of DNA *in vivo* and *in vitro*.
- Compare the properties of cloning vectors such as pUC18, bacteriophage λ , and BACs.
- Describe the activities of the enzymes required to construct a recombinant DNA molecule.
- Explain why a cloning vector usually includes a selectable marker.
- What is a DNA library and how can it be screened for a particular gene?
- What are the advantages of PCR over traditional cloning?
- What are some of the challenges of expressing a eukaryotic gene in a prokaryotic host cell?
- Explain how site-directed mutagenesis can be used to produce an altered protein in bacterial cells.
- What is the difference between manipulating a gene for gene therapy and for producing a transgenic organism?

potential benefits of this as yet rudimentary technology are enormous, there are numerous practical obstacles to overcome. For example, the retroviral vectors (RNA-containing viruses) commonly used to directly introduce genes into humans can provoke a fatal immune response.

The first documented success of gene therapy in humans occurred in children with a form of **severe combined immunodeficiency disease (SCID)** known as **SCID-X1**, which without treatment would have required their isolation in a sterile environment to prevent fatal infection. SCID-X1 is caused by a defect in the gene encoding γ **cytokine receptor**, whose action is essential for proper immune system function. Bone marrow cells (the precursors of white blood cells) were removed from the bodies of SCID-X1 victims, incubated with a vector containing a normal γ cytokine receptor gene, and returned to their bodies. The transgenic bone marrow cells restored immune system function. However, because the viral vector integrates into the genome at random, the location of the transgene may affect the expression of other genes, triggering cancer. At least two children have developed **leukemia** (a white blood cell cancer) as a result of gene therapy for SCID-X1.

Several other hereditary diseases have been successfully treated by similar techniques, including **Leber's congenital amaurosis**, a rare form of blindness; **X-linked adrenoleukodystrophy**, in which a defect in a membrane transport protein leads to brain damage; **β -thalassemia**, a type of severe anemia; and **Wiskott-Aldrich syndrome**, an immunodeficiency disease. Similarly, genetically instructing a cancer victim's immune system cells to attack the cancer cells has shown great promise in eliminating certain cancers that do not respond to standard therapies.

Summary**1 Nucleotides**

- Nucleotides consist of a purine or pyrimidine base linked to ribose to which at least one phosphate group is attached. RNA is made of ribonucleotides; DNA is made of deoxynucleotides (which contain 2'-deoxyribose).

2 Introduction to Nucleic Acid Structure

- In DNA, two antiparallel chains of nucleotides linked by phosphodiester bonds form a double helix. Bases in opposite strands pair: A with T, and G with C.
- Single-stranded nucleic acids, such as RNA, can adopt stem-loop structures.

3 Overview of Nucleic Acid Function

- DNA carries genetic information in its sequence of nucleotides. When DNA is replicated by DNA polymerase, each strand acts as a template for the synthesis of a complementary strand.
- According to the central dogma of molecular biology, one strand of the DNA of a gene is transcribed into mRNA. The RNA is then translated into protein by the ordered addition of amino acids that are bound to tRNA molecules that base-pair with the mRNA at the ribosome.

4 Nucleic Acid Sequencing

- Restriction endonucleases that recognize certain sequences of DNA are used to specifically cleave DNA molecules.

- Gel electrophoresis is used to separate and measure the sizes of DNA fragments.

- In the chain-terminator method of DNA sequencing, the sequence of nucleotides in a DNA strand is determined by enzymatically synthesizing complementary polynucleotides that terminate with a dideoxy analog of each of the four nucleotides. Polynucleotide fragments of increasing size are separated by electrophoresis to reconstruct the original sequence.

- Next-generation DNA sequencing methods, such as pyrosequencing and Illumina sequencing, are massively parallel and hence much faster than the chain-terminator method, but at the sacrifice of read lengths and accuracy.

- Mutations and other changes to DNA are the basis for the evolution of organisms.

5 Manipulating DNA

- In molecular cloning, a fragment of foreign DNA is inserted into a vector for amplification in a host cell. Transformed cells can be identified by selectable markers.

- Genomic libraries contain all the DNA of an organism. Clones harboring particular DNA sequences are identified by screening procedures.

- The polymerase chain reaction amplifies selected sequences of DNA.

- Recombinant DNA methods are used to produce wild-type or selectively mutagenized proteins in cells or entire organisms.

Problems

EXERCISES

1. Name the following nucleotide.

2. Name the following nucleotide.

3. In many organisms, DNA is modified by methylation. Draw the structure of 5-methylcytosine, a base that occurs with high frequency in inactive DNA.

4. When cytosine is treated with bisulfite, the amino group is replaced with a carbonyl group. Identify the resulting base.

5. Kinases are enzymes that transfer a phosphoryl group from a nucleoside triphosphate. Which of the following are valid kinase-catalyzed reactions?

- (a) $\text{ATP} + \text{GDP} \rightarrow \text{ADP} + \text{GTP}$
 (b) $\text{ATP} + \text{GMP} \rightarrow \text{AMP} + \text{GTP}$

6. Kinases are enzymes that transfer a phosphoryl group from a nucleoside triphosphate. Which of the following are valid kinase-catalyzed reactions?

- (a) $\text{ADP} + \text{CMP} \rightarrow \text{AMP} + \text{CDP}$
 (b) $\text{AMP} + \text{ATP} \rightarrow 2 \text{ADP}$

7. A diploid organism with a 45,000-kb haploid genome contains 21% G residues. Calculate the number of A, C, G, and T residues in the DNA of each cell in this organism.

8. A segment of DNA containing 20 base pairs includes 7 guanine residues. How many adenine residues are in the segment? How many uracil residues are in the segment?

9. Explain why the strands of a DNA molecule can be separated more easily at $\text{pH} > 11$.

10. Explain why increasing the NaCl concentration increases the temperature at which the two strands of DNA "melt" apart.

11. An enzyme from the human immunodeficiency virus (HIV, which causes AIDS) can synthesize DNA from an RNA template. Explain how this enzyme activity contradicts Crick's central dogma.

12. How many different amino acids could theoretically be encoded by nucleic acids containing four different nucleotides if (a) each nucleotide coded for one amino acid; (b) consecutive sequences of two nucleotides coded for one amino acid; (c) consecutive sequences of three nucleotides coded for one amino acid; (d) consecutive sequences of four nucleotides coded for one amino acid?

13. The human genome contains thousands of sequences known as small open reading frames, some of which encode proteins of about 30 amino acids. What is the minimum number of nucleotides required to encode such a protein?

14. By how many nucleotides, on average, do the genomes of two *Homo sapiens* differ?

15. The recognition sequence for the restriction enzyme *TaqI* is T↓CGA. Indicate the products of the reaction of *TaqI* with the DNA sequence shown.

16. Using the data in Table 3-2, identify restriction enzymes that (a) produce blunt ends; (b) recognize and cleave the same sequence (called **isoschizomers**); (c) produce identical sticky ends.

17. The 13-Mb genome of the green alga *Ostreococcus tauri* contains ~8000 genes. Compare the gene density in this eukaryote to that of *E. coli* (~4300 genes) and that of *A. thaliana* (~25,500 genes).

18. Describe how to select recombinant clones if a foreign DNA is inserted into the polylinker site of pUC18 and then introduced into *E. coli* cells.

19. Refer to the diagram of pUC18 (Fig. 3-24) to determine which restriction enzymes you could use to insert a gene that would interfere with production of β-galactosidase by the host cell.

20. Refer to the diagram of pUC18 (Fig. 3-24) to determine which restriction enzymes you could use to insert a gene that would not interfere with ampicillin resistance or production of β-galactosidase by the host cell.

21. Why is a genomic library larger than a cDNA library for a given organism?

22. Why do cDNA libraries derived from different cell types within the same organism differ from each other?

CHALLENGE QUESTIONS

23. Some RNA molecules are covalently modified by methylation at the N6 position in adenosine residues. Draw the structure of the modified nucleoside.

24. Would the modified nucleoside described in Question 23 be able to participate in standard Watson–Crick base pairing?

25. Draw the tautomeric form of adenine.

26. Draw the tautomeric form of cytosine.

27. The pK value for N1 of adenine is 3.64, whereas the pK value for N1 of guanine is 9.50. Explain this difference.

28. Use your answer to Problem 27 to determine the relative pK values of N3 in cytosine and in uracil.

29. The adenine derivative hypoxanthine can base-pair with adenine. Draw the structure of this base pair.

Hypoxanthine

30. Hypoxanthine can also base-pair with cytosine. Draw the structure of this base pair.

31. Describe the outcome of a chain-terminator sequencing procedure in which (a) too little ddNTP is added or (b) too much ddNTP is added.

32. Describe the outcome of a chain-terminator sequencing procedure in which (a) too few primers are present or (b) an excess of primers is present.

33. Calculate the number of clones required to obtain with a probability of 0.99 a specific 5-kb fragment from *C. elegans* (Table 3-3).

34. You are attempting to clone a 250-kb segment of mouse DNA in a yeast artificial chromosome. You obtain 5000 similar-sized clones

representing the entire mouse genome. How confident are you that you have cloned the DNA you are interested in?

35. Describe the possible outcome of a PCR experiment in which (a) one of the primers is inadvertently omitted from the reaction mixture and (b) one of the primers is complementary to several sites in the starting DNA sample.

36. Describe the possible outcome of a PCR experiment in which (a) there is a single-stranded break in the target DNA sequence, which is present in only one copy in the starting sample, and (b) there is a double-stranded break in the target DNA sequence, which is present in only one copy in the starting sample.

37. Write the sequences of the two 12-residue primers that could be used to amplify the following DNA segment by PCR.

38. A blood stain from a crime scene and blood samples from four suspects were analyzed by PCR using fluorescent primers associated with three STR loci: D3S1358, vWA, and FGA. The resulting electrophoretograms are shown below. The numbers beneath each peak identify the allele (upper box) and the height of the peak in relative fluorescence units (lower box).

(a) Since everyone has two copies of each chromosome and therefore two alleles of each gene, what accounts for the appearance of only one allele at some loci?

[From Thompson, W.C., Ford, S., Doom, T., Raymer, M., and Krane, D.E., Evaluating forensic DNA evidence: Essential elements of a competent defense review, *The Champion* 27, 16–25 (2003). Reprinted by permission of the National Association of Criminal Defense Lawyers.]

- (b) Which suspect is a possible source of the blood?
- (c) Could the suspect be identified using just one of the three STR loci?
- (d) What can you conclude about the amount of DNA obtained from Suspect 1 compared to Suspect 4?

Eye of Science/Science Source Images

Staphylococcus epidermidis, which grows on human skin, links the amino acid glutamate into long chains. These help protect the bacteria from changes in extracellular salt concentration that normally occur on the skin surface.

When scientists first turned their attention to nutrition, early in the nineteenth century, they quickly discovered that natural products containing nitrogen were essential for the survival of animals. In 1839, the Swedish chemist Jacob Berzelius coined the term **protein** (Greek: *proteios*, primary) for this class of compounds. The physiological chemists of that time did not realize that proteins were actually composed of smaller units, amino acids, although the first amino acids had been isolated in 1830. In fact, for many years, it was believed that substances from plants—including proteins—were incorporated whole into animal tissues. This misconception was laid to rest when the process of digestion came to light. After it became clear that ingested proteins were broken down to smaller compounds containing amino acids, scientists began to consider the nutritive qualities of those compounds (Box 4-1).

Modern studies of proteins and amino acids owe a great deal to nineteenth- and early twentieth-century experiments. We now understand that nitrogen-containing amino acids are essential for life and that they are the building blocks of proteins. The central role of amino acids in biochemistry is perhaps not surprising: Several amino acids are among the organic compounds believed to have appeared early in the earth's history (Section 1-1A). Amino acids, as ancient and ubiquitous molecules, have been co-opted by evolution for a variety of purposes in living systems. We begin this chapter by discussing the structures and chemical properties of the common amino acids, including their stereochemistry, and end with a brief summary of the structures and functions of some related compounds.

William C. Rose (1887–1985) Identifying the amino acid constituents of proteins was a scientific challenge that grew out of studies of animal nutrition. At the start of the twentieth century, physiological chemists (the term *biochemist* was not yet used) recognized that not all foods provided adequate nutrition. For example, rats fed the corn protein zein as their only source of nitrogen failed to grow unless the amino acids tryptophan and lysine were added to their diet. Knowledge of metabolism at

that time was limited mostly to information gleaned from studies in which intake of particular foods in experimental subjects (including humans) was linked to the urinary excretion of various compounds. Results of such studies were consistent with the idea that compounds could be transformed into other compounds, but clearly, nutrients were not wholly interchangeable.

At the University of Illinois, William C. Rose focused his research on nutritional studies to decipher the metabolic relationships of nitrogenous compounds. Among other things, his studies of rat growth and nutrition helped show that purines and pyrimidines were derived from amino acids but that those compounds could not replace dietary amino acids.

To examine the nutritional requirements for individual amino acids, Rose hydrolyzed proteins to obtain their component amino acids and then selectively removed certain amino acids. In one of his first experiments, he removed arginine and histidine from a hydrolysate of the milk protein casein. Rats fed on this preparation lost weight unless the amino acid histidine was added back to the food. However, adding back arginine did not compensate for the apparent requirement for histidine. These results prompted Rose to investigate the requirements for all the amino acids. Using similar experimental approaches, Rose demonstrated that cysteine,

histidine, and tryptophan could not be replaced by other amino acids.

From preparations based on hydrolyzed proteins, Rose moved to mixtures of pure amino acids. Thirteen of the 19 known amino acids could be purified, and the other six synthesized. However, rats fed these 19 amino acids as their sole source of dietary nitrogen lost weight. Although one possible explanation was that the proportions of the pure amino acids were not optimal, Rose concluded that there must be an additional essential amino acid, present in naturally occurring proteins and their hydrolysates but not in his amino acid mixtures.

After several years of effort, Rose obtained and identified the missing amino acid. In work published in 1935, Rose showed that adding this amino acid to the other 19 could support rat growth. Thus, the twentieth and last amino acid, threonine, was discovered.

Experiments extending over the next 20 years revealed that 10 of the 20 amino acids found in proteins are nutritionally essential, so that removal of one of these causes growth failure and eventually death in experimental animals. The other 10 amino acids were considered “dispensable” since animals could synthesize adequate amounts of them.

Rose’s subsequent work included verifying the amino acid requirements of humans, using graduate students as subjects. Knowing which amino acids were required for normal health—and in what amounts—made it possible to evaluate the potential nutritive value of different types of food proteins. Eventually, these findings helped guide the formulations used for intravenous feeding.

1 Amino Acid Structure

KEY CONCEPTS

- The 20 standard amino acids share a common structure but differ in their side chains.
- Peptide bonds link amino acid residues in a polypeptide.
- Some amino acid side chains contain ionizable groups whose pK values may vary.

The analyses of a vast number of proteins from almost every conceivable source have shown that *all proteins are composed of 20 “standard” amino acids*. Not every protein contains all 20 types of amino acids, but most proteins contain most, if not all, of the 20 types.

The common amino acids are known as **α -amino acids** because they have a primary amino group ($-\text{NH}_2$) as a substituent of the **α carbon** atom, the carbon next to the carboxylic acid group ($-\text{COOH}$; **Fig. 4-1**). The sole exception is proline, which has a secondary amino group ($-\text{NH}-$), although for uniformity we will refer to proline as an α -amino acid. The 20 standard amino acids differ in the structures of their side chains (**R groups**). **Table 4-1** displays the names and complete chemical structures of the 20 standard amino acids.

FIG. 4-1 General structure of an α -amino acid. The R groups differentiate the 20 standard amino acids.

? Identify the functional groups in this structure.

^aThe three- and one-letter symbols for asparagine *or* aspartic acid are Asx and B, whereas for glutamine *or* glutamic acid they are Glx and Z. The one-letter symbol for an undetermined or "nonstandard" amino acid is X.

^fBoth neutral and protonated forms of histidine are present at pH 7.0, since its pK_R is close to 7.0.

FIG. 4-2 A dipolar amino acid. At physiological pH, the amino group is protonated and the carboxylic acid group is unprotonated.

A Amino Acids Are Dipolar Ions

The amino and carboxylic acid groups of amino acids ionize readily. The pK values of the carboxylic acid groups (represented by pK_1 in Table 4-1) lie in a small range around 2.2, while the pK values of the α -amino groups (pK_2) are near 9.4. At physiological pH (~ 7.4), the amino groups are protonated and the carboxylic acid groups are in their conjugate base (carboxylate) form (Fig. 4-2). An amino acid can therefore act as both an acid and a base. Table 4-1 also lists the pK values for the seven side chains that contain ionizable groups (pK_R).

Molecules such as amino acids, which bear charged groups of opposite polarity, are known as **dipolar ions** or **zwitterions**. Amino acids, like other ionic compounds, are more soluble in polar solvents than in nonpolar solvents. As we will see, the ionic properties of the side chains influence the physical and chemical properties of free amino acids and amino acids in proteins.

B Peptide Bonds Link Amino Acids

Amino acids can be polymerized to form chains. This process can be represented as a **condensation reaction** (bond formation with the elimination of a water molecule), as shown in Fig. 4-3. The resulting CO—NH linkage, an amide linkage, is known as a **peptide bond**.

FIG. 4-3 Condensation of two amino acids. Formation of a CO—NH bond with the elimination of a water molecule produces a dipeptide. The peptide bond is shown in red. The residue with a free amino group is the N-terminus of the peptide, and the residue with a free carboxylate group is the C-terminus.

? Draw a tripeptide resulting from the condensation of a third amino acid.

GATEWAY CONCEPT: Molecular Visualization

Two-dimensional representations of amino acids and other small biological molecules indicate the bonding arrangements among atoms. However, since the covalent bonds from C, N, P, and S atoms often extend toward the corners of a tetrahedron, molecules containing such atoms occupy three dimensions, and if each atom's electrons—those in bonds and in nonbonded pairs—are represented as occupying a cloud around each atom's nucleus, the molecule can be pictured as a solid object. Structural formulas, ball-and-stick models, and space-filling models can therefore emphasize different aspects of the same molecular structure.

Polymers composed of two, three, a few (3–10), and many amino acid units are known, respectively, as **dipeptides**, **tripeptides**, **oligopeptides**, and **polypeptides**. These substances, however, are often referred to simply as “peptides.” After they are incorporated into a peptide, the individual amino acids (the monomeric units) are referred to as amino acid **residues**.

Polypeptides are linear polymers rather than branched chains; that is, each amino acid residue participates in two peptide bonds and is linked to its neighbors in a head-to-tail fashion. The residues at the two ends of the polypeptide each participate in just one peptide bond. The residue with a free amino group (by convention, the leftmost residue, as shown in Fig. 4-3) is called the **amino terminus** or **N-terminus**. The residue with a free carboxylate group (at the right) is called the **carboxyl terminus** or **C-terminus**.

Proteins are molecules that contain one or more polypeptide chains. *Variations in the length and the amino acid sequence of polypeptides are major contributors to the diversity in the shapes and biological functions of proteins*, as we will see in succeeding chapters.

C Amino Acid Side Chains Are Nonpolar, Polar, or Charged

The most useful way to classify the 20 standard amino acids is by the polarities of their side chains. According to the most common classification scheme, there are three major types of amino acids: (1) those with nonpolar R groups, (2) those with uncharged polar R groups, and (3) those with charged polar R groups.

The Nonpolar Amino Acid Side Chains Have a Variety of Shapes and Sizes. Nine amino acids are classified as having nonpolar side chains. The three-dimensional shapes of some of these amino acids are shown in Fig. 4-4. **Glycine** has the smallest possible side chain, an H atom. **Alanine**, **valine**, **leucine**, and **isoleucine** have aliphatic hydrocarbon side chains ranging in size from a methyl group for alanine to isomeric butyl groups for leucine and isoleucine. **Methionine** has a thioether side chain that resembles an *n*-butyl group in many of its physical properties (C and S have nearly equal electronegativities, and S is about the size of a methylene group). **Proline** has a cyclic pyrrolidine side group. **Phenylalanine** (with its phenyl moiety) and **tryptophan** (with its indole group) contain aromatic side groups, which are characterized by bulk as well as nonpolarity.

FIG. 4-4 Some amino acids with nonpolar side chains. The amino acids are shown as ball-and-stick models embedded in transparent space-filling models. The atoms are colored according to type, with C green, H white, N blue, and O red.

Uncharged Polar Side Chains Have Hydroxyl, Amide, or Thiol Groups. Six amino acids are commonly classified as having uncharged polar side chains (Table 4-1 and Fig. 4-5). **Serine** and **threonine** bear hydroxylic R groups of different sizes. **Asparagine** and **glutamine** have amide-bearing side chains of different sizes. **Tyrosine** has a phenolic group (and, like phenylalanine and tryptophan, is aromatic). **Cysteine** is unique among the 20 amino acids in that it has a thiol group that can form a disulfide bond with another cysteine through the oxidation of the two thiol groups (Fig. 4-6).

FIG. 4-5 Some amino acids with uncharged polar side chains. Atoms are represented and colored as in Fig. 4-4. Note the presence of electronegative atoms on the side chains.

GATEWAY CONCEPT: Functional Groups and Molecular Behavior

In addition to the amino and carboxylate groups that characterize all amino acids, some amino acids have side chains with acid–base groups. The protonation or deprotonation of these functional groups determines whether the side chain has an ionic charge. Consequently, the side chains can participate in chemical reactions as acids and bases, and their ionization states determine other aspects of molecular behavior, including water solubility and the ability to interact electrostatically with other charged or polar groups.

FIG. 4-6 Disulfide-bonded cysteine residues. The disulfide bond forms when the two thiol groups are oxidized.

FIG. 4-7 Some amino acids with charged polar side chains. Atoms are represented and colored as in Fig. 4-4.

Charged Polar Side Chains Are Positively or Negatively Charged. Five amino acids have charged side chains (Table 4-1 and Fig. 4-7). The side chains of the basic amino acids are positively charged at physiological pH values. **Lysine** has a butylammonium side chain, and **arginine** bears a guanidino group. As shown in Table 4-1, **histidine** carries an imidazolium moiety. Note that only histidine, with a pK_R of 6.04, readily ionizes within the physiological pH range. Consequently, both the neutral and cationic forms occur in proteins. In fact, the protonation–deprotonation of histidine side chains is a feature of numerous enzymatic reaction mechanisms.

The side chains of the acidic amino acids, **aspartic acid** and **glutamic acid**, are negatively charged above pH 3; in their ionized state, they are often referred to as **aspartate** and **glutamate**. Asparagine and glutamine are, respectively, the amides of aspartic acid and glutamic acid.

The foregoing allocation of the 20 amino acids among the three different groups is somewhat arbitrary. For example, glycine and alanine, the smallest of the amino acids, and tryptophan, with its heterocyclic ring, might just as well be classified as uncharged polar amino acids. Similarly, tyrosine and cysteine, with their ionizable side chains, might also be thought of as charged polar amino acids, particularly at higher pH values. In fact, the deprotonated side chain of cysteine (which contains the thiolate anion, S^-) occurs in a variety of enzymes, where it actively participates in chemical reactions.

Inclusion of a particular amino acid in one group or another reflects not just the properties of the isolated amino acid, but its behavior when it is part of a polypeptide. The structures of most polypeptides depend on a tendency for polar and ionic side chains to be hydrated and for nonpolar side chains to associate with each other rather than with water. This property of polypeptides is the hydrophobic effect (Section 2-1C) in action. As we will see, the chemical and physical properties of amino acid side chains also govern the chemical reactivity of the polypeptide. It is therefore worthwhile studying the structures of the 20 standard amino acids in order to appreciate how they vary in polarity, acidity, aromaticity, bulk, conformational flexibility, ability to cross-link, ability to hydrogen bond, and reactivity toward other groups.

D The pK Values of Ionizable Groups Depend on Nearby Groups

The α -amino acids have two or, for those with ionizable side chains, three acid–base groups. At very low pH values, these groups are fully protonated, and at very high pH values, these groups are unprotonated. At intermediate pH values, the acidic groups tend to be unprotonated, and the basic groups tend to be protonated. Thus, for the amino acid glycine, below pH 2.35 (the pK value of its carboxylic acid group), the $^+H_3NCH_2COOH$ form predominates. Above pH 2.35, the carboxylic acid is mostly ionized but the amino group is still mostly protonated ($^+H_3NCH_2COO^-$). Above pH 9.78 (the pK value of the amino group), the $H_2NCH_2COO^-$ form predominates. Note that *in aqueous solution, the un-ionized form (H_2NCH_2COOH) is present only in vanishingly small quantities.*

The pH at which a molecule carries no net electric charge is known as its **isoelectric point, pI** . For the α -amino acids,

$$pI = \frac{1}{2}(pK_i + pK_j) \quad [4-1]$$

where K_i and K_j are the dissociation constants of the two ionizations involving the neutral species. For monoamino, monocarboxylic acids such as glycine, K_i and K_j represent K_1 and K_2 . However, for aspartic and glutamic acids, K_i and K_j are K_1 and K_R , whereas for arginine, histidine, and lysine, these quantities are K_R and K_2 (see Sample Calculation 4-1).

Of course, amino acid residues in the interior of a polypeptide chain do not have free α -amino and α -carboxyl groups that can ionize (these groups are joined

SAMPLE CALCULATION 4-1

Calculate the isoelectric point of aspartic acid.

In the neutral species, the α -carboxylate group is deprotonated and the α -amino group is protonated. Protonation of the α -carboxylate group or deprotonation of the β -carboxylate group would both yield charged species. Therefore, the pK values for these groups (1.99 and 3.90; see Table 4-1) should be used with Equation 4-1:

$$pI = (pK_i + pK_j)/2 \\ = (1.99 + 3.90)/2 = 2.94$$

WPLS See Sample Calculation Videos.

in peptide bonds; Fig. 4-3). Furthermore, the pK values of all ionizable groups, including the N- and C-termini, usually differ from the pK values listed in Table 4-1 for free amino acids. For example, the pK values of α -carboxyl groups in unfolded proteins range from 3.5 to 4.0. In the free amino acids, the pK values are much lower, because the positively charged ammonium group electrostatically stabilizes the COO^- group, in effect making it easier for the carboxylic acid group to ionize. Similarly, the pK values for α -amino groups in proteins range from 7.5 to 8.5. In the free amino acids, the pK values are higher, due to the electron-withdrawing character of the nearby carboxylate group, which makes it more difficult for the ammonium group to become deprotonated. In addition, the three-dimensional structure of a folded polypeptide chain may bring polar side chains and the N- and C-termini close together. The resulting electrostatic interactions between these groups may shift their pK values up to several pH units from the values for the corresponding free amino acids. For this reason, the pI of a polypeptide, which is a function of the pK values of its many ionizable groups, is not easily predicted and is usually determined experimentally.

E Amino Acid Names Are Abbreviated

The three-letter abbreviations for the 20 standard amino acids given in Table 4-1 are widely used in the biochemical literature. Most of these abbreviations are taken from the first three letters of the name of the corresponding amino acid and are pronounced as written. The symbol **Glx** indicates Glu or Gln, and similarly, **Asx** means Asp or Asn. This ambiguous notation stems from laboratory experience: Asn and Gln are easily hydrolyzed to Asp and Glu, respectively, under the acidic or basic conditions often used to recover them from proteins. Without special precautions, it is impossible to tell whether a detected Glu was originally Glu or Gln, and likewise for Asp and Asn.

The one-letter symbols for the amino acids are also given in Table 4-1. This more compact code is often used when comparing the amino acid sequences of several similar proteins. Note that the one-letter symbol is usually the first letter of the amino acid's name. However, for sets of residues that have the same first letter, this is true only of the most abundant residue of the set.

Amino acid residues in polypeptides are named by dropping the suffix, usually **-ine**, in the name of the amino acid and replacing it by **-yl**. Polypeptide chains are described by starting at the N-terminus and proceeding to the C-terminus. The amino acid at the C-terminus is given the name of its parent amino acid. Thus, the compound

is called alanyltyrosylaspartylglycine. Obviously, such names for polypeptide chains of more than a few residues are extremely cumbersome. The tetrapeptide above can also be written as Ala-Tyr-Asp-Gly using the three-letter abbreviations, or AYDG using the one-letter symbols.

The various atoms of the amino acid side chains are often named in sequence with the Greek alphabet, starting at the carbon atom adjacent to the peptide

CHECKPOINT

- Draw a generic amino acid and identify its α carbon and its substituents.
- Draw the structures of the 20 standard amino acids and give their one- and three-letter abbreviations.
- Draw a Cys–Gly–Asn tripeptide. Identify the peptide bond and the N- and C-termini, and determine the peptide's net charge at neutral pH.
- Classify the 20 standard amino acids by polarity, structure, type of functional group, and acid–base properties.
- Why do the pK values of ionizable groups differ between free amino acids and amino acid residues in polypeptides?

FIG. 4-8 Greek nomenclature for amino acids. The carbon atoms are assigned sequential letters in the Greek alphabet, beginning with the carbon next to the carbonyl group.

carbonyl group. Therefore, as **Fig. 4-8** indicates, the Lys residue is said to have an ϵ -amino group and Glu has a γ -carboxyl group. Unfortunately, this labeling system is ambiguous for several amino acids. Consequently, standard numbering schemes for organic molecules are also employed (and are indicated in Table 4-1 for the heterocyclic side chains).

2 Stereochemistry

KEY CONCEPTS

- Amino acids and many other biological compounds are chiral molecules whose configurations can be depicted by Fischer projections.
- The amino acids in proteins all have the L stereochemical configuration.

With the exception of glycine, all the amino acids recovered from polypeptides are **optically active**; that is, they rotate the plane of polarized light. The direction and angle of rotation can be measured using an instrument known as a **polarimeter** (**Fig. 4-9**).

Optically active molecules are asymmetric; that is, they are not superimposable on their mirror image in the same way that a left hand is not superimposable on its mirror image, a right hand. This situation is characteristic of

FIG. 4-9 Diagram of a polarimeter. This device is used to measure optical rotation.

substances containing tetrahedral carbon atoms that have four different substituents. For example, the two molecules depicted in Fig. 4-10 are not superimposable; they are mirror images. The central atoms in such molecules are known as **asymmetric centers** or **chiral centers** and are said to have the property of **chirality** (Greek: *cheir*, hand). The C_α atoms of the amino acids (except glycine) are asymmetric centers. Glycine, which has two H atoms attached to its C_α atom, is superimposable on its mirror image and is therefore not optically active. Many biological molecules in addition to amino acids contain one or more chiral centers.

Chiral Centers Give Rise to Enantiomers. Molecules that are nonsuperimposable mirror images are known as **enantiomers** of one another. Enantiomeric molecules are physically and chemically indistinguishable by most techniques. *Only when probed asymmetrically, for example, by plane-polarized light or by reactants that also contain chiral centers, can they be distinguished or differentially manipulated.*

Unfortunately, there is no clear relationship between the structure of a molecule and the degree or direction to which it rotates the plane of polarized light. For example, leucine isolated from proteins rotates polarized light 10.4° to the left, whereas arginine rotates polarized light 12.5° to the right. (The enantiomers of these compounds rotate polarized light to the same degree but in the opposite direction.) It is not yet possible to predict optical rotation from the structure of a molecule or to derive the **absolute configuration** (spatial arrangement) of chemical groups around a chiral center from optical rotation measurements.

The Fischer Convention Describes the Configuration of Asymmetric Centers. Biochemists commonly use the **Fischer convention** to describe different forms of chiral molecules. In this system, the configuration of the groups around an asymmetric center is compared to that of **glyceraldehyde**, a molecule with one asymmetric center. In 1891, Emil Fischer proposed that the spatial isomers, or **stereoisomers**, of glyceraldehyde be designated D-glyceraldehyde and L-glyceraldehyde (Fig. 4-11). The prefix L (note the use of a small upper-case letter) signified rotation of polarized light to the left (Greek: *levo*, left), and the prefix D indicated rotation to the right (Greek: *dextro*, right) by the two forms of glyceraldehyde. Fischer assigned the prefixes to the structures shown in Fig. 4-11 without knowing whether the structure on the left and the structure on the right were actually **levorotatory** or **dextrorotatory**, respectively. Only in 1949 did experiments confirm that Fischer's guess was indeed correct.

Fischer also proposed a shorthand notation for molecular configurations, known as **Fischer projections**, which are also given in Fig. 4-11. In the Fischer convention, horizontal bonds extend above the plane of the paper and vertical bonds extend below the plane of the paper.

The configuration of groups around any chiral center can be related to that of glyceraldehyde by chemically converting the groups to those of glyceraldehyde. For α -amino acids, the amino, carboxyl, R, and H groups around the C_α atom correspond to the hydroxyl, aldehyde, CH_2OH , and H groups, respectively, of glyceraldehyde.

Therefore, L-glyceraldehyde and L- α -amino acids are said to have the same **relative configuration**. *All amino acids derived from proteins have the L stereochemical*

FIG. 4-10 The two enantiomers of fluorochlorobromomethane. The four substituents are tetrahedrally arranged around the central carbon atom. A dotted line indicates that a substituent lies behind the plane of the paper, a wedged line indicates that it lies above the plane of the paper, and a thin line indicates that it lies in the plane of the paper. The mirror plane relating the enantiomers is represented by a vertical dashed red line.

FIG. 4-11 The Fischer convention. The enantiomers of glyceraldehyde are shown as geometric formulas (*top*) and as Fischer projections (*bottom*). In a Fischer projection, horizontal lines represent bonds that extend above the page and vertical lines represent bonds that extend below the page (in some Fischer projections, the central chiral carbon atom is not shown explicitly).

? Draw Fischer projections for the two enantiomers of alanine or use a molecular model kit to prove that the two isomers are nonsuperimposable mirror images.

Box 4-2 Perspectives in Biochemistry The *RS* System

A system to unambiguously describe the configurations of molecules with more than one asymmetric center was devised in 1956 by Robert Cahn, Christopher Ingold, and Vladimir Prelog. In the **Cahn-Ingold-Prelog** or ***RS* system**, the four groups surrounding a chiral center are ranked according to a specific, though arbitrary, priority scheme: Atoms of higher atomic number rank above those of lower atomic number (e.g., —OH ranks above —CH₃). If the first substituent atoms are identical, the priority is established by the next atom outward from the chiral center (e.g., —CH₂OH takes precedence over —CH₃). The order of priority of some common functional groups is

The prioritized groups are assigned the letters W, X, Y, Z such that their order of priority ranking is $W > X > Y > Z$. To establish the configuration of the chiral center, it is viewed from the asymmetric center toward the Z group (lowest priority). If the order of the groups $W \rightarrow X \rightarrow Y$ is clockwise, the configuration is designated *R* (Latin: *rectus*, right). If the order of $W \rightarrow X \rightarrow Y$ is counterclockwise, the configuration is designated *S* (Latin: *sinistrus*, left).

L-Glyceraldehyde is (*S*)-glyceraldehyde because the three highest priority groups are arranged counterclockwise when the H atom (*dashed lines*) is positioned behind the chiral C atom (*large circle*).

L-Glyceraldehyde **(*S*)-Glyceraldehyde**

All the L-amino acids in proteins are (*S*)-amino acids except cysteine, which is (*R*)-cysteine because the S in its side chain increases its priority. Other closely related compounds with the same designation under the Fischer DL convention may have different representations under the *RS* system. The *RS* system is particularly useful for describing the chiralities of compounds with multiple asymmetric centers. Thus, L-threonine can also be called (*2S,3R*)-threonine.

configuration; that is, they all have the same relative configuration around their C_α atoms. Of course, the L or D designation of an amino acid does not indicate its ability to rotate the plane of polarized light. Many L-amino acids are dextrorotatory.

The Fischer system has some shortcomings, particularly for molecules with multiple asymmetric centers. Each asymmetric center can have two possible configurations, so a molecule with *n* chiral centers has 2^{*n*} different possible stereoisomers. Threonine and isoleucine, for example, each have two chiral carbon atoms, and therefore each has four stereoisomers, or two pairs of enantiomers. [The enantiomers (mirror images) of the L forms are the D forms.] For most purposes, the Fischer system provides an adequate description of biological molecules. A more precise nomenclature system is also occasionally used by biochemists (see Box 4-2).

Life Is Based on Chiral Molecules. Consider the ordinary chemical synthesis of a chiral molecule, which produces a **racemic mixture** (containing equal amounts of each enantiomer). To obtain a product with net asymmetry, a chiral process must be employed. One of the most striking characteristics of life is its production of optically active molecules. *Biosynthetic processes almost invariably produce pure stereoisomers.* The fact that the amino acid residues of proteins all have the L configuration is just one example of this phenomenon. Furthermore, because most biological molecules are chiral, a given molecule—present in a single enantiomeric form—will bind to or react with only a single enantiomer of another compound. For example, a protein made of L-amino acid residues that reacts with a particular L-amino acid does not readily react with the D form of that amino acid. An otherwise identical synthetic protein made of D-amino acid residues, however, readily reacts only with the corresponding D-amino acid.

D-Amino acid residues are components of some relatively short (<20 residues) bacterial polypeptides. These polypeptides are perhaps most widely distributed as constituents of bacterial cell walls (Section 8-3B). The presence of the D-amino acids renders bacterial cell walls less susceptible to attack by the **peptidases** (enzymes that hydrolyze peptide bonds) that are produced by

Ibuprofen

FIG. 4-12 Ibuprofen. Only the enantiomer shown has anti-inflammatory action. The chiral carbon is red.

Thalidomide

FIG. 4-13 Thalidomide. This drug was widely used in Europe as a mild sedative in the early 1960s. Its inactive enantiomer (not shown), which was present in equal amounts in the formulations used, causes severe birth defects in humans when taken during the first trimester of pregnancy. Thalidomide was often prescribed to alleviate the nausea (morning sickness) that is common during this period. In recent years, however, it was found that thalidomide is an effective drug for the treatment of the immune system cancer **multiple myeloma**.

other organisms to digest bacteria. Likewise, D-amino acids are components of many bacterially produced peptide antibiotics. Most peptides containing D-amino acids are not synthesized by the standard protein synthetic machinery, in which messenger RNA is translated at the ribosome by transfer RNA molecules with attached L-amino acids (Chapter 27). Instead, the D-amino acids are directly joined together by the action of specific bacterial enzymes.

 The importance of stereochemistry in living systems is also a concern of the pharmaceutical industry. *Many drugs are chemically synthesized as racemic mixtures, although only one enantiomer has biological activity.* In most cases, the opposite enantiomer is biologically inert and is therefore packaged along with its active counterpart. This is true, for example, of the anti-inflammatory agent **ibuprofen**, only one enantiomer of which is physiologically active (**Fig. 4-12**). Occasionally, the inactive enantiomer of a useful drug produces harmful effects and must therefore be eliminated from the racemic mixture. The most striking example of this is the drug **thalidomide** (**Fig. 4-13**), a mild sedative whose inactive enantiomer causes severe birth defects. Partly because of the unanticipated problems caused by inactive drug enantiomers, **chiral organic synthesis** has become an active area of medicinal chemistry.

CHECKPOINT

- Explain why all the amino acids except for glycine are chiral.
- Identify all the chiral carbons in the amino acids shown in Table 4-1.
- Explain how the Fischer convention describes the absolute configuration of a chiral molecule.
- Explain why an enzyme can catalyze a chemical reaction involving just one enantiomer of a compound.

3 Amino Acid Derivatives

KEY CONCEPTS

- The side chains of amino acid residues in proteins may be covalently modified.
- Some amino acids and amino acid derivatives function as hormones and regulatory molecules.

The 20 common amino acids are by no means the only amino acids that occur in biological systems. “Nonstandard” amino acid residues are often important constituents of proteins and biologically active peptides. In addition, many amino

acids are not constituents of polypeptides at all but independently play a variety of biological roles.

A Protein Side Chains May Be Modified

The “universal” genetic code, which is nearly identical in all known life-forms (Section 27-1), specifies only the 20 standard amino acids of Table 4-1. Nevertheless, many other amino acids, some of which are shown in Fig. 4-14, are components of certain proteins. *In almost all cases, these unusual amino acids result from the specific modification of an amino acid residue after the polypeptide chain has been synthesized.*

Amino acid modifications include the simple addition of small chemical groups to certain amino acid side chains: hydroxylation, methylation, acetylation, carboxylation, and phosphorylation. Larger groups, including lipids and carbohydrate polymers, are attached to particular amino acid residues of certain proteins. The free amino and carboxyl groups at the N- and C-termini of a polypeptide can also be chemically modified. These modifications are often important, if not essential, for the function of the protein. In some cases, several amino acid side chains together form a novel structure (Box 4-3).

B Some Amino Acids Are Biologically Active

The 20 standard amino acids undergo a bewildering number of chemical transformations to other amino acids and related compounds as part of their normal cellular synthesis and degradation. In a few cases, the intermediates of amino acid metabolism have functions beyond their immediate use as precursors or degradation products of the 20 standard amino acids. Moreover, many amino acids are synthesized not to be residues of polypeptides but to function independently. We will see that many organisms use certain amino acids to transport nitrogen in the form of amino groups (Section 21-2A). Amino acids may also be oxidized as metabolic fuels to provide energy (Section 21-4). In addition, amino

FIG. 4-14 Some modified amino acid residues in proteins. The side chains of these residues are derived from one of the 20 standard amino acids after the polypeptide has been synthesized. The standard R groups are red, and the modifying groups are blue.

? Explain how each modification alters the polarity of the parent amino acid.

Box 4-3 Perspectives in Biochemistry Green Fluorescent Protein

Genetic engineers often link a protein-coding gene to a “reporter gene”—for example, the gene for an enzyme that yields a colored reaction product. The intensity of the colored compound can be used to estimate the level of expression of the engineered gene. One of the most useful reporter genes is the one that codes for **green fluorescent protein (GFP)**. This protein, from the bioluminescent jellyfish *Aequorea victoria*, fluoresces with a peak wavelength of 508 nm (green light) when irradiated by ultraviolet or blue light (optimally 400 nm).

Green fluorescent protein is nontoxic and intrinsically fluorescent; it requires no substrate or small molecule cofactor to fluoresce, as do other highly fluorescent proteins. Consequently, when the gene for green fluorescent protein is linked to another gene, the level of expression of the fused genes can be measured noninvasively by fluorescence microscopy.

Green fluorescent protein consists of a chain of 238 amino acid residues. The light-emitting group is a derivative of three consecutive amino acids: Ser, Tyr, and Gly. After the protein has been synthesized,

the three amino acids undergo spontaneous cyclization and oxidation. The carbonyl C atom of Ser forms a covalent bond to the amino N atom contributed by Gly, followed by the elimination of water and the oxidation of the C_α—C_β bond of Tyr to a double bond. The resulting structure contains a system of conjugated double bonds that gives the protein its fluorescent properties.

Cyclization between Ser and Gly is probably rapid, and the oxidation of the Tyr side chain (by O₂) is probably the rate-limiting step of fluorophore generation. Genetic engineering has introduced site-specific mutations that enhance fluorescence intensity and shift the wavelength of the emitted light to different colors, thereby making it possible to simultaneously monitor the expression of two or more different genes.

Dr. Kevin Rasikoff

acids and their derivatives often function as chemical messengers for communication between cells (Fig. 4-15). For example, glycine, **γ-aminobutyric acid (GABA)**; a glutamate decarboxylation product), and **dopamine** (a tyrosine derivative) are **neurotransmitters**, substances released by nerve cells to alter the behavior of their neighbors. **Histamine** (the decarboxylation product of histidine) is a potent local mediator of allergic reactions. **Thyroxine** (another tyrosine

FIG. 4-15 Some biologically active amino acid derivatives. The remaining portions of the parent amino acids are black and red, and additional groups are blue.

derivative) is an iodine-containing thyroid hormone that generally stimulates vertebrate metabolism.

Many peptides containing only a few amino acid residues have important physiological functions as hormones or other regulatory molecules. One nearly ubiquitous tripeptide called **glutathione** plays a role in cellular metabolism. Glutathione is a Glu–Cys–Gly peptide in which the γ -carboxylate group of the glutamate side chain forms an **isopeptide bond** with the amino group of the Cys residue (so called because a standard peptide bond is taken to be the amide bond formed between an α -carboxylate and an α -amino group of two amino acids). Two of these tripeptides (abbreviated **GSH**) undergo oxidation of their SH groups to form a dimeric disulfide-linked structure called **glutathione disulfide (GSSG)**:

CHECKPOINT

- List some covalent modifications of amino acids in proteins.
- Cover the labels in Figs. 4-14 and 4-15 and identify each parent amino acid and the type of chemical modification that has occurred.
- List some functions of amino acid derivatives.

Glutathione helps inactivate oxidative compounds that could potentially damage cellular structures, since the oxidation of GSH to GSSG is accompanied by the reduction of another compound (shown as O_2 above):

GSH must then be regenerated in a separate reduction reaction.

Summary

1 Amino Acid Structure

- At neutral pH, the amino group of an amino acid is protonated and its carboxylic acid group is ionized.
- Proteins are polymers of amino acids joined by peptide bonds.
- The 20 standard amino acids can be classified as nonpolar (Gly, Ala, Val, Leu, Ile, Met, Pro, Phe, Trp), uncharged polar (Ser, Thr, Asn, Gln, Tyr, Cys), and charged (Lys, Arg, His, Asp, Glu).
- The pK values of the ionizable groups of amino acids may be altered when the amino acid is part of a polypeptide.

2 Stereochemistry

- Amino acids are chiral molecules. Only L-amino acids occur in proteins (some bacterial peptides contain D-amino acids).

3 Amino Acid Derivatives

- Amino acids may be covalently modified after they have been incorporated into a polypeptide.
- Individual amino acids and their derivatives have diverse physiological functions.

Problems

EXERCISES

- Identify the amino acids that differ from each other by a single methyl or methylene group.
- Glutamate, a 5-carbon amino acid, is the precursor of three other amino acids that contain a 5-carbon chain. Identify these amino acids.
- The 20 standard amino acids are called α-amino acids. Certain β-amino acids are found in nature. Draw the structure of β-alanine (3-amino-*n*-propionate).
- Taurine (2-aminoethanesulfonic acid) is sometimes called an amino acid.

- Explain why this designation is not valid. (b) From which of the 20 standard amino acids is taurine derived? Describe the chemical change(s) that occurred.
- Draw the dipeptide Asp–His at pH 7.0.
 - Calculate the number of possible pentapeptides that contain one residue each of Ala, Gly, His, Lys, and Val.
 - Identify the hydrogen bond donor and acceptor groups in asparagine.
 - In some proteins, the side chain of serine appears to undergo ionization. Explain why ionization would be facilitated by the presence of an aspartate residue nearby.
 - Determine the net charge of the predominant form of Asp at (a) pH 1.0, (b) pH 3.0, (c) pH 6.0, and (d) pH 11.0.
 - Determine the net charge of the predominant form of Arg at (a) pH 1.0, (b) pH 5.0, (c) pH 10.5, and (d) pH 13.5.
 - Indicate whether the following familiar objects are chiral or nonchiral: (a) a glove; (b) a tennis ball; (c) a screw; (d) this page; (e) a snowflake; (f) a spiral staircase; and (g) a shoe.
 - Circle the chiral carbons in the following compounds:

- Some amino acids are synthesized by replacing the keto group (C=O) of an organic acid known as an α-keto acid with an amino group (C–NH₃⁺). Identify the amino acids that can be produced this way from the following α-keto acids:

- Patients with Parkinson's disease are sometimes given L-DOPA (3,4-dihydroxyphenylalanine). What neurotransmitter is produced by the decarboxylation of L-DOPA?
- Over time, the glutamine residues of polypeptides are susceptible to deamidation, a reaction in which the amide group is replaced by a carboxylate group. What amino acid is produced when glutamine is deamidated?
- Some hormone-signaling pathways result in the phosphorylation of tyrosine residues in proteins. Draw the structure of a phosphotyrosine side chain.
- Which amino acids have side chains that are capable of forming isopeptide bonds?
- Draw the structure of Lys and Ala linked by an isopeptide bond.
- Some bacteria produce poly-γ-glutamic acid, a polymer in which the amino group of each glutamate residue is condensed with the γ-carboxylate group of the adjacent residue. Draw the repeating structure of this polymer.
- Lanthionine is a nonstandard amino acid consisting of two alanine residues linked via their β carbon atoms by a thioether (–S–) linkage. Draw the structure of lanthionine.

CHALLENGE QUESTIONS

- A sample of the amino acid tyrosine is barely soluble in water. Would a polypeptide containing only Tyr residues, poly(Tyr), be more or less soluble, assuming the total number of Tyr groups remains constant?
- (a) What is the net charge at neutral pH of a tripeptide containing only alanine? (b) How does the total number of negative and positive charges change following hydrolysis of the tripeptide?
- Calculate the pI of (a) Ala, (b) His, and (c) Glu.

24. Estimate the isoelectric point of a Ser-His dipeptide. Explain why this value is only an estimate.

25. Draw the peptide ATLDAK. (a) Calculate its approximate pI . (b) What is its net charge at $pH\ 7.0$?

26. The protein insulin consists of two polypeptides termed the A and B chains. Insulins from different organisms have been isolated and sequenced. Human and duck insulins have the same amino acid sequence with the exception of six amino acid residues, as shown below. Is the pI of human insulin lower than or higher than that of duck insulin?

Amino acid residue	A8	A9	A10	B1	B2	B27
Human	Thr	Ser	Ile	Phe	Val	Thr
Duck	Glu	Asn	Pro	Ala	Ala	Ser

27. Draw the four stereoisomers of threonine as Fischer projections.

28. The two $C_\alpha H$ atoms of Gly are said to be prochiral, because when one of them is replaced by another group, C_α becomes chiral. Draw a Fischer projection of Gly and indicate which H must be replaced with CH_3 to yield D-Ala.

29. The bacterially produced antibiotic gramicidin A forms channels in cell membranes that allow the free diffusion of Na^+ and K^+ ions, thereby killing the cell. This peptide consists of a sequence of D- and L-amino acids. The sequence of a segment of five amino acids in gramicidin A is R-Gly-L-Ala-D-Leu-L-Ala-D-Val-R'. Complete the Fischer projection below by adding the correct group to each vertical bond.

30. Describe isoleucine (as shown in Table 4-1) using the RS system.

31. Identify the amino acid residue from which the following groups are synthesized:

32. Describe how each of the amino acid modifications shown in Fig. 4-14 would affect the pI of a peptide containing that modified amino acid residue.

33. Draw the structure of the dipeptide β -alanylhistidine, also known as carnosine.

34. What is the approximate net charge of carnosine (a) at $pH\ 3$, (b) $pH\ 5$, (c) $pH\ 7$, and (d) $pH\ 9$?

BIOINFORMATICS

Brief Exercises Brief, online homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Drawing and Analyzing Amino Acids and Peptides

Exercise 2 Chemical Properties and Amino Acid Composition of Green Fluorescent Protein

MORE TO EXPLORE Presumably, the mix of prebiotic compounds on early earth included both D- and L-amino acids. What are some hypotheses that attempt to explain why cells build proteins only from the L forms?

Paleobiologists use techniques such as mass spectrometry to analyze the proteins in ancient animal bones to identify the species—such as sheep or goat—and draw conclusions about early human farming practices. Unlike PCR, mass spectrometry does not require intact macromolecules for analysis and is not as sensitive to contamination.

Proteins are at the center of action in biological processes. Nearly all the molecular transformations that define cellular metabolism are mediated by protein catalysts. Proteins also perform regulatory roles, monitoring extracellular and intracellular conditions and relaying information to other cellular components. In addition, proteins are essential structural components of cells. A complete list of known protein functions would contain many thousands of entries, including proteins that transport other molecules and proteins that generate mechanical and electrochemical forces, and such a list would not account for the thousands of proteins whose functions are not yet fully characterized or, in many cases, are completely unknown.

One of the keys to deciphering the function of a given protein is to understand its structure. Like the other major biological macromolecules, the nucleic acids (Section 3-2) and the polysaccharides (Section 8-2), proteins are polymers of smaller units. But unlike many nucleic acids, proteins do not have uniform, regular structures. This is, in part, because the 20 kinds of amino acid residues from which proteins are made have widely differing chemical and physical properties (Section 4-1C). The sequence in which these amino acids are strung together can be analyzed directly, as we describe in this chapter, or indirectly, via DNA sequencing (Section 3-4). In either case, amino acid sequence information provides insights into the chemical and physical properties of proteins, their relationships to other proteins, and, ultimately, their mechanisms of action in living organisms. After a brief introduction to the variety in protein structure we will examine some methods for purifying and analyzing proteins, procedures for determining the sequence of amino residues, and, finally, some approaches to understanding protein evolution.

1 Polypeptide Diversity

KEY CONCEPTS

- In theory, the sizes and compositions of polypeptide chains are unlimited.
- In cells, this potential variety is limited by the efficiency of protein synthesis and by the ability of the polypeptide to fold into a functional structure.

Like all polymeric molecules, proteins can be described in terms of levels of organization; in this case, their primary, secondary, tertiary, and quaternary structures. A protein's **primary structure** is the amino acid sequence of its polypeptide chain, or chains if the protein consists of more than one polypeptide. An example of an amino acid sequence is given in Fig. 5-1. Each residue is linked to the next via a peptide bond (Fig. 4-3). Higher levels of protein structure—secondary, tertiary, and quaternary—refer to the three-dimensional shapes of folded polypeptide chains and will be described in the next chapter.

Proteins are synthesized *in vivo* by the stepwise polymerization of amino acids in the order specified by the sequence of nucleotides in a gene. The direct correspondence between one linear polymer (DNA) and another (a polypeptide) illustrates the elegant simplicity of living systems and allows us to extract information from one polymer and apply it to the other.

The Theoretical Possibilities for Polypeptides Are Unlimited. With 20 different choices available for each amino acid residue in a polypeptide chain, it is easy to see that a huge number of different protein molecules are possible. For a protein of n residues, there are 20^n possible sequences. A relatively small protein molecule may consist of a single polypeptide chain of 100 residues. There are $20^{100} \approx 1.27 \times 10^{130}$ possible unique polypeptide chains of this length, a quantity vastly greater than the estimated number of atoms in the universe (9×10^{78}). Clearly, evolution has produced only a tiny fraction of the theoretical possibilities—a fraction that nevertheless represents an astronomical number of different polypeptides.

Actual Polypeptides Are Somewhat Limited in Size and Composition. In general, proteins contain at least 40 residues or so; polypeptides smaller than that are simply called **peptides**. The largest known polypeptide chain belongs to the 35,213-residue **titin**, a giant (3906 kD) protein that helps arrange the repeating structures of muscle fibers (Section 7-2A). However, *the vast majority of polypeptides contain between 100 and 1000 residues, with the average being 355 residues* (Table 5-1). **Multisubunit proteins** contain several identical and/or nonidentical chains called **subunits**. Some proteins are synthesized as single polypeptides that are later cleaved into two or more chains that remain associated; **insulin** is such a protein (Fig. 5-1).

The size range in which most polypeptides fall probably reflects the optimization of several biochemical processes:

1. Forty residues appears to be near the minimum for a polypeptide chain to fold into a discrete and stable shape that allows it to carry out a particular function.
2. Polypeptides with well over 1000 residues may approach the limits of efficiency of the protein synthetic machinery. The longer the polypeptide

FIG. 5-1 The primary structure of bovine insulin. Note the intrachain and interchain disulfide bond linkages.

TABLE 5-1 Compositions of Some Proteins

Protein	Amino Acid Residues	Subunits	Protein Molecular Mass (D)
Proteinase inhibitor III (bitter melon)	30	1	3,427
Cytochrome <i>c</i> (human)	104	1	11,617
Myoglobin (horse)	153	1	16,951
Interferon- γ (rabbit)	288	2	33,842
Chorismate mutase (<i>Bacillus subtilis</i>)	381	3	43,551
Triose phosphate isomerase (<i>E. coli</i>)	510	2	53,944
Hemoglobin (human)	574	4	61,986
RNA polymerase (bacteriophage T7)	883	1	98,885
Nucleoside diphosphate kinase (<i>Dictyostelium discoideum</i>)	930	6	100,764
Pyruvate decarboxylase (yeast)	2,252	4	245,456
Glutamine synthetase (<i>E. coli</i>)	5,616	12	621,264
Titin (mouse)	35,213	1	3,906,488

(and the longer its corresponding mRNA), the greater the likelihood of introducing errors during transcription and translation.

In addition to these mild constraints on size, polypeptides are subject to more severe limitations on amino acid composition. The 20 standard amino acids do not appear with equal frequencies in proteins. (Table 4-1 lists the average occurrence of each amino acid residue.) For example, the most abundant amino acids in proteins are Leu, Ala, Gly, Val, Glu, and Ser; the rarest are Trp, Cys, Met, and His.

Because each amino acid residue has characteristic chemical and physical properties, its presence at a particular position in a protein influences the properties of that protein. In particular, as we will see, the three-dimensional shape of a folded polypeptide chain is a consequence of the intramolecular forces among its various residues. In general, a protein's hydrophobic residues cluster in its interior, out of contact with water, whereas its hydrophilic side chains tend to occupy the protein's surface.

The characteristics of an individual protein depend more on its amino acid sequence than on its amino acid composition per se, for the same reason that "kitchen" and its anagram "thicken" are quite different words. In addition, many proteins consist of more than just amino acid residues. They may form complexes with metal ions such as Zn^{2+} and Ca^{2+} ; they may covalently or noncovalently bind certain small organic molecules; and they may be covalently modified by the post-translational attachment of groups such as phosphates and carbohydrates.

CHECKPOINT

- Explain why polypeptides have such variable sequences.
- What factors limit the size and compositions of polypeptides?

2 Protein Purification and Analysis

KEY CONCEPTS

- Environmental conditions such as pH and temperature affect a protein's stability during purification.
- An assay based on a protein's chemical or binding properties may be used to quantify a protein during purification.
- Fractionation procedures take advantage of a protein's unique structure and chemistry in order to separate it from other molecules.

- Increasing the salt concentration causes selective “salting out” (precipitation) of proteins with different solubilities.
- A protein’s ionic charge, polarity, size, and ligand-binding ability influence its chromatographic behavior.
- Gel electrophoresis and its variations can separate proteins according to charge, size, and isoelectric point.
- The overall size and shape of macromolecules and larger assemblies can be assessed through ultracentrifugation.

Purification is an all but mandatory step in studying macromolecules, but it is not necessarily easy. Typically, a substance that makes up <math><0.1\%</math> of a tissue’s dry weight must be brought to $\sim 98\%$ purity. Purification problems of this magnitude would be considered unreasonably difficult by most synthetic chemists! The following sections outline some of the most common techniques for purifying and, to some extent, characterizing proteins. Most of these techniques can be used, sometimes in modified form, for nucleic acids and other types of biological molecules.

A Purifying a Protein Requires a Strategy

The task of purifying a protein present in only trace amounts was once so arduous that many of the earliest proteins to be characterized were studied in part because they are abundant and easily isolated. For example, hemoglobin, which accounts for about one-third the weight of red blood cells, has historically been among the most extensively studied proteins. Most of the enzymes that mediate basic metabolic processes or that are involved in the expression and transmission of genetic information are common to all species. For this reason, a given protein is frequently obtained from a source chosen primarily for convenience—for example, tissues from domesticated animals or easily obtained microorganisms such as *E. coli* and *Saccharomyces cerevisiae* (baker’s yeast).

Molecular cloning techniques (Section 3-5) allow almost any protein-encoding gene to be isolated from its parent organism, specifically altered (genetically engineered) if desired, and expressed at high levels in a microorganism. Indeed, the cloned protein may constitute up to 40% of the microorganism’s total cell protein (Fig. 5-2). This high level of protein production generally renders the cloned protein far easier to isolate than it would be from its parent organism (in which it may occur in vanishingly small amounts).

The first step in the isolation of a protein or other biological molecule is to get it out of the cell and into solution. Many cells require some sort of mechanical disruption to release their contents. Most of the procedures for lysing cells use some variation of crushing or grinding followed by filtration or centrifugation to remove large, insoluble particles. If the target protein is tightly associated with a lipid membrane, a detergent or organic solvent may be used to solubilize the lipids and recover the protein.

pH, Temperature, and Other Conditions Must Be Controlled to Keep Proteins Stable. Once a protein has been removed from its natural environment, it becomes exposed to many agents that can irreversibly damage it. These influences must be carefully controlled at all stages of a purification process. The following factors should be considered:

1. **pH.** Biological materials are routinely dissolved in buffer solutions effective in the pH range over which the materials are stable (buffers are described in Section 2-2C). Failure to do so could cause their **denaturation** (structural disruption), if not their chemical degradation.
2. **Temperature.** The thermal stability of proteins varies. Although some proteins denature at low temperatures, most proteins denature at high temperatures, sometimes only a few degrees higher than their native environment. Protein purification is normally carried out at temperatures near 0°C.

FIG. 5-2 Inclusion body. A genetically engineered organism that produces large amounts of a foreign protein often sequesters it in **inclusion bodies**. This electron micrograph shows an inclusion body of the protein prochlorosin in an *E. coli* cell.

- 3. Presence of degradative enzymes.** Destroying tissues to liberate the molecule of interest also releases degradative enzymes, including **proteases** and **nucleases**. Degradative enzymes can be inhibited by adjusting the pH or temperature to values that inactivate them (provided this does not adversely affect the protein of interest) or by adding compounds that specifically block their action.
- 4. Adsorption to surfaces.** Many proteins are denatured by contact with the air–water interface or with glass or plastic surfaces. Hence, protein solutions are handled so as to minimize foaming and are kept relatively concentrated.
- 5. Long-term storage.** All the factors listed above must be considered when a purified protein sample is to be kept stable. In addition, processes such as slow oxidation and microbial contamination must be prevented. Protein solutions are sometimes stored under nitrogen or argon gas (rather than under air, which contains ~21% O₂) and/or are frozen at –80°C or –196°C (the temperature of liquid nitrogen).

Proteins Are Quantified by Assays Purifying a substance requires some means for quantitatively detecting it. Accordingly, an **assay** must be devised that is specific for the target protein, highly sensitive, and convenient to use (especially if it must be repeated at every stage of the purification process).

Among the most straightforward protein assays are those for enzymes that catalyze reactions with readily detected products, because *the rate of product formation is proportional to the amount of enzyme present*. Substances with colored or fluorescent products have been developed for just this purpose. If no such substance is available for the enzyme being assayed, the product of the enzymatic reaction may be converted, by the action of another enzyme, to an easily quantified substance. This is known as a **coupled enzymatic reaction**. Proteins that are not enzymes can be detected by their ability to specifically bind certain substances or to produce observable biological effects.

Immunochemical procedures are among the most sensitive of assay techniques. **Immunoassays** use **antibodies**, proteins produced by an animal's immune system in response to the introduction of a foreign substance (an **antigen**). Antibodies recovered from the blood serum of an immunized animal or from cultures of immortalized antibody-producing cells bind specifically to the original protein antigen.

A protein in a complex mixture can be detected by its binding to its corresponding antibodies. In one technique, known as a **radioimmunoassay (RIA)**, the protein is indirectly detected by determining the degree to which it competes with a radioactively labeled standard for binding to the antibody. Another technique, the **enzyme-linked immunosorbent assay (ELISA)**, has many variations, one of which is diagrammed in **Fig. 5-3**.

Protein Concentrations Can Be Determined by Spectroscopy. The concentration of a substance in solution can be measured by **absorbance spectroscopy**. A solution containing a solute that absorbs light does so according to the **Beer-Lambert law**,

$$A = \log\left(\frac{I_0}{I}\right) = \epsilon cl \quad [5-1]$$

where **A** is the solute's **absorbance** (alternatively, its **optical density**), **I₀** is the intensity of the incident light at a given wavelength λ , **I** is its transmitted intensity at λ , ϵ is the **absorptivity** (alternatively, the **extinction coefficient**) of the solute at λ , **c** is its concentration, and **l** is the length of the light path in centimeters. The value of ϵ varies with λ ; a plot of **A** or ϵ versus λ for the solute is called its **absorption spectrum**. If the value of ϵ for a substance is known, then its concentration can be spectroscopically determined.

FIG. 5-3 Enzyme-linked immunosorbent assay. (1) An antibody against the protein of interest is immobilized on an inert solid such as polystyrene. (2) The solution to be assayed is applied to the antibody-coated surface. The antibody binds the protein of interest, and other proteins are washed away. (3) The protein–antibody complex is reacted with a second protein-specific antibody to which an enzyme is attached. (4) Binding of the second antibody–enzyme complex is measured by assaying the activity of the enzyme. The amount of substrate converted to product indicates the amount of protein present. **WPLS** See the Animated Process Diagrams.

? How would you assay the protein of interest if the second antibody had a fluorescent group or radioactive isotope rather than an enzyme attached to it?

FIG. 5-4 UV absorbance spectra of phenylalanine, tryptophan, and tyrosine. Here the molar absorptivity (ϵ when c is expressed in $\text{mol} \cdot \text{L}^{-1}$) for each aromatic amino acid is displayed on a log scale. [After Wetlaufer, D.B., *Adv. Prot. Chem.* **7**, 310 (1962).]

? Explain why a protein's absorption depends on its amino acid composition.

TABLE 5-2 Protein Purification Procedures

Protein Characteristic	Purification Procedure
Solubility	Salting out
Ionic Charge	Ion exchange chromatography Electrophoresis Isoelectric focusing
Polarity	Hydrophobic interaction chromatography
Size	Gel filtration chromatography SDS-PAGE
Binding Specificity	Affinity chromatography

Polypeptides absorb strongly in the ultraviolet (UV) region of the spectrum ($\lambda = 200$ to 400 nm) largely because their aromatic side chains (those of Phe, Trp, and Tyr) have particularly large extinction coefficients in this spectral region (ranging into the tens of thousands when c is expressed in $\text{mol} \cdot \text{L}^{-1}$; Fig. 5-4). However, polypeptides do not absorb visible light ($\lambda = 400$ to 800 nm), so they are colorless. Nevertheless, if a protein has a **chromophore** that absorbs in the visible region of the spectrum, this absorbance can be used to assay for the presence of the protein in a mixture of other proteins.

Purification Is a Stepwise Process. Proteins are purified by **fractionation procedures**. In a series of independent steps, the various physicochemical properties of the protein of interest are used to separate it progressively from other substances. The idea is not necessarily to minimize the loss of the desired protein, but to *eliminate selectively the other components of the mixture so that only the required substance remains*.

Protein purification is considered as much an art as a science, with many options available at each step. While a trial-and-error approach can work, knowing something about the target protein (or the proteins it is to be separated from) simplifies the selection of fractionation procedures. Some of the procedures we discuss and the protein characteristics they depend on are listed in **Table 5-2**.

B Salting Out Separates Proteins by Their Solubility

Because a protein contains multiple charged groups, its solubility depends on the concentrations of dissolved salts, the polarity of the solvent, the pH, and the temperature. Some or all of these variables can be manipulated to selectively precipitate certain proteins while others remain soluble.

The solubility of a protein at low ion concentrations increases as salt is added, a phenomenon called **salting in**. The additional ions shield the protein's multiple ionic charges, thereby weakening the attractive forces between individual protein molecules (such forces can lead to aggregation and precipitation). However, as more salt is added, particularly with sulfate salts, the solubility of the protein again decreases. This **salting out** effect is primarily a result of the competition between the added salt ions and the other dissolved solutes for molecules of solvent. At very high salt concentrations, so many of the added ions are solvated that there is significantly less bulk solvent available to dissolve other substances, including proteins.

Since different proteins have different ionic and hydrophobic compositions and therefore precipitate at different salt concentrations, salting out is the basis of one of the most commonly used protein purification procedures. Adjusting the salt concentration in a solution containing a mixture of proteins to just below the precipitation point of the protein to be purified eliminates many unwanted proteins from the solution (Fig. 5-5). Then, after removing the

FIG. 5-5 Fractionation by salting out. (a) The salt of choice, usually ammonium sulfate, is added to a solution of macromolecules to a concentration just below the precipitation point of the protein of interest. (b) After centrifugation, the unwanted precipitated proteins (*red spheres*) are discarded and more salt is added to the supernatant to a concentration sufficient to salt out the desired protein (*green spheres*). (c) After a second centrifugation, the protein is recovered as a precipitate, and the supernatant is discarded.

precipitated proteins by filtration or centrifugation, the salt concentration of the remaining solution is increased to precipitate the desired protein. This procedure results in a significant purification and concentration of large quantities of protein. Ammonium sulfate, $(\text{NH}_4)_2\text{SO}_4$, is the most commonly used reagent for salting out proteins because its high solubility (3.9 M in water at 0°C) allows the preparation of solutions with high ionic strength. The pH may be adjusted to approximate the isoelectric point (pI) of the desired protein because a protein is least soluble when its net charge is zero. The pI s of some proteins are listed in [Table 5-3](#).

C Chromatography Involves Interaction with Mobile and Stationary Phases

The process of **chromatography** (Greek: *chroma*, color + *graphein*, to write) was discovered in 1903 by Mikhail Tswett, who separated solubilized plant pigments using solid adsorbents. In most modern chromatographic procedures, a mixture of substances to be fractionated is dissolved in a liquid (the “mobile” phase) and percolated through a column containing a porous solid matrix (the “stationary” phase). As solutes flow through the column, they interact with the stationary phase and are retarded. The retarding force depends on the properties of each solute. If the column is long enough, substances with different rates of migration will be separated. The chromatographic procedures that are most useful for purifying proteins are classified according to the nature of the interaction between the protein and the stationary phase.

Early chromatographic techniques used strips of filter paper as the stationary phase, whereas modern column chromatography uses granular derivatives of cellulose, agarose, or dextran (all carbohydrate polymers) or synthetic substances such as cross-linked polyacrylamide or silica. **High-performance liquid chromatography (HPLC)** employs automated systems with precisely applied samples, controlled flow rates at high pressures (up to 5000 psi), a chromatographic matrix of specially fabricated 3- to 300- μm -diameter glass or plastic beads coated with a uniform layer of chromatographic material, and online sample detection. This greatly improves the speed, resolution, and reproducibility of the separation—features that are particularly desirable when chromatographic separations are repeated many times or when they are used for analytical rather than preparative purposes.

Ion Exchange Chromatography Separates Anions and Cations. In **ion exchange chromatography**, charged molecules bind to oppositely charged groups that are chemically linked to a matrix such as cellulose or agarose. Anions bind to cationic groups on **anion exchangers**, and cations bind to anionic groups on **cation exchangers**. Perhaps the most frequently used anion exchanger is a matrix with attached **diethylaminoethyl (DEAE)** groups, and the most frequently used cation exchanger is a matrix bearing **carboxymethyl (CM)** groups.

Proteins and other **polyelectrolytes** (polyionic polymers) that bear both positive and negative charges can bind to both cation and anion exchangers. *The binding affinity of a particular protein depends on the presence of other ions that compete with the protein for binding to the ion exchanger and on the pH of the solution, which influences the net charge of the protein.*

The proteins to be separated are dissolved in a buffer of an appropriate pH and salt concentration and are applied to a column containing the ion exchanger.

GATEWAY CONCEPT: Molecular Behavior

The exact charge and conformation of individual molecules vary in a population of otherwise identical molecules. For example, acid–base groups exist in equilibrium between protonated and unprotonated forms, and the vibrational and rotational motions of bonded atoms mean that macromolecules can assume a large number of subtly differing shapes. Techniques for isolating molecules are therefore based on the average chemical or physical properties of a population of molecules.

TABLE 5-3 Isoelectric Points of Several Common Proteins

Protein	pI
Pepsin	<1.0
Ovalbumin (hen)	4.6
Serum albumin (human)	4.9
Tropomyosin	5.1
Insulin (bovine)	5.4
Fibrinogen (human)	5.8
γ -Globulin (human)	6.6
Collagen	6.6
Myoglobin (horse)	7.0
Hemoglobin (human)	7.1
Ribonuclease A (bovine)	9.4
Cytochrome <i>c</i> (horse)	10.6
Histone (bovine)	10.8
Lysozyme (hen)	11.0
Salmine (salmon)	12.1

FIG. 5-6 Ion exchange chromatography. The tan region of the column represents the ion exchanger and the colored bands represent proteins. (a) A mixture of proteins dissolved in a small volume of buffer is applied to the top of the matrix in the column. (b) As elution progresses, the proteins separate into discrete bands as a result of their different affinities for the exchanger. In this diagram, the first protein (*red*) has passed through the column and has been isolated as a separate

fraction. The other proteins pass through the column more slowly. (c and d) The salt concentration in the eluant is increased to elute the remaining proteins. (e) The elution diagram of the protein mixture from the column. **WPLS** See the Animated Figures.

? How could ion exchange be used to concentrate a dilute solution of protein?

The column is then washed with the buffer (Fig. 5-6). As the column is washed, proteins with relatively low affinities for the ion exchanger move through the column faster than proteins that bind with higher affinities. The column effluent is collected in a series of fractions. Proteins that bind tightly to the ion exchanger can be **eluted** (washed through the column) by applying a buffer, called the **eluant**, that has a higher salt concentration or a pH that reduces the affinity with which the matrix binds the protein. In most cases, the separation is enhanced by gradually increasing the eluant's salt concentration or pH change over the course of the elution. The column effluent can be monitored for the presence of protein by measuring its absorbance at 280 nm. The eluted fractions can also be tested for the protein of interest using a more specific assay.

Hydrophobic Interaction Chromatography Purifies Nonpolar Molecules. Hydrophobic interactions between proteins and the chromatographic matrix can be exploited to purify the proteins. In **hydrophobic interaction chromatography**, the matrix material is lightly substituted with octyl or phenyl groups. At high salt concentrations, nonpolar groups on the surface of proteins "interact" with the hydrophobic groups; that is, both types of groups are excluded by the polar solvent (hydrophobic effects are augmented by increased ionic strength). The eluant is typically an aqueous buffer with decreasing salt concentrations, increasing concentrations of detergent (which disrupts hydrophobic interactions), or changes in pH.

Gel Filtration Chromatography Separates Molecules According to Size. In **gel filtration chromatography** (also called **size exclusion** or **molecular sieve chromatography**), molecules are separated according to their size and shape. The stationary phase consists of gel beads containing pores that span a relatively narrow size range. The pore size is typically determined by the extent of cross-linking between the polymers of the gel material. If an aqueous solution of molecules of various sizes is passed through a column containing such “molecular sieves,” the molecules that are too large to pass through the pores are excluded from the solvent volume inside the gel beads. *These large molecules therefore traverse the column more rapidly than small molecules that pass through the pores (Fig. 5-7).* Because the pore size in any gel varies to some degree, gel filtration can be used to separate a range of molecules; larger molecules with access to fewer pores elute sooner (i.e., in a smaller volume of eluant) than smaller molecules that have access to more of the gel’s interior volume.

Within the size range of molecules separated by a particular pore size, there is a linear relationship between the relative elution volume of a substance and the logarithm of its molecular mass (assuming the molecules have similar shapes). If a given gel filtration column is calibrated with several proteins of known molecular mass, the mass of an unknown protein can be conveniently estimated by its elution position.

FIG. 5-7 Gel filtration chromatography. (a) A gel bead consists of a gel matrix (wavy rods) that encloses an internal solvent space. Small molecules (red dots) can freely enter the internal space of the gel bead. Large molecules (blue dots) cannot penetrate the gel pores. (b) The sample solution is applied to the top of the column (the gel beads are represented as tan spheres). (c) The small molecules can penetrate the gel and consequently migrate through the column more slowly than the large molecules that are

excluded from the gel. (d and e) The large molecules elute first and are collected as fractions. Small molecules require a larger volume of solvent to elute. (f) The elution diagram, or chromatogram, indicating the complete separation of the two components. **WPLS See the Animated Figures.**

? How could gel filtration be used to reduce the salt concentration of a protein solution?

FIG. 5-8 Affinity chromatography. A ligand (shown here as *black dots*) is immobilized by covalently binding it to the chromatographic matrix. The orange, blue, and green shapes represent macromolecules whose cutout regions symbolize their ligand-binding sites. Only certain molecules (represented by *orange circles*) specifically bind to the ligand. The other components are washed through the column.

Affinity Chromatography Exploits Specific Binding Behavior. A striking characteristic of many proteins is their ability to bind specific molecules tightly but noncovalently. This property can be used to purify such proteins by **affinity chromatography** (Fig. 5-8). In this technique, a molecule (a **ligand**) that specifically binds to the protein of interest (e.g., a nonreactive analog of an enzyme's substrate) is covalently attached to an inert matrix. *When an impure protein solution is passed through this chromatographic material, the desired protein binds to the immobilized ligand, whereas other substances are washed through the column with the buffer.* The desired protein can then be recovered in highly purified form by changing the elution conditions to release the protein from the matrix. The great advantage of affinity chromatography is its ability to exploit the desired protein's unique biochemical properties rather than the small differences in physicochemical properties between proteins exploited by other chromatographic methods. Accordingly, the separation power of affinity chromatography for a specific protein is often greater than that of other chromatographic techniques.

Affinity chromatography columns can be constructed by chemically attaching small molecules or proteins to a chromatographic matrix. In **immunoaffinity chromatography**, an antibody is attached to the matrix to purify the protein against which the antibody was raised. In all cases, the ligand must have an affinity high enough to capture the protein of interest, but not so high as to prevent the protein's subsequent release without denaturing it. The bound protein can be eluted by washing the column with a solution containing a high concentration of free ligand or a solution of different pH or ionic strength.

In **metal chelate affinity chromatography**, a divalent metal ion such as Zn^{2+} or Ni^{2+} is attached to the chromatographic matrix so that proteins bearing metal-chelating groups (e.g., multiple His side chains) can be retained. Recombinant DNA techniques (Section 3-5) can be used to append a segment of six consecutive His residues, known as a **His tag**, to the N- or C-terminus of the polypeptide to be isolated. This creates a metal ion-binding site that allows the recombinant protein to be purified by metal chelate chromatography. After the protein has been eluted, usually by altering the pH, the His tag can be removed by the action of a specific protease whose recognition sequence separates the (His)₆ sequence from the rest of the protein.

D Electrophoresis Separates Molecules According to Charge and Size

Electrophoresis, the migration of ions in an electric field, is described in Section 3-4B. **Polyacrylamide gel electrophoresis (PAGE)** of proteins is typically carried out in polyacrylamide gels with a characteristic pore size, so *the molecular separations are based on gel filtration (size and shape) as well as electrophoretic mobility (electric charge)*. However, electrophoresis differs from gel filtration in that the electrophoretic mobility of smaller molecules is greater than the mobility of larger molecules with the same charge density. The pH of the gel is high enough (usually about pH 9) so that nearly all proteins have net negative charges and move toward the positive electrode when the current is switched on. Molecules of similar size and charge move as a band through the gel.

Following electrophoresis, the separated bands may be visualized in the gel by an appropriate technique, such as soaking the gel in a solution of a stain that binds tightly to proteins. If the proteins in a sample are radioactive, the gel can be dried and then clamped over a sheet of X-ray film. After a time, the film is developed and the resulting **autoradiograph** shows the positions of the radioactive components by a blackening of the film. If an antibody to a protein of interest is

FIG. 5-9 SDS-PAGE. Samples of proteins were electrophoresed from top (–) to bottom (+) in parallel lanes in a polyacrylamide slab, which was then stained to reveal the proteins. Lanes 1, 2, 10, and 17 contain molecular mass standards whose molecular masses are indicated on the left. [Image courtesy of Thermo Scientific Pierce Protein Research Products.]

available, it can be used to specifically detect the protein on a gel in the presence of many other proteins, a process called **immunoblotting** or **Western blotting** that is similar to ELISA (Fig. 5-3). Depending on the dimensions of the gel and the visualization technique used, samples containing less than a nanogram of protein can be separated and detected by gel electrophoresis.

SDS-PAGE Separates Proteins by Mass. In one form of polyacrylamide gel electrophoresis, the detergent sodium dodecyl sulfate (SDS)

is added to denature proteins. Amphiphilic molecules (Section 2-1C) such as SDS interfere with the hydrophobic interactions that normally stabilize proteins. Proteins assume a rodlike shape in the presence of SDS. Furthermore, most proteins bind SDS in a ratio of about 1.4 g SDS per gram protein (about one SDS molecule for every two amino acid residues). The large negative charge that the SDS imparts masks the proteins' intrinsic charge. The net result is that SDS-treated proteins have similar shapes and charge-to-mass ratios. **SDS-PAGE therefore separates proteins purely by gel filtration effects**, that is, according to molecular mass. **Figure 5-9** shows examples of the resolving power and the reproducibility of SDS-PAGE.

In SDS-PAGE, the relative mobilities of proteins vary approximately linearly with the logarithm of their molecular masses (**Fig. 5-10**). Consequently, the molecular mass of a protein can be determined with about 5 to 10% accuracy by electrophoresing it together with several “marker” proteins of known molecular masses that bracket that of the protein of interest. Because SDS disrupts noncovalent interactions between polypeptides, SDS-PAGE yields the molecular masses of the subunits of multisubunit proteins. The possibility that subunits are linked by disulfide bonds can be tested by preparing samples for SDS-PAGE in the presence and absence of a reducing agent, such as **2-mercaptoethanol** ($\text{HSCH}_2\text{CH}_2\text{OH}$), that breaks those bonds (Section 5-3A).

Capillary Electrophoresis Rapidly Separates Charged Molecules. Although gel electrophoresis in its various forms is highly effective at separating charged molecules, it can require up to several hours and is difficult to quantitate and automate. These disadvantages are largely overcome through the use of **capillary electrophoresis (CE)**, a technique in which electrophoresis is carried out in very thin capillary tubes (20- to 100- μm inner diameter). Such narrow capillaries rapidly dissipate heat and hence permit the use of very high electric fields, which reduces separation times to a few minutes. The CE

FIG. 5-10 Logarithmic relationship between the molecular mass of a protein and its electrophoretic mobility in SDS-PAGE. The masses of 37 proteins ranging from 11 to 70 kD are plotted. [After Weber, K. and Osborn, M., *J. Biol. Chem.* **244**, 4406 (1969).]

? What is the approximate mass of a protein with a relative mobility of 0.5?

techniques have extremely high resolution and can be automated in much the same way as is HPLC—that is, with automatic sample loading and online sample detection. Since CE can separate only small amounts of material, it is largely limited to use as an analytical tool.

Two-Dimensional Electrophoresis Resolves Complex Mixtures of Proteins. A protein has charged groups of both polarities and therefore has an isoelectric point, pI , at which it is immobile in an electric field. *If a mixture of proteins is electrophoresed through a solution or gel that has a stable pH gradient in which the pH increases smoothly from anode to cathode, each protein will migrate to the position in the pH gradient corresponding to its pI .* If a protein molecule diffuses away from this position, its net charge will change as it moves into a region of different pH and the resulting electrophoretic forces will move it back to its isoelectric position. Each species of protein is thereby “focused” into a narrow band about its pI . This type of electrophoresis is called **isoelectric focusing (IEF)**.

IEF can be combined with SDS-PAGE in an extremely powerful separation technique named **two-dimensional (2D) gel electrophoresis**. First, a sample of proteins is subjected to IEF in one direction, and then the separated proteins are subjected to SDS-PAGE in the perpendicular direction. This procedure generates an array of spots, each representing a protein (**Fig. 5-11**). Up to 5000 proteins have been observed on a single two-dimensional gel electrophoretogram.

Two-dimensional gel electrophoresis is a valuable tool for **proteomics**, a field of study that involves cataloging all of a cell’s expressed proteins with emphasis on their quantitation, localization, modifications, interactions, and activities. Individual protein spots in a stained 2D gel can be excised with a scalpel, destained, and the protein eluted from the gel fragment for identification and/or characterization, often by mass spectrometry (Section 5-3D). Two-dimensional electrophoretograms can be analyzed by computer after they have been scanned and digitized. This facilitates the detection of variations in the positions and intensities of protein spots in samples obtained from different tissues or under different growth conditions. Numerous reference 2D gels are publicly available for this purpose in the web-accessible databases listed at <http://world-2dpage.expasy.org/repository/>. These databases contain images of 2D gels of a variety of organisms and tissues and identify many of their component proteins. Their use is illustrated in Bioinformatics Project 2.

E Ultracentrifugation Separates Macromolecules by Mass

Macromolecules in solution do not respond to the earth’s gravity by settling, because their random thermal (Brownian) motion keeps them uniformly distributed

FIG. 5-11 Two-dimensional gel electrophoresis. In this example, *E. coli* proteins that had been labeled with ^{14}C -amino acids were subjected to isoelectric focusing (horizontally) followed by SDS-PAGE (vertically). More than 1000 spots can be resolved in the autoradiogram shown here.

Courtesy of Patrick O'Farrell, University of California at San Francisco

FIG. 5-12 Ultracentrifugation. The sample is layered onto a preformed sucrose density gradient (*left*). During centrifugation (*middle*), each particle sediments at a rate that depends largely on its mass. After centrifugation, the tube is punctured and the separated particles are collected (*right*). In some cases, the centrifuge tube is filled with a sample solution containing CsCl, which forms a density gradient as the tube spins.

throughout the solution. *Only when subjected to enormous accelerations do macromolecules begin to sediment, much like grains of sand in water.*

Modern versions of the **ultracentrifuge**, an instrument developed around 1923 by the Swedish biochemist The Svedberg, can attain rotational speeds as high as 100,000 rpm to generate centrifugal fields in excess of 1,000,000g. Using his original ultracentrifuge, Svedberg first demonstrated that proteins are macromolecules with homogeneous compositions and that many proteins contain subunits.

The rate at which a particle sediments in the ultracentrifuge is related to its mass (the density of the solution and the shape of the particle also affect the sedimentation rate). A protein's sedimentation coefficient (its sedimentation velocity per unit of centrifugal force) is usually expressed in units of 10^{-13} s, which are known as **Svedbergs (S)**. The relationship between molecular mass and sedimentation coefficient is not linear; therefore, values of sedimentation coefficients are not additive. The sedimentation coefficients of proteins range from about 1S to about 50S; viruses have sedimentation coefficients in the range of 40S to 1000S. Subcellular particles such as mitochondria have sedimentation coefficients of tens of thousands.

Today, ultracentrifugation is rarely used as an analytical tool, but it is useful for fractionating macromolecules. Typically, sedimentation is carried out in a solution of an inert substance in which the concentration, and therefore the density, of the solution increases from the top to the bottom of the centrifuge tube. Such **density gradients** can be generated by filling the centrifuge tube with layers of sucrose solutions of decreasing concentrations, with the sample of macromolecules on the very top. During centrifugation, each species of macromolecule moves through the preformed gradient at a rate largely determined by its sedimentation coefficient and therefore travels as a zone that can be separated from other such zones (**Fig. 5-12**). After centrifugation, the tube is punctured to collect fractions containing the separated macromolecules. Alternatively, the sample may be dissolved in a relatively concentrated solution of a dense, fast-diffusing substance such as CsCl, which forms a density gradient under the high gravitational field produced at high spin rates. The sample components form bands at positions where their densities are equal to that of the solution.

CHECKPOINT

- What are some environmental conditions that must be controlled while purifying a protein?
- Describe how a protein may be quantified by an assay or by absorbance spectroscopy.
- Explain how salting out is used in protein fractionation.
- Explain how an antibody could be useful for purifying a protein and for determining its concentration.
- Describe the basis for separating proteins by ion exchange, hydrophobic interaction, gel filtration, and affinity chromatography.
- Describe the processes of gel electrophoresis, SDS-PAGE, and 2D gel electrophoresis.
- What kinds of information can be gathered by ultracentrifugation?

3 Protein Sequencing

KEY CONCEPTS

- To be sequenced, a protein must be separated into individual polypeptides that can be cleaved into sets of overlapping fragments.
- The amino acid sequence can be determined by Edman degradation, a procedure for removing N-terminal residues one at a time.
- Mass spectrometry can identify amino acid sequences from the mass-to-charge ratios of gas-phase protein fragments.
- Protein sequence data are deposited in online databases.

WileyPLUS Learning Space

See **Guided Exploration**
Protein sequence determination

Once a pure sample of protein has been obtained, it may be used for a variety of purposes. However, if the protein has not previously been characterized, the next step is often determining its sequence of amino acid residues. Frederick Sanger determined the first known protein sequence, that of bovine insulin, in 1953, thereby definitively establishing that proteins have unique covalent structures (Box 5-1). Since then, many additional proteins have been sequenced, and the sequences of many more proteins have been inferred from their DNA sequences. All told, the amino acid sequences of around 50 million polypeptides comprising nearly 16 billion amino acid residues are now known. Such information is valuable for the following reasons:

1. Knowledge of a protein's amino acid sequence is a prerequisite for determining its three-dimensional structure and is essential for understanding its molecular mechanism of action.
2. Sequence comparisons among analogous proteins from different species yield insights into protein function and reveal evolutionary relationships among the proteins and the organisms that produce them.
3. Many inherited diseases are caused by mutations that result in an amino acid change in a protein. Amino acid sequence analysis can assist in the development of diagnostic tests and effective therapies.

Sanger's determination of the sequence of insulin's 51 residues (Fig. 5-1) took about 10 years and required ~100 g of protein. Procedures for primary structure determination have since been so refined and automated that most proteins can be sequenced within a few hours or days using only a few micrograms of material. Regardless of the technique used, the basic approach for sequencing proteins is similar to the procedure developed by Sanger. *The protein must be broken down into fragments small enough to be individually sequenced, and the primary structure of the intact protein is then reconstructed from the sequences of overlapping fragments (Fig. 5-13).* Such a procedure, as we have seen (Section 3-4C), is also used to sequence DNA.

A The First Step Is to Separate Subunits

The complete amino acid sequence of a protein includes the sequence of each of its subunits, if any, so the subunits must be identified and isolated before sequencing begins.

N-Terminal Analysis Reveals the Number of Different Types of Subunits. Each polypeptide chain (if it is not chemically blocked) has an N-terminal residue. *Identifying this "end group" can establish the number of chemically distinct polypeptides in a protein.* For example, insulin has equal amounts of the N-terminal residues Gly and Phe, which indicates that it has equal numbers of two nonidentical polypeptide chains.

The N-terminus of a polypeptide can be determined by several methods. The fluorescent compound **5-dimethylamino-1-naphthalenesulfonyl chloride (dansyl chloride)** reacts with primary amines to yield dansylated

PROCESS DIAGRAM

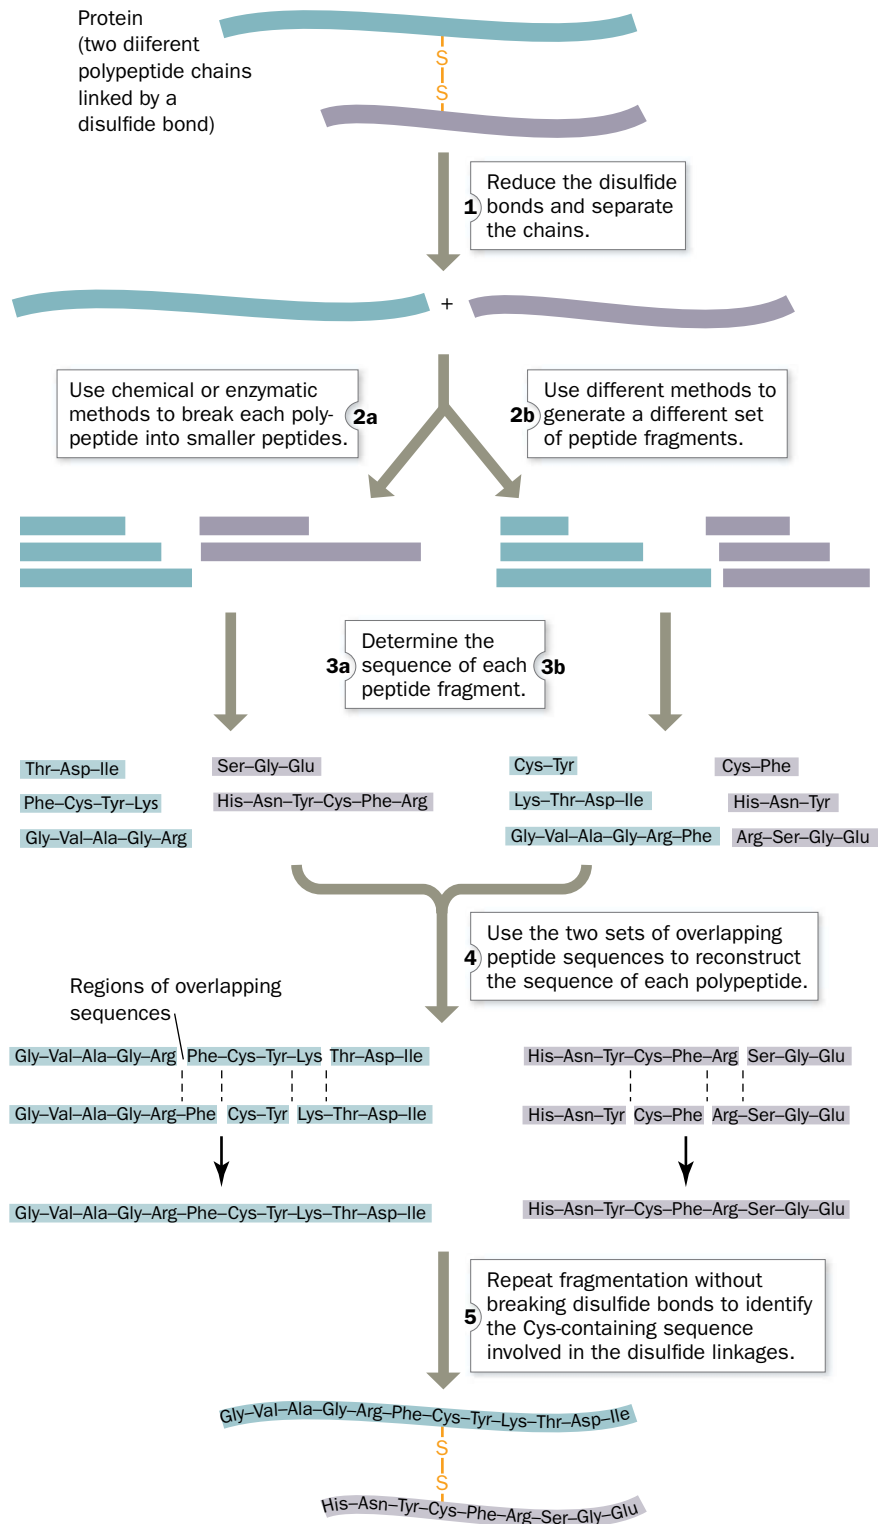

FIG. 5-13 Overview of protein sequencing. **WPLS** See the Animated Process Diagrams.

Frederick Sanger (1918–2013) At one time, many biochemists believed that proteins were amorphous “colloids” of variable size, shape, and composition. This view was largely abandoned by the 1940s, when it became possible to determine the amino acid composition of a protein—that is, the number of each kind of constituent amino acid. However, such information revealed nothing about the order in which the amino acids were combined. In fact, skeptics still questioned whether proteins even had unique sequences. One plausible theory was

that proteins were populations of related molecules that were probably assembled from shorter pieces. Some studies went so far as to describe the rules governing the relative stoichiometries and spacing of the various amino acids in proteins.

During the 1940s, the accuracy of amino acid analysis began to improve as a result of the development of chromatographic techniques for separating amino acids and the use of the reagent **ninhydrin**, which forms colored adducts with amino acids, for chemically quantifying them (previous methods used cumbersome biological assays). Frederick Sanger, who began his work on protein sequencing in 1943, used these new techniques as well as classic organic chemistry. Sanger did not actually set out to sequence a protein; his first experiments were directed toward devising a better method for quantifying free amino groups such as the amino groups corresponding to the N-terminus of a polypeptide.

Sanger used the reagent 2,4-dinitrofluorobenzene, which forms a yellow dinitrophenyl (DNP) derivative at terminal amino groups without breaking any peptide bonds.

When the protein is subsequently hydrolyzed to break its peptide bonds, the N-terminal amino acid retains its DNP label and can be identified when the hydrolysis products are separated by chromatography. Sanger found that some DNP-amino acid derivatives were unstable during hydrolysis, so this step had to be shortened. In comparing the results of long and short hydrolysis times, Sanger observed extra yellow spots corresponding to dipeptides or other small peptides with intact peptide bonds. He could then isolate the dipeptides and identify the second residue. Sanger's genius was to recognize that by determining the sequences of overlapping small peptides from an incompletely hydrolyzed protein, the sequence of the intact protein could be determined.

An enormous amount of work was required to turn the basic principle into a sound laboratory technique for sequencing a protein. Sanger chose insulin as his subject, because it was one of the smallest known proteins. Insulin contains 51 amino acids in two polypeptide chains (called A and B). The sequence of the 30 residues in the B chain was completed in 1951, and the sequence of the A chain (21 residues) in 1953. Because the two chains are linked through disulfide bonds, Sanger also endeavored to find the optimal procedure for cleaving those bonds and then identifying their positions in the intact protein, a task he completed in 1955.

Sanger's work of more than a decade, combining his expertise in organic chemistry (the cleavage and derivatization reactions) with the development of analytical tools for separating and identifying the reaction products, led to his winning a Nobel prize in 1958 [he won a second Nobel prize in 1980, for his invention of the chain-terminator method of nucleic acid sequencing (Section 3-4C)]. A testament to

Sanger's brilliance is that his basic approaches to sequencing polypeptides and nucleic acids are still widely used.

Publication of the sequence of insulin in 1955 convinced skeptics that a protein has a unique amino acid sequence. Sanger's work also helped catalyze thinking about the existence of a genetic code that would link the amino acid sequence of a protein to the nucleotide sequence of DNA, a molecule whose structure had just been elucidated in 1953.

Sanger, F., Sequences, sequences, sequences, *Annu. Rev. Biochem.* **57**, 1–28 (1988). [A scientific autobiography that provides a glimpse of the early difficulties in sequencing proteins.]

Sanger, F., Thompson, E.O.P., and Kitai, R., The amide groups of insulin, *Biochem. J.* **59**, 509–518 (1955).

polypeptides (**Fig. 5-14**). The treatment of a dansylated polypeptide with aqueous acid at high temperature hydrolyzes its peptide bonds. This liberates the dansylated N-terminal residue, which can then be separated chromatographically from the other amino acids and identified by its intense yellow fluorescence. The N-terminal residue can also be identified by performing the first step of Edman degradation (Section 5-3C), a procedure that liberates amino acids one at a time from the N-terminus of a polypeptide. SDS-PAGE of a protein (Section 5-2D) also reveals its number of different subunits.

Disulfide Bonds between and within Polypeptides Are Cleaved. Disulfide bonds between Cys residues must be cleaved to separate polypeptide chains—if they are disulfide-linked—and to ensure that polypeptide chains are fully linear (residues in polypeptides that are “knotted” with disulfide bonds may not be accessible to all the enzymes and reagents for sequencing). Disulfide bonds

FIG. 5-14 The dansyl chloride reaction. The reaction of dansyl chloride with primary amino groups is used for end group analysis.

can be reductively cleaved by treating them with 2-mercaptoethanol or another **mercaptan** (a compound that contains an —SH group):

The resulting free sulfhydryl groups are then alkylated, usually by treatment with **iodoacetate**, to prevent the re-formation of disulfide bonds through oxidation by O_2 :

B The Polypeptide Chains Are Cleaved

Polypeptides that are longer than 25 to 100 residues cannot be directly sequenced and must therefore be cleaved, either enzymatically or chemically, to specific fragments that are small enough to be sequenced. Various **endopeptidases** (enzymes that catalyze the hydrolysis of internal peptide bonds, as opposed to **exopeptidases**, which catalyze the hydrolysis of N- or C-terminal residues) can be used to fragment polypeptides. Both endopeptidases and exopeptidases (which collectively are called **proteases**) have side chain requirements for the residues flanking the scissile peptide bond (i.e., the bond that is to be cleaved; **Table 5-4**). The digestive enzyme **trypsin** has the greatest specificity and is therefore the most valuable member of the arsenal of endopeptidases used to fragment polypeptides. It cleaves peptide bonds on the C side (toward the carboxyl terminus) of the positively charged residues Arg and Lys if the next residue is not Pro.

The other endopeptidases listed in Table 5-4 exhibit broader side chain specificities than trypsin and often yield a series of peptide fragments with overlapping sequences. However, through **limited proteolysis**, that is, by adjusting reaction conditions and limiting reaction times, these less specific endopeptidases can yield a set of discrete, nonoverlapping fragments.

Several chemical reagents promote peptide bond cleavage at specific residues. The most useful of these, **cyanogen bromide** (CNBr), cleaves on the C side of Met residues (**Fig. 5-15**).

C Edman Degradation Removes a Peptide's N-Terminal Amino Acid Residue

Once the peptide fragments formed through specific cleavage reactions have been isolated, their amino acid sequences can be determined. This can be accomplished through repeated cycles of **Edman degradation**. In this process (named after its inventor, Pehr Edman), **phenylisothiocyanate** (PITC; also known as **Edman's reagent**) reacts with the N-terminal amino group of a polypeptide under mildly alkaline conditions to form a **phenylthiocarbamyl** (PTC) adduct (**Fig. 5-16**). This product is treated with anhydrous **trifluoroacetic acid**, which

FIG. 5-15 Cyanogen bromide cleavage of a polypeptide. CNBr reacts specifically with Met residues, resulting in cleavage of the peptide bond on their C-terminal side. The newly formed C-terminal residue forms a cyclic structure known as a **peptidyl homoserine lactone**.

TABLE 5-4 Specificities of Various Endopeptidases

$$\begin{array}{c} R_{n-1} \quad O \quad R_n \quad O \\ | \quad || \quad | \quad || \\ -NH-CH-C-NH-CH-C- \\ \uparrow \\ \text{Scissile} \\ \text{peptide bond} \end{array}$$

Enzyme	Source	Specificity	Comments
Trypsin	Bovine pancreas	R_{n-1} = positively charged residues: Arg, Lys; $R_n \neq$ Pro	Highly specific
Chymotrypsin	Bovine pancreas	R_{n-1} = bulky hydrophobic residues: Phe, Trp, Tyr; $R_n \neq$ Pro	Cleaves more slowly for R_{n-1} = Asn, His, Met, Leu
Elastase	Bovine pancreas	R_{n-1} = small neutral residues: Ala, Gly Ser, Val; $R_n \neq$ Pro	
Thermolysin	<i>Bacillus thermoproteolyticus</i>	R_n = Ile, Met, Phe, Trp, Tyr, Val; $R_{n-1} \neq$ Pro	Occasionally cleaves at R_n = Ala, Asp, His, Thr; heat stable
Pepsin	Bovine gastric mucosa	R_n = Leu, Phe, Trp, Tyr; $R_{n-1} \neq$ Pro	Also others; quite nonspecific; pH optimum = 2
Endopeptidase V8	<i>Staphylococcus aureus</i>	R_{n-1} = Glu	

cleaves the N-terminal residue as a thiazolinone derivative but does not hydrolyze other peptide bonds. Edman degradation therefore releases the N-terminal amino acid residue but leaves intact the rest of the polypeptide chain. The thiazolinone-amino acid is selectively extracted into an organic solvent and is converted to the more stable **phenylthiohydantoin (PTH)** derivative by treatment with aqueous acid. This PTH-amino acid can later be identified by chromatography.

The two steps of the peptide cleavage process take place under different conditions. Hence, *the amino acid sequence of a polypeptide chain can be determined from the N-terminus inward by subjecting the polypeptide to repeated cycles of Edman degradation and, after every cycle, identifying the newly liberated PTH-amino acid.*

The Edman degradation technique has been automated and refined, resulting in great savings of time and material. In the most advanced instruments, the peptide sample is dried onto a disk of glass fiber paper, and accurately measured quantities of reagents are delivered and products removed as vapors in a stream of argon at programmed intervals. Up to 100 residues can be identified before the cumulative effects of incomplete reactions, side reactions, and peptide loss make further amino acid identification unreliable. Since less than a picomole of a PTH-amino acid can be detected and identified, sequence analysis can be carried out on as little as 5 to 10 pmol of a peptide (<0.1 μg —an invisibly small amount).

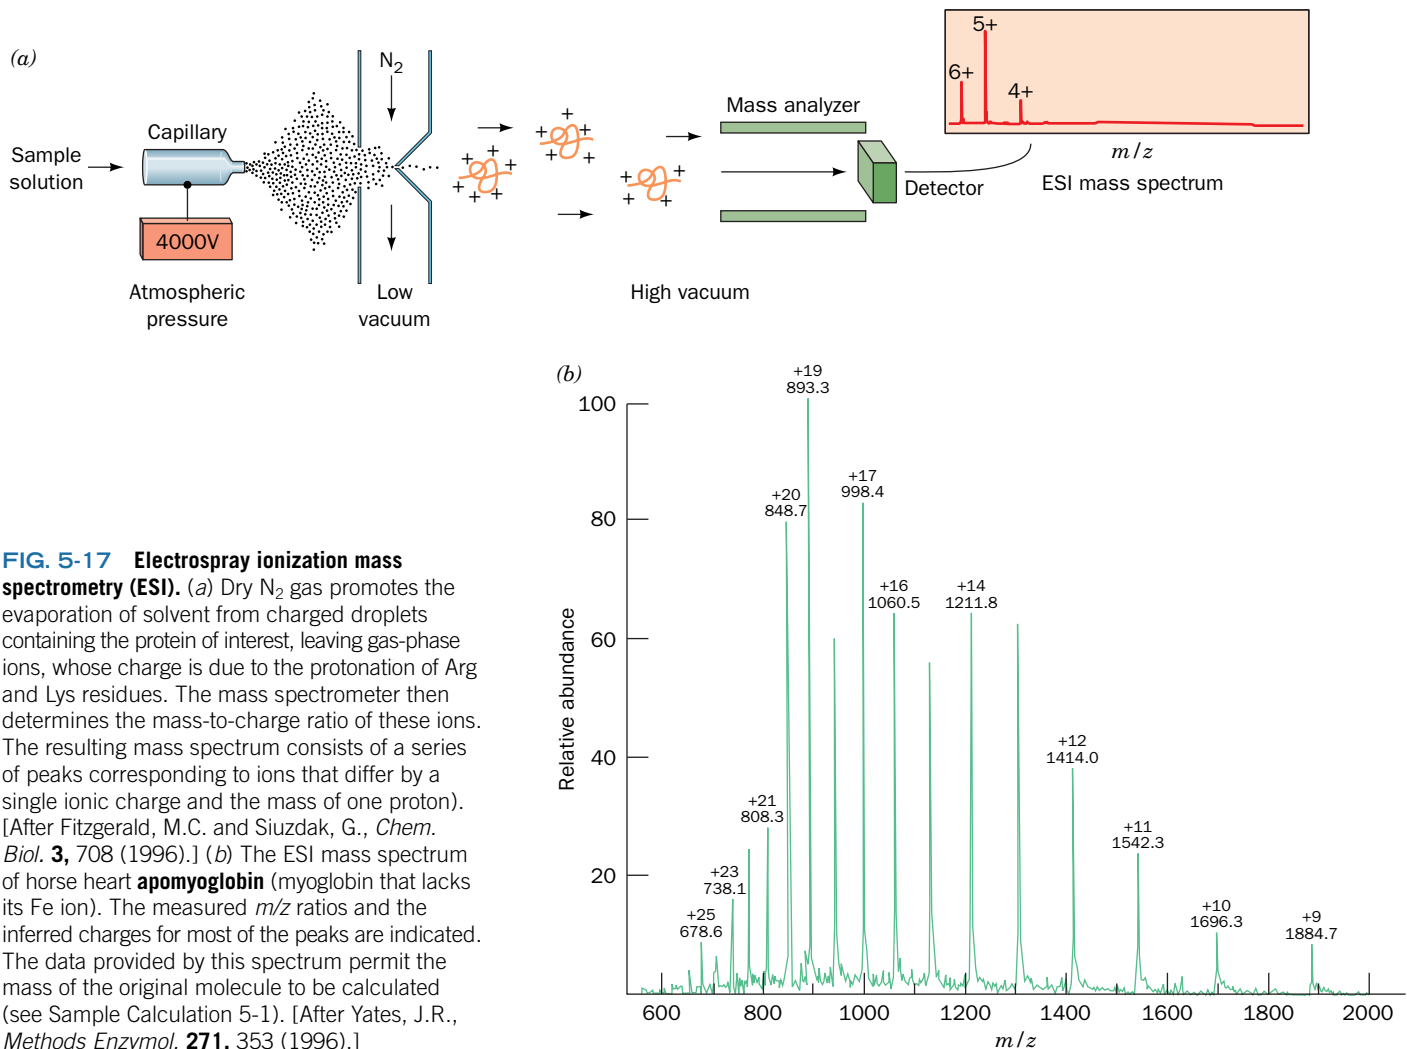

FIG. 5-17 Electrospray ionization mass spectrometry (ESI). (a) Dry N_2 gas promotes the evaporation of solvent from charged droplets containing the protein of interest, leaving gas-phase ions, whose charge is due to the protonation of Arg and Lys residues. The mass spectrometer then determines the mass-to-charge ratio of these ions. The resulting mass spectrum consists of a series of peaks corresponding to ions that differ by a single ionic charge and the mass of one proton. [After Fitzgerald, M.C. and Siuzdak, G., *Chem. Biol.* **3**, 708 (1996).] (b) The ESI mass spectrum of horse heart **apomyoglobin** (myoglobin that lacks its Fe ion). The measured m/z ratios and the inferred charges for most of the peaks are indicated. The data provided by this spectrum permit the mass of the original molecule to be calculated (see Sample Calculation 5-1). [After Yates, J.R., *Methods Enzymol.* **271**, 353 (1996).]

D Peptides Can Be Sequenced by Mass Spectrometry

Mass spectrometry has emerged as the dominant technique for characterizing and sequencing proteins. Mass spectrometry accurately measures the mass-to-charge (m/z) ratio for ions in the gas phase (where m is the ion's mass and z is its charge). Until about 1985, macromolecules such as proteins and nucleic acids could not be analyzed by mass spectrometry. This was because macromolecules were destroyed during the production of gas-phase ions, which required vaporization by heating followed by ionization via bombardment with electrons.

Newer techniques have addressed this shortcoming. For example, in **electrospray ionization (ESI)**, a method developed by John Fenn, a solution of a macromolecule such as a peptide is sprayed from a narrow capillary tube maintained at high voltage (~ 4000 V), forming fine, highly charged droplets from which the solvent rapidly evaporates (Fig. 5-17a). This yields a series of gas-phase macromolecular ions that typically have ionic charges in the range $+0.5$ to $+2$ per kilodalton. The charges result from the protonation of basic side chains such as Arg and Lys. The ions are directed into the mass spectrometer, which measures their m/z values with an accuracy of $\sim 0.01\%$ (Fig. 5-17b). Consequently, determining an ion's z permits its molecular mass to be determined with far greater accuracy than by any other method (see Sample Calculation 5-1).

Mass spectrometry can be used to identify a protein. For example, in a technique known as **protein mass fingerprinting**, an unidentified protein (e.g., extracted from a spot in a 2D gel electrophoretogram; Fig. 5-11) is cleaved into defined fragments, as described in Section 5-3B, and their masses are determined. The members of a database of proteins of known sequences (see below) are theoretically subjected to the same cleavage method and the masses of the resulting peptides are calculated. A match between the experimental and a theoretical set of masses identifies the protein.

Short polypeptides (<25 residues) can be directly sequenced through the use of a tandem mass spectrometer (two mass spectrometers coupled in series; Fig. 5-18). The first mass spectrometer functions to select and separate the peptide ion of interest from peptide ions of different masses, as well as any contaminants that may be present. The selected peptide ion is then passed into a collision cell, where it collides with chemically inert atoms such as helium. The energy thereby imparted to the peptide ion causes it to fragment predominantly at only one of its several peptide bonds, thereby yielding one or two charged fragments per original ion. The molecular masses of the numerous charged fragments so produced are then determined by the second mass spectrometer.

By comparing the molecular masses of successively larger members of a family of fragments, the molecular masses and therefore the identities of successive

FIG. 5-18 Tandem mass spectrometry in peptide sequencing. Electrospray ionization (ESI), the ion source, generates gas-phase peptide ions, labeled P_1 , P_2 , etc., from a digest of the protein to be sequenced. These peptides are separated by the first mass spectrometer (MS-1) according to their m/z values, and one of them (here, P_3) is directed into the collision cell, where it collides with helium atoms. This treatment breaks the peptide into fragments (F_1 , F_2 , etc.), which are directed into the second mass spectrometer (MS-2) for determination of their m/z values. This latter process is carried out for each of the P_n peptide ions. [After Biemann, K. and Scoble, H.A., *Science* **237**, 992 (1987).]

SAMPLE CALCULATION 5-1

An ESI mass spectrum such as that of apomyoglobin (Fig. 5-17b) contains a series of peaks, each corresponding to the m/z ratio of an $(M + nH)^{n+}$ ion. Two successive peaks in this mass spectrum have measured m/z ratios of 1414.0 and 1542.3. What is the molecular mass of the original apomyoglobin molecule, how does it compare with the value given for it in Table 5-1, and what are the charges of the ions causing these peaks?

The first peak ($p_1 = 1414.0$) arises from an ion with charge z and mass $M + z$, where M is the molecular mass of the original protein. Then the adjacent peak ($p_2 = 1542.3$), which is due to an ion with one less proton, has charge $z - 1$ and mass $M + z - 1$. The m/z ratios for these ions, p_1 and p_2 , are therefore given by the following expressions.

$$p_1 = (M + z)/z$$

$$p_2 = (M + z - 1)/(z - 1)$$

These two linear equations can readily be solved for their unknowns, M and z . Solve the first equation for M .

$$M = z(p_1 - 1)$$

Then plug this result into the second equation.

$$p_2 = \frac{z(p_1 - 1) + z - 1}{z - 1}$$

$$= \frac{zp_1 - 1}{z - 1}$$

$$zp_2 - p_2 = zp_1 - 1$$

$$z = (p_2 - 1)/(p_2 - p_1)$$

$$M = (p_2 - 1)/(p_1 - 1)/(p_2 - p_1)$$

Plugging in the values for p_1 and p_2 ,

$$M = (1542.3 - 1)(1414.0 - 1) / (1542.3 - 1414.0) = 16,975D$$

which is only 0.14% larger than the 16,951 D for horse apomyoglobin given in Table 5-1. For the charge on ion 1,

$$z = (1542.3 - 1)/(1542.3 - 1414.0) = +12$$

The ionic charge on ion 2 is $12 - 1 = +11$.

WPLS See Sample Calculation Videos.

FIG. 5-19 Determining the positions of disulfide bonds.

amino acid residues in a polypeptide are determined. Computerization of the mass-comparison process has reduced the time required to sequence a short polypeptide to only a few minutes (one cycle of Edman degradation may take an hour). However, mass spectrometry cannot distinguish the isomeric residues Ile and Leu because they have exactly the same mass, and it cannot always reliably distinguish Gln and Lys residues because their molecular masses differ by only 0.036 D. Mass spectrometry can be used to sequence peptides with chemically blocked N-termini (which prevents Edman degradation) and to characterize other posttranslational modifications such as the addition of phosphate or carbohydrate groups.

E Reconstructed Protein Sequences Are Stored in Databases

After individual peptide fragments have been sequenced, their order in the original polypeptide must be elucidated. This, as is indicated in Fig. 5-13, is accomplished by conducting a second round of protein cleavage with a reagent of different specificity and then comparing the amino acid sequences of the overlapping sets of peptide fragments. The reads in DNA sequencing are similarly ordered (Section 3-4C).

The final step in an amino acid sequence analysis is to determine the positions (if any) of the disulfide bonds. This can be done by cleaving a sample of the protein, with its disulfide bonds intact, to yield pairs of peptide fragments, each containing a single Cys, that are linked by a disulfide bond. After isolating a disulfide-linked polypeptide fragment, the disulfide bond is cleaved and alkylated (Section 5-3A), and the sequences of the two peptides are determined (Fig. 5-19). The various pairs of such polypeptide fragments are identified by comparing their sequences with that of the protein, thereby establishing the locations of the disulfide bonds.

Sequences Are Recorded in Databases. After a protein's amino acid sequence has been determined, the information is customarily deposited in a public database. Databases for proteins as well as DNA sequences are accessible via the Internet (Table 5-5). Electronic links between databases allow rapid updates and cross-checking of sequence information.

Most sequence databases use similar conventions. For example, the protein may be given an ID code that includes information about its source (e.g., HUMAN or ECOLI). This is accompanied by an accession number, which is assigned by the database as a way of identifying an entry even if its ID code must be changed (for example, see Fig. 5-20). The entry includes a description of the protein, its function (if known), its sequence, and features such as disulfide bonds, posttranslational modifications, and binding sites. The entry ends with a list of pertinent references (which are linked to PubMed) and links to other databases.

Q15848 - ADIPO_HUMAN

Protein: **Adiponectin**
Gene: **ADIPOQ**
Organism: **Homo sapiens (Human)**

Status: **Reviewed** • Annotation score: ********* • Experimental evidence at protein level¹

Function¹
Important adipokine involved in the control of fat metabolism and insulin sensitivity, with direct anti-diabetic, anti-atherogenic and anti-inflammatory activities. Stimulates AMPK phosphorylation and activation in the liver and the skeletal muscle, enhancing glucose utilization and fatty-acid combustion. Antagonizes TNF-alpha by negatively regulating its expression in various tissues such as liver and macrophages, and also by counteracting its effects. Inhibits endothelial NF-kappa-B signaling through a cAMP-dependent pathway. May play a role in cell growth, angiogenesis and tissue remodeling by binding and sequestering various growth factors with distinct binding affinities, depending on the type of complex, LMW, HMW or HMW-H.

This information pertains to the protein **adiponectin**, which is produced by adipose (fat) tissue and helps regulate fuel metabolism (Section 22-3B). The complete entry includes additional information and references as well as the protein's sequence. [*Nucleic Acids Res.* **43**, D204-D212 (2015). UniProtKB/Swiss-Prot entry Q15848]

Armed with the appropriate software (which is often publicly available at the database sites), a researcher can search a database to find proteins with similar sequences in various organisms. The sequence of even a short peptide fragment may be sufficient to “fish out” the parent protein or its counterpart from another species (see the Bioinformatics Projects).

Protein sequence information is no less valuable when the base sequence of the corresponding gene is known, because a protein sequence provides information about protein structure that is not revealed by nucleic acid sequencing (see Section 3-4). For example, only direct protein sequencing can reveal the locations of disulfide bonds in proteins. In addition, many proteins are modified after they are synthesized. For example, certain residues may be excised to produce the “mature” protein (insulin, shown in Fig. 5-1, is actually synthesized as an 84-residue polypeptide, whose central 31-residue so-called C-chain is proteolytically removed to yield the mature two-chain form). Amino acid side chains may also be modified by the addition of carbohydrates, phosphate groups, or acetyl groups, to name only a few. Although some of these modifications occur at characteristic amino acid sequences and are therefore identifiable in nucleotide sequences, only the actual protein sequence can confirm whether and where they occur. Conversely, gene sequences can be used to eliminate the ambiguities in the corresponding protein sequences.

CHECKPOINT

- Summarize the steps involved in sequencing a protein.
- Why is it important to identify the N-terminal residue(s) of a protein?
- What are some advantages of sequencing peptides by mass spectrometry rather than by Edman degradation?
- Explain why long polypeptides must be broken into at least two different sets of peptide fragments for sequencing.
- What types of information can be retrieved from a protein sequence database?

4 Protein Evolution

KEY CONCEPTS

- Sequence comparisons reveal the evolutionary relationships between proteins.
- Protein families evolve by the duplication and divergence of genes encoding protein domains.
- The rate of evolution varies from protein to protein.

Because an organism's genetic material specifies the amino acid sequences of all its proteins, changes in genes due to random mutation can alter a protein's

Number of different amino acids: 1 3 5 5 5 1 3 3 4 1 4 3 2 1 3 1 1 1 1 4 2 4 1 2 3 2 1 4 1 1 2 1 5 1 3 3 2 1 3 2 1 3 3

^aThe amino acid side chains have been shaded according to their polarity characteristics so that an invariant or conservatively substituted residue is identified by a vertical band of a single color. The letter a at the beginning of the chain indicates that the N-terminal amino group is acetylated; an h indicates that the acetyl group is absent.

? How different are the human and rhesus monkey sequences? How different are the rhesus monkey and horse sequences?

primary structure. A mutation in a protein is propagated only if it somehow increases, or at least does not decrease, the probability that its owner will survive to reproduce. Many mutations are deleterious or produce lethal effects and therefore rapidly die out. On rare occasions, however, a mutation arises that improves the fitness of its host under the prevailing conditions. This is the essence of **evolution** by **natural selection**.

A Protein Sequences Reveal Evolutionary Relationships

The primary structures of a given protein from related species closely resemble one another. Consider **cytochrome c**, a protein found in nearly all eukaryotes. Cytochrome *c* is a component of the mitochondrial electron-transport system (Section 18-2), which is believed to have taken its present form between 1.5 and 2 billion years ago, when organisms developed mechanisms for aerobic respiration. Emanuel Margoliash, Emil Smith, and others elucidated the amino acid sequences of the cytochromes *c* from more than 100 eukaryotic species ranging in complexity from yeast to humans. The cytochromes *c* from different species are single polypeptides of 104 to 112 residues. The sequences of 38 of these proteins are arranged in **Table 5-6** to show the similarities between

vertically aligned residues (the residues have been color-coded according to their physical properties). A survey of the aligned sequences (bottom line of Table 5-6) shows that the same amino acid residue appears at 38 positions in all species (23 positions in the complete set of >100 sequences). Most of the remaining positions are occupied by chemically similar residues in different organisms. In only eight positions does the sequence accommodate six or more different residues.

Evolutionary theory indicates that related species have evolved from a common ancestor, so it follows that the genes specifying each of their proteins must likewise have evolved from the corresponding gene in that ancestor. The sequence of the ancestral cytochrome *c* is accessible only indirectly, by examining the sequences of extant proteins.

Sequence Comparisons Provide Information on Protein Structure and Function. *In general, comparisons of the primary structures of **homologous proteins** (evolutionarily related proteins) indicate which of the protein's residues are essential to its function, which are less significant, and which have little specific function.* Finding the same residue at a particular position in the amino acid sequence of a series of related proteins suggests that the chemical or structural properties of that so-called **invariant residue** uniquely suit it to some essential function of the protein. For example, its side chain may be necessary for binding another molecule or for participating in a catalytic process. Other amino acid positions may have less stringent side chain requirements and can therefore accommodate residues with similar characteristics (e.g., Asp or Glu, Ser or Thr, etc.); such positions are said to be **conservatively substituted**. On the other hand, a particular amino acid position may tolerate many different amino acid residues, indicating that the functional requirements of that position are rather nonspecific. Such a position is said to be **hypervariable**.

Why is cytochrome *c*—an ancient and essential protein—not identical in all species? Even a protein that is well adapted to its function, that is, one that is not subject to physiological improvement, nevertheless continues evolving. The random nature of mutational processes will, in time, change such a protein in ways that do not significantly affect its function, a process called **neutral drift** (deleterious mutations are, of course, rapidly rejected through natural selection). Hypervariable residues are apparently particularly subject to neutral drift.

Phylogenetic Trees Depict Evolutionary History. Far-reaching conclusions about evolutionary relationships can be drawn by comparing the amino acid sequences of homologous proteins (or their corresponding DNA sequences). The simplest way to assess evolutionary differences is to count the amino acid differences between proteins. For example, the data in Table 5-6 show that primate cytochromes *c* more nearly resemble those of other mammals than they do those of insects (8–12 differences among mammals versus 26–31 differences between mammals and insects). Similarly, the cytochromes *c* of fungi differ as much from those of mammals (45–51 differences) as they do from those of insects (41–47) or higher plants (47–54). The order of these differences largely parallels that expected from classical taxonomy, which is based primarily on morphological rather than molecular characteristics.

The amino acid or DNA sequences of homologous proteins can be analyzed by computer to construct a **phylogenetic tree**, a diagram that indicates the ancestral relationships among organisms that produce the protein. The phylogenetic tree for cytochrome *c* is sketched in Fig. 5-21. Similar trees have been derived for other proteins. Each branch point of the tree represents a putative common ancestor for all the organisms above it. The distances between branch points are expressed as the number of amino acid differences per 100 residues of the protein. Such trees present a more quantitative measure of the degree of relatedness of the various species than macroscopic taxonomy can provide.

Note that the evolutionary distances from all modern cytochromes *c* to the lowest point, the earliest common ancestor producing this protein, are approximately the same. Thus, “lower” organisms do not represent life-forms that appeared early in history and ceased to evolve further. The cytochromes *c* of all the species included in Fig. 5-21—whether called “primitive” or “advanced”—have evolved to about the same extent.

B Proteins Evolve by the Duplication of Genes or Gene Segments

The effort to characterize protein evolution and create databases of related proteins was pioneered by Margaret Dayhoff, beginning in the 1960s. Since then,

FIG. 5-21 Phylogenetic tree of cytochrome *c*. Each branch point represents an organism ancestral to the species connected above it. The number beside each branch indicates the number of inferred differences per 100 residues between the cytochromes *c* of the flanking branch points or species. Note that existing organisms are located only

at the periphery of the phylogenetic tree. [After Dayhoff, M.O., Park, C.M., and McLaughlin, P.J., in Dayhoff, M.O. (Ed.), *Atlas of Protein Sequence and Structure*, p. 8, National Biomedical Research Foundation (1972).]

more than 50 million protein sequences have been catalogued as the result of direct protein sequencing or DNA sequencing projects. This has led to the development of mathematically sophisticated computer algorithms to identify similarities between sequences. These search protocols can detect similarities between proteins that have evolved to the extent that their amino acid sequences are <20% identical and have acquired several sequence insertions and/or deletions of various lengths. The use of such sequence alignment programs, which are publicly available, is demonstrated in Bioinformatics Project 2.

Analysis of a large number of proteins indicates that evolutionarily conserved sequences are often segments of about 40 to 200 residues, called **domains**. Originally, this term referred to a portion of discrete protein structure, but the usage has expanded to include the corresponding amino acid sequence. As we shall see in Section 6-2D, structural similarities between two domains may be apparent even when the sequences have few residues in common.

Protein domains can be grouped into an estimated 1000–1400 different families, but about half of all known domains fall into just 200 families. Most protein

families have only a few members, and 10–20% of proteins appear to be unique, although it is also possible that they represent family members whose sequences have simply diverged beyond recognition. Domains whose sequences are more than about 40% identical usually have the same function; domains with less than about 25% sequence identity usually perform different roles.

Protein Families Can Arise through Gene Duplication. It is not surprising that proteins with similar functions have similar sequences; such proteins presumably evolved from a common ancestor. Homologous proteins with the same function in different species (e.g., the cytochromes *c* shown in Table 5-6) are said to be **orthologous**.

Within a species, similar proteins arise through **gene duplication**, an aberrant genetic recombination event in which one member of a chromosome pair acquires both copies of the primordial gene (genetic recombination is discussed in Section 25-6). Following duplication, the sequences may diverge as mutations occur over time. *Gene duplication is a particularly efficient mode of evolution because one copy of the gene evolves a new function through natural selection while its counterpart continues to direct the synthesis of the original protein.* Two independently evolving genes that are derived from a duplication event are said to be **paralogous**. In prokaryotes, approximately 60% of protein domains have been duplicated; in many eukaryotes the figure is ~90%, and in humans, ~98%.

The **globin** family of proteins provides an excellent example of evolution through gene duplication and divergence. **Hemoglobin**, which transports O₂ from the lungs (or gills or skin) to the tissues, is a tetramer with the subunit composition $\alpha_2\beta_2$ (i.e., two α polypeptides and two β polypeptides). The sequences of the α and β subunits are similar to each other and to the sequence of the protein **myoglobin**, which facilitates oxygen diffusion through muscle tissue (hemoglobin and myoglobin are discussed in more detail in Chapter 7). The primordial globin probably functioned simply as an oxygen-storage protein. Gene duplication allowed one globin to evolve into a monomeric hemoglobin α chain. Duplication of the α chain gene gave rise to the paralogous gene for the β chain. Other members of the globin family include the β -like γ chain that is present in fetal hemoglobin, an $\alpha_2\gamma_2$ tetramer, and the β -like ϵ and α -like ζ chains that appear together early in embryogenesis as $\zeta_2\epsilon_2$ hemoglobin. Primates contain a relatively recently duplicated globin, the β -like δ chain, which appears as a minor component (~1%) of adult hemoglobin. Although the $\alpha_2\delta_2$ hemoglobin has no known unique function, perhaps it may eventually evolve one. The genealogy of the members of the globin family is diagrammed in Fig. 5-22. The human genome also contains the relics of globin genes that are not expressed. These **pseudogenes** can be considered the dead ends of protein evolution. Note that a duplicated and therefore initially superfluous gene has only a limited time to evolve a new functionality that provides a selective advantage to its host before it is inactivated through mutation, that is, becomes a pseudogene.

FIG. 5-22 Genealogy of the globin family.

Each branch point represents a gene duplication event. Myoglobin is a single-chain protein. The globins identified by Greek letters are subunits of hemoglobins.

The Rate of Sequence Divergence Varies. The sequence differences between orthologous proteins can be plotted against the time when, according to the fossil record, the species producing the proteins diverged. The plot for a given protein is essentially linear, indicating that its mutations accumulate at a constant rate over a geological time scale. However, rates of evolution vary among proteins (Fig. 5-23). This does not imply that the rates of mutation of the DNAs specifying those proteins differ, but rather that *the rate at which mutations are accepted into a protein varies*.

A major contributor to the rate at which a protein evolves is the effect of amino acid changes on the protein's function. For example, Fig. 5-23 shows that **histone H4**, a protein that binds to DNA in eukaryotes (Section 24-5A), is among

FIG. 5-23 Rates of evolution of four proteins. The graph was constructed by plotting the number of different amino acid residues in the proteins on two sides of a branch point of a phylogenetic tree versus the time, according to the fossil record, since the corresponding species diverged from their common ancestor. [Illustration, Irving Geis/Geis Archives Trust. Copyright Howard Hughes Medical Institute. Reproduced with permission.]

the most highly conserved proteins (the histones H4 from peas and cows, species that diverged 1.2 billion years ago, differ by only two conservative changes in their 102 residues). Evidently, histone H4 is so finely tuned to its function of packaging DNA in cells that it is extremely intolerant of any mutations. Cytochrome *c* is only slightly more tolerant. It is a relatively small protein that binds to several other proteins. Hence, any changes in its amino acid sequence must be compatible with all its binding partners (or they would have to simultaneously mutate to accommodate the altered cytochrome *c*, an unlikely event). Hemoglobin, which functions as a free-floating molecule, is subject to less selective pressure than histone H4 or cytochrome *c*, so its surface residues are more easily substituted by other amino acids. The **fibrinopeptides** are ~20-residue fragments that are cleaved from the vertebrate protein **fibrinogen** to induce blood clotting (Box 11-4). Once they have been removed, the fibrinopeptides are discarded, so that they are subject to little selective pressure to maintain their amino acid sequences.

The rate of protein evolution also depends on the protein's structural stability. For example, a mutation that slowed the rate at which a newly synthesized polypeptide chain folds into its functional three-dimensional shape could affect the cell's survival, even if the protein ultimately functioned normally. Such mutations would be especially critical for proteins that are produced at high levels, since the not-yet-folded proteins could swamp the cell's protein-folding mechanisms. In fact, the genes for highly expressed proteins appear to evolve more slowly than the genes for rarely expressed proteins.

Mutational changes in proteins do not account for all evolutionary changes among organisms. The DNA sequences that control the expression of proteins (Chapters 26, 27, and 28) are also subject to mutation. These sequences control where, when, and how much of the corresponding protein is made. Thus, although the proteins of humans and chimpanzees are >99% identical on average (e.g., their cytochromes *c* are identical), their anatomical and behavioral differences are so great that they are classified as belonging to different families.

Many Proteins Contain Domains That Occur in Other Proteins. Gene duplication is not the only mechanism that generates new proteins. Analysis of protein sequences has revealed that many proteins, particularly those made by eukaryotes, are mosaics of sequence motifs or domains of about 40–100 amino acid residues.

- Unique domain

FIG. 5-24 Construction of some multidomain proteins. Each shape represents a segment of ~40 to 100 residues that appears, with some sequence variation, several times in the same protein or in a number of related proteins. (a) **Fibronectin**, an ~500-kD protein of the extracellular matrix, is composed mostly of repeated domains of three types.

(b) Some of the proteins that participate in blood clotting are built from a small set of domains. (The epidermal growth factor domain is so named because it was first observed as a component of **epidermal growth factor**.) [After Baron, M., Norman, D.G., and Campbell, I.D., *Trends Biochem. Sci.* **16**, 14 (1991).]

CHECKPOINT

- How can sequence comparisons reveal which amino acid residues are essential for a protein's function?
- Using Table 5-6, identify some invariant, conservative, and hypervariable positions. What types of amino acids appear at conservatively substituted sites?
- Explain how the number of amino acid differences between homologous proteins can be used to construct a phylogenetic tree.
- Explain the origin of orthologous proteins, paralogous proteins, and multidomain proteins.
- Why do different proteins appear to evolve at different rates?

These domains occur in several other proteins in the same organism and may be repeated numerous times within a given protein (**Fig. 5-24a**). For example, most of the proteins involved in blood clotting are composed of sets of smaller domains (**Fig. 5-24b**). The sequence identity between homologous domains is imperfect since each domain evolves independently. The functions of individual domains are not always known: Some appear to have discrete activities, such as catalyzing a certain chemical reaction or binding a particular molecule, but others may merely be spacers or scaffolding for other domains.

We will see in Section 25-6C how gene segments encoding protein domains are copied and inserted into other positions in a genome to generate new genes that encode proteins with novel sequences. Such domain shuffling is a much faster process than the duplication of an entire gene followed by its evolution of a new functionality. Nevertheless, both mechanisms have played important roles in the evolution of proteins.

Summary

1 Polypeptide Diversity

- The properties of proteins depend largely on the sizes and sequences of their component polypeptides.

2 Protein Purification and Analysis

- Protein purification requires controlled conditions such as pH and temperature, and a means to quantify the protein (an assay).
- Fractionation procedures are used to purify proteins on the basis of solubility, charge, polarity, size, and binding specificity.
- Differences in solubility permit proteins to be concentrated and purified by salting out.
- Chromatography, the separation of soluble substances by their rate of movement through an insoluble matrix, is a technique for purifying molecules by charge (ion exchange chromatography), hydrophobicity (hydrophobic interaction chromatography), size (gel filtration chromatography), and binding specificity (affinity chromatography). Binding and elution often depend on the salt concentration and pH.
- Electrophoresis separates molecules by charge and size; SDS-PAGE separates them primarily by size. 2D electrophoresis can resolve thousands of proteins.

- A macromolecule's rate of sedimentation in an ultracentrifuge is related to its mass.

3 Protein Sequencing

- Analysis of a protein's sequence begins with end group analysis, to determine the number of different subunits, and the cleavage of disulfide bonds.
- Polypeptides are cleaved into fragments suitable for sequencing, either by Edman degradation, in which residues are removed, one at a time, from the N-terminus, or by mass spectrometry.
- A protein's sequence is reconstructed from the sequences of overlapping peptide fragments and from information about the locations of disulfide bonds. The sequences of numerous proteins are archived in publicly available databases.

4 Protein Evolution

- Proteins evolve through changes in primary structure. Protein sequences can be compared to construct phylogenetic trees and to identify essential amino acid residues.
- New proteins arise as a result of the duplication of genes or gene segments specifying protein domains, followed by their divergence.

Problems

EXERCISES

- It has been hypothesized that early life-forms used only eight different amino acids to build small peptides. How many different 10-residue peptides could be constructed from eight amino acids?
- If insulin (Fig. 5-1) were treated with mercaptoethanol to break its disulfide bonds, and then the mercaptoethanol were removed so that disulfide bonds could re-form, how many different ways could the two polypeptide chains become linked to each other (assuming that one or two disulfide bonds can form between the two chains)?
- Which peptide has greater absorbance at 280 nm?
 - Gln–Leu–Glu–Phe–Thr–Leu–Asp–Gly–Tyr
 - Ser–Val–Trp–Asp–Phe–Gly–Tyr–Trp–Ala
- Protein X has an absorptivity of $0.4 \text{ mL} \cdot \text{mg}^{-1} \cdot \text{cm}^{-1}$ at 280 nm. What is the absorbance at 280 nm of a $2.0 \text{ mg} \cdot \text{mL}^{-1}$ solution of protein X? (Assume the light path is 1 cm.)
- You are using ammonium sulfate to purify protein Q ($pI = 5.0$) by salting out from a solution at pH 7.0. How should you adjust the pH of the mixture to maximize the amount of protein Q that precipitates?
- The blood of individuals with cryoglobulinemia contains proteins, mostly immunoglobulins, that, in contrast to most blood proteins, become less soluble at cold temperatures. Explain why a prominent symptom of cryoglobulinemia is damage to blood vessels and nearby cells in the skin.
- (a) In what order would the amino acids Arg, His, and Leu be eluted from a carboxymethyl column at pH 6? (b) In what order would Glu, Lys, and Val be eluted from a diethylaminoethyl column at pH 8?
- Explain how you could use a column containing carboxymethyl groups to separate serum albumin and ribonuclease A (see Table 5-3).
- Explain why a certain protein has an apparent molecular mass of 90 kD when determined by gel filtration and 60 kD when determined by SDS-PAGE in the presence or absence of 2-mercaptoethanol. Which molecular mass determination is more accurate?
- Determine the subunit composition of a protein from the following information:
 - Molecular mass by gel filtration: 200 kD
 - Molecular mass by SDS-PAGE: 100 kD

Molecular mass by SDS-PAGE with 2-mercaptoethanol:
 40 kD and 60 kD

- Explain why a protein, which has a sedimentation coefficient of 2.6S when ultracentrifuged in a solution containing 0.1 M NaCl, has a sedimentation coefficient of 4.3S in a solution containing 1 M NaCl.
- A protein has an apparent mass of 800 kD by gel filtration chromatography, but SDS-PAGE shows a single band at a position corresponding to 200 kD. In an ultracentrifuge, will the protein exhibit a sedimentation coefficient corresponding to 200 kD or 800 kD?
- Explain why the dansyl chloride treatment of a single polypeptide chain followed by its complete acid hydrolysis yields several dansylated amino acids.
- Identify the first residue obtained by Edman degradation of cytochrome *c* from (a) *Drosophila*, (b) baker's yeast, and (c) wheat germ (see Table 5-6).
- A pentapeptide has the sequence NNKNN (using one-letter symbols for amino acids). Calculate the mass of this peptide, as determined by mass spectrometry, to three significant figures.
- The peptide in Problem 15 was sequenced by tandem mass spectrometry. What are the expected masses of the peptide fragments obtained by this method?
- In site-directed mutagenesis experiments, Gly is often successfully substituted for Val, but Val can rarely substitute for Gly. Explain.
- Below is a list of the first 10 residues of the B helix in myoglobin from different organisms.

Position	1	2	3	4	5	6	7	8	9	10
Human	D	I	P	G	H	G	Q	E	V	L
Chicken	D	I	A	G	H	G	H	E	V	L
Alligator	K	L	P	E	H	G	H	E	V	I
Turtle	D	L	S	A	H	G	Q	E	V	I
Tuna	D	Y	T	T	M	G	G	L	V	L
Carp	D	F	E	G	T	G	G	E	V	L

Based on this information, which positions (a) appear unable to tolerate substitutions, (b) can tolerate conservative substitution, and (c) are highly variable?

19. Sketch a phylogenetic tree for the family of homologous proteins whose partial sequences are given below.

```

Protein A  T L A D K A I S L H D S
Protein B  T L G D K A V S I H E S
Protein C  T L A D K A I S V H D S
  
```

20. Draw a different phylogenetic tree based on the data in Problem 19.

CHALLENGE QUESTIONS

21. Explain how you would use salting out to prepare a more concentrated solution of a protein.

22. You are trying to purify a protein that is soluble in a solution of 2 M ammonium sulfate. After centrifugation to remove other proteins that have precipitated at this high salt concentration, you recover the supernatant to assay the target protein's activity in a cell culture system. (a) Explain why the cells die when incubated with the supernatant. (b) What procedure could you perform to correct the problem? (*Hint*: See Section 2-1D).

23. What fractionation procedure could be used to purify protein 1 from a mixture of three proteins whose amino acid compositions are as follows?

- 25% Ala, 20% Gly, 20% Ser, 10% Ile, 10% Val, 5% Asn, 5% Gln, 5% Pro
- 30% Gln, 25% Glu, 20% Lys, 15% Ser, 10% Cys
- 25% Asn, 20% Gly, 20% Asp, 20% Ser, 10% Lys, 5% Tyr

All three proteins are similar in size and *pI*, and there is no antibody available for protein 1.

24. Consult Table 5-1 to complete the following: (a) On a plot of absorbance at 280 nm versus elution volume, sketch the results of gel filtration of a mixture containing human cytochrome *c* and bacteriophage T7 RNA polymerase and identify each peak. (b) Sketch the results of SDS-PAGE of the same protein mixture showing the direction of migration and identifying each band.

25. Purification tables are often used to keep track of the yield and purification of a protein. The specific activity is a ratio of the amount of the protein of interest, in this case Mb, obtained at a given step (μmol or enzyme units) divided by the amount (mg) of total protein. The yield is the ratio of the amount of the protein of interest obtained at a given step (μmol or enzyme units) divided by the original amount present in the crude extract, often converted to percent yield by multiplying by 100. The fold purification is the ratio of the specific activity of the purified protein to that of the crude preparation.

(a) For the purification table below, calculate the specific activity, % yield, and fold purification for the empty cells.

(b) Which step—DEAE or affinity chromatography—causes the greatest loss of Mb?

(c) Which step causes the greater purification of Mb?

(d) If you wanted to use only one purification step, which technique would you choose?

26. A 50-mL crude extract of skeletal muscle contains 32 mg of protein per mL. Ten μL of the extract catalyzes a reaction at a rate of 0.14 μmol product formed per minute. The extract was fractionated by ammonium sulfate precipitation, and the fraction precipitating between 20% and 40% saturation was redissolved in 10 mL. This solution contains 50 mg/mL protein. Ten μL of this purified fraction catalyzes the reaction at a rate of 0.65 $\mu\text{mol}/\text{min}$. (a) What is the degree of purification (fold purification)? (b) What is the percent yield of the enzyme recovered in the purified fraction?

27. You must cleave the following peptide into smaller fragments. Which of the proteases listed in Table 5-4 would be likely to yield the most fragments? The fewest?

NMTQGRCKPVNTFVHEPLVDVQNVCFKE

28. You wish to determine the sequence of a polypeptide that has the following amino acid composition.

1 Ala 4 Arg 2 Asn 3 Asp 4 Cys 3 Gly 1 Gln 4 Glu
1 His 1 Lys 1 Met 1 Phe 2 Pro 4 Ser 2 Tyr 1 Trp

(a) What is the maximum number of peptides you can expect if you cleave the polypeptide with cyanogen bromide?

(b) What is the maximum number of peptides you can expect if you cleave the polypeptide with chymotrypsin?

(c) Analysis of the intact polypeptide reveals that there are no free sulfhydryl groups. How many disulfide bonds are likely to be present?

(d) How many different arrangements of disulfide bonds are possible?

29. Electrospray ionization mass spectrometry (ESI-MS) of proteins involves creating positively charged ions of the protein and separating them according to their mass-to-charge ratio (*m/z*).

(a) What causes the different positive charges on different particles of the protein?

(b) The amino acid composition (in numbers of residues per chain) of hen egg-white lysozyme (HEWL) is as follows:

P	2	Y	3	N	14	H	1
D	7	M	2	L	8	E	2
C	8	R	11	G	12	F	3
A	12	I	6	K	6	V	6
S	10	W	6	T	7	Q	3

What is the maximum positive charge that can be present on a HEWL ion?

Purification Table for Problem 25

Step	Total Protein (mg)	Mb (μmol)	Specific Activity		
			($\mu\text{mol Mb}/\text{mg Total Protein}$)	% Yield	Fold Purification
1. Crude extract	1550	0.75		100	1
2. DEAE-cellulose chromatography	550	0.35			
3. Affinity chromatography	5.0	0.28			

30. (a) The ESI-MS spectrum below was obtained for hen egg-white lysozyme (HEWL). Using peaks 5 and 6, calculate the molecular mass of HEWL (see Sample Calculation 5-1).

[<http://www.astbury.leeds.ac.uk/facil/MStut/mstutorial.htm>.
Published by A.E. Ashcroft, Astbury Centre for Structural Molecular Biology, University of Leeds (2000)]

(b) What is the charge on the ion that makes peak 5?

31. You wish to determine the sequence of a short peptide. Cleavage with trypsin yields three smaller peptides with the sequences Leu–Glu, Gly–Tyr–Asn–Arg, and Gln–Ala–Phe–Val–Lys. Cleavage with chymotrypsin yields three peptides with the sequences Gln–Ala–Phe, Asn–Arg–Leu–Glu, and Val–Lys–Gly–Tyr. What is the sequence of the intact peptide?

32. Separate cleavage reactions of a polypeptide by CNBr and chymotrypsin yield fragments with the following amino acid sequences. What is the sequence of the intact polypeptide?

CNBr treatment

1. Arg–Ala–Tyr–Gly–Asn
2. Leu–Phe–Met
3. Asp–Met

Chymotrypsin

4. Met–Arg–Ala–Tyr
5. Asp–Met–Leu–Phe
6. Gly–Asn

33. Treatment of a polypeptide with 2-mercaptoethanol yields two polypeptides:

1. Ala–Val–Cys–Arg–Thr–Gly–Cys–Lys–Asn–Phe–Leu
2. Tyr–Lys–Cys–Phe–Arg–His–Thr–Lys–Cys–Ser

Treatment of the intact polypeptide with trypsin yields fragments with the following amino acid compositions:

3. (Ala, Arg, Cys₂, Ser, Val)
4. (Arg, Cys₂, Gly, Lys, Thr, Phe)
5. (Asn, Leu, Phe)
6. (His, Lys, Thr)
7. (Lys, Tyr)

Indicate the positions of the disulfide bonds in the intact polypeptide.

34. You wish to sequence the light chain of a protease inhibitor from the *Brassica nigra* plant. Cleavage of the light chain by trypsin and chymotrypsin yields the following fragments. What is the sequence of the light chain?

Chymotrypsin

1. Leu–His–Lys–Gln–Ala–Asn–Gln–Ser–Gly–Gly–Gly–Pro–Ser
2. Gln–Gln–Ala–Gln–His–Leu–Arg–Ala–Cys–Gln–Gln–Trp
3. Arg–Ile–Pro–Lys–Cys–Arg–Lys–Phe

Trypsin

4. Arg
5. Ala–Cys–Gln–Gln–Trp–Leu–His–Lys
6. Cys–Arg
7. Gln–Ala–Asn–Gln–Ser–Gly–Gly–Gly–Pro–Ser
8. Phe–Gln–Gln–Ala–Gln–His–Leu–Arg
9. Ile–Pro–Lys
10. Lys

BIOINFORMATICS

Brief Exercises Brief, online homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Globin Sequence Alignment and Evolution

Exercise 2 Protein Properties and Purification Methods

Exercise 3 Sequence Alignment of Subunit 1 of Cytochrome *c* Oxidase

Exercise 4 Using BLAST to Identify an Unknown Protein

Exercise 5 Proteolytic and Chemical Fragmentation of Green Fluorescent Protein

Extended Exercises Bioinformatics projects are available on the book companion site (www.wiley.com/college/voet), as well as in WileyPLUS Learning Space.

Project 2 Using Databases to Compare and Identify Related Protein Sequences

1. **Obtaining Sequences from BLAST.** Using a known protein sequence, find and retrieve the sequences of related proteins from other organisms.
2. **Multiple Sequence Alignment.** Examine the various sequences for similarities.
3. **Phylogenetic Trees.** Set up and interpret phylogenetic trees to explore the evolutionary relationships between related protein sequences.
4. **One-Dimensional Electrophoresis.** Perform an SDS-PAGE electrophoresis simulation with known and unknown proteins.
5. **Two-Dimensional Electrophoresis.** Explore the predicted and observed electrophoretic parameters (*pI*, molecular mass, and fragmentation pattern) for a known protein.

CASE STUDIES www.wiley.com/college/voet

Case 2 Histidine–Proline-Rich Glycoprotein as a Plasma pH Sensor

Focus concept: A histidine–proline-rich glycoprotein may serve as a plasma sensor and regulate local pH in extracellular fluid during ischemia or metabolic acidosis.

Prerequisites: Chapters 4 and 5

- Acidic/basic properties of amino acids
- Amino acid structure and protein structure

MORE TO EXPLORE Select one of the proteins listed in Table 5-1 or 5-3. How is this protein purified? What is the source of the protein? What types of chromatography are typically used? What chemical or biological feature is used to detect it or quantify it? Is there anything unusual about its amino acid sequence? Does it contain any disulfide bonds? Is it present only in animals or does it also occur in prokaryotes?

Proteins: Three-Dimensional Structure

Chapter Contents

1 Secondary Structure

- A The Planar Peptide Group Limits Polypeptide Conformations
- B The Most Common Regular Secondary Structures Are the α Helix and the β Sheet
- C Fibrous Proteins Have Repeating Secondary Structures
- D Most Proteins Include Nonrepetitive Structure

2 Tertiary Structure

- A Protein Structures Are Determined by X-Ray Crystallography, Nuclear Magnetic Resonance, or Cryo-Electron Microscopy
- B Side Chain Location Varies with Polarity
- C Tertiary Structures Contain Combinations of Secondary Structure
- D Structure Is Conserved More Than Sequence
- E Structural Bioinformatics Provides Tools for Storing, Visualizing, and Comparing Protein Structural Information

3 Quaternary Structure and Symmetry

4 Protein Stability

- A Proteins Are Stabilized by Several Forces
- B Proteins Can Undergo Denaturation and Renaturation
- C Proteins Are Dynamic

5 Protein Folding

- A Proteins Follow Folding Pathways
- B Molecular Chaperones Assist Protein Folding
- C Many Diseases Are Caused by Protein Misfolding

Olga Khorooshunova/Stockphoto

The blue plumage of this penguin, *Eudyptula minor*, is not due to the presence of blue pigment molecules but results from the light scattered by parallel bundles of the protein beta keratin.

For many years, it was thought that proteins were colloids of random structure and that the enzymatic activities of certain crystallized proteins were due to unknown entities associated with an inert protein carrier. In 1934, J.D. Bernal and Dorothy Crowfoot Hodgkin showed that a crystal of the protein **pepsin** yielded a discrete diffraction pattern when placed in an X-ray beam. This result provided convincing evidence that pepsin was not a random colloid, but an ordered array of atoms organized into a large yet uniquely structured molecule.

Even relatively small proteins contain thousands of atoms, almost all of which occupy definite positions in space. The first X-ray structure of a protein, that of sperm whale myoglobin, was reported in 1958 by John Kendrew and co-workers. At the time—only 5 years after James Watson and Francis Crick had elucidated the simple and elegant structure of DNA (Section 3-2B)—protein chemists were chagrined by the complexity and apparent lack of regularity in the structure of myoglobin. In retrospect, such irregularity seems essential for proteins to fulfill their diverse biological roles. However, comparisons of the ~110,000 protein structures now known have revealed that proteins actually exhibit a remarkable degree of structural regularity.

As we saw in Section 5-1, the primary structure of a protein is its linear sequence of amino acids. In discussing protein structure, three further levels of structural complexity are customarily invoked:

- **Secondary structure** is the local spatial arrangement of a polypeptide's backbone atoms without regard to the conformations of its side chains.
- **Tertiary structure** refers to the three-dimensional structure of an entire polypeptide, including its side chains.

- Many proteins are composed of two or more polypeptide chains, loosely referred to as subunits. A protein's **quaternary structure** refers to the spatial arrangement of its subunits.

The four levels of protein structure are summarized in **Fig. 6-1**.

In this chapter, we explore secondary through quaternary structures, including examples of proteins that illustrate each of these levels. We also discuss the process of protein folding and the forces that stabilize folded proteins.

1 Secondary Structure

KEY CONCEPTS

- The planar character of the peptide group limits the conformational flexibility of the polypeptide chain.
- The α helix and the β sheet allow the polypeptide chain to adopt favorable ϕ and ψ angles and to form hydrogen bonds.
- Fibrous proteins contain long stretches of regular secondary structure, such as the coiled coils in α keratin and the triple helix in collagen.
- Not all polypeptide segments form regular secondary structures such as α helices or β sheets.

Protein secondary structure includes the regular polypeptide folding patterns such as helices, sheets, and turns. However, before we discuss these basic structural elements, we must consider the geometric properties of peptide groups, which underlie all higher order structures.

A The Planar Peptide Group Limits Polypeptide Conformations

Recall from Section 4-1B that a polypeptide is a polymer of amino acid residues linked by amide (peptide) bonds. In the 1930s and 1940s, Linus Pauling and

FIG. 6-1 Levels of protein structure. (a) Primary structure, (b) secondary structure, (c) tertiary structure, and (d) quaternary structure. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

FIG. 6-2 The **trans peptide group**. The bond lengths (in angstroms) and angles (in degrees) are derived from X-ray crystal structures. [After Marsh, R.E. and Donohue, J., *Adv. Protein Chem.* **22**, 249 (1967).]

Robert Corey determined the X-ray structures of several amino acids and dipeptides in an effort to elucidate the conformational constraints on a polypeptide chain. These studies indicated that the **peptide group** has a rigid, planar structure as a consequence of resonance interactions that give the peptide bond $\sim 40\%$ double-bond character:

This explanation is supported by the observations that a peptide group's C—N bond is 0.13 \AA shorter than its N—C $_{\alpha}$ single bond and that its C=O bond is 0.02 \AA longer than that of aldehydes and ketones. The planar conformation maximizes π -bonding overlap, which accounts for the peptide group's rigidity.

Peptide groups, with few exceptions, assume the **trans conformation**, in which successive C $_{\alpha}$ atoms are on opposite sides of the peptide bond joining them (Fig. 6-2). The **cis conformation**, in which successive C $_{\alpha}$ atoms are on the same side of the peptide bond, is $\sim 8 \text{ kJ} \cdot \text{mol}^{-1}$ less stable than the trans conformation because of steric interference between neighboring side chains. However, this steric interference is reduced in peptide bonds to Pro residues, so $\sim 10\%$ of the Pro residues in proteins follow a cis peptide bond.

Torsion Angles between Peptide Groups Describe Polypeptide Chain Conformations. The **backbone** or **main chain** of a protein refers to the atoms that participate in peptide bonds, ignoring the side chains of the amino acid residues. The backbone can be drawn as a linked sequence of rigid planar peptide groups (Fig. 6-3). The conformation of the backbone can therefore be described by the **torsion angles** (also called **dihedral angles** or rotation angles) around the C $_{\alpha}$ —N bond (ϕ) and the C $_{\alpha}$ —C bond (ψ) of each residue

FIG. 6-3 Extended conformation of a polypeptide. The backbone is shown as a series of planar peptide groups. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

FIG. 6-4 Torsion angles of the polypeptide backbone. Two planar peptide groups are shown. The only reasonably free movements are rotations around the C_{α} -N bond (measured as ϕ) and the C_{α} -C bond (measured as ψ). By convention, both ϕ and ψ are 180° in the conformation shown and increase, as indicated, when the peptide plane is rotated in the clockwise direction as viewed from C_{α} . [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

(Fig. 6-4). These angles, ϕ and ψ , are both defined as 180° when the polypeptide chain is in its fully extended conformation and increase clockwise when viewed from C_{α} .

The conformational freedom, and therefore the torsion angles of a polypeptide backbone, are sterically constrained. Rotation around the C_{α} -N and C_{α} -C bonds to form certain combinations of ϕ and ψ angles will cause the amide hydrogen, the carbonyl oxygen, or the substituents of C_{α} of adjacent residues to collide (e.g., Fig. 6-5). Certain conformations of longer polypeptides can similarly produce collisions between residues that are far apart in sequence.

The Ramachandran Diagram Indicates Allowed Conformations of Polypeptides.

The sterically allowed values of ϕ and ψ can be calculated. Sterically forbidden conformations, such as the one shown in Fig. 6-5, have ϕ and ψ values that would bring atoms closer than the corresponding van der Waals distance (the distance of closest contact between nonbonded atoms). Such information is summarized in a **Ramachandran diagram** (Fig. 6-6), which is named after its inventor, G. N. Ramachandran.

FIG. 6-5 Steric interference between adjacent peptide groups. Rotation can result in a conformation in which the amide hydrogen of one residue and the carbonyl oxygen of the next are closer than their van der Waals distance. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

FIG. 6-6 The Ramachandran diagram. The blue-shaded regions indicate the sterically allowed ϕ and ψ angles for all residues except Gly and Pro. The green-shaded regions indicate the more crowded (outer limit) ϕ and ψ angles. The yellow circles represent conformational angles of several secondary structures: α , right-handed α helix; $\uparrow\uparrow$, parallel β sheet; $\uparrow\downarrow$, antiparallel β sheet; C, collagen helix; α_L , left-handed α helix.

Most areas of the Ramachandran diagram (most combinations of ϕ and ψ) represent forbidden conformations of a polypeptide chain. Only three small regions of the diagram are physically accessible to most residues. The observed ϕ and ψ values of accurately determined structures nearly always fall within these allowed regions of the Ramachandran plot. There are, however, some notable exceptions:

1. The cyclic side chain of Pro limits its range of ϕ values to angles of around -60° , making it, not surprisingly, the most conformationally restricted amino acid residue.
2. Gly, the only residue without a C_β atom, is much less sterically hindered than the other amino acid residues. Hence, its permissible range of ϕ and ψ covers a larger area of the Ramachandran diagram. At Gly residues, polypeptide chains often assume conformations that are forbidden to other residues.

B The Most Common Regular Secondary Structures Are the α Helix and the β Sheet

A few elements of protein secondary structure are so widespread that they are immediately recognizable in proteins with widely differing amino acid sequences. Both the **α helix** and the **β sheet** are such elements; they are called **regular secondary structures** because they are composed of sequences of residues with repeating ϕ and ψ values.

The α Helix Has a Regularly Repeating Structure. Only one polypeptide helix has both a favorable hydrogen bonding pattern and ϕ and ψ values that fall within the fully allowed regions of the Ramachandran diagram: the α helix. Its discovery by Linus Pauling in 1951, through model building, ranks as one of the landmarks of structural biochemistry (Box 6-1).

Stable helices in proteins:
the α helix

Linus Pauling (1901–1994) Linus Pauling, the only person to have been awarded two unshared Nobel prizes, is clearly the dominant figure in twentieth-century chemistry and one of the greatest scientific figures of all time. He received his B.Sc. in chemical engineering from Oregon Agricultural College (now Oregon State University) in 1922 and his Ph.D. in chemistry from the California Institute of Technology in 1925, where

he spent most of his career.

The major theme throughout Pauling's long scientific life was the study of molecular structures and the nature of the chemical bond. He began this career by using the then recently invented technique of X-ray crystallography to determine the structures of simple minerals and inorganic salts. At that time, methods for solving the phase problem (Box 7-2) were unknown, so X-ray structures could be determined only using trial-and-error techniques. This limited the possible molecules that could be effectively studied to those with few atoms and high symmetry such that their atomic coordinates could be fully described by only a few parameters (rather than the three-dimensional coordinates of each of its atoms). Pauling realized that the positions of atoms in molecules were governed by fixed atomic radii, bond distances, and bond angles and used this information to make educated guesses about molecular structures. This greatly extended the complexity of the molecules whose structures could be determined.

In his next major contribution, occurring in 1931, Pauling revolutionized the way that chemists viewed molecules by applying the then infant field of quantum mechanics to chemistry. Pauling formulated the theories of orbital hybridization, electron-pair bonding, and resonance and thereby explained the nature of covalent bonds. This work was summarized in his highly influential monograph, *The Nature of the Chemical Bond*, which was first published in 1938.

In the mid-1930s, Pauling turned his attention to biological chemistry. He began these studies in collaboration with his colleague, Robert Corey, by determining the X-ray structures of several amino acids and dipeptides. At that time, the X-ray structural determination of even such small molecules required around a year of intense effort, largely because the numerous calculations required to solve a structure had to be made by hand (electronic computers had yet to be invented). Nevertheless, these studies led Pauling and Corey to the conclusions that the peptide bond is planar, which Pauling explained from resonance considerations (Section 6-1A), and that hydrogen bonding plays a central role in maintaining macromolecular structures.

In the 1940s, Pauling made several unsuccessful attempts to determine whether polypeptides have any preferred conformations. Then, in 1948, while visiting Oxford University, he was confined to bed by a cold. He eventually tired of reading detective stories and science fiction and again turned his attention to proteins. By folding drawings of polypeptides in various ways, he discovered the α helix, whose existence was rapidly confirmed by X-ray

studies of α keratin (Section 6-1C). This work was reported in 1951, and later that year Pauling and Corey also proposed both the parallel and antiparallel β pleated sheets. For these groundbreaking insights, Pauling received the Nobel Prize in Chemistry in 1954, although α helices and β sheets were not actually visualized until the first X-ray structures of proteins were determined, five to ten years later.

Pauling made numerous additional pioneering contributions to biological chemistry, most notably that the heme group in hemoglobin changes its electronic state on binding oxygen (Section 7-1A), that vertebrate hemoglobins are $\alpha_2\beta_2$ heterotetramers (Section 7-1B), that the denaturation of proteins is caused by the unfolding of their polypeptide chains, that sickle-cell anemia is caused by a mutation in the β chain of normal adult hemoglobin (the first so-called molecular disease to be characterized; Section 7-1E), that molecular complementarity plays an important role in antibody–antigen interactions (Section 7-3B) and, by extension, all macromolecular interactions, that enzymes catalyze reactions by preferentially binding their transition states (Section 11-3E), and that the comparison of the sequences of the corresponding proteins in different organisms yields evolutionary insights (Section 5-4).

Pauling was also a lively and stimulating lecturer who for many years taught a general chemistry course [which one of the authors of this textbook (DV) had the privilege of taking]. His textbook, *General Chemistry*, revolutionized the way that introductory chemistry was taught by presenting it as a subject that could be understood in terms of atomic physics and molecular structure. For a book of such generality, an astounding portion of its subject matter had been elucidated by its author. Pauling's amazing grasp of chemistry was demonstrated by the fact that he dictated each chapter of the textbook in a single sitting.

By the late 1940s, Pauling became convinced that the possibility of nuclear war posed an enormous danger to humanity and calculated that the radioactive fallout from each aboveground test of a nuclear bomb would ultimately cause cancer in thousands of people. He therefore began a campaign to educate the public about the hazards of bomb testing and nuclear war. The political climate in the United States at the time was such that the government considered Pauling to be subversive and his passport was revoked (and returned only two weeks before he was to leave for Sweden to receive his first Nobel prize). Nevertheless, Pauling persisted in this campaign, which culminated, in 1962, with the signing of the first nuclear test ban treaty. For his efforts, Pauling was awarded the 1962 Nobel Peace Prize.

Pauling saw science as the search for the truth, which included politics and social causes. In his later years, he became a vociferous promoter of what he called orthomolecular medicine, the notion that large doses of vitamins could ward off and cure many human diseases, including cancer. In the best known manifestation of this concept, Pauling advocated taking large doses of vitamin C to prevent the common cold and lessen its symptoms, advice still followed by millions of people, although the medical evidence supporting this notion is scant. It should be noted, however, that Pauling, who followed his own advice, remained active until he died in 1994 at the age of 93.

FIG. 6-7 The α helix. This right-handed helical conformation has 3.6 residues per turn. Dashed lines indicate hydrogen bonds between C=O groups and N—H groups that are four residues farther along the polypeptide chain. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.] **WPLS** See the Animated Figures.

? How many amino acid residues are in this helix? How many intrachain hydrogen bonds?

The α helix (Fig. 6-7) is right-handed; that is, it turns in the direction that the fingers of a right hand curl when its thumb points in the direction that the helix rises (Fig. 3-7). The α helix, which ideally has $\phi = -57^\circ$ and $\psi = -47^\circ$, has 3.6 residues per turn and a **pitch** (the distance the helix rises along its axis per turn) of 5.4 Å. The α helices of proteins have an average length of ~ 12 residues, which corresponds to more than three helical turns, and a length of ~ 18 Å.

In the α helix, the backbone hydrogen bonds are arranged such that the peptide C=O bond of the n th residue points along the helix axis toward the peptide N—H group of the $(n + 4)$ th residue. This results in a strong hydrogen bond that has the nearly optimum N \cdots O distance of 2.8 Å. Amino acid side chains project outward and downward from the helix (Fig. 6-8), thereby avoiding steric interference with the polypeptide backbone and with each other. The core of the helix is tightly packed; that is, its atoms are in van der Waals contact.

FIG. 6-8 Space-filling model of an α helix.

The backbone atoms are colored according to type with C green, N blue, O red, and H white. The side chains (*gold*) project away from the helix. This α helix is a segment of sperm whale myoglobin. [Based on an X-ray structure by Ilme Schlichting, Max Planck Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1A6M (for the definition of “PDBid” see Section 6-2E).]

FIG. 6-9 β Sheets. Dashed lines indicate hydrogen bonds between polypeptide strands. Side chains are omitted for clarity. (a) An antiparallel β sheet. (b) A parallel β sheet. Hydrogen bonding in β sheets

β Sheets Are Formed from Extended Chains. In 1951, the same year Pauling proposed the α helix, Pauling and Corey postulated the existence of a different polypeptide secondary structure, the β sheet. Like the α helix, the β sheet uses the full hydrogen-bonding capacity of the polypeptide backbone. *In β sheets, however, hydrogen bonding occurs between neighboring polypeptide chains rather than within one, as in an α helix.*

Sheets come in two varieties:

1. The **antiparallel β sheet**, in which neighboring hydrogen-bonded polypeptide chains run in opposite directions (**Fig. 6-9a**).
2. The **parallel β sheet**, in which the hydrogen-bonded chains extend in the same direction (**Fig. 6-9b**).

The conformations in which these β structures are optimally hydrogen bonded vary somewhat from that of the fully extended conformation ($\phi = \psi = \pm 180^\circ$) shown in Figs. 6-3 and 6-4. They therefore have a rippled or pleated edge-on appearance (**Fig. 6-10**) and for that reason are sometimes called “pleated sheets.” Note that the side chains in a β sheet (its $C_\alpha-C_\beta$ bonds) extend perpendicularly to the plane of the sheet, with successive side chains located on its opposite sides. Thus, each strand of a β sheet has a two-residue repeat with a repeat distance of 7.0 Å.

β Sheets in proteins contain 2 to as many as 22 polypeptide strands, with an average of 6 strands. Each strand may contain up to 15 residues, the average being 6 residues. A seven-stranded antiparallel β sheet is shown in **Fig. 6-11**.

Parallel β sheets containing fewer than five strands are rare. This observation suggests that parallel β sheets are less stable than antiparallel β sheets, possibly because the hydrogen bonds of parallel sheets are distorted compared to those of the antiparallel sheets (**Fig. 6-9**). β Sheets containing mixtures of parallel and antiparallel strands frequently occur.

FIG. 6-10 Pleated appearance of a β sheet. Dashed lines indicate hydrogen bonds. The R groups (*purple*) on each polypeptide chain alternately extend to opposite sides of the sheet and are in register on adjacent chains. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

? How many residues are in this β sheet? How many interchain hydrogen bonds?

β Sheets almost invariably exhibit a pronounced right-handed twist when viewed along their polypeptide strands (Fig. 6-12). Conformational energy calculations indicate that the twist is a consequence of interactions between chiral L-amino acid residues in the extended polypeptide chains. The twist distorts and weakens the β sheet's interchain hydrogen bonds. The geometry of a particular β sheet is thus a compromise between optimizing the conformational energies of its polypeptide chains and preserving its hydrogen bonding.

The **topology** (connectivity) of the polypeptide strands in a β sheet can be quite complex. The connection between two antiparallel strands may be just a

FIG. 6-11 Space-filling model of a β sheet. The backbone atoms are colored according to type with C green, N blue, O red, and H white. The R groups are represented by large magenta spheres. This seven-stranded antiparallel β sheet, which is shown with its polypeptide strands approximately horizontal, is from the jack bean protein concanavalin A. [Based on an X-ray structure by Gerald Edelman, The Rockefeller University. PDBid 2CNA.]

FIG. 6-12 X-Ray structure of bovine carboxypeptidase A. The polypeptide backbone is drawn in ribbon form with α helices depicted as cyan coils, the strands of the β sheet represented by flat green arrows pointing toward the C-terminus, and its remaining portions portrayed by orange worms. Side chains are not shown. The eight-stranded β sheet forms a saddle-shaped curved surface with a right-handed twist. [Based on an X-ray structure by William Lipscomb, Harvard University. PDBid 3CPA.]

FIG. 6-13 Connections between adjacent strands in β sheets. (a) Antiparallel strands may be connected by a small loop. (b) Parallel strands require a more extensive crossover connection that almost always has a right-handed helical sense, as is shown, because it better accommodates a β sheet's inherent right-handed twist. [After Richardson, J.S., *Adv. Protein Chem.* **34**, 196 (1981).]

small loop (**Fig. 6-13a**), but the link between tandem parallel strands must be a crossover connection that is out of the plane of the β sheet (**Fig. 6-13b**). The connecting link in either case can be extensive, often containing helices (e.g., **Fig. 6-12**).

Turns Connect Some Units of Secondary Structure. Polypeptide segments with regular secondary structure, such as α helices or the strands of β sheets, are often joined by stretches of polypeptide that abruptly change direction. Such **reverse turns** or **β bends** (so named because they often connect successive strands of antiparallel β sheets; **Fig. 6-13a**) almost always occur at protein surfaces. They usually involve four successive amino acid residues arranged in one of two ways, Type I and Type II, that differ by a 180° flip of the peptide unit linking residues 2 and 3 (**Fig. 6-14**). Both types of turns are stabilized by a hydrogen bond, although deviations from these ideal conformations often disrupt this hydrogen bond. In Type II turns, the oxygen atom of residue 2 crowds the C_β atom of residue 3, which is therefore usually Gly. Residue 2 of either type of turn is often Pro, since it can assume the required conformation.

C Fibrous Proteins Have Repeating Secondary Structures

Proteins have historically been classified as either **fibrous** or **globular**, depending on their overall morphology. This dichotomy predates methods for determining protein structure on an atomic scale and does not do justice to proteins that contain stiff, elongated, fibrous regions as well as more compact, highly folded, globular regions. Nevertheless, the division helps emphasize the properties of fibrous proteins, which often have a protective, connective, or supportive role in living organisms. The two well-characterized fibrous proteins we discuss here—keratin and collagen—are highly elongated molecules whose shapes are dominated by a single type of secondary structure. They are therefore useful examples of these structural elements.

α Keratin Is a Coiled Coil. **Keratin** is a mechanically durable and relatively unreactive protein that occurs in all higher vertebrates. It is the principal component of their outer epidermal (skin) layer and its related appendages, such as hair, horn, nails, and feathers. Keratins have been classified as either α keratins, which occur in mammals, or β keratins, which occur in birds and reptiles. Humans have more than 50 keratin genes that are expressed in a tissue-specific manner.

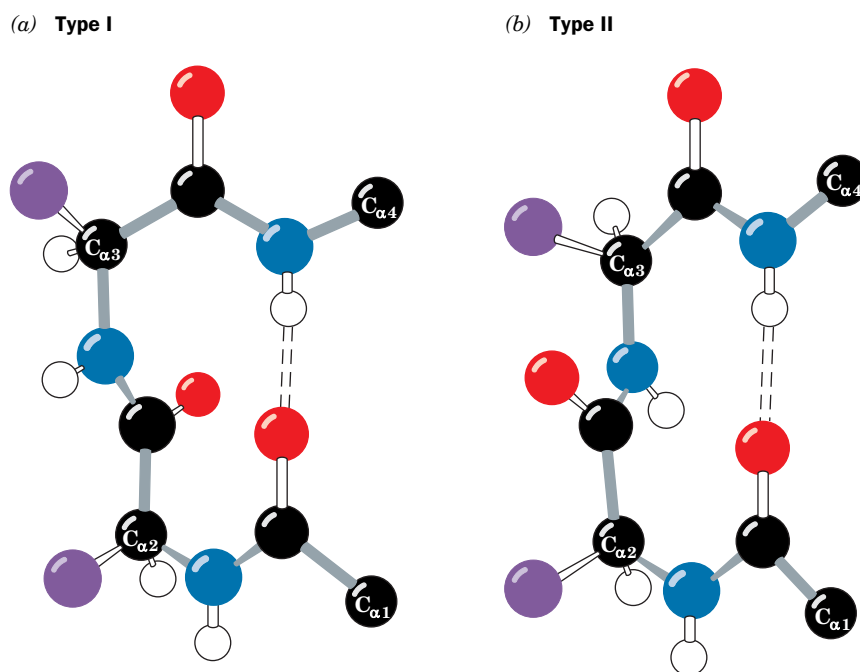

FIG. 6-14 Reverse turns in polypeptide chains. Dashed lines represent hydrogen bonds. (a) Type I. (b) Type II. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

FIG. 6-15 A coiled coil. (a) View down the coil axis showing the alignment of nonpolar residues along one side of each α helix. The helices have the pseudorepeating sequence *a-b-c-d-e-f-g* in which residues *a* and *d* are predominately nonpolar. [After McLachlan, A.D. and Stewart, M., *J. Mol. Biol.* **98**, 295 (1975).] (b) Side view of the polypeptide backbones in stick form (left) and of the entire polypeptides in space-filling form (right). The atoms are colored according to type, with C green in one chain and cyan in the other, N blue, O red, and S yellow. The 81-residue chains are parallel with their N-terminal ends above. Note that in the space-filling model, the side chains of the two polypeptides contact each other. This coiled coil is a portion of the muscle protein tropomyosin (Section 7-2A). [Based on an X-ray structure by Carolyn Cohen, Brandeis University. PDBid 1IC2.]

? Which amino acids would you not expect to occur in a coiled coil structure?

The X-ray diffraction pattern of α keratin resembles that expected for an α helix (hence the name α keratin). However, α keratin exhibits a 5.1-Å spacing rather than the 5.4-Å distance corresponding to the pitch of the α helix. This discrepancy is the result of *two α keratin polypeptides, each of which forms an α helix, twisting around each other to form a left-handed coil*. The normal 5.4-Å repeat distance of each α helix in the pair is thereby tilted relative to the axis of this assembly, yielding the observed 5.1-Å spacing. The assembly is said to have a **coiled coil** structure because each α helix itself follows a helical path.

The conformation of α keratin's coiled coil is a consequence of its primary structure: The central ~310-residue segment of each polypeptide chain has a 7-residue pseudorepeat, *a-b-c-d-e-f-g*, with nonpolar residues predominating at positions *a* and *d*. Because an α helix has 3.6 residues per turn, α keratin's *a* and *d* residues line up along one side of each α helix (Fig. 6-15a). The hydrophobic strip along one helix associates with the hydrophobic strip on another helix. Because the 3.5-residue repeat in α keratin is slightly smaller than the 3.6 residues per turn of a standard α helix, the two keratin helices are inclined about 18° relative to one another, resulting in the coiled coil arrangement (Fig. 6-15b). Coiled coils also occur in numerous other proteins, some of which are globular rather than fibrous.

The higher order structure of α keratin is not well understood. The N- and C-terminal domains of each polypeptide facilitate the assembly of coiled coils (dimers) into protofilaments, two of which constitute a protofibril (Fig. 6-16). Four protofibrils constitute a microfibril, which associates with other microfibrils to form a macrofibril. A single mammalian hair consists of layers of dead cells, each of which is packed with parallel macrofibrils.

α Keratin is rich in Cys residues, which form disulfide bonds that cross-link adjacent polypeptide chains. The α keratins are classified as “hard” or “soft” according to whether they have a high or low sulfur content. Hard keratins, such as those of hair, horn, and nail, are less pliable than soft keratins, such as those of skin and callus, because the disulfide bonds resist deformation. The disulfide bonds can be reductively cleaved by disulfide interchange with mercaptans (Section 5-3A). Hair thus treated can be curled and set in a “permanent wave” by applying an oxidizing agent that reestablishes the disulfide bonds in the new “curled” conformation. Conversely, curly hair can be straightened by the same process.

FIG. 6-16 Higher order α keratin structure. (a) Two keratin polypeptides form a dimeric coiled coil. (b) Protofilaments are formed from two staggered rows of head-to-tail associated coiled coils. (c) Protofilaments dimerize to form a protofibril, four of which form a microfibril. The structures of the latter assemblies are poorly characterized.

The springiness of hair and wool fibers is a consequence of the coiled coil's tendency to recover its original conformation after being untwisted by stretching. If some of its disulfide bonds have been cleaved, however, an α keratin fiber can be stretched to over twice its original length. At this point, the polypeptide chains assume a β sheet conformation. β Keratin, such as that in feathers, exhibits a β -like pattern in its native state.

Collagen Is a Triple Helix. **Collagen**, which occurs in all multicellular animals, is the most abundant vertebrate protein. Its strong, insoluble fibers are the major stress-bearing components of connective tissues such as bone, teeth, cartilage, tendon, and the fibrous matrices of skin and blood vessels. A single collagen molecule consists of three polypeptide chains. Vertebrates have 46 genetically distinct polypeptide chains that are assembled into 28 collagen varieties found in different tissues in the same individual. One of the most common collagens, called Type I, consists of two α_1 (I) chains and one α_2 (I) chain. It has a molecular mass of ~ 285 kD, a width of ~ 14 Å, and a length of ~ 3000 Å.

Collagen has a distinctive amino acid composition: Nearly one-third of its residues are Gly; another 15 to 30% of its residues are Pro and **4-hydroxyprolyl (Hyp)**. **3-Hydroxyprolyl** and **5-hydroxylysyl (Hyl)** residues also occur in collagen, but in smaller amounts.

4-Hydroxyprolyl residue (Hyp)

3-Hydroxyprolyl residue

5-Hydroxylysyl residue (Hyl)

These nonstandard residues are formed after the collagen polypeptides are synthesized. For example, Pro residues are converted to Hyp in a reaction catalyzed by **prolyl hydroxylase**. This enzyme requires **ascorbic acid (vitamin C)** to maintain its activity. The disease **scurvy** results from the dietary deficiency of vitamin C (Box 6-2).

Ascorbic acid (vitamin C)

The amino acid sequence of a typical collagen polypeptide consists of monotonously repeating triplets of sequence Gly-X-Y over a segment of ~ 1000 residues, where X is often Pro and Y is often Hyp. Hyl sometimes appears at the Y position. Collagen's Pro residues prevent it from forming an α helix (Pro residues cannot assume the α -helical backbone conformation and lack the backbone N—H groups that form the intrahelical hydrogen bonds shown in Fig. 6-7). Instead, *the collagen polypeptide assumes a left-handed helical conformation with about three residues per turn. Three parallel chains wind around each other with a gentle, right-handed, ropelike twist to form the triple-helical structure of a collagen molecule (Fig. 6-17).*

This model of the collagen structure has been confirmed by Barbara Brodsky and Helen Berman, who determined the X-ray crystal structure of a collagen-like

FIG. 6-17 The collagen triple helix. Left-handed polypeptide helices are twisted together to form a right-handed superhelical structure. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

Some collagen diseases have dietary causes. In scurvy (caused by vitamin C deficiency), Hyp production decreases because prolyl hydroxylase requires vitamin C. Thus, in the absence of vitamin C, newly synthesized collagen cannot form fibers properly, resulting in skin lesions, fragile blood vessels, poor wound healing, and, ultimately, death. Scurvy was the principal killer of sailors on long voyages, because their diets were devoid of fresh foods. For instance, in Magellan's voyage of 1520, 208 of his crew of 230 died, mainly due to scurvy. In 1747, the Scottish physician James Lind, in what is considered the first clinical trial, showed that the consumption of citrus fruits alleviated scurvy. Yet it took another 50 years before the British navy adopted lemon or lime juice as part of its standard shipboard diet (which led to the derogatory nickname "limey" for British sailors, and eventually for all British people). Nevertheless, it was not until 1932 that Albert Szent-Györgi isolated ascorbic acid and Charles King proved it to be the antiscorbutic (anti-scurvy) factor.

The disease **lathyrism** is caused by regular ingestion of the seeds from the sweet pea *Lathyrus odoratus*, which contain a compound that specifically inactivates lysyl oxidase (see below). The resulting reduced cross-linking of collagen fibers produces serious abnormalities of the bones, joints, and large blood vessels.

Several rare heritable disorders of collagen are known. Mutations of Type I collagen, which constitutes the major structural protein in most human tissues, usually result in **osteogenesis imperfecta** (brittle bone disease). The severity of this disease varies with the nature and position of the mutation: Even a single amino acid change can have lethal consequences. For example, the central Gly → Ala substitution in the model polypeptide shown in Fig. 6-18 locally distorts the already internally crowded collagen helix. This ruptures the hydrogen bond from the backbone N—H of each Ala (normally Gly) to the carbonyl group of the adjacent Pro in a neighboring chain, thereby reducing the stability of the collagen structure. Mutations may affect the structure of the collagen molecule or how it forms fibrils. These mutations tend to be dominant because they affect either the folding of the triple helix or fibril formation even when normal chains are also involved.

Many collagen disorders are characterized by deficiencies in the amount of a particular collagen type synthesized, or by abnormal activities of collagen-processing enzymes such as lysyl hydroxylase and lysyl oxidase. One group of at least 10 different collagen-deficiency diseases, the **Ehlers-Danlos syndromes**, are all characterized by the hyperextensibility of the joints and skin. The "India-rubber man" of circus fame had an Ehlers-Danlos syndrome.

model polypeptide. Every third residue of each polypeptide chain passes through the center of the triple helix, which is so crowded that only a Gly side chain can fit there. This crowding explains the absolute requirement for a Gly at every third position of a collagen polypeptide chain. The three polypeptide chains are staggered so that a Gly, X, and Y residue occurs at each level along the triple helix axis (Fig. 6-18a). The peptide groups are oriented such that the N—H of each Gly makes a strong hydrogen bond with the carbonyl oxygen of an X (Pro) residue on a neighboring chain (Fig. 6-18b). The bulky and relatively inflexible Pro and Hyp residues confer rigidity on the entire assembly.

FIG. 6-18 Structure of a collagen model peptide. In this X-ray structure of (Pro-Hyp-Gly)₁₀, the fifth Gly of each peptide has been replaced by Ala. (a) A stick model of the middle portion of the triple helix oriented with its N-termini at the bottom. The C atoms of the three chains are colored orange, magenta, and gray. The N and O atoms on all chains are blue and red. Note how the replacement of Gly with the bulkier Ala (C atoms green) distorts the triple helix. (b) This view from the N-terminus down the helix axis shows the interchain hydrogen-bonding associations. Three consecutive residues from each chain are shown in stick form (C atoms green). Hydrogen bonds are represented by dashed lines from Gly N atoms to Pro O atoms in adjacent chains. Dots represent the van der Waals surfaces of the backbone atoms of the central residue in each chain. Note the close packing of the atoms along the triple helix axis. [Based on an X-ray structure by Helen Berman, Rutgers University, and Barbara Brodsky, UMDNJ—Robert Wood Johnson Medical School. PDBid 1CAG.]

FIG. 6-19 Electron micrograph of collagen fibrils from skin.

Courtesy of Jerome Gross, Massachusetts General Hospital

Collagen's well-packed, rigid, triple-helical structure is responsible for its characteristic tensile strength. The twist in the helix cannot be pulled out under tension because its component polypeptide chains are twisted in the opposite direction (Fig. 6-17). Successive levels of fiber bundles in high-quality ropes and cables, as well as in other proteins such as keratin (Fig. 6-16), are likewise oppositely twisted.

Several types of collagen molecules assemble to form loose networks or thick fibrils arranged in bundles or sheets, depending on the tissue (e.g., Fig. 6-19). The collagen molecules in fibrils are organized in staggered arrays that are stabilized by hydrophobic interactions resulting from the close packing of triple-helical units. Collagen is also covalently cross-linked, which accounts for its poor solubility. The cross-links cannot be disulfide bonds, as in keratin, because collagen is almost devoid of Cys residues. Instead, up to four Lys, Hyl, and His side chains are covalently cross-linked to form compounds such as **histidinodehydrohydroxymerodesmosine**.

Histidinodehydrohydroxymerodesmosine

Lysyl oxidase, an enzyme that converts Lys residues to those of the aldehyde **allysine**, is the only enzyme implicated in this cross-linking process.

Allysine

The cross-links do not form at random, but tend to occur near the N- and C-termini of the collagen molecules. The degree of cross-linking in a particular tissue increases with age, which is why meat from older animals is tougher than meat from younger animals.

D Most Proteins Include Nonrepetitive Structure

The majority of proteins are globular proteins that, unlike the fibrous proteins discussed above, may contain several types of regular secondary structure, including α helices, β sheets, and other recognizable elements. A significant portion of a protein's structure may also be irregular or unique. Segments of polypeptide chains whose successive residues do not have similar ϕ and ψ values are sometimes called coils. However, you should not confuse this term with the appellation **random coil**, which refers to the totally disordered and rapidly fluctuating conformations assumed by **denatured** (fully unfolded) proteins in solution. In **native** (folded) proteins, *nonrepetitive structures are no less ordered than are helices or β sheets; they are simply irregular and hence more difficult to describe.*

Sequence Affects Secondary Structure. *Variations in amino acid sequence, as well as the overall structure of the folded protein, can distort the regular conformations*

of secondary structural elements. For example, the α helix frequently deviates from its ideal conformation in the initial and final turns of the helix. Similarly, a strand of polypeptide in a β sheet may contain an “extra” residue that is not hydrogen bonded to a neighboring strand, producing a distortion known as a **β bulge**.

Many of the limits on amino acid composition and sequence (Section 5-1) may be due in part to conformational constraints in the three-dimensional structure of proteins. For example, a Pro residue produces a kink in an α helix or β sheet. Similarly, steric clashes between several sequential amino acid residues with large branched side chains (e.g., Ile and Tyr) can destabilize α helices.

Analysis of known protein structures by Peter Chou and Gerald Fasman revealed the propensity P of a residue to occur in an α helix or a β sheet (Table 6-1). Chou and Fasman also discovered that certain residues not only have a high propensity for a particular secondary structure but they tend to disrupt or break other secondary structures. Such data are useful for predicting the secondary structures of proteins with known amino acid sequences.

The presence of certain residues outside of α helices or β sheets may also be nonrandom. For example, α helices are often flanked by residues such as Asn and Gln, whose side chains can fold back to form hydrogen bonds with one of the four terminal residues of the helix, a phenomenon termed **helix capping**. Recall that the four residues at each end of an α helix are not hydrogen bonded to neighboring backbone segments (Fig. 6-7).

2 Tertiary Structure

KEY CONCEPTS

- X-Ray crystallography, NMR spectroscopy, and cryo-electron microscopy are used to determine the positions of atoms in proteins.
- Nonpolar residues tend to occur in the protein interior and polar residues on the exterior.
- A protein's tertiary structure consists of secondary structural elements that combine to form motifs and domains.
- Over evolutionary time, a protein's structure is more highly conserved than its sequence.
- Bioinformatics databases store macromolecular structure coordinates. Software makes it possible to visualize proteins and compare their structural features.

The tertiary structure of a protein describes the folding of its secondary structural elements and specifies the positions of each atom in the protein, including those of its side chains. This information is deposited in a database and is readily available via the Internet, which allows the tertiary structures of a variety of proteins to be analyzed and compared. The common features of protein tertiary structures reveal much about the biological functions of proteins and their evolutionary origins.

A Protein Structures Are Determined by X-Ray Crystallography, Nuclear Magnetic Resonance, and Cryo-Electron Microscopy

X-Ray crystallography is a technique that directly images molecules. X-Rays must be used to do so because, according to optical principles, the uncertainty in locating an object is approximately equal to the wavelength of the radiation used to observe it (covalent bond distances and the wavelengths of the X-rays used in structural studies are both $\sim 1.5 \text{ \AA}$; individual molecules cannot be seen in a light microscope because visible light has a minimum wavelength of 4000 \AA). There is, however, no such thing as an X-ray microscope because there are no X-ray

CHECKPOINT

- Describe the four levels of protein structure. Do all proteins exhibit all four levels?
- Without looking at Fig. 6-3, draw the structure of a polypeptide backbone.
- Explain why the conformational freedom of peptide bonds is limited.
- Summarize the features of an α helix and a parallel and antiparallel β sheet.
- Count the number of α helices and β sheets in carboxypeptidase A (Fig. 6-12).
- What properties do fibrous proteins confer on substances such as hair and bones?
- Describe the features of the amino acid sequences that are necessary to form a coiled coil or a left-handed triple helix.
- What distinguishes regular and irregular secondary structures?

TABLE 6-1 Propensities of Amino Acid Residues for α Helical and β Sheet Conformations

Residue	P_{α}	P_{β}
Ala	1.42	0.83
Arg	0.98	0.93
Asn	0.67	0.89
Asp	1.01	0.54
Cys	0.70	1.19
Gln	1.11	1.10
Glu	1.51	0.37
Gly	0.57	0.75
His	1.00	0.87
Ile	1.08	1.60
Leu	1.21	1.30
Lys	1.16	0.74
Met	1.45	1.05
Phe	1.13	1.38
Pro	0.57	0.55
Ser	0.77	0.75
Thr	0.83	1.19
Trp	1.08	1.37
Tyr	0.69	1.47
Val	1.06	1.70

FIG. 6-22 A thin section through a 1.5-Å-resolution electron density map of a protein that is contoured in three dimensions. Only a single contour level (cyan) is shown, together with a ball-and-stick model of the corresponding polypeptide segments colored according to atom type with C yellow, N blue, and O red. A water molecule is represented by a red sphere.

lenses. Rather, a crystal of the molecule to be imaged (e.g., Fig. 6-20) is exposed to a collimated beam of X-rays and the resulting **diffraction pattern**, which arises from the regularly repeating positions of atoms in the crystal, is recorded by a radiation detector or, now infrequently, on photographic film (Fig. 6-21). The X-rays used in structural studies are produced by laboratory X-ray generators or, now commonly, by **synchrotrons**, particle accelerators that produce X-rays of far greater intensity. The intensities of the diffraction peaks (darkness of the spots on a film) are then used to construct mathematically the three-dimensional image of the crystal structure through methods that are beyond the scope of this text. In what follows, we discuss some of the special problems associated with interpreting the X-ray crystal structures of proteins.

X-Rays interact almost exclusively with the electrons in matter, not the nuclei. An X-ray structure is therefore an image of the **electron density** of the object under study. Such **electron density maps** are usually presented with the aid of computer graphics as one or more sets of **contours**, in which a contour represents a specific level of electron density in the same way that a contour on a topographic map indicates locations that have a particular altitude. A portion of an electron density map of a protein is shown in Fig. 6-22.

Most Protein Crystal Structures Exhibit Less than Atomic Resolution. The molecules in protein crystals, as in other crystalline substances, are arranged in regularly repeating three-dimensional lattices. Protein crystals, however, differ from those of most small organic and inorganic molecules in being highly hydrated; they are typically 40 to 60% water by volume. The aqueous solvent of crystallization is necessary for the structural integrity of the protein crystals, because water is required for the structural integrity of native proteins themselves (Section 6-4).

The large solvent content of protein crystals gives them a soft, jellylike consistency so that their molecules usually lack the rigid order characteristic of crystals of small molecules such as NaCl or glycine. The molecules in a protein crystal are typically disordered by more than an angstrom, so the corresponding electron density map lacks information concerning structural details of smaller size. The crystal is therefore said to have a resolution limit of that size. Protein crystals typically have resolution limits in the range 1.5 to 3.0 Å, although some are better ordered (have higher resolution; that is, a lesser resolution limit) and many are less ordered (have lower resolution).

Because an electron density map of a protein must be interpreted in terms of its atomic positions, the accuracy, and even the feasibility, of a crystal structure analysis depends on the crystal's resolution limit. Indeed, the inability to obtain crystals of sufficiently high resolution is a major limiting factor in determining the X-ray crystal structure of a protein or other macromolecule. Figure 6-23 indicates how the quality (degree of focus) of an electron density map varies with its resolution limit. At 6-Å resolution, the presence of a molecule the size of diketopiperazine is difficult to discern. At 2.0-Å resolution, its individual atoms cannot yet be distinguished, although its molecular shape has become reasonably evident. At 1.5-Å resolution, which roughly corresponds to a bond distance, individual atoms become partially resolved. At 1.1-Å resolution, atoms are clearly visible.

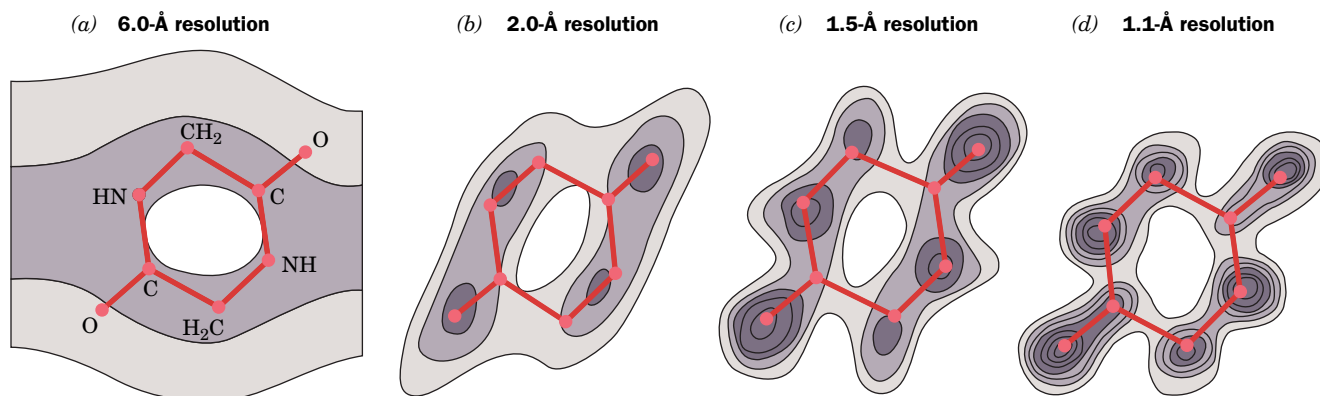

FIG. 6-23 Electron density maps of diketopiperazine at different resolution levels. Hydrogen atoms are not visible in these maps because of their low electron density. [After Hodgkin, D.C., *Nature* **188**, 445 (1960).]

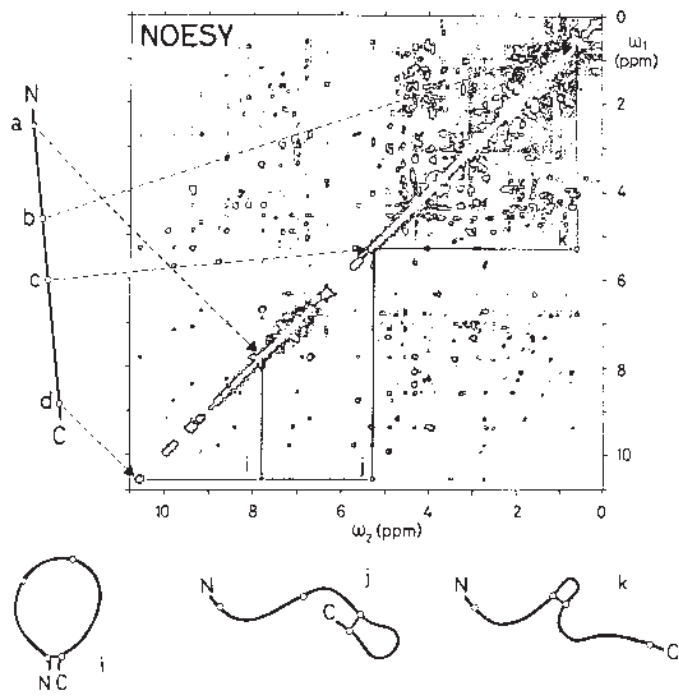

Most protein crystal structures are too poorly resolved for their electron density maps to reveal clearly the positions of individual atoms (e.g., Fig. 6-23). Nevertheless, the distinctive shape of the polypeptide backbone usually permits it to be traced, which, in turn, allows the positions and orientations of its side chains to be deduced (e.g., Fig. 6-22). Yet side chains of comparable size and shape, such as those of Leu, Ile, Thr, and Val, cannot always be differentiated (hydrogen atoms, having only one electron, are visible only if the resolution limit is less than ~ 1.2 Å). Consequently, a protein structure cannot be elucidated from its electron density map alone, but knowing the primary structure of the protein permits the sequence of amino acid residues to be fitted to the electron density map. Mathematical refinement can then reduce the uncertainty in the crystal structure's atomic positions to as little as 0.1 Å.

Most Crystalline Proteins Maintain Their Native Conformations. Does the structure of a protein in a crystal accurately reflect the structure of the protein in solution, where globular proteins normally function? Several lines of evidence indicate that *crystalline proteins assume very nearly the same structures that they have in solution*:

1. A protein molecule in a crystal is essentially in solution because it is bathed by solvent of crystallization over all of its surface except for the few, generally small, patches that contact neighboring protein molecules.
2. In cases when different crystal forms of a protein have been analyzed, or when a crystal structure has been compared to a solution structure (determined by NMR; see below), the molecules have virtually identical conformations. Evidently, crystal packing forces do not greatly perturb the structures of protein molecules.
3. Many enzymes are catalytically active in the crystalline state. Because the activity of an enzyme is very sensitive to the positions of the groups involved in binding and catalysis (Chapter 11), the crystalline enzymes must have conformations that closely resemble their solution conformations.

Protein Structures Can Be Determined by NMR. The basis of **nuclear magnetic resonance (NMR)** is that certain atomic nuclei, including ^1H , ^2H , ^{13}C , ^{15}N , and ^{31}P , when placed in a magnetic field, absorb radio-frequency radiation at frequencies that vary with each type of nucleus, its electronic environment, and its interactions with nearby nuclei. The development of NMR techniques since the mid-1980s, in large part by Richard Ernst and Kurt Wüthrich, has made it possible to determine the three-dimensional structures of globular proteins in aqueous solution.

FIG. 6-24 NOESY spectrum of a protein. The diagonal represents the conventional one-dimensional NMR spectrum presented as a contour plot. Note that it is too crowded with peaks to be directly interpretable (even a small protein has hundreds of protons). The cross (off-diagonal) peaks each arise from the interaction of two protons that are $<5 \text{ \AA}$ apart in space (their one-dimensional NMR peaks are located where horizontal and vertical lines intersect the diagonal). The line to the left of the spectrum represents the extended polypeptide chain with its N- and C-termini labeled N and C and the positions of four protons labeled a to d. The dashed arrows indicate the diagonal NMR peaks to which these protons give rise. Cross peaks, such as i, j, and k, each located at the intersection of the corresponding horizontal and vertical lines, show that two protons are $<5 \text{ \AA}$ apart. These distance relationships are schematically drawn as three looped structures of the polypeptide chain below the spectrum. The assignment of a distance relationship between two protons in a polypeptide requires that the NMR peaks to which they give rise and their positions in the polypeptide be known, which requires that the polypeptide's amino acid sequence has been previously determined. [After Wüthrich, K., *Science* **243**, 45 (1989).]

A protein's conventional (one-dimensional) proton (^1H) NMR spectrum is crowded with overlapping peaks, since even a small protein has hundreds of protons. This problem is addressed by **two-dimensional (2D) NMR spectroscopy**, which yields additional peaks arising from the interactions of protons that are less than 5 \AA apart. Correlation spectroscopy (COSY) provides interatomic distances between protons that are covalently connected through one or two other atoms, such as the H atoms attached to the N and C_α of the same amino acid (corresponding to the ϕ torsion angle). Nuclear Overhauser spectroscopy (NOESY) provides interatomic distances for protons that are close in space, although they may be far apart in the protein sequence. An example of a NOESY spectrum is shown in **Fig. 6-24**.

Interatomic distance measurements between identified pairs of atoms, together with known geometric constraints such as covalent bond distances and angles, group planarity, chirality, and van der Waals radii, are used to compute the protein's three-dimensional structure. However, because interproton distance measurements are imprecise, they cannot imply a unique structure but rather are consistent with an ensemble of closely related structures. Consequently, an NMR structure of a protein (or another macromolecule) is often presented as a sample of structures that are consistent with the data (e.g., **Fig. 6-25**). The "tightness" of a bundle of such structures is indicative both of the accuracy with which the structure is known, which in the most favorable cases is roughly comparable to that of an X-ray crystal structure with a resolution of 2 to 2.5 \AA , and of the conformational fluctuations that the protein undergoes (Section 6-4A). The proton 2D-NMR spectra of proteins larger than $\sim 30 \text{ kD}$ are so crowded with cross peaks that it is all but impossible to interpret them. This problem has been alleviated by

FIG. 6-25 The NMR structure of a protein. The drawing represents 20 superimposed structures of a 64-residue polypeptide comprising the **Src protein SH3 domain** (Section 13-2B). The polypeptide backbone (its connected C_α atoms) is white, and its Phe, Tyr, and Trp side chains are yellow, red, and blue, respectively. The polypeptide backbone folds into two 3-stranded antiparallel β sheets that form a sandwich.

? Propose an explanation of why some portions of the protein structure exhibit greater variability than others.

the development of multidimensional NMR techniques (which spreads these peaks into three or four dimensions) in which specific residues of a protein are enriched by genetic engineering techniques with ^{15}N and/or ^{13}C (replacing the far more naturally abundant but NMR-inactive ^{14}N and ^{12}C). Present NMR methods are limited to determining the structures of macromolecules with molecular masses no greater than ~ 100 kD, but recent advances in NMR technology suggest that this limit may eventually increase to ~ 1000 kD or more.

Around 12,000 NMR structures of proteins and nucleic acids have been determined. In cases in which both the X-ray and NMR structures of a protein are known, they exhibit very few significant differences, thus indicating that crystallization does not perturb the structure of a protein. Moreover, because NMR can probe motions over time scales spanning 10 orders of magnitude, it can also be used to study protein folding and dynamics (Sections 6-4 and 6-5).

Cryo-Electron Microscopy Directly Images Macromolecular Structures. As explained by the wave-particle duality, electrons, like all particles, have wavelike properties, with a wavelength $\lambda = h/mv$, where h is Planck's constant, m is the particle's mass, and v is its velocity. Thus, a beam of electrons of sufficiently high energy ($E = 1/2mv^2$) will have a wavelength small enough to image molecules at atomic resolution (recall that the uncertainty in locating an object is approximately equal to the wavelength of the radiation used to observe it). However, in conventional electron microscopy, samples must be thoroughly dried (to maintain the high vacuum through which the electron beam travels), which greatly distorts biological molecules. This led to the development of **cryo-electron microscopy (cryo-EM)**; Greek: *kryos*, icy cold), in which a hydrated sample is cooled to near-liquid nitrogen temperatures (-196°C) so rapidly (in a few milliseconds) that the water in the sample does not have time to crystallize (which would destroy the sample), but rather assumes a vitreous (glasslike) state. Consequently, the sample remains hydrated and retains its native structure. This, together with ongoing technological and theoretical advances in electron microscopy, has permitted, in recent years, the direct visualization of large molecular complexes, such as ribosomes, at near-atomic resolution (as little as 3.0 \AA). Cryo-EM therefore holds great promise for determining the structures of fragile or flexible complexes that are difficult to crystallize and too large to visualize by NMR methods.

Proteins Can Be Depicted in Different Ways. The huge number of atoms in proteins makes it difficult to visualize them using the same sorts of models employed for small organic molecules. Ball-and-stick representations showing all or most atoms in a protein (as in Figs. 6-7 and 6-10) are exceedingly cluttered, and space-filling models (as in Figs. 6-8 and 6-11) obscure the internal details of the protein. Accordingly, computer-generated or artistic renditions (e.g., Fig. 6-12) are often more useful for representing protein structures. The course of the polypeptide chain can be followed by tracing the positions of its C_α atoms or by representing helices as helical ribbons or cylinders and β sheets as sets of flat arrows pointing from the N- to the C-termini.

B Side Chain Location Varies with Polarity

In the years since Kendrew solved the structure of myoglobin, around 110,000 protein structures have been reported. No two are exactly alike, but they exhibit remarkable consistencies. The primary structures of globular proteins generally lack the repeating sequences that support the regular conformations seen in fibrous proteins. However, *the amino acid side chains in globular proteins are spatially distributed according to their polarities:*

1. The nonpolar residues Val, Leu, Ile, Met, and Phe occur mostly in the interior of a protein, out of contact with the aqueous solvent. The hydrophobic effects that promote this distribution are largely responsible for the three-dimensional structure of native proteins.

GATEWAY CONCEPT Molecular Visualization

Ribbon diagrams of proteins reveal the overall folding pattern of a protein's polypeptide backbone but ignore its side chains. A protein typically has thousands of atoms. However, its many hydrogen atoms, which actually outnumber its C, N, O, and S atoms, are rarely depicted in ball-and-stick and space-filling models. Because each atom's outermost electron shell defines its surface, a protein is a solid object.

FIG. 6-26 Side chain locations in an α helix and a β sheet. In these space-filling models, the main chain is gray, nonpolar side chains are gold, and polar side chains are purple. (a) An α helix from sperm whale myoglobin. Note that the nonpolar residues are primarily on one side of the helix. (b) An antiparallel β sheet from concanavalin A (*side view*). The protein interior is to the right and the exterior is to the left. [Based on X-ray structures by Ilme Schlichting, Max Planck Institut für Molekulare Physiologie, Dortmund, Germany, and Gerald Edelman, The Rockefeller University. PDBids 1A6M and 2CNA.]

2. The charged polar residues Arg, His, Lys, Asp, and Glu are usually located on the surface of a protein in contact with the aqueous solvent. This is because immersing an ion in the virtually anhydrous interior of a protein is energetically unfavorable.
3. The uncharged polar groups Ser, Thr, Asn, Gln, and Tyr are usually on the protein surface but also occur in the interior of the molecule. When buried in the protein, these residues are almost always hydrogen bonded to other groups; in a sense, the formation of a hydrogen bond “neutralizes” their polarity. This is also the case with the polypeptide backbone.

These general principles of side chain distribution are evident in individual elements of secondary structure (Fig. 6-26) as well as in whole proteins (Fig. 6-27). Polar side chains tend to extend toward—and thereby help form—the protein’s surface, whereas nonpolar side chains largely extend toward—and thereby occupy—its interior. Turns and loops joining secondary structural elements usually occur at the protein surface.

Most proteins are quite compact, with their interior atoms packed together even more efficiently than the atoms in a crystal of small organic molecules. Nevertheless, the atoms of protein side chains almost invariably have low-energy arrangements. Evidently, interior side chains adopt relaxed conformations despite the profusion of intramolecular interactions. Closely packed protein interiors generally exclude water. When water molecules are present, they often occupy specific positions where they can form hydrogen bonds, sometimes acting as a bridge between two hydrogen-bonding protein groups.

C Tertiary Structures Contain Combinations of Secondary Structure

Globular proteins—each with a unique tertiary structure—are built from combinations of secondary structural elements. The proportions of α helices and β sheets and the order in which they are connected provide an informative way of classifying and analyzing protein structure.

(a)

FIG. 6-27 Side chain distribution in horse heart cytochrome c. In these paintings, based on an X-ray structure determined by Richard Dickerson, the protein is illuminated by its single iron atom centered in

(b)

a heme group. Hydrogen atoms are not shown. In (a) the hydrophilic side chains are green, and in (b) the hydrophobic side chains are orange.

Certain Combinations of Secondary Structure Form Motifs. Groupings of secondary structural elements, called **supersecondary structures** or **motifs**, occur in many unrelated globular proteins:

1. The most common form of supersecondary structure is the **$\beta\alpha\beta$ motif**, in which an α helix connects two parallel strands of a β sheet (**Fig. 6-28a**).

FIG. 6-28 Schematic diagrams of supersecondary structures. (a) A $\beta\alpha\beta$ motif, (b) a β hairpin motif, (c) an $\alpha\alpha$ motif, and (d) a Greek key motif, showing how it is constructed from a folded-over β hairpin. The polypeptide backbones are drawn as ribbons, with β strands shown as flat arrows pointing from N- to C-terminus, and α helices represented by cylinders.

FIG. 6-29 A selection of protein structures. The proteins are represented by their peptide backbones, drawn in ribbon form, with β strands shown as flat arrows pointing from N- to C-terminus and α helices depicted as coils. The polypeptide chain is colored, from N- to C-terminus, in rainbow order from red to blue. Below each drawing is the corresponding topological diagram indicating the connectivity of its helices (cylinders) and β strands (flat arrows). (a) *E. coli* cytochrome b_{562} (106 residues), which forms an up-down-up-down 4-helix bundle. Its bound heme group is shown in ball-and-stick form with C magenta, N blue, O red, and Fe orange. (b) The N-terminal domain of the human immunoglobulin fragment **Fab New** (103 residues) showing its immunoglobulin fold. The polypeptide chain is folded into a sandwich of 3- and 4-stranded antiparallel β sheets. (c) The N-terminal domain of dogfish lactate dehydrogenase (163 residues). It contains a 6-stranded parallel β sheet in which the crossovers between β strands all contain an α helix that forms a right-handed helical turn with its flanking β strands. [Based on X-ray structures by (a) F. Scott Matthews, Washington University School of Medicine; (b) Roberto Poljak, The Johns Hopkins School of Medicine; and (c) Michael Rossmann, Purdue University. PDBids (a) 256B, (b) 7FAB, and (c) 6LDH.]

? Cover the topology diagrams and practice drawing one for each protein structure.

- Another common supersecondary structure, the **β hairpin motif**, consists of antiparallel strands connected by relatively tight reverse turns (Fig. 6-28b).
- In an **$\alpha\alpha$ motif**, two successive antiparallel α helices pack against each other with their axes inclined. This permits energetically favorable intermeshing of their contacting side chains (Fig. 6-28c). Similar associations stabilize the coiled coil conformation of α keratin and tropomyosin (Fig. 6-15b), although their helices are parallel rather than antiparallel.
- In the **Greek key motif** (Fig. 6-28d; named after an ornamental design commonly used in ancient Greece; see inset), a β hairpin is folded over to form a 4-stranded antiparallel β sheet.

Most Proteins Can Be Classified as α , β , or α/β . The major types of secondary structural elements occur in globular proteins in varying proportions and combinations. Some proteins, such as *E. coli* cytochrome b_{562} (Fig. 6-29a), consist only of

α helices spanned by short connecting links and are therefore classified as **α proteins**. Others, such as immunoglobulins, which contain the **immunoglobulin fold** (Fig. 6-29b), are called **β proteins** because they have a large proportion of β sheets and are devoid of α helices. Most proteins, however, including **lactate dehydrogenase** (Fig. 6-29c) and carboxypeptidase A (Fig. 6-12), are known as **α/β proteins** because they largely consist of mixtures of both types of secondary structure (proteins, on average, contain $\sim 31\%$ α helix and $\sim 28\%$ β sheet).

The α , β , and α/β classes of proteins can be further categorized according to their topology; that is, according to how their secondary structural elements are connected. For example, extended β sheets often roll up to form **β barrels**. Three different types of 8-stranded β barrels, each with a different topology, are shown in Fig. 6-30. Two of these (Fig. 6-30a,b) are all- β structures containing multiple

FIG. 6-30 X-Ray structures of β barrels. Each polypeptide is drawn and colored and accompanied by its corresponding topological diagram as is described in the legend to Fig. 6-29. (a) Human **retinol binding protein** showing its 8-stranded up-and-down β barrel (residues 1–142 of the 182-residue protein). Note that each β strand is linked via a short loop to its clockwise-adjacent strand as seen from the top. The protein's bound retinol molecule is represented by a gray ball-and-stick model. (b) **Peptide- N^4 -(N -acetyl- β - D -glucosaminy)asparagine amidase F** from *Flavobacterium meningosepticum* (residues 1–140 of the 340-residue enzyme). Note how its 8-stranded β barrel is formed by rolling up a 4-segment β hairpin. Here the two β strands in each segment of the β hairpin are colored alike with strands 1 and 8 (the N- and C-terminal strands) red, strands 2 and 7 orange, strands 3 and 6 cyan, and strands 4 and 5 blue. This motif, which is known as a **jelly roll** or **Swiss roll barrel**, is so named because of its topological resemblance to the rolled-up pastries. (c) Chicken muscle **triose phosphate isomerase (TIM; 247 residues)** forms a so-called **α/β barrel** in which eight pairs of alternating β strands and α helices roll up to form an inner barrel of eight parallel β strands surrounded by an outer barrel of eight parallel α helices. The protein is viewed approximately along the axis of the α/β barrel. Note that the α/β barrel is essentially a series of linked $\beta\alpha\beta$ motifs. [Based on X-ray structures by (a) T. Alwyn Jones, Biomedical Center, Uppsala, Sweden; (b) Patrick Van Roey, New York State Department of Health, Albany, New York; and (c) David Phillips, Oxford University, Oxford, U.K. PDBids (a) 1RBP, (b) 1PNG, and (c) 1TIM.]

? Cover the topology diagrams and practice drawing one for each protein structure.

FIG. 6-31 The two-domain protein glyceraldehyde-3-phosphate dehydrogenase. The N-terminal domain (*light blue*) binds NAD^+ (drawn in stick form and colored according to atom type with C green, N blue, O red, and P magenta), and the C-terminal domain (*orange*) binds glyceraldehyde-3-phosphate (not shown). [Based on an X-ray structure by Alan Wonacott, Imperial College, London, U.K. PDBid 1GD1.]

? Identify the supersecondary structures within each domain.

β hairpin motifs. The third, known as an α/β barrel (Fig. 6-30c), can be considered as a set of overlapping $\beta\alpha\beta$ motifs (and is a member of the α/β class of proteins).

Large Polypeptides Form Domains. Polypeptide chains containing more than ~200 residues usually fold into two or more globular clusters known as **domains**, which give these proteins a bi- or multilobal appearance. Each subunit of the enzyme **glyceraldehyde-3-phosphate dehydrogenase**, for example, has two distinct domains (Fig. 6-31). Most domains consist of 40 to 200 amino acid residues and have an average diameter of ~25 Å. An inspection of the various protein structures diagrammed in this chapter reveals that domains each consist of two or more layers of secondary structural elements. The reason for this is clear: At least two such layers are required to seal off a domain's hydrophobic core from its aqueous environment. Thus, polypeptides shorter than 40 residues are unlikely to form stable structures in solution. On the other hand, domains much longer than 200 residues will fold too slowly.

A polypeptide chain wanders back and forth within a domain, but neighboring domains are usually connected by only one or two polypeptide segments. *Consequently, many domains are structurally independent units that have the characteristics of small globular proteins.* Nevertheless, the domain structure of a protein is not necessarily obvious, as its domains may make such extensive contacts with each other that the protein appears to be a single globular entity.

Domains often have a specific function such as the binding of a small molecule. In Fig. 6-31, for example, the dinucleotide NAD^+ (nicotinamide adenine dinucleotide; Fig. 11-4) binds to the N-terminal domain of glyceraldehyde-3-phosphate dehydrogenase. Michael Rossmann has shown that a $\beta\alpha\beta\alpha\beta$ unit, in which the β strands form a parallel sheet with α helical connections, often acts as a nucleotide-binding site. Two of these $\beta\alpha\beta\alpha\beta$ units combine to form a domain known as a **dinucleotide-binding fold**, or **Rossmann fold**. Glyceraldehyde-3-phosphate dehydrogenase's N-terminal domain contains such a fold, as does lactate dehydrogenase (Fig. 6-29c). In some multidomain proteins, binding sites occupy the clefts between domains; that is, small molecules are bound by groups from two domains. In such cases, the relatively pliant covalent connection between the domains allows flexible interactions between the protein and the small molecule.

D Structure Is Conserved More Than Sequence

Y The many thousands of known protein structures, comprising an even greater number of separate domains, can be grouped into families by examining the overall paths followed by their polypeptide chains. Although it is estimated that there are as many as 1400 different protein domain families, approximately 200 different folding patterns account for about half of all known protein structures. As described in Section 5-4B, the domain is the fundamental unit of protein evolution. Apparently, the most common protein domains are evolutionary sinks—domains that arose and persisted because of their ability (1) to form stable folding patterns; (2) to tolerate amino acid deletions, substitutions, and insertions, thereby making them more likely to survive evolutionary changes; and/or (3) to support essential biological functions.

FIG. 6-32 Three-dimensional structures of *c*-type cytochromes. The polypeptide backbones (*blue*) are shown in analogous orientations such that their heme groups (*red*) are viewed edge-on. The Cys, Met, and His side chains that covalently link the heme to the protein are also shown. (a) Cytochrome *c₅₅₀* from *Paracoccus denitrificans*,

(b) cytochrome *c₂* from *Rhodospirillum rubrum*, (c) cytochrome *c* from tuna, and (d) cytochrome *c₅₅₅* from *Chlorobium limicola*. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

Polypeptides with similar sequences tend to adopt similar backbone conformations. This is certainly true for evolutionarily related proteins that carry out similar functions. For example, the cytochromes *c* of different species are highly conserved proteins with closely similar sequences (Table 5-6) and three-dimensional structures.

Cytochrome *c* occurs only in eukaryotes, but prokaryotes contain proteins, known as ***c*-type cytochromes**, which perform the same general function (that of an electron carrier). The *c*-type cytochromes from different species exhibit only low degrees of sequence similarity to each other and to eukaryotic cytochromes *c*. However, their X-ray structures are clearly similar, particularly in polypeptide chain folding and side chain packing in the protein interior (Fig. 6-32). The major structural differences among *c*-type cytochromes lie in the various polypeptide loops on their surfaces. The sequences of the *c*-type cytochromes have diverged so far from one another that, in the absence of their X-ray structures, they can be properly aligned only through the use of mathematically sophisticated computer programs. Thus, *it appears that the essential structural and functional elements of proteins, rather than their amino acid residues, are conserved during evolution.*

E Structural Bioinformatics Provides Tools for Storing, Visualizing, and Comparing Protein Structural Information

The data obtained by X-ray crystallography, NMR spectroscopy, and certain other techniques take the form of three-dimensional coordinates describing the spatial positions of atoms in molecules. This kind of information can be easily stored, displayed, and compared, much like sequence information obtained by nucleotide or protein sequencing methods (Sections 3-4 and 5-3). **Bioinformatics** is the rapidly growing discipline that deals with the burgeoning amount of information related to molecular sequences and structures. **Structural bioinformatics** is a branch of bioinformatics that is concerned with how macromolecular structures are displayed and compared. Some of the databases and analytical tools that are used in structural bioinformatics are listed in Table 6-2 and described in Bioinformatics Project 3.

The Protein Data Bank Is the Repository for Structural Information. The atomic coordinates of more than 120,000 macromolecular structures, including proteins, nucleic acids, and carbohydrates, are archived in the **Protein Data Bank (PDB)**. Indeed, most scientific journals that publish macromolecular structures require that authors deposit their structures' coordinates in the PDB.

Each independently determined structure in the PDB is assigned a unique four-character identifier (its **PDBid**). For example, the PDBid for the structure of sperm whale myoglobin is 1MBO. A coordinate file includes the macromolecule's source (the organism from which it was obtained), the author(s) who determined the structure, key journal references, information about how the structure was determined, and indicators of its accuracy. The sequences of the structure's various chains are then listed together with the descriptions and formulas of its so-called HET (for heterogen) groups, which are molecular entities that are not among the "standard" amino acid or nucleotide residues (for example, organic molecules, nonstandard residues such as Hyp, metal ions, and bound water molecules). The positions of the structure's secondary structural elements and its disulfide bonds are then provided.

The bulk of a PDB file consists of a series of records (lines), each of which provides the three-dimensional (x , y , z) coordinates in angstroms of one atom in the structure. Each atom is identified by a serial number, an atom name (for example, C and O for an amino acid residue's carbonyl C and O atoms, CA and CB for C_{α} and C_{β} atoms), the name of the residue, and a letter to identify the chain to which it belongs (for structures that have more than one chain). For NMR-based structures, the PDB file contains a full set of records for each member of the ensemble of structures (the most representative member of such a coordinate set can be obtained from another database; see Table 6-2).

A particular PDB file may be located according to its PDBid or, if this is unknown, by searching with a variety of criteria including a protein's name, its source, or the author(s). Selecting a particular macromolecule in the PDB initially displays a summary page with options for viewing the structure (either statically or interactively), for viewing or downloading the coordinate file, and for classifying or analyzing the structure in terms of its geometric properties and sequence. The **Nucleic Acid Database (NDB)** archives the atomic coordinates of

structures that contain nucleic acids, using roughly the same format as PDB files (most of this information is also stored in the PDB).

Molecular Graphics Programs Interactively Show Macromolecules in Three Dimensions. The most informative way to examine a macromolecular structure is through the use of molecular graphics programs that permit the user to interactively rotate a macromolecule and thereby perceive its three-dimensional structure. This impression may be further enhanced by simultaneously viewing the macromolecule in stereo. Most molecular graphics programs use PDB files as input. The programs described here can be downloaded from the Internet addresses listed in Table 6-2, some of which also provide instructions for the program's use.

Jmol, which functions as both a web browser-based applet or as a stand-alone program, allows the user to display user-selected macromolecules in a variety of colors and formats (e.g., wire frame, ball-and-stick, backbone, space-filling, and cartoons). The Interactive Exercises on the website that accompanies this textbook (<http://www.wiley.com/college/voet/>) all use Jmol. **FirstGlance** uses Jmol to display macromolecules via a user-friendly interface. **KiNG**, which also has web browser-based and stand-alone versions, displays the so-called **Kinemages** on this textbook's accompanying website. KiNG provides a generally more author-directed user environment than does Jmol. Macromolecules can be displayed directly from their corresponding PDB page using Jmol. The **Swiss-PDB Viewer** (also called **Deep View**), in addition to displaying molecular structures, provides tools for basic model building, homology modeling, energy minimization, and multiple sequence alignment. One advantage of the Swiss-PDB Viewer is that it allows users to easily superimpose two or more models. **Proteopedia** is a 3D interactive encyclopedia of proteins and other macromolecules that resembles Wikipedia in that it is user edited. It uses mainly Jmol as a viewer.

Structure Comparisons Reveal Evolutionary Relationships. Most proteins are structurally related to other proteins, as *evolution tends to conserve the structures of proteins rather than their sequences*. The computational tools described below facilitate the classification and comparison of protein structures. These programs can be accessed directly via their Internet addresses and, in some cases, through the PDB. Studies using these programs yield functional insights, reveal distant evolutionary relationships that are not apparent from sequence comparisons, generate libraries of unique folds for structure prediction, and provide indications as to why certain types of structures are preferred over others.

1. **CATH** (for Class, Architecture, Topology and Homologous superfamily), as its name suggests, categorizes proteins in a four-level structural hierarchy: (1) Class, the highest level, places the selected protein in one of four levels of gross secondary structure (Mainly α , Mainly β , α/β , and Few Secondary Structures); (2) Architecture, the gross arrangement of secondary structure; (3) Topology, which depends on both the overall shape of the protein domain and the connectivity of its secondary structural elements; and (4) Homologous Superfamily, which identifies the protein as a member of a group that shares a common ancestor.
2. **CE** (for Combinatorial Extension of the optimal path) finds all proteins in the PDB that can be structurally aligned with the query structure to within user-specified geometric criteria. CE can optimally align and display two user-selected structures.
3. **Pfam** (for Protein families) is a database of more than 12,000 multiple sequence alignments of protein domains (called Pfam families). Using Pfam, one can analyze a protein for Pfam matches (74% of proteins have at least one match in Pfam), determine the domain organization of a protein based on its sequence or its structure, examine the phylogenetic tree of a Pfam family, and view the occurrence of a protein's domains across different species.

CHECKPOINT

- List some of the relative advantages and disadvantages of using X-ray crystallography, NMR spectroscopy, and cryo-electron microscopy to determine the structure of a protein.
- Explain why knowing a protein's amino acid sequence is required to determine its tertiary structure.
- Why do turns and loops most often occur on the protein surface?
- Which side chains usually occur on a protein's surface? In its interior?
- Describe some of the common protein structural motifs.
- Why does a protein domain consist of at least 40 amino acid residues?
- Explain why a protein's sequence evolves faster than its structure.
- Summarize the types of information provided in a PDB file.
- Why is it useful to compare protein structures in addition to protein sequences?

4. **SCOP** (Structural Classification Of Proteins) classifies protein structures based mainly on manually generated topological considerations according to a six-level hierarchy: Class (e.g., all- α , all- β , α/β), Fold (based on the arrangement of secondary structural elements), Superfamily (indicative of distant evolutionary relationships based on structural criteria and functional features), Family (indicative of near evolutionary relationships based on sequence as well as on structure), Protein, and Species. SCOP permits the user to navigate through its tree-like hierarchical organization and lists the known members of any particular branch.
5. **VAST** (Vector Alignment Search Tool), a component of the National Center for Biotechnology Information (NCBI) Entrez system, reports a precomputed list of proteins of known structure that structurally resemble the query protein ("structure neighbors"). The VAST system uses the **Molecular Modeling Database (MMDB)**, an NCBI-generated database that is derived from PDB coordinates but in which molecules are represented by connectivity graphs rather than sets of atomic coordinates. VAST displays the superposition of the query protein in its structural alignment with up to five other proteins using the molecular graphics program **Cn3D**. VAST also reports a precomputed list of proteins that are similar to the query protein in sequence ("sequence neighbors").

3 Quaternary Structure and Symmetry

KEY CONCEPT

- Some proteins contain multiple subunits, usually arranged symmetrically.

Most proteins, particularly those with molecular masses >100 kD, consist of more than one polypeptide chain. *These polypeptide subunits associate with a specific geometry.* The spatial arrangement of these subunits is known as a protein's quaternary structure.

There are several reasons why multisubunit proteins are so common. In large assemblies of proteins, such as collagen fibrils, the advantages of subunit construction over the synthesis of one huge polypeptide chain are analogous to those of using prefabricated components in constructing a building: Defects can be repaired by simply replacing the flawed subunit; the site of subunit manufacture can be different from the site of assembly into the final product; and the only genetic information necessary to specify the entire edifice is the information specifying its few different self-assembling subunits. In the case of enzymes, increasing a protein's size tends to better fix the three-dimensional positions of its reacting groups. *Increasing the size of an enzyme through the association of identical subunits is more efficient than increasing the length of its polypeptide chain because each subunit has an active site. More importantly, the subunit construction of many enzymes provides the structural basis for the regulation of their activities* (Sections 7-1D and 12-3).

FIG. 6-33 Quaternary structure of hemoglobin. In this space-filling model, the α_1 , α_2 , β_1 , and β_2 subunits are colored yellow, green, cyan, and blue, respectively. Heme groups are red. [Based on an X-ray structure by Max Perutz, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2DHB.]

? Draw a circle around one protomer.

Subunits Usually Associate Noncovalently. A multisubunit protein may consist of identical or nonidentical polypeptide chains. Hemoglobin, for example, has the subunit composition $\alpha_2\beta_2$ (Fig. 6-33). Proteins with more than one subunit are called **oligomers**, and their identical units are called **protomers**. A protomer may therefore consist of one polypeptide chain or several unlike polypeptide chains. In this sense, hemoglobin is a dimer of $\alpha\beta$ protomers.

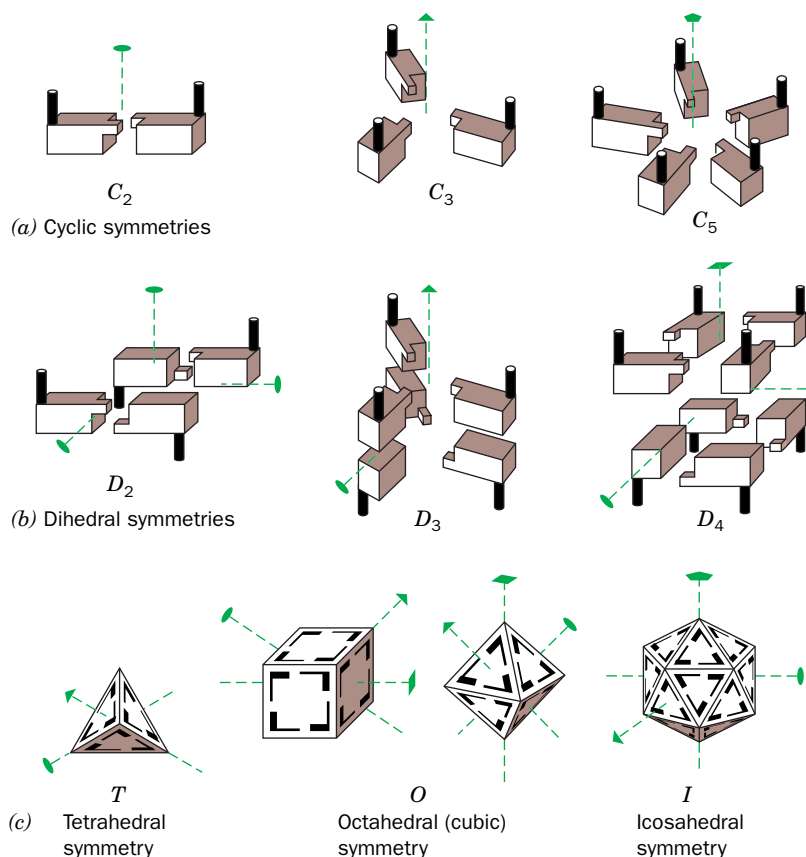

FIG. 6-34 Symmetries of oligomeric proteins.

The oval, the triangle, the square, and the pentagon at the ends of the dashed green lines indicate, respectively, the unique twofold, threefold, fourfold, and fivefold rotational axes of the objects shown. (a) Assemblies with cyclic symmetry. In these objects, a twofold axis is perpendicular to another rotational axis. (b) Assemblies with dihedral symmetry. In these objects, a twofold axis is perpendicular to another rotational axis. (c) Assemblies with the rotational symmetries of a tetrahedron, a cube or octahedron, and an icosahedron. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

WPLS See the Animated Figures.

The contact regions between subunits resemble the interior of a single-subunit protein: They contain closely packed nonpolar side chains, hydrogen bonds involving the polypeptide backbones and their side chains, and, in some cases, interchain disulfide bonds. However, the subunit interfaces of proteins that dissociate *in vivo* have lesser hydrophobicities than do permanent interfaces.

Subunits Are Symmetrically Arranged. In the vast majority of oligomeric proteins, the protomers are symmetrically arranged; that is, each protomer occupies a geometrically equivalent position in the oligomer. Proteins cannot have inversion or mirror symmetry, however, because bringing the protomers into coincidence would require converting chiral L residues to D residues. Thus, *proteins can have only rotational symmetry.*

In the simplest type of rotational symmetry, **cyclic symmetry**, protomers are related by a single axis of rotation (Fig. 6-34a). Objects with two-, three-, or n -fold rotational axes are said to have C_2 , C_3 , or C_n symmetry, respectively. C_2 symmetry is the most common; higher cyclic symmetries are relatively rare.

Dihedral symmetry (D_n), a more complicated type of rotational symmetry, is generated when an n -fold rotation axis intersects a twofold rotation axis at right angles (Fig. 6-34b). An oligomer with D_n symmetry consists of $2n$ protomers. D_2 symmetry is the most common type of dihedral symmetry in proteins.

Other possible types of rotational symmetry are those of a tetrahedron, cube, and icosahedron (Fig. 6-34c). Some multienzyme complexes and spherical viruses are built on these geometric plans.

CHECKPOINT

- List the advantages of multiple subunits in proteins.
- Why can't proteins have mirror symmetry?

4 Protein Stability

KEY CONCEPTS

- Protein stability depends primarily on hydrophobic effects and secondarily on electrostatic interactions.
- A protein that has been denatured may undergo renaturation.
- Protein structures are flexible and may include unfolded regions.

TABLE 6-3 Hydrophathy Scale for Amino Acid Side Chains

Side Chain	Hydrophathy
Ile	4.5
Val	4.2
Leu	3.8
Phe	2.8

GATEWAY CONCEPT The Hydrophobic Effect

Unlike the charged or polar functional groups that contain oxygen or nitrogen atoms, hydrocarbon-rich molecular groups are nonpolar and do not experience strong attractive and repulsive forces. These groups tend to associate due to the hydrophobic effect, which maximizes the entropy of the surrounding water molecules. Only when nonpolar groups are in close proximity, such as in the core of a folded polypeptide structure, do they exert weak attractive forces (van der Waals interactions).

Incredible as it may seem, thermodynamic measurements indicate that *native proteins are only marginally stable under physiological conditions*. The free energy required to denature them is $\sim 0.4 \text{ kJ} \cdot \text{mol}^{-1}$ per amino acid residue, so a fully folded 100-residue protein is only about $40 \text{ kJ} \cdot \text{mol}^{-1}$ more stable than its unfolded form (for comparison, the energy required to break a typical hydrogen bond is $\sim 20 \text{ kJ} \cdot \text{mol}^{-1}$). The various noncovalent influences on proteins—hydrophobic effects, electrostatic interactions, and hydrogen bonding—each have energies that may total thousands of kilojoules per mole over an entire protein molecule. Consequently, a protein structure is the result of a delicate balance among powerful countervailing forces.

A Proteins Are Stabilized by Several Forces

Protein structures are governed primarily by hydrophobic effects and, to a lesser extent, by interactions between polar residues, and by other types of associations.

The Hydrophobic Effect Has the Greatest Influence on Protein Stability. *The hydrophobic effect, which causes nonpolar substances to minimize their contacts with water (Section 2-1C), is the major determinant of native protein structure.* The aggregation of nonpolar side chains in the interior of a protein is favored by the increase in entropy of the water molecules that would otherwise form ordered “cages” around the hydrophobic groups. The combined hydrophobic and hydrophilic tendencies of individual amino acid residues in proteins can be expressed as **hydropathies** (Table 6-3). The greater a side chain’s hydropathy, the more likely it is to occupy the interior of a protein, and vice versa. Hydropathies are good predictors of which portions of a polypeptide chain are inside a protein, out of contact with the aqueous solvent, and which portions are outside (Fig. 6-35).

Site-directed mutagenesis experiments in which individual interior residues have been replaced by a number of others suggest that the factors that affect stability are, in order, the hydrophobicity of the substituted residue, its steric compatibility, and, last, the volume of its side chain.

FIG. 6-35 A hydropathic index plot for bovine chymotrypsinogen. The sum of the hydropathies of nine consecutive residues is plotted versus residue number. A large positive hydropathic index indicates a hydrophobic region of the polypeptide, whereas a large negative value indicates a hydrophilic region. The upper bars denote the protein’s interior regions, as determined by X-ray crystallography, and the lower bars denote the protein’s exterior regions. [After Kyte, J. and Doolittle, R.F., *J. Mol. Biol.* **157**, 111 (1982).]

Electrostatic Interactions Contribute to Protein Stability. In the closely packed interiors of native proteins, van der Waals forces, which are relatively weak (Section 2-1A), are nevertheless an important stabilizing influence. This is because these forces act only over short distances and hence are lost when the protein is unfolded.

Perhaps surprisingly, *hydrogen bonds, which are central features of protein structures, make only minor contributions to protein stability.* This is because hydrogen-bonding groups in an unfolded protein form hydrogen bonds with water molecules. Thus the contribution of a hydrogen bond to the stability of a native protein is the small difference in hydrogen bonding free energies between the native and unfolded states (-2 to $8 \text{ kJ} \cdot \text{mol}^{-1}$ as determined by site-directed mutagenesis studies). Nevertheless, hydrogen bonds are important determinants of native protein structures, because if a protein folded in a way that prevented a hydrogen bond from forming, the stabilizing energy of that hydrogen bond would be lost. Hydrogen bonding therefore fine-tunes tertiary structure by “selecting” the unique native structure of a protein from among a relatively small number of hydrophobically stabilized conformations.

The association of two ionic protein groups of opposite charge (e.g., Lys and Asp) is known as an **ion pair** or a **salt bridge**. About 75% of the charged residues in proteins are members of ion pairs that are located mostly on the protein surface (Fig. 6-36). Despite the strong electrostatic attraction between the oppositely charged members of an ion pair, these interactions contribute little to the stability of a native protein. This is because the free energy of an ion pair’s charge–charge interactions usually fails to compensate for the loss of entropy of the side chains and the loss of solvation free energy when the charged groups form an ion pair. This accounts for the observation that ion pairs are poorly conserved among homologous proteins.

Disulfide Bonds Cross-Link Extracellular Proteins. Disulfide bonds (Fig. 4-6) within and between polypeptide chains form as a protein folds to its native conformation. Some polypeptides whose Cys residues have been derivatized or mutagenically replaced to prevent disulfide bond formation can still assume their fully active conformations, suggesting that disulfide bonds are not essential stabilizing forces. They may, however, be important for “locking in” a particular backbone folding pattern as the protein proceeds from its fully extended state to its mature form.

Disulfide bonds are rare in intracellular proteins because the cytoplasm is a reducing environment. Most disulfide bonds occur in proteins that are secreted from the cell into the more oxidizing extracellular environment. The relatively hostile extracellular milieu (e.g., uncontrolled temperature and pH) apparently requires the additional structural constraints conferred by disulfide bonds.

Metal Ions Stabilize Some Small Domains. Metal ions may also function to internally cross-link proteins. For example, at least ten motifs collectively known as **zinc fingers** have been described in nucleic acid-binding proteins. These structures contain about 25 to 60 residues arranged around one or two Zn^{2+} ions that are tetrahedrally coordinated by the side chains of Cys, His, and occasionally Asp or Glu (Fig. 6-37). The Zn^{2+} ion allows relatively short stretches of polypeptide chain to fold into stable units that can interact with nucleic acids. Zinc fingers are too small to be stable in the absence of Zn^{2+} . Zinc is ideally suited to its structural role in intracellular proteins: Its filled *d* electron shell permits it to interact strongly with a variety of ligands (e.g., sulfur, nitrogen, or oxygen) from different amino acid

FIG. 6-36 Examples of ion pairs in myoglobin. In each case, oppositely charged side chain groups from residues far apart in sequence closely approach each other through the formation of ion pairs.

FIG. 6-37 X-Ray structure of a zinc finger motif of the DNA-binding protein Zif268. The polypeptide chain is drawn in ribbon form and colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The side chains of the Cys and His residues that tetrahedrally ligand a Zn^{2+} ion (cyan sphere) are drawn in stick form with C green, N blue, and S yellow. [Based on an X-ray structure by Carl Pabo, MIT. PDBid 1ZAA.]

residues. In addition, zinc has only one stable oxidation state (unlike, for example, copper and iron), so it does not undergo oxidation–reduction reactions in the cell.

B Proteins Can Undergo Denaturation and Renaturation

The low conformational stabilities of native proteins make them easily susceptible to denaturation by altering the balance of the weak nonbonding forces that maintain the native conformation. Proteins can be denatured by a variety of conditions and substances:

1. Heating causes a protein's conformationally sensitive properties, such as optical rotation (Section 4-2), viscosity, and UV absorption, to change abruptly over a narrow temperature range. Such a sharp transition indicates that the entire polypeptide unfolds or “melts” **cooperatively**, that is, nearly simultaneously. Most proteins have melting temperatures that are well below 100°C. Among the exceptions are the proteins of thermophilic bacteria (**Box 6-3**).
2. pH variations alter the ionization states of amino acid side chains, thereby changing protein charge distributions and hydrogen-bonding requirements.
3. Detergents associate with the nonpolar residues of a protein, thereby interfering with the hydrophobic interactions responsible for the protein's native structure.
4. The **chaotropic agents** guanidinium ion and urea,

in concentrations in the range 5 to 10 M, are the most commonly used protein denaturants. Chaotropic agents are ions or small organic molecules that increase the solubility of nonpolar substances in water. Their effectiveness as denaturants stems from their ability to disrupt hydrophobic interactions, although their mechanism of action is not well understood.

Box 6-3 Perspectives in Biochemistry

Thermostable Proteins

Certain species of bacteria known as **hyperthermophiles** grow at temperatures near 100°C. They live in such places as hot springs and submarine hydrothermal vents, with the most extreme, the archaeobacterium *Pyrolobus fumarii*, able to grow at temperatures as high as 113°C. These organisms have many of the same metabolic pathways as do **mesophiles** (organisms that grow at “normal” temperatures). However, most mesophilic proteins denature at temperatures at which hyperthermophiles thrive. What is the structural basis for the thermostability of hyperthermophilic proteins?

The difference in the thermal stabilities of the corresponding (hyper)thermophilic and mesophilic proteins does not exceed $\sim 100 \text{ kJ} \cdot \text{mol}^{-1}$, the equivalent of a few noncovalent interactions. This is probably why comparisons of the X-ray structures of hyperthermophilic enzymes with their mesophilic counterparts have failed to reveal any striking differences between them. These proteins exhibit some variations in secondary structure but no more than would be expected for homologous proteins from distantly related mesophiles. However, several of these thermostable enzymes have a superabundance of salt bridges on their surfaces, many of which are arranged in extensive networks containing up to 18 side chains.

The idea that salt bridges can stabilize a protein structure appears to contradict the conclusion of Section 6-4A that ion pairs are, at best,

marginally stable. The key to this apparent paradox is that *the salt bridges in thermostable proteins form networks*. Thus, the gain in charge–charge free energy on associating a third charged group with an ion pair is comparable to that between the members of this ion pair, whereas the free energy lost on desolvating and immobilizing the third side chain is only about half that lost in bringing together the first two side chains. The same, of course, is true for the addition of a fourth, fifth, etc., side chain to a salt bridge network.

Not all thermostable proteins have such a high incidence of salt bridges. Structural comparisons suggest that these proteins are stabilized by a combination of small effects, the most important of which are an increased size of the protein's hydrophobic core, an increased size of the interface between its domains and/or subunits, and a more tightly packed core as evidenced by a reduced surface-to-volume ratio.

The fact that the proteins of hyperthermophiles and mesophiles are homologous and carry out much the same functions indicates that mesophilic proteins are by no means maximally stable. This, in turn, strongly suggests *that the marginal stability of most proteins under physiological conditions (averaging $\sim 0.4 \text{ kJ} \cdot \text{mol}^{-1}$ of amino acid residues) is an essential property that has arisen through natural selection*. Perhaps this marginal stability helps confer the structural flexibility that many proteins require to carry out their physiological functions.

Many Denatured Proteins Can Be Renatured. In 1957, the elegant experiments of Christian Anfinsen on **ribonuclease A (RNase A)** showed that proteins can be denatured reversibly. RNase A, a 124-residue single-chain protein, is completely unfolded and its four disulfide bonds reductively cleaved in an 8 M urea solution containing 2-mercaptoethanol. Dialyzing away the urea and reductant and exposing the resulting solution to O₂ at pH 8 (which oxidizes the SH groups to form disulfides) yields a protein that is virtually 100% enzymatically active and physically indistinguishable from native RNase A (**Fig. 6-38**). The protein must therefore **renature** spontaneously.

The renaturation of RNase A demands that its four disulfide bonds re-form. The probability of one of the eight Cys residues randomly forming a disulfide bond with its proper mate among the other seven Cys residues is 1/7; that of one of the remaining six Cys residues then randomly forming its proper disulfide bond is 1/5; and so on. Thus the overall probability of RNase A re-forming its four native disulfide links at random is

$$\frac{1}{7} \times \frac{1}{5} \times \frac{1}{3} \times \frac{1}{1} = \frac{1}{105}$$

PROCESS DIAGRAM

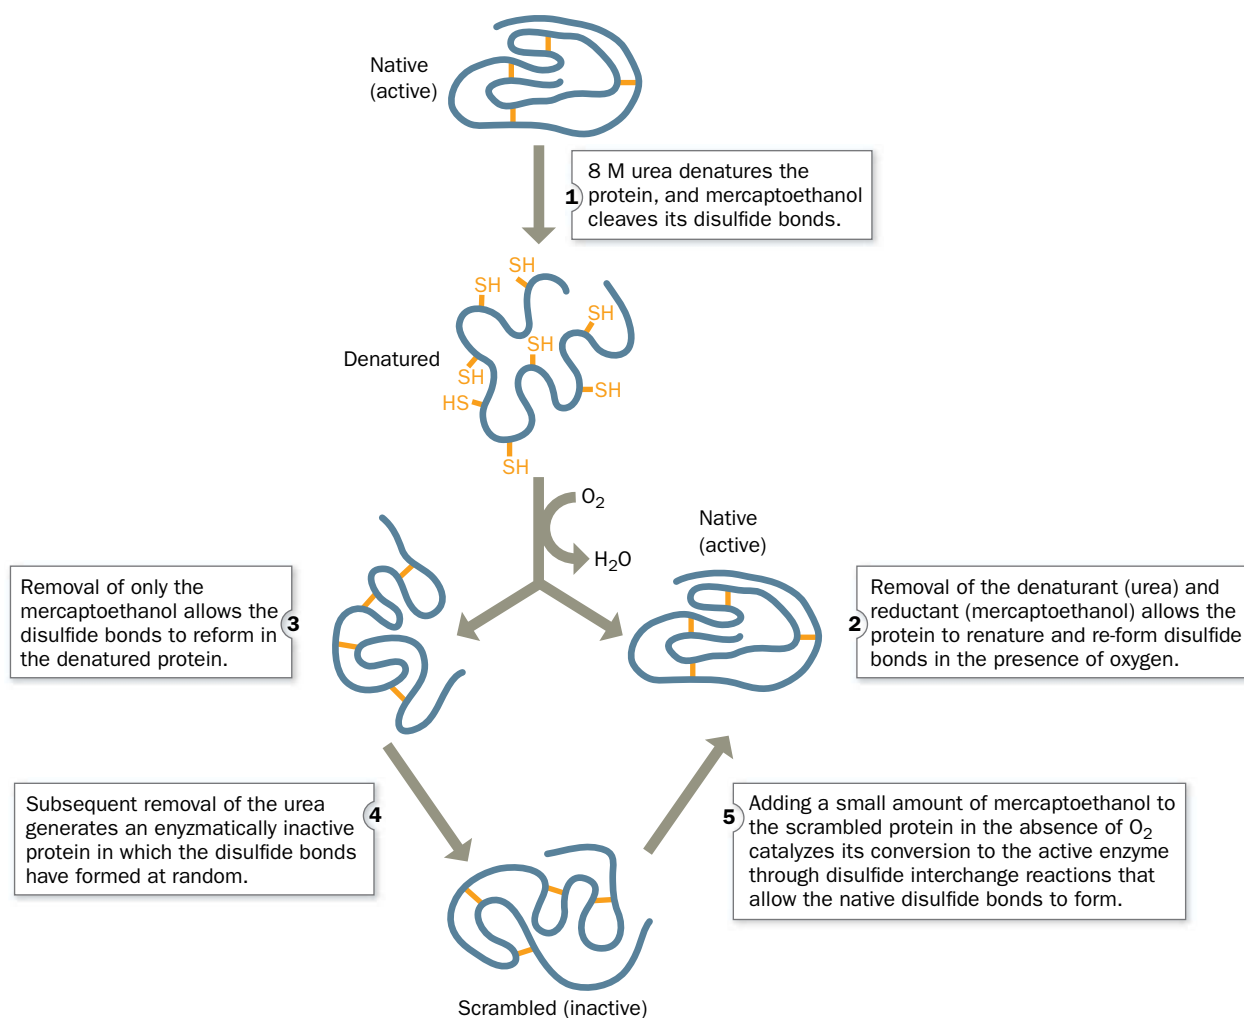

FIG. 6-38 Denaturation and renaturation of RNase A. The polypeptide is represented by a blue line, with its disulfide bonds in yellow. **WPLS** See the Animated Process Diagrams.

Clearly, the disulfide bonds do not randomly re-form under renaturing conditions, since, if they did, only 1% of the refolded protein would be catalytically active. Indeed, if the RNase A is reoxidized in 8 M urea so that its disulfide bonds re-form while the polypeptide chain is a random coil, then after removal of the urea, the RNase A is, as expected, only ~1% active (Fig. 6-38, Steps 3–4). This “scrambled” protein can be made fully active by exposing it to a trace of 2-mercaptoethanol, which breaks the improper disulfide bonds and allows the proper bonds to form. *Anfinsen’s work demonstrated that proteins can fold spontaneously into their native conformations under physiological conditions. This implies that a protein’s primary structure dictates its three-dimensional structure.*

C Proteins Are Dynamic

The static way that protein structures are usually portrayed may leave the false impression that proteins have fixed and rigid structures. In fact, proteins are flexible and rapidly fluctuating molecules whose structural mobilities are functionally significant. Groups ranging in size from individual side chains to entire domains or subunits may be displaced by up to several angstroms through random intramolecular movements or in response to a trigger such as the binding of a small molecule. Extended side chains, such as those of Lys, and the N- and C-termini of polypeptide chains are especially prone to wave around in solution because there are few forces holding them in place.

Theoretical calculations by Martin Karplus indicate that a protein’s native structure probably consists of a large collection of rapidly interconverting conformations that have essentially equal stabilities (Fig. 6-39). Conformational flexibility, or **breathing**, with structural displacement of up to ~2 Å, allows small molecules to diffuse in and out of the interior of certain proteins. In some cases, a protein’s conformational flexibility includes two stable alternatives in dynamic equilibrium. A change in cellular conditions, such as pH or oxidation state, or the presence of a binding partner can tip the balance toward one conformation or the other.

Many Proteins Contain Unfolded Regions. An entire protein or a long polypeptide segment (>30 residues) may lack defined structure in its native state. Such **intrinsically disordered proteins** are characterized by sequences rich in certain polar and charged amino acids (Gln, Ser, Pro, Glu, Lys, Gly, and Ala) and lacking in bulky hydrophobic groups (Val, Leu, Ile, Met, Phe, Trp, and Tyr). Sequence analysis suggests that nearly half of all eukaryotic proteins contain long disordered segments, whereas only a few percent of prokaryotic proteins do. Not surprisingly, programs designed to predict intrinsic disorder indicate that the polypeptides in sequence databases contain a far greater proportion of intrinsically disordered regions than do the polypeptides in the much smaller structural databases. Also, disease-associated proteins are predicted to be rich in disordered regions. In general, intrinsically disordered proteins tend to participate in signaling and regulation, whereas ordered proteins are involved largely in catalytic reactions, transport processes, and structural functions.

Intrinsically disordered proteins often adopt a specific secondary or tertiary structure when they bind to other molecules such as ions, organic molecules, proteins, and nucleic acids. For example, the transcription factor known as **CREB (cyclic AMP response element-binding protein)** is disordered when

FIG. 6-39 Molecular dynamics of myoglobin. Several “snapshots” of the protein calculated at intervals of 5×10^{-12} s are superimposed. The backbone is blue, the heme group is yellow, and the His side chain linking the heme to the protein is orange.

FIG. 6-40 Conformational change in a CREB domain. The backbone of the kinase-inducible domain (KID) of CREB is drawn as a pink worm. It is unstructured when free in solution (*left*) but becomes two perpendicular helices when it forms a complex with the KID-binding domain of another protein (shown with its solvent-accessible surface in gray, *right*). The KID residues Ser 133, which has a covalently attached phosphoryl group, and Leu 141 are drawn in ball-and-stick form with C green, O red, and P yellow. [Courtesy of Peter Wright, Scripps Research Institute, La Jolla, California. PDBid 1KDX.]

free in solution but folds to an ordered conformation when it interacts with the CREB-binding protein (Fig. 6-40). Apparently, the increased flexibility of disordered protein segments enables them to perform a relatively unhindered conformational search when binding to their target molecules. In some cases, it also allows them to bind to several different target proteins in different conformations. It has been suggested that a structured globular protein would have to be two to three times larger than a disordered protein to provide the same size intermolecular interface; hence, the use of disordered proteins provides genetic economy and reduces intracellular crowding.

CHECKPOINT

- Describe the hydrophobic index plot for a fibrous protein such as collagen or keratin.
- Describe the forces that stabilize proteins, and rank their relative importance.
- Summarize the results of Anfinsen's experiment with RNase A.
- Why would it be advantageous for a protein or a segment of a protein to lack defined secondary or tertiary structure?

5 Protein Folding

KEY CONCEPTS

- A folding protein follows a pathway from high energy and high entropy to low energy and low entropy.
- Protein disulfide isomerase catalyzes disulfide bond formation.
- A variety of molecular chaperones assist protein folding via an ATP-dependent bind-and-release mechanism.
- Amyloid diseases result from protein misfolding.
- The misfolded proteins form fibrils containing extensive β structure.

Studies of protein stability and renaturation suggest that protein folding is directed largely by the residues that occupy the interior of the folded protein. But *how* does a protein fold to its native conformation? One might guess that this process occurs through the protein's random exploration of all the conformations available to it until it eventually stumbles onto the correct one. A simple calculation first made by Cyrus Levinthal, however, convincingly demonstrates that this cannot possibly be the case: Assume that an n -residue protein's 2^n torsion angles, ϕ and ψ , each have three stable conformations. This yields $3^{2n} \approx 10^n$ possible conformations for the protein (a gross underestimate because we have completely neglected its side chains). Then, if the protein could explore a new conformation every 10^{-13} s (the rate at which single bonds reorient), the time t , in seconds, required for the protein to explore all the conformations available to it is

$$t = \frac{10^n}{10^{13}}$$

For a small protein of 100 residues, $t = 10^{87}$ s, which is immensely greater than the apparent age of the universe (~ 13.7 billion years = 4.3×10^{17} s). Clearly, proteins must fold more rapidly than this.

A Proteins Follow Folding Pathways

Experiments have shown that many proteins fold to their native conformations in less than a few seconds (and even microseconds for some small proteins). This is

FIG. 6-41 Hypothetical protein folding pathway. This example shows a linear pathway for folding a two-domain protein. [After Goldberg, M.E., *Trends Biochem. Sci.* **10**, 389 (1985).]

because *proteins fold to their native conformations via directed pathways rather than stumbling on them through random conformational searches*. Thus, as a protein folds, its conformational stability increases sharply (i.e., its free energy decreases sharply), which makes folding a one-way process. A hypothetical folding pathway is diagrammed in **Fig. 6-41**.

Experimental observations indicate that protein folding begins with the formation of local segments of secondary structure (α helices and β sheets). This early stage of protein folding is extremely rapid, with much of the native secondary structure in small proteins appearing within 5 ms of the initiation of folding. Because native proteins contain compact hydrophobic cores, it is likely that the driving force in protein folding is what has been termed a **hydrophobic collapse**. The collapsed state is known as a **molten globule**, a species that has much of the secondary structure of the native protein but little of its tertiary structure. Theoretical studies suggest that helices and sheets form in part because they are particularly compact ways of folding a polypeptide chain.

Over the next 5 to 1000 ms, the secondary structure becomes stabilized and tertiary structure begins to form. During this intermediate stage, the natively like elements are thought to take the form of subdomains that are not yet properly docked to form domains. In the final stage of folding, which for small, single-domain proteins occurs over the next few seconds, the protein undergoes a series of complex rearrangements in which it attains its relatively stable internal side chain packing and hydrogen bonding while it expels the remaining water molecules from its hydrophobic core.

In multidomain and multisubunit proteins, the respective units then assemble in a similar manner, with a few slight conformational adjustments required to produce the protein's native tertiary or quaternary structure. Thus, *proteins appear to fold in a hierarchical manner, with small local elements of structure forming and then coalescing to yield larger elements, which coalesce with other such elements to form yet larger elements, etc.*

Folding, like denaturation, is a cooperative process, with small elements of structure accelerating the formation of additional structures. A folding protein must proceed from a high-energy, high-entropy state to a low-energy, low-entropy state. This energy–entropy relationship, which is diagrammed in **Fig. 6-42**, is known as a **folding funnel**. An unfolded polypeptide has

FIG. 6-42 Energy–entropy diagram for protein folding. The surface of the folding funnel represents all possible conformations that the polypeptide can assume with each point on it corresponding to a specific conformation. The height of each point is indicative of the conformation's energy, and the funnel's width at that energy is indicative of the polypeptide's entropy (number of different conformations it can assume with that energy). The unfolded polypeptide proceeds from a high-energy, high-entropy (*wide*), disordered state to a low-energy, low-entropy (*narrow*), native conformation. Note that folding can occur via multiple trajectories (e.g., *arrows*), each starting from a different unfolded structure at the top of the energy landscape, and that it has many high-energy, partially folded structures (occupying the false energy minima) and only a few low-energy, native structures (at the global energy minimum). [Courtesy of Ken Dill, Stony Brook University.]

many possible conformations (high entropy). As it folds into an ever-decreasing number of possible conformations, its entropy and free energy decrease. The energy–entropy diagram is not a smooth valley, but a jagged landscape. The minor clefts and gullies on the sides of the funnel (false energy minima) represent partially folded conformations that are temporarily trapped until, through random thermal activation or the action of molecular chaperones (Section 6-5B), they overcome an “uphill” free energy barrier and can then proceed to a lower energy conformation. Evidently, *proteins have evolved to have efficient folding pathways as well as stable native conformations.*

Understanding the process of protein folding as well as the forces that stabilize folded proteins is essential for elucidating the rules that govern the relationship between a protein’s amino acid sequence and its three-dimensional structure. Such information will prove useful in predicting the structures of the millions of proteins that are known only from their sequences (Box 6-4).

Box 6-4 Perspectives in Biochemistry

Protein Structure Prediction and Protein Design

Around 50 million polypeptide sequences are known, yet the structures of only ~110,000 proteins have been determined. Consequently there is a need to develop robust techniques for predicting a protein’s structure from its amino acid sequence. This represents a formidable challenge but promises great rewards in terms of understanding protein function, identifying diseases related to abnormal protein sequences, and designing drugs to alter protein structure or function.

There are several major approaches to protein structure prediction. The simplest and most reliable approach, **homology modeling**, aligns the sequence of interest with the sequence of a homologous protein or domain of known structure—compensating for amino acid substitutions, insertions, and deletions—through modeling and energy minimization calculations. This method yields reliable models for proteins that have as little as 25% sequence identity with a protein of known structure, although, of course, the accuracy of the model increases with the degree of sequence identity. The field of **structural genomics**, which seeks to determine the X-ray structures of all representative domains, is aimed at expanding this predictive technique. The identification of structural homology is likely to provide clues as to a protein’s function even with imperfect structure prediction.

Distantly related proteins may be structurally similar even though they have diverged to such an extent that their sequences show no obvious resemblance. **Threading** is a computational technique that attempts to determine the unknown structure of a protein by ascertaining whether it is consistent with a known protein structure. It does so by placing (threading) the unknown protein’s residues along the backbone of a known protein structure and then determining whether the amino acid side chains of the unknown protein are stable in that arrangement. This method is not yet reliable, although it has yielded encouraging results.

Empirical methods based on experimentally determined statistical information such as the α helix and β sheet propensities deduced by Chou and Fasman (Table 6-1) have been moderately successful in predicting the secondary structures of proteins. Their main drawback is that neighboring residues in a polypeptide sometimes exert strong influence on a given residue’s tendency to form a particular secondary structure.

Because the native structure of a protein ultimately depends on its amino acid sequence, it should be possible, in principle, to predict the structure of a protein based only on its chemical and physical properties (e.g., the hydrophobicity, size, hydrogen-bonding propensity, and charge of each of its amino acid residues). Among the most successful of these *ab initio* (from the beginning) methods is the **Rosetta** program, formulated by David Baker. To satisfy the program’s computational needs, a volunteer network of ~100,000 computers, known as Rosetta@home, provides the 500,000 or so hours of processing time required to generate a structure. Two examples of successful protein structure prediction by Rosetta appear above, marked (a) and (b). The predicted model (*gray*) for each of these bacterial proteins is superimposed on the experimentally determined X-ray structure, colored in rainbow order from N-terminus (*blue*) to C-terminus (*red*) with core side chains drawn as sticks.

Protein design, the experimental inverse of protein structure prediction, has provided insights into protein folding and stability. Protein design attempts to construct an amino acid sequence that will form a structure such as a sandwich of β sheets or a bundle of α helices. The

designed polypeptide is then chemically or biologically synthesized, and its structure is determined. Experimental results suggest that the greatest challenge of protein design may lie not in getting the polypeptide to fold to the desired conformation but in preventing it from folding into other unwanted conformations. In this respect, science lags far behind nature.

The first wholly successful *de novo* (beginning anew) protein design, accomplished by Stephen Mayo, was for a 28-residue $\beta\beta\alpha$ motif that has a backbone conformation designed to resemble a zinc finger (Fig. 6-37) but contains no stabilizing metal ions. A computational design process considered the interactions among side chain and backbone atoms, screened all possible amino acid sequences, and, in order to take into account side chain flexibility, tested all sets of energetically allowed torsion angles for each side chain. The number of amino acid sequences to be tested was limited to 1.9×10^{27} , representing 1.1×10^{62} possible conformations! The design process yielded an optimal sequence of 28 residues, which was chemically synthesized and its structure determined by NMR spectroscopy. The designed protein, called FSD-1, closely resembled its predicted structure, and its backbone conformation (*blue*) was nearly

superimposable on that of a known zinc finger motif (*red*). Although FSD-1 is relatively small, it folds into a unique stable structure, thereby demonstrating the power of protein design techniques.

Protein Disulfide Isomerase Acts during Protein Folding. Even under optimal experimental conditions, proteins often fold more slowly *in vitro* than they fold *in vivo*. One reason is that folding proteins often form disulfide bonds not present in the native proteins, and then slowly form native disulfide bonds through the process of disulfide interchange. **Protein disulfide isomerase (PDI)** catalyzes this process. Indeed, the observation that RNase A folds so much faster *in vivo* than *in vitro* led Anfinsen to discover this enzyme.

PDI binds to a wide variety of unfolded polypeptides via a hydrophobic patch on its surface. A Cys—SH group on reduced (SH-containing) PDI reacts with a disulfide group on the polypeptide to form a mixed disulfide and a Cys—SH group on the polypeptide (Fig. 6-43a). Another disulfide group on the polypeptide, brought into proximity by the spontaneous folding of the polypeptide, is attacked by this Cys—SH group. The newly liberated Cys—SH group then repeats this process with another disulfide bond, and so on, ultimately yielding the polypeptide containing only native disulfide bonds, along with regenerated PDI.

Oxidized (disulfide-containing) PDI also catalyzes the initial formation of a polypeptide's disulfide bonds by a similar mechanism (Fig. 6-43b). In this case, the reduced PDI reaction product must be reoxidized by cellular oxidizing agents in order to repeat the process.

B Molecular Chaperones Assist Protein Folding

Proteins begin to fold as they are being synthesized, so the renaturation of a denatured protein *in vitro* may not entirely mimic the folding of a protein *in vivo*. In addition, proteins fold *in vivo* in the presence of extremely high concentrations of other proteins with which they can potentially interact. **Molecular chaperones are essential proteins that bind to unfolded and partially folded polypeptide chains to disrupt the improper association of exposed hydrophobic segments that would otherwise lead to non-native folding as well as polypeptide aggregation and precipitation.** In essence, molecular chaperones function to lift folding polypeptides out of the false minima in their folding funnels (Fig. 6-42). This is especially important for multidomain and multisubunit proteins, whose components must fold fully before they can properly associate with each other.

Many molecular chaperones were first described as **heat shock proteins (Hsp)** because their rate of synthesis is increased at elevated temperatures. Presumably, the additional chaperones are required to recover heat-denatured proteins or to prevent misfolding under conditions of environmental stress.

FIG. 6-43 Mechanism of protein disulfide isomerase. (a) Reduced (SH-containing) PDI catalyzes the rearrangement of a polypeptide's non-native disulfide bonds via disulfide interchange reactions to yield native disulfide bonds. (b) Oxidized (disulfide-containing) PDI

catalyzes the initial formation of a polypeptide's disulfide bonds through the formation of a mixed disulfide. Reduced PDI can then react with a cellular oxidizing agent to regenerate oxidized PDI. **WPLS See the Animated Figures.**

Cells Contain a Variety of Molecular Chaperones. There are several classes of molecular chaperones in both prokaryotes and eukaryotes, including the following:

1. The **Hsp70**, a family of highly conserved 70-kD proteins in both prokaryotes and eukaryotes. In association with the **cochaperone** protein **Hsp40**, they facilitate the folding of newly synthesized proteins and reverse the denaturation and aggregation of proteins. Hsp70 proteins also function to unfold proteins in preparation for their transport through membranes (Section 9-4D) and to subsequently refold them.
2. **Trigger factor**, a ribosome-associated chaperone in prokaryotes that prevents the aggregation of polypeptides as they emerge from the ribosome (Section 27-5A). Trigger factor and Hsp70 are the first chaperones a newly made prokaryotic protein encounters. Subsequently, many partially folded proteins are handed off to other chaperones to complete the folding process. *E. coli* can tolerate the elimination of trigger factor or Hsp70, but not both, thereby indicating that they are functionally redundant. Eukaryotes lack trigger factor but contain other small chaperones that have similar functions.

3. The **chaperonins**, which form large, multisubunit, cage-like assemblies in both prokaryotes and eukaryotes. They bind improperly folded proteins and induce them to refold inside an internal cavity (see below).
4. The **Hsp90**, a family of 90-kD eukaryotic proteins that mainly facilitate the late stages of folding of proteins involved in cellular signaling (Chapter 13). Hsp90 proteins are among the most abundant proteins in eukaryotes, accounting for up to 6% of cellular protein under stressful conditions that destabilize proteins.

Most Chaperones Require ATP. All molecular chaperones operate by binding to an unfolded or aggregated protein's solvent-exposed hydrophobic surface and subsequently releasing it. The disruption of intramolecular and/or intermolecular aggregates by chaperone binding permits the substrate protein to continue folding after its release. In most cases, this bind-and-release process is repeated several times before the substrate protein reaches its native state, whereupon it no longer has the exposed hydrophobic surfaces to which chaperones bind.

Most molecular chaperones are **ATPases**; that is, enzymes that catalyze the hydrolysis of ATP (adenosine triphosphate) to ADP (adenosine diphosphate) and P_i (inorganic phosphate):

The ATP complex of the chaperone binds the unfolded or aggregated substrate protein, whereas its ADP complex releases it. Thus, the favorable free energy change of ATP hydrolysis drives the chaperone's bind-and-release reaction cycle.

The GroEL/ES Chaperonin Forms Closed Chambers in Which Proteins Fold. The chaperonins in *E. coli* consist of two types of subunits named **GroEL** and **GroES**. The X-ray structure of a GroEL–GroES–(ADP)₇ complex (Fig. 6-44), determined by Arthur Horwich and Paul Sigler, reveals 14 identical 549-residue GroEL subunits arranged in two stacked rings of seven subunits each. This complex is capped at one end by a dome-like heptameric ring of 97-residue GroES

FIG. 6-44 X-Ray structure of the GroEL–GroES–(ADP)₇ complex.

(a) A space-filling drawing as viewed perpendicularly to the complex's sevenfold axis with the GroES ring orange, the cis ring of GroEL green, and the trans ring of GroEL red with one subunit of each ring shaded more brightly. The dimensions of the complex are indicated. Note the different conformations of the two GroEL rings. The ADPs, whose binding sites are in the base of each cis ring GroEL subunit, are not seen because they are surrounded by protein. (b) As in Part a but

viewed along the sevenfold axis. (c) As in Part a but with the two GroEL subunits closest to the viewer in both the cis and trans rings removed to expose the interior of the complex. The level of fog increases with the distance from the viewer. Note the much larger size of the cavity formed by the cis ring and GroES in comparison to that of the trans ring. [Based on an X-ray structure by Paul Sigler, Yale University. PDBid 1AON.]

subunits to form a bullet-shaped complex with C_7 symmetry. The two GroEL rings each enclose a central chamber with a diameter of $\sim 45 \text{ \AA}$ in which partially folded proteins fold to their native conformations. A barrier in the center of the complex (Fig. 6-44c) prevents a folding protein from passing between the two GroEL chambers. The GroEL ring that contacts the GroES heptamer is called the cis ring; the opposing GroEL ring is known as the trans ring.

ATP Binding and Hydrolysis Drive the Conformational Changes in GroEL/ES.

Each GroEL subunit has a binding pocket for ATP that catalyzes the hydrolysis of its bound ATP to ADP + P_i . When the cis ring subunits hydrolyze their bound ATP molecules and release the product P_i , the protein undergoes a conformational change that widens and elongates the cis inner cavity so as to more than double its volume from $85,000 \text{ \AA}^3$ to $175,000 \text{ \AA}^3$. (In the structure shown in Fig. 6-44, the cis ring has already hydrolyzed its seven molecules of ATP to ADP.) The expanded cavity can enclose a partially folded substrate protein of at least 70 kD. *All seven subunits of the GroEL ring act in concert; that is, they are mechanically linked such that they change their conformations simultaneously.*

The cis and trans GroEL rings undergo conformational changes in a reciprocating fashion, with events in one ring influencing events in the other ring. The entire GroEL/ES chaperonin complex functions as follows (Fig. 6-45):

1. One GroEL ring that has bound 7 ATP also binds an improperly folded substrate protein, which associates with hydrophobic patches that line the inner wall of the GroEL chamber. The GroES cap then binds to the GroEL ring like a lid on a pot, inducing a conformational change in the resulting cis ring that buries the hydrophobic patches, thereby depriving the substrate

PROCESS DIAGRAM

FIG. 6-45 Reaction cycle of the GroEL/ES chaperonin. The protein complex is colored as in Fig. 6-44. See the text for an explanation.
WPLS See the Animated Process Diagrams.

protein of its binding sites. This releases the substrate protein into the now enlarged and closed cavity, where it commences folding. The cavity, which is now lined only with hydrophilic groups, provides the substrate protein with an isolated microenvironment that prevents it from nonspecifically aggregating with other misfolded proteins. Moreover, the conformational change that buries GroEL's hydrophobic patches stretches and thereby partially unfolds the improperly folded substrate protein before it is released. This rescues the substrate protein from a local energy minimum in which it had become trapped (Fig. 6-42), thereby permitting it to continue its conformational journey down the folding funnel toward its native state (the state of lowest free energy).

2. Within, ~ 10 s (the time the substrate protein has to fold), the cis ring catalyzes the hydrolysis of its 7 bound ATPs to ADP + P_i and the P_i is released. The absence of ATP's γ phosphate group weakens the interactions that bind GroES to GroEL.
3. A second molecule of improperly folded substrate protein binds to the trans ring followed by 7 ATP. Conformational linkages between the cis and trans rings prevent the binding of both substrate protein and ATP to the trans ring until the ATP in the cis ring has been hydrolyzed.
4. The binding of substrate protein and ATP to the trans ring conformationally induces the cis ring to release its bound GroES, 7 ADP, and the presumably now better-folded substrate protein. This leaves ATP and substrate protein bound only to the trans ring of GroEL, which now becomes the cis ring as it binds GroES.

Steps 1 through 4 are then repeated. The GroEL/ES system expends 7 ATPs per folding cycle. If the released substrate protein has not achieved its native state, it may subsequently rebind to GroEL (a substrate protein that has achieved its native fold lacks exposed hydrophobic groups and hence cannot rebind to GroEL). Typically, only $\sim 5\%$ of substrate proteins fold to their native state in each reaction cycle. Thus, to fold half the substrate protein present would require $\log(1 - 0.5)/\log(1 - 0.05) \approx 14$ reaction cycles and hence $7 \times 14 = 98$ ATPs (which appears to be a profligate use of ATP but constitutes only a small fraction of the thousands of ATPs that must be hydrolyzed to synthesize a typical polypeptide and its component amino acids). Because protein folding occurs alternately in the two GroEL rings, the proper functioning of the chaperonin requires both GroEL rings, even though their two cavities are unconnected.

Experiments indicate that the GroEL/ES system interacts with only a subset of *E. coli* proteins, most with molecular masses in the range 20 to 60 kD. These proteins tend to contain two or more α/β domains that mainly consist of open β sheets. Such proteins are expected to fold only slowly to their native state because the formation of hydrophobic sheets requires a large number of specific long-range interactions. Proteins dissociate from GroEL/ES after folding, but some frequently revisit the chaperonin, apparently because they are structurally labile or prone to aggregate and must return to GroEL for periodic maintenance.

Eukaryotic cells contain the chaperonin **TRiC**, with double rings of eight nonidentical subunits, each of which resembles a GroEL subunit. However, the TRiC proteins contain an additional segment that acts as a built-in lid, so the complex encloses a polypeptide chain and mediates protein folding without the assistance of a GroES-like cochaperone. Like its bacterial counterpart, TRiC operates in an ATP-dependent fashion. Around 10% of eukaryotic proteins transiently interact with TRiC.

Chaperones Facilitate Protein Evolution. Chaperones may reduce the effects of a mutation in a protein that would otherwise preclude its proper folding. Subsequent mutations could then improve the protein's folding efficiency and solubility, thereby reducing its dependence on chaperones and increasing its abundance. Thus, chaperones increase the range of mutations that are subject to Darwinian selection.

TABLE 6-4 Some Protein Misfolding Diseases

Disease	Defective Protein
Alzheimer's disease	Amyloid- β protein
Amyotrophic lateral sclerosis	Superoxide dismutase
Fibrinogen amyloidosis	Fibrinogen α chain
Huntington's disease	Huntingtin with polyglutamate expansion
Light chain amyloidosis	Immunoglobulin light chain
Lysozyme amyloidosis	Lysozyme
Parkinson's disease	α -Synuclein
Transmissible spongiform encephalopathies (TSEs)	Prion protein

C Many Diseases Are Caused by Protein Misfolding

Most proteins in the body maintain their native conformations or, if they become partially denatured, are either renatured through the auspices of molecular chaperones or are proteolytically degraded (Section 21-1). However, at least 35 different—and usually fatal—human diseases are associated with the extracellular deposition of normally soluble proteins in certain tissues in the form of insoluble fibrous aggregates (Table 6-4). The aggregates are known as **amyloids**, a term that means starchlike because it was originally thought that they resembled starch.

The diseases, known as **amyloidoses**, are a set of relatively rare inherited diseases in which mutant forms of normally occurring proteins [e.g., **lysozyme**, an enzyme that hydrolyzes bacterial cell walls (Section 11-4), and **fibrinogen**, a blood plasma protein that is the precursor of **fibrin**, which forms blood clots (Box 11-4)] accumulate in a variety of tissues as amyloids. The symptoms of amyloidoses usually do not become apparent until the third to seventh decade of life and typically progress over 5 to 15 years, ending in death.

Amyloid- β Protein Accumulates in Alzheimer's Disease. **Alzheimer's disease**, a neurodegenerative condition that strikes mainly the elderly, causes devastating mental deterioration and eventual death (it affects ~10% of those over 65 and ~50% of those over 85). It is characterized by brain tissue containing abundant amyloid **plaques** (deposits) surrounded by dead and dying neurons (Fig. 6-46). The amyloid plaques consist mainly of fibrils of a 40- to 42-residue protein named **amyloid- β protein (A β)**. A β is a fragment of a 770-residue membrane protein called the **A β precursor protein (APP)**, whose normal function is unknown. A β is excised from APP in a multistep process through the actions of two proteolytic enzymes dubbed **β -** and **γ -secretases**. The neurotoxic effects of A β begin even before significant amyloid deposits appear (see below).

The age dependence of Alzheimer's disease suggests that A β deposition is an ongoing process. Indeed, several rare mutations in the APP gene that increase the rate of A β production result in the onset of Alzheimer's disease as early as the fourth decade of life. A similar phenomenon occurs in individuals with **Down syndrome**, a condition characterized by mental retardation and a distinctive physical appearance caused by the trisomy (3 copies per cell) of chromosome 21 rather than the normal two copies. These individuals invariably develop Alzheimer's disease by their 40th year because the gene encoding APP is located on chromosome 21 and hence individuals with Down syndrome produce APP and presumably A β at an accelerated rate. Consequently, a promising strategy for halting the progression of Alzheimer's disease is to develop drugs that selectively inhibit the action of the β - and/or γ -secretases to decrease the rate of A β production.

FIG. 6-46 Brain tissue from an individual with Alzheimer's disease. The two circular objects in this photomicrograph are plaques that consist of amyloid deposits of A β protein surrounded by a halo of neurites (axons and dendrites) from dead and dying neurons.

Prion Diseases Are Infectious. Certain diseases that affect the mammalian central nervous system were originally thought to be caused by “slow viruses” because they take months, years, or even decades to develop. Among them are **scrapie** (a neurological disorder of sheep and goats), **bovine spongiform encephalopathy (BSE or mad cow disease)**, and **kuru** (a degenerative brain disease in humans that was transmitted by ritual cannibalism among the Fore people of Papua New Guinea; *kuru* means “trembling”). There is also a sporadic (spontaneously arising) human disease with similar symptoms, **Creutzfeldt–Jakob disease (CJD)**, which strikes one person per million per year and which may be identical to kuru. In all these invariably fatal diseases, neurons develop large vacuoles that give brain tissue a spongelike microscopic appearance. Hence the diseases are collectively known as **transmissible spongiform encephalopathies (TSEs)**.

Unlike other infectious diseases, *the TSEs are not caused by a virus or microorganism*. Indeed, extensive investigations have failed to show that they are associated with any nucleic acid. Instead, as Stanley Prusiner demonstrated for scrapie, the infectious agent is a protein called a **prion** (for *proteinaceous infectious particle* that lacks nucleic acid); hence TSEs are alternatively called **prion diseases**. The scrapie prion, which is named **PrP** (for *Prion Protein*), consists of 208 mostly hydrophobic residues. This hydrophobicity causes partially proteolyzed PrP to aggregate as clusters of rodlike particles that closely resemble the amyloid fibrils seen on electron microscopic examination of prion-infected brain tissue (**Fig. 6-47**). These fibrils presumably form the amyloid plaques that accompany the neuronal degeneration in TSEs.

How are prion diseases transmitted? **PrP** is the product of a normal cellular gene that has no known function (genetically engineered mice that fail to express PrP appear to be normal). Infection of cells by prions somehow alters the PrP protein. Various methods have demonstrated that the scrapie form of PrP (**PrP^{Sc}**) is identical to normal cellular PrP (**PrP^C**) in sequence but differs in secondary and/or tertiary structure. This suggests that *PrP^{Sc} induces PrP^C to adopt the conformation of PrP^{Sc}*; that is, a small amount of PrP^{Sc} triggers the formation of additional PrP^{Sc} from PrP^C, which triggers more PrP^{Sc} to form, and so on. This accounts for the observation that mice that do not express the gene encoding PrP cannot be infected with scrapie.

Human PrP^C consists of a disordered (and hence unseen) 98-residue N-terminal “tail” and a 110-residue C-terminal globular domain containing three α helices and a short two-stranded antiparallel β sheet (**Fig. 6-48a**). Unfortunately the insolubility of PrP^{Sc} has precluded its structural determination, but spectroscopic methods indicate that it has a lower α helix content and a higher β sheet content than PrP^C. This suggests that the protein has refolded (**Fig. 6-48b**). The high β sheet content of PrP^{Sc} presumably facilitates the aggregation of PrP^{Sc} as amyloid fibrils (see below).

TSEs can be transmitted by the consumption of nerve tissue from infected individuals, as illustrated by the incidence of BSE. This disease was unknown before 1985 but reached epidemic proportions among cattle in the U.K. in 1993. The rise in BSE reflects the practice, beginning in the 1970s, of feeding cattle preparations of meat and bone meal that were derived from other animals by a method that failed to inactivate prions. The BSE epidemic abated due to the banning of such feeding in 1988, together with the slaughter of large numbers of animals at risk for having BSE. However, it is now clear that BSE was transmitted to humans who ate meat from BSE-infected cattle: Some 200 cases of so-called **new variant CJD** have been reported to date, almost entirely in the U.K., many of which occurred in teenagers and young adults. Before 1994, however, CJD under the age of 40 was extremely rare. It should be noted that the transmission of BSE from cattle to humans was unexpected: Scrapie-infected sheep have long been consumed worldwide and yet the incidence of CJD in mainly meat-eating countries such as the U.K. (in which sheep are particularly abundant) was no greater than that in largely vegetarian countries such as India.

Evidence is accumulating that many neurodegenerative diseases are prion diseases. For example, the intracerebral inoculation of marmoset monkeys with brain homogenates from humans with Alzheimer’s disease produced A β plaques

FIG. 6-48 Prion protein conformations. (a) The NMR structure of human prion protein (PrP^C). The protein, missing its first 23 residues, is drawn in ribbon form with helices red, β sheets green, and other segments orange. Its disulfide bond is shown in yellow. (b) A plausible model for the structure of PrP^{Sc} represented as in Part a. Note the formation of structure in what was the flexibly disordered N-terminal region. [Courtesy of Fred Cohen, University of California at San Francisco. Part a based on an NMR structure by Kurt Wüthrich, Eidgenössische Technische Hochschule, Zurich, Switzerland. PDBid 1QLX.]

in the monkeys with an incubation time of 3.5 years. Similarly, fetal brain cells that had been grafted into individuals with **Parkinson's disease** (a neurodegenerative disease of mainly the elderly whose symptoms include tremors, rigidity, and slowness of movement and which is characterized by the neuronal accumulation of the protein **α -synuclein** into amyloid inclusions called **Lewy bodies**), exhibited Lewy bodies a decade after their transplantation. Prusiner has therefore postulated that all neurodegenerative diseases are prion diseases.

Amyloid Fibrils Are β Sheet Structures. The amyloid fibers that characterize the amyloidoses, Alzheimer's disease, and the TSEs are built from proteins that exhibit no structural or functional similarities in their native states. In contrast, the appearance of their fibrillar forms is strikingly similar. Spectroscopic analysis of amyloid fibrils indicates that they are rich in β structure, with individual β strands oriented perpendicular to the fiber axis (Fig. 6-49). Furthermore, the ability to form amyloid fibrils is not unique to the small set of proteins associated with specific diseases. Under the appropriate conditions, almost any protein can be induced to aggregate. Thus, *the ability to form amyloid may be an intrinsic property of all polypeptide chains.*

A variety of experiments indicate that amyloidogenic mutant proteins are significantly less stable than their wild-type counterparts (e.g., they have significantly lower melting temperatures). This suggests that the partially unfolded, aggregation-prone forms are in equilibrium with the native conformation even under conditions in which the native state is thermodynamically stable [keep in mind that the equilibrium ratio of unfolded (U) to native (N) protein molecules in the reaction $N \rightleftharpoons U$ is governed by Eq. 1-17: $K_{eq} = [U]/[N] = e^{-\Delta G^{\circ'}/RT}$, where $\Delta G^{\circ'}$ is the

FIG. 6-49 Model of an amyloid fibril. (a) The model, based on X-ray fiber diffraction measurements, is viewed normal to the fibril axis (above) and along the fibril axis (below). The arrowheads indicate the path but not necessarily the direction of the β strands. (b) A single β sheet, which is shown for clarity. The loop regions connecting the β strands have unknown structure.

CHECKPOINT

- Describe the energy and entropy changes that occur during protein folding.
- Explain why it is important for protein disulfide isomerase to catalyze both the breaking and formation of disulfide bonds.
- How does protein renaturation *in vitro* differ from protein folding *in vivo*?
- Explain why a protein such as RNase A can be easily denatured and renatured *in vitro*, whereas most proteins that are denatured do not refold properly *in vitro*.
- Explain the role of ATP in the action of Hsp70 and GroEL/ES.
- Why would cells need more than one type of chaperone?
- Why do proteins vary in their need for chaperones?
- What are amyloid fibrils, what is their origin, and why are they harmful?
- Explain what must happen in order for a folded globular protein to form an amyloid fiber.
- Why are amyloid diseases more common in older individuals?

standard free energy of unfolding, so that as ΔG° decreases, the equilibrium proportion of U increases]. It is therefore likely that fibril formation is initiated by the association of the β domains of two or more partially unfolded amyloidogenic proteins to form a more extensive β sheet. This would provide a template or nucleus for the recruitment of additional polypeptide chains to form the growing fibril. Because most amyloid diseases require several decades to become symptomatic, the development of an amyloid nucleus must be a rare event. Once an amyloid fiber begins to grow, however, its development is more rapid.

The factors that trigger amyloid formation remain obscure, even when mutations (in the case of hereditary amyloidoses) or infection (in the case of TSEs) appear to be the cause. After it has formed, an amyloid fibril is virtually indestructible under physiological conditions, possibly due to the large number of main-chain hydrogen bonds that must be broken to separate the individual polypeptide strands (side chain interactions are less important in stabilizing β sheets). It seems likely that protein folding pathways have evolved not only to allow polypeptides to assume stable native structures but also to avoid forming interchain hydrogen bonds that would lead to fibril formation.

Are fibrillar deposits directly responsible for the neurodegeneration seen in many amyloid diseases? A growing body of evidence suggests that cellular damage begins when the misfolded proteins first aggregate but are still soluble. For example, in mouse models of Alzheimer's disease, cognitive impairment is evident before amyloid plaques develop. Other experiments show that the most infectious prion preparations contain just 14 to 28 PrP^{Sc} molecules; that is, a nucleus for a fibril, not the fibril itself. Even a modest number of misfolded protein molecules could be toxic if they prevented the cell's chaperones from assisting other more critical proteins to fold. The appearance of extracellular—and sometimes intracellular—amyloid fibrils may simply represent the accumulation of protein that has overwhelmed the cellular mechanisms that govern protein folding or the disposal of misfolded proteins.

Summary

1 Secondary Structure

- Four levels of structural complexity are used to describe the three-dimensional shapes of proteins.
- The conformation of a polypeptide backbone is described by its ϕ and ψ torsion angles.
- The α helix is a regular secondary structure in which hydrogen bonds form between backbone groups four residues apart. In the β sheet, hydrogen bonds form between the backbones of separate polypeptide segments.
- Fibrous proteins are characterized by a single type of secondary structure: α keratin is a left-handed coil of two α helices, and collagen is a left-handed triple helix in which each strand has the repeating sequence Gly-X-Y, where X is often Pro and Y is often Hyp.

2 Tertiary Structure

- The structures of proteins have been determined mainly by X-ray crystallography, NMR spectroscopy, and cryo-EM.
- The nonpolar side chains of a globular protein tend to occupy the protein's interior; the polar side chains tend to define its surface.
- Protein structures can be classified on the basis of motifs, secondary structure content, topology, or domain architecture. Structural elements are more likely to be evolutionarily conserved than are amino acid sequences.
- Structural bioinformatics is concerned with the storage, visualization, analysis, and comparison of macromolecular structures.

3 Quaternary Structure and Symmetry

- The individual subunits of multisubunit proteins are usually symmetrically arranged.

4 Protein Stability

- Native protein structures are only slightly more stable than their denatured forms. The hydrophobic effect is the primary determinant of protein stability. Hydrogen bonding and ion pairing contribute relatively little to a protein's stability.
- Studies of protein denaturation and renaturation indicate that the primary structure of a protein determines its three-dimensional structure.

5 Protein Folding

- Proteins fold to their native conformations via directed pathways in which small elements of structure coalesce into larger structures.
- Molecular chaperones facilitate protein folding *in vivo* by repeatedly binding and releasing a polypeptide, usually in an ATP-dependent manner, and in the case of chaperonins, providing it with an isolated microenvironment in which to fold.
- Diseases caused by protein misfolding include the amyloidoses, Alzheimer's disease, Parkinson's disease, and the transmissible spongiform encephalopathies (TSEs), all of which may be transmitted by prions.

Problems

EXERCISES

- Draw a cis peptide bond and identify the groups that experience steric interference.
- How many peptide bonds are shown in the structure drawn in Fig. 6-7?
- Why would you be unlikely to see an α helix containing only the following amino acids: Arg, Lys, Met, Phe, Trp, Tyr, Val?
- Calculate the length in angstroms of a 100-residue segment of the α keratin coiled coil.
- The digestive tract of the larvae of clothes moths is a strongly reducing environment. Why is this beneficial to the larvae?
- Collagen IV, which occurs in basement membranes, contains a sulfimine bond (colored red in the structure below) that crosslinks two collagen triple helices. Identify the parent amino acid residues that participate in this linkage.

$$\begin{array}{ccccccc}
 | & & & & & & | \\
 \text{C}=\text{O} & & & \text{OH} & & & \text{C}=\text{O} \\
 | & & & | & & & | \\
 \text{CH}-\text{CH}_2-\text{CH}_2-\text{CH}-\text{CH}_2-\text{N}=\text{S}-\text{CH}_2-\text{CH}_2-\text{CH} \\
 | & & & & & & | \\
 \text{NH} & & & & \text{CH}_3 & & \text{NH} \\
 | & & & & & & |
 \end{array}$$
- Describe the primary, secondary, tertiary, and quaternary structures of collagen.
- Explain why gelatin, which is mostly collagen, is nutritionally inferior to other types of protein.
- Globular proteins are typically constructed from several layers of secondary structure, with a hydrophobic core and a hydrophilic surface. Is this true for a fibrous protein such as α keratin?
- Is it possible for a native protein to be entirely irregular—that is, without α helices, β sheets, or other repetitive secondary structures?
- The X-ray crystallographic analysis of a protein often fails to reveal the positions of the first few and/or the last few residues of a polypeptide chain. Explain.
- (a) Is Trp or Gln more likely to be on a protein's surface? (b) Is Ser or Val less likely to be in a protein's interior? (c) Is Leu or Ile less likely to be found in a middle of an α helix? (d) Is Cys or Ser more likely to be in a β sheet?
- Classify the following proteins as α , β , or α/β :
 - KcsA K^+ channel (Fig. 10-4)
 - thioredoxin (Fig. 23-11)
- Classify the following proteins as α , β , or α/β :
 - Grb2 (Fig. 13-9)
 - plastocyanin (Fig. 19-19)
- You are performing site-directed mutagenesis to test predictions about which residues are essential for a protein's function. Which of each pair of amino acid substitutions listed below would you expect to disrupt protein structure the most? Explain.
 - Val replaced by Ala or Phe
 - Lys replaced by Asp or Arg
 - Gln replaced by Glu or Asn
 - Pro replaced by His or Gly
- Laboratory techniques for randomly linking together amino acids typically generate an insoluble polypeptide, yet a naturally occurring polypeptide of the same length is usually soluble. Explain.
- Researchers introduced prions into normal mice and mice that were genetically predisposed to develop a disease resembling Alzheimer's. Explain why the Alzheimer's-prone mice displayed symptoms of the prion disease much sooner than did the normal mice.
- The genetically engineered proteins that accumulate in bacterial inclusion bodies (Fig. 5-2) form amyloid structures. Such proteins are often difficult to recover in functional form from the bacteria. Explain.
- In some proteins, the side-chain carboxylate carbon of an N-terminal glutamate residue reacts with the free amino group to form a pentagonal lactam, a cyclic structure containing a $\text{C}=\text{O}$ group. Draw the resulting pyroglutamate residue.
- Experiments in mice suggest that pyroglutamylation (see Problem 19) increases the rate of aggregation of amyloid- β protein. Propose an explanation for this observation.

CHALLENGE QUESTIONS

21. Helices can be described by the notation n_m , where n is the number of residues per helical turn and m is the number of atoms, including H, in the ring that is closed by the hydrogen bond. (a) What is this notation for the α helix? (b) Is the 3_{10} helix steeper or shallower than the α helix?
22. Hydrophobic residues usually appear at the first and fourth positions in the seven-residue repeats of polypeptides that form coiled coils. (a) Why do polar or charged residues usually appear in the remaining five positions? (b) Why is the sequence Ile–Gln–Glu–Val–Glu–Arg–Asp more likely than the sequence Trp–Gln–Glu–Tyr–Glu–Arg–Asp to appear in a coiled coil?
23. Which of the following polypeptides is most likely to form an α helix?
- CRAGNRKIVLETY
 - SEDNFGAPKSILW
 - QKASVEMAVRNSG
24. Which of the peptides in Problem 23 is least likely to form a β strand?
25. Explain why Pro residues can occupy the N-terminal turn of an α helix.
26. What types of rotational symmetry are possible for a protein with (a) four or (b) six identical subunits?
27. Bacterial glutamate synthetase consists of 12 identical subunits arranged in two stacked rings of six subunits. How would you describe this protein's symmetry?
28. Proteins in solution are often denatured if the solution is shaken violently enough to cause foaming. Indicate the mechanism of this process. (*Hint:* The nonpolar groups of detergents extend into the air at air–water interfaces.)
29. Given enough time, will all denatured proteins spontaneously renature?
30. Describe the intra- and intermolecular bonds or interactions that are broken or retained when collagen is heated to produce gelatin.
31. Under physiological conditions, polylysine assumes a random coil conformation. Under what conditions might it form an α helix?
32. Would intrinsically disordered polypeptide segments contain relatively more hydrophilic or hydrophobic residues? Explain.
33. It is often stated that proteins are quite large compared to the molecules they bind. However, what constitutes a large number depends on your point of view. Calculate the ratio of the volume of a hemoglobin molecule (65 kD) to that of the four O_2 molecules that it binds and the ratio of the volume of a typical office ($4 \times 4 \times 3$ m) to that of the typical (70-kg) office worker that occupies it. Assume that the molecular volumes of hemoglobin and O_2 are in equal proportions to their molecular masses and that the office worker has a density of 1.0 g/cm^3 . Compare these ratios. Is this the result you expected?
34. In prokaryotes, the error rate in protein synthesis may be as high as 5×10^{-4} per codon. What fraction of polypeptides containing (a) 500 residues or (b) 2000 residues would you expect to contain at least one amino acid substitution?
35. The coat protein of **tomato bushy stunt virus** consists of 180 chemically identical subunits, each of which is composed of ~ 386 amino acid residues. The probability that a wrong amino acid residue will be biosynthetically incorporated in a polypeptide chain is 1 part in 3000 per residue. (a) Calculate the average number of coat protein subunits that would have to be synthesized to produce a perfect viral coat. (b) What would this number be if the viral coat were a single polypeptide chain with the same number of residues that it actually has?
36. Not all heat shock proteins are chaperones; some are proteins that facilitate the degradation rather than the refolding of other proteins. Explain why the rate of protein degradation would increase during heat shock.
37. Protein denaturation can be triggered by a variety of environmental insults, including high temperature, covalent modification, and oxidation. Explain why researchers have observed a correlation between the

level of heat shock proteins and the ratio of oxidized to reduced glutathione (see Section 4-3B) in cells subjected to oxidative stress.

38. Explain why β sheets are less likely to form than α helices during the earliest stages of protein folding.
39. The GroEL/ES cycle diagrammed in Fig. 6-45 circulates only in the clockwise direction. Explain the basis for this irreversibility in terms of the sequence of structural and binding changes in the GroEL/ES system.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

- Exercise 1** Visualizing and Analyzing α Helices
- Exercise 2** Visualizing and Analyzing β Sheets
- Exercise 3** Visualizing and Identifying Supersecondary Structures
- Exercise 4** Visualizing and Analyzing Cytochrome *c*
- Exercise 5** Visualizing and Analyzing Hemoglobin

Extended Exercises Bioinformatics projects are available on the book companion site (www.wiley.com/college/voet), as well as in WileyPLUS Learning Space.

Project 3 Visualizing Three-Dimensional Protein Structures Using the Molecular Visualization Programs Jmol and PyMOL

There are two halves to Project 3. The first half contains the exercises using Jmol and the second half contains the same exercises using PyMOL.

- Obtaining Structural Information.** Compare different secondary structure predictions for a given protein sequence, then inspect its X-ray crystallographic structure.
- Exploring the Protein Data Bank.** Learn how to locate and download specific protein structure files, sequences, and images. Explore additional educational resources such as Molecule of the Month and links to additional structural biology resources.
- Examining Protein Structures.** Examine a protein structure file and use molecular modeling programs to visualize the protein and highlight selected features.
- Protein Families.** Identify homologous proteins in other structural databases.

Project 4 Structural Alignment and Protein Folding

- Alignment of Small Molecules.** Use MarvinSketch software to draw small molecules—ethane and the amino acid lysine.
- Alignment of Peptides.** Construct and optimize a small peptide with MarvinSketch, then align its 3D structure with the structure of the same peptide sequence found in a protein.
- CASP and Protein Structure Prediction.** Researchers spend up to two years predicting the structure of a protein based on its amino acid sequence, then meet at the CASP conference, where the newly determined structure is released and teams are evaluated on how closely their predictions align with the new structures. Learn more about CASP, explore some of the literature, and then compare 3D alignments of proteins using the Protein Data Bank web site.

CASE STUDIES www.wiley.com/college/voet

Case 4 The Structure of Insulin

Focus concept: The primary structure of insulin is examined, and the sequences of various animal insulins are compared.

Prerequisites: Chapters 4, 5, and 6

- Amino acid structure
- Protein architecture
- Basic immunology

Case 5 Characterization of Subtilisin from the Antarctic Psychrophile *Bacillus* TA41

Focus concept: The structural features involved in protein adaptation to cold temperatures are explored.

Prerequisite: Chapter 6

- Protein architecture
- Principles of protein folding

Case 6 A Collection of Collagen Cases

Focus concept: Factors important in the stability of collagen are examined.

Prerequisites: Chapters 4, 5, and 6

- Amino acid structures and properties
- Primary and secondary structure
- Basic collagen structure

MORE TO EXPLORE A number of human diseases are caused by point mutations that alter a single amino acid in a polypeptide. (a) Explain how such a small change in a collagen subunit can destabilize the entire collagen structure. (b) Investigate how an amino acid substitution in an enzyme can render the enzyme inactive. (c) Investigate how an amino acid substitution can affect a protein's folding efficiency without affecting its ultimate structure or function.

CHAPTER 7

Protein Function: Myoglobin and Hemoglobin, Muscle Contraction, and Antibodies

Doug Allan / Getty Images

The nearly colorless icefish is the only adult vertebrate that lacks hemoglobin. It can survive without this otherwise essential oxygen-binding protein because in the cold (-1.9°C) Antarctic waters where it lives, the fish consumes little oxygen and the solubility of oxygen is relatively high.

Chapter Contents

1 Oxygen Binding to Myoglobin and Hemoglobin

- A Myoglobin Is a Monomeric Oxygen-Binding Protein
- B Hemoglobin Is a Tetramer with Two Conformations
- C Oxygen Binds Cooperatively to Hemoglobin
- D Hemoglobin's Two Conformations Exhibit Different Affinities for Oxygen
- E Mutations May Alter Hemoglobin's Structure and Function

2 Muscle Contraction

- A Muscle Consists of Interdigitated Thick and Thin Filaments
- B Muscle Contraction Occurs when Myosin Heads Walk Up Thin Filaments
- C Actin Forms Microfilaments in Nonmuscle Cells

3 Antibodies

- A Antibodies Have Constant and Variable Regions
- B Antibodies Recognize a Huge Variety of Antigens

The preceding two chapters have painted a broad picture of the chemical and physical properties of proteins but have not delved deeply into their physiological functions. Nevertheless, it should come as no surprise that the structural complexity and variety of proteins allow them to carry out an enormous array of specialized biological tasks. For example, the enzyme catalysts of virtually all metabolic reactions are proteins (we consider enzymes in detail in Chapters 11 and 12). Genetic information would remain locked in DNA were it not for the proteins that participate in decoding and transmitting that information. Remarkably, the thousands of proteins that participate in building, supporting, recognizing, transporting, and transforming cellular components act with incredible speed and accuracy and, in most cases, are subject to multiple regulatory mechanisms.

The specialized functions of proteins, from the fibrous proteins we examined in Section 6-1C to the precisely regulated metabolic enzymes we discuss in later chapters, can all be understood in terms of how proteins bind to and interact with other components of living systems. In this chapter, we focus on three sets of proteins: the oxygen-binding proteins myoglobin and hemoglobin, the actin and myosin proteins responsible for muscle contraction, and antibody molecules. The molecular structures and physiological roles of these proteins are known in detail, and their proper functioning is vital for human health. In addition, these proteins serve as models for many of the proteins we will examine later when we discuss metabolism and the management of genetic information.

1 Oxygen Binding to Myoglobin and Hemoglobin

KEY CONCEPTS

- Myoglobin, with its single heme prosthetic group, exhibits a hyperbolic O_2 -binding curve.
- Hemoglobin can adopt the deoxy (T) or oxy (R) conformation, which differ in O_2 -binding affinity.
- Oxygen binding triggers conformational changes in hemoglobin so that oxygen binds to the protein cooperatively, yielding a sigmoidal binding curve.
- The Bohr effect and BPG alter hemoglobin's O_2 -binding affinity.
- Mutations can change hemoglobin's O_2 -binding properties and cause disease.

We begin our study of protein function with two proteins that reversibly bind molecular oxygen (O_2). **Myoglobin**, the first protein whose structure was determined by X-ray crystallography, is a small protein with relatively simple oxygen-binding behavior. **Hemoglobin**, a tetramer of myoglobin-like polypeptides, is a more complicated protein that functions as a sophisticated system for delivering oxygen to tissues throughout the body. The efficiency with which hemoglobin binds and releases O_2 is reminiscent of the specificity and efficiency of metabolic enzymes. It is worthwhile to study hemoglobin's structure and function because many of the theories formulated to explain O_2 binding to hemoglobin also explain the control of enzyme activity.

A Myoglobin Is a Monomeric Oxygen-Binding Protein

Myoglobin is a small intracellular protein in vertebrate muscle. Its X-ray structure, determined by John Kendrew in 1959, revealed that most of myoglobin's 153 residues are members of eight α helices (traditionally labeled A through H) that are arranged to form a globular protein with approximate dimensions $44 \times 44 \times 25 \text{ \AA}$ (Fig. 7-1).

FIG. 7-1 Structure of sperm whale myoglobin. This 153-residue monomeric protein consists of eight α helices, labeled A through H, that are connected by short polypeptide links (corners) named for the helices they connect (e.g., the GH corner links helices G and H and NA is the N-terminal segment preceding the A helix; the last half of what was originally thought to be the EF corner has been shown to form a short helix that is designated the F' helix). The heme group is shown in red. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

FIG. 7-2 The heme group. The central Fe(II) atom is shown liganded to the four N atoms of the porphyrin ring, whose pyrrole groups are labeled A–D. The heme is a conjugated system, so all the Fe–N bonds are equivalent. The Fe(II) is also liganded to a His side chain and, when it is present, to O₂. The six ligands are arranged at the corners of an octahedron centered on the Fe ion (octahedral geometry).

Myoglobin Contains a Heme Prosthetic Group. Myoglobin, other members of the **globin** family of proteins (Section 5-4B), and a variety of other proteins such as cytochrome *c* (Sections 5-4A and 6-2D) all contain a single **heme** group (Fig. 7-2). The heme is tightly wedged in a hydrophobic pocket between the E and F helices in myoglobin. The heterocyclic ring system of heme is a **porphyrin** derivative containing four **pyrrole** groups (labeled A–D) linked by methene bridges (other porphyrins vary in the substituents attached to rings A–D). The Fe(II) atom at the center of heme is coordinated by the four porphyrin N atoms and one N from a His side chain (called, in a nomenclature peculiar to myoglobin and hemoglobin, His F8 because it is the eighth residue of the F helix). A molecule of oxygen (O₂) can act as a sixth ligand to the iron atom. His E7 (the seventh residue of helix E) hydrogen bonds to the O₂ with the geometry shown in Fig. 7-3. Two hydrophobic side chains on the O₂-binding side of the heme, Val E11 and Phe CD1 (the first residue in the segment linking helices C and D), help hold the heme in place. These side chains presumably swing aside as the protein “breathes” (Section 6-4C), allowing O₂ to enter and exit.

When exposed to oxygen, the Fe(II) atom of isolated heme is irreversibly oxidized to Fe(III), a form that cannot bind O₂. The protein portion of myoglobin (and of hemoglobin, which contains four heme groups in four globin chains) prevents this oxidation and makes it possible for O₂ to bind reversibly to the heme group. **Oxygenation** alters the electronic state of the Fe(II)–heme complex, as indicated by its color change from dark purple (the color of hemoglobin in venous blood) to brilliant scarlet (the color of hemoglobin in arterial blood). Under some conditions, the Fe(II) of myoglobin or hemoglobin becomes oxidized to Fe(III) to form **metmyoglobin** or **methemoglobin**, respectively; these proteins are responsible for the brown color of old meat and dried blood.

In addition to O₂, certain other small molecules, such as CO, NO, and H₂S, can bind to heme groups in proteins. These other compounds bind with much

FIG. 7-3 The heme complex in myoglobin. In the upper drawing, atoms are represented in space-filling form (H atoms are not shown). The lower drawing shows the corresponding skeletal model with a dashed line representing the hydrogen bond between His E7 and the bound O₂. [Based on an X-ray structure by Simon Phillips, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1MBO.]

higher affinity than O_2 , which accounts for their toxicity. CO, for example, has 200-fold greater affinity for hemoglobin than does O_2 .

Myoglobin Binds O_2 to Facilitate Its Diffusion. Although myoglobin was originally thought to be only an oxygen-storage protein, it is now apparent that *its major physiological role is to facilitate oxygen diffusion in muscle* (the most rapidly respiring tissue under conditions of high exertion). The rate at which O_2 can diffuse from the capillaries to the tissues is limited by its low solubility in aqueous solution ($\sim 10^{-4}$ M in blood). Myoglobin increases the effective solubility of O_2 in muscle cells, acting as a kind of molecular bucket brigade to boost the O_2 diffusion rate. The oxygen-storage function of myoglobin is probably significant only in aquatic mammals such as seals and whales, whose muscle myoglobin concentrations are up to 30-fold greater than those in terrestrial mammals (which is one reason why Kendrew chose the sperm whale as a source of myoglobin for his X-ray crystallographic studies). Nevertheless, mice in which the gene for myoglobin has been “knocked out” appear to be normal, although their muscles are lighter in color than those of wild-type mice. However, closer scrutiny revealed several compensatory adaptations in these mice, including a greater concentration of red blood cells and increased capillary density in their muscles. Moreover, many of the mutant embryos died *in utero* due to cardiovascular defects. Vertebrates also express two other globins: **neuroglobin**, which is present mainly in brain, retina, and endocrine tissues, and **cytoglobin**, which occurs in most tissues. Neuroglobin protects neurons (nerve cells) from damage under conditions of **ischemia** (inadequate blood flow, as in a stroke), most likely by preventing **reperfusion injury** (the damage caused by the oxygen radicals generated when blood flow is restored). Cytoglobin may have similar functions.

Myoglobin's Oxygen-Binding Curve Is Hyperbolic. The reversible binding of O_2 to myoglobin (**Mb**) is described by a simple equilibrium reaction:

The dissociation constant, K , for the reaction is

$$K = \frac{[\text{Mb}][\text{O}_2]}{[\text{MbO}_2]} \quad [7-1]$$

Note that biochemists usually express equilibria in terms of dissociation constants, the reciprocal of the association constants favored by chemists. The O_2 dissociation of myoglobin can be characterized by its **fractional saturation, Y_{O_2}** , which is defined as the fraction of O_2 -binding sites occupied by O_2 :

$$Y_{O_2} = \frac{[\text{MbO}_2]}{[\text{Mb}] + [\text{MbO}_2]} \quad [7-2]$$

Y_{O_2} ranges from zero (when no O_2 is bound to the myoglobin molecules) to one (when the binding sites of all the myoglobin molecules are occupied). Equation 7-1 can be rearranged to

$$[\text{MbO}_2] = \frac{[\text{Mb}][\text{O}_2]}{K} \quad [7-3]$$

When this expression for $[\text{MbO}_2]$ is substituted into Eq. 7-2, the fractional saturation becomes

$$Y_{O_2} = \frac{\frac{[\text{Mb}][\text{O}_2]}{K}}{[\text{Mb}] + \frac{[\text{Mb}][\text{O}_2]}{K}} \quad [7-4]$$

Factoring out the $[Mb]/K$ term in the numerator and denominator gives

$$Y_{O_2} = \frac{[O_2]}{K + [O_2]} \quad [7-5]$$

Since O_2 is a gas, its concentration is conveniently expressed by its **partial pressure, pO_2** (also called the oxygen tension). Equation 7-5 can therefore be expressed as

$$Y_{O_2} = \frac{pO_2}{K + pO_2} \quad [7-6]$$

This equation describes a rectangular **hyperbola** and is identical in form to the equations that describe a hormone binding to its cell-surface receptor or a small molecular substrate binding to the active site of an enzyme. This hyperbolic function can be represented graphically as shown in Fig. 7-4. At low pO_2 , very little O_2 binds to myoglobin (Y_{O_2} is very small). As the pO_2 increases, more O_2 binds to myoglobin. At very high pO_2 , virtually all the O_2 -binding sites are occupied and myoglobin is said to be **saturated** with O_2 .

The steepness of the hyperbola for a simple binding event, such as O_2 binding to myoglobin, increases as the value of K decreases. This means that *the lower the value of K , the tighter is the binding*. K is equivalent to the concentration of ligand at which half the binding sites are occupied. In other words, when $pO_2 = K$, myoglobin is half-saturated with oxygen. This can be shown algebraically by substituting pO_2 for K in Eq. 7-6:

$$Y_{O_2} = \frac{pO_2}{K + pO_2} = \frac{pO_2}{2pO_2} = 0.5 \quad [7-7]$$

Thus, K can be operationally defined as the value of pO_2 at which $Y = 0.5$ (Fig. 7-4).

It is convenient to define K as p_{50} —that is, the oxygen pressure at which myoglobin is 50% saturated. The p_{50} for myoglobin is 2.8 torr (760 torr = 1 atm). Over the physiological range of pO_2 in the blood (100 torr in arterial blood and 30 torr in venous blood), myoglobin is almost fully saturated with oxygen; for example, $Y_{O_2} = 0.97$ at $pO_2 = 100$ torr and 0.91 at 30 torr (see Sample Calculation 7-1). Consequently, *myoglobin efficiently relays oxygen from the capillaries to muscle cells*.

Myoglobin, a single polypeptide chain with one heme group and hence one oxygen-binding site, is a useful model for other binding proteins. Even proteins with multiple binding sites for the same small molecule, or **ligand**, may generate hyperbolic binding curves like myoglobin's. A *hyperbolic binding curve occurs when ligands interact independently with their binding sites*. In practice, the affinity of a ligand for its binding protein may not be known. Constructing a binding curve such as the one shown in Fig. 7-4 may provide this information.

FIG. 7-4 Oxygen-binding curve of myoglobin. Myoglobin is half-saturated with O_2 ($Y_{O_2} = 0.5$) at an oxygen partial pressure (pO_2) of 2.8 torr (dashed lines). The hyperbolic shape of myoglobin's binding curve is typical of the simple binding of a small molecule to a protein. The background is shaded to indicate the color change that myoglobin undergoes as it binds O_2 .

? How much does fractional saturation change between pO_2 values of 5 and 15, and 15 and 25 torr?

SAMPLE CALCULATION 7-1

At what oxygen concentration will myoglobin be 75% saturated with oxygen?

Rearrange Eq. 7-6 and let $p_{50} = 2.8$ torr.

$$Y_{O_2} = \frac{pO_2}{p_{50} + pO_2}$$

$$pO_2 = Y_{O_2} (p_{50} + pO_2)$$

$$pO_2 = Y_{O_2} p_{50} + Y_{O_2} pO_2$$

$$pO_2 - Y_{O_2} pO_2 = Y_{O_2} p_{50}$$

$$pO_2 = \frac{Y_{O_2} p_{50}}{(1 - Y_{O_2})}$$

$$pO_2 = \frac{(0.75)(2.8 \text{ torr})}{(1 - 0.75)} = 8.4 \text{ torr}$$

WPLS See Sample Calculation Videos.

B Hemoglobin Is a Tetramer with Two Conformations

Hemoglobin (Greek: *haima*, blood), the intracellular protein that gives blood its color, is one of the best-characterized proteins and was one of the first proteins to be associated with a specific physiological function (oxygen transport). Animals that are too large (>1 mm thick) for simple diffusion to deliver sufficient oxygen to their tissues have circulatory systems containing hemoglobin or a protein of similar function that does so (Box 7-1). In vertebrates, hemoglobin is contained in **erythrocytes** (red blood cells; Greek: *erythros*, red + *kytos*, a hollow vessel), 6–9 μm diameter, biconcave disk-shaped cells that contain ~34% hemoglobin by weight. In mammals, they are devoid of intracellular organelles (e.g., nuclei and mitochondria), thus providing more space for hemoglobin.

Mammalian hemoglobin, as we saw in Fig. 6-33, is an $\alpha_2\beta_2$ tetramer (a dimer of $\alpha\beta$ protomers). The α and β subunits are structurally and evolutionarily related to each other and to myoglobin. The structure of hemoglobin was determined by Max Perutz (Box 7-2). Only about 18% of the residues are identical in myoglobin and in the α and β subunits of hemoglobin, but the three polypeptides have remarkably similar tertiary structures (hemoglobin subunits follow the myoglobin helix-labeling system, although the α chain has no D helix). The $\alpha\beta$ protomers of hemoglobin are symmetrically related by a 2-fold rotation (i.e., a rotation of 180° brings the protomers into coincidence). In addition, hemoglobin's structurally similar α and β subunits are related by an approximate 2-fold rotation (pseudosymmetry) whose axis is perpendicular to that of the exact 2-fold rotation. Thus, hemoglobin has exact C_2 symmetry and pseudo- D_2

Box 7-1 Perspectives in Biochemistry

Other Oxygen-Transport Proteins

The presence of O_2 in the earth's atmosphere and its utility in the oxidation of metabolic fuels have driven the evolution of various mechanisms for storing and transporting oxygen. Small organisms rely on diffusion to supply their respiratory oxygen needs. However, since the rate at which a substance diffuses varies inversely with the square of the distance it must diffuse, organisms of >1-mm thickness overcome the constraints of diffusion with circulatory systems and boost the low solubility of O_2 in water with specific O_2 -transport proteins.

Many invertebrates, and even some plants and bacteria, contain heme-based O_2 -binding proteins. Single-subunit and multimeric hemoglobins are found both as intracellular proteins and as extracellular components of blood and other body fluids. The existence of hemoglobin-like proteins in some species of bacteria is evidence of gene transfer from animals to bacteria at one or more points during evolution. In bacteria, these proteins may function as sensors of environmental conditions such as local O_2 concentration. In some leguminous plants, the so-called **leghemoglobins** bind O_2 that would otherwise interfere with nitrogen fixation carried out by bacteria that colonize plant root nodules (Section 21-7). The **chlorocruorins**, which occur in some annelids (e.g., earthworms), contain a somewhat differently derivatized porphyrin than that in hemoglobin, which accounts for the green color of chlorocruorins.

The two other types of O_2 -binding proteins, **hemerythrin** and **hemocyanin** (neither of which contains heme groups), occur only in invertebrate animals. Hemerythrin, which occurs in only a few species of marine worms, is an intracellular protein with a subunit mass of ~13 kD. It contains two Fe atoms liganded by His and acidic residues. It is violet-pink when oxygenated and colorless when deoxygenated.

Hemocyanins, which are exclusively extracellular, transport O_2 in mollusks and arthropods. The molluscan and arthropod hemocyanins

are large multimeric proteins that differ in their primary through quaternary structures. However, their oxygen-binding sites are highly similar, consisting of a pair of copper atoms, each liganded by three His residues.

In this model of the O_2 -binding site of hemocyanin from the horseshoe crab *Limulus polyphemus*, atoms are colored according to type with C gray, N blue, O red, and Cu purple. The otherwise colorless complex turns blue when it binds O_2 .

Hemocyanins must be present at high concentrations in order to function efficiently as oxygen carriers. For example, octopus **hemolymph** (its equivalent of blood) contains about 100 mg/mL hemocyanin. To minimize the osmotic pressure of so much protein, hemocyanins form multimeric structures with masses as great as 9×10^6 D in some species. Hemocyanins are often the predominant extracellular protein and may therefore have additional functions as buffers against pH changes and osmotic fluctuations. In some invertebrates, hemocyanins may serve as a nutritional reserve, for example, during metamorphosis or molting.

[Figure based on an X-ray structure by Wim Hol, University of Washington School of Medicine. PDBid 1OXY.]

Max Perutz (1914–2002) The determination of the three-dimensional structures of proteins has become so commonplace that it is difficult to appreciate the challenges that faced the first protein crystallographers. Max Perutz was a pioneer in this area, spending many years determining the structure of hemoglobin at atomic resolution and then using this information to explain the physiological function of the protein.

In 1934, two years before Perutz began his doctoral studies in Cambridge, J.D. Bernal and Dorothy Crowfoot Hodgkin had placed a crystal of the protein pepsin in an X-ray beam and obtained a diffraction pattern. Perutz tried the same experiment with hemoglobin, chosen because of its abundance, ease of crystallization, and obvious physiological importance. Hemoglobin crystals yielded diffraction patterns with thousands of diffraction maxima (called reflections), the result of X-ray scattering by the thousands of atoms in each protein molecule. At the time, X-ray crystallography had been used to determine the structures of molecules containing no more than around 40 atoms, so the prospect of using the technique to determine the atomic structure of hemoglobin seemed impossible. Nevertheless, Perutz took on the challenge and spent the rest of his long career working with hemoglobin.

In X-ray crystallography, the intensities and the positions of the reflections can be readily determined, but the values of their phases (the relative positions of the wave peaks, the knowledge of which is as important as wave amplitude for image reconstruction) cannot be measured directly. Although computational techniques for determining the values of the phases had been developed for small molecules, methods for solving this so-called phase problem for such complex entities as proteins seemed hopelessly out of reach. In 1952, Perutz realized that the method of isomorphous replacement might suffice to solve the phase problem for hemoglobin. In this method, a heavy atom such as a Hg^{2+} ion, which is rich in electrons (the particles that scatter X-rays), must bind to specific sites on the protein without significantly disturbing its

structure (which would change the positions of the reflections). If this causes measurable changes in the intensities of the reflections, these differences would provide the information to determine their phases. With trepidation followed by jubilation, Perutz observed that Hg-doped hemoglobin crystals indeed yielded reflections with measurable changes in intensity but no changes in position. Still, it took another 5 years to obtain the three-dimensional structure of hemoglobin at low (5.5-Å) resolution and it was not until 1968, some 30 years after he began the project, that he determined the structure of hemoglobin at near atomic (2.8-Å) resolution. In the meantime, Perutz's colleague John Kendrew used the method of isomorphous replacement to solve the structure of myoglobin, a smaller and simpler relative of hemoglobin. For their groundbreaking work, Perutz and Kendrew were awarded the 1962 Nobel Prize in Chemistry.

For Perutz, obtaining the structure of hemoglobin was only part of his goal of understanding hemoglobin. For example, functional studies indicated that the four oxygen-binding sites of hemoglobin interacted, as if they were in close contact, but Perutz's structure showed that the binding sites lay in deep and widely separated pockets. Perutz was also intrigued by the fact that crystals of hemoglobin prepared in the absence of oxygen would crack when they were exposed to air (the result, it turns out, of a dramatic conformational change). Although many other researchers also turned their attention to hemoglobin, Perutz was foremost among them in ascribing oxygen-binding behavior to protein structural features. He also devoted considerable effort to relating functional abnormalities in mutant hemoglobins to structural changes.

Perutz's groundbreaking work on the X-ray crystallography of proteins paved the way for other studies. For example, the first X-ray structure of an enzyme, lysozyme, was determined in 1965. The ~110,000 macromolecular structures that have been obtained since then owe a debt to Perutz and his decision to pursue an "impossible" task and to follow through on his structural work to the point where he could use his results to explain biological phenomena.

Perutz, M.F., Rossmann, M.G., Cullis, A.F., Muirhead, H., Will, G., and North, A.C.T., Structure of haemoglobin: A three-dimensional Fourier synthesis at 5.5 Å resolution, obtained by X-ray analysis. *Nature* **185**, 416–422 (1960).

symmetry (Section 6-3; objects with D_2 symmetry have the rotational symmetry of a tetrahedron). The hemoglobin molecule has overall dimensions of about $64 \times 55 \times 50$ Å.

Oxygen binding alters the structure of the entire hemoglobin tetramer, so the structures of **deoxyhemoglobin** (Fig. 7-5a) and **oxyhemoglobin** (Fig. 7-5b) are noticeably different. In both forms of hemoglobin, the α and β subunits form extensive contacts: Those at the α_1 - β_1 interface (and its α_2 - β_2 symmetry equivalent) involve 35 residues, and those at the α_1 - β_2 (and α_2 - β_1) interface involve 19 residues. These associations are predominantly hydrophobic, although numerous hydrogen bonds and several ion pairs are also involved. Note, however, that the α_1 - α_2 and β_1 - β_2 interactions are tenuous at best because these subunit pairs are separated by an ~20-Å-diameter solvent-filled channel that parallels the 50-Å length of hemoglobin's exact 2-fold axis (Fig. 7-5).

When oxygen binds to hemoglobin, the α_1 - β_2 (and α_2 - β_1) contacts shift, producing a change in quaternary structure. Oxygenation rotates one $\alpha\beta$ dimer ~15° with respect to the other $\alpha\beta$ dimer (gray arrows in Fig. 7-5b), which brings the β subunits closer together and narrows the solvent-filled central channel (Fig. 7-5). Some atoms in the α_1 - β_2 and α_2 - β_1 interfaces shift by as much as 6 Å (oxygenation causes such extensive quaternary structural changes that crystals of deoxyhemoglobin shatter on exposure to O_2). This structural rearrangement is a crucial element of hemoglobin's oxygen-binding behavior.

FIG. 7-5 Hemoglobin structure. (a) Deoxyhemoglobin and (b) oxyhemoglobin. The $\alpha_1\beta_1$ protomer is related to the $\alpha_2\beta_2$ protomer by a 2-fold axis of symmetry (*lenticular symbol*), which is perpendicular to the page. Oxygenation causes one protomer to rotate $\sim 15^\circ$ relative to the other, bringing the β chains closer together (compare the lengths of the double-headed arrows) and shifting the contacts between subunits at the $\alpha_1\text{-}\beta_2$ and $\alpha_2\text{-}\beta_1$ interfaces (some of the relevant side chains are drawn in black). The large gray arrows in Part b indicate the molecular movements that accompany oxygenation. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

C Oxygen Binds Cooperatively to Hemoglobin

Hemoglobin has a p_{50} of 26 torr (i.e., hemoglobin is half-saturated with O_2 at an oxygen partial pressure of 26 torr), which is nearly 10 times greater than the p_{50} of myoglobin. Moreover, hemoglobin does not exhibit a myoglobin-like hyperbolic oxygen-binding curve. Instead, O_2 binding to hemoglobin is described by a

FIG. 7-6 Oxygen-binding curve of hemoglobin. In whole blood, hemoglobin is half-saturated at an oxygen pressure of 26 torr. The normal sea level values of human arterial and venous pO_2 are indicated (atmospheric pO_2 is 160 torr at sea level). The O_2 -binding curve for myoglobin is included for comparison. The dashed line is a hyperbolic O_2 -binding curve with the same p_{50} as hemoglobin. The background is shaded to indicate the color change that hemoglobin undergoes as it binds O_2 . **WPLS** See the Animated Figures.

? Explain why myoglobin, if present in the blood, would be an inefficient O_2 carrier molecule.

sigmoidal (S-shaped) curve (Fig. 7-6). This permits the blood to deliver much more O_2 to the tissues than if hemoglobin had a hyperbolic curve with the same p_{50} (dashed curve in Fig. 7-6). For example, hemoglobin is nearly fully saturated with O_2 at arterial oxygen pressures ($Y_{O_2} = 0.95$ at 100 torr) but only about half-saturated at venous oxygen pressures ($Y_{O_2} = 0.55$ at 30 torr). This 0.40 difference in oxygen saturation, a measure of hemoglobin's ability to deliver O_2 from the lungs to the tissues, would be only 0.25 if hemoglobin exhibited hyperbolic binding behavior.

In any binding system, a sigmoidal curve is diagnostic of a **cooperative interaction between binding sites**. This means that the binding of a ligand to one site affects the binding of additional ligands to the other sites. In the case of hemoglobin, O_2 binding to one subunit increases the O_2 affinity of the remaining subunits. The initial slope of the oxygen-binding curve (Fig. 7-6) is low, as hemoglobin subunits independently compete for the first O_2 . However, an O_2 molecule bound to one of hemoglobin's subunits increases the O_2 -binding affinity of its other subunits, thereby accounting for the increasing slope of the middle portion of the sigmoidal curve.

The Hill Equation Describes Hemoglobin's O_2 -Binding Curve. The earliest attempt to analyze hemoglobin's sigmoidal O_2 dissociation curve was formulated by Archibald Hill in 1910. Hill assumed that hemoglobin (**Hb**) bound n molecules of O_2 in a single step,

that is, with infinite cooperativity. Thus, in analogy with the derivation of Eq. 7-6,

$$Y_{O_2} = \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n} \quad [7-8]$$

which is known as the **Hill equation**. Like Eq. 7-6, it describes the degree of saturation of hemoglobin as a function of pO_2 (see Sample Calculation 7-2).

Infinite O_2 binding cooperativity, as Hill assumed, is a physical impossibility. Nevertheless, n may be taken to be a nonintegral parameter related to the degree of cooperativity among interacting hemoglobin subunits rather than the number of subunits that bind O_2 in one step. The Hill equation can then be taken as a useful empirical curve-fitting relationship rather than as an indicator of a particular model of ligand binding.

SAMPLE CALCULATION 7-2

Calculate the fractional saturation of hemoglobin at $pO_2 = 50$ torr and $n = 3$.

Use Eq. 7-8 and let $p_{50} = 26$ torr.

$$\begin{aligned} Y_{O_2} &= \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n} \\ &= \frac{(50)^3}{(26)^3 + (50)^3} = \frac{125,000}{17,576 + 125,000} = 0.88 \end{aligned}$$

WPLS See Sample Calculation Videos.

The quantity n , the **Hill constant**, increases with the degree of cooperativity of a reaction and therefore provides a convenient although simplistic characterization of a ligand-binding reaction. If $n = 1$, Eq. 7-8 describes a hyperbola as does Eq. 7-6 for myoglobin, and the O_2 -binding reaction is said to be **noncooperative**. If $n > 1$, the reaction is described as being **positively cooperative**,

because O_2 binding increases the affinity of hemoglobin for further O_2 binding (cooperativity is infinite in the limit that $n = 4$, the number of O_2 binding sites in hemoglobin). Conversely, if $n < 1$, the reaction is said to be **negatively cooperative**, because O_2 binding would then reduce the affinity of hemoglobin for subsequent O_2 binding.

The Hill constant, n , and the value of p_{50} that best describe hemoglobin's saturation curve can be graphically determined by rearranging Eq. 7-8. First, divide both sides by $1 - Y_{O_2}$:

$$\frac{Y_{O_2}}{1 - Y_{O_2}} = \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n} = \frac{(pO_2)^n}{1 - \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n}} \quad [7-9]$$

Factoring out the $[(p_{50})^n + (pO_2)^n]$ term gives

$$\frac{Y_{O_2}}{1 - Y_{O_2}} = \frac{(pO_2)^n}{[(p_{50})^n + (pO_2)^n] - (pO_2)^n} = \frac{(pO_2)^n}{(p_{50})^n} \quad [7-10]$$

Taking the log of both sides yields a linear equation:

$$\log\left(\frac{Y_{O_2}}{1 - Y_{O_2}}\right) = n \log pO_2 - n \log p_{50} \quad [7-11]$$

The linear plot of $\log[Y_{O_2}/(1 - Y_{O_2})]$ versus $\log pO_2$, the **Hill plot**, has a slope of n and an intercept on the $\log pO_2$ axis of $\log p_{50}$ (recall that the linear equation $y = mx + b$ describes a line with a slope of m and an x intercept of $-b/m$).

Figure 7-7 shows the Hill plots for myoglobin and purified hemoglobin. For myoglobin, the plot is linear with a slope of 1, as expected. Although all subunits of hemoglobin do not bind O_2 in a single step as was assumed in deriving the Hill

FIG. 7-7 Hill plots for myoglobin and purified hemoglobin. Note that this is a log-log plot. At $pO_2 = p_{50}$, $Y_{O_2}/(1 - Y_{O_2}) = 1$. [The p_{50} for hemoglobin *in vivo* is higher than the p_{50} of purified hemoglobin due to its binding of certain substances present in the red cell (see below).]

equation, its Hill plot is essentially linear for values of Y_{O_2} between 0.1 and 0.9. When $pO_2 = p_{50}$, $Y_{O_2} = 0.5$, and

$$\frac{Y_{O_2}}{1 - Y_{O_2}} = \frac{0.5}{1 - 0.5} = 1.0 \quad [7-12]$$

As can be seen in Fig. 7-7, this is the region of maximum slope, whose value is customarily taken to be the Hill constant, n . For normal human hemoglobin, the Hill constant is between 2.8 and 3.0; that is, hemoglobin's oxygen binding is highly, but not infinitely, cooperative. Many abnormal hemoglobins exhibit smaller Hill constants (Section 7-1E), indicating that they have a less than normal degree of cooperativity.

At Y_{O_2} values near zero, when few hemoglobin molecules have bound even one O_2 molecule, the Hill plot for hemoglobin assumes a slope of 1 (Fig. 7-7, lower asymptote) because the hemoglobin subunits independently compete for O_2 as do molecules of myoglobin. At Y_{O_2} values near 1, when at least three of hemoglobin's four O_2 -binding sites are occupied, the Hill plot also assumes a slope of 1 (Fig. 7-7, upper asymptote) because the few remaining unoccupied sites are on different molecules and therefore bind O_2 independently.

Extrapolating the lower asymptote in Fig. 7-7 to the horizontal axis indicates, according to Eq. 7-11, that $p_{50} = 30$ torr for binding the first O_2 to purified hemoglobin. Likewise, extrapolating the upper asymptote yields $p_{50} = 0.3$ torr for binding hemoglobin's fourth O_2 . Thus, *the fourth O_2 binds to hemoglobin with 100-fold greater affinity than the first*. This difference, as we will see below, is entirely due to the influence of the globin chain on the O_2 affinity of heme.

D Hemoglobin's Two Conformations Exhibit Different Affinities for Oxygen

The cooperativity of oxygen binding to hemoglobin arises from the effect of the ligand-binding state of one heme group on the ligand-binding affinity of another. Yet the hemes are 25 to 37 Å apart—too far to interact electronically. Instead, information about the O_2 -binding status of a heme group is mechanically transmitted to the other heme groups by motions of the protein. These movements are responsible for the different quaternary structures of oxy- and deoxyhemoglobin depicted in Fig. 7-5.

FIG. 7-8 Movements of the heme and F helix during the T \rightarrow R transition in hemoglobin. In the T form (blue), the Fe is 0.6 Å above the center of the domed porphyrin ring. On assuming the R form (red), the Fe moves into the plane of the now undomed porphyrin, where it can more tightly bind O_2 , and, in doing so, pulls His F8 and its attached F helix with it. **WPLS** See the **Animated Figures**.

Oxygen Binding to Hemoglobin Triggers a Conformational Change from T to R. On the basis of the X-ray structures of oxy- and deoxyhemoglobin, Perutz formulated a model for hemoglobin oxygenation. *In the **Perutz mechanism**, hemoglobin has two stable conformational states, the **T state** (the conformation of deoxyhemoglobin) and the **R state** (the conformation of oxyhemoglobin).* The conformations of all four subunits in T-state hemoglobin differ from those in the R state. Oxygen binding initiates a series of coordinated movements that result in a shift from the T state to the R state within a few microseconds:

1. In the T state, the Fe(II) in each of the four hemes is situated ~ 0.6 Å out of the heme plane because of a pyramidal doming of the porphyrin group toward His F8 and because the Fe—N_{porphyrin} bonds are too long to allow the Fe to lie in the porphyrin plane (Fig. 7-8). O_2 binding changes the heme's electronic state, which shortens the Fe—N_{porphyrin} bonds by ~ 0.1 Å and causes the porphyrin doming to subside. Consequently, during the T \rightarrow R transition, the Fe(II) moves into the center of the heme plane.
2. The Fe(II) drags the covalently linked His F8 along with it. However, the direct movement of His F8 by 0.6 Å toward the heme plane would cause it to collide with the heme. To avoid this steric clash, the attached F helix tilts and translates by ~ 1 Å across the heme plane.

3. The changes in tertiary structure are coupled to a shift in the arrangement of hemoglobin's four subunits. The largest change produced by the T \rightarrow R transition is the result of movements of residues at the α_1 - β_2 and α_2 - β_1 interfaces, that is, at the interface between the two protomeric units of hemoglobin. In the T state, His 97 in the β chain contacts Thr 41 in the α chain (Fig. 7-9a). In the R state, His 97 contacts Thr 38, which is positioned one turn back along the C helix (Fig. 7-9b). In both conformations, the "knobs" on one subunit mesh nicely with the "grooves" on the other. An intermediate position would

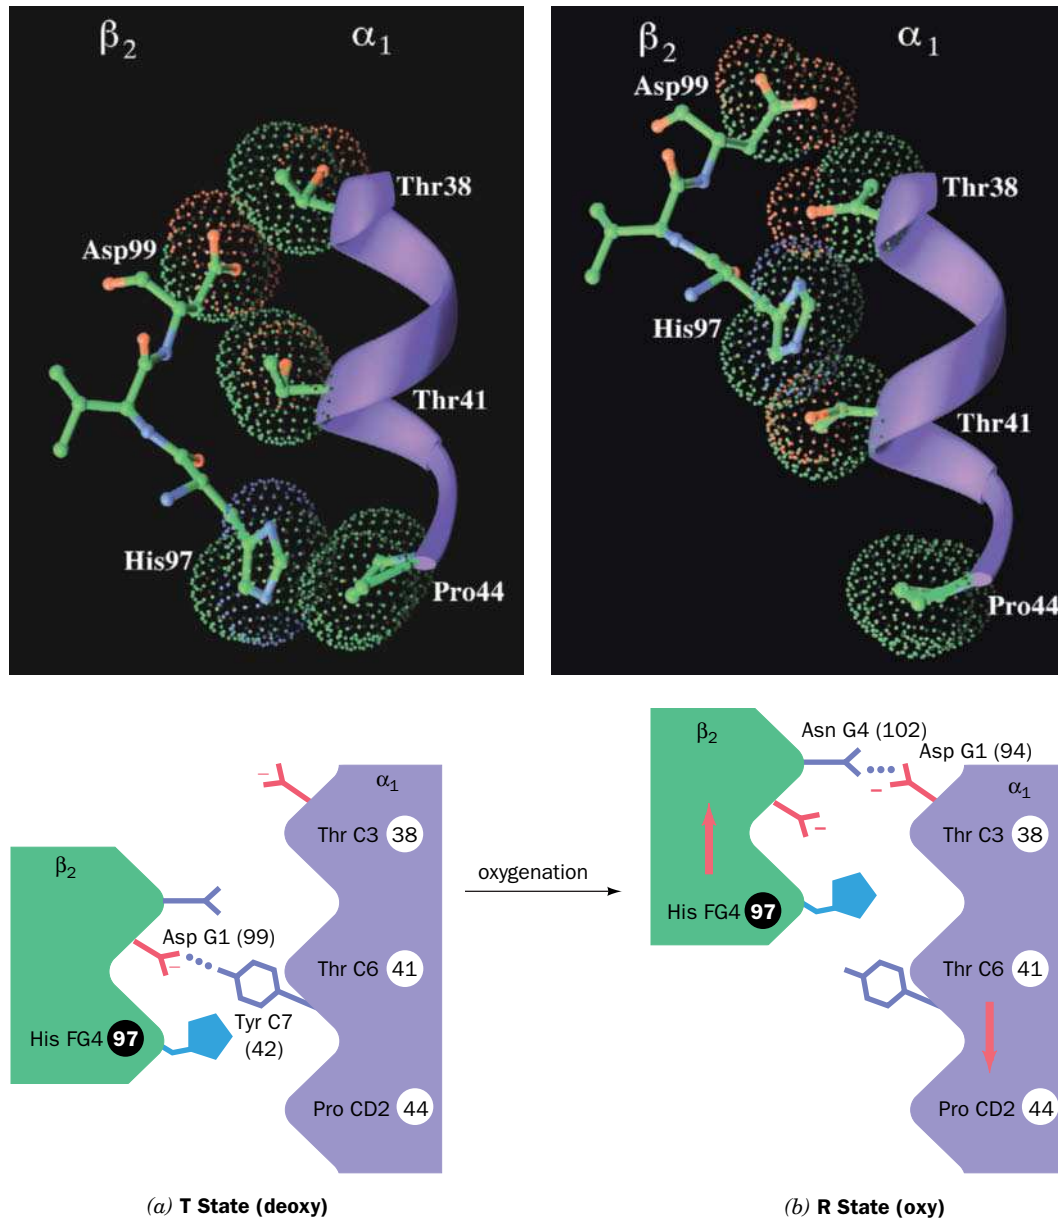

FIG. 7-9 Changes at the α_1 - β_2 interface during the T \rightarrow R transition in hemoglobin. (a) The T state and (b) the R state. In the upper drawings, the α C helix is represented by a purple ribbon, the contacting residues forming the α_1 C- β_2 FG contact are shown in ball-and-stick form colored by atom type (C green, N blue, and O red), and their van der Waals surfaces are outlined by like-colored dots. The lower drawings are the corresponding schematic diagrams of the α_1 C- β_2 FG contact. Upon a T \rightarrow R transformation, the β_2 FG region shifts by one turn along the α_1 C

helix with no stable intermediate (note how in both conformations, the knobs formed by the side chains of His 97 β and Asp 99 β fit between the grooves on the C helix formed by the side chains of Thr 38 α , Thr 41 α , and Pro 44 α). The subunits are joined by different hydrogen bonds in the two quaternary states. Figure 7-5 provides another view of these interactions. [Based on X-ray structures by Giulio Fermi, Max Perutz, and Boaz Shaanan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBids (a) 2HHB and (b) 1HHO.]

(a) α Chains(b) β Chains

FIG. 7-10 Networks of ion pairs and hydrogen bonds in deoxyhemoglobin. These bonds, which involve the last two residues of (a) the α chains and (b) the β chains, are ruptured in the T \rightarrow R transition. Two groups that become partially deprotonated in the R state (part of the

Bohr effect) are indicated by white plus signs. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

be severely strained because it would bring His 97 and Thr 41 too close together (i.e., knobs on knobs).

- The C-terminal residues of each subunit (Arg 141 α and His 146 β) in T-state hemoglobin each participate in a network of intra- and intersubunit ion pairs (Fig. 7-10) that stabilize the T state. However, the conformational shift in the T \rightarrow R transition tears away these ion pairs in a process that is driven by the energy of formation of the Fe—O₂ bonds.

The essential feature of hemoglobin's T \rightarrow R transition is that *its subunits are so tightly coupled that large tertiary structural changes within one subunit cannot occur without quaternary structural changes in the entire tetrameric protein.* Hemoglobin is limited to only two quaternary forms, T and R, because the intersubunit contacts shown in Fig. 7-9 act as a binary switch that permits only two stable positions of the subunits relative to each other. The inflexibility of the α_1 – β_1 and α_2 – β_2 interfaces requires that the T \rightarrow R shift occur simultaneously at both the α_1 – β_2 and α_2 – β_1 interfaces. No one subunit or dimer can greatly change its conformation independently of the others.

We are now in a position to structurally rationalize the cooperativity of oxygen binding to hemoglobin. The T state of hemoglobin has low O₂ affinity, mostly because of the 0.1 Å greater length of its Fe—O₂ bond relative to that of the R state (see the blue structure shown in Fig. 7-8). Experimental evidence indicates that when at least one O₂ has bound to each $\alpha\beta$ dimer, the strain in the T-state hemoglobin molecule is sufficient to tear away the C-terminal ion pairs, thereby snapping the protein into the R state. All the subunits are thereby simultaneously converted to the R-state conformation whether or not they have bound O₂. Unliganded subunits in the R-state conformation have increased oxygen affinity because they are already in the O₂-binding conformation. This accounts for the high O₂ affinity of nearly saturated hemoglobin.

GATEWAY CONCEPT Molecular Behavior

If the hemoglobin tetramer shifts abruptly from one conformation to the other, why is its oxygen-binding behavior described by a smooth curve? The binding curve depicts the collective O₂-binding activity of a population of hemoglobin molecules, which make the conformational shift at slightly varying points. We observe their average behavior rather than the behavior of an individual molecule.

The Bohr Effect Enhances Oxygen Transport. The conformational changes in hemoglobin that occur on oxygen binding decrease the pK's of several groups. Recall that the tendency for a group to ionize depends on its micro-environment, which may include other ionizable groups. For example, in T-state hemoglobin, the N-terminal amino groups of the α subunits and the

C-terminal His of the β subunits are positively charged and participate in ion pairs (see Fig. 7-10). The formation of ion pairs increases the pK values of these groups (makes them less acidic and therefore less likely to give up their protons). In R-state hemoglobin, these ion pairings are absent, and the pK 's of the groups decrease (making them more acidic and more likely to give up protons). Consequently, under physiological conditions, hemoglobin releases ~ 0.6 protons for each O_2 it binds. Conversely, increasing the pH, that is, removing protons, stimulates hemoglobin to bind more O_2 (Fig. 7-11). This phenomenon is known as the **Bohr effect** after Christian Bohr (father of the physicist Niels Bohr), who first reported it in 1904.

The Bohr effect has important physiological functions in transporting O_2 from the lungs to respiring tissue and in transporting the CO_2 produced by respiration back to the lungs (Fig. 7-12). The CO_2 produced by respiring tissues diffuses from the tissues to the capillaries. This dissolved CO_2 forms bicarbonate (HCO_3^-) only very slowly, by the reaction

However, in the erythrocyte, the enzyme **carbonic anhydrase** greatly accelerates this reaction. Accordingly, most of the CO_2 in the blood is carried in the form of bicarbonate (in the absence of carbonic anhydrase, bubbles of CO_2 would form in the blood).

In the capillaries, where pO_2 is low, the H^+ generated by bicarbonate formation is taken up by hemoglobin in forming the ion pairs of the T state, thereby inducing hemoglobin to unload its bound O_2 . This H^+ uptake, moreover, facilitates CO_2 transport by stimulating bicarbonate formation. Conversely, in the lungs, where pO_2 is high, O_2 binding by hemoglobin disrupts the T-state ion pairs to form the R state, thereby releasing the Bohr protons, which recombine with bicarbonate to drive off CO_2 . These reactions are closely matched, so they cause very little change in blood pH (see Box 2-2).

The Bohr effect provides a mechanism whereby additional oxygen can be supplied to highly active muscles, where the pO_2 may be < 20 torr. Such muscles generate lactic acid (Section 15-3A) so fast that they lower the pH of the blood passing through them from 7.4 to 7.2. At a pO_2 of 20 torr, hemoglobin releases $\sim 10\%$ more O_2 at pH 7.2 than it does at pH 7.4 (Fig. 7-11).

FIG. 7-11 The Bohr effect. The O_2 affinity of hemoglobin increases with increasing pH. The dashed line indicates the pO_2 in actively respiring muscle. [After Benesch, R.E. and Benesch, R., *Adv. Protein Chem.* **28**, 212 (1974).] **WPLS** See the Animated Figures.

? Is the effect of pH on oxygen binding greater at higher or lower oxygen concentrations?

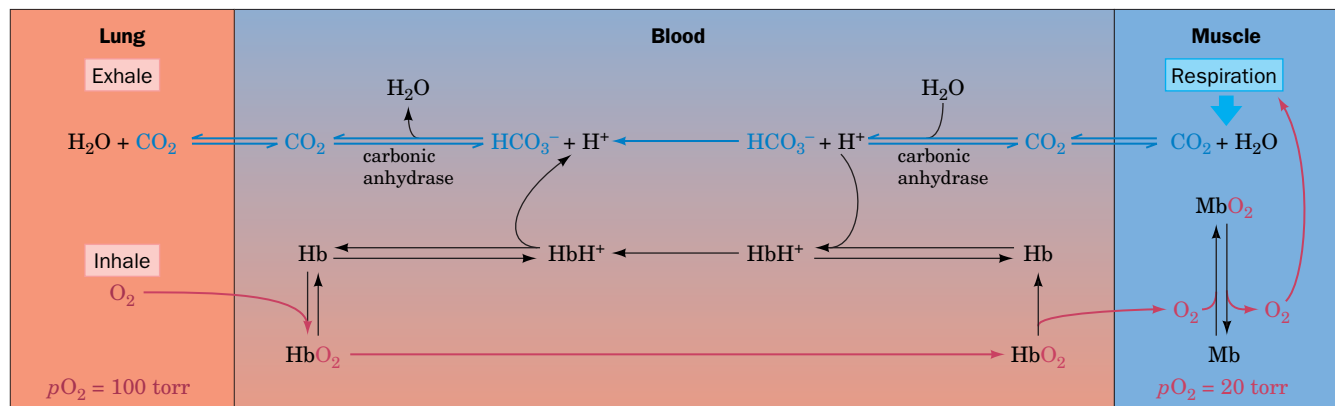

FIG. 7-12 The roles of hemoglobin and myoglobin in O_2 and CO_2 transport. Oxygen is inhaled into the lungs at high pO_2 , where it binds to hemoglobin in the blood. The O_2 is then transported to respiring tissue, where the pO_2 is low. The O_2 therefore dissociates from the Hb and diffuses into the tissues, where it is used to oxidize metabolic fuels to CO_2 and H_2O . In rapidly respiring muscle tissue, the O_2 first binds to myoglobin (whose oxygen affinity is higher than that of hemoglobin).

This increases the rate at which O_2 can diffuse from the capillaries to the tissues by, in effect, increasing its solubility. The Hb and CO_2 (mostly as HCO_3^-) are then returned to the lungs, where the CO_2 is exhaled.

? Explain how carbonic anhydrase affects CO_2 transport by hemoglobin.

FIG. 7-13 The effects of BPG and CO₂ on hemoglobin's O₂ dissociation curve. Stripped hemoglobin (*left*) has higher O₂ affinity than whole blood (*red curve*). Adding BPG or CO₂ or both to hemoglobin shifts the dissociation curve back to the right (lowers hemoglobin's O₂ affinity). [After Kilmartin, J.V. and Rossi-Bernardi, L., *Physiol. Rev.* 53, 884 (1973).] **WPLS** See the Animated Figures.

CO₂ also modulates O₂ binding to hemoglobin by combining reversibly with the N-terminal amino groups of blood proteins to form **carbamates**:

The T (deoxy) form of hemoglobin binds more CO₂ as carbamate than does the R (oxy) form. When the CO₂ concentration is high, as it is in the capillaries, the T state is favored, stimulating hemoglobin to release its bound O₂. The protons released by carbamate formation further promote O₂ release through the Bohr effect. Although the difference in CO₂ binding between the oxy and deoxy states of hemoglobin accounts for only ~5% of the total blood CO₂, it is nevertheless responsible for around half the CO₂ transported by the blood. This is because only ~10% of the total blood CO₂ is lost through the lungs in each circulatory cycle.

Bisphosphoglycerate Binds to Deoxyhemoglobin. Highly purified (“stripped”) hemoglobin has a much greater oxygen affinity than hemoglobin in whole blood (**Fig. 7-13**). This observation led Joseph Barcroft, in 1921, to speculate that blood contains some other substance besides CO₂ that affects oxygen binding to hemoglobin. This compound is **D-2,3-bisphosphoglycerate (BPG)**.

D-2,3-Bisphosphoglycerate (BPG)

BPG binds tightly to deoxyhemoglobin but only weakly to oxyhemoglobin. *The presence of BPG in mammalian erythrocytes therefore decreases hemoglobin's oxygen affinity by keeping it in the deoxy conformation.* In other vertebrates, different phosphorylated compounds elicit the same effect.

BPG has an indispensable physiological function: In arterial blood, where pO_2 is ~100 torr, hemoglobin is ~95% saturated with O₂, but in venous blood, where pO_2 is ~30 torr, it is only 55% saturated (Fig. 7-6). Consequently, in passing through the capillaries, hemoglobin unloads ~40% of its bound O₂. In the absence of BPG, little of this bound O₂ would be released since hemoglobin's O₂ affinity is increased, thus shifting its O₂ dissociation curve significantly toward lower pO_2 (Fig. 7-13, *left*). BPG also plays an important role in adaptation to high altitudes (Box 7-3).

The X-ray structure of a BPG–deoxyhemoglobin complex shows that BPG binds in the central cavity of deoxyhemoglobin (**Fig. 7-14**). The anionic groups of BPG are within hydrogen-bonding and ion-pairing distances of the N-terminal amino groups of both β subunits. The T → R transformation brings the two β H helices together, which narrows the central cavity (compare Figs. 7-5a and 7-5b) and expels the BPG. It also widens the distance between the β N-terminal amino groups from 16 to 20 Å,

FIG. 7-14 Binding of BPG to deoxyhemoglobin. BPG (*red*) binds in hemoglobin's central cavity. The BPG, which has a charge of -5 under physiological conditions, is surrounded by eight cationic groups (*blue*) extending from the two β subunits. In the R state, the central cavity is too narrow to contain BPG. Some of the ion pairs and hydrogen bonds that help stabilize the T state (Fig. 7-10b) are indicated at the lower right. [Illustration, Irving Geis. Image from the Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only]

Atmospheric pressure decreases with altitude, so that the oxygen pressure at 3000 m (10,000 feet) is only ~ 110 torr, 70% of its sea-level pressure. A variety of physiological responses are required to maintain normal oxygen delivery (without adaptation, pO_2 levels of 85 torr or less result in mental impairment).

High-altitude adaptation is a complex process that involves increases in the number of erythrocytes and the amount of hemoglobin per erythrocyte. It normally requires several weeks to complete. Yet, as is clear to anyone who has climbed to high altitude, even a 1-day stay there results in a noticeable degree of adaptation. This effect results from a rapid increase in the amount of BPG synthesized in erythrocytes (from ~ 4 mM to ~ 8 mM; BPG cannot cross the erythrocyte membrane). As illustrated by plots of Y_{O_2} versus pO_2 , the high altitude-induced increase in BPG causes the O_2 -binding curve of hemoglobin to shift from its sea-level position (black line) to a lower affinity position (red line).

At sea level, the difference between arterial and venous pO_2 is 70 torr (100 torr – 30 torr), and hemoglobin unloads 38% of its bound O_2 . However, when the arterial pO_2 drops to 55 torr, as it does at an altitude of 4500 m, hemoglobin would be able to unload only 30% of its O_2 . High-altitude adaptation (which decreases the amount of O_2 that hemoglobin can bind in the lungs but, to a greater extent, increases the amount of O_2 it releases at the tissues) allows hemoglobin to deliver a near-normal 37% of its bound O_2 . BPG concentrations also increase in individuals suffering from disorders that limit the oxygenation of the blood (hypoxia), such as various anemias and cardiopulmonary insufficiency.

The BPG concentration in erythrocytes can be adjusted more rapidly than hemoglobin can be synthesized (Box 15-2; erythrocytes lack nuclei and therefore cannot synthesize proteins). An altered BPG level is also a more sensitive regulator of oxygen delivery than an altered respiratory rate. Hyperventilation, another early response to high altitude, may lead to respiratory alkalosis (Box 2-2). Interestingly, individuals in long-established Andean and Himalayan populations exhibit high lung capacity, along with high hemoglobin levels and, often, enlarged right

ventricles (reflecting increased cardiac output), compared to individuals from low-altitude populations.

In contrast to the mechanism of human adaptation to high altitude, most mammals that normally live at high altitudes (e.g., the llama) have genetically altered hemoglobins that have higher O_2 -binding affinities than do their sea-level cousins. Thus, both raising and lowering hemoglobin's p_{50} can provide high-altitude adaptation.

which prevents their simultaneous hydrogen bonding with BPG's phosphate groups. BPG therefore binds to and stabilizes only the T conformation of hemoglobin by cross-linking its β subunits. This shifts the $T \rightleftharpoons R$ equilibrium toward the T state, which lowers hemoglobin's O_2 affinity.

Fetal Hemoglobin Has Low BPG Affinity. The effects of BPG also help supply the fetus with oxygen. A fetus obtains its O_2 from the maternal circulation via the placenta. The concentration of BPG is the same in adult and fetal erythrocytes, but BPG binds more tightly to adult hemoglobin than to fetal hemoglobin. The higher oxygen affinity of fetal hemoglobin facilitates the transfer of O_2 to the fetus.

Fetal hemoglobin has the subunit composition $\alpha_2\gamma_2$ in which the γ subunit is a variant of the β chain (Section 5-4B). Residue 143 of the β chain of adult hemoglobin has a cationic His residue, whereas the γ chain has an uncharged Ser residue. The absence of this His eliminates a pair of interactions that stabilize the BPG–deoxyhemoglobin complex (Fig. 7-14).

Hemoglobin Is a Model Allosteric Protein. The cooperativity of oxygen binding to hemoglobin is a classic model for the behavior of many other multisubunit proteins (including many enzymes) that bind small molecules. In some cases, binding of a ligand to one site increases the affinity of other binding sites on the same protein (as in O_2 binding to hemoglobin). In other cases, a ligand decreases the affinity of other binding sites (as when BPG binding decreases the O_2 affinity of hemoglobin).

All these effects are the result of **allosteric interactions** (Greek: *allos*, other + *stereos*, solid or space). *Allosteric effects*, in which the binding of a ligand at one site affects the binding of another ligand at another site, generally require interactions among subunits of oligomeric proteins. The T \rightarrow R transition in hemoglobin subunits explains the difference in the oxygen affinities of oxy- and deoxyhemoglobin. Other proteins exhibit similar conformational shifts, although, in many cases, the molecular mechanisms that underlie these phenomena are poorly understood.

Two models that account for cooperative ligand binding have received the most attention. One of them, the **symmetry model of allostery**, formulated in 1965 by Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux, is defined by the following rules:

1. An allosteric protein is an oligomer of symmetrically related subunits (although the α and β subunits of hemoglobin are only pseudosymmetrically related).
2. Each oligomer can exist in two conformational states, designated R and T; these states are in equilibrium.
3. The ligand can bind to a subunit in either conformation. *Only the conformational change alters the affinity for the ligand.*
4. *The molecular symmetry of the protein is conserved during the conformational change.* The subunits must therefore change conformation in a concerted manner; in other words, there are no oligomers that simultaneously contain R- and T-state subunits.

The symmetry model is diagrammed for a tetrameric binding protein in **Fig. 7-15**. If a ligand binds more tightly to the R state than to the T state, ligand binding will promote the T \rightarrow R shift, thereby increasing the affinity of the unliganded subunits for the ligand.

One major objection to the symmetry model is that it is difficult to believe that oligomeric symmetry is perfectly preserved in all proteins, that is, that the T \rightarrow R shift occurs simultaneously in all subunits regardless of the number of ligands bound. In addition, the symmetry model can account only for positive cooperativity, although some proteins exhibit negative cooperativity.

An alternative to the symmetry model is the **sequential model of allostery**, proposed by Daniel Koshland. According to this model, ligand binding induces a conformational change in the subunit to which it binds, and cooperative interactions arise through the influence of those conformational changes on neighboring subunits. The conformational changes occur sequentially as more ligand-binding sites are occupied (**Fig. 7-16**). The ligand-binding affinity of a subunit varies with its conformation and may be higher or lower than that of the subunits in the ligand-free protein. Thus, proteins that follow the sequential model of allostery may be positively or negatively cooperative.

If the mechanical coupling between subunits in the sequential model is particularly strong, the conformational changes occur simultaneously and the oligomer retains its symmetry, as in the symmetry model. Thus, the symmetry model of allostery may be considered to be an extreme case of the more general sequential model.

Oxygen binding to hemoglobin exhibits features of both models. The quaternary T \rightarrow R conformational change is concerted, as the symmetry model requires. Yet ligand binding to the T state does cause small tertiary structural changes, as the sequential model predicts. These minor conformational shifts are undoubtedly responsible for the buildup of strain that eventually triggers the T \rightarrow R transition.

Despite the foregoing, the Perutz mechanism does not appear to be the whole story. For example, Chien Ho effectively detached His F8 from hemoglobin's

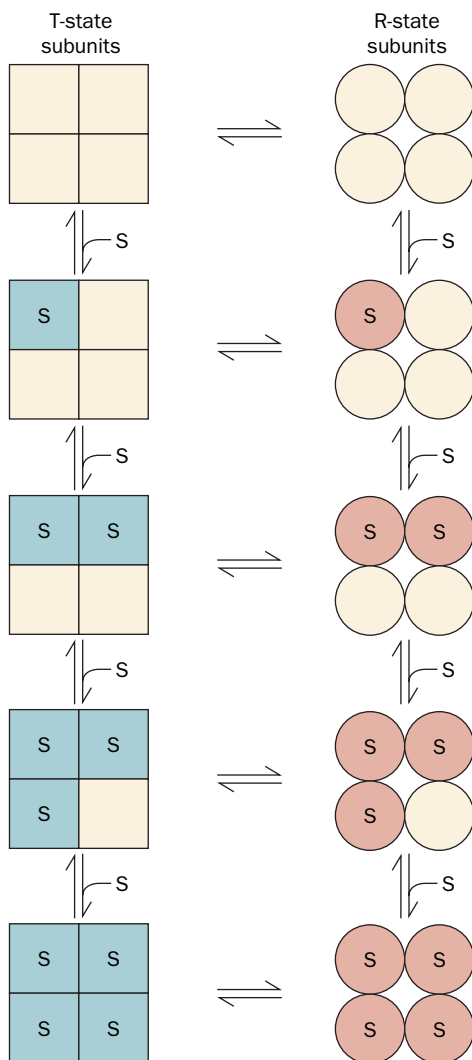

FIG. 7-15 The symmetry model of allostery. Squares and circles represent T- and R-state subunits, respectively, of a tetrameric protein. The T and R states are in equilibrium regardless of the number of ligands (represented by S) that have bound to the protein. All the subunits must be in either the T or the R form; the model does not allow combinations of T- and R-state subunits in the same protein.

FIG. 7-16 The sequential model of allosterism. Ligand binding progressively induces conformational changes in the subunits, with the greatest changes occurring in those subunits that have bound ligand. The symmetry of the oligomeric protein is not preserved in this process as it is in the symmetry model.

polypeptide backbone by mutagenically replacing it with Gly in one or both types of subunits and replacing the missing imidazole rings with free imidazole, which a variety of evidence indicates binds to the heme Fe as does His F8. All of these mutant hemoglobins, in accord with the Perutz mechanism, have significantly increased ligand-binding affinity, reduced cooperativity, and do not undergo a $T \rightarrow R$ transition. Nevertheless, all of them exhibit a small degree of cooperativity, suggesting that the heme groups also communicate via pathways that do not require covalent coupling between His F8 and the F helix. It therefore appears that the complexity of ligand–protein interactions in hemoglobin and other proteins allows binding processes to be fine-tuned to the needs of the organism under changing internal and external conditions. We will revisit allosteric effects when we discuss enzymes in Chapter 12.

E Mutations May Alter Hemoglobin's Structure and Function

Before the advent of recombinant DNA techniques, mutant hemoglobins provided what was an almost unique opportunity to study structure–function relationships in proteins. This is because, for many years, hemoglobin was the only protein of known structure that had a large number of well-characterized naturally occurring **variants**. The examination of individuals with physiological disabilities, together with the routine electrophoretic screening of human blood samples, has led to the discovery of more than 1000 variant hemoglobins, >90% of which result from single amino acid substitutions in a globin polypeptide chain. Indeed, about 5% of the world's human population are carriers of an inherited variant hemoglobin.

Not all hemoglobin variants produce clinical symptoms, but some abnormal hemoglobin molecules do cause debilitating diseases (~300,000 individuals with serious hemoglobin disorders are born every year; naturally occurring hemoglobin variants that are lethal are, of course, never observed). **Table 7-1** lists several hemoglobin variants. Mutations that destabilize hemoglobin's tertiary or quaternary structure alter hemoglobin's oxygen-binding affinity (p_{50}) and

TABLE 7-1 Some Hemoglobin Variants

Name ^a	Mutation	Effect
Hammersmith	Phe CD1(42) β \rightarrow Ser	Weakens heme binding
Bristol	Val E11(67) β \rightarrow Asp	Weakens heme binding
Bibba	Leu H19(136) α \rightarrow Pro	Disrupts the H helix
Savannah	Gly B6(24) β \rightarrow Val	Disrupts the B–E helix interface
Philly	Tyr C1(35) β \rightarrow Phe	Disrupts hydrogen bonding at the α_1 – β_1 interface
Boston	His E7(58) α \rightarrow Tyr	Promotes methemoglobin formation
Milwaukee	Val E11(67) β \rightarrow Glu	Promotes methemoglobin formation
Iwate	His F8(87) α \rightarrow Tyr	Promotes methemoglobin formation
Yakima	Asp G1(99) β \rightarrow His	Disrupts a hydrogen bond that stabilizes the T conformation
Kansas	Asn G4(102) β \rightarrow Thr	Disrupts a hydrogen bond that stabilizes the R conformation

^aHemoglobin variants are usually named after the place where they were discovered (e.g., hemoglobin Boston).

reduce its cooperativity (Hill constant). Moreover, the unstable hemoglobins are degraded by the erythrocytes, and their degradation products often cause the erythrocytes to **lyse** (break open). The resulting **hemolytic anemia** (anemia is a deficiency of red blood cells) compromises O_2 delivery to tissues.

Certain mutations at the O_2 -binding site of either the α or β chain favor the oxidation of Fe(II) to Fe(III). Individuals carrying the resulting methemoglobin subunit exhibit **cyanosis**, a bluish skin color, due to the presence of methemoglobin in their arterial blood. These hemoglobins have reduced cooperativity (Hill constant ~ 1.2 compared to a maximum value of 2, since only two subunits in each of these methemoglobins can bind oxygen).

Mutations that increase hemoglobin's oxygen affinity lead to increased numbers of erythrocytes to compensate for the less than normal amount of oxygen released in the tissues. Individuals with this condition, which is named **polycythemia**, often have a ruddy complexion.

A Single Amino Acid Change Causes Sickle-Cell Anemia. Most harmful hemoglobin variants occur in only a few individuals, in many of whom the mutation apparently originated. However, $\sim 10\%$ of African-Americans and as many as 25% of black Africans carry a single copy of (are **heterozygous** for) the gene for **sickle-cell hemoglobin (hemoglobin S)**. Individuals who carry two copies of (are **homozygous** for) the gene for hemoglobin S suffer from **sickle-cell anemia**, in which deoxyhemoglobin S forms insoluble filaments that deform erythrocytes (**Fig. 7-17**). In this painful, debilitating, and often fatal disease, the rigid, sickle-shaped cells cannot easily pass through the capillaries. Consequently, in a sickle-cell "crisis," the blood flow to some tissues may be completely blocked, resulting in tissue death. In addition, the mechanical fragility of the misshapen cells results in hemolytic anemia. Heterozygotes, whose hemoglobin is $\sim 40\%$ hemoglobin S, usually lead a normal life, although their erythrocytes have a shorter-than-normal lifetime.

In 1945, Linus Pauling hypothesized that sickle-cell anemia was the result of a mutant hemoglobin, and in 1949 he showed that the mutant hemoglobin had a less negative ionic charge than normal adult hemoglobin. This was the first evidence that a disease could result from an alteration in the molecular structure of a protein. Furthermore, since sickle-cell anemia is an inherited disease, a defective gene must be responsible for the abnormal protein. Nevertheless, the molecular defect in sickle-cell hemoglobin was not identified until 1956, when Vernon Ingram showed that hemoglobin S contains Val rather than Glu at the sixth position of each β chain. This was the first time an inherited disease was shown to arise from a specific amino acid change in a protein.

The X-ray structure of deoxyhemoglobin S has revealed that one mutant Val side chain in each hemoglobin S tetramer nestles into a hydrophobic pocket on the surface of a β subunit in another hemoglobin tetramer (**Fig. 7-18**). This intermolecular contact allows hemoglobin S tetramers to form linear polymers. Aggregates of 14 strands wind around each other to form rigid fibers that extend throughout the length of the erythrocyte (**Fig. 7-19**). The hydrophobic pocket on the β subunit cannot accommodate the normally occurring Glu side chain, and the pocket is absent in oxyhemoglobin. Consequently, neither normal hemoglobin nor oxyhemoglobin S can polymerize. In fact, hemoglobin S fibers dissolve essentially instantaneously on oxygenation, so none are present in arterial blood. The danger of sickling is greatest when erythrocytes pass

(a)

(b)

FIG. 7-17 Scanning electron micrographs of human erythrocytes. (a) Normal erythrocytes are flexible, biconcave disks that can tolerate slight distortions as they pass through the capillaries (many of which have smaller diameters than erythrocytes). (b) Sickled erythrocytes from an individual with sickle-cell anemia are elongated and rigid and cannot easily pass through capillaries.

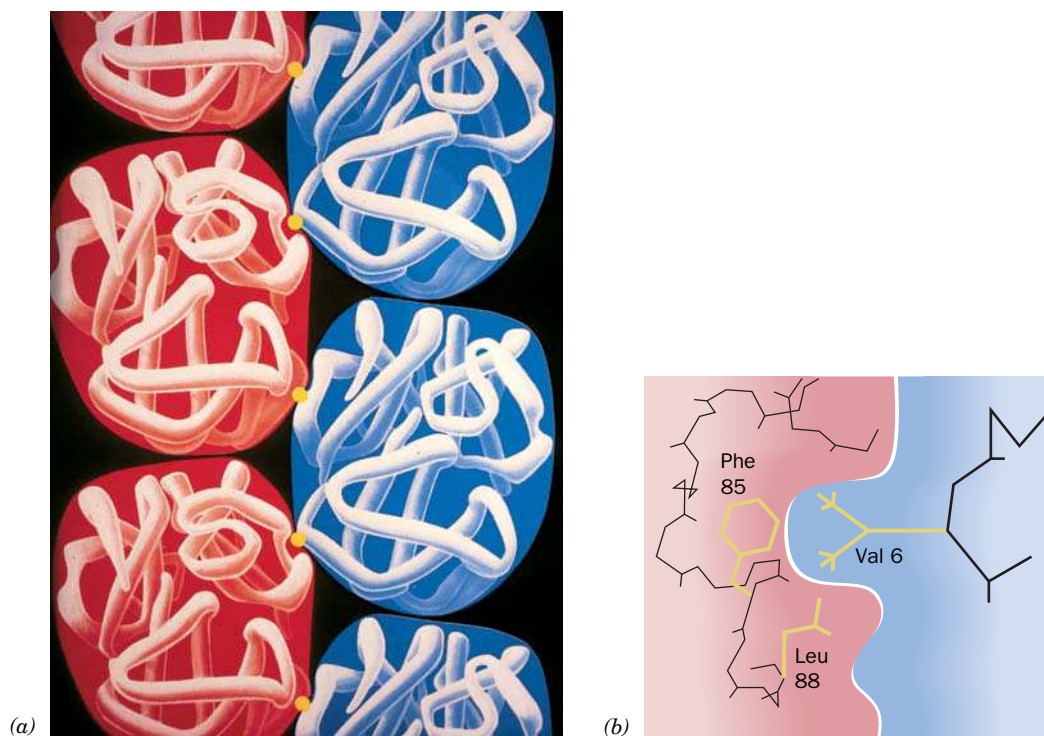

FIG. 7-18 Structure of a deoxyhemoglobin S fiber. (a) The arrangement of deoxyhemoglobin S molecules in the fiber. Only three subunits of each deoxyhemoglobin S molecule are shown. (b) The side chain of the mutant Val 6 in the β_2 chain of one hemoglobin S molecule (yellow knob in Part a) binds to a hydrophobic pocket on the β_1 subunit of a neighboring deoxyhemoglobin S molecule. through the capillaries, where deoxygenation occurs. The polymerization of hemoglobin S molecules is time and concentration dependent, which explains why blood flow blockage occurs only sporadically (in a sickle-cell “crisis”).

Interestingly, many hemoglobin S homozygotes have only a mild form of sickle-cell anemia because they express relatively high levels of fetal hemoglobin, which contains γ chains rather than the defective β chains. The fetal hemoglobin dilutes the hemoglobin S, making it more difficult for hemoglobin S to aggregate during the 10–20 s it takes for an erythrocyte to travel from the tissues to the lungs for reoxygenation. The administration of **hydroxyurea**,

the first and as yet the only effective treatment for sickle-cell anemia, ameliorates the symptoms of sickle-cell anemia by increasing the fraction of cells containing fetal hemoglobin (although the mechanism whereby hydroxyurea acts is unknown).

Hemoglobin S Protects Against Malaria. Before the advent of modern palliative therapies, individuals with sickle-cell anemia rarely survived to maturity. Natural selection has not minimized the prevalence of the hemoglobin S variant, however, because heterozygotes are more resistant to **malaria**, an often lethal infectious disease. Of the 2.5 billion people living within malaria-endemic areas, 100 million are clinically ill with the disease at any given time and around

FIG. 7-20 Correspondence between malaria and the sickle-cell gene. The blue areas of the map indicate regions where malaria is or was prevalent. The pink areas represent the distribution of the gene for hemoglobin S. Note the overlap (purple) of the distributions.

CHECKPOINT

- Describe the O_2 -binding behavior of myoglobin in terms of pO_2 and K . How is K defined?
- Explain the structural basis for cooperative oxygen binding to hemoglobin.
- Sketch a binding curve (% bound ligand versus ligand concentration) for cooperative and noncooperative binding.
- Explain why the O_2 -binding behavior of myoglobin and hemoglobin can be summed up by a single number (the p_{50}).
- Could a binding protein have a Hill constant of zero?
- Describe how myoglobin and hemoglobin function in delivering O_2 from the lungs to respiring tissues.
- What is the physiological relevance of the Bohr effect and BPG?
- Explain why mutations can increase or decrease the oxygen affinity and cooperativity of hemoglobin. How can the body compensate for these changes?

1 million, mostly very young children, die from it each year. Malaria is caused by the mosquito-borne protozoan *Plasmodium falciparum*, which resides within erythrocytes during much of its 48-h life cycle. Infected erythrocytes adhere to capillary walls, causing death when cells impede blood flow to a vital organ.

The regions of equatorial Africa where malaria is a major cause of death coincide closely with the areas where the sickle-cell gene is prevalent (Fig. 7-20), thereby suggesting that the sickle-cell gene confers resistance to malaria. How does it do so? Plasmodia increase the acidity of infected erythrocytes by ~ 0.4 pH units. The lower pH favors the formation of deoxyhemoglobin via the Bohr effect, thereby increasing the likelihood of sickling in erythrocytes that contain hemoglobin S. Erythrocytes damaged by sickling are normally removed from the circulation by the spleen. During the early stages of a malarial infection, parasite-enhanced sickling probably allows the spleen to preferentially remove infected erythrocytes. In the later stages of infection, when the parasitized erythrocytes attach to the capillary walls (presumably to prevent the spleen from removing them from the circulation), sickling may mechanically disrupt the parasite. Consequently, heterozygous carriers of hemoglobin S in a malarial region have an adaptive advantage: They are more likely to survive to maturity than individuals who are homozygous for normal hemoglobin. Thus, in malarial regions, the fraction of the population who are heterozygotes for the sickle-cell gene increases until their reproductive advantage is balanced by the correspondingly increased proportion of homozygotes (who, without modern medical treatment, die in childhood).

2 Muscle Contraction

KEY CONCEPTS

- Myosin is a motor protein that undergoes conformational changes as it hydrolyzes ATP.
- The sliding filament model of muscle contraction describes the movement of thick filaments relative to thin filaments.
- The globular protein actin can form structures such as microfilaments and the thin filaments of muscle.

One of the most striking characteristics of living things is their capacity for organized movement. Such phenomena occur at all structural levels and include such diverse vectorial processes as the separation of replicated chromosomes during cell division, the beating of flagella and cilia, and, most obviously, muscle contraction. In this section, we consider the structural and

chemical basis of movement in **striated muscle**, one of the best-understood mobility systems.

A Muscle Consists of Interdigitated Thick and Thin Filaments

The voluntary muscles, which include the skeletal muscles, have a striated (striped) appearance when viewed by light microscopy (Fig. 7-21). Such muscles consist of long multinucleated cells (the muscle fibers) formed from numerous cells that have fused together and which contain parallel bundles of ~1,000 **myofibrils** (Greek: *myos*, muscle; Fig. 7-22). A single muscle fiber, which is 20–100 μm in diameter, often runs the length of the muscle. Electron micrographs show that muscle striations arise from the banded structure of multiple in-register myofibrils. The bands are formed by alternating regions of greater and lesser electron density called **A bands** and **I bands**, respectively (Fig. 7-23). The myofibril's repeating unit, the **sarcomere** (Greek: *sarkos*, flesh), is bounded by **Z disks** at the center of each I band. The A band is centered on the **H zone**, which in turn is centered on the **M disk**. The A band contains 150-Å-diameter **thick filaments**, and the I band contains 70-Å-diameter **thin filaments**. The two sets of filaments are linked by cross-bridges where they overlap.

FIG. 7-21 Photomicrograph of a muscle fiber. The longitudinal axis of the fiber is horizontal (perpendicular to the striations). The alternating pattern of dark A bands and light I bands from multiple in-register myofibrils is clearly visible.

J.C. Revy, CNRU/Photo Researchers

FIG. 7-22 Skeletal muscle organization. A muscle (a) consists of bundles of muscle fibers (b), each of which is a long, thin, multinucleated cell (c) that may run the length of the muscle. Muscle fibers contain bundles of laterally aligned myofibrils (d), which, in turn, consist of bundles of alternating thick and thin filaments.

FIG. 7-23 Anatomy of the myofibril. The electron micrograph shows parts of three myofibrils, which are separated by horizontal gaps. The accompanying interpretive drawing shows the major features of the myofibril: the light I band, which contains only thin filaments; the A band, whose dark H zone contains only thick filaments and whose darker outer segments contain overlapping thick and thin filaments; the Z disk, which bisects the I band and to which the thin filaments are anchored; and the M disk, which arises from a bulge at the center of each thick filament. The myofibril's functional unit, the sarcomere, is the region between two successive Z disks. [Courtesy of Hugh Huxley, Brandeis University.]

A contracted muscle can be as much as one-third shorter than its fully extended length. The contraction results from a decrease in the length of the sarcomere, caused by reductions in the lengths of its I band and H zone (Fig. 7-24a). These observations, made by Hugh Huxley in 1954 (Box 7-4), are explained by the **sliding filament model** in which interdigitated thick and thin filaments slide past each other (Fig. 7-24b). Thus, during a contraction, a muscle becomes shorter, and because its total volume does not change, it also becomes thicker.

Thick Filaments Consist Mainly of Myosin. Vertebrate thick filaments are composed almost entirely of a single type of protein, **myosin**, which consists of six polypeptide chains: two 220-kD **heavy chains** and two pairs of different

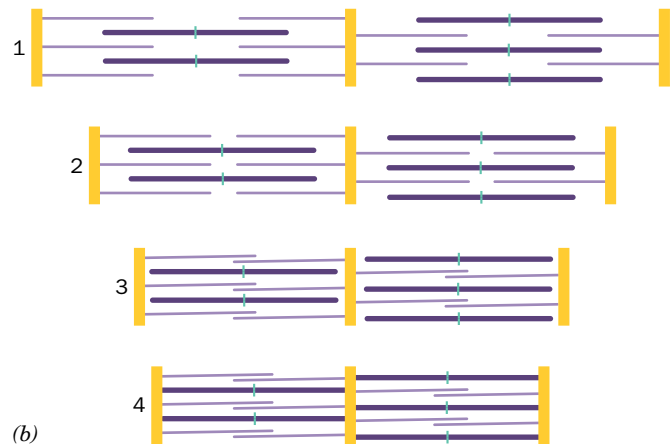

FIG. 7-24 Myofibril contraction. (a) Electron micrographs showing myofibrils in progressively more contracted states. The lengths of the I band and H zone decrease on contraction, whereas the lengths of

the thick and thin filaments remain constant. (b) Interpretive drawings showing interpenetrating sets of thick and thin filaments sliding past each other. [Courtesy of Hugh Huxley, Brandeis University.]

Hugh Huxley (1924–2013) The mechanism of muscle action has fascinated scientists for hundreds if not thousands of years. The first close look at muscle fibers came in 1682, when Antoni van Leeuwenhoek's early microscope revealed a pattern of thin longitudinal fibers. In the modern era, research on muscle has followed one of two approaches. First, it is possible to study muscle as an energy-transducing system, in which metabolic energy is generated and consumed.

This line of research received a tremendous boost in the 1930s with the discovery that ATP is the energy source for muscle contraction. The second approach involves treating muscle as a mechanical system—that is, sorting out its rods and levers. Ultimately, a molecular approach united the mechanical and energetic aspects of muscle research. The insights of Hugh Huxley made this possible.

The molecular characterization of muscle did not occur overnight. In 1859, Willi Kühne isolated a proteinaceous substance from muscle tissue that he named “myosin” (almost certainly a mixture of many proteins), but it tended to aggregate and was therefore not as popular a study subject as the more soluble proteins such as hemoglobin. A major breakthrough in muscle protein chemistry came in 1941, when the Hungarian biochemist Albert Szent-Györgyi showed that two types of protein could be extracted from ground muscle by a solution with high salt concentration (Szent-Györgyi also contributed to the elucidation of the citric acid cycle; Box 17-1). Extraction for 20 minutes yielded a protein he named myosin A but which is now called myosin. However, extraction overnight yielded a second protein, which he named myosin B but is now called actomyosin. It soon became apparent that myosin B was a mixture of two proteins, myosin and a new protein, which was named actin. Further work showed that threads of actomyosin contracted to ~10% of their original length in the presence of ATP. Since actin and myosin alone do not contract in the presence of ATP, the contraction must have resulted from their interaction. However, it took another decade to develop a realistic model of how myosin and actin interact.

A number of theories had been advanced to explain muscle contraction. According to one theory, the cytoplasm of muscle cells moved like that of an amoeba. Other theories proposed that muscle fibers took up and gave off water or repelled and attracted other fibers electrostatically. Linus Pauling, who had recently discovered the structures of the α helix and β sheet (Box 6-1), ventured that myosin could change its length by shifting between the two protein conformations. Huxley formulated an elegant—and correct—explanation in his sliding filament model for muscle contraction.

In 1948, Huxley began his doctoral research at Cambridge University in the United Kingdom, in the laboratory of John Kendrew (who, 10 years later, determined the first X-ray structure of a protein, that of myoglobin; Section 7-1A). There, through X-ray studies on frog muscle fibers, Huxley established that the X-ray diffraction pattern changes with the muscle's physiological state. Furthermore, he showed that muscle contained two sets of parallel fibers, rather than one, and

that these fibers were linked together by multiple cross-links. These observations became the germ for further research, which he carried out at MIT in 1953 and 1954. He teamed up with Jean Hanson, a Briton who was also working at MIT. Hanson made good use of her knowledge of muscle physiology and her expertise in phase-contrast microscopy, a technique that could visualize the banded patterns of muscle fibers. Huxley and Hanson observed rabbit muscle fibers under different experimental conditions, making precise measurements of the width of the A and I bands in sarcomeres (Fig. 7-23). In one experiment, they extracted myosin from the muscle fiber, noted the loss of the dark A band, and concluded that the A band consists of myosin. When they extracted both actin and myosin, all identifiable structure was lost, and they concluded that actin is present throughout the sarcomere.

When ATP was added, the muscle slowly contracted, and Huxley and Hanson were able to measure the shortening of the I band. The A band maintained a constant length but became darker. A muscle fiber under the microscope could also be stretched by pulling on the coverslip. As the muscle “relaxed,” the I band increased in width and the A band became less dense. Measurements were made for muscle fibers contracted to 60% of their original length and stretched to 120% of their original length.

The key to the sliding filament model that Huxley described and subsequently refined is that the individual molecules (that is, their observable fibrous forms) do not shrink or extend but instead slide past each other. During contraction, actin filaments (thin filaments) in the I band are drawn into the A band, which consists of stationary myosin-containing filaments (thick filaments). During stretching, the actin filaments withdraw from the A band. Similar conclusions were reached by the team of Andrew Huxley (no relation to Hugh) and Rolf Niedergerke, who examined the contraction of living frog muscle fibers. Both groups published their work in back-to-back papers in *Nature* in 1954.

Hugh Huxley went on to supply additional details to his sliding filament model. For example, he showed that myosin forms cross-bridges with actin fibers. However, these bridges are asymmetric, pointing in opposite directions in the two halves of the sarcomere. This arrangement allows myosin to pull thin filaments in opposite directions toward the center of the sarcomere (Fig. 7-24).

While Huxley was describing the mechanism of muscle contraction, Watson and Crick discovered the structure of DNA, and Max Perutz made a decisive breakthrough in the use of heavy metal atoms to solve the phase problem in his X-ray studies of hemoglobin (Box 7-2). Collectively, these discoveries indicated the tremendous potential for describing biological phenomena in molecular terms. Subsequent studies of muscle contraction have used electron microscopy, X-ray crystallography, and enzymology to probe the fine details of the sliding filament model, including the structure of myosin's lever arm, the composition of the thin filament, and the exact role of ATP in triggering conformational changes that generate mechanical force.

Huxley, H.E. and Hanson, J., Changes in the cross-striations of muscle during contraction and stretch and their structural interpretation, *Nature* **173**, 973–976 (1954).

light chains, the so-called **essential** and **regulatory light chains (ELC and RLC)** that vary in size between 15 and 22 kD, depending on their source. X-Ray structure determinations by Ivan Rayment and Hazel Holden of the N-terminal half of the myosin heavy chain, the so-called **myosin head**, reveal that it forms an elongated ($55 \times 165 \text{ \AA}$) globular head to which one subunit

(a)

(b)

FIG. 7-25 Structure of myosin. (a) A ribbon diagram of the myosin head from chicken muscle. The heavy chain is represented by a ribbon diagram embedded in its semi-transparent molecular surface with different portions green, blue, and red. The essential and regulatory light chains, RLC and ELC, are drawn in worm form with each colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). A sulfate ion, shown in space-filling form (O red and S yellow), occupies the binding site of ATP's β -phosphate group. An RLC-bound Ca^{2+} ion (*lower left*) is represented by a cyan sphere. [Based on an X-ray structure by Ivan Rayment and Hazel Holden, University of Wisconsin. PDBid 2MYS.] (b) Diagram of the myosin molecule. Its two identical heavy chains (*green and orange*) each have an N-terminal globular head and an α -helical tail. Between the head and tail is an α helix, the lever arm, that associates with the two kinds of light chains (*magenta and yellow*). The tails wind around each other to form a 1600-Å-long parallel coiled coil.

each of ELC and RLC bind (**Fig. 7-25a**). The C-terminal half of the heavy chain forms a long fibrous α -helical tail, two of which associate to form a left-handed coiled coil. Thus, *myosin consists of a 1600-Å-long rodlike segment with two globular heads* (**Fig. 7-25b**). The amino acid sequence of myosin's α -helical tail is characteristic of coils such as those in keratin (Section 6-1C): It has a seven-residue pseudorepeat, *a-b-c-d-e-f-g*, with nonpolar residues predominating at positions *a* and *d*.

Under physiological conditions, several hundred myosin molecules aggregate to form a thick filament. The rodlike tails pack end to end in a regular staggered array, leaving the globular heads projecting to the sides on

FIG. 7-26 Structure of the thick filament. (a) Electron micrograph showing the myosin heads projecting from the thick filament. [From Trinick, J. and Elliott, A., *J. Mol. Biol.* **131**, 135 (1977).] (b) Drawing of

a thick filament, in which several hundred myosin molecules form a staggered array with their globular heads pointing away from the filament.

both ends (Fig. 7-26). These myosin heads form the cross-bridges to thin filaments in intact myofibrils. The myosin head, which is an **ATPase** (ATP-hydrolyzing enzyme), has its ATP-binding site located in a 13-Å-deep V-shaped pocket.

Thin Filaments Consist Mainly of Actin. Thin filaments consist mainly of polymers of **actin**, the most abundant cytosolic protein in eukaryotes. In its monomeric form, this ~375-residue protein is known as **G-actin** (G for globular); when polymerized, it is called **F-actin** (F for fibrous). Each actin subunit has binding sites for ATP and a Ca^{2+} or Mg^{2+} ion that are located in a deep cleft (Fig. 7-27). ATP hydrolysis to $\text{ADP} + \text{P}_i$ is not required for actin polymerization but occurs afterward (Section 7-2C).

The fibrous nature of F-actin and its variable fiber lengths have thwarted its crystallization in a manner suitable for X-ray crystallographic analysis. Consequently, our current understanding of the atomic structure of F-actin is based on electron micrographs (Fig. 7-28a) together with low-resolution models based on X-ray studies of oriented gels of F-actin into which high-resolution atomic models of G-actin have been fitted (Fig. 7-28b). These models indicate that the actin polymer is a double-stranded helix of subunits in which each subunit contacts four others. Each actin subunit has the same head-to-tail orientation (e.g., all the nucleotide-binding clefts open upward

FIG. 7-27 X-Ray structure of rabbit muscle G-actin in complex with ATP and a Ca^{2+} ion. The four domains of the protein are colored cyan, magenta, orange, and yellow, and the N- and C-termini are labeled. The ATP, which is drawn in space-filling form with C green, N blue, O red, and P orange, binds at the bottom of a deep cleft between the domains. The Ca^{2+} ion is represented by a light green sphere. [Based on an X-ray structure by Leslie Burtnik, University of British Columbia, Vancouver, British Columbia. PDBid 3HBT.]

FIG. 7-28 Structure of the actin filament. (a) Cryoelectron microscopy-based image. The tropomyosin binding sites (see below) are blue. [Courtesy of Daniel Safer, University of Pennsylvania, and Ronald Milligan, The Scripps Research Institute, La Jolla, California.] (b) Model based on fitting a known X-ray structure of G-actin to a cryoEM-based image of F-actin, represented by five consecutive actin · ADP subunits drawn in ribbon form, each with a different color, embedded in their semitransparent molecular surface. The ADPs are drawn in space-filling form with C green, N blue, O red, and P orange. The central subunit (magenta), whose four domains are numbered, is oriented as is the G-actin in Fig. 7-27. [Based on an X-ray structure by Leslie Burtnik, University of British Columbia, Vancouver, British Columbia. PDBid 3HBT.]

FIG. 7-29 Model of the myosin–actin interaction.

This space-filling model was constructed from the X-ray structures of actin and the myosin head and electron micrographs of their complex. The actin filament is at the top, with two of its subunits colored tan and violet. The myosin heavy chain is colored as in Fig. 7-25 and the light chains are yellow and magenta. The coiled-coil tail is not shown. An ATP-binding site is located in a cleft in the blue domain of the myosin head. In a myofibril, every actin monomer has the potential to bind a myosin head, and the thick filament has many myosin heads projecting from it. [Modified from a drawing by Ivan Rayment and Hazel Holden, University of Wisconsin.]

in Fig. 7-28*b*), so the assembled fiber has a distinct polarity. The end of the fiber toward which the nucleotide-binding sites open is known as the **(–) end**, and its opposite end is the **(+) end**. The (+) ends of the thin filaments bind to the Z disk (Fig. 7-23).

Each of muscle F-actin's monomeric units can bind a single myosin head (Fig. 7-29), probably by ion pairing and by the association of hydrophobic patches on each protein. Electron micrographs indicate that the myosin heads bound to an F-actin filament all have the same orientation (Fig. 7-30) and that in thin filaments that are still attached to the Z disk, the myosin heads all point away from the Z disk.

Tropomyosin and Troponin Are Thin Filament Components. Myosin and actin, the major components of muscle, account for 60 to 70% and 20 to 25% of total muscle protein, respectively. Of the remainder, two proteins that are associated with the thin filaments are particularly prominent:

1. **Tropomyosin**, a homodimer whose two 284-residue α -helical subunits wrap around each other to form a parallel coiled coil that extends nearly the entire 400-Å length of the molecule (a portion of which is shown in Fig. 6-15*b*). Multiple copies of these rod-shaped proteins are joined head-to-tail to form cables wound in the grooves of the F-actin helix such that each tropomyosin molecule contacts seven consecutive actin subunits in a quasi-equivalent manner (Fig. 7-30).

FIG. 7-30 Cryoelectron microscopy–based image at <25-Å resolution of a thin filament decorated with myosin heads. F-actin is red, tropomyosin is blue, the myosin motor domain is yellow, and the essential light chain is green. The helical filament has a pitch (rise per turn) of 370 Å.

2. **Troponin**, which consists of three subunits: **TnC**, a Ca^{2+} -binding protein; **TnI**, which binds to actin; and **TnT**, an elongated molecule, which binds to tropomyosin at its head-to-tail junctions. The X-ray structure of troponin in complex with four Ca^{2+} ions (Fig. 7-31), determined by Robert Fletterick, reveals that TnC closely resembles the myosin light chains and that the inhibitory segment of TnI binds to TnC's rigid central helix in this Ca^{2+} -activated state.

The tropomyosin–troponin complex, as we will see below, regulates muscle contraction by controlling the access of the myosin heads to their binding sites on actin.

Muscle Contains Numerous Minor Proteins That Organize Its Structure.

Other proteins serve to form the Z disk and the M disk and to organize the arrays of thick and thin filaments. For instance, **α -actinin**, a rodlike homodimeric protein that cross-links F-actin filaments, is localized in the Z disk's interior and is therefore thought to attach oppositely oriented thin filaments to the Z disk.

One of the more unusual muscle proteins, **titin**, the longest known polypeptide chain (35,213 residues), is composed of ~ 300 repeating globular domains. Three to six titin molecules associate with each thick filament, spanning the 1- μm distance between the M and Z disks. Titin is believed to function as a molecular bungee cord to keep the thick filament centered on the sarcomere: During muscle contraction, it compresses as the sarcomere shortens, but when the muscle relaxes, titin resists sarcomere extension past the starting point.

Nebulin, which is also extremely large (6669 residues), is a mainly α -helical protein that is associated with the thin filament. It is thought to set the length of the thin filament by acting as a template for actin polymerization. This length is held constant by **tropomodulin**, which caps the (–) end of the thin filament (the end not attached to the Z disk), thereby preventing further actin polymerization and depolymerization. **CapZ** (also called **β -actinin**) is an α -actinin-associated heterodimer that similarly caps the (+) end of F-actin.

The M disk (Fig. 7-23) arises from the local enlargement of in-register thick filaments. Two proteins that are associated with this structure, **myomensin** and **M-protein**, bind to titin and are therefore likely to participate in thick filament assembly, as does the thick filament-associated **myosin-binding protein C**.

 **Duchenne muscular dystrophy (DMD)** and the less severe **Becker muscular dystrophy (BMD)** are both sex-linked muscle-wasting diseases. In DMD, which has an onset age of 2 to 5 years, muscle degeneration exceeds muscle regeneration, causing progressive muscle weakness and ultimately death, typically due to respiratory disorders or heart failure, usually by age 25. In BMD, the onset age is 5 to 10 years and there is an overall less progressive course of muscle degeneration and a longer (sometimes normal) life span than in individuals with DMD.

The gene responsible for DMD/BMD encodes a 3685-residue protein named **dystrophin**, which has a normal abundance in muscle tissue of 0.002%. Individuals with DMD usually have no detectable dystrophin in their muscles, whereas those with BMD have mostly dystrophins of altered sizes. Evidently, the dystrophins of individuals with DMD are rapidly degraded, whereas those of individuals with BMD are semifunctional.

Dystrophin is a member of a family of flexible rod-shaped proteins that includes other actin-binding cytoskeletal components. Dystrophin associates on the inner surface of the muscle plasma membrane with a transmembrane glycoprotein complex, where it helps anchor F-actin to the extracellular matrix and thereby protects the plasma membrane from being torn by the mechanical stress of muscle contraction. Although such small tears are common in muscle cells, they occur much more frequently in dystrophic cells, leading to a greatly increased rate of cell death.

FIG. 7-31 X-Ray structure of chicken skeletal muscle troponin. TnC is red, TnI is blue, and TnT is gold. The four Ca^{2+} ions bound by TnC are represented by cyan spheres. [Based on an X-ray structure by Robert Fletterick, University of California at San Francisco. PDBid 1YTZ.]

B Muscle Contraction Occurs when Myosin Heads Walk Up Thin Filaments

To complete our description of muscle contraction, we must determine how ATP hydrolysis is coupled to the sliding filament model. If the sliding filament model is correct then it would be impossible for a myosin cross-bridge to remain attached to the same point on a thin filament during muscle contraction. Rather, it must repeatedly detach and then reattach itself at a new site further along the thin filament toward the Z disk. This, in turn, suggests that *muscular tension is generated through the interaction of myosin cross-bridges with thin filaments*. The actual contractile force is provided by ATP hydrolysis. Thus, myosin is a **motor protein** that converts the chemical energy of ATP hydrolysis to the mechanical energy of movement. Edwin Taylor formulated a model for myosin-mediated ATP hydrolysis, which has been refined by the structural studies of Rayment, Holden, and Ronald Milligan as follows (**Fig. 7-32**):

1. ATP binds to a myosin head in a manner that causes myosin's actin-binding site to open up and release its bound actin.
2. Myosin's active site (distinct from its actin-binding site) closes around the ATP. The resulting hydrolysis of the ATP to ADP + P_i "cocks" the myosin head—that is, puts it into its "high energy" conformation in which it is approximately perpendicular to the thick filament.
3. The myosin head binds weakly to an actin monomer that is closer to the Z disk than the one to which it had been bound previously.
4. Myosin releases P_i, which causes its actin-binding site to close, thereby increasing its affinity for actin.
5. The resulting transient state is immediately followed by the power stroke, a conformational shift that sweeps the myosin head's C-terminal tail by an estimated ~100 Å toward the Z disk relative to the actin-binding site on its head, thus translating the attached thin filament by this distance toward the M disk.
6. ADP is released, thereby completing the cycle.

Because the reaction cycle involves several steps, some of which are irreversible (e.g., ATP hydrolysis and P_i release), the entire cycle is unidirectional. The ~500 myosin heads on every thick filament asynchronously cycle through this reaction sequence about five times each per second during a strong muscular contraction. *The myosin heads thereby "walk" or "row" up adjacent thin filaments toward the Z disk with the concomitant contraction of the muscle*. Although myosin is dimeric, its two heads function independently.

Calcium Triggers Muscle Contraction. Highly purified actin and myosin can contract regardless of the Ca²⁺ concentration, but preparations containing intact thin filaments contract only in the presence of Ca²⁺, due to the regulatory action of troponin C (Fig. 7-31). Stimulation of a myofibril by a nerve impulse results in the release of Ca²⁺ from the **sarcoplasmic reticulum** (a network of flattened vesicles derived from the endoplasmic reticulum that surround each myofibril). As a result, the intracellular [Ca²⁺] increases from ~10⁻⁷ to ~10⁻⁵ M. The higher calcium concentration triggers the conformational change in the troponin-tropomyosin complex that exposes the site on actin where the myosin head binds

FIG. 7-32 Mechanism of force generation in muscle. (*Opposite*) The myosin head "walks" up the actin thin filament through a unidirectional cyclic process that is driven by ATP hydrolysis to ADP and P_i. Only one myosin head is shown. The actin monomer to which the myosin head is bound at the beginning of the cycle is more darkly colored for reference. [After Rayment, I. and Holden, H., *Curr. Opin. Struct. Biol.* **3**, 949 (1993).] **WPLS See the Animated Process Diagrams.**

? Why doesn't "ATP hydrolysis" fully describe the role of ATP in muscle contraction?

FIG. 7-33 Comparison of the positions of tropomyosin on the thin filament in the absence and presence of Ca^{2+} . In this superposition of cryoelectron microscopy–based images, the F-actin filament is gold, the tropomyosin in the absence of Ca^{2+} is red, and that in the presence of Ca^{2+} is green. The shift is 23 Å.

(Fig. 7-33), thereby increasing myosin’s affinity for actin by $\sim 10,000$ fold. When the myofibril $[\text{Ca}^{2+}]$ is low (Ca^{2+} is rapidly pumped back into the sarcoplasmic reticulum by ATP-requiring Ca^{2+} pumps; Section 10-3B), the troponin–tropomyosin complex assumes its resting conformation, blocking myosin binding to actin and causing the muscle to relax.

C Actin Forms Microfilaments in Nonmuscle Cells

Although actin and myosin are most prominent in muscle, they also occur in other tissues. In fact, actin is ubiquitous and is usually the most abundant cytoplasmic protein in eukaryotic cells, typically accounting for 5 to 10% of their total protein. Nonmuscle actin forms $\sim 70\text{-Å}$ -diameter fibers known as **microfilaments** that can be visualized by **immunofluorescence microscopy** (in which a fluorescent-tagged antibody is used to “stain” the actin to which it binds; Fig. 7-34). In nonmuscle cells, actin plays an essential role in many processes, including changes in cell shape, cell division, endocytosis, and organelle transport.

Microfilament Treadmilling Can Mediate Locomotion. ATP–G-actin binds to both ends of an F-actin filament but with a greater affinity for its (+) end (hence its name). This polymerization activates F-actin subunits to hydrolyze their bound ATP to ADP + P_i with the subsequent dissociation of P_i . The resulting conformation change reduces the affinity of an ADP–F-actin subunit for its neighboring subunits relative to that of ATP–F-actin. Since F-actin–catalyzed ATP hydrolysis occurs more slowly than actin polymerization and F-actin’s bound nucleotide does not exchange with those in solution (its nucleotide-binding site is blocked by its associated subunits), F-actin’s more recently polymerized and hence predominantly ATP-containing subunits occur largely at its (+) end, whereas its (–) end consists mainly of less recently polymerized and hence predominantly ADP-containing subunits. The lesser affinity of ADP-containing actin subunits for F-actin results in their net dissociation from the (–) end of the polymer.

The steady state (when the microfilament maintains a constant length) occurs when the net rate of addition of subunits at the (+) end matches the net rate of dissociation of subunits at the (–) end. Then, *subunits that have added to the (+) end move toward the (–) end where they dissociate, a process called treadmilling*

FIG. 7-34 Actin microfilaments. The microfilaments in a fibroblast resting on the surface of a culture dish are revealed by immunofluorescence microscopy using a fluorescently labeled antibody to actin. When the cell begins to move, the filaments disassemble.

Courtesy of John Victor Small, Austrian Academy of Sciences, Salzburg

FIG. 7-35 Microfilament treadmilling. In the steady state, actin monomers continually add to the (+) end of the filament (*left*) but dissociate at the same rate from the (-) end (*right*). The filament thereby maintains a constant length while its component monomers translocate from left to right. For reference, a cluster of actin subunits is colored bright green.

? Indicate which end of the actin filament is rich in ADP or ATP.

FIG. 7-36 Scanning electron micrograph of a crawling macrophage. The leading edge of this white blood cell (*top*) is ruffled where it has become detached from the surface and is in the process of extending. The cell's trailing edge or tail (*bottom*), which is still attached to the surface, is gradually being pulled toward the leading edge. The rate of actin polymerization is greatest at the leading edge. The macrophage is in the course of engulfing *Staphylococcus sp.* bacteria (*orange globules*) by a process known as **phagocytosis**.

(**Fig. 7-35**). Thus, a fluorescently labeled actin monomer is seen to move from the (+) end of the microfilament toward its (-) end. Treadmilling is driven by the free energy of ATP hydrolysis and hence is not at equilibrium.

The directional growth of actin filaments exerts force against the plasma membrane, allowing a cell to extend its cytoplasm in one direction. If the cytoplasmic protrusion anchors itself to the underlying surface, then the cell can use the adhesion point for traction to advance further. In order for the cell to crawl, however, the trailing edge of the cell must release its contacts with the surface while newer contacts are being made at the leading edge (**Fig. 7-36**). In addition, as microfilament polymerization proceeds at the leading edge, depolymerization must occur elsewhere in the cell, since the pool of G-actin is limited. A variety of actin-binding proteins modulate the rate of actin depolymerization and re-polymerization *in vivo*.

Actin-mediated cell locomotion—that is, amoeboid motion—is the most primitive mechanism of cell movement. Nevertheless, virtually all eukaryotic cells undertake some version of it, even if it involves just a small patch of actin near the cell surface. More extensive microfilament rearrangements are essential for cells such as neutrophils (a type of white blood cell) that travel relatively long distances to sites of infection or inflammation.

CHECKPOINT

- Explain how myosin structure relates to its function as a motor protein.
- Draw a diagram of the components of a sarcomere, including the locations of all the proteins mentioned in the text. Which components are globular and which are fibrous?
- Explain the molecular basis of the sliding filament model of muscle contraction.
- What are the roles of Ca^{2+} and ATP in muscle contraction?
- Is it possible to construct a fibrous protein from globular subunits?
- Describe the process of treadmilling in a microfilament.
- How does a microfilament differ from the thin filament in a myofibril?
- Describe the process of actin polymerization and depolymerization during cell crawling.

3 Antibodies

KEY CONCEPTS

- The humoral immune response is mediated by antibodies, which include constant domains as well as variable domains that recognize specific antigens.
- Antibody gene rearrangement and hypermutation contribute to antibody diversity.

All organisms are continually subject to attack by other organisms, including disease-causing microorganisms and viruses. In higher animals, these **pathogens** may penetrate the physical barrier presented by the skin and mucous membranes (a first line of defense) only to be identified as foreign invaders and destroyed by the **immune system**. Two types of immunity have been distinguished:

1. **Cellular immunity**, which plays a role in fighting most pathogens and is particularly effective at eliminating virally infected cells, is mediated by **T lymphocytes** or **T cells**, so called because they mature in the thymus.
2. **Humoral immunity** (*humor* is an archaic term for fluid), which is most effective against bacterial infections and the extracellular phases of viral infections, is mediated by an enormously diverse collection of related proteins known as **antibodies** or **immunoglobulins**. Antibodies are produced by **B lymphocytes** or **B cells**, which in mammals mature in the bone marrow.

In this section we focus on the structure, function, and generation of antibodies.

The immune response is triggered by the presence of a foreign macromolecule, often a protein or carbohydrate, known as an **antigen**. B cells display immunoglobulins on their surfaces. If a B cell encounters an antigen that binds to its particular immunoglobulin, it engulfs the antigen-antibody complex, degrades it, and displays the antigen fragments on the cell surface. T cells then stimulate the B cell to proliferate. Most of the B cell progeny are circulating cells that secrete large amounts of the antigen-specific antibody. These antibodies can bind to additional antigen molecules, thereby marking them for destruction by other components of the immune system. Although most B cells live only a few weeks unless stimulated by their corresponding antigen, a few long-lived **memory B cells** can recognize antigen several months or even many years later and can mount a more rapid and massive immune response (called a secondary response) than B cells that have not yet encountered their antigen (Fig. 7-37).

A Antibodies Have Constant and Variable Regions

The immunoglobulins form a related but enormously diverse group of proteins. All immunoglobulins contain at least four subunits: two identical

FIG. 7-37 Primary and secondary immune responses. Antibodies to antigen A appear in the blood following primary immunization on day 0 and secondary immunization on day 28. Antigen B is included in the secondary immunization to demonstrate the specificity of immunological memory for antigen A. The secondary response to antigen A is both faster and greater than the primary response.

~23-kD **light chains (L)** and two identical 53- to 75-kD **heavy chains (H)**. These subunits associate by disulfide bonds and by noncovalent interactions to form a roughly Y-shaped symmetric molecule with the formula $(LH)_2$ (Fig. 7-38).

The five classes of immunoglobulin (**Ig**) differ in the type of heavy chain they contain and, in some cases, in their subunit structure (Table 7-2). For example, **IgM** consists of five Y-shaped molecules arranged around a central **J subunit**; **IgA** occurs as monomers, dimers, trimers, and tetramers. The various immunoglobulin classes also have different physiological functions. **IgM** is most effective against microorganisms and is the first immunoglobulin to be secreted in response to an antigen. **IgG**, the most common immunoglobulin, is equally distributed between the blood and the extravascular fluid. **IgA** occurs predominantly in the intestinal tract and defends against pathogens by adhering to their antigenic sites to block their attachment to epithelial (outer) surfaces. **IgE**, which is normally present in the blood in minute concentrations, protects against parasites and has been implicated in allergic reactions. **IgD**, which is also present in small amounts, has no clearly known function. Our discussion of antibody structure will focus on **IgG**.

IgG can be cleaved through limited proteolysis with the enzyme **papain** into three ~50-kD fragments: two identical **Fab fragments** and one **Fc fragment**. The Fab fragments are the “arms” of the Y-shaped antibody and contain an entire

FIG. 7-38 X-Ray structure of an antibody. The protein is shown in ribbon form with its two heavy chains gold and cyan and its two light chains both magenta. Its two identical carbohydrate chains are drawn in space-filling form with C green, N blue, and O red. The antigen-binding sites are located at the ends of the two approximately horizontal Fab arms formed by the association of the light chains with the heavy chains. This particular antibody recognizes canine lymphoma (a type of cancer) and is therapeutically useful against it. [Based on an X-ray structure by Alexander McPherson, University of California at Irvine. PDBid 1IGT.]

? How many discrete protein domains are visible in this model?

TABLE 7-2 Classes of Human Immunoglobulins

Class	Heavy Chain	Light Chain	Subunit Structure	Molecular Mass (kD)
IgA	α	κ or λ	$(\alpha_2\kappa_2)_n J^a$ or $(\alpha_2\lambda_2)_n J^a$	180–720
IgD	δ	κ or λ	$\delta_2\kappa_2$ or $\delta_2\lambda_2$	160
IgE	ϵ	κ or λ	$\epsilon_2\kappa_2$ or $\epsilon_2\lambda_2$	190
IgG ^b	γ	κ or λ	$\gamma_2\kappa_2$ or $\gamma_2\lambda_2$	150
IgM	μ	κ or λ	$(\mu_2\kappa_2)_5 J$ or $(\mu_2\lambda_2)_5 J$	950

^a $n = 1, 2, 3, \text{ or } 4$.

^bIgG has four subclasses, IgG1, IgG2, IgG3, and IgG4, which differ in their γ chains.

FIG. 7-39 Diagram of human immunoglobulin G (IgG). Each light chain contains a variable (V_L) and a constant (C_L) region, and each heavy chain contains one variable (V_H) and three constant (C_{H1} , C_{H2} , and C_{H3}) regions. Each of the variable and constant domains contains a disulfide bond, and the four polypeptide chains are linked by disulfide bonds. Hypervariable loops, three in each variable domain (*fuzzy lines*), determine antigen specificity. The proteolytic enzyme papain cleaves IgG at the hinge region to yield two Fab fragments and one Fc fragment. CHO represents carbohydrate chains. [Illustration, Irving Geis. Image from Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Reproduction by permission only.]

L chain and the N-terminal half of an H chain (Fig. 7-39). These fragments contain IgG's antigen-binding sites (the "ab" in Fab stands for *antigen binding*). The Fc portion ("c" because it crystallizes easily) derives from the "stem" of the antibody and consists of the C-terminal halves of two H chains. The arms of the Y are connected to the stem by a flexible hinge region. The hinge angles may vary, so an antibody molecule may not be perfectly symmetrical (e.g., Fig. 7-38).

Although all IgG molecules have the same overall structure, IgGs that recognize different antigens have different amino acid sequences. The light chains of different antibodies differ mostly in their N-terminal halves. These polypeptides are therefore said to have a **variable region**, V_L (residues 1 to ~108), and a **constant region**, C_L (residues 109 to 214). Comparisons of H chains, which have ~446 residues, reveal that H chains also have a variable region, V_H , and a constant region, C_H . As indicated in Fig. 7-39, the C_H region consists of three ~110-residue segments, C_{H1} , C_{H2} , and C_{H3} , which are homologous to each other and to C_L . In fact, all the constant and variable regions resemble each other in sequence and in disulfide-bonding pattern. These similarities suggest that the six different homology units of an IgG evolved through the duplication of a primordial gene encoding an ~110-residue protein.

A given B cell can produce only one species of heavy chain and one species of light chain and hence only a single species of immunoglobulin. However, the immunoglobulins an animal produces upon exposure to a specific antigen are heterogeneous (**polyclonal**) because they are generated by many different B cells.

B Antibodies Recognize a Huge Variety of Antigens

The immunoglobulin homology units all have the same characteristic **immunoglobulin fold**: a sandwich composed of three- and four-stranded antiparallel β sheets that are linked by a disulfide bond (Fig. 6-29b). Nevertheless, the basic immunoglobulin structure must accommodate an enormous variety of antigens. The ability to recognize antigens resides in three loops in each variable domain (Fig. 7-40). Most of the amino acid variation among antibodies is concentrated in these three short segments, called **hypervariable** sequences. As hypothesized by Elvin Kabat, the hypervariable sequences line an immunoglobulin's antigen-binding site, so that their amino acids determine its binding specificity.

FIG. 7-40 Immunoglobulin folds in a light chain. Both the constant and variable domains consist of a sandwich of a four-stranded antiparallel β sheet (blue) and a three-stranded antiparallel β sheet (orange) that are linked by a disulfide bond (yellow). The positions of the three hypervariable sequences in the variable domain are indicated. [After Schiffer, M., Girling, R.L., Ely, K.R., and Edmundson, A.B., *Biochemistry* **12**, 4628 (1973).]

Scientists have determined the X-ray structures of Fab fragments from **monoclonal antibodies** (Box 7-5) and monospecific antibodies isolated from patients with **multiple myeloma** (a disease in which a cancerous B cell proliferates and produces massive amounts of a single immunoglobulin; the polyclonal immunoglobulins isolated from ordinary blood cannot be used for detailed structural studies). As predicted by the positions of the hypervariable sequences, the antigen-binding site is located at the tip of each Fab fragment in a crevice between its V_L and V_H domains.

The association between antibodies and their antigens involves van der Waals, hydrophobic, hydrogen bonding, and ionic interactions. Their dissociation constants range from 10^{-4} to 10^{-10} M, comparable (or even greater) in strength to the associations between enzymes and their substrates. The specificity and strength of an antigen–antibody complex are a function of the exquisite structural complementarity between the antigen and the antibody (e.g., Fig. 7-41). These are also the features that make antibodies such useful laboratory reagents (Fig. 5-3, for example).

Most immunoglobulins are divalent molecules; that is, they can bind two identical antigens simultaneously (IgM and IgA are multivalent). A foreign substance or organism usually has multiple antigenic regions, and a typical immune response generates a mixture of antibodies with different specificities. Divalent binding allows antibodies to cross-link antigens to form an extended lattice (Fig. 7-42), which hastens the removal of the antigen and triggers B cell proliferation.

Antibody Diversity Results from Gene Rearrangement and Mutation. A novel antigen does not direct a B cell to begin manufacturing a new immunoglobulin to which it can bind. Rather, *an antigen stimulates the proliferation of a preexisting B cell whose antibodies happen to recognize the antigen*. The immune system has the potential to produce an enormous number of different antibodies, probably $>10^{18}$. Even though this number is so large that an individual can synthesize only a small fraction of its potential immunoglobulin repertoire during its lifetime, this fraction is still sufficient to react with almost any antigen the individual might encounter. Yet the number of immunoglobulin genes is far too small to account for the observed level of antibody diversity. The diversity in antibody sequences arises instead from genetic changes during B lymphocyte development.

Each chain of an immunoglobulin molecule is encoded by multiple DNA segments: V, J, and C segments for the light chains, and V, D, J, and C segments

FIG. 7-42 Antigen cross-linking by antibodies. A mixture of divalent antibodies that recognizes the several different antigenic regions of an intruding particle such as a toxin molecule or a bacterium can form an extensive lattice of antigen and antibody molecules.

? Draw a similar diagram showing antigen cross-linking by IgA with the subunit structure $(\alpha_2\kappa_2)_2J$.

FIG. 7-41 Interaction between an antigen and an antibody. This X-ray structure shows a portion of the solvent-accessible surface of a monoclonal antibody Fab fragment (blue-green) with a stick model of a bound nine-residue fragment of its peptide antigen (lavender).

GATEWAY CONCEPT: Intermolecular Binding

The forces that allow one molecule to recognize and bind another are noncovalent: ionic interactions, hydrogen bonds, van der Waals interactions, and the hydrophobic effect. Such interactions can be extremely specific (one antibody recognizes only one antigen) and extremely tight (many antigen–antibody complexes exhibit K_D values in the nanomolar range).

Introducing a foreign molecule into an animal induces the synthesis of large amounts of antigen-specific but heterogeneous antibodies. One might expect that a single lymphocyte from such an animal could be cloned (allowed to reproduce) to yield a harvest of homogeneous immunoglobulin molecules. Unfortunately, lymphocytes do not grow continuously in culture. In the late 1970s, however, César Milstein and Georges Köhler developed a technique for immortalizing such cells so that they can grow continuously and secrete virtually unlimited quantities of a specific antibody. Typically, lymphocytes from a mouse that has been immunized with a particular antigen are harvested and fused with mouse myeloma cells (a type of blood system cancer), which can multiply indefinitely (see figure). The cells are then incubated in a selective medium that inhibits the synthesis of purines, which are essential for myeloma growth [the myeloma cells lack the enzyme **hypoxanthine phosphoribosyl transferase (HPRT)**, which could otherwise participate in a purine nucleotide salvage pathway; Section 23-1D]. The only cells that can grow in the selective medium are fused cells, known as **hybridoma** cells, that combine the missing HPRT (it is supplied by the lymphocyte) with the immortal attributes of the myeloma cells. Clones derived from single fused cells are then screened for the presence of antibodies to the original antigen. Antibody-producing cells can be grown in large quantities in tissue culture or as semisolid tumors in mouse hosts.

Monoclonal antibodies are used to purify macromolecules (Section 5-2), to identify infectious diseases, and to test for the presence of drugs and other substances in body tissues. Because of their purity and specificity and, to some extent, their biocompatibility, monoclonal antibodies also hold considerable promise as therapeutic agents against cancer and other diseases. For example, the monoclonal antibody known as **Herceptin** binds specifically to the growth factor receptor **HER2** that is overexpressed in about one-quarter of breast cancers. Herceptin binding to HER2 blocks its growth-signaling activity, thereby causing the tumor to stop growing or even regress. **Antibody–drug conjugates**, in which an antitumor antibody is coupled to a cytotoxic agent via a cleavable linker, are beginning to achieve some success as selective antitumor agents.

Other monoclonal antibodies have been developed to bind to and interfere with components of the inflammatory response in order to treat the symptoms of diseases such as rheumatoid arthritis. In many cases, these “biologic” drugs have been genetically engineered to make them less mouselike and more humanlike and therefore less likely to be recognized and rejected as foreign by the patient’s own immune system.

for heavy chains. These segments are joined together by **somatic recombination** during B cell development before being transcribed and translated into protein. The process is called somatic (Greek: *soma*, body) to distinguish it from the recombination that occurs in reproductive cells. Because there are multiple versions of the V, D, J, and C segments in the genome, the combinatorial possibilities are enormous. In addition, the recombination process sometimes adds or deletes nucleotides at the junctions between gene segments, further contributing to the diversity of the encoded protein. The generation of antibody diversity is further discussed in Section 28-3D.

Additional changes can occur after a B cell has encountered its antigen and begun secreting antibody molecules. As the antibody-producing B cells divide, their rate of immunoglobulin gene mutation increases dramatically, favoring the substitution of one nucleotide for another and leading to an average of one amino

TABLE 7-3 Some Antibody-Mediated Autoimmune Diseases

Disease	Target Tissue	Major Symptoms
Addison's disease	Adrenal cortex	Low blood glucose, muscle weakness, Na ⁺ loss, K ⁺ retention, increased susceptibility to stress
Graves' disease	Thyroid gland	Oversecretion of thyroid hormone resulting in increased appetite accompanied by weight loss
Insulin-dependent (type 1) diabetes mellitus	Pancreatic β cells	Loss of ability to make insulin
Myasthenia gravis	Acetylcholine receptors at nerve–muscle synapses	Progressive muscle weakness
Rheumatoid arthritis	Connective tissue	Inflammation and degeneration of the joints
Systemic lupus erythematosus	DNA, phospholipids, other tissue components	Rash, joint and muscle pain, anemia, kidney damage, mental dysfunction

acid change for every cell generation. This process, which is called **somatic hypermutation**, permits the antigen specificity of the antibody to be fine-tuned over many cell generations, because the rate of B cell proliferation increases with the antigen-binding affinity of the antibody it produces.

 **The Immune System Loses Its Tolerance in Autoimmune Diseases.** Another remarkable property of the immune system is that its power is unleashed only against foreign substances and not against any of the tens of thousands of endogenous (self) molecules of various sorts. Virtually all macromolecules are potentially antigenic, as can be demonstrated by transplanting tissues from one individual to another, even within a species. This incompatibility presents obvious challenges for therapies ranging from routine blood transfusions to organ transplants.

The mechanism whereby an individual's immune system distinguishes self from non-self is not completely understood but includes the elimination of self-reactive B and T cells before they are fully mature. Self-tolerance begins to develop around the time of birth and must be ongoing, since new lymphocytes arise throughout an individual's lifetime. Occasionally, the immune system loses tolerance to some of its self-antigens, resulting in an **autoimmune disease**.

All the body's organ systems are theoretically susceptible to attack by an immune system that has lost its self-tolerance, but some tissues are attacked more often than others. Some of the most common antibody-mediated autoimmune diseases are listed in **Table 7-3** (other autoimmune diseases result mainly from inappropriate T cell activation). The symptoms of a particular disease reflect the type of tissue with which the autoantibodies react or, in the case of systemic diseases, the accumulation of antigen–antibody complexes in multiple locations. In general, autoimmune diseases are chronic, often with periods of remission, and their clinical severity may differ among individuals.

The loss of tolerance to one's own antigens may result from an innate malfunctioning of the mechanism by which the immune system distinguishes self from non-self, possibly precipitated by an event, such as trauma or infection, in which tissues that are normally sequestered from the immune system are exposed to lymphocytes. For example, breaching the blood–brain barrier may allow lymphocytes access to the brain or spinal cord, and injury may allow access to the spaces at joints, which are not normally served by blood vessels. There is also evidence that some autoimmune diseases are caused by antibodies to certain viral or bacterial antigens that cross-react with endogenous substances because of chance antigenic similarities. Some diseases, such as systemic lupus erythematosus, represent a more generalized breakdown of the immune system, so that antibodies to many endogenous substances (e.g., DNA and phospholipids) may be generated.

CHECKPOINT

- Without looking at Fig. 7-39, draw a diagram of an IgG molecule and identify the heavy and light chains, the constant and variable domains, and the antigen-binding site(s).
- Explain how a single human can potentially generate trillions of different antibody molecules.
- What are some factors that might contribute to the development of an autoimmune disease?
- Why do the symptoms of an autoimmune disease often differ between individuals?

Summary

1 Oxygen Binding to Myoglobin and Hemoglobin

- Myoglobin, a monomeric heme-containing muscle protein, reversibly binds a single O_2 molecule.
- Hemoglobin, a tetramer with pseudo- D_2 symmetry, has distinctly different conformations in its oxy and deoxy states.
- Oxygen binds to hemoglobin in a sigmoidal fashion, indicating cooperative binding.
- O_2 binding to a heme group induces a conformational change in the entire hemoglobin molecule that includes movements at the subunit interfaces and the disruption of ion pairs. The result is a shift from the T to the R state.
- CO_2 promotes O_2 dissociation from hemoglobin through the Bohr effect. BPG decreases hemoglobin's O_2 affinity by binding to deoxyhemoglobin.
- The symmetry and sequential models of allosterism explain how binding of a ligand at one site affects binding of another ligand at a different site.
- Hemoglobin variants have revealed structure–function relationships. Hemoglobin S produces the symptoms of sickle-cell anemia by forming rigid fibers in its deoxy form.

2 Muscle Contraction

- The thick filaments of a sarcomere are composed of the motor protein myosin and the thin filaments are composed mainly of actin.
- The heads of myosin molecules in thick filaments form bridges to actin in thin filaments such that the detachment and reattachment of the myosin heads cause the thick and thin filaments to slide past each other during muscle contraction. The contractile force derives from conformational changes in myosin that are triggered by ATP hydrolysis.
- In nonmuscle cells, actin forms microfilaments, which are components of the cytoskeleton. Microfilaments are dynamic structures whose growth and regression are responsible for certain types of cell movement.

3 Antibodies

- The immune system responds to foreign macromolecules through the production of antibodies (immunoglobulins).
- The Y-shaped IgG molecule consists of two heavy and two light chains. The two antigen-binding sites are formed by the hypervariable sequences in the variable domains at the ends of a heavy and a light chain.
- Antibody diversity results from somatic recombination during B cell development and from somatic hypermutation.

Problems

EXERCISES

1. Estimate K from the following data describing ligand binding to a protein.

[Ligand] (mM)	Y
0.25	0.30
0.5	0.45
0.8	0.56
1.4	0.66
2.2	0.80
3.0	0.83
4.5	0.86
6.0	0.93

2. Which set of binding data is likely to represent cooperative ligand binding to an oligomeric protein?

(a) [Ligand] (mM)	Y	(b) [Ligand] (mM)	Y
0.1	0.3	0.2	0.1
0.2	0.5	0.3	0.3
0.4	0.7	0.4	0.6
0.7	0.9	0.6	0.8

3. Use Eq. 7-8 to estimate the fractional saturation of hemoglobin when pO_2 is (a) 20 torr, (b) 40 torr, and (c) 60 torr.
 4. Calculate the p_{50} value for hemoglobin if $Y_{O_2} = 0.82$ when $pO_2 = 25$ torr.

5. Drinking a few drops of a commercial preparation called “vitamin O,” which consists of oxygen and sodium chloride dissolved in water, is claimed to increase the concentration of oxygen in the body. (a) Use your knowledge of oxygen transport to evaluate this claim. (b) Would vitamin O be more or less effective if it were infused directly into the bloodstream?
6. Explain why long-distance runners prefer to train at high altitude even when the race is to be held at sea level. Why must the runners spend more than a day or two at the higher elevation?
7. Is the p_{50} higher or lower than normal in (a) hemoglobin Yakima and (b) hemoglobin Kansas? Explain.
8. In hemoglobin Rainier, Tyr 145 β is replaced by Cys, which forms a disulfide bond with another Cys residue in the same subunit. This prevents the formation of ion pairs that normally stabilize the T state. How does hemoglobin Rainier differ from normal hemoglobin with respect to (a) oxygen affinity, (b) the Bohr effect, and (c) the Hill constant?
9. Hemoglobin S homozygotes who are severely anemic often have elevated levels of BPG in their erythrocytes. Is this a beneficial effect?
10. In the variant hemoglobin C, glutamate at position 6 of the β chain has been replaced with lysine. (a) Would you expect this mutant hemoglobin to polymerize as hemoglobin S does? (b) Red blood cells containing hemoglobin C have a shorter lifespan than red blood cells containing normal hemoglobin. How might this affect a person’s resistance to malaria?
11. Is myosin a fibrous protein or a globular protein? Explain.
12. In striated muscle, cells undergo mitosis (nuclear division) without cytokinesis (cellular division), giving rise to large multinucleate cells. Explain why muscle cells would be less effective if cytokinesis occurred with every round of mitosis.
13. A myosin head can undergo five ATP hydrolysis cycles per second, each of which moves an actin monomer by ~ 100 Å. How is it possible for an entire sarcomere to shorten by 1000 Å in this same period?
14. **Rigor mortis**, the stiffening of muscles after death, is caused by depletion of cellular ATP. Describe the molecular basis of rigor.
15. The force generated by a muscle fiber increases as the sarcomere shortens but decreases at very short sarcomere lengths. Explain this observation. (*Hint*: Recall that cell volume remains constant during muscle contraction.)

16. Antibodies are well suited for recognizing extracellular substances from invading bacteria and viruses. However, the immune system must also be able to respond to intracellular infections. Explain why the immune system includes binding proteins that recognize F-actin.
17. Give the approximate molecular masses of an immunoglobulin G molecule analyzed by (a) gel filtration chromatography, (b) SDS-PAGE, and (c) SDS-PAGE in the presence of 2-mercaptoethanol.
18. Many fish produce a tetrameric IgM. If each H chain has a mass of 70 kD, each light chain has a mass of 25 kD, and each J chain has a mass of 15 kD, what is the approximate mass of the IgM molecule?
19. Explain why the variation in V_L and V_H domains of immunoglobulins is largely confined to the hypervariable loops.
20. How many hypervariable loops are present in (a) IgG and (b) IgM?

CHALLENGE QUESTIONS

21. In active muscles, the pO_2 may be 10 torr at the cell surface and 1 torr at the mitochondria (the organelles where oxidative metabolism occurs). Use Eq. 7-6 to show how myoglobin ($p_{50} = 2.8$ torr) facilitates the diffusion of O_2 through these cells.
22. If myoglobin had the same p_{50} value as hemoglobin, how well would it facilitate O_2 diffusion under the conditions described in Problem 21?
23. Some primitive animals have a hemoglobin that consists of two identical subunits. Sketch an oxygen-binding curve for this protein.
24. What is the likely range of the Hill constant for the hemoglobin described in Problem 23?
25. In humans, the urge to breathe results from high concentrations of CO_2 in the blood; there are no direct physiological sensors of blood pO_2 . Skindivers often hyperventilate (breathe rapidly and deeply for several minutes) just before making a dive in the belief that this will increase the O_2 content of their blood. (a) Does it do so? (b) Use your knowledge of hemoglobin function to evaluate whether this practice is useful.
26. The crocodile, which can remain under water without breathing for up to 1 h, drowns its air-breathing prey and then dines at its leisure. An adaptation that aids the crocodile in doing so is that it can utilize virtually 100% of the O_2 in its blood, whereas humans, for example, can extract only $\sim 65\%$ of the O_2 in their blood. Crocodile Hb does not bind BPG. However, crocodile deoxyHb preferentially binds HCO_3^- . How does this help the crocodile obtain its dinner?
27. An anemic individual, whose blood has only half the normal Hb content, may appear to be in good health. Yet a normal individual is incapacitated by exposure to sufficient carbon monoxide to occupy half of his/her heme sites (pCO of 1 torr for ~ 1 h; CO binds to Hb with 200-fold greater affinity than does O_2). Explain.
28. When you hold a weight at arm’s length, you are not doing any thermodynamic work but the muscles supporting the weight are nevertheless consuming energy. Describe, on the molecular level, how muscles might maintain such state of constant tension without contracting. Why does this state consume ATP?
29. Explain why a microfilament is polar, whereas a filament of keratin is not.
30. Cells contain an assortment of proteins that promote microfilament disassembly during cell shape changes. How can such proteins distinguish newly synthesized microfilaments from older microfilaments?
31. Why do antibodies raised against a native protein sometimes fail to bind to the corresponding denatured protein?
32. Antibodies raised against a macromolecular antigen usually produce an antigen–antibody precipitate when mixed with that antigen. Explain why no precipitate forms when (a) Fab fragments from those antibodies are mixed with the antigen; (b) antibodies raised against a small antigen are mixed with that small antigen; and (c) the antibody is in great excess over the antigen and vice versa.
33. Some bacteria produce proteases that can cleave the hinge region of IgA molecules without affecting antigen binding. Explain why these proteases would give the bacteria a better chance of starting an infection.
34. Individuals with the autoimmune disease systemic lupus erythematosus (SLE) produce antibodies to DNA and phospholipids. (a) Explain why normal individuals do not make antibodies to these substances. (b) During a normal response to a viral or bacterial infection, the immune system produces large amounts of antigen-specific antibodies, and the resulting antigen–antibody complexes are subsequently removed from the circulation and degraded. Explain why antigen–antibody complexes accumulate in the tissues of individuals with SLE.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Structural Homology of Globins

Exercise 2 Deoxyhemoglobin and Oxyhemoglobin

Exercise 3 Antibody–Antigen Complexes

Case 8 Hemoglobin, the Oxygen Carrier

Focus concept: A mutation in the gene for hemoglobin results in an altered protein responsible for the disease sickle-cell anemia. An understanding of the biochemistry of the disease may suggest possible treatments.

Prerequisite: Chapter 7

- Hemoglobin structure and function

Case 9 Allosteric Interactions in Crocodile Hemoglobin

Focus concept: The effect of allosteric modulators on oxygen affinity for crocodile hemoglobin differs from that of other species.

Prerequisite: Chapter 7

- Hemoglobin structure and function

Case 10 The Biological Roles of Nitric Oxide

Focus concept: Nitric oxide, a small lipophilic molecule, acts as a second messenger in blood vessels.

Prerequisite: Chapter 7

- Hemoglobin structure and function

MORE TO EXPLORE (a) Look up information about hemoglobin variants. Why don't they generate the same symptoms? How do the symptoms of thalassemias differ? Which hemoglobin variants appear to offer a selective advantage under certain conditions? (b) In addition to myosin, which interacts with actin filaments, cells contain several other motor protein systems. Describe the structure and activity of the motor proteins kinesin and dynein. Against what fibrous proteins do they exert force? How do these systems differ from the actin–myosin system? (c) Explain how immunological memory is exploited in the development of vaccines for viral and bacterial infections. What factors make a vaccine most effective in preventing disease?

Sharon Dominick/Stockphoto

Approximately half the dry mass of corn (maize) kernels is starch, a polysaccharide that is broken down to glucose during digestion. Starch, along with the indigestible polysaccharide cellulose, is also the starting material for production of the biofuel ethanol.

Carbohydrates or **saccharides** (Greek: *sakcharon*, sugar) are the most abundant biological molecules. They are chemically simpler than nucleotides or amino acids, containing just three elements—carbon, hydrogen, and oxygen—combined according to the formula $(C \cdot H_2O)_n$, where $n \geq 3$. The basic carbohydrate units are called **monosaccharides**. There are numerous different types of monosaccharides, which, as we discuss below, differ in their number of carbon atoms and in the arrangement of the H and O atoms attached to the carbons. Furthermore, monosaccharides can be strung together in almost limitless ways to form **polysaccharides**.

Until the 1960s, carbohydrates were thought to have only passive roles as energy sources (e.g., glucose and starch) and as structural materials (e.g., cellulose). Carbohydrates, as we will see, do not catalyze complex chemical reactions as do proteins, nor do carbohydrates replicate themselves as do nucleic acids. And because polysaccharides are not built according to a genetic “blueprint,” as are nucleic acids and proteins, they tend to be much more heterogeneous—both in size and in composition—than other biological molecules.

However, it has become clear that the innate structural variation in carbohydrates is fundamental to their biological activity. The apparently haphazard arrangements of carbohydrates on proteins and on the surfaces of cells are the key to many recognition events between proteins and between cells. An understanding of carbohydrate structure, from the simplest monosaccharides to the most complex branched polysaccharides, is essential for appreciating the varied functions of carbohydrates in biological systems.

1 Monosaccharides

KEY CONCEPTS

- The smallest sugars are aldoses or ketoses, with the formula $(C \cdot H_2O)_n$.
- Monosaccharides cyclize to form α or β anomers.
- The derivatives of monosaccharides include the aldonic acids, uronic acids, alditols, deoxy sugars, and amino sugars.
- Monosaccharides can be linked to each other or to other molecules by glycosidic bonds.

A Monosaccharides Are Aldoses or Ketoses

Monosaccharides are aldehyde or ketone derivatives of straight-chain polyhydroxy alcohols containing at least three carbon atoms. They are classified according to the chemical nature of their carbonyl group and the number of their C atoms. If the carbonyl group is an aldehyde, the sugar is an **aldose**. If the carbonyl group

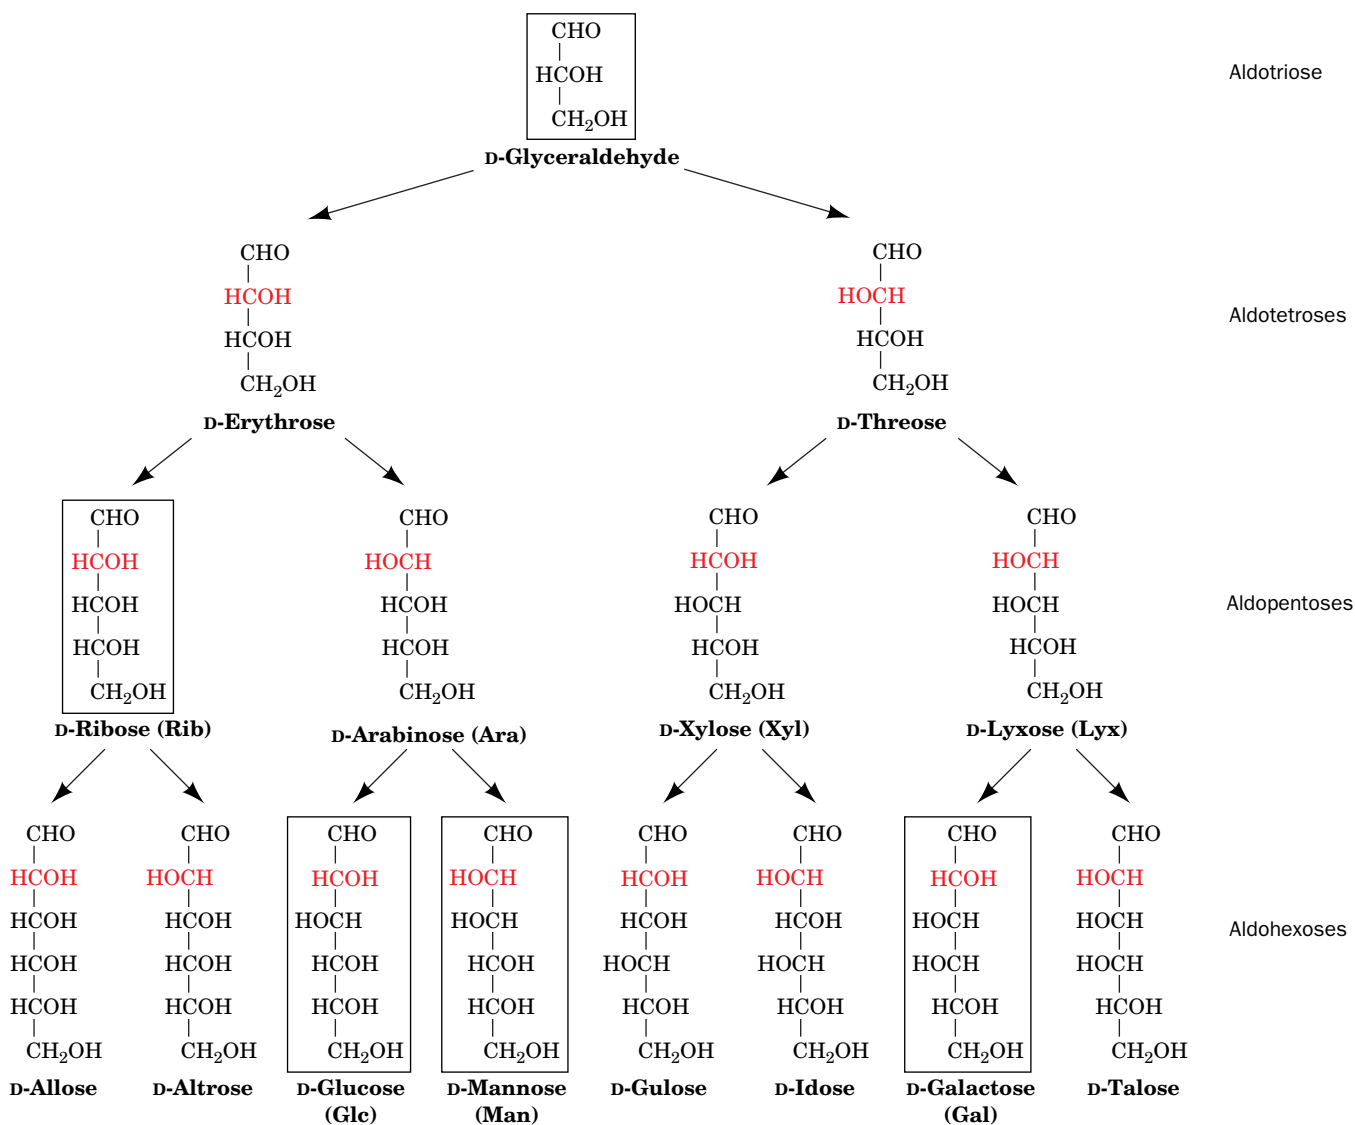

FIG. 8-1 The D-aldoses with three to six carbon atoms. The arrows indicate stereochemical relationships (not biosynthetic pathways). The configuration around C2 (red) distinguishes the members of each pair

of monosaccharides. The L counterparts of these 15 sugars are their mirror images. The biologically most common aldoses are boxed.

is a ketone, the sugar is a **ketose**. The smallest monosaccharides, those with three carbon atoms, are **trioses**. Those with four, five, six, seven, etc. C atoms are, respectively, **tetroses**, **pentoses**, **hexoses**, **heptoses**, etc.

The aldohexose **D-glucose** has the formula $(C \cdot H_2O)_6$:

All but two of its six C atoms, C1 and C6, are chiral centers, so D-glucose is one of $2^4 = 16$ possible stereoisomers. The stereochemistry and nomenclature of the D-aldoses are presented in Fig. 8-1. The assignment of D or L is made according to the Fischer convention (Section 4-2): *D sugars have the same absolute configuration at the asymmetric center farthest from their carbonyl group as does D-glyceraldehyde* (i.e., the —OH at C5 of D-glucose is on the right in a Fischer projection). The L sugars are the mirror images of their D counterparts. Because L sugars are biologically much less abundant than D sugars, the D prefix is often omitted.

Sugars that differ only by the configuration around one C atom are known as **epimers** of one another. Thus, D-glucose and **D-mannose** are epimers with respect to C2. The most common aldoses include the six-carbon sugars glucose, mannose, and **galactose**. The pentose **ribose** is a component of the ribonucleotide residues of RNA. The triose **glyceraldehyde** occurs in several metabolic pathways.

The most common ketoses are those with their ketone function at C2 (Fig. 8-2). The position of their carbonyl group gives ketoses one less asymmetric center than their isomeric aldoses, so a ketohexose has only $2^3 = 8$ possible stereoisomers (4 D sugars and 4 L sugars). The most common ketoses are **dihydroxyacetone**, **ribulose**, and **fructose**, which we will encounter in our studies of metabolism.

FIG. 8-2 The D-ketoses with three to six carbon atoms. The configuration around C3 (red) distinguishes the members of each pair. The biologically most common ketoses are boxed.

? What is the number of L-ketoses?

B Monosaccharides Vary in Configuration and Conformation

Alcohols react with the carbonyl groups of aldehydes and ketones to form **hemiacetals** and **hemiketals**, respectively:

FIG. 8-3 Cyclization of glucose and fructose. (a) The linear form of D-glucose yielding the cyclic hemiacetal β -D-glucopyranose. (b) The linear form of D-fructose yielding the cyclic hemiketal β -D-fructofuranose. The cyclic sugars are shown as both Haworth projections and in stick form embedded in their semitransparent space-filling models with C green, H white, and O red.

? In a Haworth projection, which hydroxyl groups correspond to the hydroxyl groups on the left in a Fischer projection?

The hydroxyl and either the aldehyde or the ketone functions of monosaccharides can likewise react intramolecularly to form cyclic hemiacetals and hemiketals (Fig. 8-3). The configurations of the substituents of each carbon atom in these sugar rings are conveniently represented by their **Haworth projections**, in which the heavier ring bonds project in front of the plane of the paper and the lighter ring bonds project behind it.

A sugar with a six-membered ring is known as a **pyranose** in analogy with **pyran** (at left), the simplest compound containing such a ring. Similarly, sugars with five-membered rings are designated **furanoses** in analogy with **furan** (at left). The cyclic forms of glucose and fructose with six- and five-membered rings are therefore known as **glucopyranose** and **fructofuranose**, respectively.

Cyclic Sugars Have Two Anomeric Forms. When a monosaccharide cyclizes, the carbonyl carbon, called the **anomeric carbon**, becomes a chiral center with two possible configurations. The pair of stereoisomers that differ in configuration at the anomeric carbon are called **anomers**. In the **α anomer**, the OH substituent of the anomeric carbon is on the opposite side of the sugar ring from the CH_2OH group at the chiral center that designates the D or L configuration (C5 in hexoses). The other form is known as the **β anomer** (Fig. 8-4).

The two anomers of D-glucose have slightly different physical and chemical properties, including different optical rotations (Section 4-2). *The anomers freely interconvert in aqueous solution*, a process called **mutarotation**, so at equilibrium, D-glucose is a mixture of the β anomer (63.6%) and the α anomer (36.4%). The linear form is normally present in only minute amounts.

Sugars Can Adopt Different Conformations. A given hexose or pentose can assume pyranose or furanose forms. In principle, hexoses and larger sugars can

FIG. 8-4 α and β anomers. The monosaccharides α -D-glucopyranose and β -D-glucopyranose, drawn as Haworth projections and ball-and-stick models, interconvert through the linear form. They differ only by their configuration about the anomeric carbon, C1.

form rings of seven or more atoms, but such rings are rarely observed because of the greater stabilities of the five- and six-membered rings. The internal strain of three- and four-membered rings makes them less stable than the linear forms.

The use of Haworth formulas may lead to the erroneous impression that furanose and pyranose rings are planar. This cannot be the case, however, because all the atomic orbitals in the ring atoms are tetrahedrally (sp^3) hybridized. The pyranose ring, like the cyclohexane ring, can assume a chair conformation, in which the substituents of each atom are arranged tetrahedrally. Of the two possible chair conformations, the one that predominates is the one in which the bulkiest ring substituents occupy **equatorial** positions rather than the more crowded **axial** positions (Fig. 8-5). Only β -D-glucose can simultaneously have all five of its non-H substituents in equatorial positions. Perhaps this is why glucose is the most abundant monosaccharide in nature.

Furanose rings can also adopt different conformations, whose stabilities depend on the arrangements of bulky substituents. Note that a monosaccharide can readily shift its *conformation*, because no bonds are broken in the process. The shift in *configuration* between the α and β anomeric forms or between the pyranose and furanose forms, which requires breaking and re-forming bonds, occurs slowly in aqueous solution. Other changes in configuration, such as **epimerization**, do not occur under physiological conditions without the appropriate enzyme.

C Sugars Can Be Modified and Covalently Linked

Because the cyclic and linear forms of aldoses and ketoses do interconvert, these sugars undergo reactions typical of aldehydes and ketones.

1. Oxidation of an aldose converts its aldehyde group to a carboxylic acid group, thereby yielding an **aldonic acid** such as **gluconic acid** (at right). Aldonic acids are named by appending the suffix *-onic acid* to the root name of the parent aldose.

FIG. 8-5 The two chair conformations of β -D-glucopyranose. In the conformation on the left, which predominates, the relatively bulky OH and CH_2OH substituents all occupy equatorial positions, where they extend alternately above and below the ring. In the conformation on the right (drawn in ball-and-stick form in Fig. 8-4, right), the bulky groups occupy the more crowded axial (vertical) positions.

D-Glucuronic acid

- Oxidation of the primary alcohol group of aldoses yields **uronic acids**, which are named by appending *-uronic acid* to the root name of the parent aldose, for example, **D-glucuronic acid** (at left). Uronic acids can assume the pyranose, furanose, and linear forms.
- Aldoses and ketoses can be reduced under mild conditions—for example, by treatment with NaBH_4 —to yield polyhydroxy alcohols known as **alditols**, which are named by appending the suffix *-itol* to the root name of the parent aldose. **Ribitol** is a component of flavin coenzymes (Fig. 14-13), and **glycerol** and the cyclic polyhydroxy alcohol **myo-inositol** are important lipid components (Section 9-1). **Xylitol** is a sweetener that is used in “sugarless” gum and candies:

Ribitol

Xylitol

Glycerol

myo-Inositol

- Monosaccharide units in which an OH group is replaced by H are known as **deoxy sugars**. The biologically most important of these is **β -D-2-deoxyribose**, the sugar component of DNA's sugar-phosphate backbone (Section 3-2B). **L-Fucose** is one of the few L sugar components of polysaccharides.

α -D-Glucosamine
(2-amino-2-deoxy- α -D-glucopyranose)

α -D-Galactosamine
(2-amino-2-deoxy- α -D-galactopyranose)

 β -D-2-Deoxyribose α -L-Fucose

- In **amino sugars**, one or more OH groups have been replaced by an amino group, which is often acetylated. **D-Glucosamine** and **D-galactosamine** (at left) are the most common. **N-Acetylneuraminic acid**, which is derived from **N-acetylmannosamine** and **pyruvic acid** (Fig. 8-6), is an

FIG. 8-6 N-Acetylneuraminic acid. In the cyclic form of this nine-carbon monosaccharide, the pyranose ring incorporates the pyruvic acid residue (blue) and part of the mannose moiety.

? How many different types of functional groups and linkages occur in this molecule?

FIG. 8-7 Formation of glycosides. The acid-catalyzed condensation of $\alpha\text{-D-glucose}$ with methanol yields an anomeric pair of **methyl-D-glucosides**.

important constituent of **glycoproteins** and **glycolipids** (proteins and lipids with covalently attached carbohydrate). *N*-Acetylneuraminic acid and its derivatives are often referred to as **sialic acids**.

Glycosidic Bonds Link the Anomeric Carbon to Other Compounds. The anomeric group of a sugar can condense with an alcohol to form α - and β -**glycosides** (Greek: *glykys*, sweet; **Fig. 8-7**). The bond connecting the anomeric carbon to the alcohol oxygen is termed a **glycosidic bond**. *N*-Glycosidic bonds, which form between the anomeric carbon and an amine, are the bonds that link *D*-ribose to purines and pyrimidines in nucleic acids:

Like peptide bonds, glycosidic bonds hydrolyze extremely slowly under physiological conditions in the absence of appropriate hydrolytic enzymes. Consequently, an anomeric carbon that is involved in a glycosidic bond cannot freely convert between its α and β anomeric forms. Saccharides bearing anomeric carbons that have not formed glycosides are termed **reducing sugars**, because the free aldehyde group that is in equilibrium with the cyclic form of the sugar reduces mild oxidizing agents (such as Cu^{2+} , which is reduced to Cu^+). The identification of a sugar as **nonreducing** is evidence that it is a glycoside.

CHECKPOINT

- How does an aldose differ from a ketose?
- Draw a Fischer projection of *D*-glucose. Draw two stereoisomers of this molecule, including one that is an epimer.
- Show how aldoses and ketoses can form five- and six-membered rings.
- Draw a Haworth projection of *D*-glucose and identify it as an α or β anomer.
- Explain why anomers of a monosaccharide can readily interconvert, whereas epimers do not.
- Describe aldonic acids, uronic acids, alditols, deoxy sugars, and amino sugars.
- Explain why a sugar can form at least two different glycosides.

2 Polysaccharides

KEY CONCEPTS

- Disaccharides such as lactose and sucrose consist of two sugars linked by specific glycosidic bonds.
- Cellulose and chitin are polymers of $\beta(1\rightarrow4)$ -linked glucose residues.
- In starch and glycogen, glucose residues are linked mainly by $\alpha(1\rightarrow4)$ bonds.
- Glycosaminoglycans and other large heteropolysaccharides typically have a gel-like structure.

*Polysaccharides, which are also known as **glycans**, consist of monosaccharides linked together by glycosidic bonds. They are classified as **homopolysaccharides** or **heteropolysaccharides** if they consist of one type or more than one type of monosaccharide. Although the monosaccharide sequences of heteropolysaccharides can, in principle, be even more varied than those of proteins, many are composed of only a few types of monosaccharides that alternate in a repetitive sequence.*

Polysaccharides, in contrast to proteins and nucleic acids, form branched as well as linear polymers. This is because glycosidic linkages can be made to any of the hydroxyl groups of a monosaccharide. Fortunately for structural biochemists, most polysaccharides are linear and those that branch do so in only a few well-defined ways.

A complete description of an **oligosaccharide** or polysaccharide includes the identities, anomeric forms, and linkages of all its component monosaccharide units. Some of this information can be gathered through the use of specific **exoglycosidases** and **endoglycosidases**, enzymes that hydrolyze monosaccharide units in much the same way that exopeptidases and endopeptidases cleave amino acid residues from polypeptides (Section 5-3B). NMR measurements are also invaluable in determining both sequences and conformations of polysaccharides.

A Lactose and Sucrose Are Disaccharides

Oligosaccharides containing three or more residues are relatively rare, occurring almost entirely in plants. **Disaccharides**, the simplest polysaccharides, are more common. Many occur as the hydrolysis products of larger molecules. However, two disaccharides are notable in their own right. **Lactose** (at left; here the curved lines represent normal C—O covalent bonds), for example, occurs naturally only in milk, where its concentration ranges from 0 to 7% depending on the species (Box 8-1). The systematic name for lactose, *O*- β -D-galactopyranosyl-(1 \rightarrow 4)-D-glucopyranose, specifies its monosaccharides, their ring types, and how they are linked together. The symbol (1 \rightarrow 4) combined with the β in the prefix indicates that the glycosidic bond links C1 of the β anomer of galactose to O4 of glucose. Note that lactose has a free anomeric carbon on its glucose residue and is therefore a reducing sugar.

Box 8-1 Biochemistry in Health and Disease

Lactose Intolerance

In infants, lactose (also known as milk sugar) is hydrolyzed by the intestinal enzyme (**β -D-galactosidase** or **lactase**) to its component monosaccharides for absorption into the bloodstream. The galactose is enzymatically converted (epimerized) to glucose, which is the primary metabolic fuel of many tissues.

Since mammals are unlikely to encounter lactose after they have been weaned, most adult mammals have low levels of β -galactosidase. Consequently, much of the lactose they might ingest moves through their digestive tract to the colon, where bacterial fermentation generates large quantities of CO_2 , H_2 , and irritating organic acids. These products

cause the embarrassing and often painful digestive upset known as **lactose intolerance**.

Lactose intolerance, which was once considered a metabolic disturbance, is actually the norm in adult humans, particularly those of African and Asian descent. Interestingly, however, β -galactosidase levels decrease only mildly with age in descendants of populations that have historically relied on dairy products for nutrition throughout life. Modern food technology has come to the aid of milk lovers who develop lactose intolerance: Milk in which the lactose has been hydrolyzed enzymatically is widely available.

The most abundant disaccharide is **sucrose** (*at right*), the major form in which carbohydrates are transported in plants. Sucrose is familiar to us as common table sugar. The systematic name for sucrose, *O*- α -D-glucopyranosyl-(1 \rightarrow 2)- β -D-fructofuranoside, indicates that the anomeric carbon of each sugar (C1 in glucose and C2 in fructose) participates in the glycosidic bond, and hence sucrose is not a reducing sugar. Noncarbohydrate molecules that mimic the taste of sucrose are used as sweetening agents in foods and beverages (Box 8-2).

Box 8-2 Perspectives in Biochemistry Artificial Sweeteners

Artificial sweeteners are added to processed foods and beverages to impart a sweet taste without adding calories. This is possible because the compounds mimic sucrose in its interactions with taste receptors but either are not metabolized or contribute very little to energy metabolism because they are used at such low concentrations.

Naturally occurring saccharides, such as fructose, are slightly sweeter than sucrose. Honey, which contains primarily fructose, glucose, and maltose (a glucose disaccharide), is about 1.5 times as sweet as sucrose. How is sweetness measured? There is no substitute for the human sense of taste, so a panel of individuals samples solutions of a compound and compares them to a reference solution containing sucrose. The very sweet compounds listed below must be diluted significantly before testing in this manner.

Compound	Sweetness Relative to Sucrose
Acesulfame	200
Alitame	2000
Aspartame	180
Saccharin	350
Sucralose	600

One of the oldest artificial sweeteners is saccharin, discovered in 1879 and commonly consumed as Sweet'N Low[®]. In the 1970s, extremely high doses of saccharin were found to cause cancer in laboratory rats. Such doses are now considered to be so far outside of the range used for sweetening as to be of insignificant concern to users.

Aspartame, the active ingredient in NutraSweet[®] and Equal[®], was approved for human use in 1981 and is currently the market leader:

Aspartylphenylalanine methyl ester (aspartame)

Saccharin

Unlike saccharin, which is not metabolized by the human body, aspartame is broken down into its components: aspartate (*green*), phenylalanine (*red*), and methanol (*blue*). The Asp and Phe, like all amino acids, can be metabolized, so aspartame is not calorie-free. Methanol in large amounts is toxic; however, the amount derived from an aspartame-sweetened drink is comparable to the amount naturally present in the same volume of fruit juice. Individuals with the genetic disease **phenylketonuria**, who are unable to metabolize phenylalanine, are advised to avoid ingesting excess Phe in the form of aspartame (or any other polypeptide). The greatest drawback of aspartame may be its instability to heat, which makes it unsuitable for baking. In addition, aspartame in soft drinks hydrolyzes over a period of months and hence loses its flavor.

Acesulfame is sometimes used in combination with aspartame, since the two compounds act synergistically (i.e., their sweetness when combined is greater than the sum of their individual sweetnesses).

Acesulfame

Other artificial sweeteners are derivatives of sugars, such as sucralose (Splenda[®]; see Problem 8-26), or of aspartame (e.g., alitame). Some plant extracts (e.g., *Stevia*) are also used as artificial sweeteners.

The market for artificial sweeteners is worth several billion dollars annually. But surprisingly, the most successful sweetening agents have not been the result of dedicated research efforts. Instead, they were discovered by chance or mishap. For example, aspartame was discovered in 1965 by a synthetic chemist who unknowingly got a small amount of the compound on his fingers and happened to lick them. Sucralose came to light in 1975 when a student was asked to "test" a compound and misunderstood the directions as "taste" the compound.

Biophoto Associates/Photo Researchers

FIG. 8-8 Electron micrograph of cellulose fibers. The cellulose fibers in this sample of cell wall from the alga *Chaetomorpha* are arranged in layers.

B Cellulose and Chitin Are Structural Polysaccharides

Plants have rigid cell walls that can withstand osmotic pressure differences between the extracellular and intracellular spaces of up to 20 atm. In large plants, such as trees, the cell walls also have a load-bearing function. **Cellulose**, the primary structural component of plant cell walls (Fig. 8-8), accounts for over half of the carbon in the biosphere: Approximately 10^{15} kg of cellulose is estimated to be synthesized and degraded annually.

Cellulose is a linear polymer of up to 15,000 D-glucose residues linked by $\beta(1 \rightarrow 4)$ glycosidic bonds:

Cellulose

X-Ray and other studies of cellulose fibers reveal that cellulose chains are flat ribbons in which successive glucose rings are turned over 180° with respect to each other. This permits the C3—OH group of each glucose residue to form a hydrogen bond with the ring oxygen (O5) of the next residue. Parallel cellulose chains form sheets with interchain hydrogen bonds, including O2—H \cdots O6 and O6—H \cdots O3 bonds (Fig. 8-9). Stacks of these sheets are held together by hydrogen bonds and van der Waals interactions. This highly cohesive structure gives cellulose fibers exceptional strength and makes them water insoluble despite their hydrophilicity. In plant cell walls, the cellulose fibers are embedded in and cross-linked by a matrix containing other polysaccharides and **lignin**, a plasticlike phenolic polymer. The resulting composite material can withstand large stresses because the matrix evenly distributes the stresses among the cellulose reinforcing elements. The difficulty of removing these other substances,

FIG. 8-9 Model of cellulose. Cellulose fibers consist of ~ 40 parallel, extended glycan chains. Each of the $\beta(1 \rightarrow 4)$ -linked glucose units in a chain is rotated 180° with respect to its neighboring residues and is held in this position by intrachain hydrogen bonds (dashed lines). The glycan chains line up laterally to form sheets, and these sheets stack vertically so they are staggered by half the length of a glucose unit. The entire assembly is stabilized by intermolecular hydrogen bonds. Hydrogen atoms not participating in hydrogen bonds have been omitted for clarity. [Illustration, Irving Geis. ? Locate the glycosidic bonds in this diagram of cellulose.

however, is one of the main reasons that the cellulose in wood and agricultural waste, despite its abundance, cannot be easily converted to biofuels.

Although vertebrates themselves do not possess an enzyme capable of hydrolyzing the $\beta(1\rightarrow4)$ linkages of cellulose, the digestive tracts of herbivores contain symbiotic microorganisms that secrete a series of enzymes, collectively known as **cellulases**, that do so. The same is true of termites. Nevertheless, the degradation of cellulose is a slow process because its tightly packed and hydrogen-bonded glycan chains are not easily accessible to cellulase and do not separate readily even after many of their glycosidic bonds have been hydrolyzed. Thus, cows and other ruminants must chew their cud.

Chitin is the principal structural component of the exoskeletons of invertebrates such as crustaceans, insects, and spiders and is also present in the cell walls of most fungi and many algae. It is therefore the second most abundant biomolecule, after cellulose. Chitin is a homopolymer of $\beta(1\rightarrow4)$ -linked *N*-acetyl-D-glucosamine residues:

Chitin

It differs chemically from cellulose only in that each C2—OH group is replaced by an acetamido group. X-Ray analysis indicates that chitin and cellulose have similar structures.

C Starch and Glycogen Are Storage Polysaccharides

Starch is a mixture of glycans that plants synthesize as their principal energy reserve. It is deposited in the chloroplasts of plant cells as insoluble granules composed of **α -amylose** and **amylopectin**. α -Amylose is a linear polymer of several thousand glucose residues linked by $\alpha(1\rightarrow4)$ bonds.

α -Amylose

Note that although α -amylose is an isomer of cellulose, it has very different structural properties. While cellulose's β -glycosidic linkages cause it to assume a tightly packed, fully extended conformation (Fig. 8-9), α -amylose's α -glycosidic bonds cause it to adopt an irregularly aggregating helically coiled conformation (Fig. 8-10).

FIG. 8-10 α -Amylose. This regularly repeating polymer forms a left-handed helix. Note the great differences in structure and properties that result from changing α -amylose's $\alpha(1\rightarrow4)$ linkages to the $\beta(1\rightarrow4)$ linkages of cellulose (Fig. 8-9). [Illustration, Irving Geis/Geis Archives Trust. Copyright Howard Hughes Medical Institute. Reproduced with permission.]

? Locate the glycosidic bonds in this diagram of amylose.

Amylopectin (at left) consists mainly of $\alpha(1\rightarrow4)$ -linked glucose residues but is a branched molecule with $\alpha(1\rightarrow6)$ branch points every 24 to 30 glucose residues on average. Amylopectin molecules contain up to 10^6 glucose residues, making them some of the largest molecules in nature. The storage of glucose as starch greatly reduces the large intracellular osmotic pressure that would result from its storage in monomeric form, because osmotic pressure is proportional to the number of solute molecules in a given volume (Section 2-1D). Starch is a reducing sugar, although it has only one residue, called the **reducing end**, that lacks a glycosidic bond.

The digestion of starch, the main carbohydrate source in the human diet, begins in the mouth. Saliva contains an **amylase**, which randomly hydrolyzes the $\alpha(1\rightarrow4)$ glycosidic bonds of starch. Starch digestion continues in the small intestine under the influence of pancreatic amylase, which degrades starch to a mixture of small oligosaccharides. Further hydrolysis by an **α -glucosidase**, which removes one glucose residue at a time, and by a **debranching enzyme**, which hydrolyzes $\alpha(1\rightarrow6)$ as well as $\alpha(1\rightarrow4)$ bonds, produces monosaccharides that are absorbed by the intestine and transported to the bloodstream.

Glycogen, the storage polysaccharide of animals, is present in all cells but is most prevalent in skeletal muscle and in liver, where it occurs as cytoplasmic granules (Fig. 8-11). The primary structure of glycogen resembles that of amylopectin, but glycogen is more highly branched, with branch points occurring every 8 to 14 glucose residues. In the cell, glycogen is degraded for metabolic use by **glycogen phosphorylase**, which phosphorolytically cleaves glycogen's $\alpha(1\rightarrow4)$ bonds sequentially inward from its nonreducing ends. *Glycogen's highly branched structure, which has many nonreducing ends, permits the rapid mobilization of glucose in times of metabolic need.* The $\alpha(1\rightarrow6)$ branches of glycogen are cleaved by **glycogen debranching enzyme** (glycogen breakdown is discussed further in Section 16-1).

D Glycosaminoglycans Form Highly Hydrated Gels

The extracellular spaces, particularly those of connective tissues such as cartilage, tendon, skin, and blood vessel walls, contain collagen (Section 6-1C) and other proteins embedded in a gel-like matrix that is composed largely of **glycosaminoglycans**. These unbranched polysaccharides consist of alternating uronic acid and hexosamine residues. Solutions of glycosaminoglycans have a slimy, mucuslike consistency that results from their high viscosity and elasticity.

Hyaluronate Acts as a Shock Absorber and Lubricant. **Hyaluronic acid (hyaluronate)** is an important glycosaminoglycan component of connective tissue, synovial fluid (the fluid that lubricates joints), and the vitreous humor of the eye. In most mammals, hyaluronate molecules are composed of 80 to 8000 $\beta(1\rightarrow4)$ -linked disaccharide units that consist of D-glucuronic acid and **N-acetyl-D-glucosamine (GlcNAc)** linked by a $\beta(1\rightarrow3)$ bond (Fig. 8-12). Hyaluronate is an extended, rigid molecule whose numerous repelling anionic groups bind cations and water molecules. In solution, hyaluronate occupies a volume ~ 1000 times that in its dry state.

Hyaluronate solutions have a viscosity that is shear dependent (an object under shear stress has equal and opposite forces applied across its opposite faces). At low shear rates, hyaluronate molecules form tangled masses that greatly impede flow; that is, the solution is quite viscous. As the shear stress increases, the stiff hyaluronate molecules tend to line up with the flow and thus offer less resistance to it. This viscoelastic behavior makes hyaluronate solutions excellent biological shock absorbers and lubricants.

Hyaluronate has an unanticipated property. The naked mole rat is a hairless, mouse-sized rodent (it resembles a pink sausage with teeth) that has a longer life span (>30 years) than any other rodent. This is, in part, because cancer has never been observed in naked mole rats (in contrast, mice and rats, which live ~ 4 years, have a high incidence of cancer). Naked mole rat cells secrete extremely high molecular-mass hyaluronate; it consists of 16 to 32 thousand disaccharide units. This interferes

FIG. 8-11 Glycogen granules in a liver cell.

In this photomicrograph, glycogen granules are pink, the greenish objects are mitochondria, and the yellow object is a fat globule. The glycogen content of liver may reach 10% of its net weight.

? Determine the net charge of each of these disaccharide units.

with the signaling pathways that support malignant transformation (cancer formation; Box 13-3). Consequently, reducing the amount of high molecular-mass hyaluronate in a culture of naked mole rat cells by either mutationally underexpressing the enzyme that synthesizes the hyaluronate or overexpressing the enzyme that degrades it yields cells that are susceptible to malignant transformation.

Some Glycosaminoglycans Are Sulfated. The other common glycosaminoglycans shown in Fig. 8-12 consist of 50 to 1000 sulfated disaccharide units. **Chondroitin-4-sulfate** and **chondroitin-6-sulfate** differ only in the sulfation of their *N*-acetylgalactosamine (GalNAc) residues. **Dermatan sulfate** is derived from chondroitin by enzymatic epimerization of the C5 of glucuronate residues to form **iduronate** residues. **Keratan sulfate** (not to be confused with the fibrous protein keratin; Section 6-1C) is the most heterogeneous of the major glycosaminoglycans in that its sulfate content is variable and it contains small amounts of fucose, mannose, GlcNAc, and sialic acid. **Heparin** is also variably sulfated, with an average of 2.5 sulfate residues per disaccharide unit, which makes it the most highly charged polymer in mammalian tissues (**Fig. 8-13**).

FIG. 8-13 NMR structure of heparin. Three consecutive disaccharide units of this helical polymer are drawn in stick form. Atoms are colored according to type with glucosamine C green, iduronate C cyan, H white, N blue, O red, and S yellow. The helical repeat unit is two disaccharides with a pitch (rise per turn) of 17.5 Å. Note the high density of anionic sulfate groups. ? What chemical property of glycans allows them to retain moisture?

CHECKPOINT

- Describe the monosaccharide units and their linkages in the common disaccharides and polysaccharides.
- Explain why the systematic name of an oligosaccharide must include more than just the names of the component monosaccharides.
- Compare and contrast the structures and functions of cellulose, chitin, starch, and glycogen.
- How do the physical properties of glycosaminoglycans and similar molecules relate to their biological roles?

In contrast to the other glycosaminoglycans, heparin is not a constituent of connective tissue but occurs almost exclusively in the intracellular granules of the mast cells that occur in arterial walls. It inhibits the clotting of blood, and its release, through injury, is thought to prevent runaway clot formation. Heparin is therefore in wide clinical use to inhibit blood clotting—for example, in postsurgical patients.

Heparan sulfate, a ubiquitous cell-surface component as well as an extracellular substance in blood vessel walls and brain, resembles heparin but has a far more variable composition, with fewer *N*- and *O*-sulfate groups and more *N*-acetyl groups. Heparan sulfate plays a critical role in development and in wound healing. Various **growth factors** bind to heparan sulfate, and the formation of complexes of the glycosaminoglycan, the growth factor, and the growth factor receptor is required to initiate cell differentiation and proliferation. Specific sulfation patterns on heparan sulfate are required for the formation of these ternary complexes.

Plants Produce Pectin. Plants do not synthesize glycosaminoglycans, but the **pectins**, which are major components of cell walls, may function similarly as shock absorbers. Pectins are heterogeneous polysaccharides with a core of $\alpha(1\rightarrow4)$ -linked galacturonate residues interspersed with the hexose **rhamnose**.

The galacturonate residues may be modified by the addition of methyl and acetyl groups. Other polysaccharide chains, some containing the pentoses arabinose and xylose and other sugars, are attached to the galacturonate. The aggregation of pectin molecules to form bundles requires divalent cations (usually Ca^{2+}), which form cross-links between the anionic carboxylate groups of neighboring galacturonate residues. The tendency for pectin to form highly hydrated gels is exploited in the manufacture of jams and jellies, to which pectin is often added to augment the endogenous pectin content of the fruit.

Bacterial Biofilms Are a Type of Extracellular Matrix. Outside the laboratory, bacteria are most often found growing on surfaces as a **biofilm**, an association of cells in a semisolid matrix (**Fig. 8-14**). The extracellular material of the biofilm consists mostly of highly hydrated polysaccharides such as anionic poly-D-glucuronate, poly-*N*-acetylglucosamine, cellulose-like molecules, and acetylated glycans. A biofilm is difficult to characterize, as it typically houses a mixture of species, and the proportions of its component polysaccharides can vary over time and space.

The gel-like consistency of a biofilm—for example, the plaque that forms on teeth—prevents bacterial cells from being washed away and protects them from desiccation. Biofilms that develop on medical apparatus, such as catheters, are problematic because they offer a foothold for pathogenic organisms and create a barrier to soluble antimicrobial agents.

3 Glycoproteins

KEY CONCEPTS

- Proteoglycans are large, glycosaminoglycan-containing proteins.
- Bacterial cell walls consist of glycan chains cross-linked by peptides.
- The oligosaccharide chains covalently attached to eukaryotic glycoproteins may play a role in protein structure and recognition.

Many proteins are actually glycoproteins, with carbohydrate contents varying from <1% to >90% by weight. Glycoproteins occur in all forms of life and have functions that span the entire spectrum of protein activities, including those of enzymes, transport proteins, receptors, hormones, and structural proteins. The polypeptide chains of glycoproteins, like those of all proteins, are synthesized under genetic control. Their carbohydrate chains, in contrast, are enzymatically generated and covalently linked to the polypeptide without the rigid guidance of nucleic acid templates. For this reason, glycoproteins tend to have variable carbohydrate composition, a phenomenon known as **microheterogeneity**. Characterizing the structures of carbohydrates—and their variations—is one goal of the field of **glycomics**, which complements the studies of genomics (for DNA) and proteomics (for proteins).

A Proteoglycans Contain Glycosaminoglycans

Proteins and glycosaminoglycans in the extracellular matrix aggregate covalently and noncovalently to form a diverse group of macromolecules known as **proteoglycans**. Electron micrographs (Fig. 8-15a) and other evidence indicate that proteoglycans have a bottlebrush-like molecular architecture, with “bristles” noncovalently attached to a filamentous hyaluronate “backbone.” The bristles consist of a **core protein** to which glycosaminoglycans, most often chains of keratan sulfate and chondroitin sulfate, are covalently linked (Fig. 8-15b). The interaction between the core protein and the hyaluronate is stabilized by a **link protein**. Smaller oligosaccharides are usually attached to the core protein near its site of attachment to hyaluronate. These oligosaccharides are glycosidically linked to the protein via the amide N of specific Asn residues (and are therefore known as **N-linked oligosaccharides**; Section 8-3C). The keratan sulfate and chondroitin sulfate chains are glycosidically linked to the core protein via oligosaccharides that are covalently bonded to side chain O atoms of specific Ser or Thr residues (i.e., **O-linked oligosaccharides**).

Altogether, a central strand of hyaluronate, which varies in length from 4000 to 40,000 Å, can have up to 100 associated core proteins, each of which binds ~50 keratan sulfate chains of up to 250 disaccharide units and ~100 chondroitin sulfate chains of up to 1000 disaccharide units each. This accounts for the enormous molecular masses of many proteoglycans, which range up to tens of millions of daltons.

The extended brushlike structure of proteoglycans, together with the polyanionic character of their keratan sulfate and chondroitin sulfate components, cause these complexes to form highly hydrated gels. Cartilage, which consists of a meshwork of collagen fibrils that is filled in by proteoglycans, is characterized by its high resilience: The application of pressure on cartilage squeezes water away from the charged regions of its proteoglycans until charge–charge repulsions prevent further compression. When the pressure is released, the water returns. Indeed, the cartilage in the joints, which lacks blood vessels, is nourished by this flow of liquid brought about by body movements. This explains why long periods of inactivity cause cartilage to become thin and fragile.

B Bacterial Cell Walls Are Made of Peptidoglycan

Bacteria are surrounded by rigid cell walls that give them their characteristic shapes (Fig. 1-7) and permit them to live in **hypotonic** (less

than intracellular salt concentration) environments that would otherwise cause them to swell osmotically until their plasma (cell) membranes lysed (burst). Bacterial cell walls are of considerable medical significance because they are, in part, responsible for bacterial **virulence** (disease-evoking power). In fact, the symptoms of many bacterial diseases can be elicited in animals merely by injecting bacterial cell walls. Furthermore, bacterial cell wall components are antigenic (Section 7-3B), so such injections often invoke immunity against these bacteria.

Bacteria are classified as **gram-positive** or **gram-negative** according to whether or not they take up Gram stain (a procedure developed in 1884 by Christian Gram in which heat-fixed cells are successively treated with the dye crystal violet and iodine and then destained by ethanol or acetone). Gram-positive bacteria (Fig. 8-16a) have a thick cell wall ($\sim 250 \text{ \AA}$) surrounding their plasma membrane, whereas gram-negative bacteria (Fig. 8-16b) have a thin cell wall ($\sim 30 \text{ \AA}$) covered by a complex outer membrane. This outer membrane functions, in part, to exclude substances toxic to the bacterium, including Gram stain. This accounts for the observation that gram-negative bacteria are more resistant to antibiotics than are gram-positive bacteria.

The cell walls of bacteria consist of covalently linked polysaccharide and polypeptide chains, which form a baglike macromolecule that completely encases the cell. This framework, whose structure was elucidated in large part by Jack Strominger, is known as a **peptidoglycan**. Its polysaccharide component consists of linear chains of alternating $\beta(1\rightarrow4)$ -linked GlcNAc and *N*-acetylmuramic acid (Latin: *murus*, wall). The lactic acid group of *N*-acetylmuramic acid forms an amide bond with a D-amino acid-containing tetrapeptide to form the peptidoglycan repeating unit (Fig. 8-17). Neighboring parallel peptidoglycan chains are covalently cross-linked through their tetrapeptide side chains, although only $\sim 40\%$ of possible cross-links are made.

In the bacterium *Staphylococcus aureus*, whose tetrapeptide has the sequence L-Ala-D-isoglutamyl-L-Lys-D-Ala, the cross-link consists of a pentaglycine chain that extends from the terminal carboxyl group of one tetrapeptide to the ϵ -amino group of the Lys in a neighboring tetrapeptide. To explore this structure, Simon Foster has used **atomic force microscopy (AFM)**, an imaging technique that reports the variation in the force between a probe that is several nanometers in diameter and a surface of interest as the probe is scanned over the surface; its resolution is as little as several ångströms. Foster's model of the cell wall of the gram-negative bacterium *Bacillus subtilis* is shown in Figure 8-18. Several glycan chains are cross-linked much as described above to form a peptidoglycan "rope," which due to its natural twist, forms an $\sim 50\text{-nm}$ -diameter helical cable up to $50 \mu\text{m}$ in length that coils around the long axis of the bacterium to form its

FIG. 8-17 Peptidoglycan. (a) The repeating unit of peptidoglycan is an *N*-acetylglucosamine–*N*-acetylmuramic acid disaccharide whose lactyl side chain forms an amide bond with a tetrapeptide. The tetrapeptide of *S. aureus* is shown. The isoglutamyl residue is so designated because it forms a peptide link via its γ -carboxyl group. (b) The *S. aureus* bacterial cell wall peptidoglycan, showing its pentaglycine connecting bridges (purple).

cell wall. This structure is presumably stabilized by the formation of covalent cross-links between neighboring segments of the coil. The cell walls of gram-negative bacteria appear to be only one layer thick, whereas as those of gram-positive bacteria are postulated to consist of several such layers. How the peptidoglycan imposes cell shape is unknown.

The D-amino acids of peptidoglycans render them resistant to proteases, which are mostly specific for L-amino acids. However, **lysozyme**, an enzyme that is present in tears, mucus, and other vertebrate body secretions, as well as in egg whites, catalyzes the hydrolysis of the $\beta(1\rightarrow4)$ glycosidic linkage between *N*-acetylmuramic acid and *N*-acetylglucosamine (the structure and mechanism of lysozyme are examined in detail in Section 11-4). The cell wall is also compromised by antibiotics that inhibit its biosynthesis (Box 8-3).

FIG. 8-18 Model of the *B. subtilis* cell wall. The cell wall consists of a right-handed helical cable composed of several peptidoglycan strands that wraps about the bacterium's plasma membrane. The cell is $\sim 3 \mu\text{m}$ long.

In 1928, Alexander Fleming noticed that the chance contamination of a bacterial culture plate with the mold *Penicillium notatum* resulted in the lysis of the bacteria in the vicinity of the mold. This was caused by the presence of **penicillin**, an antibiotic secreted by the mold. Penicillin contains a thiazolidine ring (red) fused to a β -lactam ring (blue). A variable R group is bonded to the β -lactam ring via a peptide link.

Penicillin specifically binds to and inactivates enzymes that cross-link the peptidoglycan strands of bacterial cell walls. Since cell wall expansion in growing cells requires that their rigid cell walls be opened up for the insertion of new cell wall material, exposure of growing bacteria to penicillin results in cell lysis. However, since no human enzyme binds penicillin specifically, it is not toxic to humans and is therefore therapeutically useful.

Most bacteria that are resistant to penicillin secrete the enzyme **penicillinase** (also called **β -lactamase**), which inactivates penicillin by cleaving the amide bond of its β -lactam ring. Attempts to overcome this resistance have led to the development of β -lactamase inhibitors such as **sulbactam** that are often administered in combination with penicillin derivatives.

Multiple-drug-resistant bacteria are a growing problem. For many years, **vancomycin**, the so-called antibiotic of last resort, has been used to treat bacterial infections that do not succumb to other antibiotics. Vancomycin inhibits the transpeptidation (cross-linking) reaction of bacterial cell wall synthesis by binding to the peptidoglycan precursor. However, bacteria can become resistant to vancomycin by acquiring a gene that allows cell wall synthesis from a slightly different precursor sequence, to which vancomycin binds much less effectively.

One limitation of drugs such as vancomycin and penicillin, particularly for slow-growing bacteria, is that the drug may halt bacterial growth without actually killing the cells. For this reason, effective antibacterial treatments may require combinations of antibiotics over a course of several weeks.

C Many Eukaryotic Proteins Are Glycosylated

Almost all the secreted and membrane-associated proteins of eukaryotic cells are **glycosylated**. Oligosaccharides are covalently attached to proteins by either *N*-glycosidic or *O*-glycosidic bonds.

***N*-Linked Oligosaccharides Are Attached to Asparagine.** In *N*-linked oligosaccharides, *GlcNAc* is invariably β -linked to the amide nitrogen of an *Asn* residue in the sequence *Asn*-*X*-*Ser* or *Asn*-*X*-*Thr*, where *X* is any amino acid except *Pro* and only rarely *Asp*, *Glu*, *Leu*, or *Trp*.

N-Glycosylation occurs **cotranslationally**—that is, while the polypeptide is being synthesized. Proteins containing *N*-linked oligosaccharides typically are glycosylated and then **processed** as elucidated, in large part, by Stuart Kornfeld (Fig. 8-19):

1. An oligosaccharide containing 9 mannose residues, 3 glucose residues, and 2 *GlcNAc* residues is attached to the *Asn* of a growing polypeptide chain that is being synthesized by a ribosome associated with the endoplasmic reticulum (Section 9-4D).
2. Some of the sugars are removed during processing, which begins in the lumen (internal space) of the endoplasmic reticulum and continues in the Golgi apparatus (Fig. 1-8). Enzymatic trimming is accomplished by glucosidases and mannosidases.

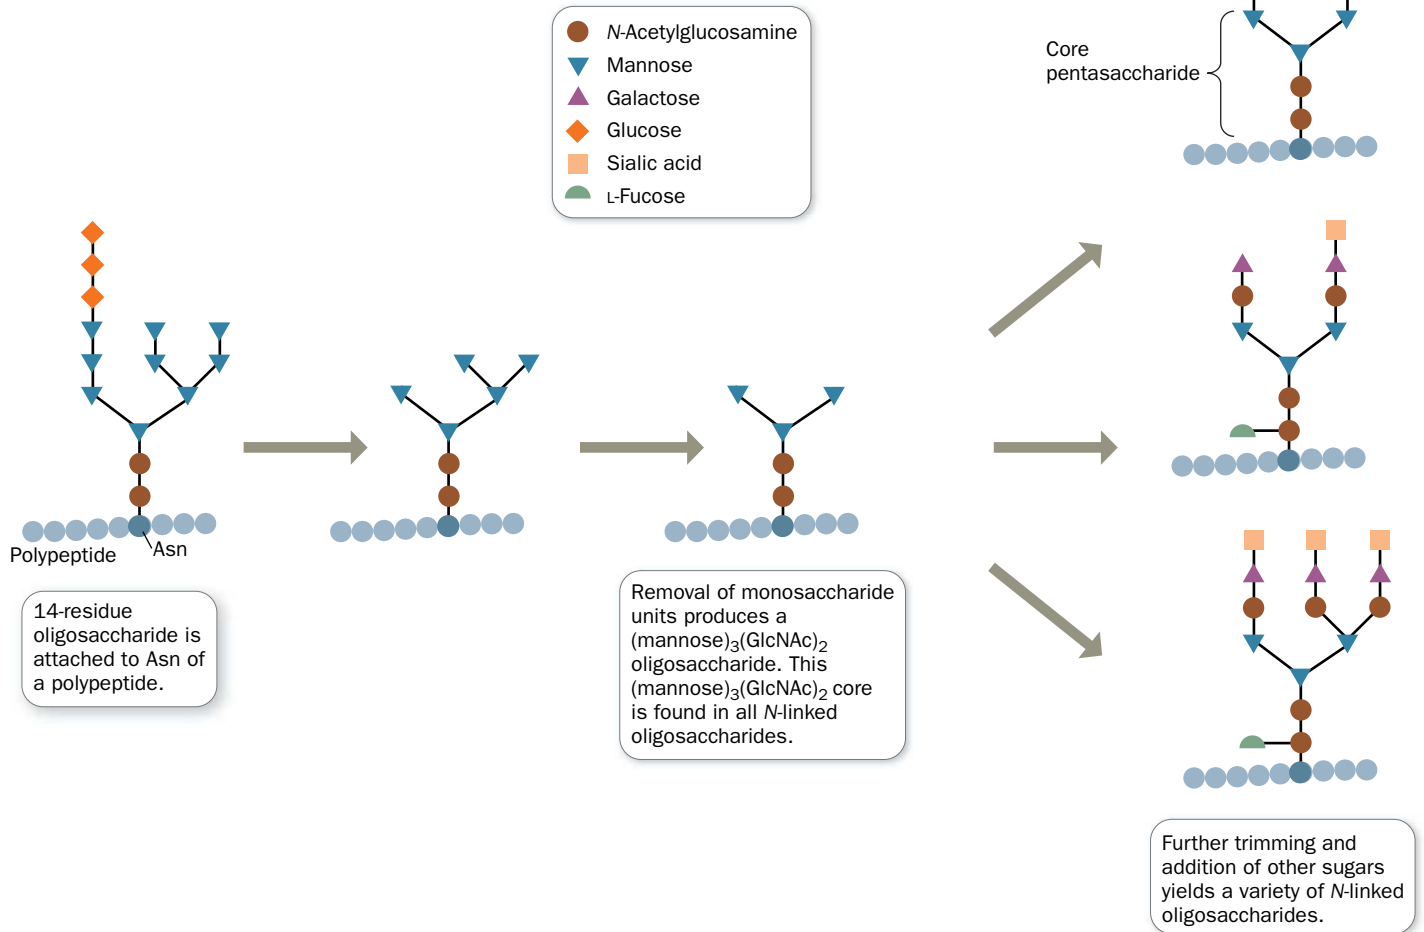

FIG. 8-19 Synthesis of N-linked oligosaccharides. The addition of a (mannose)₉(glucose)₃(GlcNAc)₂ oligosaccharide is followed by removal of monosaccharides as catalyzed by glycosidases, and the addition of

other monosaccharides as catalyzed by glycosyltransferases. The core pentasaccharide occurs in all N-linked oligosaccharides. [Adapted from Kornfeld, R. and Kornfeld, S., *Annu. Rev. Biochem.* **54**, 640 (1985).]

- Additional monosaccharide residues, including GlcNAc, galactose, fucose, and sialic acid, are added by the action of specific **glycosyltransferases** in the Golgi apparatus.

The exact steps of N-linked oligosaccharide processing vary with the identity of the glycoprotein and the battery of endoglycosidases in the cell, but all N-linked oligosaccharides have a common core pentasaccharide with the following structure:

In some glycoproteins, processing is limited, leaving “high-mannose” oligosaccharides; in other glycoproteins, extensive processing generates large oligosaccharides containing several kinds of sugar residues. *There is enormous diversity among the oligosaccharides of N-linked glycoproteins.* Indeed, even glycoproteins with a given polypeptide chain exhibit considerable microheterogeneity, presumably as a consequence of incomplete glycosylation and lack of absolute specificity on the part of glycosidases and glycosyltransferases.

O-Linked Oligosaccharides Are Attached to Serine or Threonine. The most common *O*-glycosidic attachment involves the disaccharide core β -galactosyl-(1 \rightarrow 3)- α -*N*-acetylgalactosamine linked to the OH group of either Ser or Thr:

Less commonly, galactose, mannose, and xylose form *O*-glycosides with Ser or Thr. Galactose also forms *O*-glycosidic bonds to the 5-hydroxylysyl residues of collagen (Section 6-1C). *O*-Linked oligosaccharides vary in size from a single galactose residue in collagen to the chains of up to 1000 disaccharide units in proteoglycans.

O-Linked oligosaccharides are synthesized in the Golgi apparatus by the serial addition of monosaccharide units to a completed polypeptide chain. Synthesis starts with the transfer of GalNAc to a Ser or Thr residue on the polypeptide. *N*-Linked oligosaccharides are transferred to an Asn in a specific amino acid sequence, but *O*-glycosylated Ser and Thr residues are not members of any common sequence. Instead, the locations of glycosylation sites are specified only by the secondary or tertiary structure of the polypeptide. *O*-Glycosylation continues with stepwise addition of sugars by the corresponding glycosyltransferases. The energetics and enzymology of oligosaccharide synthesis are discussed further in Section 16-5.

D Oligosaccharides May Determine Glycoprotein Structure, Function, and Recognition

A single protein may contain several *N*- and *O*-linked oligosaccharide chains, although different molecules of the same glycoprotein may differ in the sequences, locations, and numbers of covalently attached carbohydrates (the variant species of a glycoprotein are known as its **glycoforms**). This heterogeneity makes it difficult to assign discrete biological functions to oligosaccharide chains. In fact, certain glycoproteins synthesized by cells that lack particular oligosaccharide-processing enzymes appear to function normally despite abnormal or absent glycosylation. In other cases, however, glycosylation may affect a protein's structure, stability, or activity.

Oligosaccharides Help Define Protein Structure. Oligosaccharides are usually attached to proteins at sequences that form surface loops or turns. Since sugars are hydrophilic, the oligosaccharides tend to project away from the protein surface. Because carbohydrate chains are often conformationally mobile, oligosaccharides attached to proteins can occupy time-averaged volumes of considerable size (Fig. 8-20). In this way, an oligosaccharide can shield a protein's surface, possibly modifying its activity or protecting it from proteolysis.

In addition, some oligosaccharides may play structural roles by limiting the conformational freedom of their attached polypeptide chains. Since *N*-linked oli-

FIG. 8-20 Model of oligosaccharide dynamics. The allowed conformations of a (GlcNAc)₂(mannose)₅₋₉ oligosaccharide (yellow) attached to the bovine pancreatic enzyme ribonuclease B (purple) are shown in superimposed "snapshots."

gosaccharides are added as the protein is being synthesized, the attachment of an oligosaccharide may help determine how the protein folds. In addition, the oligosaccharide may help stabilize the folded conformation of a polypeptide by reducing backbone flexibility. In particular, *O*-linked oligosaccharides, which are usually clustered in heavily glycosylated segments of a protein, may help stiffen and extend the polypeptide chain.

Oligosaccharides Mediate Recognition Events. The many possible ways that carbohydrates can be linked together to form branched structures gives them the potential to carry more biological information than either nucleic acids or proteins of similar size. For example, two different nucleotides can make only two distinct dinucleotides, but two different hexoses can combine in 36 different ways (although not all possibilities are necessarily realized in nature).

The first evidence that unique combinations of carbohydrates might be involved in intercellular communication came with the discovery that all cells are coated with sugars in the form of **glycoconjugates** such as glycoproteins and glycolipids. The oligosaccharides of glycoconjugates form a fuzzy layer up to 1 μm thick in some cells (**Fig. 8-21**).

Additional evidence that cell-surface carbohydrates have recognition functions comes from **lectins** (proteins that bind carbohydrates), which are ubiquitous in nature and frequently appear on the surfaces of cells. Lectins are exquisitely specific: They can recognize individual monosaccharides in particular linkages to other sugars in an oligosaccharide (this property also makes lectins useful laboratory tools for isolating glycoproteins and oligosaccharides). Protein–carbohydrate interactions are typically characterized by extensive hydrogen bonding (often including bridging water molecules) and the van der Waals packing of hydrophobic sugar faces against aromatic side chains (**Fig. 8-22**).

Proteins known as **selectins** mediate the attachment between **leukocytes** (circulating white blood cells) and the surfaces of endothelial cells (the cells that line cavities—in this case, blood vessels). Leukocytes constitutively (continually) express selectins on their surface; endothelial cells transiently display their own selectins in response to tissue damage from infection or mechanical injury. The selectins recognize and bind specific oligosaccharides on cell-surface glycoproteins. Reciprocal selectin–oligosaccharide interactions between the two cell types allow the endothelial cells to “capture” circulating leukocytes, which then crawl past the endothelial cells on their way to eliminate the infection or help repair damaged tissues.

Other cell–cell recognition phenomena also depend on oligosaccharides. For example, proteins on the surface of mammalian spermatozoa recognize GlcNAc or galactose residues on the glycoproteins of the ovum as part of the binding and activation events during fertilization. Many viruses, bacteria, and eukaryotic parasites invade their target tissues by binding to specific cell-surface carbohydrates.

 **Oligosaccharides Are Antigenic Determinants.** The carbohydrates on cell surfaces are some of the best known immunochemical markers. For example, the **ABO blood group antigens** are oligosaccharide components of glycoproteins and glycolipids on the surfaces of an individual’s cells (not just red blood

FIG. 8-22 Carbohydrate binding by a lectin. Human **galectin-2** binds β -galactosides, such as lactose, primarily through their galactose residue. The galactose and glucose residues are shown with C green and O red, and the lectin amino acid side chains are shown in violet. Hydrogen bonds between the side chains and the sugar residues are shown as dashed yellow lines.

TABLE 8-1 Structures of the A, B, and H Antigenic Determinants in Erythrocytes

Type	Antigen ^a
H	Galβ(1→4)GlcNAc··· ↑1,2 L-Fucα
A	GalNAcα(1→3)Galβ(1→4)GlcNAc··· ↑1,2 L-Fucα
B	Galα(1→3)Galβ(1→4)GlcNAc··· ↑1,2 L-Fucα

^aGal, galactose; GalNAc, *N*-acetylgalactosamine; GlcNAc, *N*-acetylglucosamine; L-Fuc, L-fucose.

CHECKPOINT

- Describe the general structures of proteoglycans, peptidoglycans, and glycosylated proteins.
- Why are gram-positive bacteria more susceptible to antibiotics such as penicillin?
- List the major biological functions of proteoglycans and peptidoglycans.
- Explain the difference between *N*- and *O*-linked oligosaccharides.
- Explain why the oligosaccharides of glycoproteins are more complicated to describe than amino acids or nucleotide sequences.
- How do oligosaccharides participate in biological recognition?

cells). Individuals with type A cells have A antigens on their cell surfaces and carry anti-B antibodies in their blood; those with type B cells, which bear B antigens, carry anti-A antibodies; those with type AB cells, which have both A and B antigens, carry neither anti-A nor anti-B antibodies; and type O individuals, whose cells bear neither antigen, carry both anti-A and anti-B antibodies. Consequently, the transfusion of type A blood into a type B individual, for example, results in an anti-A antibody–A antigen reaction, which agglutinates (clumps together) the transfused erythrocytes, resulting in an often fatal blockage of blood vessels.

Table 8-1 lists the oligosaccharides found in the **A, B, and H antigens** (type O individuals have the H antigen). These occur at the nonreducing ends of the oligosaccharides. The H antigen is the precursor oligosaccharide of A and B antigens. Type A individuals have a 303-residue glycosyltransferase that specifically adds a GalNAc residue to the terminal position of the H antigen. In type B individuals, this enzyme, which differs by four amino acid residues from that of type A individuals, instead adds a galactose residue. In type O individuals, the enzyme is inactive because its synthesis terminates after its 115th residue.

Summary

1 Monosaccharides

- Monosaccharides, the simplest carbohydrates, are classified as aldoses or ketoses.
- The cyclic hemiacetal and hemiketal forms of monosaccharides have either the α or β configuration at their anomeric carbon but are conformationally variable.
- Monosaccharide derivatives include aldonic acids, uronic acids, alditols, deoxy sugars, amino sugars, and α- and β-glycosides.

2 Polysaccharides

- Polysaccharides are monosaccharides linked by glycosidic bonds.
- Cellulose and chitin are polysaccharides whose β(1→4) linkages cause them to adopt rigid and extended structures.
- The storage polysaccharides starch and glycogen consist of α-glycosidically linked glucose residues.

- Glycosaminoglycans are unbranched polysaccharides containing uronic acid and amino sugars that are often sulfated.

3 Glycoproteins

- Proteoglycans are enormous molecules consisting of hyaluronate with attached core proteins that bear numerous glycosaminoglycans and oligosaccharides.
- Bacterial cell walls are made of peptidoglycan, a network of polysaccharide and polypeptide chains.
- Glycosylated proteins may contain *N*-linked oligosaccharides (attached to Asn) or *O*-linked oligosaccharides (attached to Ser or Thr) or both. Different molecules of a glycoprotein may contain different sequences and locations of oligosaccharides.
- Oligosaccharides play important roles in determining protein structure and in cell-surface recognition phenomena.

Problems

EXERCISES

- How many stereoisomers are possible for (a) a ketopentose, (b) a ketohexose, and (c) a ketoheptose?
- Are (a) D-glucitol, (b) D-galactitol, and (c) D-glycerol optically active?
- Which of the following pairs of sugars are epimers of each other?
 - D-sorbose and D-psicose
 - D-sorbose and D-fructose
 - D-erythrose and D-arabinose
- Which of the following pairs of sugars are epimers of each other?
 - D-fructose and L-fructose
 - D-arabinose and D-ribose
 - D-ribose and D-ribulose
- Draw the furanose and pyranose forms of D-ribose.
- Draw a Fischer projection of L-fucose. L-Fucose is the 6-deoxy form of which L-hexose?
- Some bacteria produce thiosugars, which contain a C—S covalent bond, such as 2-deoxy-2-thio- β -D-glucose. Draw the structure of this sugar.
- The metabolism of monosaccharides yields phosphorylated sugars such as β -D-fructose-6-phosphate. Draw its structure.
- The sucrose substitute tagatose (Fig. 8-2) is produced by hydrolyzing lactose and then chemically converting one of the two resulting aldoses to a ketose. Which residue of lactose gives rise to tagatose?
- What type of sugar derivative is rhamnose?
- Draw the structure of the mannose trisaccharide that is part of the core *N*-linked oligosaccharide.
- Identify the monosaccharides and their linkages in the following disaccharide.

- How many reducing ends are in a molecule of glycogen that contains 10,000 residues with a branch every 10 residues?

- Is amylose or amylopectin more likely to be a long-term storage polysaccharide in plants?
- “Nutraceuticals” are products that are believed to have some beneficial effect but are not strictly defined as either food or drug. Why might an individual suffering from osteoarthritis be tempted to consume the nutraceutical glucosamine?
- The core of pectin molecules is a polymer of $\alpha(1\rightarrow4)$ -linked D-galacturonate. Draw one of its residues.
- Calculate the net charge of a chondroitin-4-sulfate molecule containing 100 disaccharide units.
- Basic fibroblast growth factor binds to glycosaminoglycans in the extracellular matrix. Which amino acids would you expect to be abundant in this protein?
- In certain situations, a glycosyltransferase catalyzes the addition of a GlcNAc group to an arginine residue in a protein. Draw the structure of the modified arginine side chain.
- A protein that fails to fold properly in the endoplasmic reticulum may undergo *O*-mannosylation. Draw the structure of the resulting modified amino acid residue.
- Draw the structure of the *O*-type oligosaccharide (the H antigen, described in Table 8-1).
- During gel electrophoresis, glycoproteins migrate as relatively diffuse bands, whereas nonglycosylated proteins typically migrate as narrow, well-defined bands. Explain the difference in electrophoretic behavior.

CHALLENGE QUESTIONS

- How many different disaccharides of D-glucopyranose are possible?
- In addition to lactose, how many other heterodisaccharides can D-galactose and D-glucose form?
- (a) Deduce the structure of the disaccharide trehalose from the following information: Complete hydrolysis yields only D-glucose; it is hydrolyzed by α -glucosidase but not β -glucosidase; and it does not reduce Cu^{2+} to Cu^+ . (b) When exposed to dehydrating conditions, many plants and invertebrates synthesize large amounts of trehalose, which enables them to survive prolonged desiccation. What properties of the trehalose molecule might allow it to act as a water substitute?
- The artificial sweetener sucralose is a derivative of sucrose with the formal name 1,6-dichloro-1,6-dideoxy- β -D-fructofuranosyl-4-chloro-4-deoxy- α -D-galactopyranoside. Draw its structure.

27. Brown algae produce alginate, a polysaccharide containing β -D-mannuronate linked 1 \rightarrow 4 to its C5 epimer α -L-guluronate. Draw the structure of an alginate disaccharide.
28. Human milk contains the oligosaccharide 2'-fucosyllactose (α -L-fucose-(1 \rightarrow 2)- β -D-galactose-(1 \rightarrow 4)-D-glucose), which may help protect the newborn from bacterial infections. Draw the structure of this oligosaccharide.
29. Cellulose is treated with methanol, which methylates free anomeric carbons. (a) How many methyl groups would be incorporated per cellulose chain? (b) Cellulose is treated with dimethyl sulfate, which adds a methyl group to all free hydroxyl groups. The cellulose is then hydrolyzed to release all its monosaccharides. Draw their structure.
30. Glycogen is treated with dimethyl sulfate, which adds a methyl group to every free OH group. Next, the molecule is hydrolyzed to break all the glycosidic bonds between glucose residues. The reaction products are then chemically analyzed.
- How many different types of methylated glucose molecules are obtained?
 - Draw the structure of the one that is most abundant.
31. Following their synthesis, many proteoglycans are stored in a highly condensed state in intracellular compartments. These compartments also contain many Ca^{2+} ions, which are rapidly pumped out as the proteoglycans are released extracellularly. Explain the function of the Ca^{2+} ions.
32. The peptidoglycan cell walls of bacteria contain pores that allow the passage of substances with diameters less than 200 Å. Why is it important that the cell wall be porous rather than solid?
33. The enzyme **β -amylase** cleaves successive **maltose** units (maltose is an α (1 \rightarrow 4)-linked glucose disaccharide) from the nonreducing end of α (1 \rightarrow 4) **glucans** (polysaccharides containing only glucose residues). It will not cleave at glucose residues that have an α (1 \rightarrow 6) bond. The end products of the exhaustive digestion of amylopectin by β -amylase are known as **limit dextrins**. Draw a schematic diagram of an amylopectin molecule and indicate what part(s) of it constitutes limit dextrins.

34. One demonstration of P.T. Barnum's maxim that there's a sucker born every minute is that new "reducing aids" regularly appear on the market. An eat-all-you-want nostrum, which was touted as a "starch blocker" [and which the Food and Drug Administration (FDA) eventually banned], contained an amylase-inhibiting enzyme extracted from beans. If this substance had really worked as advertised, which it did not, what unpleasant side effects would have resulted from its ingestion with a starch-containing meal? Discuss why this substance, which inhibits amylase *in vitro*, would not do so in the intestines after oral ingestion.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Drawing Monosaccharides

Exercise 2 Introduction to Glycomics

Exercise 3 Oligosaccharides, Polysaccharides, and Glycoproteins

Extended Exercises Bioinformatics projects are available on the book companion site (www.wiley/college/voet), as well as in WileyPLUS Learning Space.

Project 5 Glycomics and the H1N1 Flu

- Looking at branched carbohydrates.** Explore some well-known glycans using MarvinSketch, PubChem, and the KEGG *N*-glycan synthesis reference pathway.
- The role of glycans in swine flu.** Review the structures of two proteins (the H and N in H1N1) that are critical to swine flu infections and vaccine development, including the glycans that are attached to these proteins. Then explore the glycan targets for swine flu.

MORE TO EXPLORE Chitosan is a substance produced from the chitin of crustacean shells (mainly from shrimp and crab). How is the chitin chemically modified, and how does this treatment affect its physical and chemical properties? What are some industrial and medical uses for chitosan? Are all the advertised uses for chitosan supported by scientific data?

Lipids and Biological Membranes

Chapter Contents

1 Lipid Classification

- A The Properties of Fatty Acids Depend on Their Hydrocarbon Chains
- B Triacylglycerols Contain Three Esterified Fatty Acids
- C Glycerophospholipids Are Amphiphilic
- D Sphingolipids Are Amino Alcohol Derivatives
- E Steroids Contain Four Fused Rings
- F Other Lipids Perform a Variety of Metabolic Roles

2 Lipid Bilayers

- A Bilayer Formation Is Driven by the Hydrophobic Effect
- B Lipid Bilayers Have Fluidlike Properties

3 Membrane Proteins

- A Integral Membrane Proteins Interact with Hydrophobic Lipids
- B Lipid-Linked Proteins Are Anchored to the Bilayer
- C Peripheral Proteins Associate Loosely with Membranes

4 Membrane Structure and Assembly

- A The Fluid Mosaic Model Accounts for Lateral Diffusion
- B The Membrane Skeleton Helps Define Cell Shape
- C Membrane Lipids Are Distributed Asymmetrically
- D The Secretory Pathway Generates Secreted and Transmembrane Proteins
- E Intracellular Vesicles Transport Proteins
- F Proteins Mediate Vesicle Fusion

MEHAU KULYK/Getty Images

Mycobacterium tuberculosis, the cause of tuberculosis, evades both the human immune system and antibiotic drugs due in part to a thick cell wall containing enormous lipids known as mycolic acids, which consist of long hydrocarbon chains with hydroxyl, carboxyl, and other functional groups.

Lipids (Greek: *lipos*, fat) are the fourth major group of molecules found in all cells. Unlike nucleic acids, proteins, and polysaccharides, lipids are not polymeric. However, they do aggregate, and it is in this state that they perform their central function as the structural matrix of biological membranes.

Lipids exhibit greater structural variety than the other classes of biological molecules. To a certain extent, lipids constitute a catchall category of substances that are similar only in that they are largely hydrophobic and only sparingly soluble in water. In general, lipids perform three biological functions (although certain lipids serve more than one purpose in some cells):

1. Lipid molecules in the form of lipid bilayers are essential components of biological membranes.
2. Lipids containing hydrocarbon chains serve as energy stores.
3. Many intra- and intercellular signaling events involve lipid molecules.

In this chapter we examine the structures and physical properties of the most common types of lipids. Next, we look at the properties of the lipid bilayer and the proteins that are situated within it. Finally, we explore current models of membrane structure. The following chapter examines membrane transport phenomena. The participation of lipids in intracellular signaling is discussed in Section 13-4.

1 Lipid Classification

KEY CONCEPTS

- The length and saturation of a fatty acid chain determine its physical properties.
- Triacylglycerols and glycerophospholipids contain fatty acids esterified to glycerol.
- Sphingolipids resemble glycerophospholipids but may include large carbohydrate groups.
- Steroids, isoprenoids, and other lipids perform a wide variety of functions.

Lipids are substances of biological origin that are soluble in organic solvents such as chloroform and methanol. Hence, they are easily separated from other biological materials by extraction into organic solvents. They can then be separated chromatographically and identified by mass spectrometry according to their masses and characteristic fragmentation patterns (Section 5-3D). Fats, oils, certain vitamins and hormones, and most nonprotein membrane components are lipids. In this section, we discuss the structures and physical properties of the major classes of lipids.

A The Properties of Fatty Acids Depend on Their Hydrocarbon Chains

Fatty acids are carboxylic acids with long-chain hydrocarbon side groups (Fig. 9-1). They usually occur in esterified form as major components of the various lipids described in this chapter. The more common biological fatty acids are listed in Table 9-1. In higher plants and animals, the predominant fatty acid residues are those of the C₁₆ and C₁₈ species: **palmitic, oleic, linoleic, and stearic acids**. Fatty acids with <14 or >20 carbon atoms are uncommon. Most fatty acids have an even number of carbon atoms because they are biosynthesized by the concatenation of C₂ units (Section 20-4).

FIG. 9-1 The structural formulas of some C₁₈ fatty acids. The double bonds all have the cis configuration.

TABLE 9-1 The Common Biological Fatty Acids

Symbol ^a	Common Name	Systematic Name	Structure	mp (°C)
Saturated fatty acids				
12:0	Lauric acid	Dodecanoic acid	CH ₃ (CH ₂) ₁₀ COOH	44.2
14:0	Myristic acid	Tetradecanoic acid	CH ₃ (CH ₂) ₁₂ COOH	53.9
16:0	Palmitic acid	Hexadecanoic acid	CH ₃ (CH ₂) ₁₄ COOH	63.1
18:0	Stearic acid	Octadecanoic acid	CH ₃ (CH ₂) ₁₆ COOH	69.6
20:0	Arachidic acid	Eicosanoic acid	CH ₃ (CH ₂) ₁₈ COOH	77
22:0	Behenic acid	Docosanoic acid	CH ₃ (CH ₂) ₂₀ COOH	81.5
24:0	Lignoceric acid	Tetracosanoic acid	CH ₃ (CH ₂) ₂₂ COOH	88
Unsaturated fatty acids (all double bonds are cis)				
16:1 _{n-7}	Palmitoleic acid	9-Hexadecanoic acid	CH ₃ (CH ₂) ₅ CH=CH(CH ₂) ₇ COOH	-0.5
18:1 _{n-9}	Oleic acid	9-Octadecanoic acid	CH ₃ (CH ₂) ₇ CH=CH(CH ₂) ₇ COOH	12
18:2 _{n-6}	Linoleic acid	9,12-Octadecadienoic acid	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₂ (CH ₂) ₆ COOH	-5
18:3 _{n-3}	α-Linolenic acid	9,12,15-Octadecatrienoic acid	CH ₃ CH ₂ (CH=CHCH ₂) ₃ (CH ₂) ₆ COOH	-11
18:3 _{n-6}	γ-Linolenic acid	6,9,12-Octadecatrienoic acid	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₃ (CH ₂) ₃ COOH	-11
20:4 _{n-6}	Arachidonic acid	5,8,11,14-Eicosatetraenoic acid	CH ₃ (CH ₂) ₄ (CH=CHCH ₂) ₄ (CH ₂) ₂ COOH	-49.5
20:5 _{n-3}	EPA	5,8,11,14,17-Eicosapentaenoic acid	CH ₃ CH ₂ (CH=CHCH ₂) ₅ (CH ₂) ₂ COOH	-54
22:6 _{n-3}	DHA	4,7,10,13,16,19-Docosohexenoic acid	CH ₃ CH ₂ (CH=CHCH ₂) ₆ CH ₂ COOH	-44
24:1 _{n-9}	Nervonic acid	15-Tetracosenoic acid	CH ₃ (CH ₂) ₇ CH=CH(CH ₂) ₁₃ COOH	39

^aNumber of carbon atoms: Number of double bonds. For unsaturated fatty acids, the quantity “*n-x*” indicates the position of the last double bond in the fatty acid, where *n* is its number of C atoms, and *x* is the position of the last double-bonded C atom counting from the methyl-terminal (ω) end.

Source: LipidBank (<http://www.lipidbank.jp>).

? How do chain length and the presence of double bonds affect the melting point?

Over half of the fatty acid residues of plant and animal lipids are **unsaturated** (contain double bonds) and are often **polyunsaturated** (contain two or more double bonds). Bacterial fatty acids are rarely polyunsaturated but are commonly branched, hydroxylated, or contain cyclopropane rings.

Table 9-1 indicates that the first double bond of an unsaturated fatty acid commonly occurs between its C9 and C10 atoms counting from the carboxyl C atom. This bond is called a Δ⁹- or 9-double bond. In polyunsaturated fatty acids, the double bonds tend to occur at every third carbon atom (e.g., —CH=CH—CH₂—CH=CH—) and so are not conjugated (as in —CH=CH—CH=CH—). Two important classes of polyunsaturated fatty acids are designated as ω-3 or ω-6 fatty acids, a nomenclature that identifies the last double-bonded carbon atom as counted from the methyl terminal (ω) end of the chain. **α-Linolenic acid** and linoleic acid (Fig. 9-1) are examples of such fatty acids.

Saturated fatty acids (which are fully reduced or “saturated” with hydrogen) are highly flexible molecules that can assume a wide range of conformations because there is relatively free rotation around each of their C—C bonds. Nevertheless, their lowest energy conformation is the fully extended conformation, which has the least amount of steric interference between neighboring methylene groups. The melting points (mp) of saturated fatty acids, like those of most substances, increase with their molecular mass (Table 9-1).

Fatty acid double bonds almost always have the cis configuration (Fig. 9-1). This puts a rigid 30° bend in the hydrocarbon chain. Consequently, unsaturated fatty acids pack together less efficiently than saturated fatty acids. The reduced

26% for women) allows them to survive starvation for 2 to 3 months. In contrast, the body's glycogen supply, which functions as a short-term energy store, can provide for the body's energy needs for less than a day. The subcutaneous fat layer also provides thermal insulation, which is particularly important for warm-blooded aquatic animals, such as whales, seals, geese, and penguins, which are routinely exposed to low temperatures.

 **Consumption of trans fats causes cardiovascular disease.** The double bonds in unsaturated fats (fats containing unsaturated fatty acid residues) slowly react with the oxygen in air to yield aldehydes and carboxylates of shorter chain length, whose increased volatility results in an unpleasant rancid odor. To increase their stability, commercial oils that are to be used in cooking are partially hydrogenated (treated with H_2 in the presence of a metallic catalyst at high temperature and pressure). This eliminates some of their double bonds and thereby increases their melting temperatures (this is how margarine is produced from vegetable oils). Unfortunately, the conditions under which hydrogenation occurs have the undesirable side effect of converting some of the cis double bonds to trans double bonds, yielding **trans fats**. In recent decades, it has become increasingly clear that the consumption of significant amounts of trans fats causes a large increase in the incidence of cardiovascular disease by increasing the level of cholesterol in the blood (Section 20-7C). As a consequence, several European countries have banned foods containing trans fats. In the United States, the trans fat level must be stated on a food's Nutritional Facts label, and several municipalities have banned their use by restaurants.

C Glycerophospholipids Are Amphiphilic

Glycerophospholipids (or **phosphoglycerides**) are the major lipid components of biological membranes. They consist of **glycerol-3-phosphate** whose C1 and C2 positions are esterified with fatty acids. In addition, the phosphoryl group is linked to another usually polar group, X (Fig. 9-3). *Glycerophospholipids are therefore amphiphilic molecules with nonpolar aliphatic (hydrocarbon) "tails" and polar phosphoryl-X "heads."*

The simplest glycerophospholipids, in which $X = H$, are **phosphatidic acids**; they are present in only small amounts in biological membranes. In the glycerophospholipids that commonly occur in biological membranes, the head groups are derived from polar alcohols (Table 9-2). Saturated C_{16} or C_{18} fatty acids usually occur at the C1 position of the glycerophospholipids, and the C2 position is often occupied by an unsaturated C_{16} to C_{20} fatty acid. Individual glycerophospholipids are named according to the identities of these fatty acid residues (e.g., Fig. 9-4). A glycerophospholipid containing two palmitoyl chains is an important component of **lung surfactant** (Box 9-1).

GATEWAY CONCEPT: Molecular Behavior

A lipid's melting point seldom refers to the shift of one individual molecule from the solid to the liquid state; instead, it refers to the temperature at which a population of molecules collectively makes the transition between states. A transition temperature is therefore also useful for describing the behavior of a group of molecules that may not be identical, such as the lipids in a sample of oil, or the lipids that make up a biological membrane.

GATEWAY CONCEPT: Functional Groups

In addition to having substantial hydrophobic regions, which classifies them as lipids, membrane lipids include numerous types of functional groups, often several in one molecule. These polar and ionic groups add functionality to what would otherwise be relatively inert molecules.

FIG. 9-3 Structure of glycerophospholipids. (a) The backbone, L-glycerol-3-phosphate. (b) The general formula of the glycerophospholipids. R_1 and R_2 are the long-chain hydrocarbon tails of fatty acids, and X is derived from a polar alcohol (Table 9-2). Note that glycerol-3-phosphate and glycerophospholipid are chiral compounds.

TABLE 9-2 The Common Classes of Glycerophospholipids

Name of X—OH	Formula of —X	Name of Phospholipid
Water	—H	Phosphatidic acid
Ethanolamine	—CH ₂ CH ₂ NH ₃ ⁺	Phosphatidylethanolamine
Choline	—CH ₂ CH ₂ N(CH ₃) ₃ ⁺	Phosphatidylcholine (lecithin)
Serine	—CH ₂ CH(NH ₃ ⁺)COO ⁻	Phosphatidylserine
<i>myo</i> -Inositol		Phosphatidylinositol
Glycerol	—CH ₂ CH(OH)CH ₂ OH	Phosphatidylglycerol
Phosphatidylglycerol		Diphosphatidylglycerol (cardiolipin)

? Identify the functional groups in the glycerophospholipids.

FIG. 9-4 The glycerophospholipid 1-stearoyl-2-oleoyl-3-phosphatidylcholine. (a) Molecular formula in Fischer projection. (b) Energy-minimized space-filling model with C green, H white, N blue, O red, and P orange. Note how the unsaturated oleoyl chain (*left*) is bent compared to the saturated stearoyl chain. [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

1-Stearoyl-2-oleoyl-3-phosphatidylcholine

Dipalmitoylphosphatidylcholine (DPPC) is the major lipid of lung surfactant, the protein–lipid mixture that is essential for normal pulmonary function. The surfaces of the cells that form the alveoli (small air spaces of the lung) are coated with surfactant, which decreases the alveolar surface tension. Lung surfactant contains 80 to 90% phospholipid by weight, and 70 to 80% of the phospholipid is phosphatidylcholine, mostly the dipalmitoyl species.

Because the palmitoyl chains of DPPC are saturated, they tend to extend straight out without bending. This allows close packing of DPPC molecules, which are oriented in a single layer with their non-polar tails toward the air and their polar heads toward the alveolar cells. When air is expired from the lungs, the volume and surface area of the alveoli decrease. The collapse of the alveolar space is

prevented by the surfactant, because the closely packed DPPC molecules resist compression. Reopening a collapsed air space requires a much greater force than expanding an already open air space.

Lung surfactant is continuously synthesized, secreted, and recycled by alveolar cells. Because surfactant production is low until just before birth, premature infants are at risk of developing **respiratory distress syndrome**, which is characterized by difficulty in breathing due to alveolar collapse. The syndrome can be treated by introducing exogenous surfactant into the lungs. A related condition in adults (**adult respiratory distress syndrome**) is characterized by insufficient surfactant, usually secondary to other lung injury. This condition, too, can be treated with exogenous surfactant.

Phospholipases Hydrolyze Glycerophospholipids. The chemical structures—including fatty acyl chains and head groups—of glycerophospholipids can be determined from the products of the hydrolytic reactions catalyzed by enzymes known as **phospholipases**. For example, **phospholipase A₂** hydrolytically excises the fatty acid residue at C2, leaving a **lysophospholipid** (Fig. 9-5). Lysophospholipids, as their name implies, are powerful detergents that disrupt cell membranes, thereby lysing cells. Bee and snake venoms are rich sources of phospholipase A₂. Other types of phospholipases act at different sites in glycerophospholipids, as shown in Fig. 9-5.

Enzymes that act on lipids have fascinated biochemists because the enzymes must gain access to portions of the lipids that are buried in a nonaqueous environment. Phospholipase A₂, which constitute some of the best understood lipid-specific enzymes, are relatively small proteins (~14 kD, ~125 amino acid residues). The X-ray structure of phospholipase A₂ from cobra venom suggests that the enzyme binds a glycerophospholipid molecule such that its polar head group fits into the enzyme's active site, whereas the hydrophobic tails, which extend beyond the active site, interact with several aromatic side chains (Fig. 9-6).

Lipases specific for triacylglycerols and membrane lipids catalyze their degradation *in vivo*. Occasionally, the hydrolysis products are not destined for further degradation but instead serve as intra- and extracellular signal molecules. For example, **lysophosphatidic acid (1-acyl-glycerol-3-phosphate)**, which is not actually lytic since it has a small head group (an unsubstituted phosphate group), is produced by hydrolysis of membrane lipids in blood platelets and injured cells and stimulates cell growth as part of the wound-repair process. **1,2-Diacylglycerol**, derived from membrane lipids by the action of **phospholipase C**, is an intracellular

FIG. 9-6 Model of phospholipase A₂ and a glycerophospholipid. The X-ray structure of the enzyme from cobra venom is shown with a space-filling model of dimyristoylphosphatidylethanolamine in its active site as located by NMR methods. A Ca²⁺ ion in the active site is shown in magenta.

? Explain why Ca²⁺ is part of the lipid-binding site.

FIG. 9-5 Action of phospholipases. Phospholipase A₂ hydrolytically excises the C2 fatty acid residue from a phospholipid to yield the corresponding lysophospholipid. The bonds hydrolyzed by other types of phospholipases, which are named according to their specificities, are also indicated.

A plasmalogen

signal molecule that activates a **protein kinase** (Section 13-4C; kinases catalyze ATP-dependent phosphoryl-transfer reactions).

Plasmalogens Contain an Ether Linkage. **Plasmalogens** (at left) are glycerophospholipids in which the C1 substituent of the glycerol moiety is linked via an α,β -unsaturated ether linkage in the cis configuration rather than through an ester linkage. **Ethanolamine, choline,** and serine (Table 9-2) form the most common plasmalogen head groups. The functions of most plasmalogens are not well understood. Because the vinyl ether group is easily oxidized, plasmalogens may react with oxygen free radicals, by-products of normal metabolism, thereby preventing free-radical damage to other cell constituents.

D Sphingolipids Are Amino Alcohol Derivatives

Sphingolipids are also major membrane components. They were named after the Sphinx because their function in cells was at first mysterious. Most sphingolipids are derivatives of the C_{18} amino alcohol **sphingosine**, whose double bond has the trans configuration. The *N*-acyl fatty acid derivatives of sphingosine are known as **ceramides**:

Ceramides are the parent compounds of the more abundant sphingolipids:

1. **Sphingomyelins**, the most common sphingolipids, are ceramides bearing either a phosphocholine (Fig. 9-7) or a phosphoethanolamine head group, so they can also be classified as **sphingophospholipids**. They typically make up 10 to 20 mol % of plasma membrane lipids. *Although sphingomyelins differ chemically from phosphatidylcholine and phosphatidylethanolamine, their conformations and charge distributions are quite*

FIG. 9-7 A sphingomyelin. (a) Molecular formula. (b) Energy-minimized space-filling model with C green, H white, N blue, O red, and P orange. [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

similar (compare Figs. 9-4 and 9-7). The membranous myelin sheath that surrounds and electrically insulates many nerve cell axons is particularly rich in sphingomyelins (Fig. 9-8).

- Cerebrosides** are ceramides with head groups that consist of a single sugar residue. These lipids are therefore **glycosphingolipids**. **Galactocerebrosides** and **glucocerebrosides** are the most prevalent. Cerebrosides, in contrast to phospholipids, lack phosphate groups and hence are nonionic.
- Gangliosides** are the most complex glycosphingolipids. They are ceramides with attached oligosaccharides that include at least one sialic acid residue. The structures of **gangliosides G_{M1} , G_{M2} , and G_{M3}** , three of the hundreds that are known, are shown in Fig. 9-9. Gangliosides are primarily components of cell-surface membranes and constitute a significant fraction (6%) of brain lipids.

 Gangliosides have considerable physiological and medical significance. Their complex carbohydrate head groups, which extend beyond the surfaces of cell membranes, act as specific receptors for certain pituitary glycoprotein hormones that regulate a number of important physiological functions. Gangliosides are also receptors for certain bacterial protein toxins such as **cholera toxin**. There is considerable evidence that gangliosides are specific determinants of cell-cell recognition, so they probably have an important role in the growth and differentiation of tissues as well as in carcinogenesis. Disorders of ganglioside breakdown are responsible for several hereditary **sphingolipid storage diseases**, such as **Tay-Sachs disease** (Box 20-4), which are characterized by an invariably fatal neurological deterioration in early childhood.

Sphingolipids, like glycerophospholipids, are a source of smaller lipids that have discrete signaling activity. Sphingomyelin itself, as well as the ceramide portions of more complex sphingolipids, appear to specifically modulate the activities of protein kinases and **protein phosphatases** (enzymes that remove phosphoryl groups from proteins) that are involved in regulating cell growth and differentiation.

Cyclopentanoperhydrophenanthrene

E Steroids Contain Four Fused Rings

Steroids, which are mostly of eukaryotic origin, are derivatives of **cyclopentanoperhydrophenanthrene** (at left), a compound that consists of four fused, nonplanar rings (labeled A–D). The much maligned **cholesterol**, which is the most abundant steroid in animals, is further classified as a **sterol** because of its C3-OH group (Fig. 9-10). Cholesterol is a major component of animal plasma membranes, typically constituting 30 to 40 mol % of plasma membrane lipids. Its polar OH group gives it a weak amphiphilic character, whereas its fused ring system provides it with greater rigidity than other membrane lipids. Cholesterol can also be esterified to long-chain fatty acids to form **cholesteryl esters**, such as **cholesteryl stearate**.

Cholesteryl stearate

Plants contain little cholesterol but synthesize other sterols. Yeast and fungi also synthesize sterols, which differ from cholesterol in their aliphatic side chains and number of double bonds. Prokaryotes contain little, if any, sterol.

In mammals, cholesterol is the metabolic precursor of **steroid hormones**, substances that control a great variety of physiological functions through their regulation of gene expression (Section 28-3B). The structures of some steroid hormones are shown in Fig. 9-11. Steroid hormones are classified according to the physiological responses they evoke:

1. The **glucocorticoids**, such as **cortisol** (a C₂₁ compound), affect carbohydrate, protein, and lipid metabolism and influence a wide variety of other vital functions, including inflammatory reactions and the capacity to cope with stress.
2. **Aldosterone** and other **mineralocorticoids** regulate the excretion of salt and water by the kidneys.
3. The **androgens** and **estrogens** affect sexual development and function. **Testosterone**, a C₁₉ compound, is the prototypic androgen (male sex hormone), whereas **β-estradiol**, a C₁₈ compound, is an estrogen (female sex hormone).

Glucocorticoids and mineralocorticoids are synthesized by the cortex (outer layer) of the adrenal gland. Both androgens and estrogens are synthesized by testes and ovaries (although androgens predominate in testes and estrogens

FIG. 9-11 Some representative steroid hormones.

predominate in ovaries) and, to a lesser extent, by the adrenal cortex. Because steroid hormones are water insoluble, they bind to proteins for transport through the blood to their target tissues.

Impaired adrenocortical function, either through disease or trauma, results in **Addison's disease**, which is characterized by **hypoglycemia** (decreased amounts of glucose in the blood), muscle weakness, Na^+ loss, K^+ retention, impaired cardiac function, and greatly increased susceptibility to stress. The victim, unless treated by the administration of glucocorticoids and mineralocorticoids, slowly languishes and dies without any particular pain or distress. Conversely, adrenocortical hyperfunction, which is often caused by a tumor of the adrenal cortex, results in **Cushing's syndrome**, which is characterized by fatigue, **hyperglycemia** (increased amount of glucose in the blood), **edema** (water retention), and a redistribution of body fat to yield a characteristic "moon face."

Vitamin D Regulates Ca^{2+} Metabolism. The various forms of **vitamin D**, which are really hormones, are sterol derivatives in which the steroid B ring is disrupted between C9 and C10:

**1 α ,25-Dihydroxycholecalciferol**

Vitamin D₂ (ergocalciferol) is nonenzymatically formed in the skin of animals through the photolytic action of UV light on the plant sterol **ergosterol**, a common milk additive, whereas the closely related **vitamin D₃ (cholecalciferol)** is similarly derived from **7-dehydrocholesterol** (hence the saying that sunlight provides vitamin D).

Vitamins D₂ and D₃ are inactive; the active forms are produced through their enzymatic hydroxylation (addition of an OH group) carried out by the liver (at C25) and by the kidney (at C1) to yield **1 α ,25-dihydroxycholecalciferol** (at left). Active vitamin D increases serum [Ca²⁺] by promoting the intestinal absorption of dietary Ca²⁺. This increases the deposition of Ca²⁺ in bones and teeth.

 Vitamin D deficiency in children produces **rickets**, a disease characterized by stunted growth and deformed bones caused by insufficient bone mineralization. Although rickets was first described in 1645, it was not until the early twentieth century that eating animal fats, particularly fish liver oils, was shown to prevent this deficiency disease. Rickets can also be prevented by exposing children to sunlight or just UV light in the wavelength range 230 to 313 nm, regardless of their diets.

Since vitamin D is water insoluble, it can accumulate in fatty tissues. Excessive intake of vitamin D over long periods results in **vitamin D intoxication**. The consequent high serum [Ca²⁺] results in aberrant calcification of soft tissues and in the development of kidney stones, which can cause kidney failure. The observation that the level of skin pigmentation in indigenous human populations tends to increase with their proximity to the equator is explained by the hypothesis that skin pigmentation functions to prevent vitamin D intoxication by filtering out excessive solar radiation.

F Other Lipids Perform a Variety of Metabolic Roles

In addition to the well-characterized lipids that are found in large amounts in cellular membranes, many organisms synthesize compounds that are not membrane components but are classified as lipids on the basis of their physical properties. For example, lipids occur in the waxy coatings of plants, where they protect cells from desiccation by creating a water-impermeable barrier.

Isoprenoids Are Built from Five-Carbon Units. Among the compounds that are not structural components of membranes—although they are soluble in the lipid bilayer—are the **isoprenoids**, which are built from five-carbon units with the same carbon skeleton as **isoprene**.

For example, the isoprenoid **ubiquinone** (also known as **coenzyme Q**) is reversibly reduced and oxidized in the mitochondrial membrane (its activity is described in more detail in Section 18-2C). Mammalian ubiquinone consists of 10 isoprenoid units.

The plant kingdom is rich in isoprenoid compounds, which serve as pigments, molecular signals (hormones and pheromones), and defensive agents. Indeed, over 50,000 isoprenoids (also known as **terpenoids**), which are mostly of plant, fungal, and bacterial origin, have been characterized. During the course of evolution,

vertebrate metabolism has co-opted several of these compounds for other purposes. Some of these compounds (e.g., vitamin D) are known as **fat-soluble vitamins** (**vitamins** are organic substances that an animal requires in small amounts but cannot synthesize and hence must acquire in its diet).

Vitamin A, or **retinol**, is derived mainly from plant products such as **β -carotene** [a red pigment that is present in green vegetables as well as in carrots (after which it is named) and tomatoes; Section 19-1B]. Retinol is oxidized to its corresponding aldehyde, **retinal** (*at right*), which functions as the eye's photoreceptor at low light intensities. Light causes the retinal to isomerize, triggering, via a complex signaling pathway, an impulse through the optic nerve. A severe deficiency of vitamin A can lead to blindness. Retinoic acid also has hormonelike properties in that it stimulates tissue repair. It is used to treat severe acne and skin ulcers and is also used cosmetically to eliminate wrinkles.

Vitamin K is a lipid synthesized by plants (as **phyloquinone**) and bacteria (as **menaquinone**):

About half of the daily requirement for humans is supplied by intestinal bacteria. Vitamin K participates in the carboxylation of Glu residues in some of the proteins involved in blood clotting (vitamin K is named for the Danish word *Koagulation*). Vitamin K deficiency prevents this carboxylation, and the resulting inactive clotting proteins lead to excessive bleeding. Compounds that interfere with vitamin K function are widely used as anti-clotting drugs (e.g., to prevent clot formation after surgery), as well as being the active ingredients in some rodent poisons.

Vitamin E is actually a group of compounds whose most abundant member is **α -tocopherol**:

This highly hydrophobic molecule is incorporated into cell membranes, where it functions as an antioxidant that prevents oxidative damage to membrane proteins and lipids. A deficiency of vitamin E elicits a variety of nonspecific symptoms, which makes the deficiency difficult to detect. The popularity of vitamin E supplements rests on the hypothesis that vitamin E protects against oxidative damage to cells and hence reduces the effects of aging. However, clinical trials have shown that this is not the case and that excessive intake of vitamin E may even increase the risk of certain cancers.

Eicosanoids Are Derived from Arachidonic Acid. Other less common lipids are derived from relatively abundant membrane lipids. **Prostaglandins** (e.g.,

X = CH₂OH

FIG. 9-12 Eicosanoids. Arachidonate is the precursor of prostaglandins (PG), prostacyclins, thromboxanes (Tx), and lipoxins (LX). Arachidonate also leads to leukotrienes. Although only a single example of each type

of eicosanoid is shown, each has numerous physiologically significant derivatives, which are designated by letters and subscripts (e.g., **PGH₂** for **prostaglandin H₂**).

? What types of modifications convert arachidonate to the other eicosanoids shown here?

CHECKPOINT

- How do lipids differ from the three other major classes of biological molecules?
- Explain the trend in melting point with increasing fatty acid chain length. Explain the trend with increasing number of double bonds.
- Explain why fats contain ~38 kJ of energy per gram, whereas carbohydrates contain ~17 kJ per gram.
- Summarize the structures and physical properties of fatty acids, triacylglycerols, glycerophospholipids, sphingolipids, and steroids.
- Which lipids can be considered to be glycolipids? Phospholipids? Which are ionic?
- Summarize the functions of steroids and eicosanoids.

(Fig. 9-12) were discovered in the 1930s by Ulf von Euler, who thought they were produced by the prostate gland. Prostaglandins and related compounds—**prostacyclins, thromboxanes, leukotrienes, and lipoxins**—are known collectively as **eicosanoids** because they are all C₂₀ compounds (Greek: *eikosi*, twenty). *The eicosanoids act at very low concentrations and are involved in the production of pain and fever, and in the regulation of blood pressure, blood coagulation, and reproduction.* Unlike most other types of hormones, eicosanoids are not transported by the bloodstream to their sites of action but tend to act locally, close to the cells that produced them. In fact, most eicosanoids decompose within seconds or minutes, which limits their effects on nearby tissues. The synthesis of the eicosanoids is discussed in Section 20-6C.

In humans, the most important eicosanoid precursor is **arachidonic acid**, a C₂₀ polyunsaturated fatty acid with four double bonds (Table 9-1). Arachidonate is stored in cell membranes as the C2 ester of **phosphatidylinositol** (Table 9-2) and other phospholipids. The fatty acid residue is released by the action of phospholipase A₂ (Fig. 9-5).

The specific products of arachidonate metabolism are tissue-dependent. For example, platelets produce thromboxanes almost exclusively, but endothelial cells that line the walls of blood vessels predominantly synthesize prostacyclins. Interestingly, thromboxanes stimulate vasoconstriction and platelet aggregation (which helps initiate blood clotting), while prostacyclins elicit the opposite effects. Thus, the two substances act in opposition to maintain a balance in the cardiovascular system.

FIG. 9-13 Aggregates of single-tailed lipids. The tapered van der Waals envelope of these lipids (a) permits them to pack efficiently to form a spheroidal micelle (b). The diameter of the micelles depends on the length of the tails. Spheroidal micelles composed of many more

lipid molecules than the optimal number (c) would have an unfavorable water-filled center (blue). Such micelles could flatten out to collapse the hollow center, but as these ellipsoidal micelles become elongated (d), they also develop water-filled spaces.

? Give an example of a single-tailed lipid.

2 Lipid Bilayers

KEY CONCEPTS

- Certain amphiphilic molecules form bilayers.
- The bilayer is a fluid structure in which lipids rapidly diffuse laterally.

In living systems, lipids are seldom found as free molecules but instead associate with other molecules, usually other lipids. In this section, we discuss how lipids aggregate to form micelles and bilayers. We are concerned with the physical properties of lipid bilayers because these aggregates form the structural basis for biological membranes.

A Bilayer Formation Is Driven by the Hydrophobic Effect

In aqueous solutions, amphiphilic molecules such as soaps and detergents form micelles (globular aggregates whose hydrocarbon groups are out of contact with water; Section 2-1C). This molecular arrangement eliminates unfavorable contacts between water and the hydrophobic tails of the amphiphiles and yet permits the solvation of the polar head groups.

The approximate size and shape of a micelle can be predicted from geometrical considerations. Single-tailed amphiphiles, such as soap anions, form spheroidal or ellipsoidal micelles because of their tapered shapes (their hydrated head groups are wider than their tails; Fig. 9-13a,b). The number of molecules in such a micelle depends on the amphiphile, but for many substances it is on the order of several hundred. Too few lipid molecules would expose the hydrophobic core of the micelle to water, whereas too many would give the micelle an energetically unfavorable hollow center (Fig. 9-13c). Of course, a large micelle could flatten out to eliminate this hollow center, but the resulting decrease of curvature at the flattened surfaces would also generate empty spaces (Fig. 9-13d).

The two hydrocarbon tails of glycerophospholipids and sphingolipids give these amphiphiles a somewhat rectangular cross section (Fig. 9-14a). The steric requirements of packing such molecules together yield large disklike micelles (Fig. 9-14b) that are really extended bimolecular leaflets. These **lipid bilayers** are ~60 Å thick, as measured by electron microscopy and X-ray diffraction techniques, the value expected for more or less fully extended hydrocarbon tails.

GATEWAY CONCEPT: The Hydrophobic Effect

The hydrophobic tails of amphiphilic lipids do not attract each other (except when they are very closely packed together). They are driven to associate with each other by the hydrophobic effect—a consequence of the surrounding water molecules maximizing their entropy.

FIG. 9-14 Bilayer formation by phospholipids. The cylindrical van der Waals envelope of these lipids (a) causes them to form extended disklike micelles (b) that are better described as lipid bilayers.

FIG. 9-15 Electron micrograph of a liposome. Its wall, as the accompanying diagram indicates, consists of a lipid bilayer.

? Explain why solutes inside the liposome do not diffuse out of the liposome.

A suspension of phospholipids (glycerophospholipids or sphingomyelins) can form **liposomes**—closed, self-sealing solvent-filled vesicles that are bounded by only a single bilayer (**Fig. 9-15**). They typically have diameters of several hundred angstroms and, in a given preparation, are rather uniform in size. Once formed, liposomes are quite stable and can be purified by dialysis, gel filtration chromatography, or centrifugation. Liposomes whose internal environment differs from the surrounding solution can therefore be readily prepared. Liposomes serve as models of biological membranes and also hold promise as vehicles for drug delivery since they are absorbed by many cells through fusion with the plasma membrane.

B Lipid Bilayers Have Fluidlike Properties

The transfer of a lipid molecule across a bilayer (**Fig. 9-16a**), a process termed **transverse** diffusion or a **flip-flop**, is an extremely rare event. This is because a flip-flop requires the hydrated, polar head group of the lipid to pass through the anhydrous hydrocarbon core of the bilayer. The flip-flop rates of phospholipids have half-times of several days or more. In contrast to their low flip-flop rates, **lipids are highly mobile in the plane of the bilayer (lateral diffusion; Fig. 9-16b)**. It has been estimated that lipids in a membrane can diffuse the 1- μm length of a bacterial cell in ~ 1 s. Because of the mobilities of the lipids, the lipid bilayer can be considered to be a two-dimensional fluid.

The interior of the lipid bilayer is in constant motion due to rotations around the C—C bonds of the lipid tails. Various physical measurements suggest that the interior of the bilayer has the viscosity of light machine oil. This feature of the bilayer core is evident in **molecular dynamics simulations**, in which the time-dependent positions of atoms are predicted from calculations of the forces acting on them (**Fig. 9-17**). The viscosity of the bilayer increases dramatically closer to

(a) **Transverse diffusion (flip-flop)**

(b) **Lateral diffusion**

FIG. 9-16 Phospholipid diffusion in a lipid bilayer. (a) Transverse diffusion (a flip-flop) is defined as the transfer of a phospholipid molecule from one bilayer leaflet to the other. (b) Lateral diffusion is defined as the pairwise exchange of neighboring phospholipid molecules in the same bilayer leaflet.

FIG. 9-17 Model (snapshot) of a lipid bilayer at an instant in time. The conformations of dipalmitoylphosphatidylcholine molecules in a bilayer surrounded by water were modeled by computer. Atom colors are chain and glycerol C gray except terminal methyl C yellow, ester O red, phosphate P and O green, and choline C and N magenta. Water molecules are represented by translucent blue spheres (those near the bilayer appear dark because they overlap head group atoms).

? If hexane molecules were added to this system, where would they be located?

(a) Above transition temperature

(b) Below transition temperature

FIG. 9-18 Phase transition in a lipid bilayer. (a) Above the transition temperature, both the lipid molecules as a whole and their nonpolar tails are highly mobile in the plane of the bilayer. (b) Below the transition temperature, the lipid molecules form a much more orderly array to yield a gel-like solid. [After Robertson, R.N., *The Lively Membranes*, pp. 69–70, Cambridge University Press (1983).]

? How would changes in fatty acid chain length and degree of saturation affect the bilayer's transition temperature?

the lipid head groups, whose rotation is limited and whose lateral mobility is more constrained by interactions between other polar or charged head groups.

Note that the hydrophobic tails of the lipids shown in Fig. 9-17 are not stiffly regimented as Fig. 9-16 might suggest, but instead bend and interdigitate. A typical biological membrane includes many different lipid molecules, some of whose tails are of different lengths or are kinked due to the presence of double bonds. Under physiological conditions, highly mobile chains fill any gaps that might form between lipids in the bilayer interior.

The model bilayer shown in Fig. 9-17 indicates that the phospholipids bob up and down to some degree. This is also the case in naturally occurring membranes, which contain a variety of different lipid head groups that must nestle among one another. The polar nature of the outer surface of the bilayer extends from the head groups to the carbonyl groups of the ester and amide bonds that link the fatty acyl chains. Consequently, water molecules penetrate a lipid bilayer to a depth of up to 15 Å, avoiding only the central ~30 Å hydrocarbon core.

The Fluidity of a Lipid Bilayer Is Temperature-Dependent. *As a lipid bilayer cools below a characteristic **transition temperature**, it undergoes a sort of phase change in which it becomes a gel-like solid; that is, it loses its fluidity (Fig. 9-18).* Above the transition temperature, the highly mobile lipids are in a state known as a **liquid crystal** because they are ordered in some directions but not in others. The bilayer is thicker in the gel state than in the liquid crystal state due to the stiffening of the hydrocarbon tails at lower temperatures.

The transition temperature of a bilayer increases with the chain length and the degree of saturation of its component fatty acid residues for the same reasons that the melting points of fatty acids increase with these quantities. The transition temperatures of most biological membranes are in the range 10 to 40°C. Bacteria and cold-blooded animals such as fish modify (through lipid synthesis and degradation) the fatty acid compositions of their membrane lipids with ambient temperature so as to maintain a constant level of fluidity. Thus, the fluidity of biological membranes is one of their important physiological attributes.

Cholesterol, which by itself does not form a bilayer, decreases membrane fluidity because its rigid steroid ring system interferes with the motions of the fatty acid side chains in other membrane lipids. It also broadens the temperature range of the phase transition. This is because cholesterol inhibits the ordering of fatty acid side chains by fitting in between them. Thus, cholesterol functions as a kind of membrane plasticizer.

CHECKPOINT

- Why do glycerophospholipids and sphingolipids—but not fatty acids—form bilayers?
- Explain why lateral diffusion of membrane lipids is faster than transverse diffusion.
- What factors influence the fluidity of a bilayer?

3 Membrane Proteins

KEY CONCEPTS

- Integral membrane proteins contain a transmembrane structure consisting of α helices or a β barrel with a hydrophobic surface.
- Lipid-linked proteins have a covalently attached prenyl group, fatty acyl group, or glycosylphosphatidylinositol group.
- Peripheral membrane proteins interact noncovalently with proteins or lipids at the membrane surface.

Biological membranes contain proteins as well as lipids. The exact lipid and protein components and the ratio of protein to lipid varies with the identity of the membrane. For example, the lipid-rich myelinated membranes that surround and insulate certain nerve axons (Fig. 9-8) are only 19% protein by mass, whereas the protein-rich inner membrane of mitochondria, which mediates numerous chemical reactions, is 76% protein by mass. Eukaryotic plasma membranes are typically $\sim 50\%$ protein by mass.

Membrane proteins catalyze chemical reactions, mediate the flow of nutrients and wastes across the membrane, and participate in relaying information about the extracellular environment to various intracellular components. Such proteins carry out their functions in association with the lipid bilayer. They must therefore interact to some degree with the hydrophobic core and/or the polar surface of the bilayer. In this section, we examine the structures of some membrane proteins, which are classified by their mode of interaction with the membrane.

A Integral Membrane Proteins Interact with Hydrophobic Lipids

Integral or **intrinsic proteins** (Fig. 9-19) associate tightly with membranes through hydrophobic interactions and can be separated from membranes only by treatment with agents that disrupt membranes. For example, detergents such as sodium dodecyl sulfate (Section 5-2D) solubilize membrane proteins by replacing the membrane lipids that normally surround the protein. The hydrophobic portions of the detergent molecules coat the hydrophobic regions of the protein, and the polar head groups render the detergent-protein complex soluble in water. Chaotropic agents such as guanidinium ion and urea (Section 6-4B) disrupt water structure, thereby reducing the hydrophobic effect, the primary force stabilizing the association of the protein with the membrane. Some integral proteins bind lipids so tenaciously that they can be freed from them only under denaturing conditions.

Once they have been solubilized, integral proteins can be purified by many of the protein fractionation methods described in Section 5-2. Since these proteins tend to aggregate and precipitate in aqueous solution, their solubility frequently requires the presence of detergents or water-miscible organic solvents such as butanol or glycerol. Although membrane proteins comprise $\sim 30\%$ of all proteins, the consequent difficulty of crystallizing them has limited the number of membrane protein X-ray structures to 2.5% of all known protein structures.

FIG. 9-19 X-Ray structure of the integral membrane protein aquaporin-0 (AQPO) in association with lipids. The protein is represented by its surface diagram, which is colored according to charge (red negative, blue positive, and white uncharged). Tightly bound molecules of dimyristoylphosphatidylcholine are drawn in space-filling form with C green, O red, and P orange. Note how the lipid tails closely conform to the nonpolar surface of the protein, thereby solvating it. The arrangement of the two rows of lipid molecules, with phosphate-phosphate distances of ~ 35 Å, matches the dimensions of a lipid bilayer. [Based on an electron crystallographic structure by Stephen Harrison and Thomas Walz, Harvard Medical School. PDBid 2B60.]

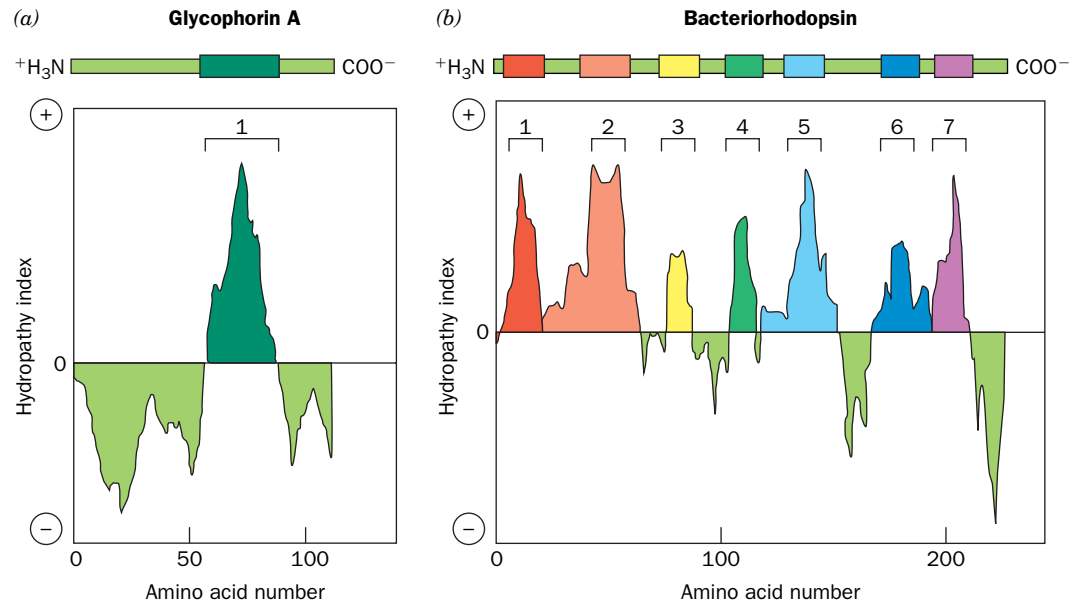

FIG. 9-21 The identification of transmembrane helices by hydropathy plots. The average of the hydropathy indices of the amino acid residues in a sliding window of defined length is plotted against the position of the first amino acid in the window. A positive value indicates that the peptide segment in the window is hydrophobic; that is, its transfer to water would require an input of free energy. Segments of >20 hydrophobic residues (sufficient for an α helix to span a bilayer) are likely to form TM helices. The plots here are for (a) glycophorin A and (b) bacteriorhodopsin. The bar above each plot and the square brackets indicate the experimentally determined positions of the TM helices in the corresponding protein. Note that glycophorin A has only one TM helix, whereas bacteriorhodopsin has seven TM helices. [After a drawing by Alberts, B., Johnson, A., Lewis, J., Morgan, D., Raff, M., Roberts, K., and Walter, P., *Molecular Biology of the Cell* (6th ed.). p. 579 (2015).

Transmembrane Proteins May Contain α Helices. For a polypeptide chain to penetrate or span the lipid bilayer, it must have hydrophobic side chains that contact the lipid tails and it must shield its polar backbone groups. This second requirement is met by the formation of secondary structure that satisfies the hydrogen-bonding capabilities of the polypeptide backbone. Consequently, all known TM segments of integral membrane proteins consist of either α helices or β sheets. For example, glycophorin A's 19-residue TM sequence, as NMR studies indicate, forms an α helix. The existence of such TM helices can be predicted with reasonable reliability by plotting the average hydropathy index (e.g., Table 6-3) in a short (10–20 residue) segment of a polypeptide versus each segment's first amino acid (Fig. 9-21). Methods for predicting the positions of TM α helices are useful because of the difficulty in crystallizing integral membrane proteins.

Nigel Unwin and Richard Henderson used **electron crystallography** to determine the structure of the integral membrane protein **bacteriorhodopsin** (Box 9-2). This 247-residue homotrimeric protein, which is produced by the halophilic (salt-loving) archaeobacterium *Halobacterium salinarum* (it grows best in 4.3 M NaCl), is a light-driven proton pump: It generates a proton concentration gradient across the cell membrane that powers ATP synthesis by a mechanism discussed in Section 18-3B. A covalently bound retinal (Section 9-1F) is the protein's light-absorbing group. Bacteriorhodopsin consists largely of a bundle of seven ~ 25 -residue α -helical rods that span the lipid bilayer in directions almost perpendicular to the bilayer plane (Fig. 9-22). As expected,

FIG. 9-22 The structure of bacteriorhodopsin. The protein is shown in ribbon form as viewed from within the membrane plane and colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Its covalently bound retinal is drawn in stick form (magenta). [Based on an X-ray structure by Nikolaus Grigorieff and Richard Henderson, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2BRD.]

? Draw lines to indicate where the surfaces of the membrane would be located.

the amino acid side chains that contact the lipid tails are highly hydrophobic (Fig. 9-21*b*). Successive membrane-spanning helices are connected in head-to-tail fashion by hydrophilic loops of varying size. This arrangement places the protein's charged residues near the surfaces of the membrane in contact with the aqueous environment.

Hydrophobic effects, as we saw in Section 6-4A, are the dominant forces stabilizing the three-dimensional structures of water-soluble globular proteins. However, since the TM regions of integral membrane proteins are immersed in nonpolar environments, what stabilizes their structures? Analysis of integral protein structures indicates that their interior residues have hydrophobicities comparable to those of water-soluble proteins. However, the membrane-exposed residues of these proteins, on average, are even more hydrophobic than their interior residues. Evidently, *the structures of both integral and water-soluble proteins are stabilized by the exclusion of their interior residues from the surrounding solvent, but in the case of integral proteins, the solvent is the*

Box 9-2 Pathways of Discovery

Richard Henderson and the Structure of Bacteriorhodopsin

Richard Henderson (1945–) Richard Henderson, like a number of other pioneering structural biologists, began his career as a physicist. He turned his attention to membrane proteins because of their importance in cellular metabolic, transport, and signaling phenomena. Unlike globular proteins, which are soluble in aqueous solution from which they can often be crystallized, integral membrane proteins aggregate in aqueous solution and hence can be kept in solution only by the presence of a suitable detergent. In spite

of this, such solubilized proteins rarely crystallize in a manner suitable for X-ray analysis (and none had been made to do so at the time that Henderson began his studies). To circumvent this obstacle, Henderson adapted the technique of electron crystallography to macromolecules, using the membrane protein bacteriorhodopsin as his subject.

Bacteriorhodopsin was discovered in 1967, and its function as a proton pump was described shortly thereafter. The protein is synthesized by halophilic archaeobacteria such as *H. salinarum* (formerly known as *H. halobium*). In addition to bacteriorhodopsin, the archaeal rhodopsin family includes chloride-pumping and sensory proteins. Similar proteins have also been identified in eubacteria and in unicellular eukaryotes. What made bacteriorhodopsin attractive as a research subject is its relatively small size (248 residues), its stability, and—most importantly—its unusual proclivity to form ordered two-dimensional arrays in the bacterial cell membrane. In *H. salinarum*, such arrays, which occur as 0.5- μ m-wide patches, are known as purple membranes due to the color of the protein's bound retinal molecule. Each purple membrane patch, which is essentially a two-dimensional crystal, consists of 75% bacteriorhodopsin and 25% lipid.

At the time that Henderson began his structural studies of bacteriorhodopsin, the X-ray structures of only around a dozen different globular proteins had been reported. Henderson, working with Nigel Unwin, adapted the principles of X-ray crystallography to the two-dimensional bacteriorhodopsin crystals by measuring the diffraction intensities generated by the electron beam (Section 6-2A) from an electron microscope impinging on a purple membrane patch. It was necessary to use an electron beam rather than X-rays because the electron microscope can focus its electron beam on the microscopically small purple membrane patches. Nevertheless, only very low electron beam intensities could be used because otherwise the resulting radiation damage would destroy the

purple membrane. Consequently, to obtain diffraction data of sufficiently high signal-to-noise ratio, the diffraction patterns of around one hundred or more purple membrane samples had to be averaged.

Working at the limits of the available technology, Henderson and Unwin, in 1975, published a low-resolution model for the structure of bacteriorhodopsin. This was the first glimpse of an integral membrane protein. Its seven transmembrane helices were clearly visible as columns of electron density that were approximately perpendicular to the plane of the membrane. However, to obtain three-dimensional diffraction data, a two-dimensional crystal must be systematically tilted relative to the electron beam. Mechanical limitations that prevented the sample from being tilted to the degree necessary to obtain a full three-dimensional data set as well as other technical difficulties therefore yielded a model that had a resolution of 7 Å in the plane of the membrane but only 14 Å in a perpendicular direction. Consequently, the polypeptide loops connecting the seven helices could not be discerned, nor were the protein's associated retinal molecule or any of its side chains visible. However, over the next 15 years, developments in electron microscopy, such as the use of better electron sources and liquid-helium temperatures to minimize radiation damage to the sample, permitted Henderson to extend the resolution of the bacteriorhodopsin structure to 3.5 Å in the plane of the membrane and 10 Å in the perpendicular direction. The resulting electron density map clearly revealed the positions of several bulky aromatic residues and the bound retinal and permitted the loops connecting the transmembrane helices to be visualized. Thus, electron crystallography has become a useful tool for determining the structures of a variety of proteins that can be induced to form two-dimensional arrays as well as those that form very thin three-dimensional crystals.

Henderson's groundbreaking work on bacteriorhodopsin made a seminal contribution to the growing body of biochemical, genetic, spectroscopic, and structural studies of bacteriorhodopsin. This information, together with more recent high-resolution X-ray structures derived from three-dimensional crystals of bacteriorhodopsin, obtained by crystallizing the protein in a lipid matrix, have led to a detailed understanding of the mechanism of the light-induced structural changes through which bacteriorhodopsin pumps protons out of the bacterial cell.

lipid bilayer. In addition, the low polarity and anhydrous environments of transmembrane proteins are likely to strengthen their hydrogen bonds relative to those of soluble proteins.

Some Transmembrane Proteins Contain β Barrels. A protein segment immersed in the nonpolar interior of a membrane must fold so that it satisfies the hydrogen-bonding potential of its polypeptide backbone. An α helix can do so as can an antiparallel β sheet that rolls up to form a barrel (a β barrel; Section 6-2C). Transmembrane β barrels of known structure consist of 8 to 22 strands. The number of strands must be even to permit the β sheet to close up on itself with all strands antiparallel.

β Barrels occur in **porins**, which are channel-forming proteins in the outer membrane of gram-negative bacteria (Section 8-3B). The outer membrane protects the bacteria from hostile environments while the porins permit the entry of small polar solutes such as nutrients. Porins also occur in eukaryotes in the outer membranes of mitochondria and chloroplasts (consistent with the descent of these organelles from free-living gram-negative bacteria; Section 1-2C).

Bacterial porins are monomers or trimers of identical 30- to 50-kD subunits. X-Ray structural studies show that most porin subunits consist largely of at least a 16-stranded antiparallel β barrel that forms a solvent-accessible central channel with a length of ~ 55 Å and a minimum diameter of ~ 7 Å (Fig. 9-23). As expected, the side chains of the protein's membrane-exposed surface are nonpolar,

thereby forming an $\sim 25\text{-\AA}$ -high hydrophobic band encircling the trimer (Fig. 9-23c). This band is flanked by more polar aromatic side chains (Table 6-3) that form interfaces with the head groups of the lipid bilayer (Fig. 9-23c). In contrast, the side chains at the solvent-exposed surface of the protein, including those lining the walls of the aqueous channel, are polar. Possible mechanisms for the solute selectivity of porins are discussed in Section 10-2B.

B Lipid-Linked Proteins Are Anchored to the Bilayer

Some membrane-associated proteins contain covalently attached lipids that anchor the protein to the membrane. The lipid group, like any modifying group, may also mediate protein–protein interactions or modify the structure and activity of the protein to which it is attached. **Lipid-linked proteins** come in three varieties: prenylated proteins, fatty acylated proteins, and glycosylphosphatidylinositol-linked proteins. A single protein may contain more than one covalently linked lipid group.

Prenylated proteins have covalently attached lipids that are built from isoprene units (Section 9-1F). The most common isoprenoid groups are the C_{15} **farnesyl** and C_{20} **geranylgeranyl** residues.

The most common prenylation site in proteins is the C-terminal tetrapeptide C–X–X–Y, where C is Cys and X is often an aliphatic amino acid residue. Residue Y influences the type of prenylation: Proteins are farnesylated when Y is Ala, Met, or Ser and geranylgeranylated when Y is Leu. In both cases, the prenyl group is enzymatically linked to the Cys sulfur atom via a thioether linkage. The X–X–Y tripeptide is then proteolytically excised, and the newly exposed terminal carboxyl group is esterified with a methyl group, producing a C-terminus with the structure shown.

Prenylated proteins are mainly anchored to intracellular membranes and to the cytoplasmic face of the plasma membrane.

Two kinds of fatty acids, myristic acid and palmitic acid, are linked to membrane proteins. Myristic acid, a biologically rare saturated C_{14} fatty acid, is appended to a protein via an amide linkage to the α -amino group of an N-terminal Gly residue. **Myristoylation** is stable: The fatty acyl group remains attached to the protein throughout its lifetime. Myristoylated proteins are located in a number of subcellular compartments, including the cytosol, the endoplasmic reticulum, the inner face of the plasma membrane, and the nucleus.

FIG. 9-24 The core structure of the GPI anchors of proteins. R₁ and R₂ represent fatty acid residues whose identities vary with the protein. The tetrasaccharide may have a variety of attached sugar residues whose identities also vary.

In **palmitoylation**, the saturated C₁₆ fatty acid palmitic acid is joined in thioester linkage to a specific Cys residue. Palmitoylated proteins occur almost exclusively on the cytoplasmic face of the plasma membrane, where many participate in transmembrane signaling. The palmitoyl group can be removed by the action of **palmitoyl thioesterases**, suggesting that reversible palmitoylation may regulate the association of the protein with the membrane and thereby modulate the signaling processes.

Glycosylphosphatidylinositol-linked proteins (GPI-linked proteins) occur in all eukaryotes but are particularly abundant in some parasitic protozoa, which contain relatively few membrane proteins anchored by transmembrane polypeptide segments. Like glycoproteins and glycolipids, GPI-linked proteins are located only on the exterior face of the plasma membrane.

The core structure of the GPI group consists of phosphatidylinositol (Table 9-2) glycosidically linked to a linear tetrasaccharide composed of three mannose residues and one glucosaminyl residue (Fig. 9-24). The mannose at the nonreducing end of this assembly forms a phosphodiester bond with a phosphoethanolamine residue that is amide-linked to the protein's C-terminal carboxyl group. The core tetrasaccharide is generally substituted with a variety of sugar residues that vary with the identity of the protein. There is likewise considerable diversity in the fatty acid residues of the phosphatidylinositol group.

C Peripheral Proteins Associate Loosely with Membranes

Peripheral or **extrinsic proteins**, unlike integral membrane proteins or lipid-linked proteins, can be dissociated from membranes by relatively mild procedures that leave the membrane intact, such as exposure to high ionic strength salt solutions or pH changes. Peripheral proteins do not bind lipid and, once purified, behave like water-soluble proteins. They associate with membranes by binding at their surfaces, most likely to certain lipids or integral proteins, through electrostatic and hydrogen-bonding interactions. Cytochrome *c* (Sections 5-4A, 6-2D, and 18-2E) is a peripheral membrane protein that is associated with the outer surface of the inner mitochondrial membrane. At physiological pH, cytochrome *c* is cationic and can interact with negatively charged phospholipids such as phosphatidylserine and phosphatidylglycerol.

CHECKPOINT

- Explain the differences between integral and peripheral membrane proteins.
- What are the two types of secondary structures that occur in transmembrane proteins?
- Describe the covalent modifications of lipid-linked proteins. Why might some of these modifications be reversible?

4 Membrane Structure and Assembly

KEY CONCEPTS

- The dynamic arrangement and interactions of membrane lipids and proteins are described by the fluid mosaic model.
- The membrane skeleton gives the cell shape, yet is flexible.
- Lipids are not distributed uniformly throughout a membrane and may form rafts.
- The secretory pathway describes the transmembrane passage of membrane and secreted proteins.
- Different types of coated vesicles transport proteins between cellular compartments.
- SNAREs bring membranes together and help mediate vesicle fusion.

Membranes were once thought to consist of a phospholipid bilayer sandwiched between two layers of unfolded polypeptide. This sandwich model, which is improbable on thermodynamic grounds, was further discredited by electron microscopic visualization of membranes and other experimental approaches. More recent studies have revealed insights into the fine structure of membranes, including a surprising degree of heterogeneity. In this section, we consider the arrangement of membrane proteins and lipids and examine some of the mechanisms by which these components move throughout the cell.

Membrane structure and the fluid mosaic model

A The Fluid Mosaic Model Accounts for Lateral Diffusion

The demonstrated fluidity of artificial lipid bilayers (Section 9-2B) suggests that biological membranes have similar properties. This idea was proposed in 1972 by S. Jonathan Singer and Garth Nicolson in their unifying theory of membrane structure known as the **fluid mosaic model**. In this model, integral proteins are visualized as “icebergs” floating in a two-dimensional lipid “sea” in a random or mosaic distribution (Fig. 9-25). A key element of the model is that integral proteins can diffuse laterally in the lipid matrix unless their movements are restricted by association with other cell components. This model of membrane fluidity

FIG. 9-25 Diagram of a plasma membrane. Integral proteins (purple) are embedded in a bilayer composed of phospholipids (blue head groups attached to wiggly tails) and cholesterol (yellow). The carbohydrate

components (green and brown beads) of glycoproteins and glycolipids occur on only the external face of the membrane. Most membranes contain a higher proportion of protein than is depicted here.

explained the earlier experimental results of Michael Edidin, who fused cultured cells and observed the intermingling of their differently labeled cell-surface proteins (Fig. 9-26).

The rates of diffusion of proteins in membranes can be determined from measurements of **fluorescence recovery after photobleaching (FRAP)**. In this technique, a **fluorophore** (fluorescent group) is specifically attached to a membrane component in an immobilized cell or in an artificial membrane system. An intense laser pulse focused on a very small area ($\sim 3 \mu\text{m}^2$) destroys (bleaches) the fluorophore there (Fig. 9-27). The rate at which the bleached area recovers its fluorescence, as monitored by fluorescence microscopy, indicates the rate at which unbleached and bleached fluorophore-labeled molecules laterally diffuse into and out of the bleached area.

PROCESS DIAGRAM

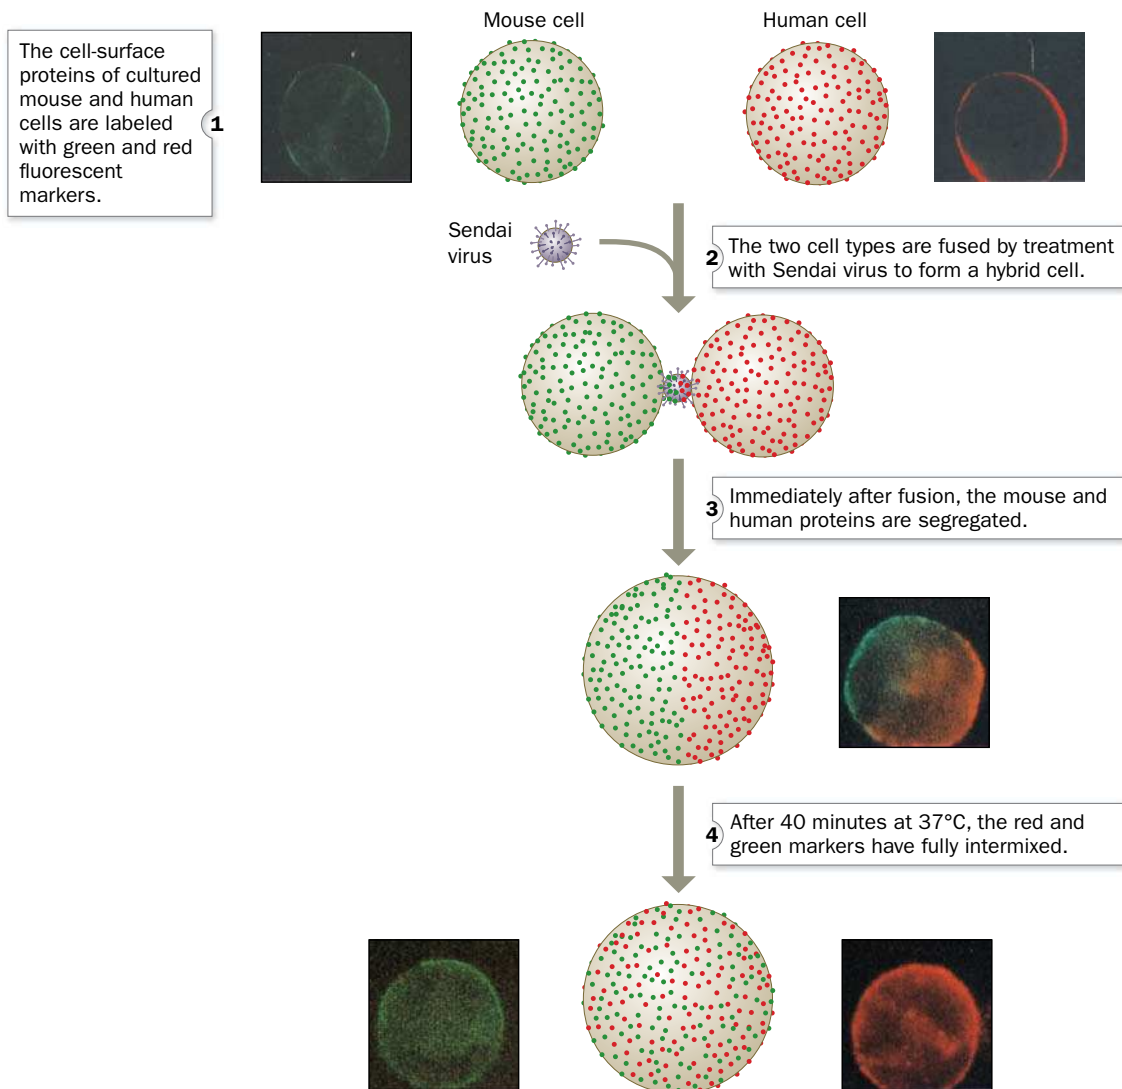

FIG. 9-26 Fusion of mouse and human cells. The accompanying photomicrographs (in square boxes) were taken through filters that allowed only red or green light to reach the camera. [Immunofluorescence

photomicrographs courtesy of Michael Edidin, The Johns Hopkins University.] **WPLS See the Animated Process Diagrams.**

? If Step 4 took place at 4°C instead of 37°C, what would happen?

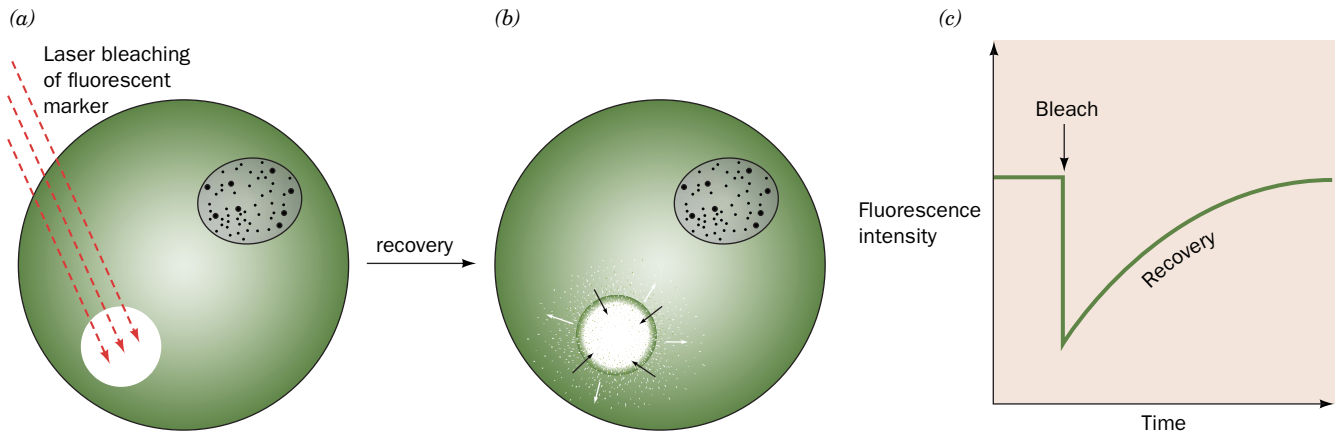

FIG. 9-27 The fluorescence recovery after photobleaching (FRAP) technique. (a) An intense laser light pulse bleaches the fluorescent markers (green) from a small region of an immobilized cell that has a fluorophore-labeled membrane component. (b) The fluorescence of

the bleached area recovers as the bleached molecules laterally diffuse out of it and intact fluorescent molecules diffuse into it. (c) The fluorescence recovery rate depends on the diffusion rate of the labeled molecule.

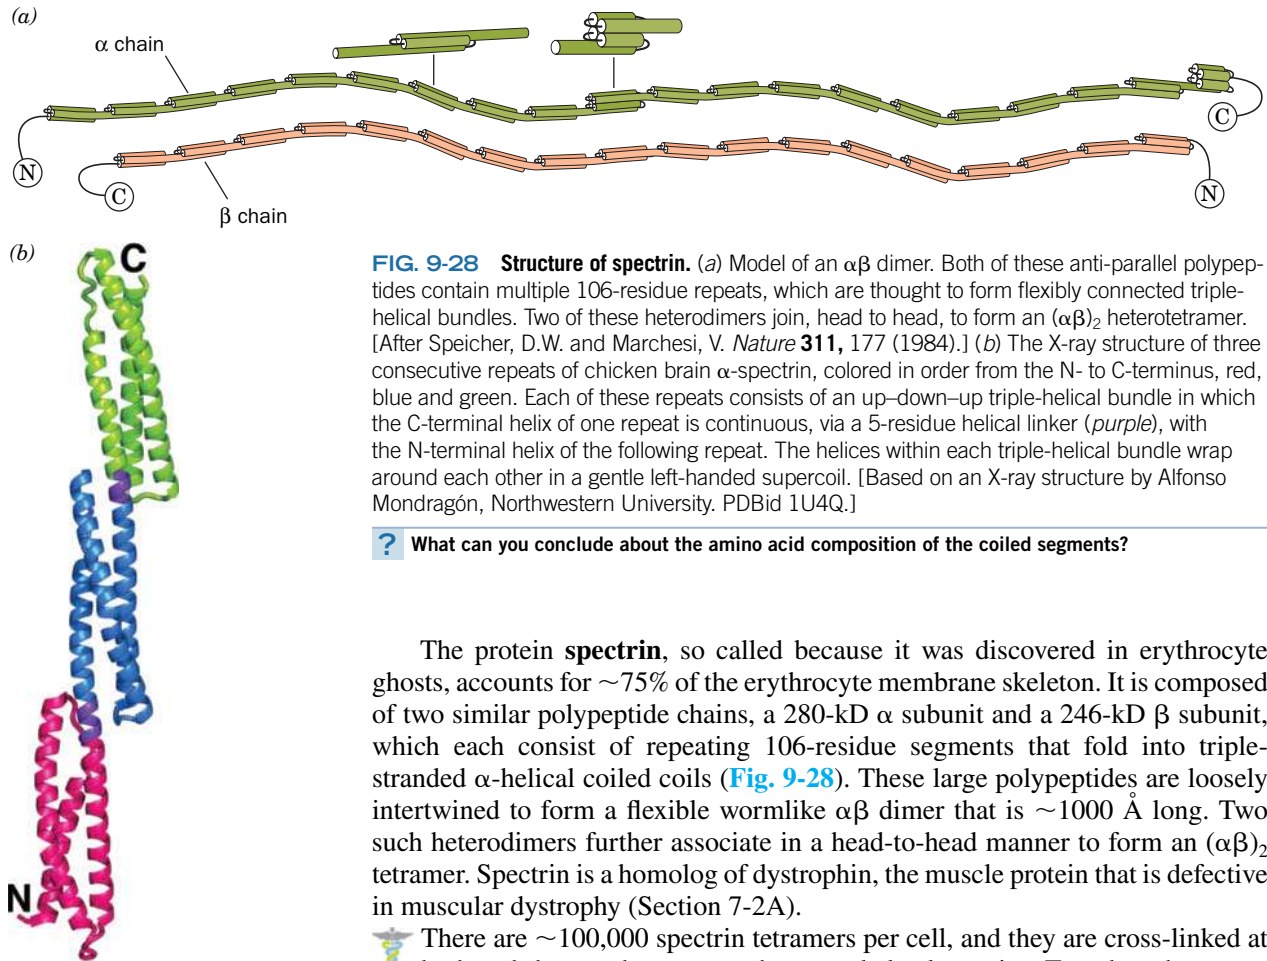

FRAP measurements demonstrate that membrane proteins vary in their lateral diffusion rates. Some 30 to 90% of these proteins are freely mobile; they diffuse at rates only an order of magnitude or so slower than those of the much smaller lipids, so they can diffuse the 20- μm length of a eukaryotic cell within an hour. Other proteins diffuse more slowly, and some are essentially immobile due to submembrane attachments.

B The Membrane Skeleton Helps Define Cell Shape

Studies of membrane structure and composition often make use of erythrocyte membranes, since these are relatively simple and easily isolated. A mature mammalian erythrocyte lacks organelles and carries out few metabolic processes; it is essentially a membranous bag of hemoglobin. Erythrocyte membranes can be obtained by osmotic lysis, which causes the cell contents to leak out. The resulting membranous particles are known as erythrocyte **ghosts** because, on return to physiological conditions, they reseal to form colorless particles that retain their original shape but are devoid of cytoplasm.

A normal erythrocyte's biconcave disklike shape (Fig. 7-17a) ensures the rapid diffusion of O_2 to its hemoglobin molecules by placing them no farther than 1 μm from the cell surface. However, the rim and the dimple regions of an erythrocyte do not occupy fixed positions on the cell membrane. This can be demonstrated by anchoring an erythrocyte to a microscope slide by a small portion of its surface and inducing the cell to move laterally with a gentle flow of buffer. A point originally on the rim of the erythrocyte will move across the dimple to the rim on the opposite side of the cell. Evidently, the membrane rolls across the cell while maintaining its shape, much like the tread of a tractor. This remarkable mechanical property of the erythrocyte membrane results from the presence of a submembranous network of proteins that function as a membrane "skeleton."

The fluidity and flexibility imparted to an erythrocyte by its membrane skeleton have important physiological consequences. A slurry of solid particles of a size and concentration equal to that of red cells in blood has flow characteristics approximating those of sand. Consequently, for blood to flow at all, much less for its erythrocytes to squeeze through capillary blood vessels smaller in diameter than they are, erythrocyte membranes, with their membrane skeletons, must be fluidlike and easily deformable.

? What can you conclude about the amino acid composition of the coiled segments?

The protein **spectrin**, so called because it was discovered in erythrocyte ghosts, accounts for $\sim 75\%$ of the erythrocyte membrane skeleton. It is composed of two similar polypeptide chains, a 280-kD α subunit and a 246-kD β subunit, which each consist of repeating 106-residue segments that fold into triple-stranded α -helical coiled coils (Fig. 9-28). These large polypeptides are loosely intertwined to form a flexible wormlike $\alpha\beta$ dimer that is ~ 1000 Å long. Two such heterodimers further associate in a head-to-head manner to form an $(\alpha\beta)_2$ tetramer. Spectrin is a homolog of dystrophin, the muscle protein that is defective in muscular dystrophy (Section 7-2A).

There are $\sim 100,000$ spectrin tetramers per cell, and they are cross-linked at both ends by attachments to other cytoskeletal proteins. Together, these proteins form a dense and irregular protein meshwork that underlies the erythrocyte plasma membrane (Fig. 9-29). A defect or deficiency in spectrin synthesis causes **hereditary spherocytosis**, in which erythrocytes are spheroidal and relatively fragile and inflexible. Individuals with the disease suffer from anemia due to erythrocyte lysis and the removal of spherocytic cells by the spleen (which normally functions to filter out aged and hence inflexible erythrocytes from the blood at the end of their ~ 120 -day lifetimes).

Spectrin also associates with an 1880-residue protein known as **ankyrin**, which binds to an integral membrane ion channel protein. This attachment anchors the membrane skeleton to the membrane. Immunochemical studies have revealed spectrin-like and ankyrin-like proteins in a variety of tissues, in addition to erythrocytes. Ankyrin's N-terminal 798-residue segment consists almost entirely of 24 tandem ~ 33 -residue repeats known as **ankyrin repeats** (Fig. 9-30), which also occur in a variety of other proteins. Each ankyrin repeat consists of two short (8- or 9-residue) antiparallel α helices followed by a long loop. These structures are arranged in a right-handed helical stack. The entire assembly forms an elongated concave surface that is postulated to bind various integral proteins as well as spectrin.

The interaction of membrane components with the underlying skeleton helps explain why integral membrane proteins exhibit different degrees of mobility within the membrane: Some integral proteins are firmly attached to elements of the cytoskeleton or are trapped within the spaces defined by those “fences.” Other membrane proteins may be able to squeeze through gaps or “gates” between cytoskeletal components, whereas still other proteins can diffuse freely without interacting with the cytoskeleton at all (Fig. 9-31). Support for this **gates and fences model** comes from the finding that partial destruction of the cytoskeleton results in freer protein diffusion.

(a)

(b)

FIG. 9-29 The human erythrocyte membrane skeleton. (a) An electron micrograph of an erythrocyte membrane skeleton that has been stretched to an area 9 to 10 times greater than that of the native membrane. Stretching makes it possible to obtain clear images of the membrane skeleton, which in its native state is densely packed and irregularly flexed. Note the predominantly hexagonal network composed of spectrin tetramers. (b) A model of the erythrocyte membrane

skeleton with an inset showing its relationship to the intact erythrocyte. The junctions between spectrin tetramers include actin and tropomyosin (Section 7-2) and **band 4.1 protein** (named after its position in an SDS-PAGE electrophoretogram). [After Goodman, S.R., Krebs, K.E., Whitfield, C.F., Riederer, B.M., and Zagen, I.S., *CRC Crit. Rev. Biochem.* **23**, 196 (1988).]

FIG. 9-30 The X-ray structure of human ankyrin repeats 13 to 24. The polypeptide is shown in ribbon form colored in rainbow order from its N-terminus (blue, repeat 13) to its C-terminus (red, repeat 24). [Based on an X-ray structure by Peter Michaely, University of Texas Southwestern Medical Center, Dallas, Texas. PDBid 1N11.]

FIG. 9-31 Model rationalizing the various mobilities of membrane proteins. Protein A, which interacts tightly with the underlying cytoskeleton, is immobile. Protein B is free to rotate within the confines of the cytoskeletal “fences.” Protein C diffuses by traveling through “gates” in the cytoskeleton. The diffusion of some membrane proteins is not affected by the cytoskeleton. [After Edidin, M., *Trends Cell Biol.* **2**, 378 (1992).]

FIG. 9-32 Asymmetric distribution of membrane phospholipids in the human erythrocyte membrane. The phospholipid content is expressed as mol %. [After Rothman, J.E. and Lenard, J., *Science* **194**, 1744 (1977).]

C Membrane Lipids Are Distributed Asymmetrically

The lipid and protein components of membranes do not occur in equal proportions on the two sides of biological membranes. For example, *membrane glycoproteins and glycolipids are invariably oriented with their carbohydrate moieties facing the cell's exterior*. The asymmetric distribution of certain membrane lipids between the inner and outer leaflets of a membrane was first established through the use of phospholipases (Section 9-1C). Phospholipases cannot pass through membranes, so phospholipids on only the external surface of intact cells are susceptible to hydrolysis by these enzymes. Such studies reveal that lipids in biological membranes are asymmetrically distributed (e.g., Fig. 9-32). How does this asymmetry arise?

In eukaryotes, the enzymes that synthesize membrane lipids are mostly integral membrane proteins of the **endoplasmic reticulum (ER)**; the interconnected membranous vesicles that occupy much of the cytosol; Fig. 9-33), whereas in prokaryotes, lipids are synthesized by integral membrane proteins in the plasma membrane. Hence, membrane lipids are fabricated on site. Eugene Kennedy and James Rothman demonstrated this to be the case in bacteria through the use of selective labeling. They gave growing bacteria a 1-minute pulse of $^{32}\text{PO}_4^{3-}$ in order to radioactively label the phosphoryl groups of only the newly synthesized phospholipids. Immediately afterward, they added **trinitrobenzenesulfonic acid (TNBS)**, a membrane-impermeable reagent that combines with phosphatidylethanolamine (**PE**; Fig. 9-34). Analysis of the resulting doubly labeled membranes showed that none of the TNBS-labeled PE was radioactively labeled. This observation indicates that *newly made PE is synthesized on the cytoplasmic face of the membrane* (Fig. 9-35, upper right).

However, if an interval of only 3 minutes was allowed to elapse between the $^{32}\text{PO}_4^{3-}$ pulse and the TNBS addition, about half of the ^{32}P -labeled PE was also TNBS labeled (Fig. 9-35, lower right). This observation indicates that the flip-flop rate of PE in the bacterial membrane is $\sim 100,000$ -fold greater than it is in bilayers consisting of only phospholipids (where the flip-flop rates have half-times of many days).

How do phospholipids synthesized on one side of the membrane reach its other side so quickly? Phospholipid flip-flops in bacteria as well as eukaryotes appear to be facilitated in two ways:

1. Membrane proteins known as **flippases** catalyze the flip-flops of specific phospholipids. These proteins tend to equilibrate the distribution of their corresponding phospholipids across a bilayer; that is, the net transport of a phospholipid is from the side of the bilayer with the higher concentration of the phospholipid to the opposite side. Such a process, as we will see in Section 10-1, is a form of **facilitated diffusion**.
2. Membrane proteins known as **phospholipid translocases** transport specific phospholipids across a bilayer in a process that is driven by ATP

FIG. 9-33 Electron micrograph of endoplasmic reticulum. This membrane network is contiguous with the nuclear membrane. The so-called **smooth ER** is the site of synthesis of membrane lipids, and the **rough ER**, with its associated ribosomes, is the site of synthesis of membrane and secretory proteins.

FIG. 9-34 The reaction of TNBS with phosphatidylethanolamine.

hydrolysis. These proteins can transport certain phospholipids from the side of a bilayer that has the lower concentration of the phospholipid to the opposite side, thereby establishing a nonequilibrium distribution of the phospholipid. Such a process, as we will see in Section 10-3, is a form of **active transport**.

The observed distribution of phospholipids across membranes (e.g., Fig. 9-32) therefore appears to arise from the membrane orientations of the enzymes that

PROCESS DIAGRAM

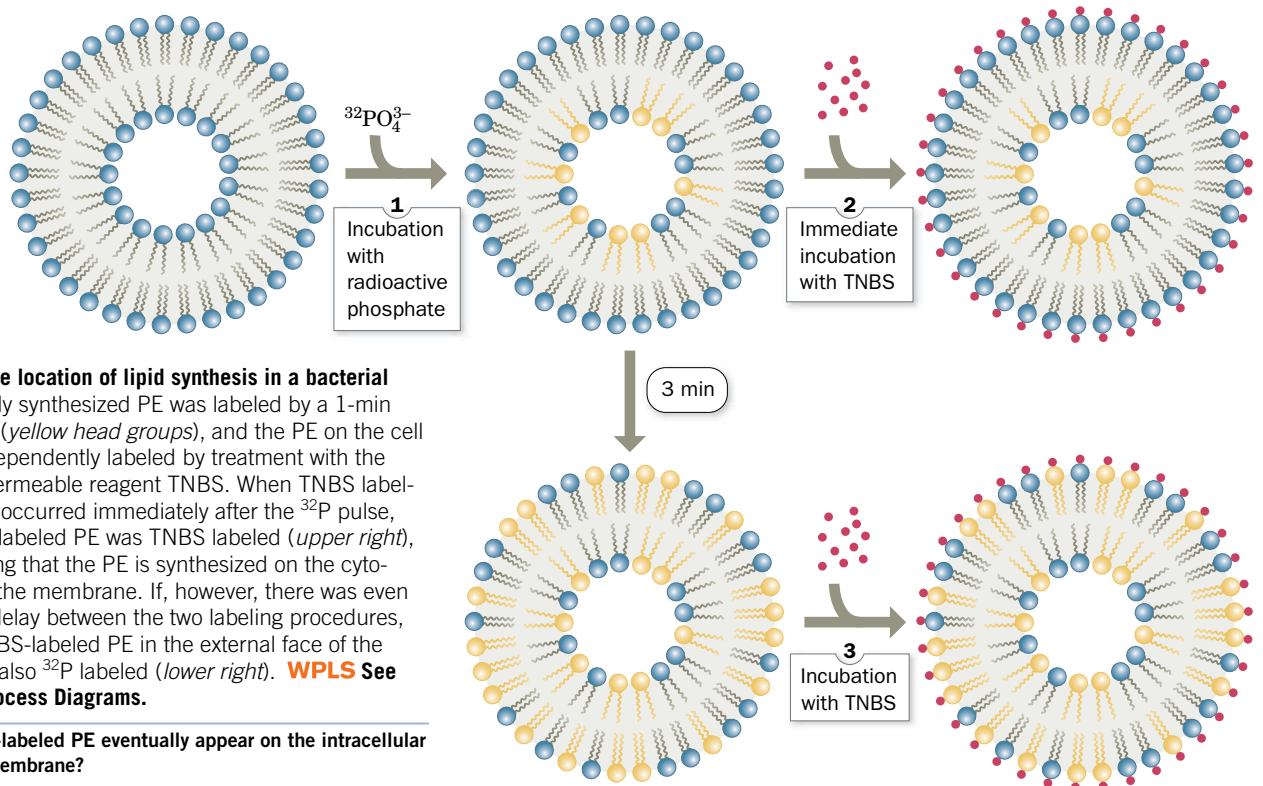

FIG. 9-35 The location of lipid synthesis in a bacterial membrane. Newly synthesized PE was labeled by a 1-min pulse of $^{32}\text{PO}_4^{3-}$ (yellow head groups), and the PE on the cell surface was independently labeled by treatment with the membrane-impermeable reagent TNBS. When TNBS labeling (red circles) occurred immediately after the ^{32}P pulse, none of the ^{32}P -labeled PE was TNBS labeled (upper right), thereby indicating that the PE is synthesized on the cytoplasmic face of the membrane. If, however, there was even a few minutes' delay between the two labeling procedures, much of the TNBS-labeled PE in the external face of the membrane was also ^{32}P labeled (lower right). **WPLS** See the Animated Process Diagrams.

? Would TNBS-labeled PE eventually appear on the intracellular face of the membrane?

synthesize phospholipids combined with the countervailing tendencies of ATP-dependent phospholipid translocases that generate asymmetric phospholipid distributions and flippases that equilibrate these distributions. The importance of these lipid transport systems is demonstrated by the observation that the presence of phosphatidylserine on the exteriors of many cells induces blood clotting (i.e., it is an indication of tissue damage) and, in erythrocytes, marks the cell for removal from the circulation.

In all cells, *new membranes are generated by the expansion of existing membranes*. In eukaryotic cells, lipids synthesized on the cytoplasmic face of the ER are transported to other parts of the cell by membranous vesicles that bud off from the ER and fuse with other cellular membranes (Section 9-4E). These vesicles also carry membrane proteins.

Lipid Rafts Are Membrane Subdomains. *Lipids and proteins in membranes can also be laterally organized.* Thus the plasma membranes of many eukaryotic cells have two or more distinct domains that have different functions. For example, the plasma membranes of epithelial cells (the cells lining body cavities and free surfaces) have an **apical domain**, which faces the lumen (interior) of the cavity and often has a specialized function (such as the absorption of nutrients in intestinal brush border cells), and a **basolateral domain**, which covers the remainder of the cell. These two domains, which do not intermix, have different compositions of both lipids and proteins.

In addition, the hundreds of different lipids and proteins within a given plasma membrane domain may not be uniformly mixed but instead often segregate to form **microdomains** that are enriched in certain lipids and proteins. This may result from specific interactions between integral membrane proteins and particular types of membrane lipids. Divalent metal ions, notably Ca^{2+} , which bind to negatively charged lipid head groups such as those of phosphatidylserine, may also cause clustering of these lipids.

One type of microdomain, termed a **lipid raft**, appears to consist of closely packed glycosphingolipids (which occur only in the outer leaflet of the plasma membrane) and cholesterol. By themselves, glycosphingolipids cannot form bilayers because their large head groups prevent the requisite close packing of their predominantly saturated hydrophobic tails. Conversely, cholesterol by itself does not form a bilayer due to its small head group. It is therefore likely that *the glycosphingolipids in lipid rafts associate laterally via weak interactions between their carbohydrate head groups, and the voids between their tails are filled in by cholesterol.*

Owing to the close packing of their component lipids and the long, saturated sphingolipid tails, sphingolipid–cholesterol rafts have a more ordered or crystalline arrangement than other regions of the membrane and are more resistant to solubilization by detergents. The rafts may diffuse laterally within the membrane. Certain proteins preferentially associate with the rafts, including many GPI-linked proteins and some of the proteins that participate in transmembrane signaling processes (Chapter 13). This suggests that lipid rafts, which are probably present in all cell types, function as platforms for the assembly of complex intercellular signaling systems. Several viruses, including influenza virus, measles virus, Ebola virus, and HIV, localize to lipid rafts, which therefore appear to be the sites from which these viruses enter uninfected cells and bud from infected cells. It should be noted that lipid rafts are highly dynamic structures that rapidly exchange both proteins and lipids with their surrounding membrane as a consequence of the weak and transient interactions between membrane components.

D The Secretory Pathway Generates Secreted and Transmembrane Proteins

In contrast to membrane lipids, membrane proteins do not change their orientation in the membrane after they are synthesized. Membrane proteins, like all proteins, are ribosomally synthesized under the direction of messenger RNA

templates (translation is discussed in Chapter 27). The polypeptide grows from its N-terminus to its C-terminus by the stepwise addition of amino acid residues. In eukaryotes, ribosomes may be free in the cytosol or bound to the ER to form the rough endoplasmic reticulum (RER, so called because of the knobby appearance its bound ribosomes give it; Fig. 9-33). *Free ribosomes synthesize mostly soluble and mitochondrial proteins, whereas membrane-bound ribosomes manufacture transmembrane proteins and proteins destined for secretion, operation within the ER, and incorporation into lysosomes* (membranous vesicles containing a battery of hydrolytic enzymes that degrade and recycle cell components). The latter proteins initially appear in the ER. In prokaryotic cells, ribosomes associate with the plasma membrane during production of membrane-embedded and secreted proteins.

Secreted and Transmembrane Proteins Pass through the ER Membrane.

How are RER-destined proteins differentiated from other proteins? And how do these large, relatively polar molecules pass through the RER membrane? In eukaryotes, these processes occur via the **secretory pathway**, which was first described by Günter Blobel, Cesar Milstein, and David Sabatini around 1975. Since ~25% of the various proteins synthesized by all types of cells are integral proteins and many others are secreted, ~40% of the various types of proteins that a cell synthesizes must be processed via the secretory pathway or some other protein targeting pathway. Here we outline the secretory pathway, which is diagrammed in Fig. 9-36:

1. All secreted, ER-resident, and lysosomal proteins, as well as many TM proteins, are synthesized with leading (N-terminal) 13- to 36-residue **signal peptides**. These signal peptides consist of a 6- to 15-residue hydrophobic core flanked by several relatively hydrophilic residues that usually include

FIG. 9-37 The N-terminal sequences of some eukaryotic preproteins. The hydrophobic cores (*tan*) of most signal peptides are preceded by basic residues (*blue*). [After Watson, M.E.E., *Nucleic Acids Res.* **12**, 5147–5156 (1984).]

one or more basic residues near the N-terminus (Fig. 9-37). Signal peptides otherwise have little sequence similarity. However, a variety of evidence indicates they form α helices in nonpolar environments.

2. When the signal peptide first protrudes beyond the ribosomal surface (when the polypeptide is at least ~ 40 residues long), the **signal recognition particle (SRP)**, a 325-kD complex of six different polypeptides and a 300-nucleotide RNA molecule, binds to both the signal peptide and the ribosome (Section 27-5B). At the same time, the SRP's bound **guanosine diphosphate (GDP;** the guanine analog of ADP) is replaced by **guanosine triphosphate (GTP;** the guanine analog of ATP). The resulting conformational change in the SRP causes the ribosome to arrest further polypeptide growth, thereby preventing the RER-destined protein from being released into the cytosol.
3. The SRP-ribosome complex diffuses to the RER surface, where it binds to the **SRP receptor (SR;** also called **docking protein**) in complex with the **translocon**, a protein pore in the ER membrane through which the growing polypeptide will be extruded. In forming the SR-translocon complex, the SR's bound GDP is replaced by GTP.
4. The SRP and SR stimulate each other to hydrolyze their bound GTP to GDP (which is energetically equivalent to ATP hydrolysis), resulting in conformational changes that cause them to dissociate from each other and from the ribosome-translocon complex. This permits the bound ribosome to resume polypeptide synthesis such that the growing polypeptide's N-terminus passes through the translocon into the lumen of the ER. Most ribosomal processes, as we will see in Section 27-4, are driven by GTP hydrolysis.
5. Shortly after the signal peptide enters the ER lumen, it is specifically cleaved from the growing polypeptide by a membrane-bound **signal peptidase** (polypeptide chains with their signal peptide still attached are known as **preproteins**; signal peptides are alternatively called **presequences**).
6. The nascent (growing) polypeptide starts to fold to its native conformation, a process that is facilitated by its interaction with the ER-resident chaperone protein Hsp70 (Section 6-5B). Enzymes in the ER lumen then initiate **posttranslational modification** of the polypeptide, such as the specific attachments of "core" carbohydrates to form glycoproteins (Section 8-3C) and the formation of disulfide bonds as facilitated by protein

disulfide isomerase (Section 6-5A). Once the protein has folded, it cannot be pulled back through the membrane. Secretory, ER-resident, and lysosomal proteins pass completely through the RER membrane into the lumen. TM proteins, in contrast, contain one or more hydrophobic ~22-residue **membrane anchor** sequences that remain embedded in the membrane.

- When the synthesis of the polypeptide is completed, it is released from both the ribosome and the translocon. The ribosome detaches from the RER, and its two subunits dissociate.

A similar pathway functions in prokaryotes for the insertion of certain proteins into the cell membrane (whose exterior is equivalent to the ER lumen). Indeed, all forms of life yet tested have homologous SRPs, SRs, and translocons. Nevertheless, it should be noted that cells have several mechanisms for installing proteins in or transporting them through membranes. For example, cytoplasmically synthesized proteins that reside in the mitochondrion reach their destinations via mechanisms that are substantially different from that of the secretory pathway.

The Translocon Is a Multifunctional Transmembrane Pore. In 1975, Blobel postulated that protein transport through the RER membrane is mediated by an aqueous TM channel. However, it was not until 1991 that he was able to experimentally demonstrate its existence. These channels, now called translocons, enclose aqueous pores that completely span the ER membrane, as shown by linking nascent polypeptide chains to fluorescent dyes whose fluorescence is sensitive to the polarity of their environment. The channel-forming component of the translocon is a heterotrimeric protein named **Sec61** in mammals and **SecY** in prokaryotes. This protein is conserved throughout all kingdoms of life and hence is likely to have a similar structure and function in all organisms.

The X-ray structure of the SecY complex from the archaeon *Methanococcus jannaschii* reveals that the α , β , and γ subunits, respectively, have 10, 1, and 1 TM α helices (Fig. 9-38). The α subunit's TM helices are wrapped around an hourglass-shaped channel whose minimum diameter is ~3 Å. The channel is

FIG. 9-38 Structure and function of the *M. jannaschii* SecY complex. (a) X-Ray structure of the complex, with shading indicating the positions of membrane phospholipid head groups (violet) and hydrocarbon tails (pink). The α subunit of SecY is colored in rainbow order from its N-terminus (dark blue) to its C-terminus (red), the β subunit is magenta, and the γ subunit is purple. (b) View of SecY from the cytosol. The translocon's putative lateral gate is on the left between helices 2 and 7. (c) Model for the insertion of a TM helix into

a membrane. The translocon (blue) is viewed as in Part b. A polypeptide chain (yellow) is shown bound in the translocon's pore during its translocation through the membrane, and a signal-anchor sequence (red) is shown passing through the translocon's lateral gate and being released into the membrane (arrow). [Parts a and b courtesy of Stephen Harrison and Tom Rapoport, Harvard Medical School. PDBid 1RH5. Part c after a drawing by Dobberstein, B. and Sinning, I., *Science* **303**, 320 (2004).]

blocked at its extracellular end by a short relatively hydrophilic helix (blue unnumbered helix in Figs. 9-38*a* and *b*). It is proposed that an incoming signal peptide pushes this helix aside and hence that the helix functions as a plug to prevent small molecules from leaking across the membrane in the absence of a translocating polypeptide. The maximum diameter of an extended polypeptide is ~ 12 Å and that of an α helix is ~ 14 Å. For SecY to function as a channel for translocating polypeptides, the central pore must expand, a structural change that would require relatively simple hingelike motions involving conserved Gly residues.

In addition to forming a conduit for soluble proteins to pass through the membrane, *the translocon must mediate the insertion of an integral protein's TM segments into the membrane*. The X-ray structure of SecY suggests that this occurs by the opening of the C-shaped α subunit, as is diagrammed in Fig. 9-38*c*, to permit the lateral installation of the TM segment into the membrane.

The signal peptides of many TM proteins are not cleaved by signal peptidase but, instead, are inserted into the membrane. Such so-called signal-anchor sequences may be oriented with either their N- or C-termini in the cytosol. If the N-terminus is installed in the cytosol, then the polypeptide must have looped around before being inserted into the membrane. Moreover, for **polytopic** (multispanning) TM proteins such as the SecY α subunit itself, this must occur for each successive TM helix. Since it seems unlikely that the SecY channel could expand to simultaneously accommodate numerous TM helices, these helices are probably installed in the membrane one or two at a time. The mechanisms by which the translocon recognizes TM segments are not well understood. For example, the experimental deletion or insertion of a TM helix in a polytopic protein does not necessarily change the membrane orientations of the succeeding TM helices; when two successive TM helices have the same preferred orientation, one of them may be forced out of the membrane.

E Intracellular Vesicles Transport Proteins

Shortly after their synthesis in the rough ER, partially processed transmembrane, secretory, and lysosomal proteins appear in the Golgi apparatus (**Fig. 9-39**). This 0.5- to 1.0- μm -diameter organelle consists of a stack of three to six or more (depending on the species) flattened and functionally distinct membranous sacs known as **cisternae**, where further posttranslational processing, mainly glycosylation, occurs (Section 8-3C). The Golgi stack (**Fig. 9-40**) has two distinct faces, each composed of a network of interconnected membranous tubules: the **cis Golgi network**, which is opposite the ER and is the port through which proteins enter the Golgi apparatus; and the **trans Golgi network**, through which processed proteins exit to their final destinations. The intervening Golgi stack contains at least three different types of sacs, the **cis**, **medial**, and **trans cisternae**, each of which contains different sets of glycoprotein-processing enzymes.

Proteins transit from one end of the Golgi stack to the other while being modified in a stepwise manner. The proteins are transported via two mechanisms:

1. They are conveyed between successive Golgi compartments in the cis to trans direction as cargo within membranous vesicles that bud off of one compartment and fuse with a successive compartment, a process known as forward or **anterograde transport**.
2. They are carried as passengers in Golgi compartments that transit the Golgi stack; that is, the cis cisternae eventually become trans cisternae, a process called **cisternal progression** or **maturation**. (Golgi-resident proteins may migrate backward by **retrograde transport** from one compartment to the preceding one via membranous vesicles.)

The cisternal progression mechanism has been clearly shown to occur, but the significance of the anterograde transport mechanism is as yet unclear. In any

FIG. 9-39 Electron micrograph of the Golgi apparatus. In this array of flattened vesicles, newly synthesized transmembrane and secretory proteins undergo processing and sorting.

FIG. 9-40 The posttranslational processing of proteins. Membrane, secretory, and lysosomal proteins are synthesized by RER-associated ribosomes (*gray dots; top*). As they are synthesized, the proteins (*red dots*) are either injected into the lumen of the ER or inserted into its membrane. After initial processing in the ER, the proteins are encapsulated in vesicles that bud off from the ER membrane and subsequently fuse with the cis Golgi network (*top*). The proteins are progressively processed in the cis, medial, and trans cisternae of the Golgi. Finally, in the trans Golgi network (*bottom*), the completed glycoproteins are sorted for delivery to their final destinations: the plasma membrane, **secretory vesicles**, or lysosomes, to which they are transported by yet other vesicles.

? List, in order, all the cellular compartments involved in synthesizing a secreted protein.

case, on reaching the trans Golgi network, the now mature proteins are sorted and sent to their final cellular destinations.

Membrane, Secretory, and Lysosomal Proteins Are Transported in Coated Vesicles. The vehicles in which proteins are transported between the RER, the different compartments of the Golgi apparatus, and their final destinations are known as **coated vesicles** (Fig. 9-41). This is because these 60- to 150-nm-diameter membranous sacs are initially encased on their outer (cytosolic) faces by specific proteins that act as flexible scaffolding in promoting vesicle formation. A vesicle buds off from its membrane of origin and later fuses to its target membrane. *This process preserves the orientation of the transmembrane*

FIG. 9-41 Electron micrographs of coated vesicles. (a) Clathrin-coated vesicles. Note their polyhedral character. (b) COP I-coated vesicles. (c) COP II-coated vesicles. The inserts in Parts b and c show the respective vesicles at higher magnification.

FIG. 9-42 Fusion of a vesicle with the plasma membrane. The inside of the vesicle and the exterior of the cell are topologically equivalent. Fusion of the vesicle with the plasma membrane preserves the orientation of the integral proteins embedded in the vesicle bilayer because the same side of the protein is always immersed in the cytosol. Note that soluble proteins packaged inside a secretory vesicle that fuses with the plasma membrane would be released outside the cell.

protein (Fig. 9-42), because the lumens of the ER and the Golgi cisternae are topologically equivalent to the outside of the cell. This explains why the carbohydrate moieties of integral glycoproteins and the GPI anchors of GPI-linked proteins occur only on the external surfaces of plasma membranes.

The three known types of coated vesicles are characterized by their protein coats:

1. **Clathrin** (Fig. 9-41a), a protein that forms a polyhedral framework around vesicles that transport TM, GPI-linked, and secreted proteins from the Golgi to the plasma membrane (see below).
2. **COPI** protein (Fig. 9-41b; COP for *coat protein*), which forms what appears to be a fuzzy rather than a polyhedral coating about vesicles that carry out both the anterograde and retrograde transport of proteins between successive Golgi compartments. In addition, COPI-coated vesicles return escaped ER-resident proteins from the Golgi back to the ER (see below). The COPI protomer, which contains seven different subunits, is named **coatomer**.
3. **COPII** protein (Fig. 9-41c), which transports proteins from the ER to the Golgi. The COPII vesicle components are then returned to the ER by COPI-coated vesicles (the COPI vesicle components entering the ER are presumably recycled by COPII-coated vesicles). The COPII coat consists of two conserved protein heterodimers.

All of the above coated vesicles also bear receptors that bind the proteins being transported, as well as proteins that mediate the fusion of these vesicles with their target membranes (Section 9-4F).

Clathrin Forms Flexible Cages. Clathrin-coated vesicles are structurally better characterized than those coated with COPI or COPII. The clathrin network is built from proteins known as **triskelions** (Fig. 9-43), which consist of three heavy chains (190 kD) that each bind one of two homologous light chains (24–27 kD). The triskelions assemble to form polyhedral cages in which each vertex is the center (hub) of a triskelion and the $\sim 150\text{-}\text{\AA}$ -long edges are formed by the overlapping legs of four triskelions (Fig. 9-44). The clathrin light chains are not required for clathrin cage assembly. In fact, they inhibit heavy chain polymerization *in vitro*, suggesting that they play a regulatory role in clathrin cage formation in the cytosol.

A clathrin polyhedron, which has 12 pentagonal faces and a variable number of hexagonal faces, is the most parsimonious way of enclosing a spheroidal object in a polyhedral cage. The volume enclosed by a clathrin polyhedron increases with the number of hexagonal faces.

The triskelion legs, which have a total length of $\sim 450\text{ \AA}$, exhibit considerable flexibility (Fig. 9-43). This is a functional necessity for the formation of different-sized vesicles as well as for the budding of a vesicle from a membrane surface, which requires a large change in its curvature. The clathrin heavy chains appear to flex mainly along a portion of the knee (Fig. 9-44b) between the proximal and distal segments that is free of contacts with other molecules in clathrin cages.

FIG. 9-43 An electron micrograph of triskelions. The variable orientations of their legs are indicative of their flexibility.

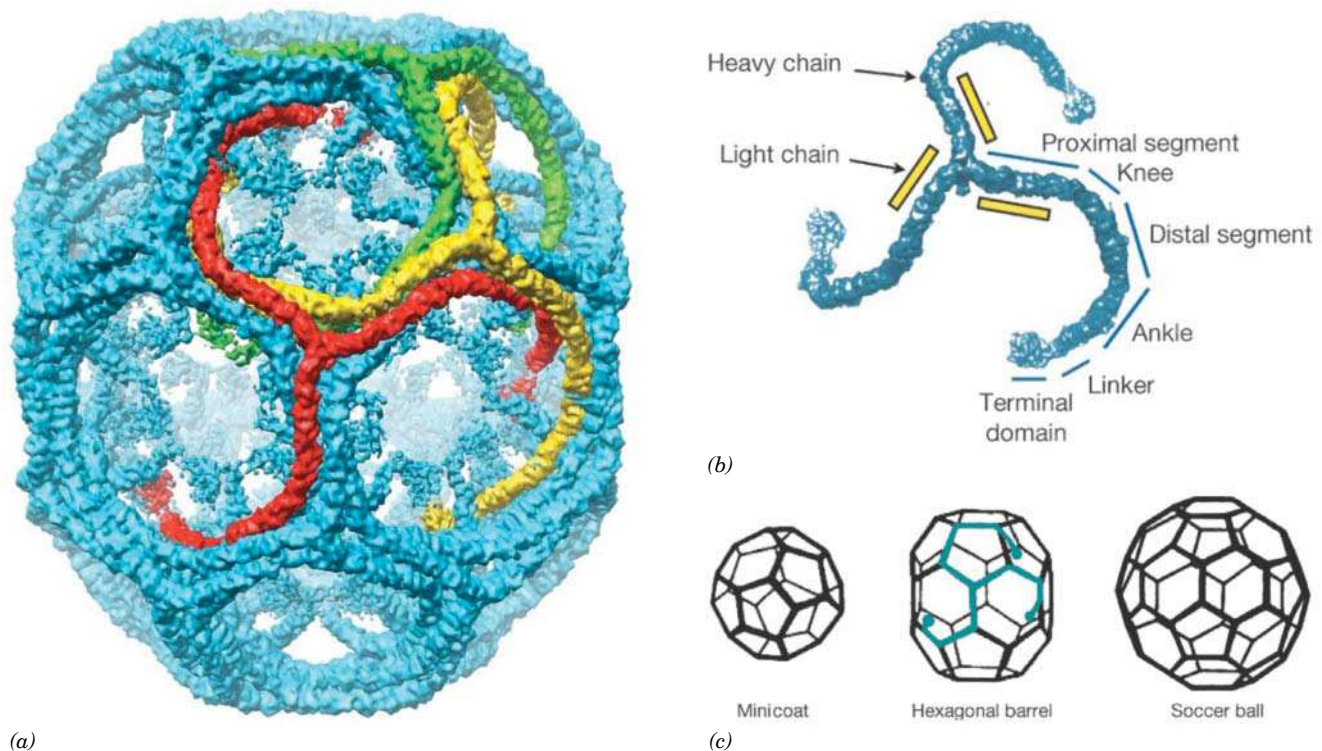

FIG. 9-44 Anatomy of clathrin-coated vesicles. (a) A cryo-EM–based image of a light chain–free clathrin cage from bovine brain at 7.9 \AA resolution. The particle shown, a so-called hexagonal barrel, which has D_6 symmetry (the symmetry of a hexagonal prism), consists of 36 triskelions. Three of its interdigitated but symmetry unrelated triskelions are drawn in red, yellow, and green. (b) A cryo-EM–based image of a triskelion labeled with the names of its various segments. The N-terminus of each heavy chain occupies the terminal domain and its C-terminus is located in the vertex joining the three heavy chains to form the triskelion. (c) Diagrams of the three polyhedral structures that are formed when triskelions assemble into clathrin cages *in vitro*. The

minicoat has tetrahedral (T) symmetry, the hexagonal barrel has D_6 symmetry, and the soccer ball has icosahedral (I) symmetry (symmetry is discussed in Section 6-3). These polyhedra consist of 28, 36, and 60 triskelions, respectively. The arrangement of one triskelion within the “hexagonal barrel” is indicated in blue. *In vivo*, clathrin forms membrane-enclosing polyhedral cages with a large range of different sizes (number of hexagons). The hexagonal barrel seen in Part a is only $\sim 700\text{ \AA}$ in diameter, whereas clathrin-coated membranous vesicles are typically $\sim 1200\text{ \AA}$ in diameter or larger. [Courtesy of Stephen Harrison, Tomas Kirchhausen, and Thomas Walz, Harvard Medical School.]

In addition to transporting membrane and secretory proteins between the Golgi apparatus and the plasma membrane, clathrin-coated vesicles participate in **endocytosis**. In this process (discussed in Section 20-1B), a portion of the plasma membrane invaginates to form a clathrin-coated vesicle that engulfs specific proteins from the extracellular medium and then transports them to intracellular destinations.

Proteins Are Directed to the Lysosome by Carbohydrate Recognition Markers. The signals that direct particular proteins to the various types of coated vesicles for transport between cellular compartments are not entirely understood. However, the trafficking of lysosomal proteins is known to depend on their oligosaccharides. A clue to the nature of this process was provided by the human hereditary defect known as **I-cell disease** (alternatively, **mucopolysaccharidosis II**) which, in homozygotes, is characterized by severe progressive psychomotor retardation, skeletal deformities, and death by age 10. The lysosomes in the connective tissue of I-cell disease victims contain large inclusions (after which the disease is named) of glycosaminoglycans and glycolipids as a result of the absence of several lysosomal hydrolases. These enzymes are synthesized on the RER with their correct amino acid sequences, but rather than being dispatched to the lysosomes are secreted into the extracellular medium. This misdirection results from the absence of a mannose-6-phosphate recognition marker on the carbohydrate moieties of these hydrolases because of a deficiency of an enzyme required for mannose phosphorylation of the lysosomal proteins. The mannose-6-phosphate residues are normally bound by a receptor in the coated vesicles that transport lysosomal hydrolases from the Golgi apparatus to the lysosomes. No doubt, other glycoproteins are directed to their intracellular destinations by similar carbohydrate markers.

ER-Resident Proteins Have the C-Terminal Sequence KDEL. Most soluble ER-resident proteins in mammals have the C-terminal sequence KDEL (HDEL in yeast), KKXX, or KXXXXX (where X represents any amino acid residue), whose alteration results in the secretion of the resulting protein. By what means are these proteins selectively retained in the ER? Since many ER-resident proteins freely diffuse within the ER, it seems unlikely that they are immobilized by membrane-bound receptors within the ER. Rather, ER-resident proteins, like secretory and lysosomal proteins, readily leave the ER via COPII-coated vesicles, but ER-resident proteins are promptly retrieved from the Golgi and returned to the ER in COPI-coated vesicles. Indeed, coatamer binds the Lys residues in the C-terminal KKXX motif of transmembrane proteins, which presumably permits it to gather these proteins into COPI-coated vesicles. Furthermore, genetically appending KDEL to the lysosomal protease **cathepsin D** causes it to accumulate in the ER, but it nevertheless acquires an *N*-acetylglucosaminyl-1-phosphate group, a modification that is made in an early Golgi compartment. Presumably, a membrane-bound receptor in a post-ER compartment binds the KDEL signal and the resulting complex is returned to the ER in a COPI-coated vesicle. **KDEL receptors** have, in fact, been identified in yeast and humans. However, the observation that former KDEL proteins whose KDEL sequences have been deleted are, nevertheless, secreted relatively slowly suggests that there are mechanisms for retaining these proteins in the ER by actively withholding them from the bulk flow of proteins through the secretory pathway.

F Proteins Mediate Vesicle Fusion

In all cells, *new membranes are generated by the expansion of existing membranes*. In eukaryotes, this process occurs mainly via vesicle trafficking in which a vesicle buds off from one membrane (e.g., that of the Golgi apparatus) and fuses to a different membrane (e.g., the plasma membrane or that of the

FIG. 9-45 Vesicle fusion at a synapse. (a) An electron micrograph of a frog neuromuscular synapse. Synaptic vesicles are undergoing fusion (arrows) with the presynaptic plasma membrane (top). (b) This process discharges the neurotransmitter contents of the synaptic vesicles into the synaptic cleft, the space between the neuron and the muscle cell (the postsynaptic cell).

Courtesy of John Heuser, Washington University School of Medicine, St. Louis, Missouri

lysosome), thereby transferring both lipids and proteins from the parent to the target membrane.

On arriving at its target membrane, a vesicle fuses with it, thereby releasing its contents on the opposite side of the target membrane (Fig. 9-42). We have already seen how proteins are transported from the ER through the Golgi apparatus and secreted by this mechanism. Other substances are also secreted in this way, such as **neurotransmitters**, the small molecules released by neurons (nerve cells; Fig. 9-45). When a nerve impulse in a presynaptic cell reaches a **synapse** (the junction between neurons or between neurons and muscles), it triggers the fusion of neurotransmitter-containing **synaptic vesicles** with the **presynaptic membrane** (a specialized section of the neuron's plasma membrane). This releases the neurotransmitter into the $\sim 200\text{-\AA}$ -wide **synaptic cleft**, a process called **exocytosis**. In less than 0.1 ms, the neurotransmitter diffuses across the synaptic cleft to the **postsynaptic membrane**, where it binds to specific receptors that then trigger the continuation of the nerve impulse or muscle contraction in the postsynaptic cell.

Biological membranes do not spontaneously fuse. Indeed, being negatively charged, they strongly repel each other at short distances. This repulsive force must be overcome if biological membranes are to fuse. How do vesicles fuse and why do they fuse only with their target membranes?

Extensive investigations, in large part by Rothman, Randy Schekman, and Thomas Südhof, have identified numerous proteins that mediate vesicle fusion with their target membranes. Among these are integral or lipid-linked proteins known as **SNAREs**. **R-SNAREs** (which contain conserved Arg residues) usually associate with vesicle membranes, and **Q-SNAREs** (which contain conserved Gln residues) usually associate with target membranes. Interactions among these proteins, as we will see, firmly anchor the vesicle to the target membrane, a process called docking.

The X-ray structure of a core SNARE complex is shown in Fig. 9-46. Four parallel ~ 65 -residue α helices wrap around each other with a gentle left-handed twist. For the most part, the sequence of each helix has the expected seven-residue repeat, $(a-b-c-d-e-f-g)_m$, with residues *a* and *d* hydrophobic (Section 6-1C). However, the central layer of side chains along the length of the four-helix bundle includes an Arg residue from the R-SNARE that is hydrogen bonded to three Gln side chains, one from each of the Q-SNARE helices. These highly conserved polar residues are sealed off from the aqueous environment so that their interactions serve to bring the four helices into proper

FIG. 9-46 X-Ray structure of a SNARE complex modeled between two membranes. The complex includes an R-SNARE (**synaptobrevin**, blue) and two Q-SNAREs (**syntaxin**, red, and **SNAP-25**, green, a two-Q-domain-containing Q-SNARE) for a total of four helices, which are shown here as ribbons. The transmembrane C-terminal extensions of syntaxin and synaptobrevin are modeled as helices (yellow-green). The peptide segment connecting the two Q-domain helices of SNAP-25 is speculatively represented as an unstructured loop (brown). The loop is anchored to the membrane via Cys-linked palmitoyl groups (not shown). The cleavage sites for various clostridial neurotoxins (causing tetanus and botulism; Box 9-3) are indicated by the arrows. [Courtesy of Axel Brunger, Stanford University.]

The frequently fatal infectious diseases **tetanus** (which arises from wound contamination) and **botulism** (a type of food poisoning) are caused by certain anaerobic bacteria of the genus *Clostridium*. These bacteria produce extremely potent protein neurotoxins that inhibit the release of neurotransmitters into synapses. In fact, botulinum toxins are the most powerful known toxins; they are ~10 million times more toxic than cyanide.

There are seven serologically distinct types of botulinum neurotoxins, designated **BoNT/A** through **BoNT/G**, and one type of tetanus neurotoxin, **TeTx**. Each of these homologous proteins is synthesized as a single ~150-kD polypeptide chain that is cleaved by host proteases to yield an ~50-kD light chain and an ~100-kD heavy chain. The heavy chains bind to specific types of neurons and facilitate the uptake of the light chain by endocytosis. *Each light chain is a protease that cleaves its*

target SNARE at a specific site (Fig. 9-46). SNARE cleavage prevents the formation of the core complex and thereby halts the exocytosis of synaptic vesicles. The heavy chain of TeTx specifically binds to inhibitory neurons (which function to moderate excitatory nerve impulses) and is thereby responsible for the spastic paralysis characteristic of tetanus. The heavy chains of the BoNTs instead bind to motor neurons (which innervate muscles) and thus cause the flaccid paralysis characteristic of botulism.

The administration of carefully controlled quantities of botulinum toxin (“Botox”) is medically useful in relieving the symptoms of certain types of chronic muscle spasms and for the relief of chronic migraine headaches. Moreover, this toxin is being used cosmetically: Its injection into the skin relaxes the small muscles causing wrinkles and hence these wrinkles disappear for ~3 months.

register. Since cells contain numerous different R-SNAREs and Q-SNAREs, it seems likely that their interactions are at least partially responsible for the specificity that vesicles exhibit in fusing with their target membranes. Bacterial proteases that cleave SNAREs interfere with vesicle fusion, with serious consequences (Box 9-3).

SNAREs Facilitate the Fusion of Membranes by Bringing Them Together.

The association of an R-SNARE on a vesicle with Q-SNAREs on its target membrane brings the two bilayers into close proximity. But what induces the fusion of the juxtaposed lipid bilayers? The answer, as is diagrammed in Fig. 9-47, is that the mechanical forces arising from the formation of a ring of several (estimated to be 5–10) SNARE complexes pulls together the apposing bilayers. This expels the contacting lipids between them so as to join their outer leaflets, a process known as **hemifusion**. Indeed, the pressure (force/area) within the ring of SNARE complexes is estimated to be 100 to 1000 atm. In the resulting transient structure, no aqueous contact between the two membrane systems has yet been established. However, as the fusion process proceeds (the SNARE complexes continue zipping up), the two inner leaflets of the now partially joined membranes come together to form a new bilayer, whose component lipids are subsequently similarly expelled to yield a **fusion pore**. The fusion pore then rapidly expands, thereby fully joining the two membranes as well as their contents. Thus, vesicle fusion is driven by the assembly of the SNARE complexes. However, *in vitro*, this process takes 30 to 40 minutes, whereas the fusion of a synaptic vesicle with the presynaptic membrane requires ~0.3 ms *in vivo*. This argues that other proteins also participate in inducing bilayer fusion and, indeed, several other proteins have been implicated.

Some Viruses Use Fusion Proteins to Infect Their Target Cells. Many viruses, including those causing influenza and AIDS, arise by budding from the plasma membrane of a virus-infected cell, much like the budding of a vesicle from a membrane. In order to infect a new cell, the membrane of the resulting **membrane-enveloped virus** must fuse with a membrane in its target cell so as to deposit the virus’ cargo of nucleic acid in the cell’s cytoplasm. Such membrane fusion events are mediated by protein systems that differ from those responsible for the vesicle fusion events we discussed above. As an example, let us discuss how **influenza virus** mediates membrane fusion (other membrane-enveloped viruses use similar systems). Virus-mediated membrane fusion occurs in three stages:

1. Host cell recognition by the virus.
2. Activation of the viral membrane fusion machinery.

PROCESS DIAGRAM

FIG. 9-47 A model for SNARE-mediated vesicle fusion. Here R-SNAREs and Q-SNAREs are schematically represented by blue and red worms. [After a drawing by Chen, Y.A. and Scheller, R.H., *Nature Rev. Mol. Cell Biol.* **2**, 98 (2001).] **WPLS** See the Animated Process Diagrams.

3. Fusion of the viral membrane with a host cell membrane so as to release the viral genome into the host cell cytoplasm.

The major integral protein component of the membrane that envelops influenza virus is named **hemagglutinin (HA)** because it causes erythrocytes to agglutinate (clump together). HA, a so-called **viral fusion protein**, mediates influenza host cell recognition by binding to specific glycoproteins that act as cell-surface receptors. These glycoproteins (like glycoporphin A in erythrocytes; Section 9-3A) bear terminal *N*-acetylneuraminic acid (sialic acid; Fig. 8-6) residues on their carbohydrate groups. HA is synthesized as a homotrimer of 550-residue subunits that are each anchored to the membrane by a single trans-membrane helix (residues 524–540). However, HA's Arg 329 is posttranslationally excised by host cell proteases to yield two peptides, designated HA1 and HA2, that remain linked by a disulfide bond.

After budding from the original host cell, an influenza virus particle can infect a new host cell. The virus binds to the plasma membrane of the new cell and is taken into the cell by the invagination of the membrane via a process known as **receptor-mediated endocytosis** (Section 20-1B) that superficially resembles the reverse of the fusion of a vesicle with a membrane (Fig. 9-42). The resulting intracellular vesicle with the virus bound to its inner surface then fuses with a vesicle known as an **endosome** that has an internal pH of ~ 5 . The consequent drop in pH triggers a conformational change in which the N-terminal end of HA2, a conserved, hydrophobic, ~ 24 -residue segment known as a **fusion**

FIG. 9-48 X-Ray structure of influenza hemagglutinin. (a) Ribbon diagram of the BHA monomer. HA1 is green and HA2 is cyan. (b) Ribbon diagram of the BHA trimer. Each HA1 and HA2 chain is drawn in a different color. The orientations of the green HA1 and the cyan HA2 are the same as in Part a. [Based on an X-ray structure by John Skehel, National Institute for Medical Research, London, U.K., and Don Wiley, Harvard University. PDBid 4HMG.]

peptide, inserts into the host cell's endosomal membrane, thereby tightly linking it to the viral membrane preparatory to their fusion.

Our understanding of how HA mediates the fusion of viral and host cell membranes is based largely on X-ray structural studies by Don Wiley and John Skehel. HA's hydrophobic membrane anchor interferes with its crystallization. However, the proteolytic removal of HA's transmembrane helix yields a crystallizable protein named BHA, whose X-ray structure includes a globular region that is perched on a long fibrous stalk projecting from the viral membrane surface (Fig. 9-48a). The globular region contains the sialic acid-binding pocket, whereas the fibrous stalk includes a remarkable 76-Å-long α helix (53 residues in 14 turns). The dominant interaction stabilizing BHA's trimeric structure is a triple-stranded coiled coil consisting of the long α helices from each of its protomers (Fig. 9-48b). Curiously, BHA's fusion peptides are buried in its hydrophobic interior, ~ 100 Å from the sialic acid-binding sites at the "top" of the protein.

In the endosome, HA undergoes a dramatic conformational change (Fig. 9-49), the nature of which was elucidated by the X-ray structure of a portion of BHA named TBHA2 that consists of BHA's long helix and some of its flanking regions. In this conformational change, segments A and B at the N-terminus of TBHA2 (the red and orange segments in Fig. 9-49) undergo a jackknife-like movement of ~ 100 Å in a way that extends the top of the long helix by ~ 10 helical turns toward the endosomal membrane. This translocates the fusion peptide (which is absent in TBHA2 but would extend beyond its N-terminus at the top of segment A) by at least ~ 100 Å above its position in BHA, thereby allowing it to insert into the host membrane. At the same time, the long helix is shortened from the bottom by similar shifts of segments D and E (green and blue in Fig. 9-49). These conformational changes, which simultaneously occur in several closely spaced HA molecules in the viral membrane, draw together the viral and host membranes so as to facilitate their fusion in a manner similar to that postulated for SNARE complexes.

CHECKPOINT

- Describe the fluid mosaic model.
- Explain how the membrane skeleton influences membrane protein distribution.
- Why are biological membranes asymmetrical?
- What are the functions of flippases and phospholipid translocases?
- Describe the structure of a lipid raft. Why might a raft be associated with a particular cellular activity?
- Summarize the steps of the secretory pathway, including the function of the translocon.
- Describe how a membrane protein, a secreted protein, and a lysosomal protein are transported from the RER to their final destinations.
- Why does it make sense that carbohydrate groups serve as intracellular addressing signals?
- Describe how SNAREs and viral fusion proteins such as hemagglutinin act to bring specific membranes close together and trigger their fusion.

FIG. 9-49 Schematic drawing comparing the structures of BHA and TBHA2. This drawing indicates the positions and heights above the viral membrane surface of TBHA2's various structural elements in the HA trimer (*left*) and in its low-pH form (*right*). In the low-pH form, the fusion peptide would protrude well above the receptor-binding heads where it would presumably insert itself into the endosomal membrane.

Summary

1 Lipid Classification

- Lipids are a diverse group of molecules that are soluble in organic solvents and, in contrast to other major types of biomolecules, do not form polymers.
- Fatty acids are carboxylic acids whose chain lengths and degrees of unsaturation vary.
- Adipocytes and other cells contain stores of triacylglycerols, which consist of three fatty acids esterified to glycerol.
- Glycerophospholipids are amphiphilic molecules that contain two fatty acid chains and a polar head group.
- The sphingolipids include sphingomyelins, cerebrosides, and gangliosides.
- Cholesterol, steroid hormones, and vitamin D are all based on a four-ring structure.
- The arachidonic acid derivatives prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins are signaling molecules that have diverse physiological roles.

2 Lipid Bilayers

- Glycerophospholipids and sphingolipids form bilayers in which their nonpolar tails associate with each other and their polar head groups are exposed to the aqueous solvent.
- Although the transverse diffusion of a lipid across a bilayer is extremely slow, lipids rapidly diffuse in the plane of the bilayer. Bilayer fluidity varies with temperature and with the chain lengths and degree of saturation of its component fatty acid residues.

3 Membrane Proteins

- The proteins of biological membranes include integral (intrinsic) proteins that contain one or more transmembrane α helices or a β barrel. In all cases, the membrane-exposed surface of the protein is hydrophobic.

- Other membrane-associated proteins may be anchored to the membrane via isoprenoid, fatty acid, or glycosylphosphatidylinositol (GPI) groups. Peripheral (extrinsic) proteins are loosely associated with the membrane surface.

4 Membrane Structure and Assembly

- The fluid mosaic model of membrane structure accounts for the lateral diffusion of membrane proteins and lipids.
- The arrangement of membrane proteins in the lipid bilayer may depend on their interactions with an underlying protein skeleton, as in the erythrocyte.
- Membrane proteins and lipids are distributed asymmetrically in the two leaflets of the bilayer and may form domains such as lipid rafts.
- Transmembrane (TM), secretory, and lysosomal proteins in eukaryotes are synthesized by means of the secretory pathway. A signal peptide directs a growing polypeptide chain through the RER membrane via a protein pore called the translocon, which also functions to laterally install TM proteins into the RER membrane.
- Coated vesicles transport membrane-embedded and luminal proteins from the ER to the Golgi apparatus for further processing, and from there to other membranes. The proteins coating these vesicles may consist largely of clathrin, which forms polyhedral cages, or COPI or COPII, which form coats with an amorphous appearance.
- The fusion of vesicles with membranes occurs via a complex process that involves SNAREs. These form four-helix bundles that bring two membranes into proximity, which in turn induces membrane fusion.
- Viral fusion proteins mediate the fusion of membrane-enveloped viruses such as influenza virus with their host cell membranes so as to release the viral nucleic acids into the host cell cytoplasm.

Problems

EXERCISES

- Does *trans*-oleic acid have a higher or lower melting point than *cis*-oleic acid? Explain.
- Which triacylglycerol yields more energy on oxidation: one containing three residues of linolenic acid or three residues of stearic acid?
- Draw the structure of a glycerophospholipid that has a saturated C₁₆ fatty acyl group at position 1, a monounsaturated C₁₈ fatty acyl group at position 2, and an ethanolamine head group.
- Name this lipid.

- How many different types of triacylglycerols could incorporate the fatty acids shown in Fig. 9-1?
- What products are obtained when 1-palmitoyl-2-oleoyl-3-phosphatidylserine is hydrolyzed by (a) phospholipase A₁; (b) phospholipase A₂; (c) phospholipase C; (d) phospholipase D?
- Which of the glycerophospholipid head groups listed in Table 9-2 can form hydrogen bonds?
- Does the phosphatidylglycerol “head group” of cardiolipin (Table 9-2) project out of a lipid bilayer like other glycerophospholipid head groups?
- Identify the hormone molecule shown here. What membrane lipid is it derived from?

- Draw the structure of the fatty acid amide that forms when arachidonate is linked to ethanolamine.
- Animals cannot synthesize linoleic acid (a precursor of arachidonic acid) and therefore must obtain this **essential fatty acid** from their diet. Explain why cultured animal cells can survive in the absence of linoleic acid.
- Many bacterial fatty acids contain branches and even rings. What effect do these lipids have on membrane fluidity, compared to their straight-chain counterparts?
- Why can't triacylglycerols be significant components of lipid bilayers?
- Why would a bilayer containing only gangliosides be unstable?
- When bacteria growing at 20°C are warmed to 30°C, are they more likely to synthesize membrane lipids with (a) saturated or unsaturated fatty acids, and (b) short-chain or long-chain fatty acids? Explain.
- Do membranes of the Antarctic icefish (see page 180) have longer and/or more saturated fatty acids compared to tropical fish? Explain.
- (a) How many turns of an α helix are required to span a lipid bilayer (~30 Å across)? (b) What is the minimum number of residues required? (c) Why do most transmembrane helices contain more than the minimum number of residues?
- The distance between successive C_α atoms in a β sheet is ~3.5 Å. Can a single 9-residue segment with a β conformation serve as the transmembrane portion of an integral membrane protein?
- Are the following lipid samples likely to correspond to the inner or outer leaflet of a eukaryotic plasma membrane? (a) 20% phosphatidylcholine, 15% phosphatidylserine, 65% other lipids. (b) 35% phosphatidylcholine, 15% gangliosides, 5% cholesterol, 45% other lipids.
- In order to consume and dispose of dying cells, macrophages (amoebalike white blood cells) recognize phosphatidylserine (PS) on the outer surface of the target cell. Why is PS a useful marker of a moribund cell?

CHALLENGE QUESTIONS

- Sphingosine-1-phosphate can serve as a cell signaling molecule. (a) Draw the structure of this compound. (b) What chemical reactions

- C ABC Transporters Are Responsible for Drug Resistance
- D Active Transport May Be Driven by Ion Gradients

Susumu Nishinaga/Photo Researchers, Inc.

This scanning electron micrograph shows a kidney glomerulus, the structure that filters small molecules from the blood. In order to eliminate the waste materials and retain the nutrients present in the filtrate, kidney cells rely on a variety of membrane proteins to transport water, ions, and other substances.

Cells are separated from their environments by plasma membranes. Eukaryotic cells, in addition, are compartmentalized by intracellular membranes that form the boundaries and internal structures of their various organelles. Biological membranes present formidable barriers to the passage of ionic and polar substances, so *these substances can traverse membranes only through the action of specific transport proteins*. Such proteins are therefore required to mediate the transmembrane movements of ions, such as Na^+ , K^+ , Ca^{2+} , and Cl^- , as well as metabolites such as pyruvate, amino acids, sugars, and nucleotides, and even water. Transport proteins are also responsible for all biological electrochemical phenomena such as neurotransmission. More complicated processes (e.g., endocytosis) are required to move larger substances such as proteins and macromolecular aggregates across membranes.

We begin our discussion of membrane transport by considering the thermodynamics of this process. We will then examine the structures and mechanisms of several different types of transport systems.

1 Thermodynamics of Transport

KEY CONCEPTS

- The free energy change for moving a substance across a membrane depends on the concentrations on each side of the membrane and, for ions, on the membrane potential.
- For a substance that cannot diffuse directly across a membrane, transport may be mediated by a protein and may require free energy input.

The diffusion of a substance between two sides of a membrane

thermodynamically resembles a chemical equilibration. We saw in Section 1-3D that the free energy of a solute, A, varies with its concentration:

$$\bar{G}_A = \bar{G}_A^{o'} + RT \ln[A] \quad [10-1]$$

where \bar{G}_A is the **chemical potential** (partial molar free energy) of A (the bar indicates quantity per mole) and $\bar{G}_A^{o'}$ is the chemical potential of its standard state. Thus, a difference in the concentrations of the substance on two sides of a membrane generates a **chemical potential difference**:

$$\Delta\bar{G}_A = \bar{G}_A(in) - \bar{G}_A(out) = RT \ln \left(\frac{[A]_{in}}{[A]_{out}} \right) \quad [10-2]$$

Consequently, if the concentration of A outside the membrane is greater than that inside, $\Delta\bar{G}_A$ for the transfer of A from outside to inside will be negative and the spontaneous net flow of A will be inward. If, however, [A] is greater inside than outside, $\Delta\bar{G}_A$ is positive and an inward net flow of A can occur only if an exergonic process, such as ATP hydrolysis, is coupled to it to make the overall free energy change negative (see Sample Calculation 10-1).

The transmembrane movement of ions also results in charge differences across the membrane, thereby generating an electrical potential difference, $\Delta\Psi = \Psi(in) - \Psi(out)$, where $\Delta\Psi$ is termed the **membrane potential**. Consequently, if A is ionic, Eq. 10-2 must be amended to include the electrical work required to transfer a mole of A across the membrane from outside to inside:

$$\Delta\bar{G}_A = RT \ln \left(\frac{[A]_{in}}{[A]_{out}} \right) + Z_A \mathcal{F} \Delta\Psi \quad [10-3]$$

where Z_A is the ionic charge of A; \mathcal{F} , the Faraday constant, is the charge of a mole of electrons ($96,485 \text{ C} \cdot \text{mol}^{-1}$; C is the symbol for coulomb); and \bar{G}_A is now termed the **electrochemical potential** of A (see Sample Calculation 10-2). The membrane potentials of living cells are commonly as large as -100 mV (inside negative; note that $1 \text{ V} = 1 \text{ J} \cdot \text{C}^{-1}$), which for a 50-\AA -thick membrane corresponds to a voltage gradient of $200,000 \text{ V} \cdot \text{cm}^{-1}$. Hence, the last term in Eq. 10-3 is often significant for ionic substances, particularly in mitochondria (Chapter 18) and in neurotransmission (Section 10-2C).

Transport May Be Mediated or Nonmediated. There are two types of transport processes: **nonmediated transport** and **mediated transport**. Nonmediated transport occurs through simple diffusion. In contrast, mediated transport occurs through the action of specific carrier proteins. The driving force for the nonmediated flow of a substance through a medium is its chemical potential gradient. Thus, *the substance diffuses in the direction that eliminates its concentration gradient, at a rate proportional to the magnitude of the gradient. The rate of diffusion of a substance also depends on its solubility in the membrane's nonpolar core.* Consequently, nonpolar molecules such as steroids and O_2 readily diffuse through biological membranes by nonmediated transport, according to their concentration gradients across the membranes.

SAMPLE CALCULATION 10-1

Show that $\Delta G < 0$ when Ca^{2+} ions move from the endoplasmic reticulum (where $[\text{Ca}^{2+}] = 1 \text{ mM}$) to the cytosol (where $[\text{Ca}^{2+}] = 0.1 \text{ }\mu\text{M}$). Assume $\Delta\Psi = 0$.

The cytosol is *in* and the endoplasmic reticulum is *out*.

$$\begin{aligned} \Delta G &= RT \ln \frac{[\text{Ca}^{2+}]_{in}}{[\text{Ca}^{2+}]_{out}} = RT \ln \frac{10^{-7}}{10^{-3}} \\ &= RT(-9.2) \end{aligned}$$

Hence, ΔG is negative.

WPLS See Sample Calculation Videos.

SAMPLE CALCULATION 10-2

Calculate the free energy required to move 1 mol of Na^+ ions from outside the cell (where $[\text{Na}^+] = 150 \text{ mM}$) to the inside (where $[\text{Na}^+] = 5 \text{ mM}$) when the membrane potential is -70 mV and the temperature is 37°C .

Use Equation 10-3:

$$\begin{aligned}\Delta G &= RT \ln \frac{[\text{Na}^+]_{in}}{[\text{Na}^+]_{out}} + Z\mathcal{F}\Delta\Psi \\ &= (8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K}) \ln(0.005/0.150) \\ &\quad + (1)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(-0.070 \text{ V}) \\ &= -8763 \text{ J} \cdot \text{mol}^{-1} - 6754 \text{ J} \cdot \text{mol}^{-1} \\ &= -15,500 \text{ J} \cdot \text{mol}^{-1} = -15.5 \text{ kJ} \cdot \text{mol}^{-1}\end{aligned}$$

WPLS See Sample Calculation Videos.

Mediated transport is classified into two categories depending on the thermodynamics of the system:

1. **Passive-mediated transport, or facilitated diffusion**, in which a specific molecule flows from high concentration to low concentration.
2. **Active transport**, in which a specific molecule is transported from low concentration to high concentration, that is, against its concentration gradient. Such an endergonic process must be coupled to a sufficiently exergonic process to make it favorable (i.e., $\Delta G < 0$).

CHECKPOINT

- How can you predict whether it will be thermodynamically favorable for an uncharged substance to move from one side of a membrane to the other?
- If the substance is charged, what additional information do you need to predict whether its transmembrane movement will be spontaneous?
- Give an example of a substance that can diffuse across a membrane. Give an example of a substance that must cross a membrane by mediated transport.

2 Passive-Mediated Transport

KEY CONCEPTS

- Passive-mediated transport is carried out by ionophores, porins, ion channels, aquaporins, and transport proteins.
- Ionophores may carry ions or form channels.
- Porins provide a passageway for ions or nonpolar solutes.
- Ion channels are highly selective and may be gated.
- The coordinated opening and closing of ion channels generates an action potential in nerve cells.
- Aquaporins mediate the transmembrane passage of water molecules.
- Transport proteins may mediate uniport, symport, and antiport transport.

Substances that are too large or too polar to diffuse across lipid bilayers on their own may be conveyed across membranes via proteins or other molecules that are variously called **carriers**, **permeases**, **channels**, and **transporters**. These transporters operate under the same thermodynamic principles but vary widely in structure and mechanism, particularly as it relates to their selectivity.

A Ionophores Carry Ions across Membranes

Ionophores are organic molecules of diverse types, usually of bacterial origin, that increase the permeability of membranes to ions. These molecules often exert an antibiotic effect by discharging the vital ion concentration gradients that cells actively maintain.

There are two types of ionophores:

1. **Carrier ionophores**, which increase the permeabilities of membranes to their selected ion by binding it, diffusing through the membrane, and

FIG. 10-1 Ionophore action. (a) Carrier ionophores transport ions by diffusing through the lipid bilayer. (b) Channel-forming ionophores span the membrane with a channel through which ions can diffuse.

? What do the ionophores do when the concentration of ions is the same on both sides of the membrane?

releasing the ion on the other side (Fig. 10-1a). For net transport to occur, the uncomplexed ionophore must then return to the original side of the membrane ready to repeat the process. Carriers therefore share the common property that *their ionic complexes are soluble in nonpolar solvents*.

2. **Channel-forming ionophores**, which form transmembrane channels or pores through which their selected ions can diffuse (Fig. 10-1b).

Both types of ionophores transport ions at a remarkable rate. For example, a single molecule of the carrier ionophore **valinomycin** transports up to 10^4 K^+ ions per second across a membrane. However, *since ionophores passively permit ions to diffuse across a membrane in either direction, their effect can only be to equilibrate the concentrations of their selected ions across the membrane*.

Valinomycin, which is one of the best characterized ionophores, specifically binds K^+ . It is a cyclic molecule containing D- and L-amino acid residues that participate in ester linkages as well as peptide bonds (Fig. 10-2a). The X-ray structure of valinomycin's K^+ complex (Fig. 10-2b) indicates that the K^+ ion is octahedrally coordinated by the carbonyl groups of its six Val residues, and the

FIG. 10-2 Valinomycin. (a) This cyclic ionophore contains ester and amide bonds and D- as well as L-amino acids. (b) X-Ray structure of valinomycin in complex with a K^+ ion colored according to atom type (C green, H white, N blue, O red, and K^+ purple) and embedded in its molecular surface (blue mesh). Note that the K^+ ion is octahedrally coordinated by the carbonyl oxygen atoms of six Val residues and that the surface of the complex is largely covered with methyl and isopropyl groups. [Based on an X-ray structure by Max Dobler, ETH, Zürich, Switzerland.]

cyclic valinomycin backbone surrounds the K^+ coordination shell. The methyl and isopropyl side chains project outward to provide the complex with a non-polar exterior that makes it soluble in the hydrophobic cores of lipid bilayers.

The K^+ ion (ionic radius, $r = 1.33 \text{ \AA}$) fits snugly into valinomycin's coordination site, but the site is too large for Na^+ ($r = 0.95 \text{ \AA}$) or Li^+ ($r = 0.60 \text{ \AA}$) to coordinate with all six carbonyl oxygens. Valinomycin therefore has 10,000-fold greater binding affinity for K^+ than for Na^+ . No other known substance discriminates better between Na^+ and K^+ .

B Porins Contain β Barrels

The porins, introduced in Section 9-3A, are β barrel structures with a central aqueous channel. In the *E. coli* OmpF porin (Fig. 9-23), the channel is constricted to form an elliptical pore with a minimum cross section of $7 \times 11 \text{ \AA}$. Consequently, solutes of more than $\sim 600 \text{ D}$ are too large to pass through the channel. OmpF is weakly cation selective; other porins are more selective for anions. In general, the size of the channel and the residues that form its walls determine what types of substances can pass through.

Solute selectivity is elegantly illustrated by **maltoporin**. This bacterial outer membrane protein facilitates the diffusion of **maltodextrins**, which are the $\alpha(1 \rightarrow 4)$ -linked glucose oligosaccharide degradation products of starch (Section 8-2C). The X-ray structure of *E. coli* maltoporin reveals that the protein is structurally similar to OmpF porin but is a homotrimer of 18-stranded rather than 16-stranded antiparallel β barrels. Three long loops from the extracellular face of each maltoporin subunit fold inward into the barrel, thereby constricting the channel near the center of the membrane to a diameter of $\sim 5 \text{ \AA}$ and giving the channel an hourglass-like cross section. The channel is lined on one side with a series of six contiguous aromatic side chains arranged in a left-handed helical path that matches the left-hand helical curvature of α -amylose (Fig. 8-10). This so-called greasy slide extends from one end of the channel, through its constriction, to the other end (Fig. 10-3).

How does the greasy slide work? The hydrophobic faces of the maltodextrin glucose residues stack on aromatic side chains, as is often observed in complexes of sugars with proteins. The glucose hydroxyl groups, which are arranged in two strips along opposite edges of the maltodextrins, form numerous hydrogen bonds with polar and charged side chains that line the channel. Tyr 118, which protrudes into the channel opposite the greasy slide, apparently functions as a steric barrier that permits the passage only of near-planar groups such as glucosyl residues. Thus, the hook-shaped sucrose (a glucose-fructose disaccharide) passes only very slowly through the maltoporin channel.

At the start of the translocation process, the entering glucosyl residue interacts with the readily accessible end of the greasy slide in the extracellular vestibule of the channel. Further translocation along the helical channel requires the maltodextrin to follow a screwlike path that maintains the helical structure of the oligosaccharide, much like the movement of a bolt through a nut, thereby excluding molecules of comparable size that have different shapes. *The translocation process is unlikely to encounter any large energy barrier due to the smooth surface of the greasy slide and the multiple polar groups at the channel constriction that would permit the essentially continuous exchange of hydrogen bonds as a maltodextrin moves through the constriction.*

C Ion Channels Are Highly Selective

All cells contain ion-specific channels that allow the rapid passage of ions such as Na^+ , K^+ , and Cl^- . The movement of these ions through such channels, along with their movement through active transporters (discussed in Section 10-3), is essential for maintaining osmotic balance, for signal transduction (Section 13-4A), and for effecting changes in membrane potential that are responsible for

GATEWAY CONCEPT Equilibrium

All reacting systems proceed toward equilibrium, which, in the case of solutes on either side of membrane, means equal concentrations on both sides. But the speed at which the solutes move depends on *how* they cross the membrane. In cells, solutes may move fast or slow, but they very seldom actually reach equilibrium.

Based on an X-ray structure by Tilman Schirmer, University of Basel, Basel, Switzerland. PDBid 1MPO

FIG. 10-3 Structure of a maltoporin subunit in complex with a maltodextrin of six glycosyl units.

The polypeptide backbone of this *E. coli* protein is represented by a multithreaded cyan ribbon. Five glucose residues of maltodextrin and the aromatic side chains lining the transport channel are shown in space-filling form with N blue, O red, protein C gold, and glucosyl C green. The "greasy slide" consists of the aromatic side chains of six residues. Tyr 118, which projects into the channel, helps restrict passage to glucosyl residues.

neurotransmission. Mammalian cells, for example, maintain a nonequilibrium distribution of ions on either side of the plasma membrane: ~ 150 mM Na^+ and ~ 4 mM K^+ in the extracellular fluid, and ~ 12 mM Na^+ and ~ 140 mM K^+ inside the cell.

The Structure of the KcsA K^+ Channel Explains Its Selectivity and Speed.

Potassium ions passively diffuse from the cytoplasm to the extracellular space through transmembrane proteins known as **K^+ channels**. Although there is a large diversity of K^+ channels, even within a single organism, all of them have similar sequences, exhibit comparable permeability characteristics, and most importantly, are at least 10,000-fold more permeable to K^+ than Na^+ . Since this high selectivity (around the same as that of valinomycin; Section 10-2A) implies energetically strong interactions between K^+ and the protein, how can the K^+ channel maintain its observed nearly diffusion-limited throughput rate of up to 10^8 ions per second (a 10^4 -fold greater rate than that of valinomycin)?

One of the best characterized ion channels is a K^+ channel from *Streptomyces lividans* named **KcsA**. This 158-residue integral membrane protein, like all known K^+ channels, functions as a homotetramer. The X-ray structure of KcsA's N-terminal 125-residue segment, determined by Roderick MacKinnon, reveals that each of its subunits contains two nearly antiparallel transmembrane helices plus a shorter helix (Fig. 10-4a). Four such subunits associate to form a fourfold symmetric assembly surrounding a central pore. The four inner helices, which largely form the pore, pack against each other near the cytoplasmic side of the

FIG. 10-4 X-Ray structure of the KcsA K^+ channel. (a) Ribbon diagram of the tetramer as viewed from within the plane of the membrane, with the cytoplasm below and the extracellular region above. The protein's fourfold axis of rotation is vertical and each of its identical subunits is differently colored, with that on the left colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Each subunit has an inner helix that forms part of the central pore, an outer helix that contacts the membrane interior, and a turret that projects out into the extracellular space. The selectivity filter at the extracellular end of the protein allows the passage of K^+ ions but not Na^+ ions. [Based on an X-ray structure by Roderick MacKinnon, Rockefeller University. PDBid 1BL8.] (b) Cutaway diagram viewed similarly to Part a in which the K^+ channel is represented by its solvent-accessible surface. The surface is colored according to its physical properties with negatively charged areas red, uncharged areas white, positively charged areas blue, and hydrophobic areas of the central pore yellow. K^+ ions are represented by green spheres.

? Explain why so much of the protein surface is nonpolar.

membrane much like the poles of an inverted teepee. The four outer helices, which face the lipid bilayer, buttress the inner helices. The central pore can accommodate several K^+ ions (Fig. 10-4b).

The 45-Å-long central pore has variable width: It starts at its cytoplasmic side as an ~ 6 -Å-diameter tunnel whose entrance is lined with four anionic side chains (red area at the bottom of Fig. 10-4b) that presumably attract cations and repel anions. The pore then widens to form an ~ 10 -Å-diameter cavity. These regions of the central pore are wide enough so that a K^+ ion could move through them in its hydrated state. However, the upper part of the pore, called the selectivity filter, narrows to 3 Å, thereby forcing a transiting K^+ ion to shed its waters of hydration. The walls of the pore and the cavity are lined with hydrophobic groups that interact minimally with diffusing ions (yellow area of the pore in Fig. 10-4b). However, the selectivity filter (red area of the pore at the top of Fig. 10-4b) is lined with closely spaced main chain carbonyl oxygens of residues from a TVGYG “signature sequence” that is highly conserved in all K^+ channels.

How does the K^+ channel discriminate so acutely between K^+ and Na^+ ions? The main chain O atoms lining the selectivity filter form a stack of rings (Fig. 10-5, top) that provide a series of closely spaced sites of appropriate dimensions for coordinating dehydrated K^+ ions but not the smaller Na^+ ions. The structure of the protein surrounding the selectivity filter suggests that the diameter of the pore is rigidly maintained, thus making the energy of a dehydrated Na^+ in the selectivity filter considerably higher than that of hydrated Na^+ and thereby accounting for the K^+ channel’s high selectivity for K^+ ions.

What is the function of the cavity? Energy calculations indicate that an ion moving through a narrow transmembrane pore must surmount an energy barrier that is maximal at the center of the membrane. The existence of the cavity reduces this electrostatic destabilization by surrounding the ion with polarizable water molecules (Fig. 10-5, bottom). The cavity holds ~ 40 additional water molecules, which are disordered and therefore not seen in the X-ray structure. Remarkably, the K^+ ion occupying the cavity is liganded by 8 ordered water molecules located at the corners of a square antiprism (a cube with one face twisted by 45° with respect to the opposite face). K^+ in aqueous solution is known to have such an inner hydration shell but it had never before been visualized.

How does KcsA support such a high throughput of K^+ ions (up to 10^8 ions per second)? Figure 10-5 shows a string of regularly spaced K^+ ions: four in the selectivity filter and two more just outside it on its extracellular (top) side. Such closely spaced positive ions would strongly repel one another and hence represent a high energy situation. However, the X-ray structure is an average of many KcsA molecules, and a variety of evidence indicates that within a single channel, the K^+ ions in the pore actually alternate with water molecules. This arrangement means that each K^+ ion is surrounded by O atoms (from H_2O or protein carbonyl groups) at each position along the selectivity filter. As a K^+ ion moves into the selectivity filter from the cavity, it exchanges some of its hydrating water molecules for protein ligands, then does the reverse to restore its hydration shell when it exits the selectivity filter to enter the extracellular solution. Within the selectivity filter, the ligands are spaced and oriented such that there is little free energy change ($<12 \text{ kJ} \cdot \text{mol}^{-1}$) as a K^+ ion moves to successive positions. This level free energy landscape allows the rapid movement of K^+ ions through the ion channel. In addition, mutual electrostatic repulsions between successive K^+ ions balance the attractive interactions holding these ions in the selectivity filter and hence further facilitate their rapid transit. Note, however, that this mechanism does not impose a direction on the migration of K^+ ions. The net flux (rate of transport per unit area) of K^+ ions depends only on the electrochemical potential across the membrane, that is, the K^+ ions undergo passive-mediated transport (Section 10-1).

FIG. 10-5 Portions of the KcsA K^+ channel responsible for its ion selectivity. The protein is viewed similarly to Fig. 10-4 but with the front and back subunits omitted for clarity. The residues forming the cavity (bottom) and selectivity filter (top) are shown with atoms colored according to type (C yellow, N blue, O red, and K^+ ions represented by green spheres). The water and protein O atoms that ligand the K^+ ions, including those contributed by the front and back subunits, are represented by red spheres. The coordination polyhedra formed by these O atoms are outlined by thin white lines.

Ion Channels Are Gated. The physiological functions of ion channels depend not only on their exquisite ion specificity and speed of transport but also on their ability to be selectively opened or closed. For example, the ion gradients across cell membranes, which are generated by specific energy-driven pumps (Section 10-3), are discharged through Na^+ and K^+ channels. However, the pumps could not keep up with the massive fluxes of ions passing through the open channels, so *ion channels are normally shut and only open transiently to perform some specific task for the cell.* The opening and closing of ion channels, a process known as **gating**, can occur in response to a variety of stimuli:

1. **Mechanosensitive channels** open in response to local deformations in the lipid bilayer. Consequently, they respond to direct physical stimuli such as touch, sound, and changes in osmotic pressure.
2. **Ligand-gated channels** open in response to an extracellular chemical stimulus such as a neurotransmitter.
3. **Signal-gated channels** open on intracellularly binding a Ca^{2+} ion or some other signaling molecule (Section 13-4B).
4. **Voltage-gated channels** open in response to a change in membrane potential. Multicellular organisms contain numerous varieties of voltage-gated channels, including those responsible for generating nerve impulses.

Nerve Impulses Are Propagated by Action Potentials. As an example of the functions of voltage-gated channels, let us consider electrical signaling events in neurons (nerve cells). The release of neurotransmitters across a synaptic junction (Fig. 9-45) causes Na^+ channels on the postsynaptic membrane to open so that Na^+ ions spontaneously flow into the downstream neuron. The consequent local increase in membrane potential induces neighboring voltage-gated Na^+ channels to open. The resulting local **depolarization** of the membrane induces nearby voltage-gated K^+ channels to open. This allows K^+ ions to spontaneously flow out of the cell in a process called **hyperpolarization** (Fig. 10-6). However, well before the distribution of Na^+ and K^+ ions across the membrane equilibrates, the Na^+ and K^+ channels spontaneously close. Yet, because depolarization of a membrane segment induces the voltage-gated Na^+ channels in a neighboring membrane segment to open, which induces their neighboring voltage-gated Na^+ channels to open, etc., a wave of transient change in the membrane potential, called an **action potential**, travels along the length of the nerve cell (which may

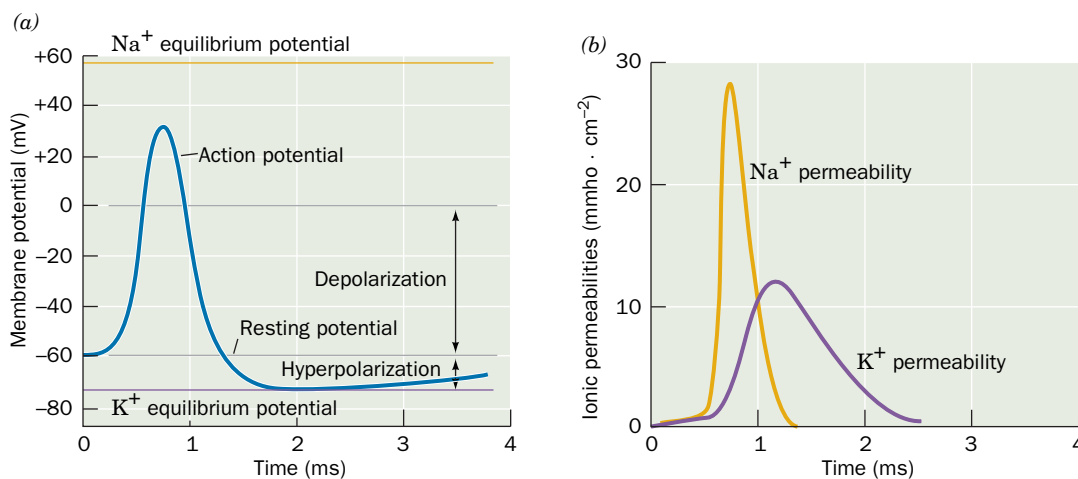

FIG. 10-6 Time course of an action potential. (a) The neuron membrane, whose resting membrane potential is inside negative, undergoes rapid depolarization, followed by a nearly as rapid hyperpolarization and then a slow recovery to its resting potential.

(b) The depolarization is caused by a transient increase in Na^+ permeability (conductance), whereas the hyperpolarization results from a more prolonged increase in K^+ permeability that begins a fraction of a millisecond later. [After Hodgkin, A.L. and Huxley, A.F., *J. Physiol.* **117**, 530 (1952).]

? Explain why Na^+ ions flow into the cell, whereas K^+ ions flow out.

be over 1 m long). The action potential, which travels at ~ 10 m/s, propagates in only one direction because, after the ion channels have spontaneously closed, they resist reopening until the membrane potential has regained its resting value, which takes a few milliseconds (Fig. 10-6).

As an action potential is propagated along the length of a nerve cell, it is continuously renewed so that its signal strength remains constant (in contrast, an electrical impulse traveling down a wire dissipates as a consequence of resistive and capacitive effects). Nevertheless, the relative ion imbalance responsible for the resting membrane potential is small; only a tiny fraction of a nerve cell's $\text{Na}^+ - \text{K}^+$ gradient (which is generated by ion pumps; Section 10-3A) is discharged by a single nerve impulse (only one K^+ ion per 3000–300,000 in the cytosol is exchanged for extracellular Na^+ as indicated by measurements with radioactive Na^+). A nerve cell can therefore transmit a nerve impulse every few milliseconds without letup. This capacity to fire rapidly is an essential feature of neuronal communications: Since action potentials all have the same amplitude, the magnitude of a stimulus is conveyed by the rate at which a nerve fires.

Voltage Gating in Kv Channels Is Triggered by the Motion of a Positively Charged Protein Helix. The subunits of all voltage-gated K^+ channels contain an ~ 220 -residue N-terminal cytoplasmic domain, an ~ 250 -residue transmembrane domain consisting of six helices, S1 to S6, and an ~ 150 -residue C-terminal cytoplasmic domain (Fig. 10-7). S5 and S6 are respectively homologous to the outer and inner transmembrane helices of the KcsA channel (Fig. 10-4), and their intervening P-loop, which forms the selectivity filter, includes the same TVGYG signature sequence that occurs in KcsA. In the voltage-gated K^+ channels known as **Kv channels**, a conserved, cytoplasmic, ~ 100 -residue so-called T1 domain precedes the transmembrane domain.

Kv channels closely resemble the KcsA channel in their tetrameric pore structure, but what is the nature of the gating machinery in the voltage-gated ion channels? The ~ 19 -residue S4 helix, which contains around five positively charged side chains spaced about every three residues on an otherwise hydrophobic polypeptide, appears to act as a voltage sensor. Various experimental approaches indicate that when the membrane potential increases (the inside becomes less negative), the S4 helix is pulled toward the extracellular side of the membrane.

The X-ray structure of a Kv channel from rat brain named **Kv1.2** (Fig. 10-8) shows how gating might occur. As the membrane begins to depolarize, the four conserved Arg residues on the S4 helix are drawn toward the extracellular surface (up in Fig. 10-9), pulling on the S4–S5 linker helix (not drawn in Fig. 10-7) and with it the S5 helix. This splays the ends of the S6 helices so as to enlarge the intracellular entrance to the K^+ channel (Fig. 10-9b). During repolarization, as the cell interior becomes more negative, the positively charged S4 helix drops back toward the cytoplasmic side of the membrane, pressing down on the S4–S5 lever to close off the channel (Fig. 10-9c).

Ion Channels Have a Second Gate. Electrophysiological measurements indicate that Kv channels spontaneously close a few milliseconds after opening and do not reopen until after the membrane has regained its resting membrane potential. Evidently, *the Kv channel contains two voltage-sensitive gates, one to open the channel on an increase in membrane potential and one to inactivate it a short time later.* This inactivation of the Kv channel is abolished by proteolytically excising its N-terminal 20-residue segment, whose NMR structure is a ball-like assembly. In the intact Kv channel, this “inactivation ball” is tethered to the end of a flexible 65-residue peptide segment (Fig. 10-7), suggesting that channel inactivation normally occurs when the ball swings around to bind in the mouth of the open K^+ pore, thereby blocking the passage of K^+ ions. The mobility of this “ball and chain” is presumably why it is not visible in the X-ray structure of Kv1.2 (Fig. 10-8).

FIG. 10-7 Topology of voltage-gated K^+ channel subunits.

FIG. 10-8 X-Ray structure of the Kv1.2 voltage-gated K^+ channel.

(a) View along the tetrameric protein's fourfold axis from the extracellular side of the membrane in which it is embedded. Each of its four identical subunits is colored differently, and the T1 domain has been omitted for clarity. The fragmented appearance of the polypeptide chains is due to the high mobilities of the missing segments. The S5 and S6 helices with their intervening P loops form the pore for K^+ ions (delineated by green spheres). Helices S1 to S4 form a separate intramembrane voltage-sensing domain that associates with the S5 and S6 helices of the clockwise

adjacent subunit, resulting in an iris-like opening and closing of the K^+ channel. (b) View perpendicular to that in Part a with the extracellular side of the membrane above. The pore and voltage sensing domains span a distance of 30 Å, the thickness of the membrane's hydrophobic core. The T1 domain, which occupies the cytoplasm, forms the vestibule of the transmembrane K^+ channel. The four large openings between the T1 domain and the K^+ channel are the portals through which K^+ ions enter the K^+ channel. [Based on an X-ray structure by Roderick MacKinnon, Rockefeller University. PDBid 2A79.]

The T1 tetramer does not have an axial channel, so the inactivation ball must find its way to block the central pore through the side portals between the T1 tetramer and the central pore (Fig. 10-8b). These portals, which are 15 to 20 Å across, are lined with negatively charged groups that presumably attract K^+ ions.

The cytoplasmic entrance to the K^+ channel pore is only 6 Å in diameter, too narrow to admit the inactivation ball. Therefore, it appears that the ball peptide must unfold in order to enter the pore. The first 10 residues of the unfolded ball peptide are predominantly hydrophobic and presumably make contact with the

FIG. 10-9 Operation of the transmembrane domain of the Kv1.2 voltage-gated K^+ channel. (a) Side view of a single subunit with its extracellular side at the top. The pore-forming helices (S5 and S6) are gray, and the voltage-sensor domain (helices S1–S4) is blue. The S4–S5 linker helix (not drawn in Fig. 10-7), which is parallel to the membrane surface, connects the voltage-sensing domain to the domain forming the K^+ pore (delineated by green spheres). Four Arg residues on S4 are shown in ball-and-stick form with C atoms gold and N atoms blue.

Two of these residues interact with the protein, and two project into the lipid bilayer. (b) Side view of the channel tetramer in its open conformation. The S5 helices are gray, the S6 helices are blue, and the S4–S5 linker helix is red. (c) Hypothetical model of the channel in its closed conformation, colored as in Part b. The downward movement of the Arg-bearing S4 helix (not shown in this drawing) pushes down on the S4–S5 linker helix to pinch off the pore at its cytoplasmic end (*bottom*). [Courtesy of Roderick MacKinnon, Rockefeller University. PDBid 2A79.]

hydrophobic residues lining the Kv channel pore. The next 10 residues, which are largely hydrophilic and contain several cationic groups, bind to anionic groups lining the entrance to the side portals in T1. Thus, the inactivation peptide acts more like a snake than a ball and chain. A Kv channel engineered so that only one subunit has an inactivation peptide still becomes inactivated but at one-fourth the rate of normal Kv channels. Apparently, any of the normal Kv channel's four inactivation peptides can block the channel and it is simply a matter of chance as to which one does so.

Other Voltage-Gated Cation Channels Contain a Central Pore. Voltage-gated Na^+ and Ca^{2+} channels resemble K^+ channels, although rather than forming homotetramers, they are monomers of four consecutive domains, each of which is homologous to a K^+ channel subunit, separated by often large cytoplasmic loops. These domains presumably assume a pseudotetrameric arrangement about a central pore resembling that of voltage-gated K^+ channels. This structural homology suggests that voltage-gated ion channels share a common architecture in which differences in ion selectivity arise from precise stereochemical variations within the central pore. However, outside of their conserved transmembrane core, voltage-gated ion channels with different ion selectivities are highly divergent. For example, the T1 domain of Kv channels is absent in other types of voltage-gated ion channels.

Cl^- Channels Differ from Cation Channels. Cl^- channels, which occur in all cell types, permit the transmembrane movement of chloride ions along their concentration gradient. In mammals, the extracellular Cl^- concentration is ~ 120 mM and the intracellular concentration is ~ 4 mM.

CIC Cl^- channels form a large family of anion channels that occur widely in both prokaryotes and eukaryotes. The X-ray structures of CIC Cl^- channels from two species of bacteria, determined by Raimund Dutzler and MacKinnon, reveal, as biophysical measurements had previously suggested, that CIC Cl^- channels are homodimers with each subunit forming an anion-selective pore (Fig. 10-10). Each subunit consists mainly of 18 mostly transmembrane α helices that are remarkably tilted with respect to the membrane plane and have variable lengths compared to the transmembrane helices in other integral proteins of known structures.

The specificity of the Cl^- channel results from an electrostatic field established by basic amino acids on the protein surface, which helps funnel anions toward the pore, and by a selectivity filter formed by the N-terminal ends of several α helices.

FIG. 10-10 X-Ray structure of the CIC Cl^- channel from *Salmonella typhimurium*. Each subunit of the homodimer contains 18 α helices of variable lengths. The subunits are drawn in ribbon form with one colored in rainbow order from its N-terminus (blue) to its C-terminus (red) and the other pink. The two Cl^- ions bound in the selectivity filter of each subunit are represented by pale green spheres. (a) View from

within the membrane with the extracellular surface above and the 2-fold axis relating the two subunits vertical. (b) View from the extracellular side of the membrane along the molecular 2-fold axis. [Based on an X-ray structure by Raimund Dutzler and Roderick MacKinnon, Rockefeller University. PDBid 1OTS.]

Because the polar groups of an α helix are all aligned (Fig. 6-7), it forms a strong electrical dipole with its N-terminal end positively charged. This feature of the selectivity filter helps attract Cl^- ions, which are specifically coordinated by main chain amide nitrogens and side chain hydroxyls from Ser and Tyr residues. A positively charged residue such as Lys or Arg, if it were present in the selectivity filter, would probably bind a Cl^- ion too tightly to facilitate its rapid transit through the channel.

Unlike the K^+ channel, which has a central aqueous cavity (Fig. 10-4b), the Cl^- channel is hourglass-shaped, with its narrowest part in the center of the membrane and flanked by wider aqueous “vestibules.” A conserved Glu side chain projects into the pore. This group would repel other anions, suggesting that rapid Cl^- flux requires a protein conformational change in which the Glu side chain moves aside. Another anion could push the Glu away, which explains why some Cl^- channels appear to be activated by Cl^- ions; that is, they open in response to a certain concentration of Cl^- in the extracellular fluid.

D Aquaporins Mediate the Transmembrane Movement of Water

The observed rapid passage of water molecules across biological membranes had long been assumed to occur via simple diffusion that was made possible by the small size of water molecules and their high concentrations in biological systems. However, certain cells, such as those in the kidney, can sustain particularly rapid rates of water transport, which can be reversibly inhibited by mercuric ions. This suggested the existence of previously unrecognized protein pores that conduct water through biological membranes. The first of these elusive proteins was discovered in 1992 by Peter Agre, who named them **aquaporins**.

Aquaporins are widely distributed in nature; plants may have as many as 50 different aquaporins. The 13 known mammalian aquaporins are expressed at high levels in tissues that rapidly transport water, including kidneys, salivary glands, sweat glands, and lacrimal glands (which produce tears). In fact, the kidney contains seven different aquaporins, each of which has a specific location, function, and regulatory properties. Aquaporins permit the passage of water molecules at an extraordinarily high rate ($\sim 3 \times 10^9$ per second) but do not permit the transport of ions, including, most surprisingly, protons (really hydronium ions; H_3O^+), whose free passage would discharge the cell's membrane potential. Several aquaporins also permit the passage of small neutral solutes such as urea and glycerol.

AQP1, which is among the most extensively characterized members of the aquaporin family, is a homotetrameric glycoprotein. Its X-ray and electron crystallographic structures reveal that each of its subunits consists mainly of six transmembrane α helices plus two shorter helices that lie within the bilayer (Fig. 10-11). These helices are arranged so as to form an elongated hourglass-shaped central pore that, at its narrowest point, the so-called constriction region, is ~ 2.8 Å wide, which is the van der Waals diameter of a water molecule (Fig. 10-12). Much of the pore is lined with hydrophobic groups whose lack of strong interactions with water molecules hastens their passage through the pore. However, for a water molecule to transit the constriction region, it must be separated from other water molecules to which it is hydrogen-bonded. This is facilitated by the side chains of highly conserved Arg and His residues as well as several backbone carbonyl groups that form hydrogen bonds to a transiting water molecule and hence readily displace its associated water molecules, much as occurs with K^+ in the selectivity filter of the KcsA channel (Section 10-2C).

If water were to pass through aquaporin as an uninterrupted chain of hydrogen-bonded molecules, then protons would pass even more rapidly through the channel via proton jumping (Fig. 2-15; in order for more than one such series of proton jumps to occur, each water molecule in the chain must reorient such that one of its protons forms a hydrogen bond to the next water

FIG. 10-11 X-Ray structure of the aquaporin AQP1 from bovine erythrocytes. (a) Ribbon diagram of an aquaporin subunit colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The view is from within the membrane with the extracellular surface above. The four water molecules that occupy the central portion of the water-transport channel are represented by red spheres. (b) View of the aquaporin tetramer from the extracellular surface. The subunit in the upper right is drawn in space-filling form with C green, N blue, and

O red; that in the upper left is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), that in the lower left is represented by its solvent-accessible surface; and that in the lower right displays the side chains (*green*) at the constriction site. Each subunit forms a water-transport channel, which is most clearly visible in the subunit drawn in space-filling form. [Based on an X-ray structure by Bing Jap, University of California at Berkeley. PDBid 1J4N.]

molecule in the chain). However, aquaporin interrupts this process by forming hydrogen bonds from the side chain NH_2 groups of two highly conserved Asn residues to a water molecule that is centrally located in the pore (Fig. 10-12). Consequently, although this central water molecule can readily donate hydrogen bonds to its neighboring water molecules in the hydrogen-bonded chain, it cannot accept one from them nor reorient, thereby severing the “proton-conducting wire.”

E Transport Proteins Alternate between Two Conformations

Up to this point, we have examined the structures and functions of membrane proteins that form a physical passageway for small molecules, ions, or water. Membrane proteins known as **connexins** also form such channels, in the form of **gap junctions** between cells (see Box 10-1). However, not all membrane transport proteins offer a discrete bilayer-spanning pore. Instead, some proteins undergo conformational changes to move substances from one side of the membrane to the other. The **erythrocyte glucose transporter** (also known as **GLUT1**) is such a protein.

FIG. 10-12 Schematic drawing of the water-conducting pore of aquaporin AQP1. The pore is viewed from within the membrane with the extracellular surface above. The positions of residues critical for preventing the passage of protons, other ions, and small molecule solutes are indicated.

Box 10-1 Perspectives in Biochemistry Gap Junctions

Most eukaryotic cells are in metabolic as well as physical contact with neighboring cells. This contact is brought about by tubular structures, named **gap junctions**, that join discrete regions of neighboring plasma membranes much like hollow rivets. Gap junctions consist of two apposed plasma membrane-embedded complexes. Small molecules and ions, but not macromolecules, can pass between cells via the gap junction's central channel.

These intercellular channels are so widespread that many whole organs are continuous from within. Thus, *gap junctions are important intercellular communication channels*. For example, the synchronized contraction of heart muscle is brought about by flows of ions through gap junctions, and gap junctions serve as conduits for some of the substances that mediate embryonic development.

Mammalian gap junction channels are 16 to 20 Å in diameter, which Werner Loewenstein established by microinjecting single cells with fluorescent molecules of various sizes and observing with a fluorescence microscope whether the fluorescent probe passed into neighboring cells. The molecules and ions that can pass freely between neighboring cells are limited in molecular mass to a maximum of ~1000 D; macromolecules such as proteins and nucleic acids cannot leave a cell via this route.

The diameter of a gap junction channel varies with Ca^{2+} concentration: The channels are fully open when the Ca^{2+} level is $<10^{-7}$ M and become narrower as the Ca^{2+} concentration increases until, above 5×10^{-5} M, they close. This shutter system is thought to protect communities of interconnected cells from the otherwise catastrophic damage that would result from the death of even one of their members. Cells generally maintain very low cytosolic Ca^{2+} concentrations ($<10^{-7}$ M) by actively pumping Ca^{2+} out of the cell as well as into their mitochondria and endoplasmic reticulum (Section 10-3B). Ca^{2+} floods back into leaky or metabolically depressed cells, thereby inducing closure of their gap junctions and sealing them off from their neighbors.

Gap junctions are constructed from a single sort of protein subunit known as a **connexin**. A single gap junction consists of two hexagonal rings of connexins, called **connexons**, one from each of the adjoining

plasma membranes. A given animal expresses numerous genetically distinct connexins (21 in humans), with molecular masses ranging from 25 to 50 kD. At least some connexons may be formed from two or more species of connexins, and the gap junctions joining two cells may consist of two different types of connexons. These various types of gap junctions presumably differ in their selectivities for the substances they transmit.

The X-ray structure of the gap junction formed by the 226-residue human **connexin 26**, determined by Tomitake Tsukihara, reveals a symmetrical assembly with a height of 155 Å and a maximal diameter of 92 Å that encloses a central channel.

Each connexin consists of an up-and-down bundle of four α helices. In this model, the protein is drawn as ribbons embedded in a semitransparent molecular surface. Each connexin of the upper connexon has a different color, whereas one connexin in the lower connexon is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) with the remaining connexins purple.

The extracellular portion of each connexin extends from the cell surface and interdigitates with the opposite connexon by 6 Å to span an intercellular gap of 40 Å. The central channel has a diameter of ~40 Å at its cytosolic entrance that funnels down to 14 Å near the extracellular surface of the membrane and then widens to 25 Å in the extracellular space. The entrance to the channel is positively charged and would attract negatively charged molecules. However, the region of maximal channel constriction is negatively charged, which should also affect the channel's charge selectivity.

PROCESS DIAGRAM

FIG. 10-13 Model for glucose transport. The transport protein alternates between two mutually exclusive conformations. Glucose (green) is not drawn to scale. [After Baldwin, S.A. and Lienhard, G.E.,

Trends Biochem. Sci. **6**, 210 (1981). **WPLS** See the Animated Process Diagrams.

? Explain why ions cannot cross a membrane via the glucose transporter.

Biochemical evidence indicates that GLUT1 has glucose-binding sites on both sides of the membrane. John Barnett showed that adding a propyl group to glucose C1 prevents glucose binding to the outer surface of the membrane, whereas adding a propyl group to C6 prevents binding to the inner surface. He therefore proposed that this transmembrane protein has two alternate conformations: one with the glucose site facing the external cell surface, requiring O1 contact and leaving O6 free, and the other with the glucose site facing the internal cell surface, requiring O6 contact and leaving O1 free. Transport apparently occurs as follows (**Fig. 10-13**):

1. Glucose binds to the protein on one face of the membrane.
2. A conformational change closes the first binding site and exposes the binding site on the other side of the membrane (transport).
3. Glucose dissociates from the protein.
4. The transport cycle is completed by the reversion of GLUT1 to its initial conformation in the absence of bound glucose (recovery).

This transport cycle can occur in either direction, according to the relative concentrations of intracellular and extracellular glucose. GLUT1 provides a means of equilibrating the glucose concentration across the erythrocyte membrane without any accompanying leakage of small molecules or ions (as might occur through an always-open channel such as a porin).

The X-ray structure of human GLUT1 in complex with a glucose derivative (**Fig. 10-14**), determined by Nieng Yan, confirms previous predictions (Section 9-3A) that GLUT1 has 12 membrane-spanning α helices with its N- and C-termini in the cytoplasm. Other members of the **major facilitator superfamily**, to which GLUT1 belongs, have a similar arrangement.

Box 10-2 Perspectives in Biochemistry

Differentiating Mediated and Nonmediated Transport

Glucose and many other compounds can enter cells by a non-mediated pathway; that is, they slowly diffuse into cells at a rate proportional to their membrane solubility and their concentrations on either side of the membrane. This is a linear process: The flux of a substance across the membrane increases with the magnitude of its concentration gradient (the difference between its internal and external concentrations). If the same substance, say glucose, moves across a membrane by means of a transport protein, its flux is no longer linear. This is one of four characteristics that distinguish mediated from nonmediated transport:

- 1. Speed and specificity.** The solubilities of the chemically similar sugars D-glucose and D-mannitol in a synthetic lipid bilayer are similar. However, the rate at which glucose moves through the erythrocyte membrane is four orders of magnitude faster than that of D-mannitol. The erythrocyte membrane must therefore contain a system that transports glucose and that can distinguish D-glucose from D-mannitol.
- 2. Saturation.** The rate of glucose transport into an erythrocyte does not increase infinitely as the external glucose concentration increases: The rate gradually approaches a maximum. Such an observation is evidence that a specific number of sites on the membrane are involved in the transport of glucose. At high [glucose], the transporters become saturated, much like myoglobin becomes saturated with O_2 at high pO_2 (Fig. 7-4). As expected, the plot of glucose flux versus [glucose] is hyperbolic. The nonmediated glucose flux increases linearly with [glucose] but would not visibly depart from the baseline on the scale of the graph.

- 3. Competition.** The above curve is shifted to the right in the presence of a substance that competes with glucose for binding to the transporter; for example, 6-*O*-benzyl-D-galactose has this effect. Competition is not a feature of nonmediated transport, since no transport protein is involved.
- 4. Inactivation.** Reagents that chemically modify proteins and hence may affect their functions may eliminate the rapid, saturable flux of glucose into the erythrocyte. The susceptibility of the erythrocyte glucose transport system to protein-modifying reagents is additional proof that it is a protein.

[Graph based on data from Stein, W.D., *Movement of Molecules across Membranes*, p. 134, Academic Press (1967).]

FIG. 10-15 Uniport, symport, and antiport translocation systems.

GLUT1 is one of a large group of transporters that move amino acids and other small molecules across membranes. *All known transport proteins appear to be asymmetrically situated transmembrane proteins that alternate between two conformational states in which the ligand binding sites are exposed, in turn, to opposite sides of the membrane.* Such a mechanism is analogous to the T→R allosteric transition of proteins such as hemoglobin (Section 7-1B). In fact, many of the features of ligand-binding proteins such as myoglobin and hemoglobin also apply to transport proteins (Box 10-2).

Some transporters can transport more than one substance. For example, the bacterial oxalate transporter transports **oxalate** into the cell and transports **formate** out.

Some transport proteins move more than one substance at a time. Hence, it is useful to categorize mediated transport according to the stoichiometry of the transport process (Fig. 10-15):

1. A **uniport** involves the movement of a single molecule at a time. GLUT1 is a uniport system.
2. A **symport** simultaneously transports two different molecules in the same direction.
3. An **antiport** simultaneously transports two different molecules in opposite directions.

These designations apply to both passive and active transport systems.

CHECKPOINT

- What are the similarities and differences among ionophores, porins, ion channels, and passive-mediated transport proteins? What determines the direction of solute movement?
- Which transporters provide an open passageway for the transmembrane movement of a solute? Which transporters undergo a conformational change as part of their transport mechanism?
- What structural features allow porins and ion channels to discriminate among ions?
- Explain how and why ion channels are gated.
- How do transport proteins prevent the transmembrane movement of water and ions?
- How do aquaporins allow the passage of H₂O but not H₃O⁺?
- Use the terminology of allosteric proteins to discuss the operation of proteins that carry out uniport, symport, and antiport transport processes.

3 Active Transport

KEY CONCEPTS

- Pumps use the free energy of ATP to transport ions against their gradient.
- ABC transporters move amphipathic substances from one side of the membrane to the other.
- Secondary active transporters use existing ion gradients to drive the unfavorable transport of a second substance.

GATEWAY CONCEPT Energy Transformation

Energy cannot be created or destroyed, but it can be transformed. In active transport systems, the favorable (negative) free energy change of the ATP hydrolysis reaction pays for the unfavorable (positive) free energy change of ion transport across a membrane. In this way, the chemical energy of ATP is transformed into the electrochemical energy of an ion gradient. Like water backed up behind a dam, an ion gradient is a form of energy—it is capable of doing work for the cell.

FIG. 10-16 X-Ray structure of shark $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$. The protein is drawn in ribbon form viewed parallel to the plane of the membrane (gray box) with the cytosol above. The α subunit is colored in rainbow order from its N-terminus (blue) to its C-terminus (red), the β subunit is magenta, and a regulatory subunit, called FXYD, is brown. Two bound K^+ ions in the transmembrane (M) domain are drawn as light blue spheres, and the MgF_4^{2-} ion, which marks the protein's ATPase active site between the N and A domains, is shown with Mg pink and F light green. [Based on an X-ray structure by Chikashi Toyoshima, University of Tokyo, Japan. PDBID 2ZXE.]

Passive-mediated transporters, including porins, ion channels, and proteins such as GLUT1, facilitate the transmembrane movement of substances according to the relative concentrations of the substance on the two sides of the membrane. For example, the glucose concentration in the blood plasma (~ 5 mM) is generally higher than in cells, so GLUT1 allows glucose to enter the erythrocyte to be metabolized. Many substances, however, are available on one side of a membrane in lower concentrations than are required on the other side of the membrane. Such substances must be actively and selectively transported across the membrane against their concentration gradients.

Active transport is an endergonic process that, in most cases, is coupled to the hydrolysis of ATP. Several families of ATP-dependent transporters have been identified:

1. **P-type ATPases** undergo phosphorylation as they transport cations such as Na^+ , K^+ , and Ca^{2+} across the membrane.
2. **F-type ATPases** are proton-transporting complexes located in mitochondria and bacterial membranes. Instead of using the free energy of ATP to pump protons against their gradient, these proteins usually operate in reverse to synthesize ATP, as we will see in Section 18-3.
3. **V-type ATPases** resemble the F-type ATPases and occur in plant vacuoles and acidic vesicles such as animal lysosomes.
4. **A-type ATPases** transport anions across membranes.
5. **ABC transporters** are named for their ATP-binding cassette and transport a wide variety of substances, including ions, small metabolites, and drug molecules.

In this section, we examine two P-type ATPases and an ABC transporter; these proteins carry out **primary active transport**. In **secondary active transport**, the free energy of the electrochemical gradient generated by another mechanism, such as an ion-pumping ATPase, is used to transport a molecule against its concentration gradient.

A The $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ Transports Ions in Opposite Directions

One of the most thoroughly studied active transport systems, the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ in the plasma membranes of higher eukaryotes, is also called the $(\text{Na}^+ - \text{K}^+) - \text{pump}$ because it pumps Na^+ out of and K^+ into the cell with the concomitant hydrolysis of intracellular ATP. The overall stoichiometry of the reaction is

This P-type ATPase is an antiport that generates a charge separation across the membrane, that is, a membrane potential, because three positive charges exit the cell for every two that enter. This extrusion of Na^+ enables animal cells to control their water content osmotically; *without a functioning $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ to maintain a low internal $[\text{Na}^+]$, water would osmotically leak in to such an extent that animal cells, which lack cell walls, would swell and burst.* The electrochemical gradient generated by the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ is also responsible for the electrical excitability of nerve cells (Section 10-2C). In fact, all cells expend a large fraction of the ATP they produce (up to 70% in nerve cells) to maintain their required cytosolic Na^+ and K^+ concentrations.

The $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$, which was first characterized by Jens Skou, is a transmembrane protein that minimally consists of two types of subunits: The ~ 1000 -residue α subunit, which contains the enzyme's ATP and ion binding sites, and the ~ 300 -residue β subunit, which facilitates the correct insertion of the α subunit into the plasma membrane. In many cases a small regulatory subunit, γ , is also associated with the protein.

The X-ray structure of shark $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ in complex with K^+ ions and an MgF_4^{2-} ion (a P_i mimic) (Fig. 10-16) was determined by Chikashi Toyoshima.

The α subunit of this $\sim 160\text{-\AA}$ -long protein consists of a transmembrane domain (M) composed of 10 helices of varied lengths that provides a pathway for Na^+ and K^+ ions to transit the membrane, and from top to bottom in Fig. 10-16, three well-separated cytoplasmic domains: the nucleotide-binding domain (N), which binds ATP; the actuator domain (A), so named because it participates in the transmission of major conformational changes (see below); and the phosphorylation domain (P), which contains the protein's phosphorylatable Asp residue.

The key to the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ is the phosphorylation of a specific Asp residue of the α subunit. ATP phosphorylates this Asp residue only in the presence of Na^+ , whereas the resulting **aspartyl phosphate** residue (*at right*) is subject to hydrolysis only in the presence of K^+ . This suggests that the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ has two conformational states, called E1 and E2, with different structures, different catalytic activities, and different ligand specificities. In particular, E1's ion-binding sites are exposed to the cytoplasm, and it has high affinity for Na^+ but low affinity for K^+ , whereas E2's ion-binding sites are exposed to the exterior of the cell and it has low affinity for Na^+ but high affinity for K^+ . The protein appears to operate in the following manner (Fig. 10-17):

1. E1 \cdot ATP, which acquired its ATP inside the cell, binds three Na^+ ions to yield the ternary complex E1 \cdot ATP \cdot 3 Na^+ .
2. The ternary complex reacts to form the "high-energy" aspartyl phosphate intermediate E1 \sim P \cdot 3 Na^+ [here the squiggle (\sim) represents a "high energy" bond (Section 14-2A)] and ADP, which is released inside the cell.
3. The "high-energy" intermediate relaxes to its "low-energy" conformation, E2 $-$ P \cdot 3 Na^+ , and releases its bound Na^+ outside the cell; that is, the Na^+ is transported through the membrane.

PROCESS DIAGRAM

FIG. 10-17 Scheme for the active transport of Na^+ and K^+ by the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$. **WPLS** See the Animated Process Diagrams.

? Draw simple shapes to represent the ATPase and its substrates and products at each step of the reaction cycle.

The cardiac glycosides are natural products that increase the intensity of heart muscle contraction. Indeed, **digitalis**, an extract of purple foxglove leaves, which contains a mixture of cardiac glycosides including **digitalin** (see below), has been used to treat congestive heart failure for centuries. The cardiac glycoside **ouabain** (pronounced wabane), a product of the East African ouabio tree, has been long used as an arrow poison.

in Fig. 10-17. The resultant increase in intracellular $[Na^+]$ stimulates the cardiac (Na^+-Ca^{2+}) antiport system, which pumps Na^+ out of and Ca^{2+} into the cell, ultimately boosting the $[Ca^{2+}]$ in the sarcoplasmic reticulum. Thus, the release of Ca^{2+} to trigger muscle contraction (Section 7-2B) produces a larger than normal increase in cytosolic $[Ca^{2+}]$, thereby intensifying the force of cardiac muscle contraction. Ouabain, which was once thought to be produced only by plants, has recently

These two steroids, which are still among the most commonly prescribed cardiac drugs, inhibit the (Na^+-K^+)-ATPase by binding strongly to an externally exposed portion of the protein so as to block Step 5

been discovered to be an animal hormone that is secreted by the adrenal cortex and functions to regulate cellular $[Na^+]$ and overall body salt and water balance.

4. $E2-P$ binds two K^+ ions from outside the cell to form an $E2-P \cdot 2K^+$ complex. This corresponds to the structure shown in Fig. 10-16.
5. The phosphate group is hydrolyzed, yielding $E2 \cdot 2K^+$.
6. $E2 \cdot 2K^+$ changes conformation to $E1$, binds ATP, and releases its two K^+ ions inside the cell, thereby completing the transport cycle.

The enzyme appears to have only one set of cation binding sites (Fig. 10-16), which apparently changes both its orientation and its specificity during the course of the transport cycle.

Although each of the above reaction steps is individually reversible, the cycle, as diagrammed in Fig. 10-17, circulates only in the clockwise direction under normal physiological conditions. This is because ATP hydrolysis and ion transport are coupled vectorial (unidirectional) processes. The vectorial nature of the reaction cycle results from the alternation of the several steps of the exergonic ATP hydrolysis reaction (Step 2, Step 5, and ATP binding in Step 6) with the several steps of the endergonic ion transport process (Steps 3 + 4 and K^+ release in Step 6). Thus, *neither reaction can go to completion unless the other one also does*. Study of the (Na^+-K^+)-ATPase has been greatly facilitated by the use of glycosides that inhibit the transporter (Box 10-3).

B The Ca^{2+} -ATPase Pumps Ca^{2+} Out of the Cytosol

Transient increases in cytosolic $[Ca^{2+}]$ trigger numerous cellular responses including muscle contraction (Section 7-2B), the release of neurotransmitters,

PROCESS DIAGRAM

FIG. 10-18 Scheme for the active transport of Ca^{2+} by the Ca^{2+} -ATPase. Here (*in*) refers to the cytosol and (*out*) refers to the outside of the cell for plasma membrane Ca^{2+} -ATPase or the lumen

of the endoplasmic reticulum (or sarcoplasmic reticulum) for the Ca^{2+} -ATPase of that membrane. **WPLS** See the Animated Process Diagrams.

? Identify the events that trigger conformational changes in the protein.

and glycogen breakdown (Section 16-3). Moreover, Ca^{2+} is an important activator of oxidative metabolism (Section 18-4).

The $[\text{Ca}^{2+}]$ in the cytosol ($\sim 0.1 \mu\text{M}$) is four orders of magnitude less than it is in the extracellular spaces [$\sim 1500 \mu\text{M}$; intracellular Ca^{2+} might otherwise combine with phosphate to form $\text{Ca}_3(\text{PO}_4)_2$, which has a maximum solubility of only $65 \mu\text{M}$]. This large concentration gradient is maintained by the active transport of Ca^{2+} across the plasma membrane and the endoplasmic reticulum (the sarcoplasmic reticulum in muscle) by a Ca^{2+} -ATPase. This Ca^{2+} pump actively pumps two Ca^{2+} ions out of the cytosol at the expense of ATP hydrolysis, while countertransporting two or three protons. The mechanism of the Ca^{2+} -ATPase (Fig. 10-18) resembles that of the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ (Fig. 10-17), to which it is closely related.

The superimposed X-ray structures of the Ca^{2+} -ATPase from rabbit muscle sarcoplasmic reticulum in its E1 and E2 conformations, determined by Toyoshima, are shown in Fig. 10-19. Two Ca^{2+} ions bind within a bundle of 10 transmembrane

FIG. 10-19 X-Ray structures of Ca^{2+} -free and Ca^{2+} -bound Ca^{2+} -ATPase. The Ca^{2+} -free form, E2, is green with black helix numbers, and the Ca^{2+} -bound form, E1 Ca^{2+} , is violet with yellow helix numbers. These proteins, which are superimposed on their transmembrane domains, are viewed from within the membrane with the cytosolic side up. Ten transmembrane helices form the M (for membrane) domain, ATP binds to the N (for nucleotide-binding) domain, the Asp residue that is phosphorylated during the reaction cycle is located on the P (for phosphorylation) domain, and the A (for actuator) domain is so named because it participates in the transmission of major conformational changes. Dashed lines highlight the orientations of a helix in the N domain in the two conformations and the horizontal green lines delineate the membrane. Compare these structures with that of the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ in Fig. 10-16. [Courtesy of Chikashi Toyoshima, University of Tokyo, Japan. PDBids 1EUL and 1WIO.]

helices. Three additional domains form a large structure on the cytoplasmic side of the membrane. The structural differences between the Ca^{2+} -bound (E1) and the Ca^{2+} -free (E2) structures indicate that the transporter undergoes extensive rearrangements, particularly in the positions of the cytoplasmic domains but also in the Ca^{2+} -transporting membrane domain, during the reaction cycle. These changes apparently mediate communication between the Ca^{2+} -binding sites and the ~ 80 -Å-distant site where bound ATP is hydrolyzed.

C ABC Transporters Are Responsible for Drug Resistance

The inability of anticancer drugs to kill cancer cells is frequently traced to the overexpression of a membrane protein known as **P-glycoprotein**. This member of the ABC family of transporters pumps a variety of amphiphilic substances—including many drugs—out of the cell, so that it is also called a **multidrug resistance (MDR) transporter**. Similar proteins in bacteria contribute to their antibiotic resistance.

The **ABC transporters**, which pump ions, sugars, amino acids, and other polar and nonpolar substances, are built from four modules: two highly conserved cytoplasmic nucleotide-binding domains, and two transmembrane domains that typically contain six transmembrane helices each. In bacteria, the four domains are contained on two or four separate polypeptides, and in eukaryotes, a single polypeptide includes all four domains. Bacterial ABC transporters mediate the uptake as well as the efflux of a variety of compounds, whereas their eukaryotic counterparts apparently operate only as exporters that transport material out of the cell or into intracellular compartments such as the endoplasmic reticulum.

The X-ray structure of mouse P-glycoprotein, determined by Geoffrey Chang, shows a dimeric protein with pseudo-2-fold symmetry (**Fig. 10-20**). Two bundles of six transmembrane α helices span the membrane and extend into the cytoplasm, defining a large internal cavity that is open to both the cytoplasm and the inner leaflet of the membrane. The two ATP-binding domains in the cytoplasm are separated by ~ 30 Å. Conformational changes resulting from ATP binding and hydrolysis in this part of the protein appear to be transmitted to the transmembrane domains in a way that allows the two subunits of the transporter to move in concert.

A lipid-soluble molecule, such as a drug molecule, apparently enters P-glycoprotein through a portal in the membrane-spanning domain and binds in a pocket defined mostly by hydrophobic and aromatic residues. ATP binding triggers a dramatic conformational change that includes dimerization of the two cytoplasmic nucleotide-binding domains and a shift to an outward-facing conformation (**Fig. 10-21**). This structural change, which has been observed in the X-ray structures of similar transporters in their nucleotide-bound state, closes off the original binding cavity and exposes the bound drug molecule to the outer leaflet or the extracellular space. ATP hydrolysis presumably restores the transporter to its inward-facing conformation, ready to bind another drug molecule. Because the transporter can bind a molecule from inside the cell or from the inner leaflet and release it outside the cell or into the outer leaflet, the transporter operates as a flippase (Section 9-4C) for lipid-soluble substances, including membrane lipids.

FIG. 10-20 X-Ray structure of mouse P-glycoprotein. The peptide chain is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The view is parallel to the membrane (delineated by the horizontal lines) with the cytoplasm below. The two cytoplasmic nucleotide-binding domains (NBD1 and NBD2) are indicated. This “inward-facing” conformation of P-glycoprotein contains no bound ligands or nucleotides. [Based on an X-ray structure by Geoffrey Chang, The Scripps Research Institute, La Jolla. PDBid 3G5U.]

FIG. 10-21 Model for P-glycoprotein function.

The gray shapes represent the surface of the transporter in its inward-facing (*left*) and outward-facing (*right*) conformations. A ligand (*magenta*) may originate from outside the cell but partitions into the inner leaflet of the plasma membrane (delineated by the horizontal lines) before entering the transporter's binding pocket, whose residues are represented by cyan spheres. The binding of ATP (*yellow*) triggers extensive conformational changes that bring the nucleotide-binding domains together and open the ligand-binding site to the extracellular space. [Courtesy of Geoffrey Chang, The Scripps Research Institute, La Jolla.]

 **CFTR Is an ABC Transporter.** Only one of the thousands of known ABC transporters (48 in humans) functions as an ion channel rather than a pump: the **cystic fibrosis transmembrane conductance regulator (CFTR)**. This 1480-residue protein, which is defective in individuals with the inherited disease **cystic fibrosis** (Box 3-1), allows Cl^- ions to flow out of the cell, following their concentration gradient. ATP binding to CFTR's two nucleotide-binding domains appears to open the Cl^- channel, and the hydrolysis of one ATP closes it (the other ATP remains intact). However, the CFTR channel can open only if its regulatory domain (which is unique among ABC transporters) has been phosphorylated, thus regulating the flow of ions across the membrane. CFTR does not exhibit high specificity for Cl^- ions, suggesting that the channel lacks a selectivity filter analogous to that in the KcsA K^+ channel (Section 10-2C).

The maintenance of electrical neutrality requires that the Cl^- ions transported by the CFTR be accompanied by positively charged ions, mainly Na^+ . The transported ions are osmotically accompanied by water, thus maintaining the proper level of fluidity in secretions of the airways, intestinal tract, and the ducts of the pancreas, testes, and sweat glands. Although more than 1000 mutations of the CFTR have been described, in about 70% of cystic fibrosis cases, Phe 508 of the CFTR has been deleted. Even though this mutant CFTR is functional, it folds much more slowly than the wild-type protein and hence is degraded before it can be installed in the plasma membrane.

Homozygotes for defective or absent CFTRs have problems in many of the organs mentioned above but especially in their lungs (heterozygotes are asymptomatic). This is because the reduced Cl^- export results in thickened mucus that the lungs cannot easily clear. Since the flow of mucus is the major way in which the lungs eliminate foreign particles such as bacteria, individuals with cystic fibrosis suffer from chronic lung infections leading to severe progressive lung damage and early death.

D Active Transport May Be Driven by Ion Gradients

Systems such as the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ generate electrochemical gradients across membranes. The free energy stored in an electrochemical gradient (Eq. 10-3) can be harnessed to power various endergonic physiological processes. For example, cells of the intestinal epithelium take up dietary glucose by Na^+ -dependent

FIG. 10-22 Glucose transport in the intestinal epithelium. The brush-like villi lining the small intestine greatly increase its surface area (a), thereby facilitating the absorption of nutrients. The brush border cells from which the villi are formed (b) concentrate glucose from the intestinal

lumen in symport with Na⁺ (c), a process that is driven by the (Na⁺-K⁺)-ATPase, which is located on the capillary side of the cell and functions to maintain a low internal [Na⁺]. The glucose is exported to the bloodstream via a separate passive-mediated uniport system similar to GLUT1.

? In Part (c), identify which solutes move down their concentration gradient and which move up their concentration gradient.

symport (Fig. 10-22). The immediate energy source for this “uphill” transport process is the Na⁺ gradient. This process is an example of secondary active transport because the Na⁺ gradient in these cells is maintained by the (Na⁺-K⁺)-ATPase. The Na⁺-glucose transport system concentrates glucose inside the cell. Glucose is then transported into the capillaries through a passive-mediated glucose uniport (which resembles GLUT1; Fig. 10-14).

Thus, since glucose enhances Na⁺ resorption, which in turn enhances water resorption, glucose (possibly as sucrose), in addition to salt and water, should be fed to individuals suffering from severe salt and water losses due to diarrhea (drinking only water or a salt solution is ineffective since they are rapidly excreted from the gastrointestinal tract). It is estimated that the introduction of this simple and inexpensive treatment, called **oral rehydration therapy**, has decreased the annual number of human deaths from severe diarrhea, mostly in children in less-developed countries, from 4.6 to 1.6 million.

Lactose Permease Requires a Proton Gradient. Gram-negative bacteria such as *E. coli* contain several active transport systems for concentrating sugars. One extensively studied system, **lactose permease** (also known as **galactoside permease**), utilizes the proton gradient across the bacterial cell membrane to cotransport H⁺ and lactose. The proton gradient is metabolically generated through oxidative metabolism in a manner similar to that in mitochondria (Section 18-2). The electrochemical potential gradient created by both these systems is used mainly to drive the synthesis of ATP.

Lactose permease is a 417-residue monomer that consists largely of 12 transmembrane helices with its N- and C-termini in the cytoplasm. Like GLUT1, it is a member of the major facilitator superfamily, and its structure and transport mechanism resemble those of GLUT1. And like (Na⁺-K⁺)-ATPase, lactose permease has two major conformational states (Fig. 10-23):

1. E-1, which has a low-affinity lactose-binding site facing the cytoplasm.
2. E-2, which has a high-affinity lactose-binding site facing the periplasm (the space between the plasma and outer membranes; Fig. 8-16).

Ronald Kaback established that E-1 and E-2 can interconvert only when their H⁺- and lactose-binding sites are either both filled or both empty. This prevents dissipation of the H⁺ gradient without cotransport of lactose into the cell. It also

PROCESS DIAGRAM

FIG. 10-23 Scheme for the cotransport of H^+ and lactose by lactose permease in *E. coli*. H^+ binds first to E-2 outside the cell, followed by lactose. They are sequentially released from E-1 inside the cell. E-2 must bind to both lactose and H^+ in order to change conformation to

E-1, thereby cotransporting these substances into the cell. E-1 changes conformation to E-2 when neither lactose nor H^+ is bound, thus completing the transport cycle. **WPLS** See the Animated Process Diagrams.

? How does operation of lactose permease affect the pH difference across the cell membrane?

prevents transport of lactose out of the cell since this would require cotransport of H^+ against its concentration gradient.

The X-ray structure of lactose permease in complex with a tight-binding lactose analog, determined by Kaback and So Iwata, reveals that this protein consists of two structurally similar and twofold pseudosymmetrically positioned domains containing six transmembrane helices each (Fig. 10-24a).

FIG. 10-24 X-Ray structure of lactose permease from *E. coli*. (a) Ribbon diagram as viewed from the membrane with the cytoplasmic side up. The protein's 12 transmembrane helices are colored in rainbow order from the N-terminus (purple) to the C-terminus (pink). The bound lactose analog is represented by black spheres. in Part a removed to reveal the lactose-binding cavity. The surface is colored according to its electrostatic potential with positively charged areas blue, negatively charged areas red, and neutral areas white. [From Abramson, J., Smirnova, I. et al. (2003) *Science* vol 301, 610–615. Structure and Mechanism of the Lactose Permease of *Escherichia coli*, Aug. 1, 2003]

CHECKPOINT

- Distinguish passive-mediated transport, active transport, and secondary active transport.
- Explain why the $(\text{Na}^+-\text{K}^+)\text{-ATPase}$ and the $\text{Ca}^{2+}\text{-ATPase}$ carry out transport in one direction only.
- Explain how an ABC transporter would operate as a flippase.
- What is the ultimate source of free energy for secondary active transport?

A large internal hydrophilic cavity is open to the cytoplasmic side of the membrane (Fig. 10-24b) so that the structure represents the E-1 state of the protein. The lactose analog is bound in the cavity at a position that is approximately equidistant from both sides of the membrane, consistent with the model that the lactose-binding site is alternately accessible from each side of the membrane (e.g., Fig. 10-13). Arg, His, and Glu residues that mutational studies have implicated in proton translocation are located in the vicinity of the lactose-binding site.

Summary

1 Thermodynamics of Transport

- The mediated and nonmediated transport of a substance across a membrane is driven by its chemical potential difference.

2 Passive-Mediated Transport

- Ionophores facilitate ion diffusion by binding an ion, diffusing through the membrane, and then releasing the ion; or by forming a channel.
- Porins form β barrel structures about a central channel that is selective for anions, cations, or certain small molecules.
- Ion channels mediate changes in membrane potential by allowing the rapid and spontaneous transport of ions. Ion channels are highly solute-selective and open and close (gate) in response to various stimuli. Nerve impulses involve ion channels.
- Aquaporins contain channels that allow the rapid transmembrane diffusion of water but not protons.

- Transport proteins such as GLUT1 alternate between two conformational states that expose the ligand-binding site to opposite sides of the membrane.

3 Active Transport

- Active transport, in most cases, is driven by ATP hydrolysis. In the $(\text{Na}^+-\text{K}^+)\text{-ATPase}$ and $\text{Ca}^{2+}\text{-ATPase}$, ATP hydrolysis and ion transport are coupled and vectorial.
- ABC transporters use ATP hydrolysis to trigger conformational changes that move substances, including amphiphilic molecules, from one side of the membrane to the other.
- In secondary active transport, an ion gradient maintained by an ATPase or other free energy-capturing cellular process drives the transport of another substance. For example, the transport of lactose into a cell by lactose permease is driven by the cotransport of H^+ , whose gradient is maintained by oxidative metabolism.

Problems

EXERCISES

1. Calculate the free energy change for glucose entry into cells when the extracellular concentration is 5 mM and the intracellular concentration is 3 mM.
2. (a) Calculate the chemical potential difference when intracellular $[\text{Na}^+] = 10$ mM and extracellular $[\text{Na}^+] = 150$ mM at 37°C . (b) What would the electrochemical potential be if the membrane potential were -60 mV (inside negative)?
3. For the problem in Sample Calculation 10-1, calculate ΔG at 37°C when the membrane potential is (a) -50 mV (cytosol negative) and

(b) $+150$ mV. In which case is Ca^{2+} movement in the indicated direction thermodynamically favorable?

4. Calculate the free energy required to move 1 mol of K^+ ions from the outside of the cell (where $[\text{K}^+] = 4$ mM) to the inside (where $[\text{K}^+] = 140$ mM) when the membrane potential is -70 mV and the temperature is 37°C .
5. Indicate whether the following compounds are likely to cross a membrane by nonmediated or mediated transport: (a) ethanol, (b) glycine, (c) cholesterol, (d) ATP.

6. Rank the rate of transmembrane diffusion of the following compounds:

A. Acetamide

B. Butyramide

C. Urea

7. The smallest β -barrel protein contains only eight β strands. Explain why porins, which are also β barrels, usually contain at least 16 or 18 strands.

8. Which amino acids would you expect to be particularly abundant at the entrance of a porin that is specific for phosphate ions?

9. The diameter of the KcsA K^+ channel is $\sim 6 \text{ \AA}$. Why can't H_2O (diameter 2.75 \AA) pass through this channel?

10. In addition to neurons, muscle cells undergo depolarization, although smaller and slower than in the neuron, as a result of the activity of the acetylcholine receptor.

(a) The acetylcholine receptor is also a gated ion channel. What triggers the gate to open?

(b) The acetylcholine receptor/ion channel is specific for Na^+ ions. Would Na^+ ions flow in or out? Why?

(c) How would the Na^+ flow through the ion channel change the membrane potential?

11. Explain why Na^+ and K^+ ions usually move more slowly through pumps than through channels.

12. Why would overexpression of an MDR transporter in a cancer cell make the cancer more difficult to treat?

13. If the ATP supply in the cell shown in Fig. 10-22c suddenly vanished, would the intracellular glucose concentration increase, decrease, or remain the same?

14. The bacterial Na^+-H^+ antiporter is a secondary active transport protein that excretes excess Na^+ from the cell. Is the extracellular pH higher or lower than the intracellular pH?

15. A certain membrane protein allows phosphate groups to enter a eukaryotic cell. (a) Would you expect the protein to function more like KcsA or more like GLUT1? (b) Phosphate ions enter the cell along with H^+ ions. Describe this transport system using the terms introduced in Fig. 10-15. (c) The eukaryotic intracellular pH is typically slightly lower than the extracellular pH. Does this suggest that the phosphate transporter carries out secondary active transport?

16. *E. coli* cells transport xylose across the cell membrane via a symport system that uses the free energy of a proton gradient. The intracellular pH is higher than the extracellular pH. (a) Is xylose moving up or down its concentration gradient? Into or out of the cell? (b) Draw a diagram of the xylose transport system.

CHALLENGE QUESTIONS

17. What happens to K^+ transport by valinomycin when the membrane is cooled below its transition temperature?

18. How long would it take 100 molecules of valinomycin to transport enough K^+ to change the concentration inside an erythrocyte of volume $100 \mu\text{m}^3$ by 10 mM ? (Assume that the valinomycin does not also transport any K^+ out of the cell, which it really does, and that the valinomycin molecules outside the cell are always saturated with K^+ .)

19. The compound shown below is the antiparasitic drug miltefosine.

Miltefosine

(a) Is this compound a glycerophospholipid?

(b) How does miltefosine likely cross the parasite cell membrane?

(c) In what part(s) of the cell would the drug tend to accumulate? Explain.

(d) Miltefosine binds to a protein that also binds some sphingolipids and some glycerophospholipids. What feature common to all these compounds is recognized by the protein? The protein does not bind triacylglycerols.

20. In eukaryotes, ribosomes (approximate mass $4 \times 10^6 \text{ D}$) are assembled inside the nucleus, which is enclosed by a double membrane. Protein synthesis occurs in the cytosol. (a) Could a protein similar to a porin or the glucose transporter be responsible for transporting ribosomes into the cytoplasm? Explain. (b) Would free energy be required to move a ribosome from the nucleus to the cytoplasm? Why or why not?

21. The rate of movement (flux) of a substance X into cells was measured at different concentrations of X to construct the following graph.

(a) Does this information suggest that the movement of X into the cells is mediated by a protein transporter? Explain.

(b) What additional experiment could you perform to verify that a transport protein is or is not involved?

22. Endothelial cells and pericytes in the retina of the eye have different mechanisms for glucose uptake. The figure shows the rate of glucose uptake for each type of cell in the presence of increasing amounts of sodium. What do these results reveal about the glucose transporter in each cell type?

23. Cells in the wall of the mammalian stomach secrete HCl at a concentration of 0.15 M . The secreted protons, which are derived from the intracellular hydration of CO_2 by carbonic anhydrase, are pumped

out by an (H^+-K^+) -ATPase antiport. A K^+-Cl^- co-transporter is also required to complete the overall transport process. (a) Calculate the pH of the secreted HCl. How does this compare to the cytosolic pH (7.4)? (b) Write the reaction catalyzed by carbonic anhydrase. (c) Draw a diagram to show how the action of both transport proteins results in the secretion of HCl.

24. Kidney cells contain a channel that allows intracellular ammonia to exit the cells. (a) Why did researchers originally believe that cells had no need for such a channel? (b) What is the free energy source for ammonia transport via the channel? (c) The same kidney cells also contain a proton pump that expels H^+ from the cells. What is the free energy source for this pump, and how does its action prevent ammonia from moving back into the kidney cells?

25. Most animals have neurons that respond to unfavorable environmental conditions by sending pain signals to the brain. For example, elevated $[\text{CO}_2]$ triggers an influx of Na^+ that opens voltage-gated Na^+ channels to initiate an action potential. The naked mole rat (Section 8-2D), which lives in crowded underground colonies, has a voltage-gated Na^+ channel that is inhibited by protons. Explain why this is advantageous.

26. Scorpion toxin triggers an action potential in pain-sensing neurons in animals by binding to a specific receptor. The toxin also acts to delay the inactivation of the neurons' voltage-gated Na^+ channels. Explain how this helps the scorpion better avoid being eaten by an animal.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Porins: Maltoporin and OmpF

CASE STUDIES www.wiley.com/college/voet

Case Study 3 Carbonic Anhydrase II Deficiency

Focus concept: Carbonic anhydrase plays a role in normal bone tissue formation.

Prerequisites: Chapters 2, 3, 4, and 10

- Amino acid structure
- The carbonic acid/bicarbonate blood buffering system
- Membrane transport proteins
- Basic genetics

Case Study 14 Shavings from the Carpenter's Bench: The Biological Role of the Insulin C-peptide

Focus concept: Recent experiments indicate that the insulin C-peptide, which is removed on conversion of proinsulin to insulin, may have biological activity in its own right.

Prerequisites: Chapters 4, 6, and 10

- Amino acid structure
- Principles of protein folding
- Membrane transport proteins

Case Study 17 A Possible Mechanism for Blindness Associated with Diabetes: Na^+ -Dependent Glucose Uptake by Retinal Cells

Focus concept: Glucose transport into cells can influence collagen synthesis, which causes the basement membrane thickening associated with diabetic retinopathy.

Prerequisite: Chapter 10

- Transport proteins
- (Na^+-K^+) -ATPase and active transport

MORE TO EXPLORE The M2 protein encoded by the influenza virus is essential for infection. What ion is transported by the M2 protein, and what role does ion transport play in the flu virus life cycle? What drugs target the M2 protein? Why is it necessary to develop new drugs to block M2 function?

CHAPTER 11

Enzymatic Catalysis

Chapter Contents

1 General Properties of Enzymes

- A Enzymes Are Classified by the Type of Reaction They Catalyze
- B Enzymes Act on Specific Substrates
- C Some Enzymes Require Cofactors

2 Activation Energy and the Reaction Coordinate

3 Catalytic Mechanisms

- A Acid–Base Catalysis Occurs by Proton Transfer
- B Covalent Catalysis Usually Requires a Nucleophile
- C Metal Ion Cofactors Act as Catalysts
- D Catalysis Can Occur through Proximity and Orientation Effects
- E Enzymes Catalyze Reactions by Preferentially Binding the Transition State

4 Lysozyme

- A Lysozyme's Catalytic Site Was Identified through Model Building
- B The Lysozyme Reaction Proceeds via a Covalent Intermediate

5 Serine Proteases

- A Active Site Residues Were Identified by Chemical Labeling
- B X-Ray Structures Provide Information about Catalysis, Substrate Specificity, and Evolution
- C Serine Proteases Use Several Catalytic Mechanisms
- D Zymogens Are Inactive Enzyme Precursors

Virtually all enzymes include a pocket, the active site, that is ideally shaped to bind specific substrates, hold them, and participate in the chemical reaction that transforms them to specific products. The structure of *E. coli* deoxyribose phosphate aldolase was determined by Chi-Huey Wong and Ian A. Wilson, The Scripps Research Institute, La Jolla, California. PDBid 1JCJ.

Living systems are shaped by an enormous variety of biochemical reactions, nearly all of which are mediated by a series of remarkable biological catalysts known as enzymes. **Enzymology**, the study of enzymes, has its roots in the early days of biochemistry; both disciplines evolved together from nineteenth-century investigations of fermentation and digestion. Initially, the inability to reproduce most biochemical reactions in the laboratory led Louis Pasteur and others to assume that living systems were endowed with a “vital force” that permitted them to evade the laws of nature governing inanimate matter. Some investigators, however, notably Justus von Liebig, argued that biological processes were caused by the action of chemical substances that were then known as “ferments.” Indeed, the name “enzyme” (Greek: *en*, in + *zyme*, yeast) was coined in 1878 in an effort to emphasize that there is something *in* yeast, as opposed to the yeast itself, that catalyzes the reactions of fermentation. Eventually, Eduard Buchner showed that a cell-free yeast extract could in fact carry out the synthesis of ethanol from glucose (**alcoholic fermentation**; Section 15-3B):

This chemical transformation actually proceeds in 12 enzyme-catalyzed steps.

The chemical composition of enzymes was not firmly established until 1926, when James Sumner crystallized jack bean **urease**, which catalyzes the hydrolysis of urea to NH_3 and CO_2 , and demonstrated that the crystals consist of protein. Enzymological experience since then has amply demonstrated that nearly all biochemical reactions are catalyzed by proteins, although there are some notable exceptions.

Certain species of RNA molecules known as **ribozymes** also have enzymatic activity. These include ribosomal RNA, which catalyzes the formation of peptide bonds between amino acids during protein synthesis. In fact, laboratory experiments

have produced ribozymes that can catalyze reactions similar to those required for replicating DNA, transcribing it to RNA, and attaching amino acids to transfer RNA. These findings are consistent with a precellular world in which RNA molecules enjoyed a more exalted position as the catalytic workhorses of biochemistry. The present-day RNA catalysts are presumably vestiges of this earlier “RNA world.” Proteins have largely eclipsed RNA as cellular catalysts, probably because of the greater chemical versatility of proteins. Whereas nucleic acids are polymers of four types of chemically similar monomeric units, proteins have at their disposal 20 types of amino acids with a greater variety of functional groups.

This chapter is concerned with one of the central questions of biochemistry: How do enzymes work? We will see that enzymes increase the rates of chemical reactions by lowering the free energy barrier that separates the reactants and products. Enzymes accomplish this feat through various mechanisms that depend on the arrangement of functional groups in the enzyme’s **active site**, the region of the enzyme where catalysis occurs. In this chapter, we describe these mechanisms, along with examples that illustrate how enzymes combine several mechanisms to catalyze biological reactions. The following chapter includes a discussion of enzyme kinetics, the study of the rates at which such reactions occur.

1 General Properties of Enzymes

KEY CONCEPTS

- Enzymes differ from ordinary chemical catalysts in reaction rate, reaction conditions, reaction specificity, and control.
- The unique physical and chemical properties of the active site limit an enzyme’s activity to specific substrates and reactions.
- Some enzymes require metal ions or organic cofactors.

Biochemical research since Pasteur’s era has shown that, although enzymes are subject to the same laws of nature that govern the behavior of other substances, enzymes differ from ordinary chemical catalysts in several important respects:

1. **Higher reaction rates.** The rates of enzymatically catalyzed reactions are typically 10^6 to 10^{12} times greater than those of the corresponding uncatalyzed reactions (**Table 11-1**) and are at least several orders of magnitude greater than those of the corresponding chemically catalyzed reactions.
2. **Milder reaction conditions.** Enzymatically catalyzed reactions occur under relatively mild conditions: temperatures below 100°C , atmospheric pressure, and nearly neutral pH. In contrast, efficient chemical catalysis often requires elevated temperatures and pressures as well as extremes of pH.
3. **Greater reaction specificity.** Enzymes have a vastly greater degree of specificity with respect to the identities of both their **substrates** (reactants)

TABLE 11-1 Catalytic Power of Some Enzymes

Enzyme	Nonenzymatic Reaction Rate (s^{-1})	Enzymatic Reaction Rate (s^{-1})	Rate Enhancement
Carbonic anhydrase	1.3×10^{-1}	1×10^6	7.7×10^6
Chorismate mutase	2.6×10^{-5}	50	1.9×10^6
Triose phosphate isomerase	4.3×10^{-6}	4300	1.0×10^9
Carboxypeptidase A	3.0×10^{-9}	578	1.9×10^{11}
AMP nucleosidase	1.0×10^{-11}	60	6.0×10^{12}
Staphylococcal nuclease	1.7×10^{-13}	95	5.6×10^{14}

Source: Radzicka, A. and Wolfenden, R., *Science* **267**, 91 (1995).

and their products than do chemical catalysts; that is, enzymatic reactions rarely have side products.

4. **Capacity for regulation.** The catalytic activities of many enzymes vary in response to the concentrations of substances other than their substrates. The mechanisms of these regulatory processes include allosteric control, covalent modification of enzymes, and variation of the amounts of enzymes synthesized.

A Enzymes Are Classified by the Type of Reaction They Catalyze

TABLE 11-2 Enzyme Classification According to Reaction Type

Classification	Type of Reaction Catalyzed
1. Oxidoreductases	Oxidation–reduction reactions
2. Transferases	Transfer of functional groups
3. Hydrolases	Hydrolysis reactions
4. Lyases	Group elimination to form double bonds
5. Isomerases	Isomerization
6. Ligases	Bond formation coupled with ATP hydrolysis

Before delving further into the specific properties of enzymes, a word on nomenclature is in order. Enzymes are commonly named by appending the suffix *-ase* to the name of the enzyme's substrate or to a phrase describing the enzyme's catalytic action. Thus, urease catalyzes the hydrolysis of urea, and **alcohol dehydrogenase** catalyzes the oxidation of primary and secondary alcohols to their corresponding aldehydes and ketones by removing hydrogen. Since there were at first no systematic rules for naming enzymes, this practice occasionally resulted in two different names being used for the same enzyme or, conversely, in the same name being used for two different enzymes. Moreover, many enzymes, such as **catalase** (which mediates the dismutation of H_2O_2 to H_2O and O_2), were given names that provide no clue to their function. In an effort to eliminate this confusion and to provide rules for rationally naming the rapidly growing number of newly discovered enzymes, the following scheme for the systematic functional classification and nomenclature of enzymes was adopted by the International Union of Biochemistry and Molecular Biology (IUBMB).

Enzymes are classified and named according to the nature of the chemical reactions they catalyze. There are six major classes of enzymatic reactions (Table 11-2), as well as subclasses and sub-subclasses. Each enzyme is assigned two names and a four-part classification number. Its **accepted** or **recommended name** is convenient for everyday use and is often an enzyme's previously used name. Its **systematic name** is used when ambiguity must be minimized; it is the name of its substrate(s) followed by a word ending in *-ase* specifying the type of reaction the enzyme catalyzes according to its major group classification. For example, the enzyme whose recommended name is aconitase (Section 17-3B) has the systematic name aconitate hydratase and the classification number EC 4.2.1.3 ("EC" stands for Enzyme Commission, and the numbers represent the class, subclass, sub-subclass, and an arbitrarily assigned serial number in the sub-subclass). For our purposes, the recommended name of an enzyme is usually adequate. However, **EC classification** numbers are increasingly used in various Internet-accessible databases (Section 14-4C). Systematic names and EC classification numbers can be obtained via the Internet (<http://expasy.org/enzyme/>).

FIG. 11-1 An enzyme–substrate complex. The geometric and the electronic complementarity between the enzyme and substrate depend on noncovalent forces. Hydrophobic groups are represented by an h in a brown circle, and dashed lines represent hydrogen bonds.

B Enzymes Act on Specific Substrates

The noncovalent forces through which substrates and other molecules bind to enzymes are similar in character to the forces that dictate the conformations of the proteins themselves (Section 6-4A). Both involve van der Waals, electrostatic, hydrogen bonding, and hydrophobic interactions. In general, a substrate-binding site consists of an indentation or cleft on the surface of an enzyme molecule that is complementary in shape to the substrate (**geometric complementarity**). Moreover, the amino acid residues that form the binding site are arranged to specifically attract the substrate (**electronic complementarity**, Fig. 11-1). Molecules that differ in shape or functional group distribution from the substrate cannot productively bind to the enzyme. X-Ray studies indicate that the substrate-binding sites of most enzymes are largely preformed but undergo some conformational change on substrate binding (a phenomenon called **induced fit**). The complementarity between enzymes and their substrates is the basis of the “lock-and-key” model of enzyme function first proposed by Emil Fischer in 1894. As we will see, such specific binding is necessary but not sufficient for efficient catalysis.

Enzymes Are Stereospecific. Enzymes are highly specific both in binding chiral substrates and in catalyzing their reactions. This **stereospecificity** arises because enzymes, by virtue of their inherent chirality (proteins consist of only L-amino acids), form asymmetric active sites. For example, the enzyme **aconitase** catalyzes the interconversion of citrate and isocitrate in the citric acid cycle (Section 17-3B):

Citrate is a **prochiral** molecule; that is, it can become chiral through the substitution of one of its two carboxymethyl ($-\text{CH}_2\text{COO}^-$) groups (chirality is discussed in Section 4-2). These groups are chemically equivalent but occupy different positions relative to the OH and COO^- groups (likewise, your body is bilaterally symmetric but has distinguishable right and left sides). Aconitase can therefore distinguish between them because citrate interacts asymmetrically with the surface of the enzyme by making a three-point attachment (Fig. 11-2). Because there is only one productive way for citrate to bind to the enzyme, only one of its $-\text{CH}_2\text{COO}^-$ groups reacts to form isocitrate. The stereospecificity of aconitase is by no means unusual. As we consider biochemical reactions, we will find that *nearly all enzymes that participate in chiral reactions are absolutely stereospecific*.

Enzymes Vary in Geometric Specificity. The stereospecificity of enzymes is not particularly surprising in light of the complementarity of an enzyme's binding site for its substrate. A substance of the wrong chirality will not fit productively into an enzymatic binding site for much the same reason that you cannot fit your right hand into your left glove. In addition to their stereospecificity, however, most enzymes are quite selective about the identities of the chemical groups on their substrates. Indeed, such **geometric specificity** is a more stringent requirement than is stereospecificity.

Enzymes vary considerably in their degree of geometric specificity. A few enzymes are absolutely specific for only one compound. Most enzymes, however, catalyze the reactions of a small range of related compounds although with different efficiencies. For example, alcohol dehydrogenase catalyzes the oxidation of **ethanol** ($\text{CH}_3\text{CH}_2\text{OH}$) to **acetaldehyde** (CH_3CHO) faster than it oxidizes **methanol** (CH_3OH) to **formaldehyde** (H_2CO) or **isopropanol** [$(\text{CH}_3)_2\text{CHOH}$] to **acetone** [$(\text{CH}_3)_2\text{CO}$], even though methanol and isopropanol differ from ethanol by only the deletion or addition of a CH_2 group.

Some enzymes, particularly digestive enzymes, are so permissive in their ranges of acceptable substrates that their geometric specificities are more accurately described as preferences. Some enzymes are not even very specific in the type of reaction they catalyze. For example, chymotrypsin, in addition to its ability to mediate peptide bond hydrolysis, also catalyzes ester bond hydrolysis.

FIG. 11-2 Stereospecificity in substrate binding. The specific binding of a prochiral molecule, such as citrate, in an enzyme active site allows the enzyme to differentiate between prochiral groups.

This property makes it convenient to measure chymotrypsin activity using small synthetic esters as substrates. Such permissiveness is much more the exception than the rule. Indeed, most intracellular enzymes function *in vivo* to catalyze a particular reaction on a particular substrate.

C Some Enzymes Require Cofactors

The functional groups of proteins, as we will see, can readily participate in acid–base reactions, form certain types of transient covalent bonds, and take part in charge–charge interactions. They are, however, less suitable for catalyzing oxidation–reduction reactions and many types of group-transfer processes. Although enzymes catalyze such reactions, they can do so only in association with small **cofactors**, which essentially act as the enzymes’ “chemical teeth” (Fig. 11-3).

Cofactors may be metal ions, such as Cu^{2+} , Fe^{3+} , or Zn^{2+} . The essential nature of these cofactors explains why organisms require trace amounts of certain elements in their diets. It also explains, in part, the toxic effects of certain heavy metals. For example, Cd^{2+} and Hg^{2+} can replace Zn^{2+} (all are in the same group of the periodic table) in the active sites of certain enzymes and thereby render these enzymes inactive.

Cofactors may also be organic molecules known as **coenzymes**. Some cofactors are only transiently associated with a given enzyme molecule, so that they function as **cosubstrates**. **Nicotinamide adenine dinucleotide (NAD⁺)** and **nicotinamide adenine dinucleotide phosphate (NADP⁺)** are examples of cosubstrates (Fig. 11-4). For instance, NAD⁺ is an obligatory oxidizing agent in the alcohol dehydrogenase (ADH) reaction:

The product NADH dissociates from the enzyme for eventual reoxidation to NAD⁺ in an independent enzymatic reaction.

FIG. 11-3 Types of cofactors.

X = H **Nicotinamide adenine dinucleotide (NAD⁺)**
 X = PO_3^{2-} **Nicotinamide adenine dinucleotide phosphate (NADP⁺)**

FIG. 11-4 The structures and reaction of nicotinamide adenine dinucleotide (NAD⁺) and nicotinamide adenine dinucleotide phosphate (NADP⁺). Their reduced forms are NADH and NADPH. These substances, which are collectively referred to as the **nicotinamide coenzymes** or **pyridine nucleotides** (nicotinamide is a pyridine derivative), function as intracellular electron carriers. Reduction (addition of electrons) formally involves the transfer of two hydrogen atoms (H[•]), or a hydride ion and a proton (H⁻ + H⁺). Note that only the nicotinamide ring is changed in the reaction.

Other cofactors, known as **prosthetic groups**, are permanently associated with their protein, often by covalent bonds. For example, a heme prosthetic group (Fig. 7-2) is tightly bound to proteins known as **cytochromes** (Fig. 6-32 and Box 18-1) through extensive hydrophobic and hydrogen-bonding interactions together with covalent bonds between the heme and specific protein side chains.

A catalytically active enzyme–cofactor complex is called a **holoenzyme**. The enzymatically inactive protein resulting from the removal of a holoenzyme's cofactor is referred to as an **apoenzyme**; that is,

Coenzymes Must Be Regenerated. Coenzymes are chemically changed by the enzymatic reactions in which they participate. *In order to complete the catalytic cycle, the coenzyme must return to its original state.* For a transiently bound coenzyme (cosubstrate), the regeneration reaction may be catalyzed by a different enzyme as we have seen to be the case for NAD^+ . However, for a prosthetic group, regeneration occurs as part of the enzyme reaction sequence.

CHECKPOINT

- What properties distinguish enzymes from other catalysts?
- Describe how different enzymes are classified and named.
- What factors influence an enzyme's substrate specificity?
- Why are cofactors required for some enzymatic reactions?
- What is the relationship between cofactors, coenzymes, cosubstrates, and prosthetic groups?

2 Activation Energy and the Reaction Coordinate

KEY CONCEPT

- An enzyme provides a lower-energy pathway from substrate to product but does not affect the overall free energy change for the reaction.

Much of our understanding of how enzymes catalyze chemical reactions comes from **transition state theory**, which was developed in the 1930s, principally by Henry Eyring. Consider a bimolecular reaction involving three atoms, such as the reaction of a hydrogen atom with diatomic hydrogen (H_2) to yield a new H_2 molecule and a different hydrogen atom:

In this reaction, H_C must approach the diatomic molecule $\text{H}_A\text{—H}_B$ so that, at some point in the reaction, there exists a high-energy (unstable) complex represented as $\text{H}_A\cdots\text{H}_B\cdots\text{H}_C$. In this complex, the $\text{H}_A\text{—H}_B$ covalent bond is in the process of breaking while the $\text{H}_B\text{—H}_C$ bond is in the process of forming. The point of highest free energy is called the **transition state** of the system.

Reactants generally approach one another along the path of minimum free energy, their so-called **reaction coordinate**. A plot of free energy versus the reaction coordinate is called a **transition state diagram** or **reaction coordinate diagram** (Fig. 11-5). The reactants and products are states of minimum free energy, and the transition state corresponds to the highest point of the diagram. For the $\text{H} + \text{H}_2$ reaction, the reactants and products have the same free energy (Fig. 11-5a). If the atoms in the reacting system are of different types, such as in the reaction

where A and B are the reactants, P and Q are the products, and X^\ddagger represents the transition state, the transition state diagram is no longer symmetrical because there is a free energy difference between the reactants and products (Fig. 11-5b). In either case, ΔG^\ddagger , the free energy of the transition state less that of the reactants, is known as the **free energy of activation**.

Passage through the transition state requires only 10^{-13} to 10^{-14} s, so the concentration of the transition state in a reacting system is small. Hence, the decomposition of the transition state to products (or back to reactants) is postulated to be the rate-determining process of the overall reaction. Thermodynamic

FIG. 11-5 Transition state diagrams. (a) The $\text{H} + \text{H}_2$ reaction. The reactants and products correspond to low free energy structures. The point of highest free energy is the transition state, in which the reactants are partially converted to products. ΔG^\ddagger is the free energy of

activation, the difference in free energy between the reactants and the transition state, X^\ddagger . (b) Transition state diagram for the reaction $\text{A} + \text{B} \rightarrow \text{P} + \text{Q}$. This is a spontaneous reaction; that is, $\Delta G_{\text{reaction}} < 0$ (the free energy of $\text{P} + \text{Q}$ is less than the free energy of $\text{A} + \text{B}$).

? Draw a transition state diagram for a nonspontaneous reaction.

arguments lead to the conclusion that the reaction rate is proportional to $e^{-\Delta G^\ddagger/RT}$, where R is the gas constant and T is the absolute temperature. Thus, *the greater the value of ΔG^\ddagger , the slower the reaction rate*. This is because the larger the ΔG^\ddagger , the smaller the number of reactant molecules that have sufficient thermal energy to achieve the transition state free energy.

Chemical reactions commonly consist of several steps. For a two-step reaction such as

where I is an intermediate of the reaction, there are two transition states and two activation energy barriers. The shape of the transition state diagram for such a reaction reflects the relative rates of the two steps (Fig. 11-6). If the activation energy of the first step is greater than that of the second step, then the first step is slower than the second step, and conversely, if the activation energy of the second

FIG. 11-6 Transition state diagram for a two-step reaction. The blue curve represents a reaction ($\text{A} \rightarrow \text{I} \rightarrow \text{P}$) whose first step is rate determining, and the red curve represents a reaction whose second step is rate determining.

FIG. 11-7 Effect of a catalyst on the transition state diagram of a reaction. Here $\Delta\Delta G_{\text{cat}}^{\ddagger} = \Delta G^{\ddagger}(\text{uncat}) - \Delta G^{\ddagger}(\text{cat})$.

? Does the catalyst affect $\Delta G_{\text{reaction}}$?

step is greater. In a multistep reaction, the step with the highest transition state free energy acts as a “bottleneck” and is therefore said to be the **rate-determining step** of the reaction.

Catalysts Reduce ΔG^{\ddagger} . Catalysts act by providing a reaction pathway with a transition state whose free energy is lower than that in the uncatalyzed reaction (Fig. 11-7). The difference between the values of ΔG^{\ddagger} for the uncatalyzed and catalyzed reactions, $\Delta\Delta G_{\text{cat}}^{\ddagger}$, indicates the efficiency of the catalyst. The **rate enhancement** (ratio of the rates of the catalyzed and uncatalyzed reactions) is given by $e^{\Delta\Delta G_{\text{cat}}^{\ddagger}/RT}$. Hence, at 25°C (298 K), a 10-fold rate enhancement requires a $\Delta\Delta G_{\text{cat}}^{\ddagger}$ of only $5.71 \text{ kJ} \cdot \text{mol}^{-1}$, which is less than half the free energy of a typical hydrogen bond. Similarly, a millionfold rate acceleration occurs when $\Delta\Delta G_{\text{cat}}^{\ddagger} \approx 34 \text{ kJ} \cdot \text{mol}^{-1}$, a small fraction of the free energy of most covalent bonds (see Sample Calculation 11-1). Thus, from a theoretical standpoint, tremendous catalytic efficiency seems within reach of the reactive groups that occur in the active sites of enzymes. How these groups actually function at the atomic level is the subject of much of this and other chapters.

Note that a catalyst lowers the free energy barrier by the same amount for both the forward and reverse reactions (Fig. 11-7). Consequently, a catalyst equally accelerates the forward and reverse reactions. Keep in mind also that while a catalyst can accelerate the conversion of reactants to products (or products back to reactants), the likelihood of the net reaction occurring in one direction or the other depends only on the free energy difference between the reactants

SAMPLE CALCULATION 11-1

By how much must an enzyme reduce the activation energy of a reaction at 37°C for the reaction to occur 50 times faster than in the absence of the enzyme?

Rate enhancement = 50 = $e^{\Delta\Delta G_{\text{cat}}^{\ddagger}/RT}$. Rearranging the equation gives

$$\begin{aligned} \ln 50 &= \Delta\Delta G_{\text{cat}}^{\ddagger}/RT \\ \Delta\Delta G_{\text{cat}}^{\ddagger} &= RT \ln 50 \\ &= (8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}) (37 + 273)\text{K} \ln 50 \\ &= 10,000 \text{ J} \cdot \text{mol}^{-1} = 10 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$

WPLS See Sample Calculation Videos.

CHECKPOINT

- Sketch and label the various parts of transition state diagrams for a reaction with and without a catalyst.
- What is the relationship between ΔG and ΔG^\ddagger ?

and the products. If $\Delta G_{\text{reaction}} < 0$, the reaction proceeds spontaneously from reactants toward products; if $\Delta G_{\text{reaction}} > 0$, the reverse reaction proceeds spontaneously. *An enzyme cannot alter $\Delta G_{\text{reaction}}$; it can only decrease ΔG^\ddagger to allow the reaction to more quickly approach equilibrium (where the rates of the forward and reverse reactions are equal) than it would in the absence of a catalyst.* The actual velocity with which reactants are converted to products is the subject of kinetics (Section 12-1).

3 Catalytic Mechanisms

KEY CONCEPTS

- Amino acid side chains that can donate or accept protons can participate in chemical reactions as acid or base catalysts.
- Nucleophilic groups can catalyze reactions through the transient formation of covalent bonds with the substrate.
- In metal ion catalysis, the unique electronic properties of the metal ion facilitate the reaction.
- Enzymes accelerate reactions by bringing reacting groups together and orienting them for reaction.
- Transition state stabilization can significantly lower the activation energy for a reaction.

Enzymes achieve their enormous rate accelerations via the same catalytic mechanisms used by chemical catalysts. Enzymes have simply been better designed through evolution. Enzymes, like other catalysts, reduce the free energy of the transition state (ΔG^\ddagger); that is, *they stabilize the transition state of the catalyzed reaction.* What makes enzymes such effective catalysts is their specificity of substrate binding combined with their arrangement of catalytic groups. As we will see, however, the distinction between substrate-binding groups and catalytic groups is somewhat arbitrary.

The types of catalytic mechanisms that enzymes employ have been classified as

1. Acid–base catalysis
2. Covalent catalysis
3. Metal ion catalysis
4. Proximity and orientation effects
5. Preferential binding of the transition state complex

In this section, we consider each of these types of mechanisms in turn. *Much can be learned about enzymatic reaction mechanisms by examining the corresponding nonenzymatic reactions of model compounds.* Both types of reactions can be described using the same conventions (Box 11-1).

A Acid–Base Catalysis Occurs by Proton Transfer

General acid catalysis is a process in which proton transfer from an acid lowers the free energy of a reaction's transition state. For example, an uncatalyzed keto–enol tautomerization reaction occurs quite slowly as a result of the high free energy of its carbanion-like transition state (Fig. 11-8a; the transition state is drawn in square brackets to indicate its instability). Proton donation to the oxygen atom (Fig. 11-8b), however, reduces the carbanion character of the transition state, thereby accelerating the reaction.

A reaction may also be stimulated by **general base catalysis** if its rate is increased by proton abstraction by a base (e.g., Fig. 11-8c). Some reactions may be simultaneously subject to both processes; these are **concerted acid–base catalyzed reactions**.

Box 11-1 Perspectives in Biochemistry Drawing Reaction Mechanisms

While it is sometimes sufficient to draw the structures of a reaction's substrates and products, a full understanding of the reaction mechanism requires knowing how electrons are reallocated as covalent bonds are broken and re-formed. Biochemists use the **curved arrow convention** to show how pairs of electrons are rearranged during a reaction. Although single-electron reactions also occur in biochemistry, we will focus on the more common two-electron reactions.

The movement of an electron pair (which may be either a lone pair or a pair forming a covalent bond) is symbolized by a curved arrow emanating from the electron pair and pointing to the electron-deficient center attracting the electron pair. For example, bond breakage is shown as

and bond formation as

An example of a more complicated reaction requiring several curved arrows is the formation of an imine (**Schiff base**), a biochemically important reaction between an amine and an aldehyde or ketone:

In the first reaction step, the amine's unshared electron pair adds to the electron-deficient carbonyl carbon while one electron pair from its C=O double bond transfers to the oxygen atom. Following tautomerization (the shift of a hydrogen atom), the unshared electron pair on the nitrogen atom of the carbinolamine intermediate adds to the electron-deficient carbon atom with the elimination of a hydroxide ion.

Familiarity with the relative electronegativities of atoms

may be helpful in predicting the movement of electrons, since electrons—either those in covalent bonds or in lone pairs—tend to move from less electronegative atoms toward more electronegative atoms. Showing lone electron pairs as dots can help identify electron-poor and electron-rich atoms. In addition, *the rules of chemical reason apply to the system*: For example, there are never five bonds to a carbon atom or two bonds to a hydrogen atom.

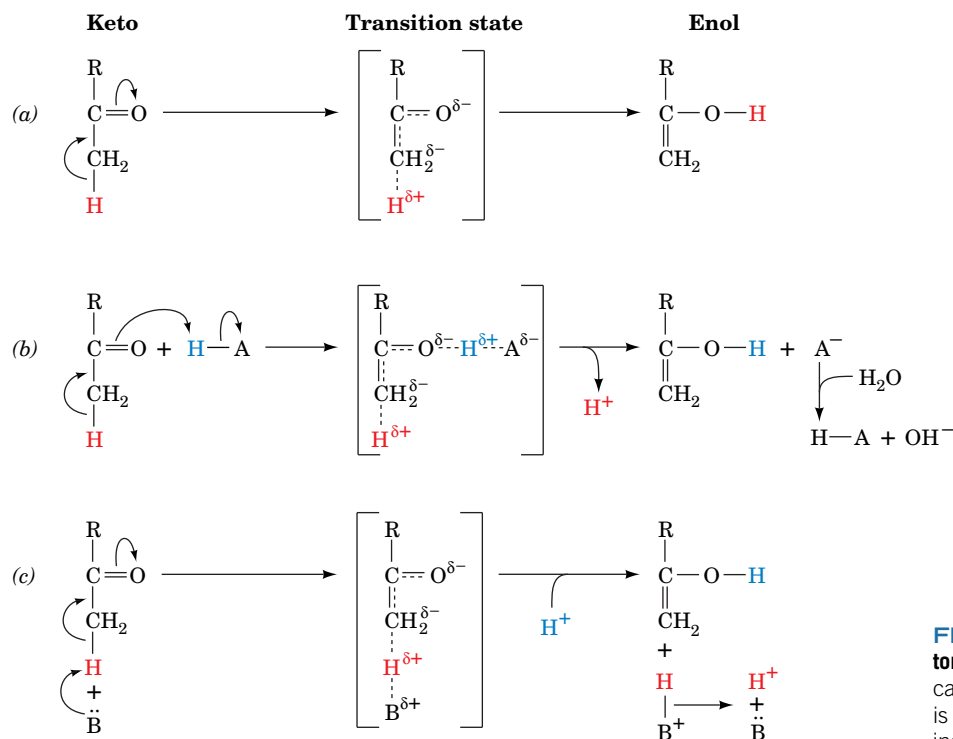

FIG. 11-8 Mechanisms of keto-enol tautomerization. (a) Uncatalyzed. (b) General acid catalyzed. (c) General base catalyzed. The acid is represented as H—A, the base as B, and δ indicates a partial negative or positive charge.

Most enzymes are active within only a narrow pH range, typically 5 to 9. This is a result of the effects of pH on a combination of factors: (1) the binding of substrate to enzyme, (2) the ionization states of the amino acid residues involved in the catalytic activity of the enzyme, (3) the ionization of the substrate, and (4) the variation of protein structure (usually significant only at extremes of pH).

The rates of many enzymatic reactions exhibit bell-shaped curves as a function of pH. For example, the pH dependence of the rate of the reaction catalyzed by **fumarase** (Section 17-3G) produces the following curve:

Such curves reflect the ionization of certain amino acid residues that must be in a specific ionization state for enzymatic activity. The observed pK 's (the inflection points of the curve) often provide valuable clues to the identities of the amino acid residues essential for enzymatic activity. For example, an observed pK of ~ 4 suggests that an Asp or Glu residue is essential to the enzyme. Similarly, pK 's of ~ 6 or ~ 10 suggest the participation of a His or a Lys residue, respectively. However, the pK of a given acid–base group may vary by as much as several pH units from its expected value, depending on its microenvironment (e.g., an Asp residue in a nonpolar environment or in close proximity to another Asp residue would attract protons more strongly than otherwise and hence have a higher pK). Furthermore, pH effects on an enzymatic rate may reflect denaturation of the enzyme rather than protonation or deprotonation of specific catalytic residues. The replacement of a particular residue by site-directed mutagenesis or comparisons of enzyme variants generated by evolution is a more reliable approach to identifying residues that are required for substrate binding or catalysis.

In addition to pH, other environmental factors, such as temperature and salt concentration, affect enzyme catalysis, typically producing bell-shaped activity curves as shown here for pH. The optimal conditions (the peak of the activity curve) frequently correspond to the prevailing environmental conditions of the cell or organism, indicating that evolution has fine-tuned enzymes for maximum efficiency.

[Figure adapted from Tanford, C., *Physical Chemistry of Macromolecules*, p. 647, Wiley (1961).]

Many types of biochemical reactions are susceptible to acid and/or base catalysis. The side chains of the amino acid residues Asp, Glu, His, Cys, Tyr, and Lys have pK 's in or near the physiological pH range (Table 4-1), which permits them to act as acid and/or base catalysts. Indeed, *the ability of enzymes to arrange several catalytic groups around their substrates makes concerted acid–base catalysis a common enzymatic mechanism*. The catalytic activity of these enzymes is sensitive to pH, since the pH influences the state of protonation of side chains at the active site (Box 11-2).

RNase A Is an Acid–Base Catalyst. **Bovine pancreatic RNase A** provides an example of enzymatically mediated acid–base catalysis. This digestive enzyme (Fig. 11-9) is secreted by the pancreas into the small intestine, where it hydrolyzes RNA to its component nucleotides. The isolation of 2',3'-cyclic nucleotides from RNase A digests of RNA indicates that 2',3'-cyclic nucleotides are intermediates in the RNase A reaction (Fig. 11-10). The pH dependence of the rate of the RNase A reaction suggests the involvement of two ionizable residues with pK values of 5.4 and 6.4. This information, together with chemical derivatization and X-ray studies, indicates that RNase A has two essential His residues, His 12 and His 119, that act in a concerted manner as general acid and base catalysts. Evidently, RNase A catalyzes a two-step reaction (Fig. 11-10):

FIG. 11-9 X-Ray structure of bovine pancreatic RNase S. A nonhydrolyzable substrate analog, the dinucleotide phosphonate UpcA (red), is bound in the active site. RNase S is a catalytically active form of RNase A in which the peptide bond between residues 20 and 21 has been hydrolyzed. [Illustration, Irving Geis. PROCESS DIAGRAM

FIG. 11-10 The RNase A mechanism. The bovine pancreatic RNase A-catalyzed hydrolysis of RNA is a two-step process with the intermediate formation of a 2',3'-cyclic nucleotide. **WPLS** See the Animated Process Diagrams.

? Assign a pK value (5.4 or 6.4) to each His residue.

1. His 12, acting as a general base, abstracts a proton from an RNA 2'-OH group, thereby promoting its nucleophilic attack on the adjacent phosphorus atom. His 119, acting as a general acid, promotes bond scission by protonating the leaving group.
2. After the leaving group departs, water enters the active site, and the 2',3'-cyclic intermediate is hydrolyzed through what is essentially the reverse of the first step. Thus, His 12 now acts as a general acid and His 119 as a general base to yield the hydrolyzed RNA and the enzyme in its original state.

B Covalent Catalysis Usually Requires a Nucleophile

Covalent catalysis accelerates reaction rates through the transient formation of a catalyst–substrate covalent bond. Usually, this covalent bond is formed by the reaction of a nucleophilic group on the catalyst with an electrophilic group on the substrate, and hence this form of catalysis is often also called **nucleophilic catalysis**. The decarboxylation of acetoacetate, as chemically catalyzed by primary amines, is an example of such a process (Fig. 11-11). In the first stage of this reaction, the amine, a nucleophile, attacks the carbonyl group of acetoacetate to form a Schiff base (imine bond; the same reaction shown in Box 11-1):

The protonated nitrogen atom of the covalent intermediate then acts as an electron sink (Fig. 11-11, *bottom*) to reduce the high-energy enolate character of the transition state. The formation and decomposition of the Schiff base occurs quite rapidly so that it is not the rate-determining step of this reaction.

Covalent catalysis can be conceptually decomposed into three stages:

1. The nucleophilic reaction between the catalyst and the substrate to form a covalent bond.

FIG. 11-11 The decarboxylation of acetoacetate.

The uncatalyzed reaction mechanism is at the top, and the mechanism as catalyzed by primary amines is at the bottom.

? Add curved arrows to describe electron movements in the steps represented by the vertical arrows.

- The withdrawal of electrons from the reaction center by the now electrophilic catalyst.
- The elimination of the catalyst, a reaction that is essentially the reverse of stage 1.

The nucleophilicity of a substance is closely related to its basicity. Indeed, the mechanism of nucleophilic catalysis resembles that of base catalysis except that, instead of abstracting a proton from the substrate, the catalyst nucleophilically attacks the substrate to form a covalent bond. Biologically important nucleophiles are negatively charged or contain unshared electron pairs that easily form covalent bonds with electron-deficient centers (Fig. 11-12a). Electrophiles, in contrast, include groups that are positively charged, contain an unfilled valence electron shell, or contain an electronegative atom (Fig. 11-12b).

An important aspect of covalent catalysis is that *the more stable the covalent bond formed, the less easily it can decompose in the final steps of a reaction*. A good covalent catalyst must therefore combine the seemingly contradictory properties of high nucleophilicity and the ability to form a good leaving group—that is, to easily reverse the bond formation step. Groups with high polarizability (highly mobile electrons), such as imidazole and thiol groups, have these properties and hence make good covalent catalysts. Functional groups in proteins that act in this way include the unprotonated amino group of Lys, the imidazole group of His, the thiol group of Cys, the carboxyl group of Asp, and the hydroxyl group of Ser. In addition, several coenzymes, notably **thiamine pyrophosphate** (Section 15-3B) and **pyridoxal phosphate** (Section 21-2A), function in association with their apoenzymes as covalent catalysts. The large variety of covalently linked enzyme–substrate reaction intermediates that have been isolated demonstrates that enzymes commonly employ covalent catalytic mechanisms.

C Metal Ion Cofactors Act as Catalysts

Nearly one-third of all known enzymes require metal ions for catalytic activity. This group of enzymes includes the **metalloenzymes**, which contain tightly bound metal ion cofactors, most commonly transition metal ions such as Fe^{2+} , Fe^{3+} , Cu^{2+} , Mn^{2+} , or Co^{2+} . These catalytically essential metal ions are distinct from ions such as Na^+ , K^+ , or Ca^{2+} , which often play a structural rather than a catalytic role in enzymes. Ions such as Mg^{2+} and Zn^{2+} may be either structural or catalytic.

FIG. 11-12 Biologically important nucleophilic and electrophilic groups. (a) Nucleophilic groups such as hydroxyl, sulfhydryl, amino, and imidazole groups are nucleophiles in their basic forms. (b) Electrophilic groups contain an electron-deficient atom (red).

FIG. 11-13 The role of Zn^{2+} in carbonic anhydrase. (a) The active site of the human enzyme. The polypeptide is shown in ribbon form (gold) with its side chains shown in stick form colored according to atom type (C green, N blue, and O red). The Zn^{2+} ion (cyan sphere) is liganded to three His side chains and the HCO_3^- ion, which is shown in ball-and-stick form. The HCO_3^- ion also makes van der Waals contacts (dot surface) and hydrogen bonds (dashed gray lines) with a Thr and Glu residue. [Based on an X-ray structure by K.K. Kannan, Bhabha Atomic Research Center, Bombay, India. PDBid 1HCB.] (b) The reaction catalyzed by carbonic anhydrase. Im represents the His imidazole group.

Metal ions participate in the catalytic process in three major ways:

1. By binding to substrates to orient them properly for reaction.
2. By mediating oxidation–reduction reactions through reversible changes in the metal ion’s oxidation state.
3. By electrostatically stabilizing or shielding negative charges.

In many metal ion–catalyzed reactions, the metal ion acts in much the same way as a proton to neutralize negative charge. Yet metal ions are often much more effective catalysts than protons because metal ions can be present in high concentrations at neutral pH (at which $[H^+] = 10^{-7}$ M) and may have charges greater than +1.

A metal ion’s charge also makes its bound water molecules more acidic than free H_2O and therefore a source of nucleophilic OH^- ions even below neutral pH. An excellent example of this phenomenon occurs in the catalytic mechanism of carbonic anhydrase (Box 2-2), a widely occurring enzyme that catalyzes the reaction

Carbonic anhydrase contains an essential Zn^{2+} ion that the enzyme’s X-ray structure indicates lies at the bottom of a 15-Å-deep active site cleft, where it is tetrahedrally coordinated by three evolutionarily invariant His side chains (Fig. 11-13a). The Zn^{2+} ion polarizes a water molecule (not visualized in Fig. 11-13a) so it ionizes to form OH^- , which nucleophilically attacks the substrate CO_2 to yield HCO_3^- (Fig. 11-13b). The proton produced in the reaction is shuttled to the enzyme’s surface through base catalysis that is facilitated by a fourth His residue (His 64). The enzyme’s catalytic site is then regenerated by the binding of another H_2O to the Zn^{2+} ion.

D Catalysis Can Occur through Proximity and Orientation Effects

Although enzymes employ catalytic mechanisms that resemble those of organic model reactions, they are far more catalytically efficient than the models. Such efficiency must arise from the specific physical conditions at enzyme catalytic sites that promote the corresponding chemical reactions. The most obvious effects are **proximity** and **orientation**: Reactants must come together with the proper spatial relationship for a reaction to occur. Consider the bimolecular reaction of imidazole with *p*-nitrophenylacetate.

The progress of the reaction is conveniently monitored by the appearance of the intensely yellow *p*-nitrophenolate ion. The related intramolecular reaction

occurs about 24 times faster. Thus, when the imidazole is covalently attached to the reactant, it is 24 times more effective than when it is free in solution. This rate enhancement results from both proximity and orientation effects.

By simply binding their substrates, enzymes facilitate their catalyzed reactions in four ways:

1. Enzymes bring substrates into contact with their catalytic groups and, in reactions with more than one substrate, with each other. However, calculations based on simple model systems suggest that such proximity effects alone can enhance reaction rates by no more than a factor of ~ 5 .
2. Enzymes bind their substrates in the proper orientations for reaction. Molecules are not equally reactive in all directions. Rather, *they react most readily if they have the proper relative orientation*. For example, in an S_N2 (bimolecular nucleophilic substitution) reaction, the incoming nucleophile optimally attacks its target along the direction opposite to that of the bond to the leaving group (Fig. 11-14). Reacting atoms whose approaches deviate by as little as 10° from this optimum direction are significantly less reactive. It is estimated that properly orienting substrates can increase reaction rates by a factor of up to ~ 100 . Enzymes, as we will see, align their substrates and catalytic groups so as to optimize reactivity.
3. Charged groups may help stabilize the transition state of the reaction, a phenomenon termed **electrostatic catalysis**. The expulsion of water from the active site may enhance this effect. The charge distribution around the active sites of enzymes may also guide polar substrates toward their binding site.
4. Enzymes freeze out the relative translational and rotational motions of their substrates and catalytic groups. This is an important aspect of catalysis because, in the transition state, the reacting groups have little relative motion. Indeed, experiments with model compounds suggest that *this effect can promote rate enhancements of up to $\sim 10^7$!*

Bringing substrates and catalytic groups together in a reactive orientation orders them and therefore has a substantial entropic penalty. The free energy required to overcome this entropy loss is supplied by the binding energy of the substrate(s)

FIG. 11-14 The geometry of an S_N2 reaction. (1) The attacking nucleophile, Y^- , must approach the tetrahedrally coordinated and hence sp^3 -hybridized C atom along the direction opposite to that of its bond to the leaving group, X. In the transition state of the reaction, the C atom becomes trigonal bipyramidal and hence sp^2-p hybridized, with the p orbital (blue) forming partial bonds to X and Y. The three sp^2 orbitals form bonds to the C atom's three other substituents

(R, R', and R''), which have shifted their positions into the plane perpendicular to the X—C—Y axis (curved arrows). Any deviation from this optimal geometry would increase the free energy of the transition state, ΔG^\ddagger , and hence reduce the rate of the reaction. (2) The transition state then decomposes to products in which R, R', and R'' have inverted their positions about the C atom, which has rehybridized to sp^3 , and X^- has been released.

to the enzyme and contributes to the decreased $\Delta\Delta G^\ddagger$. Keep in mind, however, that enzymes are dynamic molecules that may adopt a variety of different conformations before and after binding their substrates. Indeed, such flexibility is essential for an enzyme to productively interact with its substrates, transition state, and products during the course of a reaction.

E Enzymes Catalyze Reactions by Preferentially Binding the Transition State

The rate enhancements effected by enzymes are often greater than can be reasonably accounted for by the catalytic mechanisms discussed so far. However, we have not yet considered one of the most important mechanisms of enzymatic catalysis: *An enzyme may bind the transition state of the reaction it catalyzes with greater affinity than its substrates or products.* When taken together with the previously described catalytic mechanisms, preferential transition state binding explains the observed rates of enzyme-catalyzed reactions.

The original concept of transition state binding proposed that enzymes mechanically strained their substrates toward the transition state geometry through binding sites into which undistorted substrates did not fit properly. Such strain promotes many organic reactions. For example, the rate of the reaction on the left is 315 times faster when R is CH₃ rather than H because of the greater steric repulsion between the CH₃ groups and the reacting groups. The strained reactant more closely resembles the transition state of the reaction than does the corresponding unstrained reactant. Thus, as was first suggested by Linus Pauling and further amplified by Richard Wolfenden and Gustav Lienhard, *enzymes that preferentially bind the transition state structure increase its concentration and therefore proportionally increase the reaction rate.*

The more tightly an enzyme binds its reaction's transition state relative to the substrate, the greater is the rate of the catalyzed reaction relative to that of the uncatalyzed reaction; that is, catalysis results from the preferential binding and therefore the stabilization of the transition state relative to the substrate (Fig. 11-15). In other words, the free energy difference between an enzyme–substrate complex (ES) and an enzyme–transition state complex (ES[‡]) is less than the free energy difference between S and S[‡] in an uncatalyzed reaction.

As we saw in Section 11-2, the rate enhancement of a catalyzed reaction is given by $e^{\Delta\Delta G_{\text{cat}}^\ddagger/RT}$ where $\Delta\Delta G_{\text{cat}}^\ddagger$ is the difference in the values of ΔG^\ddagger for the uncatalyzed ($\Delta G_{\text{N}}^\ddagger$) and the catalyzed ($\Delta G_{\text{E}}^\ddagger$) reactions. Thus, a rate enhancement of 10⁶, which requires that an enzyme bind its transition state complex with 10⁶-fold higher affinity than its substrate, corresponds to a 34.2 kJ · mol⁻¹ stabilization at 25°C, roughly the free energy of two hydrogen bonds. Consequently, the enzymatic binding of a transition state by two hydrogen bonds that cannot form when the substrate first binds to the enzyme should result in a rate enhancement of ~10⁶ based on this effect alone.

It is commonly observed that an enzyme binds poor substrates, which have low reaction rates, as well as or even better than good ones, which have high reaction rates. Thus, a good substrate does not necessarily bind to its enzyme with high affinity, but it does so on activation to the transition state. Thus, Fischer's lock-and-key model for enzyme action applies more to transition state binding than to substrate binding.

For at least some enzymes, transition state stabilization makes only a minor contribution to rate enhancement. In many such cases, as Thomas Bruce has explained, the enzyme promotes the reaction by instead stabilizing the so-called near attack conformation, a step along the reaction coordinate in which the reactants are properly oriented and in van der Waals contact but have not yet reached the transition state. These findings suggest that enzymes have evolved to use a variety of strategies—including stabilizing the transition state or something leading up to it—to accelerate chemical reactions.

FIG. 11-15 Effect of preferential transition state binding. The reaction coordinate diagram for a hypothetical enzyme-catalyzed reaction involving a single substrate is blue, and the diagram for the corresponding uncatalyzed reaction is red. $\Delta G_{\text{N}}^\ddagger$ is the free energy of activation for the nonenzymatic reaction and $\Delta G_{\text{E}}^\ddagger$ is the free energy of activation for the enzyme-catalyzed reaction. The small dips in the reaction coordinate diagram for the enzyme-catalyzed reaction arise from the binding of substrate and product to the enzyme.

WPLS See the Animated Figures.

Transition State Analogs Are Enzyme Inhibitors. If an enzyme preferentially binds its transition state, then it can be expected that **transition state analogs**, stable molecules that geometrically and electronically resemble the transition state, are potent inhibitors of the enzyme. For example, the reaction catalyzed by **proline racemase** from *Clostridium sticklandii* is thought to occur via a planar transition state:

Proline racemase is inhibited by the planar analogs of proline, **pyrrole-2-carboxylate** and **Δ -1-pyrroline-2-carboxylate** (at right), both of which bind to the enzyme with 160-fold greater affinity than does proline. These compounds are therefore thought to be analogs of the transition state in the proline racemase reaction.

Hundreds of transition state analogs for various enzymes have been reported. Some are naturally occurring antibiotics. Others were designed to investigate the mechanism of particular enzymes or to act as specific enzyme inhibitors for therapeutic or agricultural use. Indeed, *the theory that enzymes bind transition states with higher affinity than substrates has led to a rational basis for drug design based on the understanding of specific enzyme reaction mechanisms* (Section 12-4).

Pyrrole-2-carboxylate

Δ -1-Pyrroline-2-carboxylate

CHECKPOINT

- Describe how protein functional groups can act as acid and base catalysts. How is it possible for a single amino acid side chain to function as both?
- Explain how nucleophiles function as covalent catalysts. Which amino acids are good at this?
- List the ways in which metal ions participate in catalysis.
- What roles do proximity and orientation play in enzymatic catalysis?
- Why is it unlikely that nonenzymatic catalysts operate by preferentially binding the transition state?

4 Lysozyme

KEY CONCEPTS

- Model building indicates that binding to lysozyme distorts the substrate sugar residue.
- Lysozyme's active site Asp and Glu residues promote substrate hydrolysis by acid–base catalysis, covalent catalysis, and stabilization of an oxonium ion transition state.

In the remainder of this chapter, we investigate the catalytic mechanisms of some well-characterized enzymes. In doing so, we will see how enzymes apply the catalytic principles described in the preceding section.

Lysozyme is an enzyme that destroys bacterial cell walls. It does so by hydrolyzing the $\beta(1\rightarrow4)$ glycosidic linkages from ***N*-acetylmuramic acid (NAM or MurNAc)** to ***N*-acetylglucosamine (NAG or GlcNAc)** in cell wall peptidoglycans (Fig. 11-16 and Section 8-3B). It likewise hydrolyzes $\beta(1\rightarrow4)$ -linked

FIG. 11-16 The lysozyme cleavage site. The enzyme cleaves after a $\beta(1\rightarrow4)$ linkage in the alternating NAG—NAM polysaccharide component of bacterial cell walls.

poly(NAG) (chitin; Section 8-2B), a cell wall constituent of most fungi as well as the major component of the exoskeletons of insects and crustaceans. Lysozyme occurs widely in the cells and secretions of vertebrates, where it probably functions as a bactericidal agent or helps dispose of bacteria after they have been killed by other means.

Hen egg white (HEW) lysozyme is the most widely studied species of lysozyme (in part because each chicken egg contains ~ 5 g of lysozyme) and is one of the mechanistically best understood enzymes. It is a rather small protein (14.3 kD) whose single polypeptide chain consists of 129 amino acid residues and is internally cross-linked by four disulfide bonds. Lysozyme catalyzes the hydrolysis of its substrate at a rate that is $\sim 10^8$ -fold greater than that of the uncatalyzed reaction.

A Lysozyme's Catalytic Site Was Identified through Model Building

The X-ray structure of HEW lysozyme (Fig. 11-17), which was elucidated by David Phillips in 1965 (it was the first enzyme to have its structure determined), shows that the protein molecule is roughly ellipsoidal in shape with dimensions $30 \times 30 \times 45$ Å. *Its most striking feature is a prominent cleft, the substrate-binding site, that traverses one face of the molecule.*

The elucidation of an enzyme's mechanism of action requires a knowledge of the structure of its enzyme-substrate complex. This is because, even if the active site residues have been identified through chemical and physical means, their three-dimensional arrangement relative to the substrate as well as to each other must be known in order to understand how the enzyme works. However, an enzyme binds its good substrates only transiently before it catalyzes a reaction and releases products. Consequently, much of our structural knowledge of enzyme-substrate complexes comes from X-ray studies of enzymes in their complexes with substrate analogs that bind but do not react or react very slowly.

Phillips' X-ray structure of lysozyme includes the trisaccharide (NAG)₃, which is only slowly hydrolyzed by lysozyme. However, the enzyme efficiently catalyzes the hydrolysis of substrates containing at least six saccharide units, so

GATEWAY CONCEPT Catalysis

An enzyme does not act at a distance to magically lower the activation energy for a chemical reaction. Even without forming a covalent reaction intermediate, an enzyme must interact closely with its substrates. This intimate contact makes it possible for an enzyme to provide a lower free energy of activation—and therefore faster—pathway from reactants to products than the uncatalyzed pathway.

FIG. 11-17 X-Ray structure of HEW lysozyme in complex with (NAG)₆. The protein is represented by its transparent molecular surface with its polypeptide chain in worm form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The (NAG)₆, which is drawn in stick form with its sugar rings designated A, at its nonreducing end, through F, at its reducing end, binds in a deep cleft in the enzyme surface. Rings A, B, and C (colored according to atom type with C green, N blue, and O red) are observed in the X-ray structure of the complex of (NAG)₃ with lysozyme; the positions of rings D, E, and F (C atoms cyan) were inferred by model building. The side chains of lysozyme's active site residues, Glu 35 and Asp 52, which are drawn in space-filling form (C atoms yellow), catalyze the hydrolysis of the glycosidic bond between rings D and E. [Based on an X-ray structure by David Phillips, Oxford University. PDBid 1HEW.]

? Aside from the active-site Asp and Glu, what residues would you expect to find in lysozyme's substrate-binding cleft?

FIG. 11-18 Chair and half-chair conformations.

Hexose rings normally assume the chair conformation. However, binding to lysozyme distorts the D ring into the half-chair conformation in which atoms C1, C2, C5, and O5 are coplanar.

WPLS See the Animated Figures.

? Add the appropriate substituents to each carbon to make NAG and NAM.

Phillips used model building to investigate how a larger substrate could bind to the enzyme. Lysozyme's active site cleft is long enough to accommodate an oligosaccharide of six residues (designated A to F in Fig. 11-17). However, the fourth residue (D) appeared unable to bind to the enzyme because its C6 and O6 atoms too closely contacted protein side chains and residue C. This steric interference could be relieved by distorting the glucose ring from its normal chair conformation to that of a half-chair (Fig. 11-18). This distortion moves the C6 group from its normal equatorial position to an axial position, where it makes no close contacts and can hydrogen bond to the backbone carbonyl group of Gln 57 and the backbone amido group of Val 109. The other saccharide residues apparently bind to the enzyme without distortion and with a number of favorable hydrogen-bonding and van der Waals contacts. Some of these hydrogen bonds are diagrammed in Fig. 11-19.

In the enzyme's natural substrate, every second residue is an NAM. Model building, however, indicated that the enzyme could not accommodate a lactyl side chain in subsites C or E. Hence, the NAM residues must bind at positions B, D, and F, as drawn in Fig. 11-19. Moreover, since lysozyme hydrolyzes (NAG)₆ between residues D and E, it must cleave the glycosidic bond in its natural substrate between the NAM residue in subsite D and the NAG residue in subsite E.

The bond that lysozyme cleaves was identified by allowing lysozyme to catalyze the hydrolysis of (NAG)₃ in H₂¹⁸O. The bond cleaved could either be between C1 and the bridge oxygen O1 or between O1 and C4 of the next sugar ring. The product of the hydrolysis reaction had ¹⁸O bonded to the C1

FIG. 11-19 The interactions of lysozyme with its substrate. The view is into the binding cleft with the heavier edges of the rings facing the outside of the enzyme and the lighter ones against the bottom of the cleft.

atom of its newly liberated reducing terminus, thereby demonstrating that bond cleavage occurs between C1 and O1:

In addition, this reaction occurs with retention of configuration so that the D-ring product remains the β anomer.

B The Lysozyme Reaction Proceeds via a Covalent Intermediate

The reaction catalyzed by lysozyme, the hydrolysis of a glycoside, is the conversion of an acetal to a hemiacetal. Nonenzymatic acetal hydrolysis is an acid-catalyzed reaction that involves the protonation of a reactant oxygen atom followed by cleavage of its C—O bond (Fig. 11-20). This results in the transient formation of a resonance-stabilized carbocation that is called an **oxonium ion**. To attain resonance stabilization, the oxonium ion's R and R' groups must be coplanar with its C, O, and H atoms. The oxonium ion then adds water to yield the hemiacetal and regenerate the acid catalyst. An enzyme that mediates acetal hydrolysis should therefore include an acid catalyst and possibly a group that can stabilize an oxonium ion transition state.

Glu 35 and Asp 52 Are Lysozyme's Catalytic Residues. The only functional groups in the immediate vicinity of lysozyme's reactive center that have the required catalytic properties are the side chains of Glu 35 and Asp 52. These side chains, which are disposed to either side of the glycosidic linkage to be cleaved (Fig. 11-17), have markedly different environments. Asp 52 is surrounded by several conserved polar residues with which it forms a complex hydrogen-bonded network. Asp 52 is therefore predicted to have a normal pK ; that is, it should be unprotonated and hence negatively charged throughout the 3 to 8 pH range over which lysozyme is catalytically active. Thus, Asp 52 can function to electrostatically stabilize an oxonium ion. In contrast, the carboxyl group of Glu 35 is nestled in a predominantly nonpolar pocket where it remains protonated at unusually high pH values for carboxyl groups (its pK is ~ 6.2 as determined by NMR methods). This residue can therefore act as an acid catalyst. Studies using protein-modifying reagents and site-directed mutagenesis (e.g., changing Asp 52 to Asn and Glu 35 to Gln) have verified that these residues are catalytically important.

Lysozyme's catalytic mechanism occurs as follows (Fig. 11-21):

1. The enzyme attaches to a bacterial cell wall by binding to a hexasaccharide unit. This distorts the D residue toward the half-chair conformation.
2. Glu 35 transfers its proton to the O1 atom bridging the D and E rings, thereby facilitating cleavage of the C1—O1 bond (general acid catalysis). This step converts the D ring to a resonance-stabilized oxonium ion transition state whose formation is facilitated by the strain distorting it to the half-chair conformation (catalysis by the preferential binding of the transition state). The positively charged oxonium ion is stabilized by the presence of the nearby negatively charged Asp 52 carboxylate group (electrostatic catalysis). The E-ring product is released.
3. The Asp 52 carboxylate group nucleophilically attacks the now electron-poor C1 of the D ring to form a covalent glycosyl-enzyme intermediate (covalent catalysis).
4. Water replaces the E-ring product in the active site.
5. Hydrolysis of the covalent bond with the assistance of Glu 35 (general base catalysis), which involves another oxonium ion transition state, regenerates the active site groups. The enzyme then releases the D-ring product, completing the catalytic cycle.

FIG. 11-20 The mechanism of the nonenzymatic acid-catalyzed hydrolysis of an acetal to a hemiacetal.

The reaction involves the protonation of one of the acetal's oxygen atoms followed by cleavage of its C—O bond to form an alcohol ($R''OH$) and a resonance-stabilized carbocation (oxonium ion). The addition of water to the oxonium ion forms the hemiacetal and regenerates the H^+ catalyst. Note that the oxonium ion's C, O, H, R, and R' atoms all lie in the same plane.

? Write the net equation for this reaction.

PROCESS DIAGRAM

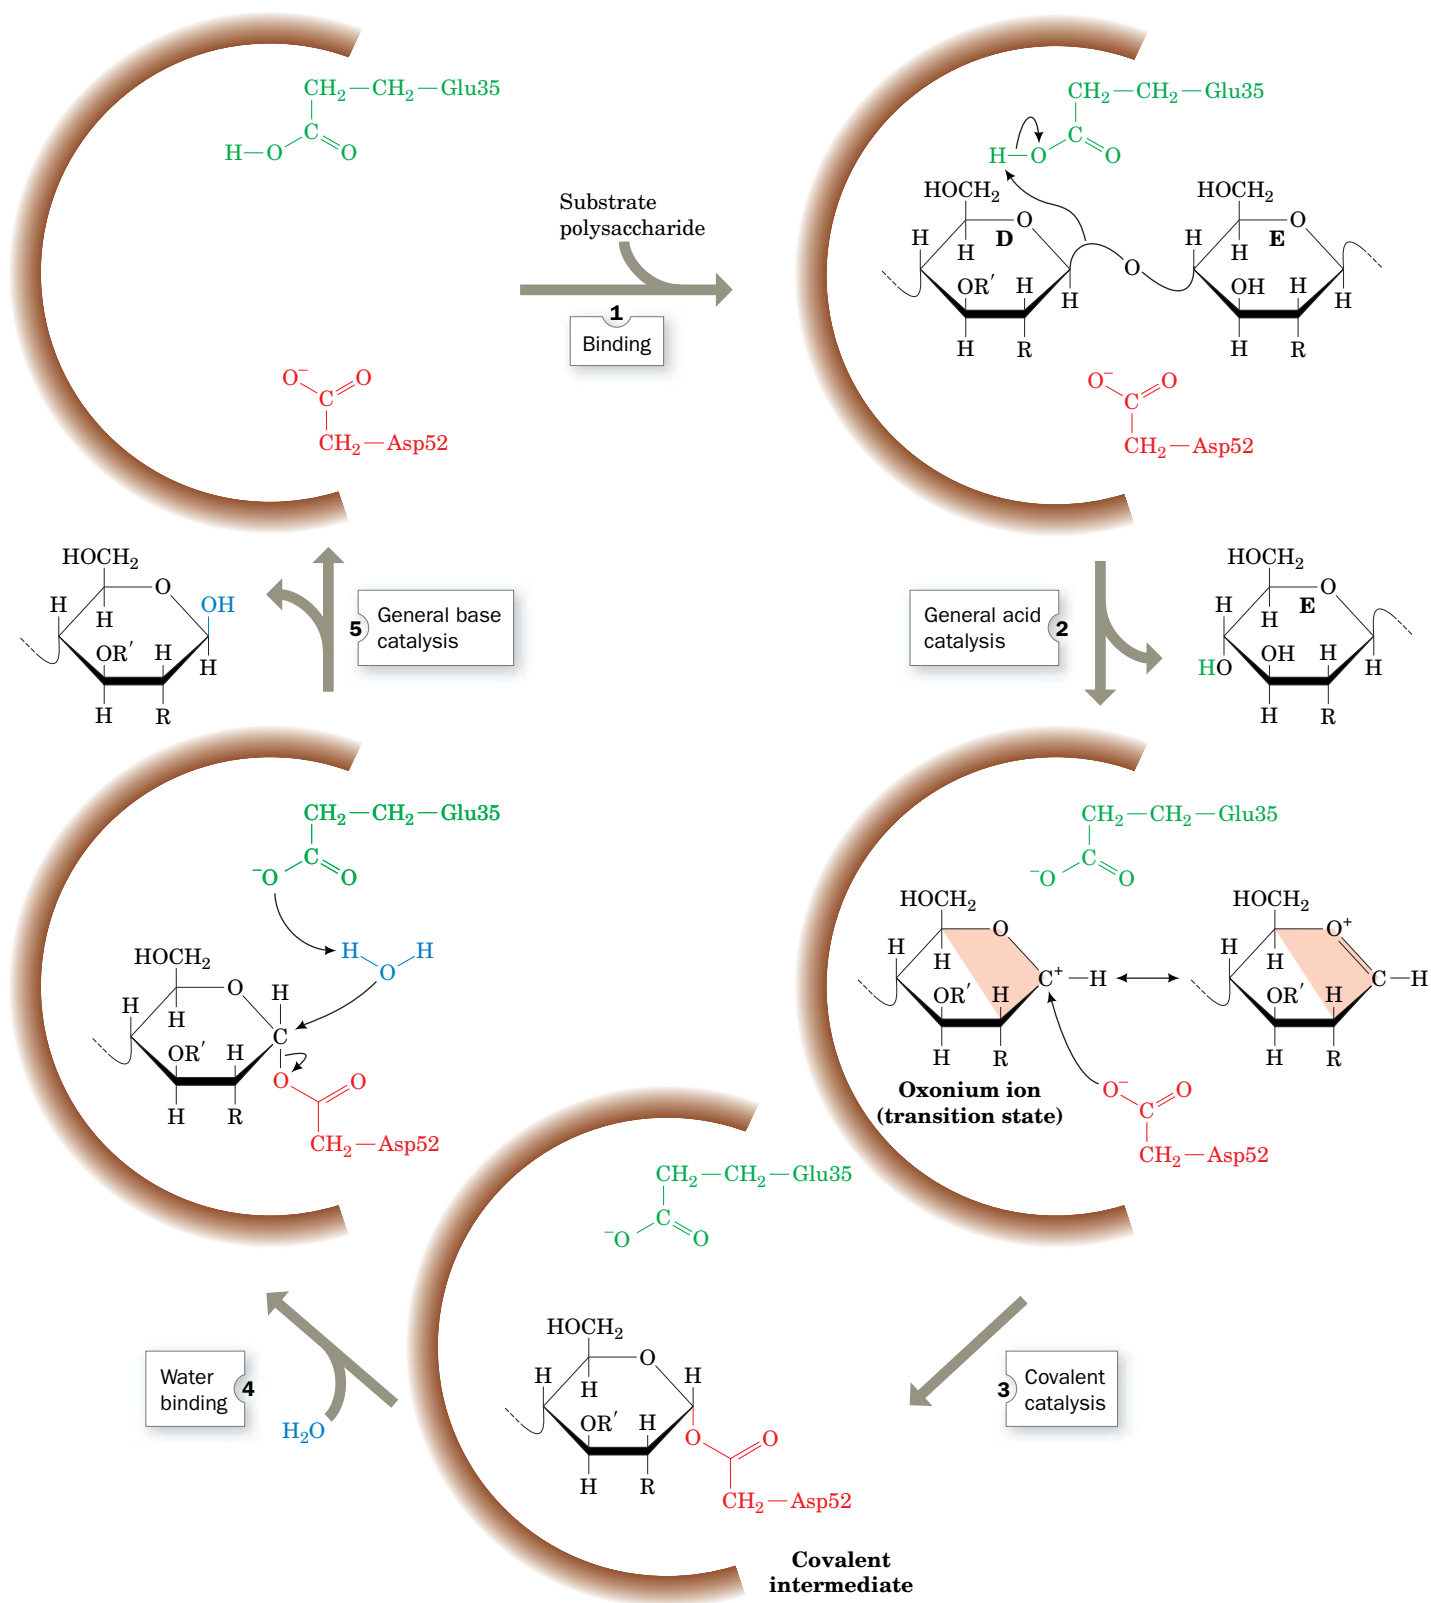

FIG. 11-21 The lysozyme reaction mechanism. Glu 35 acts as an acid catalyst, and Asp 52 acts as a covalent catalyst. Only the substrate D and E rings are shown. R represents the *N*-acetyl group at C2, and R' represents the CH_3CHCOO^- group at C3. The resonance-stabilized oxonium ion transition state requires that C1, C2, C5, and O5 be coplanar (*shading*), creating a half-chair conformation. Step 5 includes the participation of an oxonium ion transition state that is not shown. **WPLS** See the Animated Process Diagrams.

? Sketch a transition state diagram for this reaction.

FIG. 11-22 Transition state analog inhibition of lysozyme. The δ -lactone analog of (NAG)₄ (*top*) resembles the transition state of the lysozyme reaction (*bottom*). Note that atoms C1, C2, C5, and O5 in each structure are coplanar (as indicated by shading), consistent with the half-chair conformation of the hexose ring.

The double-displacement mechanism diagrammed in Fig. 11-21 allows the incoming water molecule to attach to the same face of the D residue as the E residue it replaces. Consequently, the configuration of the D residue is retained. A single-displacement reaction, in which water directly displaces the leaving group, would invert the configuration at C1 of the D ring between the substrate and product, a result that is not observed.

Experimental Evidence Supports the Role of Strain in the Lysozyme Mechanism.

Many of the structural and mechanistic investigations of lysozyme have focused on the catalytic role of strain. For example, the X-ray structure of lysozyme in complex with NAM—NAG—NAM shows that the trisaccharide binds, as predicted, to the B, C, and D subsites of lysozyme, *with the NAM in the D subsite distorted to the half-chair conformation*. This strained conformation is stabilized by a strong hydrogen bond between the D ring O6 and the backbone NH of Val 109 (as predicted by model building; Fig. 11-19). Indeed, the mutation of Val 109 to Pro, which lacks the NH group to make such a hydrogen bond, inactivates the enzyme.

As we have discussed in Section 11-3E, an enzyme that catalyzes a reaction by the preferential binding of its transition state has a greater binding affinity for an inhibitor that has the transition state geometry (a transition state analog) than it does for its substrate. The δ -lactone analog of (NAG)₄ (Fig. 11-22), which binds tightly to lysozyme, is a transition state analog of lysozyme since *this compound's lactone ring has the half-chair conformation that geometrically resembles the proposed oxonium ion transition state of the substrate's D ring*. X-Ray studies confirm that this inhibitor binds to lysozyme such that the lactone ring occupies the D subsite in a half-chair-like conformation.

Mass Spectrometry and X-Ray Crystallography Provide Support for Covalent Catalysis.

The existence of a covalent reaction intermediate was difficult to verify. The lifetime of a glucosyl oxonium ion in water is $\sim 10^{-12}$ s. For such a short-lived intermediate to be experimentally observed, its rate of formation must be made significantly greater than its rate of breakdown. To do this, Stephen Withers capitalized on three phenomena. First, if the reaction goes through an oxonium ion transition state, its formation should be slowed by the electron-withdrawing effects of substituting F (the most electronegative element) at C2 of the D ring. Second, mutating Glu 35 to Gln (E35Q) removes the general acid–base catalyst, further slowing all steps involving the oxonium ion transition state. Third, substituting an additional F atom at C1 of the D ring accelerates the formation of the intermediate because this F is a good leaving group without the need of general acid catalysis. Making all three of these changes should increase the rate of formation of the proposed covalent intermediate relative to its breakdown and hence should result in its accumulation. Withers therefore incubated E35Q HEW lysozyme with NAG- β (1 \rightarrow 4)-2-deoxy-2-fluoro- β -D-glucopyranosyl fluoride (NAG2FGlcF; *at left*). Electrospray ionization mass spectrometry (ESI-MS; Section 5-3D) of this reaction mixture revealed a sharp peak at 14,683 D, consistent with the formation of the proposed covalent intermediate [lysozyme has a molecular mass of 14,314 D and that of the NAG- β (1 \rightarrow 4)-2-deoxy-2-fluoro- β -D-glucopyranosyl group is 369 D].

CHECKPOINT

- Using lysozyme as an example, what can an enzyme's structure reveal about its catalytic mechanism?
- Why was an oxonium ion expected to be involved in the lysozyme reaction?
- Describe the experimental evidence that supports lysozyme's catalysis by acid–base catalysis, covalent catalysis, and transition state stabilization.

The X-ray structure of this covalent complex reveals an ~ 1.4 -Å-long covalent bond between C1 of the D ring and a side chain carboxyl O of Asp 52. This D ring adopts an undistorted chair conformation, thus indicating that it is a reaction intermediate rather than an approximation of the transition state. The superposition of this covalent complex with that of the above-described complex of NAM—NAG—NAM with wild-type HEW lysozyme reveals how this covalent bond forms (Fig. 11-23). The shortening of the 3.2-Å distance between the D ring C1 and the Asp 52 O in the NAM—NAG—NAM complex to ~ 1.4 Å in the covalent complex occurs as the D ring relaxes from the half-chair to the chair conformation and the Asp 52 side chain rotates $\sim 45^\circ$ about its C $_{\alpha}$ —C $_{\beta}$ bond.

FIG. 11-23 Position of the D ring during catalysis by lysozyme. The position of the substrate's C and D rings and the catalytic Asp 52 are shown in superimposed X-ray structures of the covalent complex between E35Q lysozyme and NAG2FGlcF (C green, N blue, O red, and F violet) and the noncovalent complex between lysozyme and a NAM—NAG—NAM substrate (C yellow, N blue, and O red). Note that the covalent bond between Asp 52 and C1 of the D ring forms when the D ring in the noncovalent complex relaxes from its distorted half-chair conformation to an undistorted chair conformation and the side chain of Asp 52 undergoes a 45° rotation about its C_α—C_β bond. [Based on X-ray structures by David Vocadlo and Stephen Withers, University of British Columbia, Vancouver, Canada; and Michael James, University of Alberta, Edmonton, Canada. PDBid 1H6M.]

5 Serine Proteases

KEY CONCEPTS

- The catalytically active Ser, His, and Asp residues of serine proteases were identified by chemical labeling and structural analysis.
- A binding pocket determines the substrate specificity of the various serine proteases.
- Serine proteases catalyze peptide bond hydrolysis via proximity and orientation effects, acid–base catalysis, covalent catalysis, electrostatic catalysis, and transition state stabilization.
- Zymogens are the inactive precursors of enzymes.

Our next example of enzymatic mechanisms is that of a diverse and widespread group of proteolytic enzymes known as **serine proteases**, so named because they have a common catalytic mechanism involving a peculiarly reactive Ser residue. The serine proteases include digestive enzymes from prokaryotes and eukaryotes, as well as more specialized proteins that participate in development, blood coagulation (clotting), inflammation, and numerous other processes. In this section, we focus on some of the best-studied serine proteases: chymotrypsin, trypsin, and elastase.

A Active Site Residues Were Identified by Chemical Labeling

Chymotrypsin, trypsin, and elastase are digestive enzymes that are synthesized by the pancreas and secreted into the duodenum (the small intestine's upper loop). All these enzymes catalyze the hydrolysis of peptide (amide) bonds but with different specificities for the side chains flanking the scissile (to be cleaved) peptide bond. Chymotrypsin is specific for a bulky hydrophobic residue preceding the scissile bond, trypsin is specific for a positively charged residue, and elastase is specific for a small neutral residue (Table 5-4). Together, they form a potent digestive team.

Chymotrypsin's catalytically important groups were identified by chemical labeling studies. A diagnostic test for the presence of the active site Ser of serine proteases is its reaction with **diisopropylphosphofluoridate (DIPF, at right)** which irreversibly inactivates the enzyme. Other Ser residues, including those on

Tosyl-L-lysine chloromethylketone

the same protein, do not react with DIPF. *DIPF reacts only with Ser 195 of chymotrypsin, thereby demonstrating that this residue is the enzyme's active site Ser.* This specificity makes DIPF and related compounds extremely toxic (Box 11-3).

A second catalytically important residue, His 57, was discovered through **affinity labeling**. In this technique, a substrate analog bearing a reactive group specifically binds at the enzyme's active site, where it reacts to form a stable covalent bond with a nearby susceptible group (these reactive substrate analogs have been dubbed the "Trojan horses" of biochemistry). The affinity labeled group(s) can subsequently be isolated and identified.

Chymotrypsin specifically binds **tosyl-L-phenylalanine chloromethylketone (TPCK)** because of its resemblance to a Phe residue (one of chymotrypsin's preferred substrate residues). Active site-bound TPCK's chloromethylketone group is a strong alkylating agent; it reacts only with His 57 (Fig. 11-24), thereby inactivating the enzyme. Trypsin, which prefers basic residues, is similarly inactivated by **tosyl-L-lysine chloromethylketone** (at left).

B X-Ray Structures Provide Information about Catalysis, Substrate Specificity, and Evolution

Chymotrypsin, trypsin, and elastase are strikingly similar: The primary structures of these ~240-residue enzymes are ~40% identical (for comparison, the α and β chains of human hemoglobin have 44% sequence identity). Furthermore, all these enzymes have a reactive Ser and a catalytically essential His. It therefore came as no surprise when their X-ray structures all proved to be closely related.

Box 11-3 Biochemistry in Health and Disease Nerve Poisons

The use of DIPF as an enzyme-inactivating agent came about through the discovery that organophosphorus compounds such as DIPF are potent nerve poisons. The neurotoxicity of DIPF arises from its ability to inactivate **acetylcholinesterase**, an enzyme that catalyzes the hydrolysis of **acetylcholine**:

The esterase activity of acetylcholinesterase, like that of chymotrypsin (Section 11-1B), requires a reactive Ser residue.

Acetylcholine is a **neurotransmitter**: It transmits nerve impulses across certain types of synapses (Section 9-4F). Acetylcholinesterase in the synapse normally degrades acetylcholine such that the nerve impulse has a duration of only a millisecond or so. The inactivation of acetylcholinesterase prevents hydrolysis of the neurotransmitter. As a result, the acetylcholine receptor, which is a Na^+-K^+ channel, remains open for longer than normal, thereby interfering with the regular sequence of nerve impulses. DIPF is so toxic to humans (death occurs through the inability to breathe) that it has been used militarily as a nerve gas. Related compounds, such as **parathion** and **malathion**, are useful insecticides because they are far more toxic to insects than to mammals.

Parathion

Malathion

Neurotoxins such as DIPF and **sarin** (which gained notoriety after its release by terrorists in a Tokyo subway in 1995)

Sarin

are inactivated by the enzyme **paraoxonase**. This enzyme occurs as two isoforms (one has Arg at position 192 and the other has Gln) with different activities, and individuals express widely differing levels of the enzyme. These factors may account for the large observed differences in individuals' sensitivity to nerve poisons.

FIG. 11-24 Reaction of TPCK with His 57 of chymotrypsin.

? Would the TPCK reaction with His occur more or less easily at a lower pH?

The structure of bovine chymotrypsin was elucidated in 1967 by David Blow. This was followed by the determination of the structures of bovine trypsin (**Fig. 11-25**) by Robert Stroud and Richard Dickerson, and porcine elastase by David Shotton and Herman Watson. Each of these proteins is folded into two domains, both of which have extensive regions of antiparallel β sheets in a

FIG. 11-25 X-Ray structure of bovine trypsin in covalent complex with its inhibitor leupeptin.

The protein is represented by its transparent molecular surface with its polypeptide chain in worm form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chains of the catalytic triad, Ser 195, His 57, and Asp 102, are drawn in ball-and-stick form colored according to atom type (C green, N blue, O red) with hydrogen bonds represented by dashed black lines. **Leupeptin** (acetyl-Leu-Leu-Arg in which the terminal carboxyl group is replaced by —CHO) is drawn in stick form (C cyan, N blue, O red) with its Arg side chain occupying the enzyme's specificity pocket (*magenta mesh*). L1 and L2 are surface loops that span the walls of the specificity pocket. [Based on an X-ray structure by Daniel Koshland, Jr., University of California at Berkeley. PDBid 2AGI.]

FIG. 11-26 The active site residues of chymotrypsin. The view is in approximately the same direction as in Fig. 11-25. Residues are drawn in ball-and-stick form with C green, N blue, and O red. The catalytic triad consists of Ser 195, His 57, and Asp 102. [Based on an X-ray structure by Daniel Koshland, Jr., University of California at Berkeley. PDBid 2AGL.]

? Add the appropriate H atoms to complete the structure.

FIG. 11-27 Specificity pockets of three serine proteases. The side chains of key residues that determine the size and nature of the specificity pocket are shown along with a representative substrate for each enzyme. Chymotrypsin prefers to cleave peptide bonds following large hydrophobic side chains; trypsin prefers Lys or Arg; and elastase prefers Ala, Gly, or Val. [After a drawing in Branden, C. and Tooze, J., *Introduction to Protein Structure* (2nd ed.), Garland Publishing, p. 213 (1999).]

barrel-like arrangement but contain little helix. For convenience in comparing the structures of these three enzymes, we will assign them the same residue numbering system—that of bovine **chymotrypsinogen**, the 245-residue precursor of chymotrypsin (Section 11-5D).

In all three structures, the catalytically essential His 57 and Ser 195 residues are located in the enzyme's substrate-binding site (center of Fig. 11-25). The X-ray structures also show that Asp 102, which is present in all serine proteases, is buried in a nearby solvent-inaccessible pocket. *These three invariant residues form a hydrogen-bonded constellation referred to as the **catalytic triad*** (Figs. 11-25 and 11-26).

Substrate Specificities Are Only Partially Rationalized. The X-ray structures of the above three enzymes suggest the basis for their differing substrate specificities (Fig. 11-27):

1. In chymotrypsin, the bulky aromatic side chain of the preferred Phe, Trp, or Tyr residue that contributes the carbonyl group of the scissile peptide fits snugly into a slitlike hydrophobic pocket located near the catalytic groups.
2. In trypsin, the residue corresponding to chymotrypsin Ser 189, which lies at the bottom of the binding pocket, is the anionic residue Asp. The cationic side chains of trypsin's preferred residues, Arg and Lys, can therefore form ion pairs with this Asp residue. The rest of chymotrypsin's specificity pocket is preserved in trypsin so that it can accommodate the bulky side chains of Arg and Lys (Fig. 11-25).
3. Elastase is so named because it rapidly hydrolyzes the otherwise nearly indigestible Ala, Gly, and Val-rich protein **elastin** (a major connective tissue component). Elastase's binding pocket is largely occluded by the side chains of Val and Thr residues that replace the Gly residues lining the specificity pockets in both chymotrypsin and trypsin. Consequently elastase, whose substrate-binding site is better described as merely a depression, specifically cleaves peptide bonds after small neutral residues, particularly Ala. In contrast, chymotrypsin and trypsin hydrolyze such peptide bonds extremely slowly because these small substrates cannot be sufficiently immobilized on the enzyme surface for efficient catalysis to occur.

Despite the foregoing, changing trypsin's Asp 189 to Ser by site-directed mutagenesis (Section 3-5D) does not switch its specificity to that of chymotrypsin

but instead yields a poor, nonspecific protease. Replacing additional residues in trypsin's specificity pocket with those of chymotrypsin fails to significantly increase this catalytic activity. However, trypsin is converted to a reasonably active chymotrypsin-like enzyme when two surface loops that connect the walls of the specificity pocket, L1 (residues 185–188) and L2 (residues 221–225), are also replaced by those of chymotrypsin. These loops, which are conserved in each enzyme, are apparently necessary not for substrate binding per se but for properly positioning the scissile bond. These results highlight an important caveat for genetic engineers: Enzymes are so exquisitely tailored to their functions that they often respond to mutagenic tinkering in unexpected ways.

🍷 Serine Proteases Exhibit Divergent and Convergent Evolution. We have seen that sequence and structural similarities among proteins reveal their evolutionary relationships (Sections 5-4 and 6-2D). *The great similarities among chymotrypsin, trypsin, and elastase indicate that these proteins arose through duplications of an ancestral serine protease gene followed by the divergent evolution of the resulting enzymes.* Indeed, the close structural resemblance of these pancreatic enzymes to certain bacterial proteases indicates that the primordial trypsin gene arose before the divergence of prokaryotes and eukaryotes.

There are several serine proteases whose primary and tertiary structures bear no discernible relationship to each other or to chymotrypsin. Nevertheless, these proteins also contain catalytic triads at their active sites whose structures closely resemble that of chymotrypsin. These enzymes include **subtilisin**, an endopeptidase that was originally isolated from *Bacillus subtilis*, and wheat germ **serine carboxypeptidase II**, an exopeptidase. Since the orders of the corresponding active site residues in the amino acid sequences of these serine proteases are quite different (**Fig. 11-28**), it seems highly improbable that they could have evolved from a common ancestor protein. These enzymes apparently constitute a

FIG. 11-28 Diagram indicating the relative positions of the active site residues of three unrelated serine proteases. The catalytic triads in subtilisin, chymotrypsin, and serine carboxypeptidase II each consist of Ser, His, and Asp residues. The peptide backbones of Ser 214, Trp 215, and Gly 216 in chymotrypsin, and their counterparts in subtilisin, participate in substrate-binding interactions. [After Robertus, J. D., Alden, R. A., Birktoft, J. J., Kraut, J., Powers, J. C., and Wilcox, P. E., *Biochemistry* **11**, 2449 (1972).]

remarkable example of **convergent evolution**: *Nature seems to have independently discovered the same catalytic mechanism several times.*

C Serine Proteases Use Several Catalytic Mechanisms

A catalytic mechanism based on considerable chemical and structural data has been formulated and is given here in terms of chymotrypsin (**Fig. 11-29**), although it applies to all serine proteases and certain other hydrolytic enzymes:

WileyPLUS Learning Space

See Guided Exploration

The catalytic mechanism of serine proteases

1. After chymotrypsin has bound a substrate, Ser 195 nucleophilically attacks the scissile peptide's carbonyl group to form the reaction's transition state (covalent catalysis), which for historical reasons, is also known as the **tetrahedral intermediate**. X-Ray studies indicate that Ser 195 is ideally positioned to carry out this nucleophilic attack (proximity and orientation effects). This nucleophilic attack involves transfer of a proton to the imidazole ring of His 57, thereby forming an imidazolium ion (general base catalysis). This process is aided by the polarizing effect of the unsolvated carboxylate ion of Asp 102, which is hydrogen bonded to His 57 (electrostatic catalysis). The tetrahedral intermediate has a well-defined, although transient, existence. We will see that *much of chymotrypsin's catalytic power derives from its preferential binding of this transition state (transition state binding catalysis)*.
2. The tetrahedral intermediate decomposes to the **acyl-enzyme intermediate** under the driving force of proton donation from N3 of His 57 (general acid catalysis) facilitated by the polarizing effect of Asp 102 on His 57 (electrostatic catalysis).
3. The amine leaving group ($R'NH_2$, the new N-terminal portion of the cleaved polypeptide chain) is released from the enzyme and replaced by water from the solvent.
4. The acyl-enzyme intermediate, which is highly susceptible to hydrolytic cleavage, adds water by the reversal of Step 2, yielding a second tetrahedral intermediate.
5. The reversal of Step 1 yields the carboxylate product (the new C-terminal portion of the cleaved polypeptide chain), which dissociates from the enzyme, thereby returning it to its initial state. In this process, water is the attacking nucleophile and Ser 195 is the leaving group.

Serine Proteases Preferentially Bind the Transition State. Detailed comparisons of the X-ray structures of several serine protease-inhibitor complexes have revealed a further structural basis for catalysis in these enzymes (**Fig. 11-30**):

1. The conformational rearrangement that occurs with the formation of the tetrahedral intermediate (the conversion of a trigonal sp^2 -hybridized C atom to its tetrahedral sp^3 -hybridized form) causes the now anionic carbonyl oxygen of the scissile peptide to move deeper into the active site so as to occupy a previously unoccupied position called the **oxyanion hole**.
2. There, it forms two hydrogen bonds with the enzyme that cannot form when the carbonyl group is in its normal trigonal conformation. The two enzymatic hydrogen bond donors were first noted by Joseph Kraut to occupy corresponding positions in chymotrypsin and subtilisin. He proposed the existence of the oxyanion hole on the basis of the premise that convergent evolution had made the active sites of these unrelated enzymes functionally identical.
3. The tetrahedral distortion, moreover, permits the formation of an otherwise unsatisfied hydrogen bond between the enzyme and the backbone NH group of the substrate residue preceding the scissile peptide bond.

PROCESS DIAGRAM

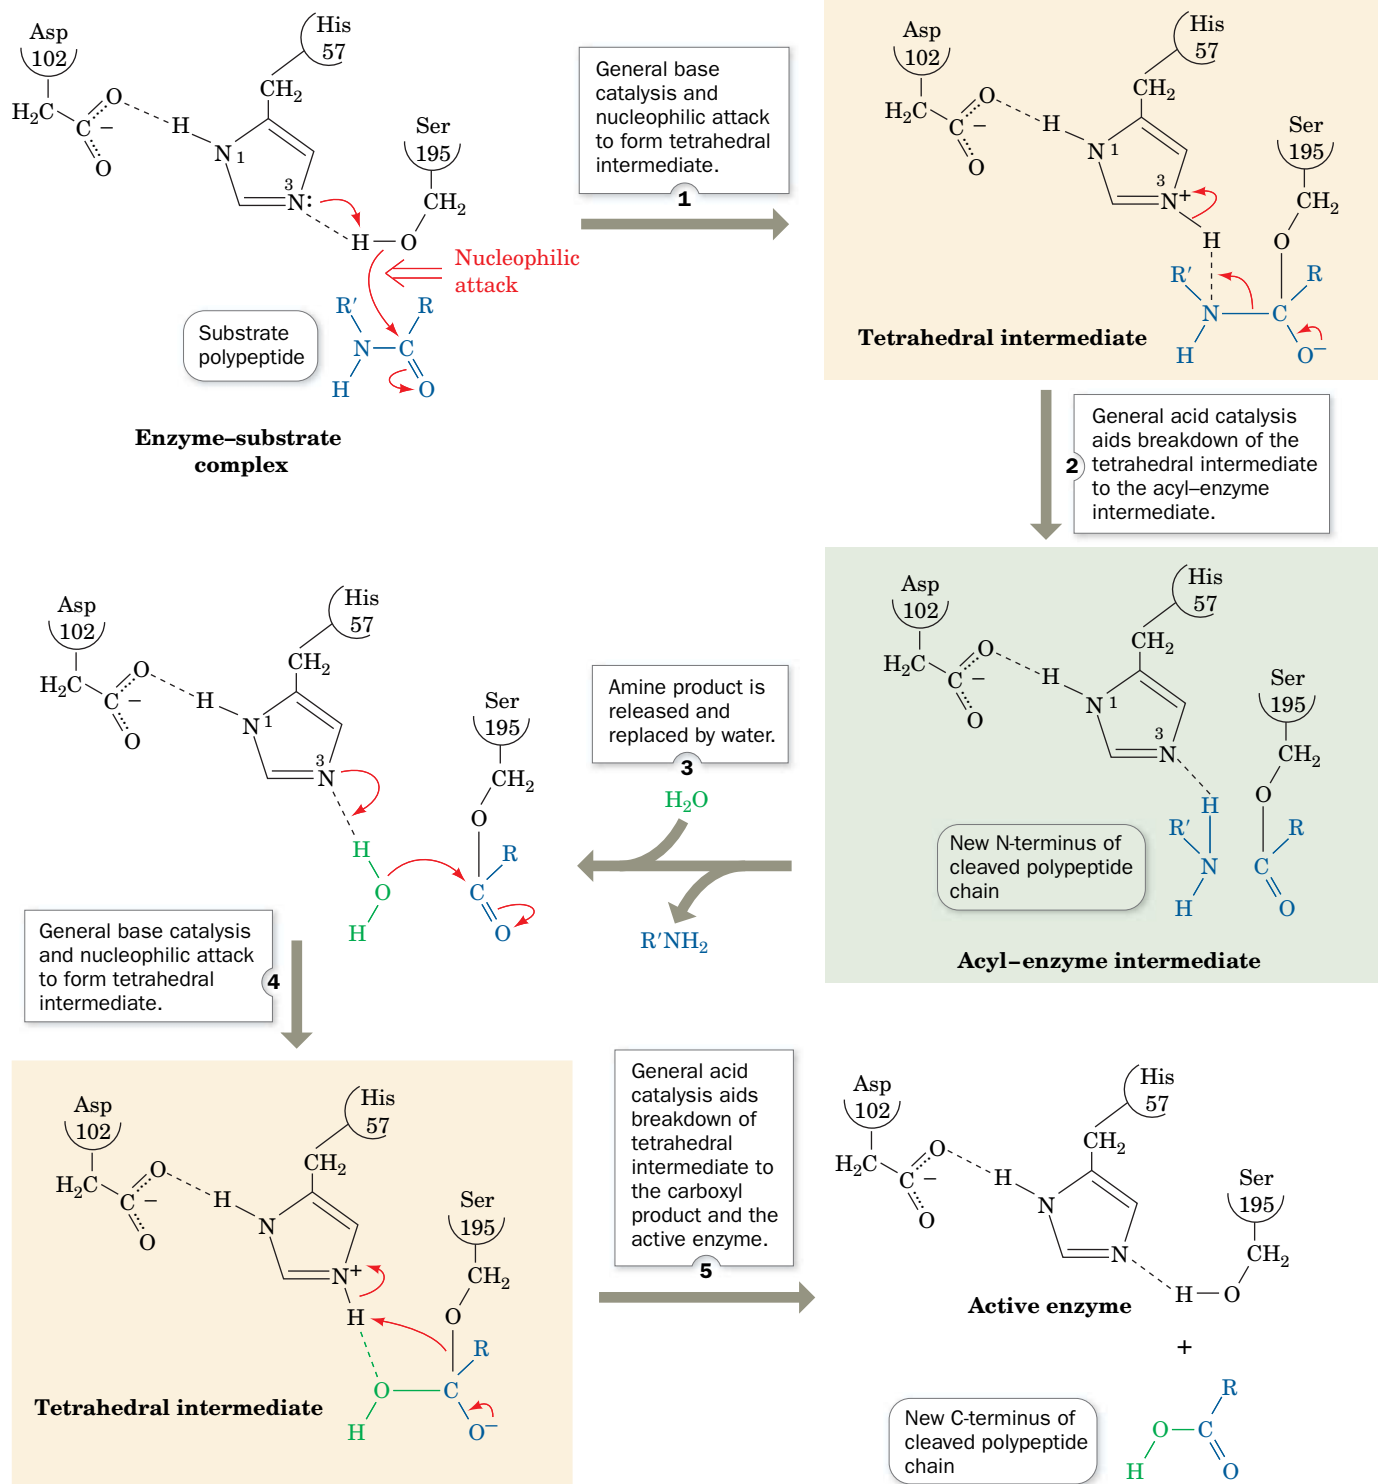

FIG. 11-29 The catalytic mechanism of the serine proteases. **WPLS** See the Animated Process Diagrams.

? Summarize the roles of Asp 102, His 57, and Ser 195 in this reaction mechanism.

FIG. 11-30 Transition state stabilization in the serine proteases. (a) When the substrate binds to the enzyme, the trigonal carbonyl carbon of the scissile peptide is conformationally constrained from binding in the oxyanion hole (*upper left*). (b) In the tetrahedral intermediate, the now charged carbonyl oxygen of the scissile peptide (the oxyanion) enters the oxyanion hole and hydrogen bonds to the backbone NH

groups of Gly 193 and Ser 195. The consequent conformational change permits the NH group of the substrate residue preceding the scissile peptide bond to form an otherwise unsatisfied hydrogen bond to Gly 193. Serine proteases therefore preferentially bind the transition state (tetrahedral intermediate). [After Robertus, J. D., Kraut, J., Alden, R. A., and Birktoft, J. J., *Biochemistry* **11**, 4302 (1972).]

? Add the DIP group to show how it acts as a transition state analog.

This preferential binding of the transition state (tetrahedral intermediate) over the enzyme–substrate complex or the acyl–enzyme intermediate is responsible for much of the catalytic efficiency of serine proteases. Thus, mutating any or all of the residues in chymotrypsin’s catalytic triad yields enzymes that still enhance proteolysis by $\sim 5 \times 10^4$ -fold over the uncatalyzed reaction (versus a rate enhancement of $\sim 10^{10}$ for the native enzyme). Similarly, the reason that DIPF is such an effective inhibitor of serine proteases is because its tetrahedral phosphate group makes this compound a transition state analog.

Low-Barrier Hydrogen Bonds May Stabilize the Transition State. The transition state of the chymotrypsin reaction is stabilized not just through the formation of additional hydrogen bonds in the oxyanion hole but possibly also by the formation of an unusually strong hydrogen bond. Proton transfers between hydrogen bonded groups ($D-H \cdots A$) occur at physiologically reasonable rates only when the pK of the proton donor is no more than 2 or 3 pH units greater than that of the protonated form of the proton acceptor. However, when the pK s of the hydrogen bonding donor (D) and acceptor (A) groups are nearly equal, the distinction between them breaks down: *The hydrogen atom becomes more or less equally shared between them ($D \cdots H \cdots A$).* Such **low-barrier hydrogen bonds (LBHBs)** are unusually short and strong. Their free energies of formation, as measured in the gas phase, are as high as -40 to $-80 \text{ kJ} \cdot \text{mol}^{-1}$ (versus -12 to $-30 \text{ kJ} \cdot \text{mol}^{-1}$ for normal hydrogen bonds) and they exhibit a $D \cdots A$ distance of $< 2.55 \text{ \AA}$ for $O-H \cdots O$ and $< 2.65 \text{ \AA}$ for $N-H \cdots O$ (versus 2.8 to 3.1 \AA for normal hydrogen bonds).

LBHBs are unlikely to exist in dilute aqueous solution because water molecules, which are excellent hydrogen bond donors and acceptors, effectively compete with $D-H$ and A for hydrogen bonding sites. However, LBHBs may exist in the nonaqueous active sites of enzymes. In fact, experimental evidence indicates that in the serine protease catalytic triad, the pK s of the protonated His and Asp are nearly equal, and the hydrogen bond between His and Asp has an unusually short $N \cdots O$ distance of 2.62 \AA with the H atom nearly centered between the N and O atoms. These findings are consistent with the formation of an LBHB in

the transition state. This suggests that the enzyme uses the “strategy” of converting a weak hydrogen bond in the initial enzyme-substrate complex to a strong hydrogen bond in the transition state, thereby facilitating proton transfer from Ser 195 to the otherwise far less basic His 57 (Fig. 11-29, Step 1), while applying the difference in the free energy between the normal and low-barrier hydrogen bonds to preferentially binding the transition state.

Although several studies have revealed the existence of unusually short hydrogen bonds in enzyme active sites, it is far more difficult to demonstrate experimentally that they are unusually strong, as LBHBs are predicted to be. In fact, several studies of the strengths of unusually short hydrogen bonds in organic model compounds in nonaqueous solutions suggest that these hydrogen bonds are not unusually strong. Consequently, a lively debate has ensued as to the catalytic significance of LBHBs. However, if enzymes do not form LBHBs, it remains to be explained how the conjugate base of an acidic group (e.g., Asp 102) partially abstracts a proton from a far more basic group (e.g., His 57), a feature of numerous enzyme mechanisms.

The Tetrahedral Intermediate Resembles the Complex of Trypsin with Trypsin Inhibitor. Perhaps the most convincing structural evidence for the existence of the tetrahedral intermediate was provided by Robert Huber in an X-ray study of the complex between **bovine pancreatic trypsin inhibitor (BPTI)** and trypsin. The 58-residue BPTI binds to the active site region of trypsin to form a complex with a tightly packed interface and a network of hydrogen-bonded cross-links. This interaction prevents any trypsin that is prematurely activated in the pancreas from digesting that organ (Section 11-5D). The complex’s 10^{13} M^{-1} association constant, among the largest of any known protein–protein interaction, emphasizes BPTI’s physiological importance.

The portion of BPTI in contact with the trypsin active site resembles bound substrate. A specific Lys side chain of BPTI occupies the trypsin specificity pocket (Fig. 11-31a), and the inhibitor’s Lys–Ala peptide bond is positioned as if it were the scissile peptide bond (Fig. 11-31b). What is most remarkable about the BPTI–trypsin complex is that its conformation is well along the reaction coordinate toward the tetrahedral intermediate: The side chain oxygen of trypsin

FIG. 11-31 The trypsin-BPTI complex. (a) The X-ray structure is shown as a cutaway model indicating how trypsin (*red*) binds BPTI (*green*). The green protrusion extending into the red cavity near the center of the figure represents the inhibitor’s Lys 15 side chain occupying trypsin’s specificity pocket. Note the close complementary fit of the two proteins. (b) Trypsin Ser 195 is in closer-than-van der Waals contact with the carbonyl carbon of BPTI’s scissile peptide (that between Lys 15I and Ala 16I), which is pyramidally distorted toward Ser 195. The normal proteolytic reaction is apparently arrested somewhere along the reaction coordinate preceding the tetrahedral intermediate.

Ser 195, the active Ser, is in closer-than-van der Waals contact (2.6 Å) with the pyramidally distorted carbonyl carbon of BPTI's "scissile" peptide. However, the proteolytic reaction cannot proceed past this point because of the rigidity of the complex and because it is so tightly sealed that the leaving group cannot leave and water cannot enter the reaction site.

Protease inhibitors are common in nature, where they have protective and regulatory functions. For example, certain plants release protease inhibitors in response to insect bites, thereby causing the offending insect to starve by inactivating its digestive enzymes. Protease inhibitors constitute ~10% of the blood plasma proteins. For instance, α_1 -proteinase inhibitor, which is secreted by the liver, inhibits **leukocyte elastase** (leukocytes are white blood cells; the action of leukocyte elastase is thought to be part of the inflammatory process). Pathological variants of α_1 -proteinase inhibitor with reduced activity are associated with **pulmonary emphysema**, a degenerative disease of the lungs resulting from the hydrolysis of its elastic fibers. Smokers also suffer from reduced activity of their α_1 -proteinase inhibitor because smoking oxidizes a required Met residue.

The Tetrahedral Intermediate Has Been Directly Observed. Because the tetrahedral intermediate is the transition state of the serine protease reaction, it is short-lived and unstable. However, a series of X-ray structures of porcine pancreatic elastase with a peptide substrate have revealed the progress of the reaction from the acyl-enzyme intermediate stage to the release of product. This second phase of the proteolysis reaction includes a tetrahedral intermediate (Fig. 11-29).

This acyl-enzyme complex, which is stable at pH 5.0, exhibits the expected structure, with the substrate's C-terminal Ile residue covalently linked via an ester bond to Ser 195 (Fig. 11-32a). In this first view of a serine

FIG. 11-32 Structure of the acyl-enzyme and tetrahedral intermediates.

Porcine pancreatic elastase was incubated with a heptapeptide substrate (YPFVEPI, using the one-letter code). Only residues 4–7 (VEPI) are visible. The protease residues are specified by the three-letter code. Atoms are colored according to type with elastase C green, substrate C cyan, N blue, O red, and S yellow. (a) At pH 5.0, a covalent bond (violet) links the Ser 195 O atom to the C-terminal (I7) C atom of the substrate. A water molecule (orange sphere) appears poised to nucleophilically attack the acyl-enzyme's carbonyl C atom. The dashed

lines represent catalytically important hydrogen bonds, and the dotted line indicates the trajectory that the water molecule presumably follows in nucleophilically attacking the acyl group's carbonyl C atom. (b) When the complex is brought to pH 9.0 and then rapidly frozen, the water molecule becomes a hydroxyl substituent (orange) to the carbonyl C atom, thereby yielding the tetrahedral intermediate. [Based on X-ray structures by Christopher Schofield and Janos Hadju, University of Oxford, U.K. PDBids (a) 1HAX and (b) 1HAZ.]

protease acyl–enzyme intermediate, the acyl group is fully planar, with no distortion toward a tetrahedral geometry. A water molecule is located near the intermediate’s ester bond, hydrogen-bonded to His 57, where it appears poised to nucleophilically attack the ester linkage. At pH 5.0, His 57 is protonated and acts as a hydrogen bond donor to water (it cannot function as a base catalyst at this pH).

To assess the next step of the reaction, the acyl–enzyme crystal was immersed in a solution of pH 9.0 (recall that protein crystals contain large solvent-filled spaces, so protons and other small substances can diffuse into and out of the crystallized enzyme’s active site; Section 6-2A). The resulting deprotonation of His 57 at pH 9.0 triggered the hydrolytic reaction (Step 4 of Fig. 11-29). After a period of 1 or 2 minutes, the crystals were frozen in liquid nitrogen to halt the reaction so that the X-ray structure of the enzyme complex could be determined. In this way, the tetrahedral intermediate was trapped and observed (Fig. 11-32b).

During formation of the tetrahedral intermediate, the oxyanion hole does not undergo any change in its structure, but the peptide substrate moves within its binding pocket and becomes distorted toward a tetrahedral geometry. The tetrahedral intermediate has the expected shape, similar to known transition state analog inhibitors. However, it does not bind so tightly to the amide group of the oxyanion hole (Fig. 11-30) that it would not be able to subsequently dissociate.

D Zymogens Are Inactive Enzyme Precursors

Proteolytic enzymes are usually biosynthesized as somewhat larger inactive precursors known as **zymogens** (enzyme precursors, in general, are known as **proenzymes**). In the case of digestive enzymes, the reason for this is clear: If these enzymes were synthesized in their active forms, they would digest the tissues that synthesized them. Indeed, **acute pancreatitis**, a painful and sometimes fatal condition that can be precipitated by pancreatic trauma, is characterized by the premature activation of the digestive enzymes synthesized by that organ.

The activation of **trypsinogen**, the zymogen of trypsin, occurs when trypsinogen enters the duodenum from the pancreas. **Enteropeptidase**, a serine protease whose secretion from the duodenal mucosa is under hormonal control, excises the N-terminal hexapeptide from trypsinogen by specifically cleaving its Lys 15–Ile 16 peptide bond (Fig. 11-33). Since this activating cleavage occurs at a trypsin-sensitive site (recall that trypsin cleaves after Arg and Lys residues), the small amount of trypsin produced by enteropeptidase also catalyzes trypsinogen activation, generating even more trypsin, etc. Thus, trypsinogen activation is said

FIG. 11-33 The activation of trypsinogen to trypsin. Proteolytic excision of the N-terminal hexapeptide is catalyzed by either enteropeptidase or trypsin. The chymotrypsinogen residue-numbering system is used here; that is, Val 10 is actually trypsinogen’s N-terminus and Ile 16 is trypsin’s N-terminus.

When a blood vessel is damaged, a clot forms as a result of the aggregation of platelets (small enucleated blood cells) and the formation of an insoluble **fibrin** network that traps additional blood cells.

Andrew Syred/Photo Researchers

Fibrin is produced from the soluble circulating protein **fibrinogen** through the action of the serine protease **thrombin**. Thrombin is the last in a series of coagulation enzymes that are sequentially activated by proteolysis of their zymogen forms. The overall process is known as the **coagulation cascade** (*opposite*), although experimental evidence shows that the pathway is not strictly linear, as the waterfall analogy might suggest.

The various components of the coagulation cascade, which include enzymes as well as nonenzymatic protein cofactors, are assigned Roman numerals, largely for historical reasons that do not reflect their order of action *in vivo*. The suffix *a* denotes an active factor. The catalytic domains of the coagulation proteases resemble trypsin in sequence and mechanism but are much more specific for their substrates. Additional domains mediate interactions with cofactors and help anchor the proteins to the platelet membrane, which serves as a stage for many of the coagulation reactions.

Coagulation is initiated when a membrane protein (**tissue factor**) exposed to the bloodstream by tissue damage forms a complex with

circulating **factor VII** or VIIa (factor VIIa is generated from factor VII by trace amounts of other coagulation proteases, including factor VIIa itself). The tissue factor–VIIa complex proteolytically converts the zymogen **factor X** to factor Xa. Factor Xa then converts **prothrombin** to thrombin, which subsequently cleaves fibrinogen to form fibrin. The tissue factor-dependent steps of coagulation are known as the **extrinsic pathway** because the source of tissue factor is extravascular. The extrinsic pathway is quickly damped through the action of a protein that inhibits factor VII once factor Xa has been generated.

Sustained thrombin activation requires the activity of the **intrinsic pathway** (so named because all its components are present in the circulation). The intrinsic pathway is stimulated by the tissue factor–VIIa complex, which converts **factor IX** to its active form, factor IXa. The ensuing thrombin activates a number of components of the intrinsic pathway, including **factor XI**, a protease that activates factor IX, to maintain coagulation in the absence of tissue factor or factor VIIa. Thrombin also activates **factors V** and **VIII**, which are cofactors rather than proteases. Factor Va promotes prothrombin activation by factor Xa by as much as 20,000-fold, and factor VIIIa promotes factor X activation by factor IXa by a similar amount. Thus, thrombin promotes its own activation through a feedback mechanism that amplifies the preceding steps of the cascade. **Factor XIII** is also activated by thrombin. Factor XIIIa, which is not a serine protease, chemically cross-links fibrin molecules through formation of peptide bonds between glutamate and lysine side chains, which forms a strong fibrin network.

The intrinsic pathway of coagulation can be triggered by exposure to negatively charged surfaces such as glass. Consequently, blood clots when it is collected in a clean glass test tube. In the absence of tissue factor, a fibrin clot may not appear for several minutes, but when tissue factor is present, a clot forms within a few seconds. This suggests that rapid blood clotting *in vivo* requires tissue factor as well as the proteins of the intrinsic pathway. Additional evidence for the importance of the extrinsic pathway is that individuals who are deficient in factor VII tend to bleed excessively. Abnormal bleeding also results from congenital defects in factor VIII (**hemophilia a**) or factor IX (**hemophilia b**).

to be **autocatalytic**. Chymotrypsinogen is then activated by trypsin-catalyzed cleavage of its Arg 15–Ile 16 peptide bond.

Proelastase, the zymogen of elastase, is activated by a single tryptic cleavage that excises a short N-terminal peptide. Trypsin also activates pancreatic **procarboxypeptidases A** and **B** and **prophospholipase A₂** (Section 9-1C). The autocatalytic nature of trypsinogen activation and the fact that trypsin activates other hydrolytic enzymes makes it essential that trypsinogen not be activated in the pancreas. We have seen that the all-but-irreversible binding of trypsin inhibitors such as BPTI to trypsin is a defense against trypsinogen's inappropriate activation.

Sequential proenzyme activation makes it possible to quickly generate large quantities of active enzymes in response to diverse physiological signals. For example, the serine proteases that lead to blood clotting are synthesized as zymogens by the liver and circulate until they are activated by injury to a blood vessel (Box 11-4).

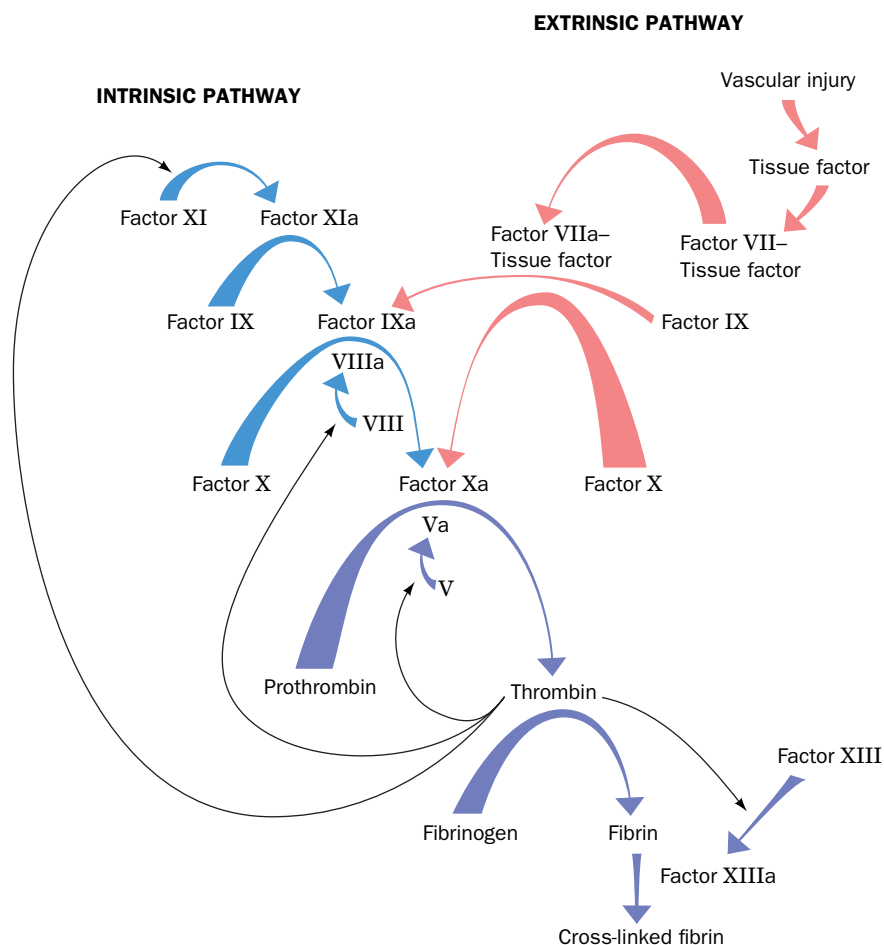

The sequential activation of zymogens in the coagulation cascade leads to a burst of thrombin activity, since trace amounts of factors VIIa, IXa, and Xa can activate much larger amounts of their respective substrates. The potential for amplification in the coagulation cascade is reflected in the plasma concentrations of the coagulation proteins (see table).

Plasma Concentrations of Some Human Coagulation Factors

Factor	Concentration (μM) ^a
XI	0.06
IX	0.09
VII	0.01
X	0.18
Prothrombin	1.39
Fibrinogen	8.82

^aConcentrations calculated from data in High, K.A. and Roberts, H.R. (Eds.), *Molecular Basis of Thrombosis and Hemostasis*, Marcel Dekker (1995).

Perhaps not surprisingly, thrombin eventually triggers mechanisms that shut down clot formation, thereby limiting the duration of the clotting process and hence the extent of the clot. Such control of clotting is of extreme physiological importance since the formation of even one inappropriate blood clot within an individual's lifetime may have fatal consequences.

[Figure adapted from David, E.W., *Thromb. Haemost.* **74**, 2 (1995).]

Zymogens Have Distorted Active Sites. Since the zymogens of trypsin, chymotrypsin, and elastase have all their catalytic residues, why aren't they enzymatically active? Comparisons of the X-ray structures of trypsinogen with that of trypsin, and of chymotrypsinogen with that of chymotrypsin, show that on activation, the newly liberated N-terminal Ile 16 residue moves from the surface of the protein to an internal position, where its free cationic amino group forms an ion pair with the invariant anionic Asp 194, which is close to the catalytic triad (Fig. 11-26). Without this conformational change, the enzyme cannot properly bind its substrate or stabilize the tetrahedral intermediate because its specificity pocket and oxyanion hole are improperly formed. This provides further structural evidence favoring the role of preferential transition state binding in the catalytic mechanism of serine proteases. Nevertheless, because their catalytic triads are structurally intact, the zymogens of serine proteases actually have low levels of enzymatic activity, an observation that was made only after the above structural comparisons suggested that this might be the case.

CHECKPOINT

- What are some ways that active site residues can be identified?
- Summarize the roles of the residues that make up the catalytic triad of serine proteases.
- Which catalytic mechanism contributes the most to rate acceleration?
- Explain the function of the oxyanion hole.
- What role do low-barrier hydrogen bonds play in serine protease catalysis?
- What does bovine trypsin inhibitor reveal about trypsin's catalytic mechanism?
- What are the advantages of synthesizing proteases as zymogens?

5. On the free energy diagram shown, label the intermediate(s) and transition state(s). Is the reaction thermodynamically favorable?

6. Draw a transition state diagram of (a) a nonenzymatic reaction and the corresponding enzyme-catalyzed reaction in which (b) S binds loosely to the enzyme and (c) S binds very tightly to the enzyme. Compare ΔG^\ddagger for each case. Why is tight binding of S not advantageous?

7. Approximately how much does staphylococcal nuclease (Table 11-1) decrease the activation free energy ΔG^\ddagger of its reaction (the hydrolysis of a phosphodiester bond) at 25°C?

8. Calculate the rate enhancement that could be accomplished by an enzyme forming one low-barrier hydrogen bond with its transition state at 25°C.

9. Explain why enzyme activity varies with temperature, as shown here.

10. The covalent catalytic mechanism of an enzyme depends on a single active site Cys whose pK is 8. A mutation in a nearby residue alters the microenvironment so that this pK increases to 10. Would the mutation cause the reaction rate to increase or decrease? Explain.

11. Studies at different pH's show that an enzyme has two catalytically important residues whose pK s are ~ 4 and ~ 10 . Chemical modification experiments indicate that a Glu and a Lys residue are essential for activity. Match the residues to their pK s and explain whether they are likely to act as acid or base catalysts.

12. Explain why RNase A cannot catalyze the hydrolysis of DNA.

13. Urease, the first enzyme to be crystallized, is inhibited in the presence of Hg, Cd, or Co ions. What does this information suggest about the catalytic mechanism of urease?

14. Wolfenden has stated that it is meaningless to distinguish between the "binding sites" and the "catalytic sites" of enzymes. Explain.

15. Explain why lysozyme cleaves the artificial substrate $(NAG)_4$ ~ 4000 times more slowly than it cleaves $(NAG)_6$.

16. Would you expect lysozyme to hydrolyze cellulose? Why or why not?

17. Design a chloromethylketone inhibitor of elastase.

18. Predict the effect of mutating Asp 102 of trypsin to Asn (a) on substrate binding and (b) on catalysis.

19. Diagram the hydrogen-bonding interactions of the catalytic triad His–Lys–Ser during catalysis in a hypothetical hydrolytic enzyme.

20. The comparison of the active site geometries of chymotrypsin and subtilisin under the assumption that their similarities have catalytic significance has led to greater mechanistic understanding of both these enzymes. Discuss the validity of this strategy.

CHALLENGE QUESTIONS

21. Using the reaction shown in Box 11-1 (the attack of an amine on the carbonyl group of a ketone) as a starting point, draw curved arrows to represent the base-catalyzed reaction (when the group —B: is present).

22. Using the reaction shown in Box 11-1 (the attack of an amine on the carbonyl group of a ketone) as a starting point, draw curved arrows to represent the acid-catalyzed reaction (when the group —A—H is present).

23. What feature of RNA would allow it to function as a ribozyme? Why are there no naturally occurring DNA enzymes?

24. Suggest a transition state analog for proline racemase that differs from those discussed in the text. Justify your suggestion.

25. Lysozyme residues Asp 101 and Arg 114 are required for efficient catalysis, although they are located at some distance from the active site Glu 35 and Asp 52. Substituting Ala for either Asp 101 or Arg 114 does not significantly alter the enzyme's tertiary structure, but it significantly reduces its catalytic activity. Explain.

26. Predict the effect on lysozyme's activity of mutating Glu 35 to Asp and Asp 52 to Glu.

27. Under certain conditions, peptide bond formation rather than peptide bond hydrolysis is thermodynamically favorable. Would you expect chymotrypsin to catalyze peptide bond formation? Explain.

28. Why is the broad substrate specificity of chymotrypsin advantageous *in vivo*? Why would this be a disadvantage for some other proteases?

29. Tofu (bean curd), a high-protein soybean product, is prepared in such a way as to remove the trypsin inhibitor present in soybeans. Explain the reason(s) for this treatment.

30. Many of the cell's hydrolytic enzymes are located in the lysosome, where the pH is ~ 5 . What would you expect to be the optimum pH for these enzymes, and why would this protect the rest of the cell from the destructive power of these enzymes upon the accidental rupture of a lysosome?

31. A genetic defect in coagulation factor IX causes hemophilia b, a disease characterized by a tendency to bleed profusely after very minor trauma. However, a genetic defect in coagulation factor XI has only mild clinical symptoms. Explain this discrepancy in terms of the mechanism for activation of coagulation proteases shown in Box 11-4.

32. Hemophiliacs who lack factor IX are sometimes given infusions of factor VII to restore normal blood clotting activity. Explain.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Introduction to Enzyme Informatics

Exercise 2 Evolution and Structures of Serine Proteases

Exercise 3 Interactions in the Serine Protease Active Site

Case 11 Nonenzymatic Deamidation of Asparagine and Glutamine Residues in Proteins

Focus concept: Factors influencing nonenzymatic hydrolytic deamidation of Asn and Gln residues in proteins are examined and possible mechanisms for the reactions are proposed.

Prerequisites: Chapters 5 and 11

- Protein analytical methods, particularly isoelectric focusing
- Enzyme mechanisms, especially proteases such as papain and chymotrypsin

Atorvastatin (Lipitor®), one of the most commonly prescribed drugs, binds to and inhibits the activity of the enzyme HMG-CoA reductase in a way that can be quantified through enzyme kinetics.

Early enzymologists, often working with crude preparations of yeast or liver cells, could do little more than observe the conversion of substrates to products catalyzed by as yet unpurified enzymes. Measuring the rates of such reactions therefore came to be a powerful tool for characterizing enzyme activity. The application of simple mathematical models to enzyme activity under varying laboratory conditions, and in the presence of competing substrates or enzyme inhibitors, made it possible to deduce the probable physiological functions and regulatory mechanisms of various enzymes.

The study of enzymatic reaction rates, or **enzyme kinetics**, is no less important now than it was early in the twentieth century. In many cases, the rate of a reaction and how the rate changes in response to different conditions reveal the path followed by the reactants and are therefore indicative of the reaction mechanism. Kinetic data, combined with detailed information about an enzyme's structure and its catalytic mechanisms, provide some of the most powerful clues to the enzyme's biological function and may suggest ways to modify it for therapeutic purposes.

We begin our consideration of enzyme kinetics by reviewing chemical kinetics. Following that, we derive the basic equations of enzyme kinetics and describe the effects of inhibitors on enzymes. We also consider some examples of enzyme control that highlight several aspects of enzyme function. Finally, we describe some practical applications of enzyme inhibition, the development of enzyme inhibitors as drugs.

CHAPTER 12

Enzyme Kinetics, Inhibition, and Control

Chapter Contents

1 Reaction Kinetics

- A Chemical Kinetics Is Described by Rate Equations
- B Enzyme Kinetics Often Follows the Michaelis–Menten Equation
- C Kinetic Data Can Provide Values of V_{\max} and K_M
- D Bisubstrate Reactions Follow One of Several Rate Equations

2 Enzyme Inhibition

- A Competitive Inhibition Involves Inhibitor Binding at an Enzyme's Substrate Binding Site
- B Uncompetitive Inhibition Involves Inhibitor Binding to the Enzyme–Substrate Complex
- C Mixed Inhibition Involves Inhibitor Binding to Both the Free Enzyme and the Enzyme–Substrate Complex

3 Control of Enzyme Activity

- A Allosteric Control Involves Binding at a Site Other than the Active Site
- B Control by Covalent Modification Usually Involves Protein Phosphorylation

4 Drug Design

- A Drug Discovery Employs a Variety of Techniques
- B A Drug's Bioavailability Depends on How It Is Absorbed and Transported in the Body
- C Clinical Trials Test for Efficacy and Safety
- D Cytochromes P450 Are Often Implicated in Adverse Drug Reactions

1 Reaction Kinetics

KEY CONCEPTS

- Simple rate equations describe the progress of first-order and second-order reactions.
- The Michaelis–Menten equation relates the initial velocity of a reaction to the maximal reaction velocity and the Michaelis constant for a particular enzyme and substrate.
- An enzyme's overall catalytic efficiency is expressed as k_{cat}/K_M .
- A Lineweaver–Burk plot can be used to present kinetic data and to calculate values for K_M and V_{max} .
- Bisubstrate reactions can occur by an Ordered or Random sequential mechanism or by a Ping Pong mechanism.

Kinetic measurements of enzymatically catalyzed reactions are among the most powerful techniques for elucidating the catalytic mechanisms of enzymes. Enzyme kinetics is a branch of chemical kinetics, so we begin this section by reviewing the principles of chemical kinetics.

A Chemical Kinetics Is Described by Rate Equations

A reaction of overall stoichiometry

where A represents reactants and P represents products, may actually occur through a sequence of **elementary reactions** (simple molecular processes) such as

Here, I_1 and I_2 symbolize **intermediates** in the reaction. Each elementary reaction can be characterized with respect to the number of reacting species and the rate at which they interact. *Descriptions of each elementary reaction collectively constitute the mechanistic description of the overall reaction process.* Even a complicated enzyme-catalyzed reaction can be analyzed in terms of its component elementary reactions.

Reaction Order Indicates the Number of Molecules Participating in an Elementary Reaction. At constant temperature, *the rate of an elementary reaction is proportional to the frequency with which the reacting molecules come together.* The proportionality constant is known as a **rate constant** and is symbolized k . For the elementary reaction $A \rightarrow P$, the instantaneous rate of appearance of product or disappearance of reactant, which is called the **velocity (v)** of the reaction, is

$$v = \frac{d[P]}{dt} = -\frac{d[A]}{dt} = k[A] \quad [12-1]$$

In other words, the reaction velocity at any time point is proportional to the concentration of the reactant A. This is an example of a **first-order reaction**. Since the velocity has units of molar per second ($M \cdot s^{-1}$), the first-order rate constant must have units of reciprocal seconds (s^{-1}). *The reaction order of an elementary reaction corresponds to the molecularity of the reaction, which is the number of molecules that must simultaneously collide to generate a product.* Thus, a first-order elementary reaction is a **unimolecular** reaction.

Consider the elementary reaction $2A \rightarrow P$. This **bimolecular** reaction is a **second-order reaction**, and its instantaneous velocity is described by

$$v = -\frac{d[A]}{dt} = k[A]^2 \quad [12-2]$$

In this case, the reaction velocity is proportional to the square of the concentration of A, and the second-order rate constant k has units of $\text{M}^{-1} \cdot \text{s}^{-1}$.

The bimolecular reaction $\text{A} + \text{B} \rightarrow \text{P}$ is also a second-order reaction with an instantaneous velocity described by

$$v = -\frac{d[\text{A}]}{dt} = -\frac{d[\text{B}]}{dt} = k[\text{A}][\text{B}] \quad [12-3]$$

Here, the reaction is said to be first order in [A] and first order in [B] (see Sample Calculation 12-1). Unimolecular and bimolecular reactions are common. **Termolecular** reactions are unusual because the simultaneous collision of three molecules is a rare event. Fourth- and higher-order reactions are unknown.

A Rate Equation Indicates the Progress of a Reaction as a Function of Time. A **rate equation** can be derived from the equations that describe the instantaneous reaction velocity. Thus, a first-order rate equation is obtained by rearranging Eq. 12-1

$$\frac{d[\text{A}]}{[\text{A}]} = d \ln[\text{A}] = -k dt \quad [12-4]$$

and integrating it from $[\text{A}]_0$, the initial concentration of A, to [A], the concentration of A at time t :

$$\int_{[\text{A}]_0}^{[\text{A}]} d \ln[\text{A}] = -k \int_0^t dt \quad [12-5]$$

This results in

$$\ln[\text{A}] = \ln[\text{A}]_0 - kt \quad [12-6]$$

or, taking the antilog of both sides,

$$[\text{A}] = [\text{A}]_0 e^{-kt} \quad [12-7]$$

Equation 12-6 is a linear equation of the form $y = mx + b$ and can be plotted as in **Fig. 12-1**. Therefore, if a reaction is first order, a plot of $\ln[\text{A}]$ versus t will yield a straight line whose slope is $-k$ (the negative of the first-order rate constant) and whose intercept on the $\ln[\text{A}]$ axis is $\ln[\text{A}]_0$.

One of the hallmarks of a first-order reaction is that *the time for half of the reactant initially present to decompose, its **half-time** or **half-life**, $t_{1/2}$, is a constant and hence independent of the initial concentration of the reactant.* This is easily demonstrated by substituting the relationship $[\text{A}] = [\text{A}]_0/2$ when $t = t_{1/2}$ into Eq. 12-6 and rearranging:

$$\ln\left(\frac{[\text{A}]_0/2}{[\text{A}]_0}\right) = -kt_{1/2} \quad [12-8]$$

Thus

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \quad [12-9]$$

Substances that are inherently unstable, such as radioactive nuclei, decompose through first-order reactions (see Sample Calculation 12-2).

In a second-order reaction with one type of reactant, $2\text{A} \rightarrow \text{P}$, the variation of [A] with time is quite different from that in a first-order reaction. Rearranging Eq. 12-2 and integrating it over the same limits used for the first-order reaction yields

$$\int_{[\text{A}]_0}^{[\text{A}]} -\frac{d[\text{A}]}{[\text{A}]^2} = k \int_0^t dt \quad [12-10]$$

SAMPLE CALCULATION 12-1

Determine the velocity of the elementary reaction $\text{X} + \text{Y} \rightarrow \text{Z}$ when the sample contains $3 \mu\text{M}$ X and $5 \mu\text{M}$ Y and k for the reaction is $400 \text{ M}^{-1} \cdot \text{s}^{-1}$.

Use Equation 12-3 and make sure that all units are consistent:

$$\begin{aligned} v &= k[\text{X}][\text{Y}] \\ &= (400 \text{ M}^{-1} \cdot \text{s}^{-1})(3 \mu\text{M})(5 \mu\text{M}) \\ &= (400 \text{ M}^{-1} \cdot \text{s}^{-1})(3 \times 10^{-6} \text{ M}) \\ &\quad (5 \times 10^{-6} \text{ M}) \\ &= 6 \times 10^{-9} \text{ M} \cdot \text{s}^{-1} \\ &= 6 \text{ nM} \cdot \text{s}^{-1} \end{aligned}$$

WPLS See Sample Calculation Videos.

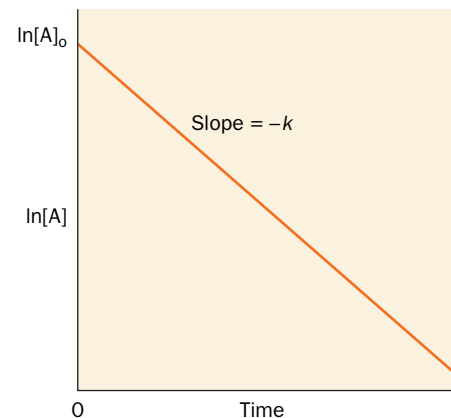

FIG. 12-1 A plot of a first-order rate equation. The slope of the line obtained when $\ln[\text{A}]$ is plotted against time gives the rate constant k .

SAMPLE CALCULATION 12-2

The decay of a hypothetical radioisotope has a rate constant of 0.01 s^{-1} . How much time is required for half of a 1-g sample of the isotope to decay?

The units of the rate constant indicate a first-order process. Thus, the half-life is independent of concentration. The half-life of the isotope (the half-time for its decay) is given by Eq. 12-9:

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{0.01 \text{ s}^{-1}} = 69.3 \text{ s}$$

WPLS See Sample Calculation Videos.

so that

$$\frac{1}{[A]} = \frac{1}{[A]_0} + kt \quad [12-11]$$

Equation 12-11 is a linear equation in terms of the variables $1/[A]$ and t . *The half-time for a second-order reaction is expressed $t_{1/2} = 1/k[A]_0$ and therefore, in contrast to a first-order reaction, depends on the initial reactant concentration.* Equations 12-6 and 12-11 may be used to distinguish a first-order from a second-order reaction by plotting $\ln[A]$ versus t and $1/[A]$ versus t and observing which, if any, of these plots is linear.

To experimentally determine the rate constant for the second-order reaction $A + B \rightarrow P$, it is often convenient to increase the concentration of one reactant relative to the other, for example, $[B] \gg [A]$. Under these conditions, $[B]$ does not change significantly over the course of the reaction. The reaction rate therefore depends only on $[A]$, the concentration of the reactant that is present in limited amounts. Hence, the reaction appears to be first order with respect to A and is therefore said to be a **pseudo-first-order reaction**. The reaction is first order with respect to B when $[A] \gg [B]$.

B Enzyme Kinetics Often Follows the Michaelis–Menten Equation

WileyPLUS Learning Space

See Guided Exploration

Michaelis–Menten kinetics, Lineweaver–Burk plots, and enzyme inhibition

Enzymes catalyze a tremendous variety of reactions using different combinations of five basic catalytic mechanisms (Section 11-3). Some enzymes act on only a single substrate molecule; others act on two or more different substrate molecules whose order of binding may or may not be obligatory. Some enzymes form covalently bound intermediate complexes with their substrates; others do not. *Yet all enzymes can be analyzed such that their reaction rates as well as their overall efficiency can be quantified.*

The study of enzyme kinetics began in 1902 when Adrian Brown investigated the rate of hydrolysis of sucrose by the yeast enzyme **β -fructofuranosidase**:

Brown found that when the sucrose concentration is much higher than that of the enzyme, the reaction rate becomes independent of the sucrose concentration; that is, the rate is **zeroth order** with respect to sucrose. He therefore proposed that the overall reaction is composed of two elementary reactions in which the substrate forms a complex with the enzyme that subsequently decomposes to products, regenerating enzyme:

Here E, S, ES, and P symbolize the enzyme, substrate, **enzyme–substrate complex**, and products, respectively. According to this model, when the substrate concentration becomes high enough to entirely convert the enzyme to the ES form, the second step of the reaction becomes rate limiting and the overall reaction rate becomes insensitive to further increases in substrate concentration.

Each of the elementary reactions that make up the above enzymatic reaction is characterized by a rate constant: k_1 and k_{-1} are the forward and reverse rate constants for formation of the ES complex (the first reaction), and k_2 is the rate constant for the decomposition of ES to P and E (the second reaction). Here we assume, for the sake of mathematical simplicity, that the second reaction is irreversible; that is, no P is converted back to S.

The Michaelis–Menten Equation Assumes that ES Maintains a Steady State.

The Michaelis–Menten equation describes the rate of the enzymatic reaction represented by Eq. 12-12 as a function of substrate concentration. In this kinetic scheme, the formation of product from ES is a first-order process. Thus, the rate of formation of product can be expressed as the product of the rate constant of the

reaction yielding product and the concentration of its immediately preceding intermediate. The general expression for the velocity (rate) of Reaction 12-12 is therefore

$$v = \frac{d[P]}{dt} = k_2[ES] \quad [12-13]$$

The overall rate of production of ES is the difference between the rates of the elementary reactions leading to its appearance and those resulting in its disappearance:

$$\frac{d[ES]}{dt} = k_1[E][S] - k_{-1}[ES] - k_2[ES] \quad [12-14]$$

This equation cannot be explicitly integrated, however, without simplifying assumptions. Two possibilities are

1. **Assumption of equilibrium.** In 1913, Leonor Michaelis and Maud Menten, building on the work of Victor Henri, assumed that $k_{-1} \gg k_2$, so that the first step of the reaction reaches equilibrium:

$$K_S = \frac{k_{-1}}{k_1} = \frac{[E][S]}{[ES]} \quad [12-15]$$

Here K_S is the dissociation constant of the first step in the enzymatic reaction. With this assumption, Eq. 12-14 can be integrated. Although this assumption is often not correct, in recognition of the importance of this pioneering work, the enzyme–substrate complex, ES, is known as the **Michaelis complex**.

2. **Assumption of steady state.** Figure 12-2 illustrates the progress curves of the various participants in Reaction 12-12 under the physiologically common condition that substrate is in great excess over enzyme ($[S] \gg [E]$). With the exception of the initial stage of the reaction, which is usually over within milliseconds of mixing E and S, $[ES]$ remains approximately constant until the substrate is nearly exhausted. Hence, the rate of synthesis of ES must equal its rate of consumption over most of the course of the reaction. In other words, ES maintains a **steady state** and $[ES]$ can be treated as having a constant value:

$$\frac{d[ES]}{dt} = 0 \quad [12-16]$$

FIG. 12-2 The progress curves for a simple enzyme-catalyzed reaction. With the exception of the initial phase of the reaction (before the darker block), the slopes of the progress curves for $[E]$ and $[ES]$ are essentially zero as long as $[S] \gg [E]$ (within the darker block). [After Segel, I.H., *Enzyme Kinetics*, p. 27, Wiley (1993).] **WPLS** See the Animated Figures.

? Describe what is happening at the far left and far right—that is, before and after the steady state.

J.B.S. Haldane (1892–1964) John Burdon Sanderson Haldane, the son of a prominent physiologist, was a gifted scientist and writer whose major contributions include the application of mathematics to areas of biology such as genetics and enzyme kinetics. As a scientist as well as a philosopher, he was aware of developments in relativity theory and quantum mechanics and was influenced by a

practical philosophy that the natural world obeyed the laws of logic and arithmetic.

When Haldane published his book *Enzymes* in 1930, the idea that enzymes are proteins, rather than small catalysts surrounded by an amorphous protein “colloid,” was still controversial. However, even in the absence of structural information, scientists such as Leonor Michaelis and Maud Menten had already applied the principles of thermodynamics to derive some basic equations related to enzyme kinetics. Michaelis and Menten proposed in 1913 that during a reaction, an enzyme and its substrate are in equilibrium with a complex of enzyme and substrate. In 1925, Haldane argued that this was not strictly true, since some enzyme–substrate complex does not dissociate to free enzyme and substrate but instead goes on to form product. When the enzyme and substrate are first mixed together, the concentration of the enzyme–substrate complex increases, but after a time the concentration of the complex levels off because the complex is constantly forming and breaking down to generate product. This

principle, the so-called steady state assumption, underlies modern theories of enzyme activity.

Even without knowing what enzymes were made of, Haldane showed great insight in proposing that an enzyme could catalyze a reaction by bringing its substrates into a strained or out-of-equilibrium arrangement. This idea refined Emil Fischer’s earlier lock-and-key simile (and was later elaborated further by Linus Pauling). Haldane’s idea of strain was not fully appreciated until around 1970, after the X-ray structures of several enzymes, including lysozyme and chymotrypsin (Chapter 11), had been examined.

In addition to his work in enzymology, Haldane articulated the role of genes in heredity and formulated mathematical estimates of mutation rates—many years before the nature of genes or the structure of DNA were known. However, in addition to being a theorist, Haldane was an experimentalist who frequently performed unpleasant or dangerous experiments on himself. For example, he ingested sodium bicarbonate and ammonium chloride in order to investigate their effect on breathing rate. Beyond the laboratory, Haldane was well known for his efforts to popularize science. In *Daedalus; or, Science and the Future*, Haldane commented on the status of various branches of science circa 1924 and speculated about future developments. His thoughts and his persona are believed to have inspired various plots and characters in other writers’ works of science fiction.

Briggs, G.E. and Haldane, J.B.S., A note on the kinetics of enzyme action, *Biochem. J.* **19**, 339 (1925).

This so-called **steady state assumption**, a more general condition than that of equilibrium, was first proposed in 1925 by George E. Briggs and John B.S. Haldane (Box 12-1). Note that *a reaction that achieves a steady state is not at equilibrium*: [S] and [P] are rapidly changing throughout the interval that [ES] and [E] are essentially constant.

To be useful, kinetic expressions for overall reactions must be formulated in terms of experimentally measurable quantities. The quantities [ES] and [E] are not, in general, directly measurable, but the total enzyme concentration

$$[E]_T = [E] + [ES] \quad [12-17]$$

is usually readily determined. The rate equation for the overall enzymatic reaction as a function of [S] and [E] can then be derived. First, Eq. 12-14 is combined with the steady state assumption (Eq. 12-16) to give

$$k_1[E][S] = k_{-1}[ES] + k_2[ES] \quad [12-18]$$

Letting $[E] = [E]_T - [ES]$ and rearranging yields

$$\frac{([E]_T - [ES])[S]}{[ES]} = \frac{k_{-1} + k_2}{k_1} \quad [12-19]$$

The **Michaelis constant**, K_M , is defined as

$$K_M = \frac{k_{-1} + k_2}{k_1} \quad [12-20]$$

so Eq. 12-19 can then be rearranged to give

$$K_M[ES] = ([E]_T - [ES])[S] \quad [12-21]$$

Solving for [ES],

$$[\text{ES}] = \frac{[\text{E}]_{\text{T}}[\text{S}]}{K_M + [\text{S}]} \quad [12-22]$$

The expression for the **initial velocity** (v_o) of the reaction, the velocity (Eq. 12-13) at $t = 0$, thereby becomes

$$v_o = \left(\frac{d[\text{P}]}{dt} \right)_{t=0} = k_2[\text{ES}] = \frac{k_2[\text{E}]_{\text{T}}[\text{S}]}{K_M + [\text{S}]} \quad [12-23]$$

Both $[\text{E}]_{\text{T}}$ and $[\text{S}]$ are experimentally measurable quantities. To meet the conditions of the steady state assumption, the concentration of the substrate must be much greater than the concentration of the enzyme, which allows each enzyme molecule to repeatedly bind a molecule of substrate and convert it to product, so that $[\text{ES}]$ is constant. The use of the initial velocity (operationally taken as the velocity measured before more than $\sim 10\%$ of the substrate has been converted to product)—rather than just the velocity—minimizes such complicating factors as the effects of reversible reactions, inhibition of the enzyme by its product(s), and progressive inactivation of the enzyme. (This is also why the rate of the reverse reaction in Eq. 12-12 can be assumed to be zero.)

The **maximal velocity** of a reaction, V_{max} , occurs at high substrate concentrations when the enzyme is **saturated**, that is, when it is entirely in the ES form:

$$V_{\text{max}} = k_2[\text{E}]_{\text{T}} \quad [12-24]$$

Therefore, combining Eqs. 12-23 and 12-24, we obtain

$$v_o = \frac{V_{\text{max}}[\text{S}]}{K_M + [\text{S}]} \quad [12-25]$$

This expression, the **Michaelis–Menten equation**, is the basic equation of enzyme kinetics. It describes a rectangular hyperbola such as that plotted in Fig. 12-3. The saturation function for oxygen binding to myoglobin (Eq. 7-6) has the same algebraic form.

The Michaelis Constant Has a Simple Operational Definition. At the substrate concentration at which $[\text{S}] = K_M$, Eq. 12-25 yields $v_o = V_{\text{max}}/2$ so that K_M is the

FIG. 12-3 A plot of the initial velocity v_o of a simple enzymatic reaction versus the substrate concentration $[\text{S}]$. Points are plotted in $0.5K_M$ intervals of substrate concentration between $0.5K_M$ and $5K_M$. **WPLS** See the Animated Figures.

? Compare the curve shown here to the oxygen saturation curve for myoglobin (Fig. 7-4).

TABLE 12-1 The Values of K_M , k_{cat} , and k_{cat}/K_M for Some Enzymes and Substrates

Enzyme	Substrate	K_M (M)	k_{cat} (s^{-1})	k_{cat}/K_M ($\text{M}^{-1} \cdot \text{s}^{-1}$)
Acetylcholinesterase	Acetylcholine	9.5×10^{-5}	1.4×10^4	1.5×10^8
Carbonic anhydrase	CO_2	1.2×10^{-2}	1.0×10^6	8.3×10^7
	HCO_3^-	2.6×10^{-2}	4.0×10^5	1.5×10^7
Catalase	H_2O_2	2.5×10^{-2}	1.0×10^7	4.0×10^8
Chymotrypsin	<i>N</i> -Acetylglycine ethyl ester	4.4×10^{-1}	5.1×10^{-2}	1.2×10^{-1}
	<i>N</i> -Acetylvaline ethyl ester	8.8×10^{-2}	1.7×10^{-1}	1.9
	<i>N</i> -Acetyltyrosine ethyl ester	6.6×10^{-4}	1.9×10^2	2.9×10^5
Fumarase	Fumarate	5.0×10^{-6}	8.0×10^2	1.6×10^8
	Malate	2.5×10^{-5}	9.0×10^2	3.6×10^7
Urease	Urea	2.5×10^{-2}	1.0×10^4	4.0×10^5

substrate concentration at which the reaction velocity is half-maximal. Therefore, if an enzyme has a small value of K_M , it achieves maximal catalytic efficiency at low substrate concentrations. Keep in mind that when $[\text{S}] \ll K_M$, the reaction rate varies linearly with $[\text{S}]$ ($v_o = V_{\text{max}}[\text{S}]/K_M$), whereas when $[\text{S}] \gg K_M$, the enzyme is saturated ($v_o = V_{\text{max}}$).

The K_M is unique for each enzyme–substrate pair: Different substrates that react with a given enzyme do so with different K_M values. Likewise, different enzymes that act on the same substrate have different K_M values. The magnitude of K_M varies widely with the identity of the enzyme and the nature of the substrate (Table 12-1). It is also a function of temperature and pH. The Michaelis constant (Eq. 12-20) can be expressed as

$$K_M = \frac{k_{-1}}{k_1} + \frac{k_2}{k_1} = K_S + \frac{k_2}{k_1} \quad [12-26]$$

Since K_S is the dissociation constant of the Michaelis complex (Eq. 12-15), as K_S decreases, the enzyme's affinity for substrate increases. K_M is therefore also a measure of the affinity of the enzyme for its substrate, provided k_2/k_1 is small compared to K_S , that is, $k_2 < k_{-1}$ so that the $\text{ES} \rightarrow \text{P}$ reaction proceeds more slowly than ES reverts to $\text{E} + \text{S}$.

k_{cat}/K_M Is a Measure of Catalytic Efficiency. We can define the **catalytic constant**, k_{cat} , of an enzyme as

$$k_{\text{cat}} = \frac{V_{\text{max}}}{[\text{E}]_T} \quad [12-27]$$

This quantity is also known as the **turnover number** of an enzyme because it is the number of reaction processes (turnovers) that each active site catalyzes per unit time. The turnover numbers for a selection of enzymes are given in Table 12-1. Note that these quantities vary by over nine orders of magnitude. Equation 12-24 indicates that for a simple system, such as the Michaelis–Menten model reaction (Eq. 12-12), $k_{\text{cat}} = k_2$. For enzymes with more complicated mechanisms (e.g., multiple substrates or multiple reaction intermediates), k_{cat} may be a function of several rate constants. Note that whereas k_{cat} is a constant, V_{max} depends on the concentration of the enzyme present in the experimental system. V_{max} increases as $[\text{E}]_T$ increases.

When $[\text{S}] \ll K_M$, very little ES is formed. Consequently, $[\text{E}] \approx [\text{E}]_T$, so Eq. 12-23 reduces to a second-order rate equation:

$$v_o = \left(\frac{k_2}{K_M} \right) [\text{E}]_T [\text{S}] \approx \left(\frac{k_{\text{cat}}}{K_M} \right) [\text{E}] [\text{S}] \quad [12-28]$$

Box 12-2 Perspectives in Biochemistry Kinetics and Transition State Theory

How is the rate of a reaction related to its activation energy (Section 11-2)? Consider a bimolecular reaction that proceeds along the following pathway:

where X^\ddagger represents the transition state. The rate of the reaction can be expressed as

$$\frac{d[P]}{dt} = k[A][B] = k'[X^\ddagger] \quad [12-A]$$

where k is the ordinary rate constant of the elementary reaction and k' is the rate constant for the decomposition of X^\ddagger to products.

Although X^\ddagger is unstable, it is assumed to be in rapid equilibrium with the reactants; that is,

$$K^\ddagger = \frac{[X^\ddagger]}{[A][B]} \quad [12-B]$$

where K^\ddagger is an equilibrium constant. This central assumption of transition state theory permits the powerful formalism of thermodynamics to be applied to the theory of reaction rates.

Since K^\ddagger is an equilibrium constant, it can be expressed as

$$-RT \ln K^\ddagger = \Delta G^\ddagger \quad [12-C]$$

where T is the absolute temperature and R ($8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$) is the gas constant (this relationship between equilibrium constants and free energy is derived in Section 1-3D). Combining the three preceding equations yields

$$\frac{d[P]}{dt} = k' e^{-\Delta G^\ddagger/RT} [A][B] \quad [12-D]$$

This equation indicates that the rate of a reaction not only depends on the concentrations of its reactants, but also decreases exponentially with ΔG^\ddagger . Thus, *the larger the difference between the free energy of the transition state and that of the reactants (the free energy of activation), that is, the less stable the transition state, the slower the reaction proceeds.*

We must now evaluate k' , the rate at which X^\ddagger decomposes. The transition state structure is held together by a bond that is assumed to be so weak that it flies apart during its first vibrational excursion. Therefore, k' is expressed

$$k' = \kappa \nu \quad [12-E]$$

where ν is the vibrational frequency of the bond that breaks as X^\ddagger decomposes to products, and κ , the **transmission coefficient**, is the probability that the breakdown of X^\ddagger will be in the direction of product formation rather than back to reactants. For most spontaneous reactions, κ is assumed to be 1.0 (although this number, which must be between 0 and 1, can rarely be calculated with confidence).

Planck's law states that

$$\nu = \epsilon/h \quad [12-F]$$

where, in this case, ϵ is the average energy of the vibration that leads to the decomposition of X^\ddagger , and h ($6.6261 \times 10^{-34} \text{ J} \cdot \text{s}$) is **Planck's constant**. Statistical mechanics tells us that at a temperature T , the classical energy of an oscillator is

$$\epsilon = k_B T \quad [12-G]$$

where k_B ($1.3807 \times 10^{-23} \text{ J} \cdot \text{K}^{-1}$) is the **Boltzmann constant** and $k_B T$ is essentially the available thermal energy. Combining Eqs. 12-E through 12-G gives

$$k' = \frac{k_B T}{h} \quad [12-H]$$

Thus, combining Eqs. 12-A, 12-D, and 12-H yields the expression for the rate constant of the elementary reaction:

$$k = \frac{k_B T}{h} e^{-\Delta G^\ddagger/RT} \quad [12-I]$$

This equation indicates that as the temperature rises, so that there is increased thermal energy available to drive the reacting complex over the activation barrier (ΔG^\ddagger), the reaction speeds up.

Here, k_{cat}/K_M is the apparent second-order rate constant of the enzymatic reaction; the rate of the reaction varies directly with how often enzyme and substrate encounter one another in solution. *The quantity k_{cat}/K_M is therefore a measure of an enzyme's catalytic efficiency.*

There is an upper limit to the value of k_{cat}/K_M : It can be no greater than k_1 ; that is, the decomposition of ES to E + P can occur no more frequently than E and S come together to form ES. The most efficient enzymes have k_{cat}/K_M values near the **diffusion-controlled limit** of 10^8 to $10^9 \text{ M}^{-1} \cdot \text{s}^{-1}$. These enzymes catalyze a reaction almost every time they encounter a substrate molecule and hence have achieved a state of virtual catalytic perfection. The relationship between the catalytic rate and the thermodynamics of the transition state can now be appreciated (Box 12-2).

C Kinetic Data Can Provide Values of V_{max} and K_M

There are several methods for determining the values of the parameters of the Michaelis–Menten equation (i.e., V_{max} and K_M). At very high values of [S], the

SAMPLE CALCULATION 12-3

An enzyme-catalyzed reaction has a K_M of 1 mM and a V_{\max} of $5 \text{ nM} \cdot \text{s}^{-1}$. What is the reaction velocity when the substrate concentration is (a) 0.25 mM, (b) 1.5 mM, or (c) 10 mM?

Use the Michaelis–Menten equation (Eq. 12-25):

$$\begin{aligned} \text{(a) } v_o &= \frac{(5 \text{ nM} \cdot \text{s}^{-1})(0.25 \text{ mM})}{(1 \text{ mM}) + (0.25 \text{ mM})} \\ &= \frac{1.25}{1.25} \text{ nM} \cdot \text{s}^{-1} \\ &= 1 \text{ nM} \cdot \text{s}^{-1} \end{aligned}$$

$$\begin{aligned} \text{(b) } v_o &= \frac{(5 \text{ nM} \cdot \text{s}^{-1})(1.5 \text{ mM})}{(1 \text{ mM}) + (1.5 \text{ mM})} \\ &= \frac{7.5}{2.5} \text{ nM} \cdot \text{s}^{-1} \\ &= 3 \text{ nM} \cdot \text{s}^{-1} \end{aligned}$$

$$\begin{aligned} \text{(c) } v_o &= \frac{(5 \text{ nM} \cdot \text{s}^{-1})(10 \text{ mM})}{(1 \text{ mM}) + (10 \text{ mM})} \\ &= \frac{50}{11} \text{ nM} \cdot \text{s}^{-1} \\ &= 4.5 \text{ nM} \cdot \text{s}^{-1} \end{aligned}$$

Note: When units in the numerator and denominator cancel, it is unnecessary to convert them to standard units before performing the calculation.

WPLS See Sample Calculation Videos.

initial velocity, v_o , asymptotically approaches V_{\max} (see Sample Calculation 12-3). In practice, however, it is very difficult to assess V_{\max} accurately from direct plots of v_o versus $[S]$ such as Fig. 12-3, because, even at substrate concentrations as high as $[S] = 10 K_M$, Eq. 12-25 indicates that v_o is only 91% of V_{\max} , so that the value of V_{\max} will almost certainly be underestimated.

A better method for determining the values of V_{\max} and K_M , which was formulated by Hans Lineweaver and Dean Burk, uses the reciprocal of the Michaelis–Menten equation (Eq. 12-25):

$$\frac{1}{v_o} = \left(\frac{K_M}{V_{\max}} \right) \frac{1}{[S]} + \frac{1}{V_{\max}} \quad [12-29]$$

This is a linear equation in $1/v_o$ and $1/[S]$. If these quantities are plotted to obtain the so-called **Lineweaver–Burk** or **double-reciprocal plot**, the slope of the line is K_M/V_{\max} , the $1/v_o$ intercept is $1/V_{\max}$, and the extrapolated $1/[S]$ intercept is $-1/K_M$ (Fig. 12-4 and Sample Calculation 12-4).

SAMPLE CALCULATION 12-4

Determine K_M and V_{\max} for an enzyme from the following data using Eq. 12-29:

[S] (mM)	v_o ($\mu\text{M} \cdot \text{s}^{-1}$)
1	2.5
2	4.0
5	6.3
10	7.6
20	9.0

First, convert the data to reciprocal form ($1/[S]$ in units of mM^{-1} , and $1/v_o$ in units of $\mu\text{M}^{-1} \cdot \text{s}$). Next, make a plot of $1/v_o$ versus $1/[S]$. The x - and y -intercepts can be estimated by extrapolation of the straight line or can be calculated by linear regression. According to Eq. 12-29 and Fig. 12-4, the y -intercept, which has a value of $\sim 0.1 \mu\text{M}^{-1} \cdot \text{s}$, is equivalent to $1/V_{\max}$, so V_{\max} (the reciprocal of the y -intercept) is $10 \mu\text{M} \cdot \text{s}^{-1}$. The x -intercept, -0.33 mM^{-1} , is equivalent to $-1/K_M$, so K_M (the negative reciprocal of the x -intercept) is equal to 3.0 mM.

WPLS See Sample Calculation Videos.

FIG. 12-4 A double-reciprocal (Lineweaver–Burk) plot. The error bars represent $\pm 0.05 V_{\max}$. The indicated points are the same as those in Fig. 12-3. Note the large effect of small errors at small $[S]$ (large $1/[S]$) and the crowding together of points at large $[S]$. **WPLS** See the Animated Figures.

? Which would provide a more reliable K_M value: collecting more data points at high $[S]$ or at low $[S]$?

As can be seen in Fig. 12-3, the best estimates of kinetic parameters are obtained by collecting data over a range of $[S]$ from $\sim 0.5 K_M$ to $\sim 5 K_M$. Thus, a disadvantage of the Lineweaver–Burk plots is that most experimental measurements of $[S]$ are crowded onto the left side of the graph (Fig. 12-4). Moreover, for small values of $[S]$, small errors in v_o lead to large errors in $1/v_o$ and hence to large errors in K_M and V_{\max} .

Several other types of plots, each with its advantages and disadvantages, can also be used to determine K_M and V_{\max} from kinetic data. However, kinetic data are now commonly analyzed by computer using mathematically sophisticated statistical treatments. Nevertheless, Lineweaver–Burk plots are still valuable for the visual presentation of kinetic data.

Steady State Kinetics Cannot Unambiguously Establish a Reaction Mechanism. Although steady state kinetics provides valuable information about the rates of buildup and breakdown of ES, it provides little insight as to the nature of ES. Thus, an enzymatic reaction may, in reality, pass through several more or less stable intermediate states, such as

or take a more complex path, such as

Unfortunately, steady state kinetic measurements are incapable of revealing the number of intermediates in an enzyme-catalyzed reaction. Thus, such measurements of a multistep reaction can be likened to a “black box” containing a system of water pipes with one inlet and one drain:

At steady state—that is, after the pipes have filled with water—the relationship between input pressure and output flow can be measured. However, such measurements yield no information concerning the detailed construction of the plumbing connecting the inlet to the drain. This would require additional information, such as opening the box and tracing the pipes. Likewise, steady state kinetic measurements can provide a phenomenological description of enzymatic behavior, but the nature of the intermediates remains indeterminate. The existence of intermediates must be verified independently, for example, by identifying them through the use of spectroscopic techniques.

The foregoing highlights a central principle of enzymology: *The steady state kinetic analysis of a reaction cannot unambiguously establish its mechanism.* This is because no matter how simple, elegant, or rational a postulated mechanism, there are an infinite number of alternative mechanisms that can also account

for the kinetic data. Usually, it is the simpler mechanism that turns out to be correct, but this is not always the case. However, *if kinetic data are not compatible with a given mechanism, then that mechanism must be rejected*. Therefore, although kinetics cannot be used to establish a mechanism unambiguously without confirming data, such as the physical demonstration of an intermediate's existence, the steady state kinetic analysis of a reaction is of great value because it can be used to eliminate proposed mechanisms.

D Bisubstrate Reactions Follow One of Several Rate Equations

We have heretofore been concerned with simple, single-substrate reactions that obey the Michaelis–Menten model (Eq. 12-12). Yet, enzymatic reactions requiring multiple substrates and yielding multiple products are far more common. Indeed, those involving two substrates and yielding two products

account for ~60% of known biochemical reactions. Almost all of these so-called **bisubstrate reactions** are either transfer reactions in which the enzyme catalyzes the transfer of a specific functional group, X, from one of the substrates to the other:

or oxidation–reduction reactions in which reducing equivalents are transferred between the two substrates. For example, the hydrolysis of a peptide bond by trypsin (Section 11-5) is the transfer of the peptide carbonyl group from the peptide nitrogen atom to water (Fig. 12-5a), whereas in the alcohol dehydrogenase reaction (Section 11-1B), a hydride ion is formally transferred from ethanol to NAD⁺ (Fig. 12-5b). Although bisubstrate reactions could, in principle, occur through a vast variety of mechanisms, only a few types are commonly observed.

Sequential Reactions Occur via Single Displacements. *Reactions in which all substrates must combine with the enzyme before a reaction can occur and products be released are known as **sequential reactions***. In such reactions, the group being transferred, X, is directly passed from A (= P–X) to B, yielding P and Q (= B–X). Hence, such reactions are also called **single-displacement reactions**.

Sequential reactions can be subclassified into those with a compulsory order of substrate addition to the enzyme, which are said to have an **Ordered mechanism**, and those with no preference for the order of substrate addition, which are described as having a **Random mechanism**. In the Ordered mechanism, the binding of the first substrate is apparently required for the enzyme to form the binding site for the second substrate, whereas in the Random mechanism, both binding sites are present on the free enzyme.

FIG. 12-5 Some bisubstrate reactions. (a) In the peptide hydrolysis reaction catalyzed by trypsin, the peptide carbonyl group, with its pendent polypeptide chain, R₁, is transferred from the peptide nitrogen atom to a water molecule. (b) In the alcohol dehydrogenase reaction, a hydride ion is formally transferred from ethanol to NAD⁺.

In a notation developed by W.W. Cleland, substrates are designated by the letters A and B in the order that they add to the enzyme, products are designated by P and Q in the order that they leave the enzyme, the enzyme is represented by a horizontal line, and successive additions of substrates and releases of products are denoted by vertical arrows. An Ordered bisubstrate reaction is thereby diagrammed:

where A and B are said to be the **leading** and **following** substrates, respectively. Many NAD⁺- and NADP⁺-requiring dehydrogenases follow an Ordered bisubstrate mechanism in which the coenzyme is the leading substrate.

A Random bisubstrate reaction is diagrammed:

Some dehydrogenases and **kinases** operate through Random bisubstrate mechanisms (kinases are enzymes that transfer phosphoryl groups from ATP to other compounds or vice versa).

Ping Pong Reactions Occur via Double Displacements. *Group-transfer reactions in which one or more products are released before all substrates have been added are known as **Ping Pong reactions**.* The Ping Pong bisubstrate reaction is represented by

Here, a functional group X of the first substrate A (= P—X) is displaced from the substrate by the enzyme E to yield the first product P and a stable enzyme form F (= E—X) in which X is tightly (often covalently) bound to the enzyme (Ping). In the second stage of the reaction, X is displaced from the enzyme by the second substrate B to yield the second product Q (= B—X), thereby regenerating the original form of the enzyme, E (Pong). Such reactions are therefore also known as **double-displacement reactions**. *Note that in Ping Pong reactions, the substrates A and B do not encounter one another on the surface of the enzyme.* Many enzymes, including trypsin (in which F is the acyl-enzyme intermediate; Section 11-5), transaminases, and some flavoenzymes, react with Ping Pong mechanisms.

Bisubstrate Mechanisms Can Be Distinguished by Kinetic Measurements. The rate equations that describe the foregoing bisubstrate mechanisms are considerably more complicated than the equation for a single-substrate reaction. In fact, the equations for bisubstrate mechanisms (which are beyond the scope of this text) contain as many as four kinetic constants versus two (V_{\max} and K_M) for the Michaelis–Menten equation. Nevertheless, steady state kinetic measurements can be used to distinguish among the various bisubstrate mechanisms.

CHECKPOINT

- Write the rate equations for a first-order and a second-order reaction.
- If you know a reaction's half-life, can you determine its rate constant? What other information do you need?
- What are the differences between instantaneous velocity, initial velocity, and maximal velocity for an enzymatic reaction?
- Derive the Michaelis–Menten equation.
- What do the values of K_M and k_{cat}/K_M reveal about an enzyme?
- Why can't an enzyme have a k_{cat}/K_M value greater than $10^9 \text{ M}^{-1} \cdot \text{s}^{-1}$?
- Write the Lineweaver–Burk (double-reciprocal) equation and describe the features of a Lineweaver–Burk plot.
- Why can't enzyme kinetics prove that a particular enzyme mechanism is correct?
- Use Cleland notation to describe Ordered and Random sequential reactions and a Ping Pong reaction.

2 Enzyme Inhibition

KEY CONCEPTS

- Enzyme inhibitors interact reversibly or irreversibly with an enzyme to alter its K_M and/or V_{\max} values.
- A competitive inhibitor binds to the enzyme's active site and increases the apparent K_M for the reaction.
- An uncompetitive enzyme inhibitor affects catalytic activity such that both the apparent K_M and the apparent V_{\max} decrease.
- A mixed enzyme inhibitor alters both catalytic activity and substrate binding such that the apparent V_{\max} decreases and the apparent K_M may increase or decrease.

Many substances alter the activity of an enzyme by combining with it in a way that influences the binding of substrate and/or its turnover number. *Substances that reduce an enzyme's activity in this way are known as inhibitors.* A large part of the modern pharmaceutical arsenal consists of enzyme inhibitors. For example, AIDS is treated almost exclusively with drugs that inhibit the activities of certain viral enzymes.

Inhibitors act through a variety of mechanisms. Irreversible enzyme inhibitors, or **inactivators**, bind to the enzyme so tightly that they permanently block the enzyme's activity. Reagents that chemically modify specific amino acid residues can act as inactivators. For example, the compounds used to identify the catalytic Ser and His residues of serine proteases (Section 11-5A) are inactivators of these enzymes.

Reversible enzyme inhibitors diminish an enzyme's activity by interacting reversibly with it. Some enzyme inhibitors are substances that structurally resemble their enzyme's substrates but either do not react or react very slowly. These substances are commonly used to probe the chemical and conformational nature of an enzyme's active site in an effort to elucidate the enzyme's catalytic mechanism. Other inhibitors affect catalytic activity without interfering with substrate binding. Many do both. In this section, we discuss several of the simplest mechanisms for reversible inhibition and their effects on the kinetic behavior of enzymes that follow the Michaelis–Menten model. As in the preceding discussion, we will base our analysis on a simple one-substrate reaction model.

A Competitive Inhibition Involves Inhibitor Binding at an Enzyme's Substrate Binding Site

A substance that competes directly with a normal substrate for an enzyme's substrate-binding site is known as a **competitive inhibitor**. Such an inhibitor usually resembles the substrate so that it specifically binds to the active site but differs from the substrate so that it cannot react as the substrate does. For example, **succinate dehydrogenase**, a citric acid cycle enzyme that converts **succinate** to **fumarate** (Section 17-3F), is competitively inhibited by **malonate**, which structurally resembles succinate but cannot be dehydrogenated:

FIG. 12-6 Oseltamivir (Tamiflu). (a) The hydrolytic reaction converting oseltamivir to its drug-active form, oseltamivir carboxylate. (b) X-Ray structure of influenza virus neuraminidase in complex with its competitive inhibitor, oseltamivir carboxylate. The active site region of the H5N1 avian flu neuraminidase is represented by its semitransparent surface diagram. The oseltamivir carboxylate is shown in spacefilling form with C green, O red, and N blue.

Based on an X-ray structure by John Skehel, MRC National Institute for Medical Research, London, U.K., PDBid 2HU4

The effectiveness of malonate as a competitive inhibitor of succinate dehydrogenase strongly suggests that the enzyme's substrate-binding site is designed to bind both of the substrate's carboxylate groups, presumably through the influence of appropriately placed positively charged residues.

Similar principles are responsible for **product inhibition**. In this phenomenon, a product of the reaction, which necessarily is able to bind to the enzyme's active site, may accumulate and compete with substrate for binding to the enzyme in subsequent catalytic cycles. Product inhibition is one way in which the cell controls the activities of its enzymes (Section 12-3).

Computer-assisted design of compounds that fit snugly into an enzyme's active site is an essential part of modern drug development (discussed further in Section 12-4). For example, the anti-influenza drug **oseltamivir (Tamiflu)** is hydrolyzed in the liver to yield **oseltamivir carboxylate** (Fig. 12-6a), a competitive inhibitor of influenza **neuraminidase** that binds to this enzyme's active site (Fig. 12-6b). Neuraminidase catalyzes the hydrolysis of neuraminic acid (sialic acid; Section 8-1C) to help the viral particles escape from the host cell surface, where membrane glycoproteins contain sialic acid residues. Oseltamivir carboxylate, which can significantly limit the production of the flu virus, has an **inhibition constant** (K_i , the dissociation constant for enzyme-inhibitor binding, see below) of less than 1 nM with neuraminidase (the enzyme's K_M is in the micromolar range).

Transition state analogs are particularly effective inhibitors. This is because effective catalysis often depends on an enzyme's ability to bind to and stabilize its reaction's transition state (Section 11-3E). A compound that mimics a transition state exploits these binding interactions in ways that a substrate analog cannot. For example, **adenosine deaminase** converts the nucleoside adenosine to inosine as follows:

The K_M of the enzyme for the substrate adenosine is 3×10^{-5} M. The product inosine acts as an inhibitor of the reaction, with a K_I value of 3×10^{-4} M. However, a transition state analog, **1,6-dihydroinosine** (at left), inhibits the reaction with a K_I of 1.5×10^{-13} M. Several of the drugs used to block **HIV protease**, an essential enzyme for production of the human immunodeficiency virus, are compounds that were designed to mimic the enzyme's transition state and bind to the enzyme with high affinity (Box 12-3).

Box 12-3 Biochemistry in Health and Disease HIV Enzyme Inhibitors

The **human immunodeficiency virus (HIV)** causes **acquired immunodeficiency syndrome (AIDS)** by infecting and destroying the host's immune system. In the first steps of infection, HIV attaches to a target cell and injects its genetic material (which is RNA rather than DNA) into the host cell. The viral RNA is transcribed into DNA by a viral enzyme called **reverse transcriptase** (Box 25-2). After this DNA is integrated into the host's genome, the cell can produce more viral RNA and proteins for packaging it into new viral particles that bud off from the host cell membrane.

Most of the viral proteins are synthesized as parts of larger polypeptide precursors known as **polyproteins**. Consequently, proteolytic processing by the virally encoded **HIV protease** to release these viral

proteins is necessary for viral reproduction. In the absence of an effective vaccine for HIV, efforts to prevent and treat AIDS have led to the development of compounds that inhibit HIV reverse transcriptase and HIV protease.

Several inhibitors of reverse transcriptase have been developed. The archetype is **AZT (3'-azido-3'-deoxythymidine; Zidovudine)**, which is taken up by cells, phosphorylated, and incorporated into the DNA chains synthesized from the HIV template by reverse transcriptase. Because AZT lacks a 3'-OH group, it cannot support further polynucleotide chain elongation and therefore terminates DNA synthesis (Section 3-4C). Most cellular DNA polymerases have a low affinity for phosphorylated AZT, but reverse transcriptase has a high affinity for this drug, which makes AZT effective against viral replication. Other nucleoside analogs that are used to treat HIV infection are **2',3'-dideoxycytidine (ddC, Zalcitabine)** and **2',3'-dideoxyinosine (ddI, Didanosine; inosine nucleotides are metabolically converted to adenosine and guanosine nucleotides), which also act as chain terminators. Nonnucleoside compounds such as nevirapine do not bind to the reverse transcriptase active site but instead bind to a hydrophobic pocket elsewhere on the enzyme.**

HIV particles budding from a lymphocyte.

3'-Azido-3'-deoxythymidine (AZT; Zidovudine)

2',3'-Dideoxycytidine (ddC, Zalcitabine)

2',3'-Dideoxyinosine (ddI, Didanosine)

Nevirapine

HIV protease is a homodimer of 99-residue subunits. Mechanistically, it is a so-called **aspartic protease**, a family of proteases that includes **pepsin** (the gastric protease that operates at low pH).

The Degree of Competitive Inhibition Varies with the Fraction of Enzyme That Has Bound Inhibitor. The general model for competitive inhibition is given by the following reaction scheme:

Comparisons among the active sites of the aspartic proteases were instrumental in designing HIV protease inhibitors. HIV protease cleaves a number of specific peptide bonds, including Phe–Pro and Tyr–Pro peptide bonds in its physiological substrates, the HIV polyproteins. Inhibitors based on these sequences should therefore selectively

inhibit the viral protease. The **peptidomimetic** (peptide-imitating) drugs **ritonavir** and **darunavir** contain phenyl and other bulky groups that bind in the HIV protease active site. Of perhaps even greater importance, these drugs have the geometry of the catalyzed reaction's tetrahedral transition state (*red*). The enzyme's peptide substrate is shown for comparison.

The efficacy of anti-HIV agents, like that of many drugs, is limited by their side effects. Despite their preference for viral enzymes, anti-HIV drugs also interfere with normal cellular processes. For example, the inhibition of DNA synthesis by reverse transcriptase inhibitors in rapidly dividing cells, such as the bone marrow cells that give rise to erythrocytes, can lead to severe anemia. Other side effects include nausea, kidney stones, and rashes. Side effects are particularly problematic in HIV infection, because drugs must be taken several times daily for many years, if not for a lifetime.

Acquired resistance also limits the effectiveness of antiviral drugs. This is a significant problem in HIV infection because the error-prone reverse transcriptase allows HIV to mutate rapidly. Numerous mutations in HIV are known to be associated with drug resistance.

In the case of HIV infection, it seems unlikely that a single drug will prove to be a “magic bullet,” in part because HIV infects many cell types, but mostly because of its ability to rapidly evolve resistance against any one drug. The outstanding success of anti-HIV therapy rests on combination therapy, in which several different drugs are administered simultaneously. This successfully keeps AIDS at bay by reducing levels of HIV, in some cases to undetectable levels, thereby reducing the probability that HIV will evolve a drug-resistant variant. The advantages of using an inhibitor “cocktail” containing inhibitors of

reverse transcriptase and HIV protease include (1) decreasing the likelihood that a viral strain will simultaneously develop resistance to every compound in the mix and (2) decreasing the doses and hence the side effects of the individual compounds.

Here, I is the inhibitor, EI is the catalytically inactive enzyme–inhibitor complex, and it is assumed that the inhibitor binds reversibly to the enzyme and is in rapid equilibrium with it so that

$$K_I = \frac{[E][I]}{[EI]} \quad [12-30]$$

A competitive inhibitor therefore reduces the concentration of free enzyme available for substrate binding.

The Michaelis–Menten equation for a competitively inhibited reaction is derived as before (Section 12-1B), but with an additional term to account for the fraction of $[E]_T$ that binds to I to form EI ($[E]_T = [E] + [ES] + [EI]$). The resulting equation,

$$v_o = \frac{V_{\max}[S]}{\alpha K_M + [S]} \quad [12-31]$$

is the Michaelis–Menten equation that has been modified by a factor, α , which is defined as

$$\alpha = 1 + \frac{[I]}{K_I} \quad [12-32]$$

Note that α , a function of the inhibitor's concentration and its affinity for the enzyme, cannot be less than 1. Comparison of Eqs. 12-25 and 12-31 indicates that $K_M^{\text{app}} = \alpha K_M$, where K_M^{app} is the apparent K_M , that is, the K_M value that would be measured in the absence of the knowledge that inhibitor is present. **Figure 12-7** shows the hyperbolic plots of Eq. 12-31 for increasing values of α . The presence of I makes $[S]$ appear to be less than it really is (makes K_M appear to be larger than it really is), a consequence of the binding of I and S to E being mutually exclusive. However, increasing $[S]$ can overwhelm a competitive inhibitor. In fact, α is the factor by which $[S]$ must be increased in order to overcome the effect of the presence of inhibitor. As $[S]$ approaches infinity v_o approaches V_{\max} for any value of α (that is, for any concentration of inhibitor). Thus, the inhibitor does not affect the enzyme's turnover number.

 Competitive inhibition is the principle behind the use of ethanol to treat methanol poisoning. Methanol itself is only mildly toxic. However, the liver enzyme alcohol dehydrogenase converts methanol to the highly toxic formaldehyde (*at left*), only small amounts of which cause blindness and death. Ethanol competes with methanol for binding to the active site of liver alcohol dehydrogenase, thereby slowing the production of formaldehyde from methanol (the ethanol is converted to the readily metabolized acetaldehyde; *at left*). Thus, through the administration of ethanol, a large portion of the methanol will be harmlessly excreted from the body in the urine before it can be converted to formaldehyde. The same principle underlies the use of ethanol to treat antifreeze (ethylene glycol, HOCH₂CH₂OH) poisoning, which, due to its sweet taste, often afflicts cats and dogs.

K_I Can Be Measured. Recasting Eq. 12-31 in the double-reciprocal form yields

$$\frac{1}{v_o} = \left(\frac{\alpha K_M}{V_{\max}} \right) \frac{1}{[S]} + \frac{1}{V_{\max}} \quad [12-33]$$

FIG. 12-7 A plot of v_o versus $[S]$ for a Michaelis–Menten reaction in the presence of different concentrations of a competitive inhibitor.

? How would the three lines appear when $[S] = 50 K_M$?

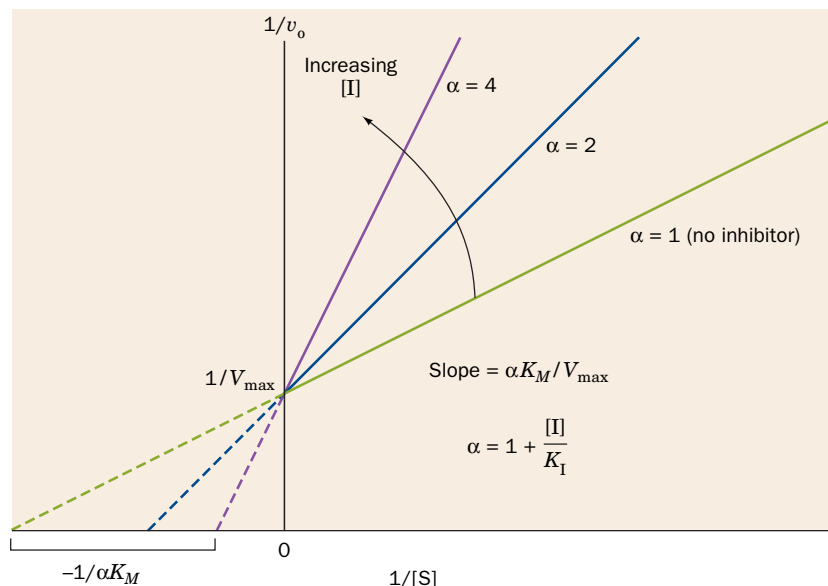

FIG. 12-8 A Lineweaver–Burk plot of the competitively inhibited Michaelis–Menten enzyme described by Fig. 12-7. Note that all lines intersect on the $1/v_0$ axis at $1/V_{\max}$. The varying slopes indicate the effect of the inhibitor on $\alpha K_M = K_M^{\text{app}}$. **WPLS** See the Animated Figures.

A plot of this equation is linear and has a slope of $\alpha K_M/V_{\max}$, a $1/[S]$ intercept of $-1/\alpha K_M$, and a $1/v_0$ intercept of $1/V_{\max}$ (Fig. 12-8). The double-reciprocal plots for a competitive inhibitor at various concentrations of I intersect at $1/V_{\max}$ on the $1/v_0$ axis, a property that is diagnostic of competitive inhibition.

The value of K_I for a competitive inhibitor can be determined from the plot of $K_M^{\text{app}} = (1 + [I]/K_I)K_M$ versus $[I]$; its intercept on the $[I]$ axis is $-K_I$. K_I can also be calculated from Eq. 12-32 if $K_M^{\text{app}} = \alpha K_M$ is determined at a known $[I]$ for an enzyme of known K_M (see Sample Calculation 12-5). Comparing the K_I values of competitive inhibitors with different structures can provide information about the binding properties of an enzyme's active site and hence its catalytic mechanism. For example, to ascertain the importance of the various segments of an ATP molecule

for binding to the active site of an ATP-requiring enzyme, one might determine the K_I , say, for ADP, AMP, ribose, triphosphate, etc. Since many of these ATP components are unreactive, inhibition studies are the most convenient method of monitoring their binding to the enzyme.

SAMPLE CALCULATION 12-5

An enzyme has a K_M of $8 \mu\text{M}$ in the absence of a competitive inhibitor and a K_M^{app} of $12 \mu\text{M}$ in the presence of $3 \mu\text{M}$ of the inhibitor. Calculate K_I .

First calculate the value of α when $K_M = 8 \mu\text{M}$ and $K_M^{\text{app}} = 12 \mu\text{M}$:

$$K_M^{\text{app}} = \alpha K_M$$

$$\alpha = \frac{K_M^{\text{app}}}{K_M}$$

$$\alpha = \frac{12 \mu\text{M}}{8 \mu\text{M}} = 1.5$$

Next, calculate K_I from Eq. 12-32:

$$\alpha = 1 + \frac{[I]}{K_I}$$

$$K_I = \frac{[I]}{\alpha - 1}$$

$$K_I = \frac{3 \mu\text{M}}{1.5 - 1} = 6 \mu\text{M}$$

WPLS See Sample Calculation Videos.

GATEWAY CONCEPT Enzyme Inhibition

In the cell, there are multiple copies of a given enzyme molecule acting on a pool of substrate molecules amid a pool of potential inhibitor molecules. Because the binding of a substrate to the active site, or of an inhibitor to its binding site, is reversible, the actual reaction velocity at any instant—that is, the ability of the enzyme to convert substrate molecules to product molecules—depends on the relative proportions of all the different forms of the enzyme: E, EI, ES, ESI (for certain types of inhibitors), and so on.

FIG. 12-9 A Lineweaver–Burk plot of a Michaelis–Menten enzyme in the presence of an uncompetitive inhibitor. Note that all lines have identical slopes of K_M/V_{\max} . **WPLS** See the Animated Figures.

C Mixed Inhibition Involves Inhibitor Binding to Both the Free Enzyme and the Enzyme–Substrate Complex

Many reversible inhibitors interact with the enzyme in a way that affects substrate binding as well as catalytic activity. In other words, both the enzyme and the enzyme–substrate complex bind inhibitor, resulting in the following model:

This phenomenon is known as **mixed inhibition** (alternatively, **noncompetitive inhibition**). Presumably, a mixed inhibitor binds to enzyme sites that participate in both substrate binding and catalysis. For example, metal ions, which do not compete directly with substrates for binding to an enzyme active site, as do competitive inhibitors, may act as mixed inhibitors. The two dissociation constants for inhibitor binding

$$K_1 = \frac{[\text{E}][\text{I}]}{[\text{EI}]} \quad \text{and} \quad K'_1 = \frac{[\text{ES}][\text{I}]}{[\text{ESI}]} \quad [12-35]$$

are not necessarily equivalent.

The Michaelis–Menten equation and the corresponding double-reciprocal equation for mixed inhibition are given in Table 12-2. As in uncompetitive inhibition, the apparent values of K_M and V_{\max} are modulated by the presence of inhibitor. The name *mixed inhibition* arises from the fact that the denominator of the Michaelis–Menten equation has the factor α multiplying K_M as in competitive inhibition and the factor α' multiplying $[\text{S}]$ as in uncompetitive inhibition. Thus $K_M^{\text{app}} = (\alpha/\alpha')K_M$ and $V_{\max}^{\text{app}} = V_{\max}/\alpha'$.

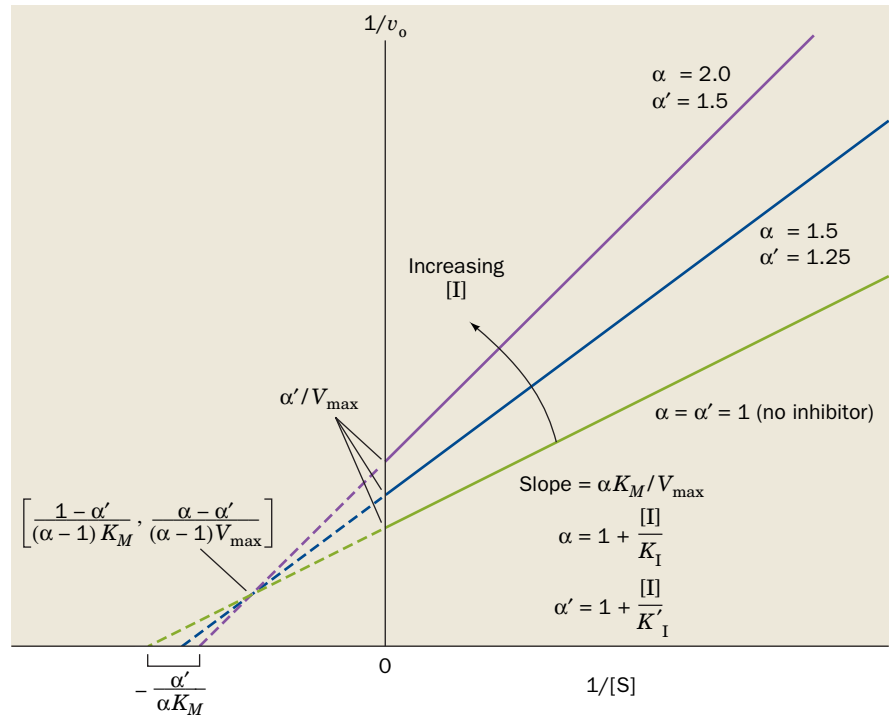

FIG. 12-10 A Lineweaver–Burk plot of a Michaelis–Menten enzyme in the presence of a mixed inhibitor. Note that the lines all intersect to the left of the $1/v_o$ axis. The coordinates of the intersection point are given in brackets. When $K_I = K_I'$ ($\alpha = \alpha'$), the lines intersect on the $1/[S]$ axis at $-1/K_M$. **WPLS** See the Animated Figures.

Depending on the relative values of α and α' (and hence K_I and K_I'), K_M^{app} may increase (as in competitive inhibition) or decrease. If the enzyme and enzyme–substrate complex bind I with equal affinity, then $\alpha = \alpha'$ and the K_M^{app} value is unchanged from the K_M for the reaction in the absence of inhibitor. In this case, only V_{max} is affected, a phenomenon that is named **pure noncompetitive inhibition**.

Double-reciprocal plots for mixed inhibition consist of lines that have the slope $\alpha K_M/V_{\text{max}}$, a $1/v_o$ intercept of α'/V_{max} , and a $1/[S]$ intercept of $-\alpha'/\alpha K_M$ (Fig. 12-10). The lines for increasing values of $[I]$ (representing increasing saturation of E and ES with I) intersect to the left of the $1/v_o$ axis. For pure noncompetitive inhibition, the lines intersect on the $1/[S]$ axis at $-1/K_M$. As with uncompetitive inhibition, substrate binding does not reverse the effects of mixed inhibition.

The kinetics of an enzyme inactivator (an irreversible inhibitor) resembles that of a pure noncompetitive inhibitor because the inactivator reduces the concentration of functional enzyme at all substrate concentrations. Consequently, V_{max} decreases and K_M is unchanged. The double-reciprocal plots for irreversible inactivation therefore resemble those for pure noncompetitive inhibition (the lines intersect on the $1/[S]$ axis).

CHECKPOINT

- What distinguishes an inhibitor from an inactivator?
- Why might an enzyme's substrate, transition state, and product all serve as starting points for the design of a competitive inhibitor?
- Describe the effects of competitive, uncompetitive, and mixed inhibitors on K_M and V_{max} .
- How can inhibitor binding to an enzyme be quantified?
- How does pure noncompetitive inhibition differ from other forms of inhibition?

3 Control of Enzyme Activity

KEY CONCEPTS

- Allosteric effectors bind to multisubunit enzymes such as aspartate transcarbamoylase, thereby inducing cooperative conformational changes that alter the enzyme's catalytic activity.
- Phosphorylation and dephosphorylation of an enzyme such as glycogen phosphorylase can control its activity by shifting the equilibrium between more active and less active conformations.

An organism must be able to control the catalytic activities of its component enzymes so that it can coordinate its numerous metabolic processes, respond to changes in its environment, and grow and differentiate, all in an orderly manner. There are two ways that this may occur:

1. **Control of enzyme availability.** The amount of a given enzyme in a cell depends on both its rate of synthesis and its rate of degradation. Each of these rates is directly controlled by the cell and is subject to dramatic changes over time spans of minutes (in bacteria) to hours (in higher organisms).
2. **Control of enzyme activity.** As we have already seen, an enzyme's activity can be inhibited by the accumulation of product and by the presence of other types of inhibitors. In fact, an enzyme's catalytic activity can be modulated—either negatively or positively—through structural alterations that influence the enzyme's substrate-binding affinity or turnover number. Just as hemoglobin's oxygen affinity is allosterically regulated by the binding of ligands such as O_2 , CO_2 , H^+ , and BPG (Section 7-1D), an enzyme's substrate-binding affinity may likewise vary with the binding of small molecules, called **allosteric effectors**. *Allosteric mechanisms can cause large changes in enzymatic activity.* The activities of many enzymes are similarly controlled by **covalent modification**, usually phosphorylation and dephosphorylation of specific Ser, Thr, or Tyr residues.

In the following sections we discuss the control of enzyme activity by allosteric interactions and covalent modification.

A Allosteric Control Involves Binding at a Site Other than the Active Site

In this section we examine allosteric control of enzymatic activity by considering one example—**aspartate transcarbamoylase (ATCase)** from *E. coli*. Other allosteric enzymes are discussed in later chapters.

The Feedback Inhibition of ATCase Regulates Pyrimidine Synthesis. Aspartate transcarbamoylase catalyzes the formation of *N*-carbamoyl aspartate from **carbamoyl phosphate** and aspartate:

This reaction is the first step unique to the biosynthesis of pyrimidines (Section 23-2A). The allosteric behavior of *E. coli* ATCase has been investigated by John Gerhart and Howard Schachman, who demonstrated that both of its substrates bind cooperatively to the enzyme. Moreover, ATCase is allosterically inhibited by **cytidine triphosphate (CTP)**, a pyrimidine nucleotide, and is allosterically activated by adenosine triphosphate (ATP), a purine nucleotide.

The v_0 versus $[S]$ curve for ATCase (Fig. 12-11) is sigmoidal, rather than hyperbolic as it is in enzymes that follow the Michaelis–Menten model. This is consistent with cooperative substrate binding (recall that

FIG. 12-11 Plot of v_0 versus $[aspartate]$ for the ATCase reaction. Reaction velocity was measured in the absence of allosteric effectors, in the presence of 0.4 mM CTP (an inhibitor), and in the presence of 2.0 mM ATP (an activator). [After Kantowitz, E.R., Pastra-Landis, S.C., and Lipscomb, W.N., *Trends Biochem. Sci.* 5, 125 (1980).] **WPLS** See the Animated Figures.

? How do ATP and CTP affect the enzyme's apparent K_m ?

FIG. 12-12 A schematic representation of the pyrimidine biosynthesis pathway. CTP, the end product of the pathway, inhibits ATCase, which catalyzes the pathway's first step.

hemoglobin's O_2 -binding curve is also sigmoidal; Fig. 7-6). ATCase's allosteric effectors shift the entire curve to the right or the left: At a given substrate concentration, CTP decreases the enzyme's catalytic rate, whereas ATP increases it.

CTP, which is a product of the pyrimidine biosynthetic pathway, is an example of a **feedback inhibitor**, since *it inhibits an earlier step in its own biosynthesis* (Fig. 12-12). Thus, when CTP levels are high, CTP binds to ATCase, thereby reducing the rate of CTP synthesis. Conversely, when cellular [CTP] decreases, CTP dissociates from ATCase and CTP synthesis accelerates.

The metabolic significance of the ATP activation of ATCase is that it tends to coordinate the rates of synthesis of purine and pyrimidine nucleotides, which are required in roughly equal amounts in nucleic acid biosynthesis. For instance, if the ATP concentration is much greater than that of CTP, ATCase is activated to synthesize pyrimidine nucleotides until the concentrations of ATP and CTP become balanced. Conversely, if the CTP concentration is greater than that of ATP, CTP inhibition of ATCase permits purine nucleotide biosynthesis to balance the ATP and CTP concentrations.

Allosteric Changes Alter ATCase's Substrate-Binding Sites. *E. coli* ATCase (300 kD) has the subunit composition c_6r_6 , where *c* and *r* represent its catalytic and regulatory subunits. The X-ray structure of ATCase (Fig. 12-13), determined by William Lipscomb, reveals that the catalytic subunits are arranged as two trimers (c_3) in complex with three regulatory dimers (r_2). Each regulatory dimer joins two catalytic subunits in different c_3 trimers.

The isolated catalytic trimers are catalytically active, have a maximum catalytic rate greater than that of intact ATCase, exhibit a noncooperative (hyperbolic) substrate saturation curve, and are unaffected by the presence of ATP or CTP. The isolated regulatory dimers bind the allosteric effectors but are devoid of enzymatic activity. Evidently, *the regulatory subunits allosterically reduce the activity of the catalytic subunits in the intact enzyme*.

As allosteric theory predicts (Section 7-1D), the activator ATP preferentially binds to ATCase's active (R or high substrate affinity) state, whereas the inhibitor CTP preferentially binds to the enzyme's inactive (T or low substrate affinity)

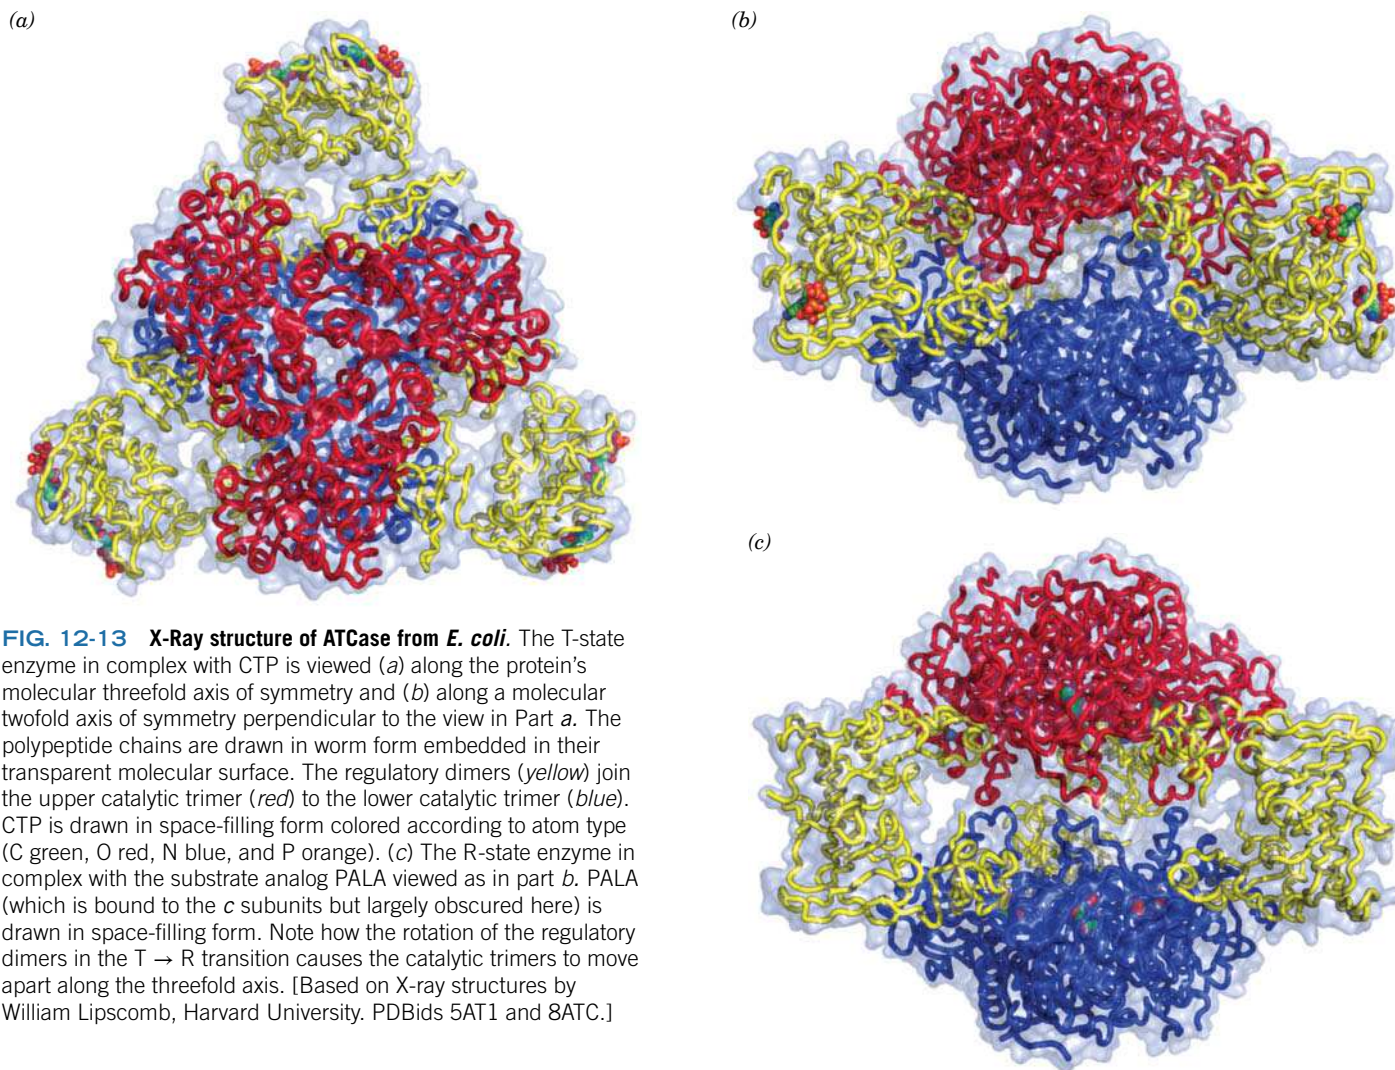

FIG. 12-13 X-Ray structure of ATCase from *E. coli*. The T-state enzyme in complex with CTP is viewed (a) along the protein's molecular threefold axis of symmetry and (b) along a molecular twofold axis of symmetry perpendicular to the view in Part a. The polypeptide chains are drawn in worm form embedded in their transparent molecular surface. The regulatory dimers (yellow) join the upper catalytic trimer (red) to the lower catalytic trimer (blue). CTP is drawn in space-filling form colored according to atom type (C green, O red, N blue, and P orange). (c) The R-state enzyme in complex with the substrate analog PALA viewed as in part b. PALA (which is bound to the c subunits but largely obscured here) is drawn in space-filling form. Note how the rotation of the regulatory dimers in the T → R transition causes the catalytic trimers to move apart along the threefold axis. [Based on X-ray structures by William Lipscomb, Harvard University. PDBids 5AT1 and 8ATC.]

state. Similarly, the unreactive bisubstrate analog *N*-(phosphonacetyl)-L-aspartate (PALA) binds tightly to R-state but not to T-state ATCase.

X-Ray structures have been determined for the T-state ATCase–CTP complex and the R-state ATCase–PALA complex (as a rule, unreactive substrate analogs, such as PALA, form complexes with an enzyme that are more amenable to structural analysis than complexes of the enzyme with rapidly reacting substrates). Structural studies reveal that in the T → R transition, the enzyme's catalytic trimers separate along the molecular threefold axis by ~11 Å and reorient around this axis relative to each other by 12° (Fig. 12-13 *b,c*). In addition, the regulatory dimers rotate clockwise by 15° around their twofold axes and separate by ~4 Å along the threefold axis. Such large quaternary shifts are reminiscent of those in hemoglobin (Section 7-1D).

Each catalytic subunit of ATCase consists of a carbamoyl phosphate-binding domain and an aspartate-binding domain. The binding of PALA to the enzyme,

which presumably mimics the binding of both substrates, induces a conformational change that swings the two domains together such that their two bound substrates can react to form product (Fig. 12-14). The conformational changes—movements of up to 8 Å for some residues—in a single catalytic subunit trigger ATCase's T → R quaternary shift. ATCase's tertiary and quaternary shifts are tightly coupled (i.e., ATCase closely follows the symmetry model of allosterism; Section 7-1D). *The binding of substrate to one catalytic subunit therefore increases the substrate-binding affinity and catalytic activity of the other five catalytic subunits* and hence accounts for the enzyme's cooperative substrate binding.

The Binding of Allosteric Modifiers Causes Structural Changes in ATCase. The structural basis for the effects of CTP and ATP on ATCase activity has been partially unveiled. Both the inhibitor CTP and the activator ATP bind to the same site on the outer edge of the regulatory subunit, about 60 Å away from the nearest catalytic site. CTP binds preferentially to the T state, increasing its stability, whereas ATP binds preferentially to the R state, increasing its stability.

The binding of CTP and ATP to their less favored enzyme states also has structural consequences. When CTP binds to R-state ATCase, it induces a contraction in the regulatory dimer that causes the catalytic trimers to come together by 0.5 Å (become more T-like; that is, less active). This, in turn, reorients key residues in the enzyme's active sites, thereby decreasing the enzyme's catalytic activity. ATP has essentially opposite effects when binding to the T-state enzyme: It causes the catalytic trimers to move apart by 0.4 Å (become more R-like; that is, more active), thereby reorienting key residues in the enzyme's active sites so as to increase the enzyme's catalytic activity.

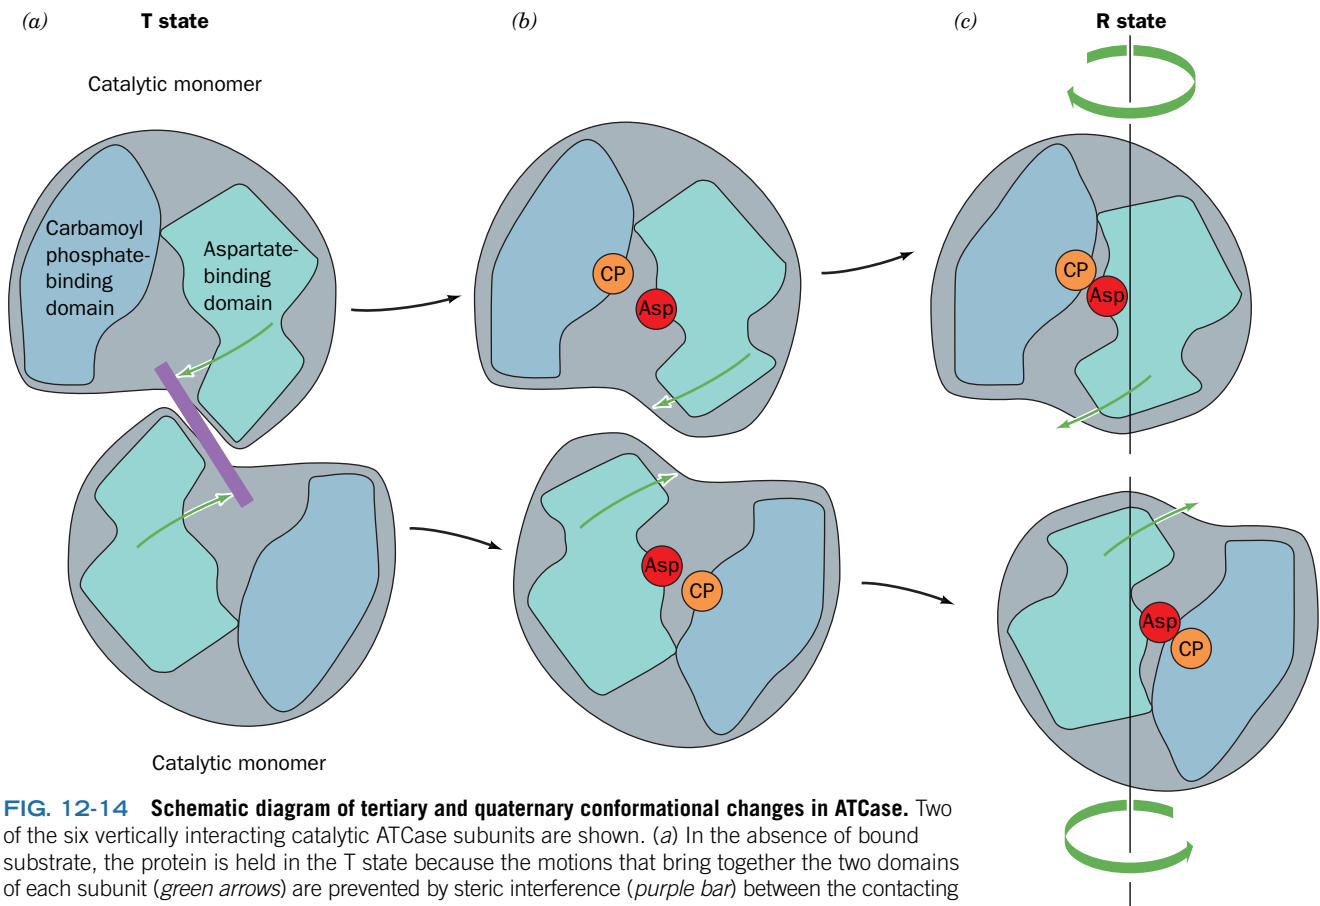

FIG. 12-14 Schematic diagram of tertiary and quaternary conformational changes in ATCase. Two of the six vertically interacting catalytic ATCase subunits are shown. (a) In the absence of bound substrate, the protein is held in the T state because the motions that bring together the two domains of each subunit (green arrows) are prevented by steric interference (purple bar) between the contacting aspartate-binding domains. (b) The binding of carbamoyl phosphate (CP) followed by aspartate (Asp) to their respective binding sites causes the subunits to move apart and rotate with respect to each other so as to permit the T → R transition. (c) In the R state, the two domains of each subunit come together to promote the reaction of their bound substrates to form products. [Illustration, Irving Geis. Allosteric Transitions in Other Enzymes Often Resemble Those of Hemoglobin and ATCase. Allosteric enzymes are widely distributed in nature and tend to occupy key regulatory positions in metabolic pathways. Such enzymes are almost always symmetrical proteins containing at least two subunits, in which quaternary structural changes communicate binding and catalytic effects among all active sites in the enzyme. The quaternary shifts are primarily rotations of subunits relative to one another. Secondary structures are largely preserved in T \rightarrow R transitions, which is probably important for mechanically transmitting allosteric effects over distances of tens of angstroms.

B Control by Covalent Modification Usually Involves Protein Phosphorylation

In addition to allosteric interactions, many enzymes may be subject to control by covalent modification. In eukaryotes, by far the most common such modification is phosphorylation and dephosphorylation (the attachment and removal of a phosphoryl group) of the hydroxyl group of a Ser, Thr, or Tyr residue.

Such enzymatic modification/demodification processes, which are catalyzed by enzymes known as **protein kinases** and **protein phosphatases**, alter the activities of the modified proteins. Indeed, ~30% of human proteins, which collectively participate in nearly all biological processes, are subject to control by reversible phosphorylation.

As an example of an enzyme whose activity is controlled by covalent modification, let us consider **glycogen phosphorylase** (or simply **phosphorylase**), which catalyzes the **phosphorolysis** (bond cleavage by the substitution of a phosphate group) of glycogen [the starchlike polysaccharide that consists mainly of $\alpha(1 \rightarrow 4)$ -linked glucose residues; Section 8-2C] to yield **glucose-1-phosphate (G1P)**:

Glucose-1-phosphate (G1P)

This is the rate-controlling step in the metabolic pathway of glycogen breakdown, an important supplier of fuel for metabolic activities (Section 16-1).

Mammals express three **isozymes** (catalytically and structurally similar but genetically distinct enzymes from the same organism; also called **isoforms**) of glycogen phosphorylase, those from muscle, brain, and liver. Muscle glycogen phosphorylase, which we discuss here, is a dimer of identical 842-residue subunits. It is regulated both by allosteric interactions and by phosphorylation/dephosphorylation. The phosphorylated form of the enzyme, **phosphorylase *a***, has a phosphoryl group esterified to its Ser 14. The dephospho form is called **phosphorylase *b***.

The X-ray structures of phosphorylase *a* and phosphorylase *b*, which were respectively determined by Robert Fletterick and Louise Johnson, are similar. Both have a large N-terminal domain (484 residues; the largest known domain) and a smaller C-terminal domain (Fig. 12-15). The N-terminal

FIG. 12-15 X-Ray structure of rabbit muscle glycogen phosphorylase. Ribbon diagram of the phosphorylase *a* homodimer viewed along its molecular twofold axis of symmetry. Each subunit consists of an N-terminal domain, which is subdivided into an interface subdomain (residues 1–315) and a glycogen-binding subdomain (residues 316–484), and a C-terminal domain (residues 485–842). The enzyme's several ligands are drawn in stick form colored according to type with N blue, O red, P orange, and C atoms as follows. The active site is marked by a bound glucose molecule (C yellow). Pyridoxal phosphate (PLP) is covalently linked to the side chain of Lys 678 in the C-terminal domain (C magenta). In addition, the enzyme binds its allosteric effector AMP (C cyan) and **maltoheptaose** (C green), an $\alpha(1 \rightarrow 4)$ -linked glucose heptamer, which is bound in the enzyme's glycogen storage site. Ser 14-P, the phosphoryl group on Ser 14, is drawn in space-filling form. [X-ray structure coordinates courtesy of Stephen Sprang, University of Texas Southwest Medical Center]

domain, which is subdivided into a glycogen-binding subdomain and an interface subdomain, contains the phosphorylation site (Ser 14), an allosteric effector site, a glycogen-binding site (called the glycogen storage site), and all the intersubunit contacts in the dimer. The enzyme's active site is located at the center of the subunit.

Phosphorylation and Dephosphorylation Can Alter Enzymatic Activity in a Manner That Resembles Allosteric Control. Glycogen phosphorylase has two conformational states, the enzymatically active R state and the enzymatically inactive T state (Fig. 12-16). The T-state enzyme is inactive because it has a malformed active site and a surface loop (residues 282–284) that blocks substrate access to its binding site. In contrast, in the R-state enzyme, the side chain of Arg 569 has reoriented so as to bind the substrate phosphate ion and the 282–284 loop no longer blocks the active site, thereby permitting the enzyme to bind substrate and efficiently catalyze the phosphorolysis of glycogen.

The phosphorylation of Ser 14 promotes phosphorylase's T (inactive) → R (active) conformational change. Moreover, these different enzymatic forms

FIG. 12-16 Conformational changes in glycogen phosphorylase. Ribbon diagrams of one subunit of the dimeric enzyme glycogen phosphorylase *b* (a) in the T state in the absence of allosteric effectors and (b) in the R state with bound AMP. The view is of the lower (orange) subunit in Fig. 12-15 rotated by $\sim 45^\circ$ about a horizontal axis. The tower helix is blue; the N-terminal helix is cyan; the N-terminal residues that change conformation on AMP binding are red; and residues 282 to 286, the 280s loop, which in the R state are disordered and hence not seen, are green. Of the groups that are shown in space-filling representation, the side chain of Ser 14, the phosphorylation site, and AMP, which binds only to the R state enzyme, have C green, N blue, O red, and P orange; the side chain of Arg 569, which reorients in the T \rightarrow R transition so as to interact with the substrate phosphate, has C cyan and N blue; and sulfate ions bound near Ser 14 and at the active site of the R state enzyme, which mimic the sterically similar phosphate ions, have O red and S orange. The PLP at the active site is drawn in stick form with C magenta, N blue, O red, and P orange. [Based on X-ray structures by Louise Johnson, Oxford University, U.K. PDBids 8GPB and 7GPB.]

? Consider the properties of a phosphate group to explain why protein phosphorylation can trigger dramatic conformational changes.

FIG. 12-17 The control of glycogen phosphorylase activity. The enzyme may assume the enzymatically inactive T conformation (*above*) or the catalytically active R form (*below*). The conformation of phosphorylase *b* is allosterically controlled by the effectors AMP, ATP, and G6P and is mostly in the T state under physiological conditions. In contrast, the phosphorylated form of the enzyme, phosphorylase *a*, is unresponsive to these effectors and is mostly in the R state unless there is a high level of glucose. Thus, under usual physiological conditions, the enzymatic activity of glycogen phosphorylase is largely determined by its rates of phosphorylation and dephosphorylation.

respond to different allosteric effectors (**Fig. 12-17**). Thus ATP and **glucose-6-phosphate [G6P]**; to which the G1P product of the glycogen phosphorylase reaction is converted (Section 16-1C)] preferentially bind to the T state of phosphorylase *b* and, in doing so, inactivate the enzyme, whereas AMP preferentially binds to the R state of phosphorylase *b* and hence activates it. In contrast, phosphorylase *a*'s only allosteric effector is glucose, which binds to the enzyme's T state and inactivates the enzyme. Note that ATP, G6P, and glucose are present in relatively high concentrations in muscle under conditions of low exertion, a state when glycogen breakdown would be superfluous, whereas AMP is present in relatively high concentration in muscles under conditions of high exertion, a state when the G1P product of the phosphorylase reaction helps fuel muscle contraction.

The phosphate group, with its double negative charge (a property not shared with naturally occurring amino acid residues) and its covalent attachment to a protein, can induce dramatic conformational changes. In phosphorylase *a*, the Ser 14 phosphate group forms ion pairs with two cationic Arg side chains, thereby linking the active site, the subunit interface, and the N-terminal region, the latter having undergone a large conformational shift from its position in the T-state enzyme (Fig. 12-16*a*). These binding interactions cause glycogen phosphorylase's tower helices (Figs. 12-15 and 12-16) to tilt and pull apart so as to pack more favorably, which in turn triggers a quaternary T → R transition, which largely consists of an ~10° relative rotation of the two subunits. Thus the Ser 14-phosphate group functions as a sort of internal allosteric effector that shifts the enzyme's T ⇌ R equilibrium in favor of the R state.

Cascades of Protein Kinases Enable Sensitive Responses to Metabolic Needs. The enzymes that catalyze the phosphorylation and dephosphorylation of glycogen phosphorylase are named **phosphorylase kinase** and **phosphoprotein**

phosphatase (Fig. 12-17). The activities of these latter enzymes are themselves controlled, both allosterically and by phosphorylation/dephosphorylation. As we will see in Section 13-2, protein kinases and protein phosphatases are often linked in series (i.e., protein kinase X phosphorylates protein kinase Y, which phosphorylates protein kinase Z). Such cascade arrangements have far greater capacities for signal amplification than simple allosteric enzymes, because in a cascade, a small fractional change in effector concentration can cause a larger fractional change in enzyme activity. In addition, the cascade system offers greater flexibility in responding to a large number of allosteric effectors because the activity of each protein in the cascade may be influenced by different sets of effectors. Indeed, just such cascades permit glycogen phosphorylase to respond with great sensitivity to the metabolic needs of the organism.

CHECKPOINT

- Compare and contrast the actions of an allosteric effector, a competitive enzyme inhibitor, and a noncompetitive inhibitor.
- Explain the structural basis for cooperative substrate binding and allosteric control in ATCase.
- Why are such allosteric enzymes composed of more than one catalytic subunit?
- Describe how phosphorylation and dephosphorylation control the activity of glycogen phosphorylase.
- List some advantages of phosphorylation/dephosphorylation cascade systems over simple allosteric regulation.

4 Drug Design

KEY CONCEPTS

- Structure-based design and combinatorial chemistry approaches are used to discover new drugs.
- A drug's interactions with the body determine its bioavailability.
- A drug's effectiveness and safety are tested in clinical trials.
- Cytochrome P450 may modify a drug to alter its bioavailability or toxicity.

The use of drugs to treat various maladies has a long history, but the modern pharmaceutical industry, which is based on science (rather than tradition or superstition), is a product of the twentieth century. For example, at the beginning of the twentieth century, only a handful of drugs, apart from folk medicines, were known, including **digitalis**, a heart stimulant from the fox-glove plant (Box 10-3); **quinine** (Fig. 12-18), obtained from the bark and roots of the *Cinchona* tree, which was used to treat malaria; and mercury, which was used to treat syphilis—a cure that was often worse than the disease. Almost all drugs in use today were discovered and developed in the past four decades. The majority of drugs act by modifying the activity of a receptor protein, with enzyme inhibitors constituting the second largest class of drugs. Indeed, the techniques of enzyme kinetics have proved to be invaluable for evaluating drug candidates.

FIG. 12-18 Quinine and chloroquine. These two compounds, which share a quinoline ring system, can be effective antimalarial agents. The *Plasmodium* parasite multiplies within red blood cells, where it proteolyzes hemoglobin to meet its nutritional needs. This process releases heme, which in its soluble form is toxic to the parasite. The parasite sequesters the heme in a crystalline (nontoxic) form. Quinine and chloroquine pass through cell membranes and inhibit heme crystallization in the parasite. Unfortunately, the widespread use of these compounds has resulted in the parasite evolving resistance to them, so that, in many areas of the world, these drugs are no longer effective.

A Drug Discovery Employs a Variety of Techniques

How are new drugs discovered? Nearly all drugs that have been in use for more than 20 years were discovered by screening large numbers of compounds—either synthetic compounds or those derived from natural products (often plants used in folk remedies). Initial screening involves *in vitro* assessment of, for example, the degree of binding of a drug candidate to an enzyme that is implicated in a disease of interest, that is, determining its K_I value. Later, as the number of drug candidates is winnowed down, more sensitive screens, such as testing in animals, are employed.

A drug candidate that exhibits a desired effect is called a **lead compound** (pronounced leed). A good lead compound binds to its target protein with a dissociation constant (for an enzyme, an inhibition constant) of less than 1 μM . Such a high affinity is necessary to minimize a drug's less specific binding to other macromolecules in the body and to ensure that only low doses of the drug need be taken.

A lead compound is used as a point of departure to design more efficacious compounds. Even minor modifications to a drug candidate can result in major changes in its pharmacological properties. Thus, substitution of methyl, chloro, hydroxyl, or benzyl groups at various places on a lead compound may improve its action. For most drugs in use today, 5000 to 10,000 related compounds were typically synthesized and tested. Drug development is a systematic and iterative process in which the most promising derivatives of the lead compound serve as the starting points for the next round of derivatization and testing.

Structure-Based Drug Design Accelerates Drug Discovery. Since the mid-1980s, dramatic advances in the speed and precision with which a macromolecular structure can be determined by X-ray crystallography and NMR (Section 6-2A) have enabled **structure-based drug design**, a process that greatly reduces the number of compounds that need be synthesized in a drug discovery program. As its name implies, structure-based drug design (also called **rational drug design**) uses the structure of a receptor or enzyme in complex with a drug candidate to guide the development of more efficacious compounds. Such a structure will reveal, for example, the positions of the hydrogen bond donors and acceptors in the binding site as well as cavities in the binding site into which substituents might be placed on a drug candidate to increase its binding affinity. These direct visualization techniques are usually supplemented with molecular modeling tools such as the computation of the minimum energy conformation of a proposed derivative, quantum mechanical calculations that determine its charge distribution and hence how it would interact electrostatically with the protein, and docking simulations in which an inhibitor candidate is computationally modeled into the binding site on the receptor to assess potential interactions (see Bioinformatics Project 6). A structure-based approach was used to develop the analgesics (pain relievers) Celebrex and Vioxx (Section 20-6C) and to develop drugs to treat HIV infection (Box 12-3).

Combinatorial Chemistry and High-Throughput Screening Are Useful Drug Discovery Tools. As structure-based methods were developed, it appeared that they would become the dominant mode of drug discovery. However, the recent advent of **combinatorial chemistry** techniques to rapidly and inexpensively synthesize large numbers of related compounds combined with the development of robotic **high-throughput screening** techniques has caused the drug discovery “pendulum” to again swing toward the “make-many-compounds-and-see-what-they-do” approach. If a lead compound can be synthesized in a stepwise manner from several smaller modules, then the substituents on each of these modules can be varied in parallel to produce a library of related compounds (Fig. 12-19).

FIG. 12-19 The combinatorial synthesis of arylidene diamides. If ten different variants of each R group are used in the synthesis, then 1000 different derivatives will be synthesized.

A variety of synthetic techniques have been developed that permit the combinatorial synthesis of thousands of related compounds in a single procedure. Thus, whereas investigations into the importance of a hydrophobic group at a particular position in a lead compound might previously have prompted the individual syntheses of only the ethyl, propyl, and benzyl derivatives of the compound, the use of combinatorial synthesis would permit the generation of perhaps 100 different groups at that position. This would far more effectively map out the potential range of the substituent and possibly identify an unexpectedly active analog.

B A Drug's Bioavailability Depends on How It Is Absorbed and Transported in the Body

The *in vitro* development of an effective drug candidate is only the first step in the drug development process. *Besides causing the desired response in its isolated target protein, a useful drug must be delivered in sufficiently high concentration to this protein where it resides in the human body.* For example, a drug that is administered orally (the most convenient route) must surmount a series of formidable barriers: (1) The drug must be chemically stable in the highly acidic environment of the stomach and must not be degraded by digestive enzymes; (2) it must be absorbed from the gastrointestinal tract into the bloodstream, that is, it must pass through several cell membranes; (3) it must not bind too tightly to other substances in the body (e.g., lipophilic substances tend to be absorbed by certain plasma proteins and by fat tissue); (4) it must survive derivatization by the battery of enzymes, mainly in the liver, that detoxify **xenobiotics** (foreign compounds; note that the intestinal blood flow drains directly into the liver via the portal vein so that the liver processes all orally ingested substances before they reach the rest of the body); (5) it must avoid rapid excretion by the kidneys; (6) it must pass from the capillaries to its target tissue; (7) if it is targeted to the brain, it must cross the **blood-brain barrier**, which blocks the passage of most polar substances; and (8) if it is targeted to an intracellular protein, it must pass through the plasma membrane and possibly one or more intracellular membranes.

The ways in which a drug interacts with the barriers listed above are known as its **pharmacokinetics**. Thus, the **bioavailability** of a drug (the extent to which it reaches its site of action, which is usually taken to be the systemic circulation) depends on both the dose given and its pharmacokinetics. *The most effective drugs are usually a compromise; they are neither too lipophilic nor too hydrophilic.* In addition, their *pK* values are usually in the range 6 to 8 so that they can readily assume both their ionized and un-ionized forms at physiological pHs. This permits them to cross cell membranes in their un-ionized form and to bind to their target protein in their ionized form.

C Clinical Trials Test for Efficacy and Safety

Above all else, a successful drug candidate must be safe and efficacious in humans. Tests for these properties are initially carried out in animals, but since humans and animals often react quite differently to a drug, it must ultimately be

tested in humans through **clinical trials**. In the United States, clinical trials are monitored by the Food and Drug Administration (FDA) and have three increasingly detailed (and expensive) phases:

- Phase I.** This phase is primarily designed to test the safety of a drug candidate but is also used to determine its dosage range and the optimal dosage method (e.g., oral versus injected) and frequency. It is usually carried out on a small number (20–100) of normal, healthy volunteers, but in the case of a drug candidate known to be highly toxic (e.g., a cancer chemotherapeutic agent), it is carried out on volunteer patients with the target disease.
- Phase II.** This phase mainly tests the efficacy of the drug against the target disease in 100 to 500 volunteer patients but also refines the dosage range and checks for side effects. The effects of the drug candidate are usually assessed via **single-blind tests**, procedures in which the patient is unaware of whether he or she has received the drug or a control substance. Usually the control substance is a **placebo** (an inert substance with the same physical appearance, taste, etc., as the drug being tested) but, in the case of a life-threatening disease, it is an ethical necessity that the control substance be the best available treatment against the disease.
- Phase III.** This phase monitors adverse reactions from long-term use as well as confirming efficacy in 1000 to 5000 patients. It pits the drug candidate against control substances through the statistical analysis of carefully designed **double-blind tests**, procedures in which neither the patients nor the clinical investigators know whether a given patient has received the drug or a control substance. This is done to minimize bias in the subjective judgments the investigators must make.

Currently, only about 5 drug candidates in 5000 that enter preclinical trials reach clinical trials. Of these, only one, on average, is ultimately approved for clinical use, with the majority failing in Phase I trials. In recent years, the preclinical portion of a drug discovery process has averaged ~3 years to complete, whereas successful clinical trials have usually required an additional 7 to 10 years. These successive stages of the drug discovery process are increasingly expensive so that successfully bringing a drug to market costs, on average, around \$300 million.

The most time-consuming and expensive aspect of a drug development program is identifying a drug candidate's rare adverse reactions. Nevertheless, it is not an uncommon experience for a drug to be brought to market only to be withdrawn some months or years later when it is found to have caused unanticipated life-threatening side effects in as few as 1 in 10,000 individuals (the post-marketing surveillance of a drug is known as its Phase IV clinical trial). For example, in 1997, the FDA withdrew its approval of the drug **fenfluramine** (**fen**; *at right*), which it had approved in 1973 for use as an appetite suppressant in short-term (a few weeks) weight-loss programs. Fenfluramine had become widely prescribed, often for extended periods, together with another appetite suppressant, **phentermine** (**phen**; approved in 1959; *at left*), a combination known as **fen-phen** (although the FDA had not approved of the use of the two drugs in combination, once it approves a drug for some purpose, a physician may prescribe it for any other purpose). The withdrawal of fenfluramine was prompted by more than 100 reports of heart valve damage in individuals (mostly women) who had taken fen-phen for an average of 12 months (phentermine was not withdrawn because the evidence indicated that fenfluramine was the responsible agent). This rare side effect had not been observed in the clinical

Fenfluramine

Phentermine

trials of fenfluramine, in part because it is such an unusual type of drug reaction that it had not been screened for.

More recently (2004), the widely prescribed analgesic **Vioxx** was withdrawn from use due to its previously undetected cardiac side effects, although the closely related analgesic **Celebrex** remains available (Section 20-6C). The diabetes drug **rosiglitazone** (**Avandia**), which is associated with an increased risk of heart attack and stroke, likewise illustrates the failure of clinical trials to detect small increases in relatively common diseases, particularly when patients (e.g., diabetics) are already ill.

D Cytochromes P450 Are Often Implicated in Adverse Drug Reactions

Why is it that a drug that is well tolerated by the majority of patients can pose a danger to others? *Differences in reactions to drugs arise from genetic differences among individuals as well as differences in their disease states, other drugs they are taking, age, sex, and environmental factors.* The **cytochromes P450**, which function in large part to detoxify xenobiotics and which participate in the metabolic clearance of the majority of drugs in use, provide instructive examples of these phenomena.

The cytochromes P450 constitute a superfamily of heme-containing enzymes that occur in nearly all living organisms, from bacteria to mammals [their name arises from the characteristic 450-nm peak in their absorption spectra when reacted in their Fe(II) state with CO]. The human genome encodes 57 isozymes of cytochrome P450, around one-third of which occur in the liver (P450 isozymes are named by the letters “CYP” followed by a number designating its family, an uppercase letter designating its subfamily, and often another number; e.g., **CYP3A4**). These **monooxygenases** (Fig. 12-20), which in animals are embedded in the endoplasmic reticulum membrane, catalyze reactions of the sort

The electrons (e^-) are supplied by NADPH, which passes them to cytochrome P450's heme prosthetic group via the intermediacy of the enzyme **NADPH-P450 reductase**. Here RH represents a wide variety of usually lipophilic compounds for which the different cytochromes P450 are specific. They include polycyclic aromatic hydrocarbons [PAHs; frequently carcinogenic (cancer-causing) compounds that are present in tobacco smoke, broiled meats, and other pyrolysis products], polycyclic biphenyls (PCBs; which were widely used in electrical insulators and as plasticizers and are also carcinogenic), steroids (in whose syntheses cytochromes P450 participate), and many different types of drugs. The xenobiotics are thereby converted to a more water-soluble form, which aids in their excretion by the kidneys. Moreover, the newly generated hydroxyl groups are often enzymatically conjugated (covalently linked) to polar substances such as glucuronic acid (Section 8-1C), glycine, sulfate, and acetate, which further enhances aqueous solubility. The many types of cytochromes P450 in animals, which have different substrate specificities (although these specificities tend to be broad and hence often overlap), are thought to have arisen in response to the numerous toxins that plants produce, presumably to discourage animals from eating them (other P450s function to catalyze specific biosynthetic reactions).

Drug–drug interactions are often mediated by cytochromes P450. For example, if drug A is metabolized by or otherwise inhibits a cytochrome P450 isozyme that also metabolizes drug B, then coadministering drugs A and B will cause the bioavailability of drug B to increase above the value it would have had if it alone had been administered. This phenomenon is of particular concern if drug B has a low **therapeutic index** (the ratio of the dose of the drug that produces toxicity to that which produces the desired effect). Conversely, if, as is often the case, drug A induces the increased

FIG. 12-20 X-Ray structure of the human cytochrome P450 CYP2C9 in complex with the blood clotting inhibitor warfarin (Coumadin). A cutaway diagram of the enzyme's active site region drawn with its surface purple and with its polypeptide backbone in ribbon form colored in rainbow order from N-terminus (blue) to C-terminus (red). The heme (seen edgewise), the Cys side chain that axially ligands the heme Fe atom, and the warfarin are shown in ball-and-stick form with C gray, N blue, O red, S yellow, and Fe orange.

expression of the cytochrome P450 isozyme that metabolizes it and drug B, then coadministering drugs A and B will reduce drug B's bioavailability, a phenomenon that was first noted when certain antibiotics caused oral contraceptives to lose their efficacy. Moreover, if drug B is metabolized to a toxic product, its increased rate of reaction may result in an adverse reaction. Environmental pollutants such as PAHs and PCBs are also known to induce the expression of specific cytochrome P450 isozymes and thereby alter the rates at which certain drugs are metabolized. Finally, some of these same effects may occur in patients with liver disease, as well as arising from age-based, gender-based, and individual differences in liver physiology.

Although many cytochromes P450 presumably evolved to detoxify and/or help eliminate harmful substances, in several cases they have been shown to participate in converting relatively innocuous compounds to toxic agents. For example, **acetaminophen**, a widely used analgesic and antipyretic (fever reducer) is quite safe when taken in therapeutic doses (1.2 g/day for an adult) but in large doses (>10 g) is highly toxic. This is because, in therapeutic amounts, 95% of the acetaminophen present is enzymatically glucuronidated or sulfated at its —OH group to the corresponding conjugates, which are readily excreted. The remaining 5% is converted, through the action of a cytochrome P450 (**CYP2E1**), to **acetimidoquinone** (Fig. 12-21), which is then conjugated with glutathione (Section 4-3B). However, when acetaminophen is taken in large amounts, the glucuronidation and sulfation pathways become saturated and hence the cytochrome P450-mediated pathway becomes increasingly important. If hepatic (liver) glutathione is depleted faster than it can be replaced, acetimidoquinone, a reactive compound, instead conjugates with

FIG. 12-21 The metabolic reactions of acetaminophen. An overdose of acetaminophen leads to the buildup of acetimidoquinone, which is toxic.

the sulfhydryl groups of cellular proteins, resulting in often fatal hepatotoxicity. Indeed, acetaminophen overdose is the leading cause of acute liver failure in the United States; ~450 people die from it annually.

Certain drugs may be used to inhibit a cytochrome P450 that degrades another drug, thereby increasing the bioavailability of the latter drug. For example, ritonavir (Box 12-3), which was originally developed as an HIV protease inhibitor, is now only rarely used in that capacity. Instead, it is administered in low doses to specifically inhibit CYP3A4, which has permitted the co-administration of lower doses of other HIV protease inhibitors, such as darunavir (Box 12-3), that are degraded by CYP3A4. This has significantly increased the efficacy of these other HIV protease inhibitors while greatly decreasing their side effects.

Many of the cytochromes P450 in humans are unusually **polymorphic**; that is, there are several common alleles (variants) of the genes encoding each of these enzymes in the human population. Alleles that cause diminished, enhanced, and qualitatively altered rates of drug metabolism have been characterized for many of the cytochromes P450. The distributions of these various alleles differs markedly among ethnic groups and hence probably arose to permit each group to cope with the toxins in its particular diet.

Polymorphism in a given cytochrome P450 results in differences between individuals in the rates at which they metabolize certain drugs. For instance, in individuals in whom a cytochrome P450 variant has absent or diminished activity, otherwise standard doses of a drug that the enzyme normally metabolizes may cause the bioavailability of the drug to reach toxic levels. Conversely, if a particular P450 enzyme has enhanced activity (usually because the gene encoding it has been duplicated one or more times), higher than normal doses of a drug that the enzyme metabolizes would have to be administered to obtain the required therapeutic effect. However, if the drug is metabolized to a toxic product, this may result in an adverse reaction. Several known P450 variants have altered substrate specificities and hence produce unusual metabolites, which also may cause harmful side effects.

Experience has amply demonstrated that *there is no such thing as a drug that is entirely free of adverse reactions*. However, as the enzymes and their variants that participate in drug metabolism are characterized and as rapid and inexpensive genotyping methods are developed, it is becoming possible to tailor drug treatment to an individual's genetic makeup rather than to the population as a whole. This rapidly developing area of study is called **pharmacogenomics**.

CHECKPOINT

- Compare structure-based drug design and combinatorial chemistry as tools for developing drug candidates.
- List the factors that influence a drug's bioavailability.
- Summarize the purpose of phases I through III of a clinical trial.
- How does cytochrome P450 participate in drug metabolism?
- Indicate how drugs that are well tolerated by the majority of the population cause adverse reactions in certain individuals.

Summary

1 Reaction Kinetics

- Elementary chemical reactions may be first order, second order, or, rarely, third order. In each case, a rate equation describes the progress of the reaction as a function of time.
- The Michaelis–Menten equation describes the relationship between initial reaction velocity and substrate concentration under steady state conditions.
- K_M is the substrate concentration at which the reaction velocity is half-maximal. The value of k_{cat}/K_M indicates an enzyme's catalytic efficiency.
- Kinetic data can be plotted in double-reciprocal form to determine K_M and V_{max} .
- Bisubstrate reactions are classified as sequential (single displacement) or Ping Pong (double displacement). A sequential reaction may proceed by an Ordered or Random mechanism.

2 Enzyme Inhibition

- Reversible inhibitors reduce an enzyme's activity by binding to the substrate-binding site (competitive inhibition), to the enzyme–substrate

complex (uncompetitive inhibition), or to both the enzyme and the enzyme–substrate complex (mixed inhibition).

3 Control of Enzyme Activity

- Enzyme activity may be controlled by allosteric effectors.
- The activity of ATCase is increased by ATP and decreased by CTP, which alter the conformation of the catalytic sites by stabilizing the R and the T states of the enzyme, respectively.
- Enzyme activity may be controlled by covalent modification.
- The enzymatic activity of glycogen phosphorylase is controlled by its phosphorylation/dephosphorylation as well as by the influence of allosteric effectors.

4 Drug Design

- An enzyme inhibitor can be developed for use as a drug through structure-based and/or combinatorial methods. It must then be tested for safety and efficacy in clinical trials.
- Adverse reactions to drugs and drug–drug interactions are often mediated by a cytochrome P450.

Problems

EXERCISES

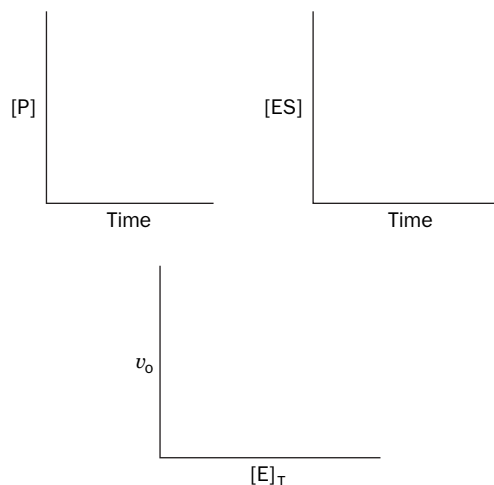

- Consider the nonenzymatic elementary reaction $A \rightarrow B$. When the concentration of A is 20 mM, the reaction velocity is measured as 5 μM B produced per minute. (a) Calculate the rate constant for this reaction. (b) What is the molecularity of the reaction?
- The hypothetical elementary reaction $2A \rightarrow B + C$ has a rate constant of $10^{-6} \text{ M}^{-1} \cdot \text{s}^{-1}$. What is the reaction velocity when the concentration of A is 10 mM?
- If there is 10 μmol of the radioactive isotope ^{32}P (half-life 14 days) at $t = 0$, how much ^{32}P will remain at (a) 7 days, (b) 14 days, (c) 21 days, and (d) 70 days?
- Calculate the half-life, in years, for the reaction $2X \rightarrow Y$ when the starting concentration of X is 6 μM and the rate constant is $3.6 \times 10^{-3} \text{ M}^{-1} \cdot \text{s}^{-1}$.
- From the reaction data below, determine whether the reaction is first order or second order and calculate the rate constant.

Time (s)	Reactant (mM)
0	6.2
1	3.1
2	2.1
3	1.6
4	1.3
5	1.1

- From the reaction data below, determine whether the reaction is first order or second order and calculate the rate constant.

Time (s)	Reactant (mM)
0	5.4
1	4.6
2	3.9
3	3.2
4	2.7
5	2.3

- For an enzymatic reaction, draw curves that show the appropriate relationships between the variables in each plot below.

- Explain why it is usually easier to calculate an enzyme's reaction velocity from the rate of appearance of product rather than the rate of disappearance of a substrate.
- At what concentration of S (expressed as a multiple of K_M) will $v_o = 0.95 V_{max}$?
- Identify the enzymes in Table 12-1 whose catalytic efficiencies are near the diffusion-controlled limit.
- Calculate K_M and V_{max} from the following data:

[S] (μM)	v_o ($\text{mM} \cdot \text{s}^{-1}$)
0.1	0.34
0.2	0.53
0.4	0.74
0.8	0.91
1.6	1.04

12. Explain why each of the following data sets from a Lineweaver–Burk plot are not individually ideal for determining K_M for an enzyme-catalyzed reaction that follows Michaelis–Menten kinetics.

Set A	1/[S] (mM ⁻¹)	1/ v_o ($\mu\text{M}^{-1} \cdot \text{s}$)
	0.5	2.4
	1.0	2.6
	1.5	2.9
	2.0	3.1

Set B	1/[S] (mM ⁻¹)	1/ v_o ($\mu\text{M}^{-1} \cdot \text{s}$)
	8	5.9
	10	6.8
	12	7.8
	14	8.7

13. The K_M for the reaction of chymotrypsin with *N*-acetylvaline ethyl ester is 8.8×10^{-2} M, and the K_M for the reaction of chymotrypsin with *N*-acetyltyrosine ethyl ester is 6.6×10^{-4} M. (a) Which substrate has the higher apparent affinity for the enzyme? (b) Which substrate is likely to give a higher value for V_{\max} ?

14. Enzyme A catalyzes the reaction $S \rightarrow P$ and has a K_M of 50 μM and a V_{\max} of 100 $\text{nM} \cdot \text{s}^{-1}$. Enzyme B catalyzes the reaction $S \rightarrow Q$ and has a K_M of 5 mM and a V_{\max} of 120 $\text{nM} \cdot \text{s}^{-1}$. When 100 μM of S is added to a mixture containing equivalent amounts of enzymes A and B, after 1 minute which reaction product will be more abundant: P or Q?

15. In a bisubstrate reaction, a small amount of the first product P is isotopically labeled (P^*) and added to the enzyme and the first substrate A. No B or Q is present. Will A ($= P-X$) become isotopically labeled (A^*) if the reaction follows a Ping Pong mechanism?

16. In a bisubstrate reaction, a small amount of the first product P is isotopically labeled (P^*) and added to the enzyme and the first substrate A. No B or Q is present. Will A ($= P-X$) become isotopically labeled (A^*) if the reaction follows a Sequential mechanism?

17. How would diisopropylphosphofluoridate (DIPF; Section 11-5A) affect the apparent K_M and V_{\max} of a sample of chymotrypsin?

18. Molecule A is the substrate for enzyme X. Which is more likely to be a competitive inhibitor of enzyme X: molecule B or molecule C? Explain.

19. Determine the type of inhibition of an enzymatic reaction from the following data collected in the presence and absence of the inhibitor.

[S] (mM)	v_o (mM \cdot min ⁻¹)	v_o with I present (mM \cdot min ⁻¹)
1	1.3	0.8
2	2.0	1.2
4	2.8	1.7
8	3.6	2.2
12	4.0	2.4

20. Estimate K_I for a competitive inhibitor when $[I] = 5$ mM gives an apparent value of K_M that is three times the K_M for the uninhibited reaction.

CHALLENGE QUESTIONS

21. Is it necessary for measurements of reaction velocity to be expressed in units of concentration per time ($\text{M} \cdot \text{s}^{-1}$, for example) to calculate an enzyme's K_M ?

22. Is it necessary to know $[E]_T$ to determine (a) K_M , (b) V_{\max} , or (c) k_{cat} ?

23. You are trying to determine the K_M for an enzyme. Due to a lab mishap, you have only two usable data points:

Substrate concentration (μM)	Reaction velocity ($\mu\text{M} \cdot \text{s}^{-1}$)
1	5
100	50

Use these data to calculate an approximate value for K_M . Is this value likely to be an overestimate or an underestimate of the true value? Explain.

24. You are attempting to determine K_M by measuring the reaction velocity at different substrate concentrations, but you do not realize that the substrate tends to precipitate under the experimental conditions you have chosen. How would this affect your measurement of K_M ?

25. You are constructing a velocity versus [substrate] curve for an enzyme whose K_M is believed to be about 2 μM . The enzyme concentration is 200 nM and the substrate concentrations range from 0.1 μM to 10 μM . What is wrong with this experimental setup and how could you fix it?

26. Enzyme X and enzyme Y catalyze the same reaction and exhibit the v_o versus [S] curves shown below. Which enzyme is more efficient at low [S]? Which is more efficient at high [S]?

27. Based on some preliminary measurements, you suspect that a sample of enzyme contains an irreversible enzyme inhibitor. You decide to dilute the sample 100-fold and remeasure the enzyme's activity. What would your results show if an irreversible inhibitor is present?

28. For the same enzyme sample described in Problem 27, what would your results show if a reversible inhibitor is present?

29. For an enzyme-catalyzed reaction, the presence of 5 nM of a reversible inhibitor yields a V_{\max} value that is 80% of the value in the absence of the inhibitor. The K_M value is unchanged. (a) What type of inhibition is likely occurring? (b) What proportion of the enzyme molecules have bound inhibitor? (c) Calculate the inhibition constant.

30. Sphingosine-1-phosphate (S1P) is important for cell survival. The synthesis of S1P from sphingosine and ATP is catalyzed by the enzyme sphingosine kinase. An understanding of the kinetics of the sphingosine kinase reaction may be important in the development of drugs to treat

cancer. The velocity of the sphingosine kinase reaction was measured in the presence and absence of *threo*-sphingosine, a stereoisomer of sphingosine that inhibits the enzyme. The results are shown below.

[Sphingosine] (μM)	v_o ($\text{mg} \cdot \text{min}^{-1}$) (no inhibitor)	v_o ($\text{mg} \cdot \text{min}^{-1}$) (with <i>threo</i> -sphingosine)
2.5	32.3	8.5
3.5	40	11.5
5	50.8	14.6
10	72	25.4
20	87.7	43.9
50	115.4	70.8

Construct a Lineweaver–Burk plot to answer the following questions:

(a) What are the apparent K_M and V_{max} values in the presence and absence of the inhibitor?

(b) What kind of an inhibitor is *threo*-sphingosine? Explain.

31. Ethanol in the body is oxidized to acetaldehyde (CH_3CHO) by liver alcohol dehydrogenase (LADH). Other alcohols are also oxidized by LADH. For example, methanol CH_3OH , which is mildly intoxicating, is oxidized by LADH to the quite toxic product formaldehyde (CH_2O). The toxic effects of ingesting methanol (a component of many commercial solvents) can be reduced by administering ethanol. The ethanol acts as a competitive inhibitor of the methanol by displacing it from LADH. This provides sufficient time for the methanol to be harmlessly excreted by the kidneys. If an individual has ingested 100 mL of methanol (a lethal dose), how much 100 proof whiskey (50% ethanol by volume) must he imbibe to reduce the activity of his LADH toward methanol to 5% of its original value? The adult human body contains ~40 L of aqueous fluids throughout which ingested alcohols are rapidly and uniformly mixed. The densities of ethanol and methanol are both $0.79 \text{ g} \cdot \text{cm}^{-3}$. Assume the K_M values of LADH for ethanol and methanol to be $1.0 \times 10^{-3} \text{ M}$ and $1.0 \times 10^{-2} \text{ M}$, respectively, and that $K_1 = K_M$ for ethanol.

32. Why are uncompetitive and mixed inhibitors generally considered to be more effective *in vivo* than competitive inhibitors?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Enzyme Cofactors and Kinetics

Exercise 2 Survey of Enzyme–Inhibitor Complexes

Extended Exercises Bioinformatic projects are available on the book companion site (www.wiley.com/college/voet), as well as in WileyPLUS Learning Space.

Project 6 Enzyme Inhibitors and Rational Drug Design

- Dihydrofolate Reductase.** Examine the structure of an enzyme with an inhibitor bound to it.
- HIV Protease.** Compare the structures of complexes containing HIV protease and an inhibitor.
- Pharmacogenomics and Single Nucleotide Polymorphisms.** Use online databases to find information on cytochrome P450 polymorphisms.

Project 7 Enzyme Commission Classes and Catalytic Site Alignments with PyMOL

- The Enzyme Commission and IUPAC classification of enzymes.** Discover the systematic nature of enzyme classification, brought to you by the same organization (IUPAC) that determines systematic nomenclature for organic molecules.
- Exploring the Catalytic Site Atlas.** The Catalytic Site Atlas is an annotated database of enzyme active sites. You'll learn to find the active sites of enzymes that you learn about in class.
- Active Site Alignment in PyMOL using the ProMOL plug-in.** The combination of the PyMOL molecular graphics environment and the ProMOL plug-in for PyMOL will enable you to study and align the catalytic sites of many different enzymes.

CASE STUDIES www.wiley.com/college/voet

Case 7 A Storage Protein from Seeds of *Brassica nigra* Is a Serine Protease Inhibitor

Focus concept: Purification of a novel seed storage protein allows sequence analysis and determination of the protein's secondary and tertiary structure.

Prerequisites: Chapters 5, 11, and 12

- Protein purification techniques, particularly gel filtration and dialysis
- Protein sequencing using Edman degradation and overlapping peptides
- Structure and mechanism of serine proteases
- Reversible inhibition of enzymes

Case 12 Production of Methanol in Ripening Fruit

Focus concept: The link between the production of methanol in ripening fruit and the activity of pectin methylesterase, the enzyme responsible for methanol production, is examined in wild-type and transgenic tomato fruit.

Prerequisite: Chapter 12

- Enzyme kinetics and inhibition

Case 13 Inhibition of Alcohol Dehydrogenase

Focus concept: The inhibition of alcohol dehydrogenase by a formamide compound is examined.

Prerequisite: Chapter 12

- Principles of enzyme kinetics
- Identification of inhibition via Lineweaver–Burk plots

Case 15 Site-Directed Mutagenesis of Creatine Kinase

Focus concept: Site-directed mutagenesis is used to create mutant creatine kinase enzymes so that the role of a single reactive cysteine in binding and catalysis can be assessed.

Prerequisites: Chapters 4, 6, 11, and 12

- Amino acid structure
- Protein architecture
- Enzyme kinetics and inhibition
- Basic enzyme mechanisms

Case 19 Purification of Rat Kidney Sphingosine Kinase

Focus concept: The purification and kinetic analysis of an enzyme that produces a product important in cell survival is the focus of this study.

Prerequisites: Chapters 5 and 12

- Protein purification techniques and protein analytical methods
- Basic enzyme kinetics

MORE TO EXPLORE What kind of inhibitor is warfarin (shown in Fig. 12-20) and what enzyme does it inhibit? What is the physiological goal of warfarin therapy? Why do individuals vary in their response to a standard dose of warfarin? Why can a patient's genotypic information help a physician choose an effective dose?

CHAPTER 13

Biochemical Signaling

Chapter Contents

1 Hormones

- A Pancreatic Islet Hormones Control Fuel Metabolism
- B Epinephrine and Norepinephrine Prepare the Body for Action
- C Steroid Hormones Regulate a Wide Variety of Metabolic and Sexual Processes
- D Growth Hormone Binds to Receptors in Muscle, Bone, and Cartilage

2 Receptor Tyrosine Kinases

- A Receptor Tyrosine Kinases Transmit Signals across the Cell Membrane
- B Kinase Cascades Relay Signals to the Nucleus
- C Some Receptors Are Associated with Nonreceptor Tyrosine Kinases
- D Protein Phosphatases Are Signaling Proteins in Their Own Right

3 Heterotrimeric G Proteins

- A G-Protein–Coupled Receptors Contain Seven Transmembrane Helices
- B Heterotrimeric G Proteins Dissociate on Activation
- C Adenylate Cyclase Synthesizes cAMP to Activate Protein Kinase A
- D Phosphodiesterases Limit Second Messenger Activity

4 The Phosphoinositide Pathway

- A Ligand Binding Results in the Cytoplasmic Release of the Second Messengers IP_3 and Ca^{2+}
- B Calmodulin is a Ca^{2+} -Activated Switch
- C DAG is a Lipid-Soluble Second Messenger that Activates Protein Kinase C
- D Epilog: Complex Systems Have Emergent Properties

Martin Harvey/Getty Images

Vanillin, an odorant extracted from vanilla beans and other sources, binds to receptors on olfactory neurons and triggers a series of intracellular events, including heterotrimeric G protein activation and second messenger production, that ultimately generate an electronic signal to the brain.

Living things coordinate their activities at every level of their organization through complex biochemical signaling systems. Intercellular signals are mediated by chemical messengers known as **hormones** and, in higher animals, by neuronally transmitted electrochemical impulses. Intracellular communications are maintained by the synthesis or alteration of a great variety of different substances that are often integral components of the processes they control. For example, metabolic pathways, as we have seen (Section 12-3), are regulated by the feedback control of allosteric enzymes by metabolites in those pathways or by the covalent modification of the enzymes. In this chapter we consider the nature of chemical signals and how the signals are transmitted.

*In general, every signaling pathway consists of a **receptor protein** that specifically binds a hormone or other ligand, a mechanism for transmitting the ligand-binding event to the cell interior, and a series of intracellular responses that may involve the synthesis of a **second messenger** and/or chemical changes catalyzed by **kinases** and **phosphatases**. These pathways often involve **enzyme cascades**, in which a succession of events amplifies the signal.*

We begin by discussing the functions of some representative human hormone systems. We then discuss the three major pathways whereby intercellular signals are converted (transduced) to intracellular signals: those that (1) involve receptor tyrosine kinases, (2) utilize heterotrimeric G proteins, and (3) employ phosphoinositide cascades. Neurotransmission is discussed in Section 10-2C.

1 Hormones

KEY CONCEPTS

- Endocrine hormones regulate a great variety of physiological processes.
- The pancreatic hormones insulin and glucagon help control fuel metabolism.
- Catecholamines produced by the adrenal medulla bind to α - and β -adrenergic receptors on target cells.
- Steroid hormones regulate fuel metabolism, salt and water balance, and sexual differentiation and function.
- Growth hormone exerts its effects by inducing dimerization of its receptor.

In higher animals, specialized ductless **endocrine glands** (Fig. 13-1) synthesize **endocrine hormones** that are released into the bloodstream in response to external stimuli. These hormones are thereby carried to their target cells (Fig. 13-2) in which they elicit a response. The human endocrine system secretes a wide variety of hormones that enable the body to:

1. Maintain **homeostasis** (a steady state; e.g., insulin and glucagon maintain the blood glucose level within rigid limits during feast or famine).
2. Respond to a wide variety of external stimuli (such as the preparation for “fight or flight” by epinephrine and norepinephrine).
3. Follow various cyclic and developmental programs (for instance, sex hormones regulate sexual differentiation, maturation, the menstrual cycle, and pregnancy).

Most hormones are either polypeptides, amino acid derivatives, or steroids, although there are important exceptions to this generalization. In any case, *only cells with a specific receptor for a given hormone will respond to its presence even though nearly all cells in the body may be exposed to the hormone.* Hormonal messages are therefore quite specifically addressed.

Although we discuss specific hormones and their function in many other chapters, in this section we outline the activities of hormones produced by some representative endocrine glands. These glands are not just a collection of independent secretory organs but also form a complex and highly interdependent

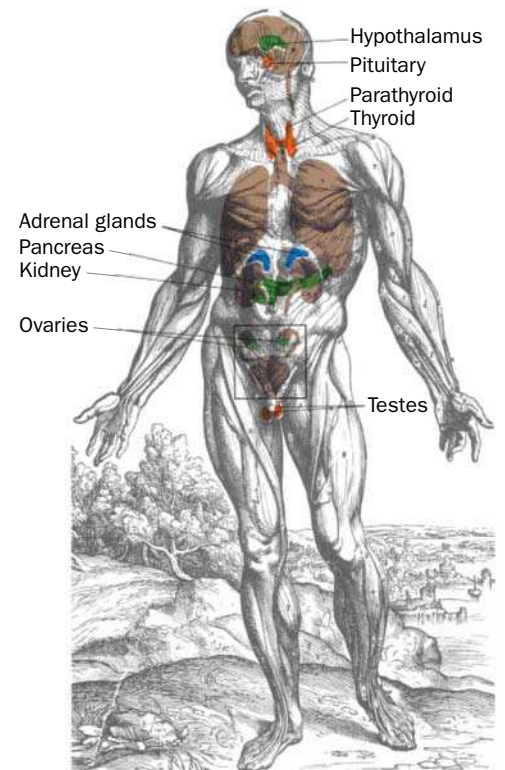

FIG. 13-1 The major glands of the human endocrine system. Other tissues, such as the intestines, also secrete endocrine hormones.

FIG. 13-2 Endocrine signaling. Hormones produced by endocrine cells reach their target cells via the bloodstream. Only cells that display the appropriate receptors can respond to the hormones.

Rosalyn Yalow (1921–2011) Rosalyn Sussman Yalow was born on July 19, 1921, in New York City. Neither of her parents had the advantage of a high school education but there was never a doubt that their two children would make it through college. While Rosalyn was at Hunter College, the college for women in New York City's college system (now the City University of New York), Eve Curie had just published the biography of her mother, Madame Marie Curie, a “must-read”

for every aspiring female scientist. Rosalyn's goal at that time was achieving a career in physics. Despite suggestions from her family that becoming an elementary school teacher would be more practical, she persisted.

In 1941, after graduating from college, Yalow received an offer of a teaching assistantship in physics at the University of Illinois in Champaign–Urbana. At the first meeting of the faculty of the College of Engineering, she discovered that she was the only woman among its 400 members. The dean of the faculty congratulated her on her achievement and told her she was the first woman there since 1917. The draft of young men into the armed forces, even before America entered World War II, had made possible her entrance into graduate school. On the first day of graduate school she met Aaron Yalow, who was also beginning graduate study in physics at Illinois and who, in 1943, was to become her husband.

In January 1945, Yalow received a Ph.D. in nuclear physics and returned to New York as assistant engineer at the Federal Telecommunications Laboratory—its only woman engineer. In 1946, she returned to Hunter College to teach physics, not to women but to returning veterans in a preengineering program. During that time she became interested in the medical aspects of radioisotopes. She joined the Bronx Veterans Administration (VA) as a part-time consultant in December 1947. Even while teaching full-time at Hunter, she equipped and developed the Radioisotope Service at the VA hospital and initiated a variety of research projects with several physicians. In January 1950, Yalow chose to leave

teaching and join the VA full time. That spring, Dr. Solomon A. Berson joined the Service and began a 22-year partnership that lasted until his death in 1972.

In their joint studies, Yalow and Berson concentrated on the application of isotopes to clinical problems such as hormone analysis. At the time, insulin was the hormone most readily available in a highly purified form. In studying the reaction of insulin with antibodies, Yalow and Berson recognized that they had a tool with the potential for measuring the concentration of insulin in a complex mixture such as blood. By 1959, they had developed a practical method for quantifying insulin in human plasma, the **radioimmunoassay (RIA)**. RIA is now used to measure hundreds of substances of biological interest.

The serum concentrations of insulin and other hormones are extremely low, generally between 10^{-12} and 10^{-7} M, so they usually must be measured by indirect means. In RIAs, the unknown concentration of a hormone, H, is determined by measuring how much of a known amount of the radioactively labeled hormone, H*, binds to a fixed quantity of anti-H antibody in the presence of H. This competition reaction is easily calibrated by constructing a standard curve indicating how much H* binds to the antibody as a function of [H]. The high binding affinity and specificity of antibodies for their ligands gives RIAs the advantages of great sensitivity and specificity.

By 1977, Yalow's hospital was affiliated with the Mount Sinai School of Medicine, and Yalow held the title of Distinguished Service Professor. She was a member of the National Academy of Sciences and was a recipient of numerous awards and honors, including the 1977 Nobel Prize in Physiology or Medicine (Berson died before this Nobel prize was awarded and so could not share the prize) and the 1988 National Medal of Science. “The excitement of learning separates youth from old age,” Rosalyn Yalow has said. “As long as you're learning, you're not old.”*

Mostly abridged from Rosalyn Yalow's autobiography, *Les Prix Nobel. The Nobel Prizes 1977*, Wilhelm Odelberg (Ed.), Nobel Foundation, 1978.

control network. Indeed, the secretion of many hormones is under feedback control through the secretion of other hormones to which the original hormone-secreting gland responds. The concentrations of circulating hormones are typically measured using the radioimmunoassay developed by Rosalyn Yalow (Box 13-1).

A Pancreatic Islet Hormones Control Fuel Metabolism

The pancreas is a large glandular organ, the bulk of which is an **exocrine gland** dedicated to producing digestive enzymes—such as trypsin, chymotrypsin, RNase A, α -amylase, and phospholipase A₂—that are secreted via the pancreatic duct into the small intestine. However, ~1 to 2% of pancreatic tissue consists of scattered clumps of cells known as **islets of Langerhans**, which comprise an endocrine gland that functions to maintain energy homeostasis. Pancreatic islets contain three types of cells, each of which secretes a characteristic polypeptide hormone:

1. The α cells secrete **glucagon** (29 residues).
2. The β cells secrete insulin (51 residues; Fig. 5-1).
3. The δ cells secrete **somatostatin** (14 residues).

Insulin, which is secreted in response to high blood glucose levels, primarily functions to stimulate muscle, liver, and adipose cells to store glucose for later use by synthesizing glycogen, protein, and fat (Section 22-2). Glucagon, which is

secreted in response to low blood glucose, has essentially the opposite effects: It stimulates the liver to release glucose through the breakdown of glycogen (**glycogenolysis**; Section 16-1) and the synthesis of glucose from noncarbohydrate precursors (**gluconeogenesis**, Section 16-4). It also stimulates adipose tissue to release fatty acids through lipolysis. Somatostatin, which is also secreted by the hypothalamus, inhibits the release of insulin and glucagon from their islet cells.

Polypeptide hormones, like other proteins destined for secretion, are ribosomally synthesized as prohormones, processed in the rough endoplasmic reticulum and Golgi apparatus to form the mature hormones, and then packaged in secretory granules to await the signal for their release by exocytosis (Sections 9-4D-F). The most potent physiological stimuli for the release of insulin and glucagon are, respectively, high and low blood glucose concentrations so that islet cells act as the body's primary glucose sensors. However, the release of the hormones is also influenced by the autonomic (involuntary) nervous system and by hormones secreted by the gastrointestinal tract.

B Epinephrine and Norepinephrine Prepare the Body for Action

The **adrenal glands** consist of two distinct types of tissue: the **medulla** (core), which is really an extension of the sympathetic nervous system (a part of the autonomic nervous system), and the more typically glandular **cortex** (outer layer). Here we consider the hormones of the adrenal medulla; those of the cortex are discussed in the following section.

The adrenal medulla synthesizes two hormonally active **catecholamines** (amine-containing derivatives of **catechol**, 1,2-dihydroxybenzene): **norepinephrine (noradrenalin)** and its methyl derivative **epinephrine (adrenalin; at right)**. These hormones are synthesized from tyrosine as is described in Section 21-6B and are stored in granules to await their exocytotic release under the control of the sympathetic nervous system.

The biological effects of catecholamines are mediated by two classes of plasma membrane receptors, the α - and β -**adrenergic receptors** (also known as **adrenoreceptors**). These transmembrane glycoproteins were originally identified on the basis of their varying responses to certain **agonists** (substances that bind to a receptor so as to evoke a response) and **antagonists** (substances that bind to a receptor but fail to elicit a response, thereby blocking agonist action). The β - but not the α -adrenergic receptors, for example, are stimulated by **isoproterenol** but blocked by **propranolol**, whereas α - but not β -adrenergic receptors are blocked by **phentolamine**.

R = H **Norepinephrine (noradrenalin)**
R = CH₃ **Epinephrine (adrenalin)**

The α - and β -adrenergic receptors, which occur on separate tissues in mammals, generally respond differently and often oppositely to catecholamines. For instance, β -adrenergic receptors stimulate glycogenolysis and gluconeogenesis in liver (Sections 16-1 and 16-4), glycogenolysis in skeletal muscle, lipolysis in adipose tissue, the relaxation of smooth (involuntary) muscle in the bronchi and

in the blood vessels supplying the skeletal (voluntary) muscles, and increased heart action. In contrast, α -adrenergic receptors stimulate smooth muscle contraction in blood vessels supplying peripheral organs such as skin and kidney, smooth muscle relaxation in the gastrointestinal tract, and blood platelet aggregation. *Most of these diverse effects are directed toward a common end: the mobilization of energy resources and their shunting to where they are most needed to prepare the body for action.*

The tissue distributions of the α - and β -adrenergic receptors and their varying responses to different agonists and antagonists have important therapeutic consequences. For example, propranolol is used to treat high blood pressure and protects against heart attacks, whereas epinephrine's bronchodilator effects make it clinically useful in the treatment of **asthma**, a breathing disorder caused by the inappropriate contraction of bronchial smooth muscle.

C Steroid Hormones Regulate a Wide Variety of Metabolic and Sexual Processes

*The adrenal cortex produces at least 50 different **adrenocortical steroids**.* These have been classified according to the physiological responses they evoke (Section 9-1E):

1. The **glucocorticoids** affect carbohydrate, protein, and lipid metabolism in a manner nearly opposite to that of insulin and influence a wide variety of other vital functions, including inflammatory reactions and the capacity to cope with stress.
2. The **mineralocorticoids** largely function to regulate the excretion of salt and water by the kidneys.
3. The **androgens** and **estrogens** affect sexual development and function. They are made in larger quantities by the gonads.

Glucocorticoids, the most common of which is **cortisol** (also known as **hydrocortisone**), and the mineralocorticoids, the most common of which is **aldosterone**, are all C_{21} compounds (Fig. 9-11).

Steroids, being water insoluble, are transported in the blood in complex with the glycoprotein **transcortin** and, to a lesser extent, with albumin. The steroids spontaneously pass through the membranes of their target cells to the cytosol, where they bind to their cognate **steroid receptors**. The steroid–receptor complexes then migrate to the cell nucleus, where they function as transcription factors to induce, or in some cases repress, the transcription of specific genes (Section 28-3B). In this way, the glucocorticoids and the mineralocorticoids influence the expression of numerous metabolic enzymes in their respective target tissues. Thyroid hormones, which are also nonpolar, function similarly. However, as we will see in the following sections, other hormones that are not lipid-soluble must bind to receptors on the cell surface in order to trigger complex cascades of events within cells that ultimately influence transcription as well as other cellular processes.

Gonadal Steroids Mediate Sexual Development and Function. *The gonads (testes in males, ovaries in females), in addition to producing sperm or ova, secrete steroid hormones (androgens and estrogens) that regulate sexual differentiation, the expression of secondary sex characteristics, and sexual behavior patterns.* Although testes and ovaries both synthesize androgens and estrogens, the testes predominantly secrete androgens, which are therefore known as **male sex hormones**, whereas ovaries produce mostly estrogens, which are consequently termed **female sex hormones**.

Androgens, of which **testosterone** (Fig. 9-11) is prototypic, lack the C_2 substituent at C_{17} that occurs in glucocorticoids and are therefore C_{19} compounds. Estrogens, such as **β -estradiol** (Fig. 9-11), resemble androgens but are

C_{18} compounds. Interestingly, testosterone is an intermediate in estrogen biosynthesis. Another class of ovarian steroids, C_{21} compounds called **progestins**, help mediate the menstrual cycle and pregnancy.

Androgens play a key role in sexual differentiation. If the gonads of an embryonic male mammal are surgically removed, that individual will become a phenotypic female. Evidently, *mammals are programmed to develop as females unless embryonically subjected to the influence of testicular hormones*. Indeed, genetic males with absent or nonfunctional cytosolic androgen receptors are phenotypic females, a condition named **testicular feminization**. Curiously, estrogens appear to play no part in embryonic female sexual development, although they are essential for female sexual maturation and function.

Androgens that promote muscle growth are known as **anabolic steroids**.

Many individuals have taken anabolic steroids, both natural and synthetic, in an effort to enhance their athletic performance or for cosmetic reasons. However, because these substances and their metabolic products interact with the various steroid receptors, their use may cause adverse side effects, including cardiovascular disease, the development of breast tissue in males, masculinization in females, temporary infertility in both sexes, and, in adolescents, stunted growth due to accelerated bone maturation and precocious and/or exaggerated sexual development. Consequently, anabolic steroids have been classified as controlled substances. Their use by competitive athletes has been banned to prevent an unfair advantage over athletes not taking steroids.

D Growth Hormone Binds to Receptors in Muscle, Bone, and Cartilage

Growth hormone (GH), a 191-residue polypeptide, is produced by the anterior lobe of the pituitary gland. Its binding to receptors directly stimulates growth and metabolism in muscle, bone, and cartilage cells. GH also acts indirectly by stimulating the liver to produce additional growth factors.

Overproduction of GH, usually a consequence of a pituitary tumor, results in excessive growth. If this condition commences while the skeleton is still growing—that is, before its growth plates have ossified—then this excessive growth is of normal proportions over the entire body, resulting in **gigantism**. Moreover, since excessive GH inhibits the testosterone production necessary for growth plate ossification, such “giants” continue growing throughout their abnormally short lives. If, however, the skeleton has already matured, GH stimulates only the growth of soft tissues, resulting in enlarged hands and feet and thickened facial features, a condition named **acromegaly**. The opposite problem, GH deficiency, which results in insufficient growth (**dwarfism**), can be treated before skeletal maturity by regular injections of human GH (**hGH**; animal GH is ineffective in humans).

Since hGH was, at first, available only from the pituitaries of cadavers, it was in very short supply. Now, however, hGH can be synthesized in virtually unlimited amounts via recombinant DNA techniques (Section 3-5D). Indeed, hGH has been taken by individuals to increase their athletic prowess, although there is no clear evidence that it does so. However, because of its adverse side effects, which include high blood pressure, joint and muscle pain, and acromegaly, as well as to eliminate any unfair competitive advantages in athletes, its nonmedical use is prohibited.

The GH Receptor Dimer Binds a Hormone. The 620-residue GH receptor is a member of a large family of structurally related proteins. These receptor proteins consist of an N-terminal extracellular ligand-binding domain, a single transmembrane segment that is almost certainly helical, and a C-terminal cytoplasmic domain that is not homologous within the superfamily but in many cases functions as a tyrosine kinase (Section 13-2A).

The X-ray structure of hGH in complex with the extracellular domain of its binding protein (**hGHbp**) reveals that the complex consists of two molecules of

GATEWAY CONCEPT Ligand Binding

A hormone binds to its receptor with high affinity and high specificity (much like a substrate binding to an enzyme's active site), but the binding interactions are noncovalent and therefore reversible. Consequently, the cell responds to the hormone only while the hormone remains associated with its receptor.

FIG. 13-3 X-Ray structure of human growth hormone (hGH) in complex with two molecules of its receptor's extracellular domain (hGHbp).

The proteins are shown in ribbon form, with the hGH magenta and the two hGHbp molecules, which together bind one molecule of hGH, each colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The dotted red lines indicate how the hGHbp chains likely penetrate the membrane (*light blue*). [Based on an X-ray structure by Abraham de Vos and Anthony Kossiakoff, Genentech Inc., South San Francisco, California. PDBid 3HHR.]

CHECKPOINT

- Explain why only certain cells respond to hormones even though all cells in the body are exposed to the hormone.
- List some hormones produced by the pancreas, adrenal medulla, and adrenal cortex. What types of molecules are these hormones?
- Summarize the biological effects of insulin, glucagon, norepinephrine, androgens, estrogens, and growth hormone.
- How do receptors respond to agonists and antagonists?
- Why are some hormone receptors intracellular proteins?
- What are some dangers of nonmedical use of steroids and growth hormone?
- What is the significance of conformational changes in the GH receptor?

hGHbp bound to a single hGH molecule (**Fig. 13-3**). hGH, like many other protein growth factors, consists largely of a four-helix bundle. Each hGHbp molecule consists of two structurally homologous domains, each of which forms a topologically identical sandwich of a three- and a four-stranded antiparallel β sheet that resembles the immunoglobulin fold (Section 7-3B).

The two hGHbp molecules bind to hGH with near twofold symmetry about an axis that is roughly perpendicular to the helical axes of the hGH four-helix bundle and, presumably, to the plane of the cell membrane to which the intact hGH receptor is anchored (Fig. 13-3). The C-terminal domains of the two hGHbp molecules are almost parallel and in contact with one another. Intriguingly, the two hGHbp molecules use essentially the same residues to bind to sites that are on opposite sides of hGH's four-helix bundle and which have no structural similarity.

Ligand binding to the extracellular domains of the receptor induces conformational changes in the intracellular portions of the protein, the first step in signal transduction. Although early models of growth hormone action proposed that ligand binding induces the dimerization of the receptor polypeptides, it has recently been shown that, in the absence of hormone, the hGH receptor forms inactive dimers through relatively weak interactions between its transmembrane segments. The binding of hGH to the receptor's two identical extracellular domains triggers structural rearrangements, including the rotation and splaying (scissoring) of intracellular domains that positions them to interact with cytosolic effector proteins. Numerous other protein growth factors exert their effects through similar receptors.

2 Receptor Tyrosine Kinases

KEY CONCEPTS

- Dimerization and autophosphorylation allow receptor tyrosine kinases to become active as protein tyrosine kinases.
- Adaptor proteins containing SH2 and SH3 domains can link a receptor tyrosine kinase with G proteins and additional kinases that operate as a cascade.
- Some receptors act via associated nonreceptor tyrosine kinases.
- Protein phosphatases participate in signaling pathways by removing phosphoryl groups from receptors and target proteins.

We have seen (Section 12-3B) that the activities of many enzymes are controlled by their covalent modification, mainly the phosphorylation of Ser and Thr residues. A similar process forms the basis of one of the major intracellular signaling

systems, the ATP-dependent phosphorylation of Tyr side chains by **protein tyrosine kinases (PTKs; at right)**:

Phospho-Tyr residues mediate protein–protein interactions that are involved in numerous cell functions. Consequently, the PTKs play a central role in signal transduction, regulation of central metabolic pathways, cell cycle control, and cell growth and differentiation. In this section, we discuss the proteins that participate in this signaling system and how their activities are orchestrated to transmit signals within the cell.

A Receptor Tyrosine Kinases Transmit Signals across the Cell Membrane

The first step in all biochemical signaling pathways is the binding of an agonist to its receptor protein. Box 13-2 discusses how receptor–ligand interactions are quantitated. Insulin and many other polypeptide growth factors bind to receptors whose C-terminal domains have tyrosine kinase activity. Such **receptor tyrosine kinases (RTKs)** typically contain only a single transmembrane segment and are monomers or loosely associated dimers in the unliganded state. These structural features make it unlikely that ligand binding to an extracellular domain manifests itself as a dramatic conformational change in an intracellular domain (such a conformational shift seems more likely to occur in receptors with multiple transmembrane segments). Instead, a plausible mechanism for activating RTKs appears to be ligand-induced dimerization of receptor proteins to form homodimers or heterodimers. Alternatively, pre-existing receptor dimers may undergo a scissors-like repositioning of their transmembrane segments, as is the case for the growth hormone receptor (Fig. 13-3), although it lacks tyrosine kinase activity. The **insulin receptor** is a dimer in its unliganded state. In this case, ligand binding apparently induces a conformational change in the receptor that activates its tyrosine kinase activity.

Autophosphorylation Activates Receptor Tyrosine Kinases. When an RTK dimerizes or its conformation changes on ligand binding, its cytoplasmic protein tyrosine kinase (PTK) domains are brought close together so that they cross-phosphorylate each other on specific Tyr residues. *This autophosphorylation activates the PTK so that it can phosphorylate other protein substrates.* Let us see how this occurs with the insulin receptor.

The insulin receptor is a dimer of $\alpha\beta$ protomers. Each protomer is synthesized as a single 1382-residue precursor peptide that is proteolytically processed to yield its 731-residue α subunit, which is entirely extracellular, and its 620-residue β subunit, which consists of a PTK domain on its cytoplasmic side that is linked to its extracellular domain via a single transmembrane helix. The α and β subunits within each protomer are disulfide-linked as are the receptor's two α subunits.

The X-ray structure of the insulin receptor's extracellular portion, its **ectodomain** (Greek: *ektos*, outside) (Fig. 13-4), reveals that each of its two $\alpha\beta$ protomers adopt a folded-over conformation to form a V-shaped dimer. The positions of the dimeric receptor's two insulin binding sites, inferred from a variety of evidence, are too far apart for a single insulin molecule to simultaneously bind to both of them (as occurs in the binding of human growth hormone to its receptor; Fig. 13-3). This suggests that the binding of insulin induces a conformational change in the insulin receptor's ectodomain that brings the two arms of the V closer together, thereby dragging their attached cytoplasmic PTK domains in close enough proximity for them to phosphorylate one another.

FIG. 13-4 X-Ray structure of the insulin receptor ectodomain. One of its $\alpha\beta$ protomers is shown in ribbon form with its six domains successively colored in rainbow order with the N-terminal domain blue and the C-terminal domain red. The other protomer is represented by its identically colored surface diagram. The β subunits consist of most of the orange and all of the red domains. The protein is viewed with the plasma membrane below and its twofold axis vertical. In the intact receptor, a single transmembrane helix connects each β subunit to its C-terminal cytoplasmic PTK domain. Hormone signaling by the receptor tyrosine kinase system

Receptors, like other proteins, bind their corresponding ligands according to the laws of mass action:

Here R and L represent receptor and ligand, and the reaction's dissociation constant is expressed:

$$K_L = \frac{[R][L]}{[R \cdot L]} = \frac{([R]_T - [R \cdot L])[L]}{[R \cdot L]} \quad [13-1]$$

where the total receptor concentration, $[R]_T$, is equal to $[R] + [R \cdot L]$. Equation 13-1 may be rearranged to a form analogous to the Michaelis–Menten equation of enzyme kinetics (Section 12-1B):

$$Y = \frac{[R \cdot L]}{[R]_T} = \frac{[L]}{K_L + [L]} \quad [13-2]$$

where Y is the fractional occupation of the ligand-binding sites. Equation 13-2 represents a hyperbolic curve (Fig. 1a) in which K_L may be operationally defined as the ligand concentration at which the receptor is half-maximally occupied by ligand.

Although K_L and $[R]_T$ may, in principle, be determined from an analysis of a hyperbolic plot such as Fig. 1a, the analysis of a linear form of the equation is a more common procedure. Equation 13-1 may be rearranged to

$$\frac{[R \cdot L]}{[L]} = \frac{([R]_T - [R \cdot L])}{K_L} \quad [13-3]$$

Now, in keeping with customary receptor-binding nomenclature, let us redefine $[R \cdot L]$ as B (for bound ligand), $[L]$ as F (for free ligand), and $[R]_T$ as B_{\max} . Then Eq. 13-3 becomes

$$\frac{B}{F} = \frac{(B_{\max} - B)}{K_L} \quad [13-4]$$

A plot of B/F versus B, which is known as a **Scatchard plot** (after George Scatchard, its originator), therefore yields a straight line of slope $-1/K_L$ whose intercept on the B axis is B_{\max} (Fig. 1b).

FIG. 1 The binding of ligand to receptor. (a) A hyperbolic plot. (b) A Scatchard plot. Here, $B = [R \cdot L]$, $F = [L]$, and $B_{\max} = [R]_T$.

Here, both B and F may be determined by filter-binding assays as follows. Most receptors are insoluble membrane-bound proteins and may therefore be separated from soluble free ligand by filtration (receptors that have been solubilized may be separated from free ligand by filtration, for example, through nitrocellulose since proteins nonspecifically bind to nitrocellulose). Hence, by using radioactively labeled ligand, the values of B and F ($[R \cdot L]$ and $[L]$) may be determined, respectively, from the radioactivity on the filter and that remaining in solution. The rate of $R \cdot L$ dissociation is generally so slow (half-times of minutes to hours) as to cause insignificant errors when the filter is washed to remove residual free ligand.

Once the receptor-binding parameters for one ligand have been determined, the dissociation constant of other ligands for the same ligand-binding site may be determined through competitive binding studies. The model describing this competitive binding is analogous to the competitive inhibition of a Michaelis–Menten enzyme (Section 12-2A):

where I is the competing ligand whose dissociation constant with the receptor is expressed:

$$K_I = \frac{[R][I]}{[R \cdot I]} \quad [13-5]$$

Thus, in direct analogy with the derivation of the equation describing competitive inhibition (Section 12-2A):

$$[R \cdot L] = \frac{[R]_T[I]}{K_L \left(1 + \frac{[I]}{K_I}\right) + [L]} \quad [13-6]$$

The relative affinities of a ligand and an inhibitor may therefore be determined by dividing Eq. 13-6 in the presence of inhibitor with that in the absence of inhibitor:

$$\frac{[R \cdot L]_i}{[R \cdot L]_o} = \frac{K_L + [L]}{K_L \left(1 + \frac{[I]}{K_I}\right) + [L]} \quad [13-7]$$

When this ratio is 0.5 (50% inhibition), the competitor concentration is referred to as $[I_{50}]$. Thus, solving Eq. 13-7 for K_I at 50% inhibition:

$$K_I = \frac{[I_{50}]}{1 + \frac{[L]}{K_L}} \quad [13-8]$$

The X-ray structure of the β subunit's 306-residue PTK domain (Fig. 13-5a) reveals a deeply clefted bilobal protein whose N-terminal domain consists of a five-stranded β sheet and an α helix, and whose larger C-terminal domain is mainly α -helical. This structure, as we will repeatedly see, is typical of the large family of protein kinases, enzymes that phosphorylate the OH groups of Tyr

FIG. 13-5 X-Ray structure of the tyrosine kinase domain of the insulin receptor. (a) The tyrosine kinase domain is shown in the “standard” protein kinase orientation with its N-terminal domain lavender, its C-terminal domain cyan, and its activation loop light blue. Three phosphorylated Tyr side chains are shown in ball-and-stick form with C green, N blue, O red, and P yellow. The ATP analog AMPPNP is shown in space-filling form. Six residues of the substrate polypeptide are shown in orange, and its phosphorylatable Tyr residue is shown in magenta. (b) The polypeptide backbones of the phosphorylated and unphosphorylated forms of the insulin receptor tyrosine kinase domain

are shown superimposed on their C-terminal lobes. The phosphorylated protein is green with its activation loop blue, and the unphosphorylated protein is yellow with its activation loop red. The cyan arrow and black axis indicate the rotation required to align the two N-terminal lobes. [Part a based on an X-ray structure by and Part b courtesy of Stevan Hubbard, New York University Medical School. PDBids 1IR3 and 1IRK.]

? Explain why phosphorylation might cause the red protein loop in Part b to change its conformation.

residues and/or Ser and Thr residues. Indeed, the human genome encodes 90 PTKs and 388 protein Ser/Thr kinases (representing >2% of human genes) that collectively phosphorylate an estimated one-third of the proteins in human cells. In doing so, they play key roles in the signaling pathways by which many hormones, growth factors, neurotransmitters, and toxins affect the functions of their target cells.

How does autophosphorylation activate the PTK activity of the insulin receptor? In the X-ray structure of the insulin receptor PTK domain (Fig. 13-5a), the nonhydrolyzable ATP analog **adenosine-5'-(β,γ -imido)triphosphate (AMPPNP; at right; alternatively ADPNP)**, is bound in the cleft between the protein domains. There, its γ -phosphate group is in close juxtaposition to the OH group of the target Tyr residue in a substrate peptide that is also bound to the protein. Three of the PTK's Tyr residues, which are located on the C-terminal domain in its so-called activation loop, are phosphorylated. In its unphosphorylated state, the 18-residue activation loop threads through the PTK active site so as to prevent the binding of both ATP and protein substrates. When the three Tyr residues are phosphorylated, the activation loop changes its conformation such that it does not occlude the active site (Fig. 13-5b) but instead forms part of the substrate recognition site. In fact, the PTK activity of the insulin receptor increases with the degree of phosphorylation of its three autophosphorylatable Tyr residues.

The conformational changes in PTK induced by phosphorylation and ligand binding are depicted in Fig. 13-5b. The PTK's N-terminal lobe undergoes a nearly rigid 21° rotation relative to the C-terminal lobe, a dramatic conformational change that presumably positions critical residues for substrate binding and catalysis.

Adenosine-5'-(β,γ -imido)triphosphate (AMPPNP)

Nearly all known PTKs have between one and three autophosphorylatable Tyr residues in their activation loops, which assume similar conformations in all phosphorylated PTKs of known structure. Moreover, many activated PTKs also phosphorylate the opposing RTK at cytoplasmic Tyr residues outside of the PTK domain. The specificity of PTKs for phosphorylating Tyr rather than Ser or Thr is explained by the observation that the side chain of Tyr, but not those of Ser or Thr, is long enough to reach the active site.

B Kinase Cascades Relay Signals to the Nucleus

Although certain autophosphorylated RTKs directly phosphorylate their ultimate target proteins, many do not do so. How, then, are these target proteins activated? The answer, as we will see, is through a highly diverse and complicated set of interconnected signaling pathways involving cascades of associating proteins.

SH2 Domains Bind Phospho-Tyr Residues. The main substrates of the insulin receptor tyrosine kinase are known as **insulin receptor substrates 1 and 2 (IRS-1 and IRS-2)**. When phosphorylated, these proteins can interact with yet another set of proteins that contain one or two conserved ~100-residue modules known as **Src homology 2 (SH2) domains** [because they are similar to the sequence of a domain in the protein named **Src** (pronounced “sarc”)]. SH2 domains bind phospho-Tyr residues with high affinity but do not bind the far more abundant phospho-Ser and phospho-Thr residues. This specificity has a simple explanation. X-Ray structural studies reveal that phospho-Tyr interacts with an Arg at the bottom of a deep pocket (**Fig. 13-6**). The side chains of Ser and Thr are too short to interact with this residue.

The SH2-containing proteins that interact with the IRSs and other phosphorylated proteins have varied functions: Some are kinases, some are phosphatases, and some are GTP-binding proteins known as **G proteins** (G proteins also play a key role in non-RTK signaling pathways, as described in Section 13-3). Consequently, hormone binding to its RTK can elicit a variety of intracellular responses.

RTKs Indirectly Activate the G Protein Ras. Molecular genetic analysis of signaling in a variety of distantly related organisms revealed a remarkably conserved pathway that regulates such essential functions as cell growth and differentiation. Briefly, growth factor binding to its cognate RTK activates a monomeric G protein named **Ras**, the prototypic member of a superfamily of monomeric G proteins that, in humans, consists of 150 members. Ras is anchored to the inner surface of the plasma membrane by prenylation (Section 9-3B). Activated Ras initiates a **kinase cascade** that relays the signal to the transcriptional apparatus in the nucleus.

The binding of a growth factor to its RTK leads to autophosphorylation of the RTK, which then interacts with an SH2-containing protein (**Fig. 13-7, top left**). Many proteins that contain SH2 domains also have one or more unrelated 50- to 75-residue **SH3 domains**. SH3 domains, which bind Pro-rich sequences of

FIG. 13-6 X-Ray structure of the Src SH2 domain in complex with a target peptide. The protein is represented by its ribbon diagram colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) and embedded in its semitransparent surface diagram. An 11-residue polypeptide containing the protein's phospho-Tyr-Glu-Glu-Ile (pYEEI) target tetrapeptide is drawn in space-filling form with backbone C cyan, side chain C green, N blue, O red, and P orange. The side chain of SH2 Arg 32, which interacts with the phosphoryl group of the peptide phospho-Tyr (pTyr) residue, is drawn in stick form. [Based on an X-ray structure by John Kuriyan, The Rockefeller University. PDBid 1SPS.]

? Draw the structures of phospho-Thr and phospho-Ser and compare them to phospho-Tyr.

PROCESS DIAGRAM

FIG. 13-7 The Ras signaling cascade. RTK binding to its cognate growth factor (1) induces the autophosphorylation of the RTK's cytosolic domain (2). Grb2/Sem-5 binds to the resulting phospho-Tyr-containing peptide segment via its SH2 domain (3) and simultaneously binds to Pro-rich segments on Sos via its two SH3 domains (4). This activates Sos to exchange Ras's bound GDP for GTP (5), which activates Ras to bind to Raf (6). Then, in a so-called kinase cascade, Raf, a Ser/Thr kinase, phosphorylates MEK (7), which in turn phosphorylates MAPK

(8), which then migrates to the nucleus (9), where it phosphorylates transcription factors such as Fos, Jun, and Myc (10), thereby modulating gene expression. Ras is eventually inactivated by GTP hydrolysis (11), a process that is accelerated by GTPase-activating proteins (GAPs). The kinase cascade eventually returns to its resting state through the action of protein phosphatases (Section 13-2D). [After Egan, S.E. and Weinberg, R.A., *Nature* 365, 782 (1993).] **WPLS See the Animated Process Diagrams.**

? Indicate the steps at which signal amplification occurs.

FIG. 13-8 X-Ray structure of the SH3 domain from Abl protein in complex with its 10-residue target Pro-rich polypeptide (APTMPPLPP). The protein is represented by its surface diagram (cyan) and the peptide is drawn in stick form with Pro C magenta, other C green, N blue, O red, and S yellow. [Based on an X-ray structure by Andrea Musacchio, European Molecular Biology Laboratory, Heidelberg, Germany. PDBid 1ABO.]

9 or 10 residues (Fig. 13-8), are also present in some proteins that lack SH2 domains. In the signaling cascade shown in Fig. 13-7, the mammalian protein known as **Grb2** (**Sem-5** in the nematode worm *Caenorhabditis elegans*) consists almost entirely of an SH2 domain flanked by two SH3 domains (Fig. 13-9). Grb2/Sem-5 links the autophosphorylated RTK (via its SH2 domain) to the Pro-rich **Sos protein** (via its SH3 domains).

Inactive Ras has GDP bound in its nucleotide-binding site. The Grb2–Sos complex activates Ras by inducing it to release its bound GDP and replace it with GTP. *Only the Ras · GTP complex is capable of further relaying the growth-promoting signal from the RTK.* Ras tightly binds both GTP and GDP and hence must interact with Sos to exchange these nucleotides. Sos is therefore known as a **guanine nucleotide exchange factor (GEF)**. Most G proteins, as we will see, have a corresponding GEF.

The X-ray structure of Grb2 (Fig. 13-9) suggests that its SH2 domain is flexibly linked to its two SH3 domains. How does the binding of such a pliable **adaptor** (a linker that lacks enzymatic activity) to a phosphorylated RTK cause Sos to activate Ras? Grb2 and Sos bind one another so tightly that they are essentially permanently associated in the cell. Hence, when Grb2 binds to a phosphorylated RTK, it recruits Sos to the inner surface of the plasma membrane, where the increased local concentration of Sos causes it to more readily bind to the membrane-anchored Ras and thus act as a GEF.

GAPs Accelerate the GTPase Activities of G Proteins. Ras is an enzyme (a **GTPase**) that catalyzes the hydrolysis of its bound GTP to GDP + P_i, thereby limiting the magnitude of the cell's response to the growth factor. Yet Ras by itself hydrolyzes only two to three GTPs per minute, too slowly for effective signal transduction. Furthermore, for a signal to be more than a one-time switch, there must be a mechanism for turning it off as well as on. These considerations led to the discovery of a 120-kD **GTPase-activating protein (GAP)** named **RasGAP** that, on binding Ras · GTP, accelerates the rate of GTP hydrolysis by a factor of 10⁵. Most G proteins, like Ras, also have a corresponding GAP.

The mechanism whereby RasGAP activates the GTPase activity of Ras was revealed by the X-ray structure of the 334-residue GTPase-activating domain of RasGAP (GAP334) bound to Ras in its complex with GDP and AlF₃ (Fig. 13-10). GAP334 interacts with Ras over an extensive surface. The AlF₃, which has trigonal planar geometry, binds to Ras at the expected position of GTP's γ phosphate group, with the Al atom opposite a bound water molecule that presumably would be the attacking nucleophile in the GTPase reaction. Since Al—F and P—O bonds have similar lengths, the GDP–AlF₃–H₂O assembly resembles the GTPase reaction's expected transition state with the AlF₃ mimicking the planar PO₃ group.

FIG. 13-9 X-Ray structure of Grb2. Its SH2 domain (green) is linked to its flanking SH3 domains (cyan and orange) via apparently unstructured and hence flexible four-residue linkers. [Based on an X-ray structure by Arnaud Ducruix, Université de Paris-Sud, Gif sur Yvette Cedex, France. PDBid 1GRI.]

FIG. 13-10 X-Ray structure of the GAP334 · Ras · GDP · AIF₃ complex. The active site regions of the proteins are shown as ribbons with Ras cyan, its Gly 12 magenta, GAP334 yellow, and its finger loop red. The GDP, AIF₃, and the side chains of Ras Gln 61 and GAP334 Arg 789 are drawn in stick form with C green, N blue, O red, F yellow-green, P orange, and Al pink; the water molecule is represented by a red sphere; and hydrogen bonds are shown as dashed lines. [Based on an X-ray structure by Alfred Wittinghofer, Max-Planck-Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1WQ1.]

GAP334 binds to Ras with GAP334's so-called finger loop inserted into the Ras active site such that an Arg residue in the loop interacts with both the GDP's β phosphate and the AIF₃. In the Ras · GTP complex, this Arg side chain would be in an excellent position to stabilize the developing negative charge in the GTPase reaction's transition state. Indeed, catalytically more efficient G proteins contain an Arg residue that occupies a nearly identical position.

A Kinase Cascade Completes the Signaling Pathway. The signaling pathway downstream of Ras consists of a linear cascade of protein kinases (Fig. 13-7, *right*). The Ser/Thr kinase **Raf**, which is activated by direct interaction with Ras · GTP, phosphorylates a protein alternatively known as **MEK** or **MAP kinase kinase**, thereby activating it as a kinase. Activated MEK phosphorylates a family of proteins variously termed **mitogen-activated protein kinases (MAPKs)** or **extracellular-signal-regulated kinases (ERKs)**. A MAPK must be phosphorylated at both its Thr and Tyr residues in the sequence Thr-Glu-Tyr for full activity. MEK (which stands for *MAP kinase/ERK kinase-activating kinase*) catalyzes both phosphorylations; it is therefore a protein Ser/Thr kinase as well as a protein Tyr kinase.

The activated MAP kinases migrate from the cytosol to the nucleus, where they phosphorylate a variety of proteins, including **Fos**, **Jun**, and **Myc**. These latter proteins are **transcription factors** (proteins that induce the transcription of their target genes; Section 28-3B): In their activated forms they stimulate various genes to produce the effects commissioned by the extracellular presence of the growth factor that initiated the signaling cascade. When insulin activates the Ras signaling pathway, the result is an increase in protein synthesis that supports cell growth and differentiation, a response consistent with insulin's function as a signal of fuel abundance. Variant proteins encoded by

The growth and differentiation of cells in the body are normally strictly controlled. Thus, with few exceptions (e.g., blood-forming cells and hair follicles), cells in the adult body are largely quiescent. However, for a variety of reasons, a cell may be made to proliferate uncontrollably to form a tumor.

Malignant tumors (cancers) grow in an invasive manner and are almost invariably life threatening. They are responsible for 20% of the mortalities in the United States.

Among the many causes of cancer are viruses that carry **oncogenes** (Greek: *onkos*, mass or tumor). For example, the **Rous sarcoma virus (RSV)**, which induces the formation of **sarcomas** (cancers arising from connective tissues) in chickens, contains four genes. Three of the genes are essential for viral replication, whereas the fourth, **v-src** (v for viral, *src* for *sarcoma*), an oncogene, induces tumor formation. What is the origin of *v-src*, and how does it function? Hybridization studies by Michael Bishop and Harold Varmus in 1976 led to the remarkable discovery that uninfected chicken cells contain a gene, **c-src** (c for cellular), that is homologous to *v-src* and that is highly conserved in a wide variety of eukaryotes, suggesting that it is an essential cellular gene. Apparently, *v-src* was originally acquired from a cellular source by a non-tumor-forming ancestor of RSV. Both *v-src* and *c-src* encode

a 60-kD tyrosine kinase. However, whereas the activity of *c-src* is strictly regulated, that of *v-src* is under no such control and hence its presence maintains the host cell in a proliferative state. Since cells are not killed by an RSV infection, this presumably enhances the viral replication rate.

Other oncogenes have been similarly linked to processes that regulate cell growth. For example, the **v-erbB** oncogene specifies a truncated version of the **epidermal growth factor (EGF) receptor**, which lacks the EGF-binding domain but retains its transmembrane segment and its tyrosine kinase domain. This kinase phosphorylates its target proteins in the absence of an extracellular signal, thereby driving uncontrolled cell proliferation.

The **v-ras** (for *rat sarcoma*) oncogene encodes a 21-kD protein, **v-Ras**, that resembles cellular Ras but hydrolyzes GTP much more slowly. The reduced braking effect of GTP hydrolysis on the rate of protein phosphorylation leads to increased activation of the kinases downstream of Ras (Fig. 13-7).

The transcription factors that respond to Ras-mediated signaling (e.g., Fos and Jun) are also encoded by **proto-oncogenes**, the normal cellular analogs of oncogenes. The viral genes **v-fos** and **v-jun** encode proteins that are nearly identical to their cellular counterparts and mimic their effects on host cells but in an uncontrolled fashion.

Oncogenes are not necessarily of viral origin. Indeed, few human cancers are caused by viruses. Rather, they are caused by proto-oncogenes that have mutated to form oncogenes. For example, a mutation in the **c-ras** gene, which converts Gly 12 of Ras to Val, reduces Ras's GTPase activity without affecting its ability to stimulate protein phosphorylation. This prolongs the time that Ras is in the "on" state, thereby inducing uncontrolled cell proliferation. In fact, oncogenic variants of *c-ras* occur in ~30% of human solid tumors, making it among the most commonly implicated oncogenes in human cancers.

To date, over 350 viral and cellular oncogenes have been identified. The subversive effects of oncogene products arise through their differences from the corresponding normal cellular proteins: They may have different rates of synthesis and/or degradation; they may have altered cellular functions; or they may resist control by cellular regulatory mechanisms. However, in order for a normal cell to undergo a **malignant transformation** (become a cancer cell), it must undergo several (an average of five) independent oncogenic events. This is a reflection of the complexity of cellular signaling networks (cells respond to a variety of hormones, growth factors, and transcription factors in partially overlapping ways) and explains why the incidence of cancer increases with age. Nevertheless, at the cellular level, a malignant transformation is an extremely rare event because oncogenic mutations are infrequent and because cells have highly effective defense mechanisms that guard against cancer.

An X-ray-based false-color image showing an axial section through a human abdomen that has cancer of the liver. The liver is the large red mass occupying much of the abdomen; the light patches on the liver are cancerous tumors. A vertebra (*dark green*) can be seen at the lower center of the image.

oncogenes subvert such signaling pathways so as to induce uncontrolled cell growth (Box 13-3).

The advantage of a kinase cascade is that *a small signal can be amplified manyfold inside the cell*. In addition, phosphorylation of more than one target protein can lead to the simultaneous activation of several intracellular processes. Thus as we will see (Section 22-2), insulin signaling mediates changes in vesicle trafficking, enzyme activation, and gene expression.

Scaffold Proteins Organize and Position Protein Kinases. Eukaryotic cells contain numerous different MAPK signaling cascades, each with a characteristic set of component kinases, which in mammals comprise 14 MAP kinases, 7 MAP kinase kinases (MKKs; e.g., MEK), and 14 MAP kinase kinase kinases (MKKKs;

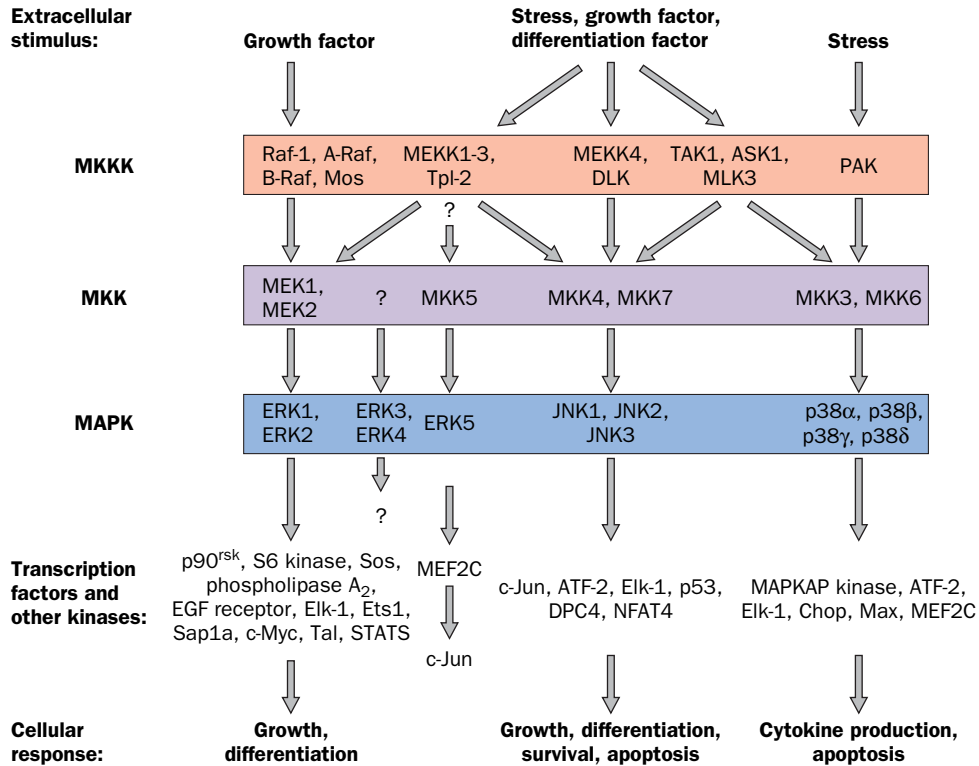

FIG. 13-11 MAP kinase cascades in mammalian cells. Each MAP kinase cascade consists of an MKKK, an MKK, and a MAPK. Various external stimuli may each activate one or more MKKKs, which in turn may activate one or more MKKs. However, the MKKs are relatively specific for their target MAPKs. The activated MAPKs phosphorylate specific transcription factors, which are then translocated to the nucleus, as well as specific kinases. The resulting activated transcription factors and kinases then induce cellular responses such as growth, differentiation, and **apoptosis** (programmed cell death; Section 28-4C). [After Garrington, T.P. and Johnson, G.L., *Curr. Opin. Cell Biol.* **11**, 212 (1999).]

e.g., Raf; Fig. 13-11). Although each MAPK is activated by a specific MKK, a given MKK can be activated by more than one MKKK. Moreover, several pathways may be activated by a single type of receptor. How then does a cell prevent inappropriate **crosstalk** between closely related signaling pathways? One way that this occurs is through the use of **scaffold proteins** that bind some or all of the component protein kinases of a particular signaling cascade so as to ensure that the protein kinases of a given pathway interact only with one another. In addition, scaffold proteins can properly orient and allosterically activate their associated kinases, can target them to specific subcellular locations, and in some cases are themselves subject to regulation by phosphorylation.

The first known scaffold protein was discovered through the genetic analysis of a MAP kinase cascade in yeast, which demonstrated that this protein, **Ste5p**, binds the MKKK, MKK, and MAPK components of the pathway and that, *in vivo*, the scaffold's absence inactivates the pathway. Mammals have a functionally similar although sequence-unrelated scaffold protein named **KSR** (for kinase suppressor of Ras). Evidently, the interactions between successive kinase components in MAP kinase cascades are, by themselves, insufficient for effective signal transmission.

C Some Receptors Are Associated with Nonreceptor Tyrosine Kinases

Many cell-surface receptors for growth factors and related molecules do not respond to ligand binding by autophosphorylation. These include the receptors for growth hormone (Fig. 13-3) and other **cytokines** (protein growth factors that regulate the differentiation, proliferation, and activities of numerous types of cells, most

conspicuously white blood cells), the **interferons** (protein growth factors that stimulate antiviral defenses), and **T cell receptors** [which control the proliferation of immune system cells known as T lymphocytes (T cells); Section 7-3]. *Ligand binding induces the dimers (both homo- and heterodimers, and in some cases, trimers) of these tyrosine kinase-associated receptors to change conformation in a way that activates their associated nonreceptor tyrosine kinases (NRTKs).*

The Structure of Src Reveals Its Autoinhibitory Mechanism. Many of the NRTKs belong to the **Src family**, which contains at least nine members, including Src, **Fyn**, and **Lck**. Most of these ~530-residue membrane-anchored (by myristoylation) proteins have both an SH2 and an SH3 domain and all have a PTK domain. Hence, a Src-related kinase may also be activated by an autophosphorylated RTK. Although Src-related kinases are each associated with different receptors, they phosphorylate overlapping sets of target proteins. This complex web of interactions explains why different ligands often activate some of the same signaling pathways.

Src consists of, from N- to C-terminus, a myristoylated N-terminal “unique” domain that differs among Src family members, an SH3 domain, an SH2 domain, a PTK domain, and a short C-terminal tail. Phosphorylation of Tyr 416 in the PTK’s activation loop activates Src, whereas phosphorylation of Tyr 527 in its C-terminal tail deactivates it. *In vivo*, Src is phosphorylated at either Tyr 416 or Tyr 527, but not at both. The dephosphorylation of Tyr 527 or the binding of external ligands to the SH2 or the SH3 domain activates Src, a state that is then maintained by the autophosphorylation of Tyr 416. When Tyr 527 is phosphorylated and no activating phosphopeptides are available, Src’s SH2 and SH3 domains function to deactivate its PTK domain; that is, Src is then autoinhibited.

The X-ray structure of Src · AMPPNP lacking its N-terminal domain and with Tyr 527 phosphorylated reveals the structural basis of Src autoinhibition (Fig. 13-12). As biochemical studies had previously shown, the SH2 domain binds phospho-Tyr 527, which occurs in the sequence pYNPG rather than the pYEEI sequence characteristic of high-affinity Src SH2 target peptides. Although the pYNP segment binds to SH2 as does the pYEE segment in Fig. 13-6, the succeeding residues are poorly ordered in the X-ray structure and, moreover, the SH2 pocket in which the Ile side chain of pYEEI binds is unoccupied. Apparently, the phospho-Tyr 527-containing peptide segment binds to the Src SH2 domain with reduced affinity relative to its target peptides.

The Src SH3 domain binds to the linker connecting the SH2 domain to the N-terminal lobe of the PTK domain. Residues 249 to 253 of the linker bind to the SH3 domain in much the same way as do SH3’s Pro-rich target peptides (Fig. 13-8). However, the only Pro in this segment is residue 250. The polar side chain of Gln 253, which occupies the position of the second Pro in SH3’s normal Pro-X-Pro target sequence, does not enter the hydrophobic binding pocket that this second Pro would occupy (Fig. 13-8) and hence the path of the peptide deviates from that of Pro-rich target peptides at this point. Apparently, this interaction is also weaker than those with Src’s SH3 target peptides.

Since Src’s SH2 and SH3 domains bind the PTK domain on the side opposite its active site, how is the PTK activity inhibited? The two lobes of Src’s PTK domain are, for the most part, closely superimposable on their counterparts in the PTK domains of phosphorylated and hence activated protein kinases (e.g., Fig. 13-5a). However, Src helix C (the only helix in the PTK’s N-terminal lobe) is displaced from the interface between the N- and C-terminal lobes, a position it occupies in other activated protein kinases (e.g., Fig. 13-5a). Helix C

FIG. 13-12 X-Ray structure of Src · AMPPNP with Tyr 527 phosphorylated. The protein, which lacks its membrane-anchored N-terminal domain, is oriented such that its PTK domain is seen in “standard” view (compare it with Fig. 13-5a). The SH3 domain is orange, the SH2 domain is magenta, the linker joining the SH2 domain to the PTK domain is green with residues 249 to 253, which interact with the SH3 domain, yellow, the N-terminal lobe of the PTK domain is lavender, its C-terminal lobe is cyan with its activation loop light blue, and its C-terminal tail is red. The AMPPNP is shown in space-filling form and Y416 (unphosphorylated) and pY527 (phosphorylated) are shown in ball-and-stick form, all with C green, N blue, O red, and P yellow. [Based on an X-ray structure by Stephen Harrison and Michael Eck, Harvard Medical School. PDBid 2SRC.]

contains the conserved residue Glu 310 (using Src numbering), which in other activated protein kinases projects into the catalytic cleft where it forms a salt bridge with Lys 295, an important ligand of the substrate ATP's α and β phosphates. In inactive Src, Glu 310 forms an alternative salt bridge with Arg 409, and Lys 295 instead interacts with Asp 404. In activated Src, Arg 409 forms a salt bridge with phospho-Tyr 416.

The foregoing structural observations suggest the following scenario for Src activation (Fig 13-13):

1. The dephosphorylation of Tyr 527 and/or the binding of the SH2 and/or SH3 domains to their target peptides (for which SH2 and SH3 have greater affinity than their internal Src-binding sites) releases these domains from their PTK-bound positions shown in Fig. 13-12, thus relaxing conformational constraints on the PTK domain. This allows the PTK's active site cleft to open, thereby disrupting the structure of its partially helical activation loop (which occupies a blocking position in the active site cleft; Fig. 13-12) so as to expose Tyr 416 to autophosphorylation.
2. The resulting phospho-Tyr 416 forms a salt bridge with Arg 409, which sterically requires the structural reorganization of the activation loop to its active, nonblocking conformation. The consequent rupture of the Glu 310–Arg 409 salt bridge frees helix C to assume its active orientation which, in turn, allows Glu 310 to form its catalytically important salt bridge to Lys 295, thereby activating the Src PTK activity.

FIG. 13-13 Schematic model of Src activation. In the autoinhibited form (*left*), the SH2 domain (*magenta*) binds to phospho-Tyr 527, and the SH3 domain (*orange*) binds to an internal Pro-containing segment (*yellow*). Glu 310 forms a salt bridge to Arg 409, the partially helical activation loop (*blue*) blocks the active site, and Tyr 416 is buried. In the active form (*right*), the SH2 and SH3 domains bind to a Src activator, Tyr 527 is dephosphorylated, the activation loop has undergone a conformational change to expose Tyr 416 to phosphorylation, Glu 310 forms a salt bridge with Lys 295, and phospho-Tyr 416 forms a salt bridge with Arg 409. The coloring scheme and viewpoint largely match those in Fig. 13-12. [After Young, M.A., Gonfloni, F., Superti-Furga, G., Roux, B., and Kuriyan, J., *Cell* **105**, 115 (2001).]

PTKs Are Targets of Anticancer Drugs. The hallmark of **chronic myelogenous leukemia (CML)** is a specific chromosomal translocation forming the so-called **Philadelphia chromosome** in which the *Abl* gene (which encodes the NRTK **Abl**) is fused with the *Bcr* gene (which encodes the protein Ser/Thr kinase **Bcr**). The Abl portion of the resulting Bcr–Abl fusion protein is constitutively activated (that is, continuously, without regulation), probably because its Bcr portion oligomerizes. Hematopoietic stem cells (from which all blood cells are descended) bearing the Philadelphia chromosome are therefore primed to develop CML (malignancy requires several independent genetic alterations; Box 13-3). Without a bone marrow transplant (a high-risk procedure that is unavailable to most individuals due to the lack of a suitable donor), CML is invariably fatal with an average survival time of ~6 years.

An inhibitor of Abl would be expected to prevent the proliferation of, and even kill, CML cells. However, to be an effective anti-CML agent, such a substance must not inhibit other protein kinases because this would almost certainly cause serious side effects. Derivatives of 2-phenylaminopyrimidine bind to Abl with exceptionally high affinity and specificity. One such derivative, **imatinib** (trade name **Gleevec**),

FIG. 13-14 X-Ray structure of the Abl PTK domain in complex with a truncated derivative of Gleevec. The protein is viewed from the right of the “standard” view of protein kinases (e.g., Figs. 13-5a and 13-12), with its N-terminal lobe lavender, its C-terminal lobe cyan, and its activation loop light blue. The truncated Gleevec, which occupies the PTK’s ATP-binding site, is shown in space-filling form with C green, N blue, and O red. [Based on an X-ray structure by John Kuriyan, The Rockefeller University. PDBid 1FPU.]

which was developed by Brian Druker and Nicholas Lydon, has caused the remission of symptoms in >90% of CML patients with almost no serious side effects. This unprecedented performance occurs, in part, because Gleevec does not bind to other protein kinases.

Abl resembles Src but lacks Src’s C-terminal regulatory phosphorylation site (Tyr 527; Figs. 13-12 and 13-13). The X-ray structure of Abl’s PTK domain in complex with a truncated form of Gleevec, determined by John Kuriyan (Fig. 13-14), reveals, as expected, that the drug binds in Abl’s ATP-binding site. Abl thereby adopts an inactive conformation in which its activation loop, which is not phosphorylated, assumes an autoinhibitory conformation.

Gleevec was the first of several 2-phenylaminopyrimidine derivatives, which inhibit specific protein kinases, to be approved by the FDA for clinical use against certain cancers. In addition, several monoclonal antibodies (Box 7-5) that bind to specific PTKs or their ligands are in clinical use as anticancer agents [e.g., **trastuzumab** (trade name **Herceptin**), which is effective against breast cancers that overexpress the RTK named **HER2**]. Such receptor-targeted therapies hold enormous promise for controlling, if not curing, cancers by specifically targeting the aberrant proteins that cause the cancers. In contrast, most chemotherapeutic agents that are presently in use indiscriminately kill fast-growing cells and hence tend to have debilitating side effects.

D Protein Phosphatases Are Signaling Proteins in Their Own Right

Intracellular signals must be “turned off” after the system has delivered its message so that the system can transmit future messages. In the case of protein kinases, their activities are balanced by the activities of **protein phosphatases** that hydrolyze the phosphoryl groups attached to Ser, Thr, or Tyr side chains and thereby limit the effects of the signal that activated the kinase. Although protein

kinases have traditionally garnered more attention, mammalian cells express ~500 protein phosphatases (about the same number as protein kinases) with substrate specificities comparable to those of kinases.

Protein Tyrosine Phosphatases Are Multidomain Proteins. The enzymes that dephosphorylate Tyr residues, the **protein tyrosine phosphatases (PTPs)**, are not just simple housekeeping enzymes but are important signal transducers. These enzymes, 107 of which are encoded by the human genome, are members of four families. Each tyrosine phosphatase contains at least one conserved ~240-residue phosphatase domain that has the 11-residue signature sequence [(I/V)HCXAGXGR(S/T)G], the so-called CX₅R motif, which contains the enzyme's catalytically essential Cys and Arg residues. During the hydrolysis reaction, the phosphoryl group is transferred from the tyrosyl residue of the substrate protein to the essential Cys on the enzyme, forming a covalent Cys–phosphate intermediate that is subsequently hydrolyzed.

Some tyrosine phosphatases are constructed much like the receptor tyrosine kinases; that is, they have an extracellular domain, a single transmembrane helix, and a cytoplasmic domain consisting of a catalytically active PTP domain that, in most cases, is followed by a second PTP domain with little or no catalytic activity. These inactive PTP domains are, nevertheless, highly conserved, which suggests that they have an important although as yet unknown function. Biochemical and structural analyses indicate that ligand-induced dimerization of a receptor-like PTP reduces its catalytic activity, probably by blocking its active sites.

A second group of PTPs, intracellular PTPs, contain only one tyrosine phosphatase domain, which is flanked by regions containing motifs, such as SH2 domains, that participate in protein–protein interactions. The PTP known as **SHP-2**, which is expressed in all mammalian cells, binds to a variety of phosphorylated (that is, ligand-activated) RTKs. The X-ray structure of SHP-2 lacking its C-terminal tail reveals two SH2 domains, followed by a tyrosine phosphatase domain (**Fig. 13-15**). The N-terminal SH2 domain (N-SH2) functions as an autoinhibitor by inserting a protein loop (labeled D'E in Fig. 13-15) into the PTP's 9-Å-deep catalytic cleft. When N-SH2 recognizes and binds a phospho-Tyr group on a substrate protein, its conformation changes, unmasking the PTP catalytic site so that the phosphatase can hydrolyze another phospho-Tyr group on the target protein (activated RTKs typically bear multiple phosphorylated Tyr residues).

The active site cleft of intracellular tyrosine phosphatases such as SHP-2 is too deep to cleave phospho-Ser/Thr side chains. However, the active site pockets of a third group of PTPs, the so-called **dual-specificity tyrosine phosphatases**, are sufficiently shallow to bind both phospho-Tyr and phospho-Ser/Thr residues.

FIG. 13-15 X-Ray structure of the protein tyrosine phosphatase SHP-2. Its N-SH2 domain is gold with its D'E loop red, its C-SH2 domain is green, and its PTP domain is cyan with its 11-residue CX₅R motif blue. The side chain of the catalytically essential Cys residue is shown in ball-and-stick form with C green and S yellow. [Based on an X-ray structure by Michael Eck and Steven Shoelson, Harvard Medical School. PDBid 2SHP.]

Bubonic Plague Virulence Requires a PTP. Bacteria lack PTKs and hence do not synthesize phospho-Tyr residues. Nevertheless, PTPs are expressed by bacteria of the genus *Yersinia*, most notably *Yersinia pestis*, the pathogen that causes **bubonic plague** (the flea-transmitted “Black Death,” which, since the sixth century, has been responsible for an estimated 200 million human deaths, including about one-third of the European population in the years 1347–1350). The *Y. pestis* PTP, **YopH**, which is required for bacterial virulence, is far more catalytically active than other known PTPs. Hence, when *Yersinia* injects YopH into a cell, the cell’s phospho-Tyr-containing proteins are catastrophically dephosphorylated. Although YopH and mammalian PTPs are only ~15% identical in sequence, they share a set of invariant residues and have similar X-ray structures. This suggests that an ancestral *Yersinia* acquired a PTP gene from a eukaryote.

Protein Ser/Thr Phosphatases Participate in Numerous Regulatory Processes. The **protein Ser/Thr phosphatases** in mammalian cells belong to two protein families: the **PPP family** and the **PPM family**. The PPP and PPM families are unrelated to each other or to the PTPs. X-Ray structures have shown that PPP catalytic centers each contain an Fe^{2+} (or possibly an Fe^{3+}) ion and a Zn^{2+} (or possibly an Mn^{2+}) ion, whereas PPM catalytic centers each contain two Mn^{2+} ions. These binuclear metal ion centers nucleophilically activate water molecules to dephosphorylate substrates in a single reaction step.

The PPP family member named **phosphoprotein phosphatase-1 (PP1)**, as we will see, plays an important role in regulating glycogen

FIG. 13-16 X-Ray structure of protein phosphatase PP2A. (a) The structure of an isolated scaffold (A) subunit. HEAT repeats, which are drawn here in different colors, each consist of two antiparallel helices joined by a short linker. These stack on one another with their corresponding helices nearly parallel to form an ~100-Å-long right-handed superhelix (helix of helices) with a hooklike shape. [Courtesy Bostjan Kobe, St. Vincent’s Institute of Medical Research, Fitzroy, Victoria, Australia.] (b) The structure of a PP2A heterotrimer

viewed with the scaffold subunit oriented approximately as in Part a. Here the scaffold (A; 589 residues) and regulatory (B; 449 residues) subunits are drawn in worm form, each colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). In addition, the A subunit is embedded in its transparent molecular surface. The catalytic (C; 309 residues) subunit (*magenta*) is drawn in ribbon form. Note the close structural resemblance of the A and B subunits. [Based on an X-ray structure by Yigong Shi, Princeton University. PDBid 2NPP.]

metabolism (Section 16-3B). The PPP member known as **PP2A** participates in a wide variety of regulatory processes including those governing metabolism, DNA replication, transcription, and development. PP2A is a heterotrimer that consists of a scaffold (A) subunit that binds both a catalytic (C) subunit and a regulatory (B) subunit. The A subunit, which consists of 15 imperfect tandem repeats of a 39-residue sequence termed HEAT (because it occurs in proteins named *Huntingtin*, *EF3*, A subunit of PP2A, and *TOR1*), has a remarkable structure in which the HEAT repeats are joined in a horseshoe-shaped solenoidal arrangement (Fig. 13-16a; *opposite*).

The X-ray structure of a PP2A **holoenzyme** (complete enzyme; Fig. 13-16b) reveals, unexpectedly, that its regulatory subunit consists of 8 tandem HEAT-like repeats arranged like those of the A subunit, despite their lack of sequence similarity. The C subunit binds to the A subunit's concave surface along a ridge of conserved hydrophobic side chains spanning HEAT repeats 11 to 15. The regulatory subunit similarly interacts with the A subunit's HEAT repeats 2 to 8 and also binds to the C subunit via a ridge spanning its own HEAT-like repeats 6 to 8. The highly acidic, convex side of the regulatory subunit (lower part of Fig. 13-16b) is thereby left unoccupied, which suggests that it interacts with substrate proteins.

PP2A's catalytic and scaffold subunits both have two isoforms, and there are 16 isoforms of the regulatory subunit. This results in an enormous panoply of enzymes that are targeted to different phosphoproteins in distinct subcellular sites during different developmental stages. This complexity is a major cause of our limited understanding of how PP2A carries out its diverse cellular functions, even though it comprises between 0.3 and 1% of cellular proteins.

The PPP family also includes **calcineurin** (also called **PP2B**), a Ser/Thr phosphatase that is activated by Ca^{2+} . Calcineurin plays an essential role in T cell proliferation. It is inhibited by the action of drugs such as **cyclosporin A**, which is used clinically to suppress immune system function following organ transplantation.

CHECKPOINT

- How does a receptor tyrosine kinase phosphorylate itself?
- Explain how the activation loop governs substrate access to the active site of a protein tyrosine kinase.
- Summarize the roles of SH2 and SH3 domains, Ras, GTP, and protein kinases in transmitting a signal from an RTK to a transcription factor.
- What is the function of a GEF and a GAP in signal transduction?
- Explain how a kinase cascade works. Why is this advantageous in the context of hormone signaling?
- What is the purpose of scaffold proteins?
- Describe how SH2 and SH3 domains and Tyr phosphorylation influence PTK activity.
- Explain why cells contain an array of protein phosphatases as well as protein kinases.

3 Heterotrimeric G Proteins

KEY CONCEPTS

- G-protein-coupled receptors contain seven membrane-spanning helices and undergo conformational changes when a hormone binds.
- Agonist binding to a G-protein-coupled receptor induces the α subunit of the associated heterotrimeric G protein to exchange GDP for GTP and dissociate from the β and γ subunits.
- Adenylate cyclase is activated to produce cAMP, which in turn activates protein kinase A.
- Signaling activity is limited through the action of phosphodiesterases that act on cAMP and cGMP.

The second major class of signal transduction pathways that we will discuss involves **heterotrimeric G proteins**. These proteins are members of the superfamily of regulatory GTPases that are collectively known as G proteins, which, as we have seen, are named for their ability to bind the guanine nucleotides GTP and GDP and hydrolyze GTP to GDP and P_i . The monomeric G proteins are essential for a wide variety of processes, including signal transduction (e.g., Ras; Section 13-2B), vesicle trafficking (Section 9-4E), the growth of actin microfilaments (Section 7-2C), translation (as ribosomal accessory factors; Section 27-4), and protein targeting [as components of the signal recognition particle (SRP) and the SRP receptor; Section 9-4D]. The many G proteins share common structural motifs that bind guanine nucleotides and catalyze the hydrolysis of GTP.

Many heterotrimeric G proteins participate in signal transduction systems that consist of three major components (Fig. 13-17):

1. **G-protein-coupled receptors (GPCRs)**, transmembrane proteins that bind their corresponding agonist (e.g., a hormone) on their extracellular side, which induces a conformational change on their cytoplasmic side.
2. Heterotrimeric G proteins, which are anchored to the cytoplasmic side of the plasma membrane and which are activated by a GPCR when it binds its corresponding agonist.
3. **Adenylate cyclase (AC)**, a transmembrane enzyme that is activated (or in some cases inhibited) by activated heterotrimeric G proteins.

Activated AC catalyzes the synthesis of **adenosine-3',5'-cyclic monophosphate (3',5'-cyclic AMP or cAMP)** from ATP.

The cAMP, in turn, binds to a variety of proteins so as to activate numerous cellular processes. Thus, as Earl Sutherland first showed, *cAMP is a second messenger; that is, it intracellularly transmits the signal originated by the extracellular ligand.*

What are the mechanisms through which the binding of an agonist to an extracellular receptor induces AC to synthesize cAMP in the cytosol? In answering this question we will see that the signaling system outlined above has a surprising complexity that endows it with immense capacity for both signal amplification and regulatory flexibility.

A G-Protein-Coupled Receptors Contain Seven Transmembrane Helices

The GPCRs form one of the largest known protein families (>800 species in humans, which comprises 4% of the ~21,000 genes in the human genome). This family includes receptors for nucleosides, nucleotides, Ca^{2+} , catecholamines (Section 13-1B) and other biogenic amines (e.g., **histamine** and **serotonin**; Section 21-6B), the various eicosanoids (Section 9-1F), and a variety of peptide and protein hormones. In addition, GPCRs have essential sensory functions: They constitute the olfactory (odorant) and gustatory (taste) receptors (of which there are estimated to be 460 different types in humans), as well as the several light-sensing proteins in the retina, which are known as **rhodopsins**. The importance of these receptors is also evident from the fact that ~30% of the therapeutic drugs presently in use target specific GPCRs.

The GPCRs, whose characterization was pioneered by Robert Lefkowitz and Brian Kobilka, are all integral membrane proteins with seven transmembrane α helices of generally uniform size: 20 to 27 residues, which is sufficient to span a lipid bilayer. However, their N- and C-terminal segments, which are respectively outside and inside the cell, and the loops connecting their transmembrane helices (three outside and three inside) vary widely in length. These are the portions of the protein that participate in binding ligands (on their extracellular side) and heterotrimeric G proteins (on their cytoplasmic

PROCESS DIAGRAM

FIG. 13-17 Overview of heterotrimeric G protein–dependent signaling. In this widely used pathway, hormone binding to its receptor stimulates an inactive heterotrimeric G protein to exchange its bound GDP for GTP, triggering a process that activates adenylate cyclase to produce the second messenger cAMP. **WPLS** See the Animated Process Diagrams.

? Explain why this pathway is irreversible.

side). Many GPCRs are posttranslationally modified by *N*-glycosylation and/or by the palmitoylation of a Cys residue, so they are also lipid-linked glycoproteins (Section 9-3B).

The structure of the GPCR β_2 -adrenergic receptor (β_2 AR) with a bound high-affinity agonist named BI167107 (an epinephrine analog; *at right*), is shown in **Figure 13-18**. The ligand-binding site is composed of a portion of the

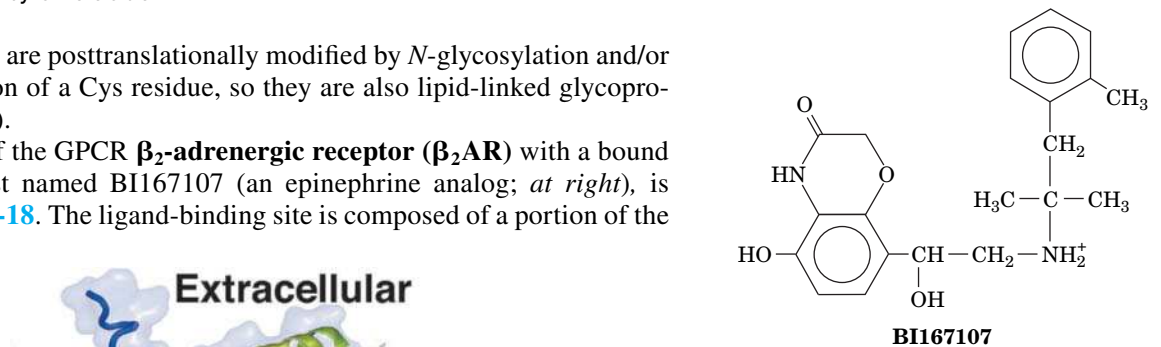

FIG. 13-18 X-Ray structure of the human β_2 -adrenergic receptor in complex with BI167107. The structure is viewed parallel to the plane of the plasma membrane with its approximate position indicated therein. The protein is represented by its semitransparent molecular surface with its polypeptide chain in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). Note its bundle of seven nearly parallel transmembrane helices. The BI167107, which binds in a cavity between the receptor's seven transmembrane helices that is open to the extracellular side of the membrane, is drawn in space-filling form with C magenta, N blue, and O red. [Based on an X-ray structure by Brian Kobilka, Stanford University. PDBid 4LDE.]

protein's helical core as well as its extracellular loops. Aside from this general location, there are few similarities in the structures of the binding sites in different GPCRs, which is consistent with the observation that each receptor is specific for only one or a few ligands.

GPCRs function much like allosteric proteins such as hemoglobin (Section 7-1). *By alternating between two discrete conformations, one with agonist bound and one without, the receptor can transmit an extracellular signal to the cell interior.* In the case of GPCRs, this conformational change is propagated through the receptor's transmembrane helices to its cytoplasmic face to permit the binding of the corresponding heterotrimeric G protein. In many cases, this also increases the affinity of the GPCR for its agonist. This model of receptor action is similar to the operation of membrane transport proteins (e.g., Fig. 10-13); in fact, some membrane-bound receptors are ion channels that switch between the open and closed conformations in response to ligand binding.

B Heterotrimeric G Proteins Dissociate on Activation

Heterotrimeric G proteins, as their name implies, are G proteins that consist of an α , β , and γ subunit (45, 37, and 9 kD, respectively). The X-ray structures of entire heterotrimeric G proteins were independently determined by Alfred Gilman and Stephan Sprang (Fig. 13-19) and by Heidi Hamm and Paul Sigler. The large α subunit, designated G_{α} , consists of two domains connected by two polypeptide linkers (Fig. 13-19a): (1) a highly conserved GTPase domain that is structurally similar to those in monomeric G proteins such as Ras and hence is known as a Ras-like domain, and (2) a helical domain that is unique to heterotrimeric G proteins. The Ras-like domain contains the guanine nucleotide-binding site in a deep cleft and is anchored to the membrane by a myristoyl or palmitoyl group, or both, covalently attached near the protein's N-terminus. The G_{β} subunit, which is anchored to the membrane via prenylation of its C-terminus,

FIG. 13-19 (a) X-Ray structure of a heterotrimeric G protein. The G_{α} subunit's Ras-like domain is pink with the segments known as Switch I, II, and III green, blue, and red, respectively, and its helical domain is light orange. A bound GDP is shown in space-filling form with C green, N blue, O red, and P yellow. The G_{β} subunit's N-terminal segment is light blue and each blade of its β propeller has a different color. The G_{γ} subunit is gold. [Based on an X-ray structure by Alfred Gilman and Stephan Sprang, University of Texas Southwestern Medical Center. PDBid 1GP2.] (b) X-Ray structure of a heterotrimeric G protein lacking

bound nucleotide in complex with β_2 -adrenergic receptor (β_2 AR) binding BI167107. The β_2 AR · BI167107 is viewed and colored as in Fig. 13-18. The heterotrimeric G protein is viewed as from the top of Part a and identically colored except that its switch regions are pink. The G_{β} subunit (lower left) is oriented to clearly display its β propeller. The approximate position of the plasma membrane is indicated by the horizontal lines. Note that the β_2 AR binds, almost exclusively, to the G_{α} subunit's Ras-like domain. [Based on an X-ray structure by Brian Kobilka, Stanford University. PDBid 3SN6.]

consists of an N-terminal helical domain followed by a C-terminal domain comprising seven 4-stranded antiparallel β sheets arranged like the blades of a propeller—a so-called **β propeller** (Fig. 13-19b). The G_γ subunit consists mainly of two helical segments joined by a polypeptide link (Fig. 13-19b). It is closely associated with G_β along its entire extended length through mainly hydrophobic interactions. G_γ binds to G_β with such high affinity that they dissociate only under denaturing conditions. Consequently, we will henceforth refer to their complex as $G_{\beta\gamma}$.

In its unactivated state, a heterotrimeric G protein maintains its heterotrimeric state and its G_α subunit binds GDP. However, *the binding of such a $G_\alpha \cdot \text{GDP}$ – $G_{\beta\gamma}$ complex to its cognate GPCR in complex with an agonist induces the G_α subunit to exchange its bound GDP for GTP.* Thus, the ligand–GPCR complex (e.g., Fig. 13-19b) functions as the G_α subunit's guanine nucleotide exchange factor (GEF).

When GTP is bound to G_α , its γ phosphoryl group promotes conformational changes in three of G_α 's so-called **switch regions** (Fig. 13-19a), *causing G_α to dissociate from $G_{\beta\gamma}$.* This occurs because the binding of GTP's γ phosphoryl group and the binding of $G_{\beta\gamma}$ to G_α are mutually exclusive; the γ phosphoryl group hydrogen bonds with side chains in Switches I and II so as to prevent these segments from interacting with the loops and turns at the bottom of G_β 's β propeller. Switches I and II have counterparts in other G proteins of known structure. Comparison of the X-ray structures of the $G_\alpha \cdot \text{GDP}$ – $G_{\beta\gamma}$ complex and $G_{\beta\gamma}$ alone indicates that the structure of $G_{\beta\gamma}$ is unchanged by its association with $G_\alpha \cdot \text{GDP}$. Nevertheless, both G_α and $G_{\beta\gamma}$ are active in signal transduction; they interact with additional cellular components, as we discuss below.

The effect of G protein activation is short-lived, because G_α is also a GTPase that catalyzes the hydrolysis of its bound GTP to $\text{GDP} + \text{P}_i$, although at the relatively sluggish rate of 2 to 3 min^{-1} . GTP hydrolysis causes the heterotrimeric G protein to reassemble as the inactive $G_\alpha \cdot \text{GDP}$ – $G_{\beta\gamma}$ complex. This prevents a runaway response to ligand binding to a GPCR.

Heterotrimeric G Proteins Activate Other Proteins. A human cell can contain numerous different kinds of heterotrimeric G proteins, since there are 21 different α subunits, 6 different β subunits, and 12 different γ subunits. This heterozygosity presumably permits various cell types to respond in different ways to a variety of stimuli.

One of the major targets of the heterotrimeric G protein system is the enzyme adenylate cyclase (AC; described more fully in the next section). For example, when a $G_\alpha \cdot \text{GTP}$ complex dissociates from $G_{\beta\gamma}$, it may bind with high affinity to AC, thereby activating the enzyme. Such a G_α protein is known as a stimulatory G protein, $G_{s\alpha}$. Other G_α proteins, known as inhibitory G proteins, $G_{i\alpha}$, inhibit AC activity. The heterotrimeric G_s and G_i proteins, which differ in their α subunits, may actually contain the same β and γ subunits. Other types of heterotrimeric G proteins—acting through their G_α or $G_{\beta\gamma}$ units—stimulate the opening of ion channels, participate in the phosphoinositide signaling system (Section 13-4), activate phosphodiesterases, and activate protein kinases.

Because a single agonist–receptor interaction can activate more than one G protein, this step of the signal transduction pathway serves to amplify the original extracellular signal. In addition, several types of ligand–receptor complexes may activate the same G protein so that different extracellular signals elicit the same cellular response.

C Adenylate Cyclase Synthesizes cAMP to Activate Protein Kinase A

Mammals have nine different isoforms of adenylate cyclase, which are each expressed in a tissue-specific manner and differ in their regulatory properties. These ~120-kD transmembrane glycoproteins each consist of a small N-terminal domain (N), followed by two repeats of a unit consisting of a transmembrane domain (M) followed by two consecutive cytoplasmic domains (C), thus forming

GATEWAY CONCEPT How Cells Use ATP and GTP

The activation and subsequent inactivation of a G protein costs the cell the free energy of the $\text{GTP} \rightarrow \text{GDP} + \text{P}_i$ reaction. Similarly, the activation of a target protein that is phosphorylated by a kinase and later dephosphorylated by a phosphatase costs the cell the free energy of the $\text{ATP} \rightarrow \text{ADP} + \text{P}_i$ reaction. Thus, the chemical free energy of the nucleoside triphosphates allows the cell, responding to a hormone signal, to do something it would not otherwise be able to do.

Hormone signaling by the adenylate cyclase system

FIG. 13-21 X-Ray structure of the catalytic (C) subunit of mouse protein kinase A (PKA) in complex with ATP and a polypeptide inhibitor. The protein, which is shown in its “standard” view, is in complex with ATP and a 20-residue peptide segment of a naturally occurring protein kinase inhibitor. The N-terminal domain is pink, the C-terminal domain is cyan, and the activation loop containing Thr 197 is light blue. The polypeptide inhibitor is orange and its pseudotarget sequence, Arg-Arg-Asn-Ala-Ile, is magenta (the Ala, which replaces the Ser or Thr of a true substrate, is white). The substrate ATP and the phosphoryl group of phospho-Thr 197 are shown in space-filling form and the side chains of the catalytically essential Arg 165, Asp 166, and Thr 197 are shown in stick form, all colored according to atom type (C green, N blue, O red, and P yellow). Note that the inhibitor’s pseudotarget sequence is close to ATP’s γ phosphate group, the group that the enzyme transfers to the Ser or Thr of the target sequence. [Based on an X-ray structure by Susan Taylor and Janusz Sowadski, University of California at San Diego. PDBid 1ATP.]

phosphorylation except that the phosphorylated Ser/Thr is replaced by Ala. Thr 197, which is part of the activation loop, must be phosphorylated for maximal activity. The phosphoryl group at Thr 197 interacts with Arg 165, a conserved catalytic residue that is adjacent to Asp 166, the catalytic base that activates the substrate protein’s target Ser/Thr hydroxyl group for phosphorylation. Thus, the phosphoryl group at PKA’s Thr 197 functions to properly orient its active site residues.

The R subunit of protein kinase A competitively inhibits its C subunit. The R subunit contains two homologous cAMP-binding domains, R_A and R_B , and a so-called **autoinhibitor segment**. In the X-ray structure of the inactive R_2C_2 complex (Fig. 13-22), the autoinhibitor segment, which resembles the C subunit’s substrate, binds in the C subunit’s active site (as does the inhibitory peptide in Fig. 13-21) so as to block substrate binding. When cAMP is present in sufficient concentration, each R subunit cooperatively binds two cAMPs. When the R_B domain lacks bound cAMP, it masks the R_A domain so as to prevent it from binding cAMP. However, the binding of cAMP to the R_B domain triggers a massive conformational change that permits the R_A domain to bind cAMP, which in turn releases the now-active C subunits from the complex.

The targets of PKA include enzymes involved in glycogen metabolism. For example, when epinephrine binds to the β -adrenergic receptor of a muscle cell, the sequential activation of a heterotrimeric G protein, adenylyl cyclase, and PKA leads to the activation of glycogen phosphorylase, thereby making glucose-6-phosphate available for glycolysis in a “fight-or-flight” response (Section 16-3).

Each step of a signal transduction pathway can potentially be regulated, so *the nature and magnitude of the cellular response ultimately reflect the presence and degree of activation or inhibition of all the preceding components of the pathway*. For example, the adenylyl cyclase signaling pathway can be limited or reversed through ligand activation of a receptor coupled to an inhibitory G protein. The activity of the cAMP second messenger can be attenuated by the action of phosphodiesterases that hydrolyze cAMP to AMP (see below). In addition, reactions catalyzed by PKA are reversed by protein Ser/Thr phosphatases (Section 13-2D). Some of these features of the adenylyl cyclase signaling pathway are

FIG. 13-22 X-Ray structure of the inactive R_2C_2 heterotetramer of mouse protein kinase A (PKA). The structure, which is drawn in ribbon form, is viewed along its twofold axis with its catalytic (C) subunits on the upper left and lower right and its regulatory (R) subunits on the upper right and lower left. The C subunit on the upper left is colored as in Fig. 13-21 and viewed approximately from its top, and that on the lower right is yellow. The R_A and R_B domains of the R subunit on the upper right are respectively colored light orange and light green, the R subunit on the

lower left is green, and the autoinhibitor segments of both R subunits are red. The lower R and C subunits are embedded in their semitransparent surface diagrams of the same color. The phosphate groups on Ser 139 and Thr 197 of the C subunits are drawn in space-filling form with O red and P yellow. Note how the autoinhibitory segment of each R subunit is inserted into the active site of the horizontally adjacent C subunit, thereby blocking substrate binding. [Based on an X-ray structure by Susan Taylor, University of California at San Diego. PDBid 3TNP.]

FIG. 13-23 The adenylate cyclase signaling system. The binding of hormone to a stimulatory receptor R_s (1) induces it to bind the heterotrimeric G protein G_s , which in turn stimulates the $G_{s\alpha}$ subunit (2) to exchange its bound GDP for GTP. The $G_{s\alpha} \cdot \text{GTP}$ complex then dissociates from $G_{\beta\gamma}$ (3) and (4) stimulates adenylate cyclase (AC) to convert ATP to cAMP (5). This stimulation stops when $G_{s\alpha}$ catalyzes the hydrolysis of its bound GTP to GDP (6). The binding of hormone to the inhibitory receptor R_i (7) triggers an almost identical chain of events (8–11) except that the presence of the $G_{i\alpha} \cdot \text{GTP}$ complex inhibits adenylate cyclase (10). cAMP activates protein kinase A (PKA; R_2C_2) by binding to the regulatory dimer

as $R_2 \cdot \text{cAMP}_4$, causing the catalytic subunit C to dissociate (12), and activates various cellular proteins (13) by catalyzing their phosphorylation. The sites of action of certain toxins are indicated. Signaling is limited by the action of phosphatases (14) and cAMP phosphodiesterase (15). Toxins such as cholera toxin and pertussis toxin act by blocking the hydrolysis of GTP from either $G_{s\alpha} \cdot \text{GTP}$ (6) or $G_{i\alpha} \cdot \text{GTP}$ (8), enhancing their activities. **WPLS** See the Animated Process Diagrams.

? Compare the effects of cholera toxin and pertussis toxin on the cellular response.

illustrated in Fig. 13-23. Many drugs and toxins exert their effects by modifying components of the adenylate cyclase system (Box 13-4).

Receptors Are Subject to Desensitization. A hallmark of biological signaling systems is that they adapt to long-term stimuli by reducing their response to them, a process named **desensitization**. *These signaling systems therefore respond to changes in stimulation levels rather than to their absolute values.* For example, in the case of the β -adrenergic receptor, its binding of an agonist such as epinephrine leads, as we have seen, to the activation of PKA through the

Complex processes such as the adenylate cyclase signaling system can be sabotaged by a variety of agents. For example, the methylated purine derivatives **caffeine** (an ingredient of coffee and tea), **theophylline** (an asthma treatment), and **theobromine** (found in chocolate)

R = CH ₃	X = CH ₃	Caffeine (1,3,7-trimethylxanthine)
R = H	X = CH ₃	Theophylline (1,3-dimethylxanthine)
R = CH ₃	X = H	Theobromine (1,7-dimethylxanthine)

are stimulants because they antagonize adenosine receptors that act through inhibitory G proteins. This antagonism results in an increase in intracellular cAMP concentration.

Deadlier effects result from certain bacterial toxins that interfere with heterotrimeric G protein function. The toxin released by *Vibrio cholerae* (the bacterium causing cholera) triggers massive fluid loss of over a liter per hour from diarrhea. Victims die from dehydration unless their lost

water and salts are replaced. **Cholera toxin**, an 87-kD protein of subunit composition AB₅, binds to ganglioside G_{M1} (Fig. 9-9) on the surface of intestinal cells via its B subunits. This permits the toxin to enter the cell, probably via receptor-mediated endocytosis, where an ~195-residue proteolytic fragment of its A subunit is released. This fragment catalyzes the transfer of the ADP-ribose unit from NAD⁺ to a specific Arg side chain of G_{sα}.

ADP-ribosylated G_{sα} · GTP can activate adenylate cyclase but cannot hydrolyze its bound GTP (Fig. 13-23). As a consequence, the adenylate cyclase is locked in its active state and cellular cAMP levels increase ~100-fold. Intestinal cells, which normally respond to small increases in cAMP by secreting digestive fluid (an HCO₃⁻-rich salt solution), pour out enormous quantities of this fluid in response to the elevated cAMP concentrations.

Other bacterial toxins act similarly. Certain strains of *E. coli* cause a diarrheal disease similar to but less serious than cholera through their production of **heat-labile enterotoxin**, a protein that is closely similar to cholera toxin (their A and B subunits are >80% identical) and has the same mechanism of action. **Pertussis toxin** [secreted by *Bordetella pertussis*, the bacterium that causes pertussis (whooping cough), which is responsible for ~400,000 infant deaths per year worldwide] is an AB₅ protein homologous to cholera toxin that ADP-ribosylates a specific Cys residue of G_{iα}. The modified G_{iα} cannot exchange its bound GDP for GTP and therefore cannot inhibit adenylate cyclase (Fig. 13-23).

intermediacy of G_{sα}, adenylate cyclase, and cAMP. Active PKA phosphorylates **β-adrenergic receptor kinase [βARK; also known as GPCR kinase 2 (GRK2)]** (among other proteins), which in turn, phosphorylates several intracellular Ser and Thr residues on the C-terminus of the hormone-receptor complex but not on the receptor alone. The phosphorylated receptor binds proteins known as **β-arrestins** to form complexes that sterically block the formation of the receptor-G_s complex, resulting in desensitization. The receptor-β-arrestin complex also recruits several members of the clathrin-dependent endocytosis machinery (Section 9-4E), leading to the internalization of the receptor in intracellular vesicles, thereby decreasing its availability on the cell surface. The internalized receptor is slowly dephosphorylated and returned to the cell surface, so if the epinephrine level is reduced, the cell's initial epinephrine sensitivity is eventually restored.

Sildenafil (Viagra)

CHECKPOINT

- Summarize the steps of signal transduction from a GPCR to phosphorylation of target proteins by PKA.
- Explain why a GPCR can be considered to be an allosteric protein.
- Describe how G proteins are activated and inactivated. What protein functions as a GEF?
- What is the function of a second messenger such as cAMP?
- How is PKA activity regulated?
- How does PKA activity affect the cell?
- Why does the adenylate cyclase signaling system include phosphodiesterases?
- What other factors limit or terminate signaling via GPCRs?

D Phosphodiesterases Limit Second Messenger Activity

In any chemically based signaling system, the signal molecule must eventually be eliminated in order to control the amplitude and duration of the signal and to prevent interference with the reception of subsequent signals. In the case of cAMP, this second messenger is hydrolyzed to AMP by enzymes known as **cAMP-phosphodiesterases (cAMP-PDEs)**.

The PDE superfamily, which includes both cAMP-PDEs and **cGMP-PDEs (cGMP is the guanine analog of cAMP)**, is encoded in mammals by at least 20 different genes grouped into 12 families (PDE1 through PDE12). Moreover, many of the mRNAs transcribed from these genes have alternative initiation sites and alternative splice sites (Section 26-3B), so that mammals express ~50 PDE isoforms. These are functionally distinguished by their substrate specificities (for cAMP, cGMP, or both) and kinetic properties, their responses (or lack of them) to various activators and inhibitors (see below), and their tissue, cellular, and subcellular distributions. The PDEs have characteristic modular architectures with a conserved ~270-residue catalytic domain near their C-termini and widely divergent regulatory domains or motifs, usually in their N-terminal portions. Some PDEs are membrane-anchored, whereas others are cytosolic.

PDE activity, as might be expected, is elaborately controlled. Depending on its isoform, a PDE may be activated by one or more of a variety of agents, including Ca^{2+} ion and phosphorylation by PKA and **insulin-stimulated protein kinase**. Phosphorylated PDEs are dephosphorylated by a variety of protein phosphatases. Thus, the PDEs provide a means for crosstalk between cAMP-based signaling systems and those using other types of signals.

PDEs are inhibited by a variety of drugs that influence such widely divergent disorders as asthma, congestive heart failure, depression, erectile dysfunction, inflammation, and retinal degeneration. **Sildenafil** (trade name **Viagra**, at upper left), a compound used to treat erectile dysfunction, specifically inhibits PDE5, which hydrolyzes only cGMP. Sexual stimulation in males causes penile nerves to release nitric oxide (NO), which activates **guanylate cyclase** to produce cGMP from GTP. The cGMP induces vascular smooth muscle relaxation in the penis, thereby increasing the inflow of blood, which results in an erection. This cGMP is eventually hydrolyzed by PDE5. Sildenafil is therefore an effective treatment in men who produce insufficient NO, and hence cGMP, to otherwise generate a satisfactory erection.

4 The Phosphoinositide Pathway

KEY CONCEPTS

- Signal transduction via the phosphoinositide pathway generates the second messenger inositol trisphosphate, which triggers Ca^{2+} release, and diacylglycerol, which activates protein kinase C.
- In the presence of Ca^{2+} , calmodulin binds and activates its target proteins.
- PKC activation depends on lipid binding.
- A hormone can activate multiple signal transduction pathways to elicit a variety of intracellular responses.

A discussion of signal transduction pathways would not be complete without a consideration of the **phosphoinositide pathway**, which mediates the effects of a variety of hormones. This signaling pathway requires a GPCR, a heterotrimeric G protein, a specific kinase, and a phosphorylated glycerophospholipid that is a minor component of the plasma membrane's inner leaflet. It involves the production of three second messengers: **inositol-1,4,5-trisphosphate (IP₃)**, Ca^{2+} , and **1,2-diacylglycerol (DAG)**.

A Ligand Binding Results in the Cytoplasmic Release of the Second Messengers IP_3 and Ca^{2+}

Agonist binding to its receptor, such as epinephrine binding to the α_1 -adrenergic receptor, activates a heterotrimeric G protein, G_q , whose membrane-anchored α subunit in complex with GTP diffuses laterally along the plasma membrane to activate the membrane-bound enzyme **phospholipase C (PLC)** (Fig. 13-24,

PROCESS DIAGRAM

FIG. 13-24 The phosphoinositide signaling system. Ligand binding to a cell-surface receptor R (1) activates phospholipase C (PLC) through the heterotrimeric G protein G_q (2). Activated phospholipase C catalyzes the hydrolysis of PIP_2 to IP_3 and DAG (3). The water-soluble IP_3 stimulates the release of Ca^{2+} sequestered in the endoplasmic reticulum (4), which in turn activates numerous cellular processes through the intermediacy of calmodulin (CaM; 5). The nonpolar DAG

remains associated with the membrane, where it activates protein kinase C (PKC; 6) to phosphorylate and thereby modulate the activities of a number of cellular proteins (7). PKC activation also requires the presence of the membrane lipid phosphatidylserine (PS) and Ca^{2+} . Phosphoinositide signaling is limited by GTP hydrolysis on $q\alpha$ (8) and by inositol polyphosphate 5-phosphatase, which acts on IP_3 (9) to yield IP_2 . **WPLS** See the Animated Process Diagrams.

? Which components of the signaling system are membrane-bound and which are soluble?

FIG. 13-25 The phospholipase C reaction.

Phospholipase C cleaves PIP₂ to produce diacylglycerol (DAG) and inositol-1,4,5-trisphosphate (IP₃), both of which are second messengers. (The *bis* and *tris* prefixes denote, respectively, two and three phosphoryl groups that are linked separately to the inositol; in di- and triphosphates, the phosphoryl groups are linked sequentially.)

FIG. 13-26 X-Ray structure of rat testis calmodulin. This monomeric 148-residue protein, which is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), contains two remarkably similar globular domains separated by a seven-turn α helix. The two Ca²⁺ ions bound to each domain are represented by cyan spheres. The side chains liganding the Ca²⁺ ions are drawn in stick form colored according to atom type (C green, N blue, and O red). [Based on an X-ray structure by Charles Bugg, University of Alabama at Birmingham. PDBid 3CLN.]

upper left). Activated PLC catalyzes the hydrolysis of **phosphatidylinositol-4,5-bisphosphate (PIP₂)** at its glycerophospho bond (Section 9-1C), yielding inositol-1,4,5-trisphosphate (IP₃) and 1,2-diacylglycerol (DAG; **Fig. 13-25**). PLC, which in mammals is actually a set of 13 isozymes, several of which have splice variants, requires the presence of Ca²⁺ for enzymatic activity. It has a hydrophobic ridge consisting of three protein loops that is postulated to penetrate into the membrane's nonpolar region during catalysis. This would explain how the enzyme can catalyze hydrolysis of the membrane-bound PIP₂, leaving the DAG product associated with the membrane.

The Charged IP₃ Molecule Is a Water-Soluble Second Messenger. The hydrolysis of PIP₂ sets in motion both cytoplasmic and membrane-bound events. While DAG acts as a second messenger in the membrane (Section 13-4C), IP₃ diffuses through the cytoplasm to the endoplasmic reticulum (ER). There, it binds to and induces the opening of a Ca²⁺ transport channel (an example of a receptor that is also an ion channel), thereby allowing the efflux of Ca²⁺ from the ER. This causes the cytosolic [Ca²⁺] to increase from ~0.1 μ M to as much as 10 mM, which triggers such diverse cellular processes as glucose mobilization and muscle contraction through the intermediacy of the Ca²⁺-binding protein **calmodulin** (see below) and its homologs. The ER contains embedded Ca²⁺-ATPases that actively pump Ca²⁺ from the cytosol back into the ER (Section 10-3B) so that in the absence of IP₃, the cytosolic [Ca²⁺] rapidly returns to its resting level.

B Calmodulin Is a Ca²⁺-Activated Switch

Calmodulin (**CaM**) is a ubiquitous, eukaryotic Ca²⁺-binding protein that participates in numerous cellular regulatory processes. In some of these, CaM functions as a free-floating monomeric protein, whereas in others it is a subunit of a larger protein. The X-ray structure of this highly conserved 148-residue protein has a curious dumbbell-like shape in which two structurally similar globular domains are connected by a seven-turn α helix (**Fig. 13-26**). Note the close structural resemblance between CaM and the Ca²⁺-binding TnC subunit of the muscle protein troponin (**Fig. 7-31**).

CaM's two globular domains each contain two high-affinity Ca²⁺-binding sites. The Ca²⁺ ion in each of these sites is octahedrally coordinated by oxygen atoms from the backbone and side chains as well as from a protein-associated water molecule. Each of the Ca²⁺-binding sites is formed by nearly superimposable helix-loop-helix motifs known as **EF hands** (**Fig. 13-27**) that form the Ca²⁺-binding sites in numerous other Ca²⁺-binding proteins of known structure.

FIG. 13-27 The EF hand. The Ca^{2+} -binding sites in many proteins that sense the level of Ca^{2+} are formed by helix-loop-helix motifs named EF hands. [After Kretsinger, R.H., *Annu. Rev. Biochem.* **45**, 241 (1976).]

Ca^{2+} -CaM Activates Its Target Proteins via an Intrasteric Mechanism. The binding of Ca^{2+} to either domain of CaM induces a conformational change in that domain, which exposes an otherwise buried Met-rich hydrophobic patch. This patch, in turn, binds with high affinity to the CaM-binding domains of numerous Ca^{2+} -regulated protein kinases. These CaM-binding domains have little mutual sequence homology but are all basic amphiphilic α helices.

Despite uncomplexed CaM's extended appearance (Fig. 13-26), a variety of studies indicate that both of its globular domains bind to a single target helix. This was confirmed by the NMR structure (Fig. 13-28) of $(\text{Ca}^{2+})_4$ -CaM in complex with a target polypeptide, a segment of skeletal muscle **myosin light chain kinase (MLCK)**. This enzyme, a homolog of the PKA C subunit, phosphorylates and thereby activates the light chains of the muscle protein myosin (Section 7-2A). Thus, CaM's central α helix serves as a flexible tether rather than a rigid spacer, a property that probably allows CaM to bind to a wide range of target polypeptides. Experiments show that both of CaM's globular domains are required for CaM to activate its targets: CaM domains that have been separated by proteolytic cleavage bind to their target peptides but do not cause enzyme activation.

How does Ca^{2+} -CaM activate its target protein kinases? MLCK contains a C-terminal segment whose sequence resembles that of MLCK's target polypeptide on the light chain of myosin but lacks a phosphorylation site. A model of MLCK, based on the X-ray structure of the 30% identical C subunit of PKA, strongly suggests that this segment of MLCK acts as an autoinhibitor by binding in the kinase's active site. Indeed, the excision of MLCK's autoinhibitor peptide by limited proteolysis permanently activates the enzyme. MLCK's CaM-binding

FIG. 13-28 NMR structure of calmodulin in complex with a target polypeptide. The N-terminal domain of CaM (from the fruit fly *Drosophila melanogaster*) is blue, its C-terminal domain is red, the 26-residue target polypeptide, which is from rabbit skeletal muscle myosin light chain kinase (MLCK), is green, and the Ca^{2+} ions are represented by cyan spheres. (a) A view of the complex in which the N-terminus of the target polypeptide is on the right. (b) The perpendicular view as seen from the right side of the structure shown

in Part a. In both views, the pseudo-twofold axis relating the N- and C-terminal domains of CaM is approximately vertical. Note how the segment that joins the two domains is unwound and bent (bottom loop in Part b) so that CaM forms a globular protein that largely encloses the helical target polypeptide within a hydrophobic tunnel in a manner resembling two hands holding a rope. [Based on an NMR structure by Marius Clore, Angela Gronenborn, and Ad Bax, NIH. PDBid 2BBM.]

FIG. 13-29 A schematic diagram of the Ca²⁺-CaM-dependent activation of protein kinases. Autoinhibited kinases have an N- or C-terminal "pseudosubstrate" sequence (pink) that binds at or near the enzyme's active site (orange) so as to inhibit its function. The autoinhibitory segment is in close proximity with or overlaps a Ca²⁺-CaM binding

sequence. Consequently, Ca²⁺-CaM (green) binds to the sequence so as to extract it from the enzyme's active site, thereby activating the enzyme to bind and phosphorylate other proteins (purple), eliciting a cellular response. [After Crivici, A. and Ikura, M., *Annu. Rev. Biophys. Biomol. Struct.* **24**, 88 (1995).] **WPLS** See the Animated Process Diagrams.

segment overlaps the autoinhibitor peptide. Thus, *the binding of Ca²⁺-CaM to this peptide segment extracts the autoinhibitor from MLCK's active site, thereby activating the enzyme (Fig. 13-29).*

Ca²⁺-CaM's other target proteins are presumably activated in the same way. In fact, the X-ray structures of several homologous protein kinases support this so-called **intrasteric mechanism**. While the details of binding of the autoinhibitory sequence differ for each of the protein kinases, the general mode of autoinhibition and activation by Ca²⁺-CaM is the same.

PKA's R subunit, as we have seen (Section 13-3C), contains a similar autoinhibitory sequence adjacent to its two tandem cAMP-binding domains. In this case, however, the autoinhibitory peptide is allosterically ejected from the C subunit's active site by the binding of cAMP to the R subunit (which lacks a Ca²⁺-CaM-binding site).

C DAG Is a Lipid-Soluble Second Messenger That Activates Protein Kinase C

The second product of the phospholipase C reaction, diacylglycerol (DAG), is a lipid-soluble second messenger. It therefore remains embedded in the plasma membrane, where in concert with Ca²⁺, it activates the membrane-bound **protein kinase C (PKC; C for Ca²⁺)** to phosphorylate and thereby modulate the

activities of several different cellular proteins (Fig. 13-24, *right*). Multiple PKC isozymes are known; they differ in tissue expression, intracellular location, and their requirement for the DAG that activates them. PKC is a phosphorylated, cytosolic protein in its resting state. DAG increases the membrane affinity of PKC and also helps stabilize its active conformation. The catalytic activities of PKC and PKA are similar: Both kinases phosphorylate Ser and Thr residues.

The X-ray structure of a DAG-bound segment of PKC shows that the 50-residue motif is largely knit together by two Zn^{2+} ions, each of which is tetrahedrally liganded by one His and three Cys side chains (Fig. 13-30). A DAG analog, **phorbol-13-acetate**,

binds in a narrow groove between two long nonpolar loops. Very few soluble proteins have such a large continuous nonpolar region, suggesting that this portion of PKC inserts into the membrane. Full activation of PKC requires phosphatidylserine (which is present only in the cytoplasmic leaflet of the plasma membrane; Fig. 9-32) and, in some cases, a Ca^{2+} ion (presumably made available through the action of the IP_3 second messenger). Like other signaling systems, the phosphoinositide system is limited by the destruction of its second messengers, for example, through the action of **inositol polyphosphate 5-phosphatase** (Fig. 13-24, *lower left*).

PLC Acts on Several Phospholipids to Release Different Second Messengers.

Choline-containing phospholipids hydrolyzed by phospholipase C yield DAGs that differ from those released from PIP_2 and exert different effects on PKC. Another lipid second messenger, sphingosine released from sphingolipids, inhibits PKC.

The phosphoinositide signaling pathway in some cells yields a DAG that is predominantly 1-stearoyl-2-arachidonoyl-glycerol. This molecule is further degraded to yield arachidonate, the precursor of the bioactive eicosanoids (prostaglandins and thromboxanes; Fig. 9-12), and hence the phosphoinositide pathway yields up to four different second messengers. In other cells, IP_3 and diacylglycerol are rapidly recycled to re-form PIP_2 in the inner leaflet of the membrane. Some receptor tyrosine kinases activate an isoform of phospholipase C that contains two SH2 domains. This is another example of crosstalk, the interactions of different signal transduction pathways.

D Epilog: Complex Systems Have Emergent Properties

Complex systems are, by definition, difficult to understand and substantiate. Familiar examples include the earth's weather system, the economies of large countries, the ecologies of even small areas, and the human brain. Biological signal transduction systems, as is amply evident from a reading of this chapter, are complex systems. Thus, a hormonal signal is typically transduced through several intracellular signaling pathways, each of which consists of numerous components, many of which interact with components of other signaling

FIG. 13-30 X-Ray structure of a portion of protein kinase C in complex with phorbol-13-acetate. The protein tetrahedrally ligands two Zn^{2+} ions (cyan spheres), each via His and Cys side chains (shown in ball-and-stick form). Phorbol-13-acetate (*top*), which mimics the natural diacylglycerol ligand, binds between two nonpolar protein loops. Atoms are colored according to type with C green, N blue, O red, and S yellow. [Based on an X-ray structure by James Hurley, NIH. PDBid 1PTR.]

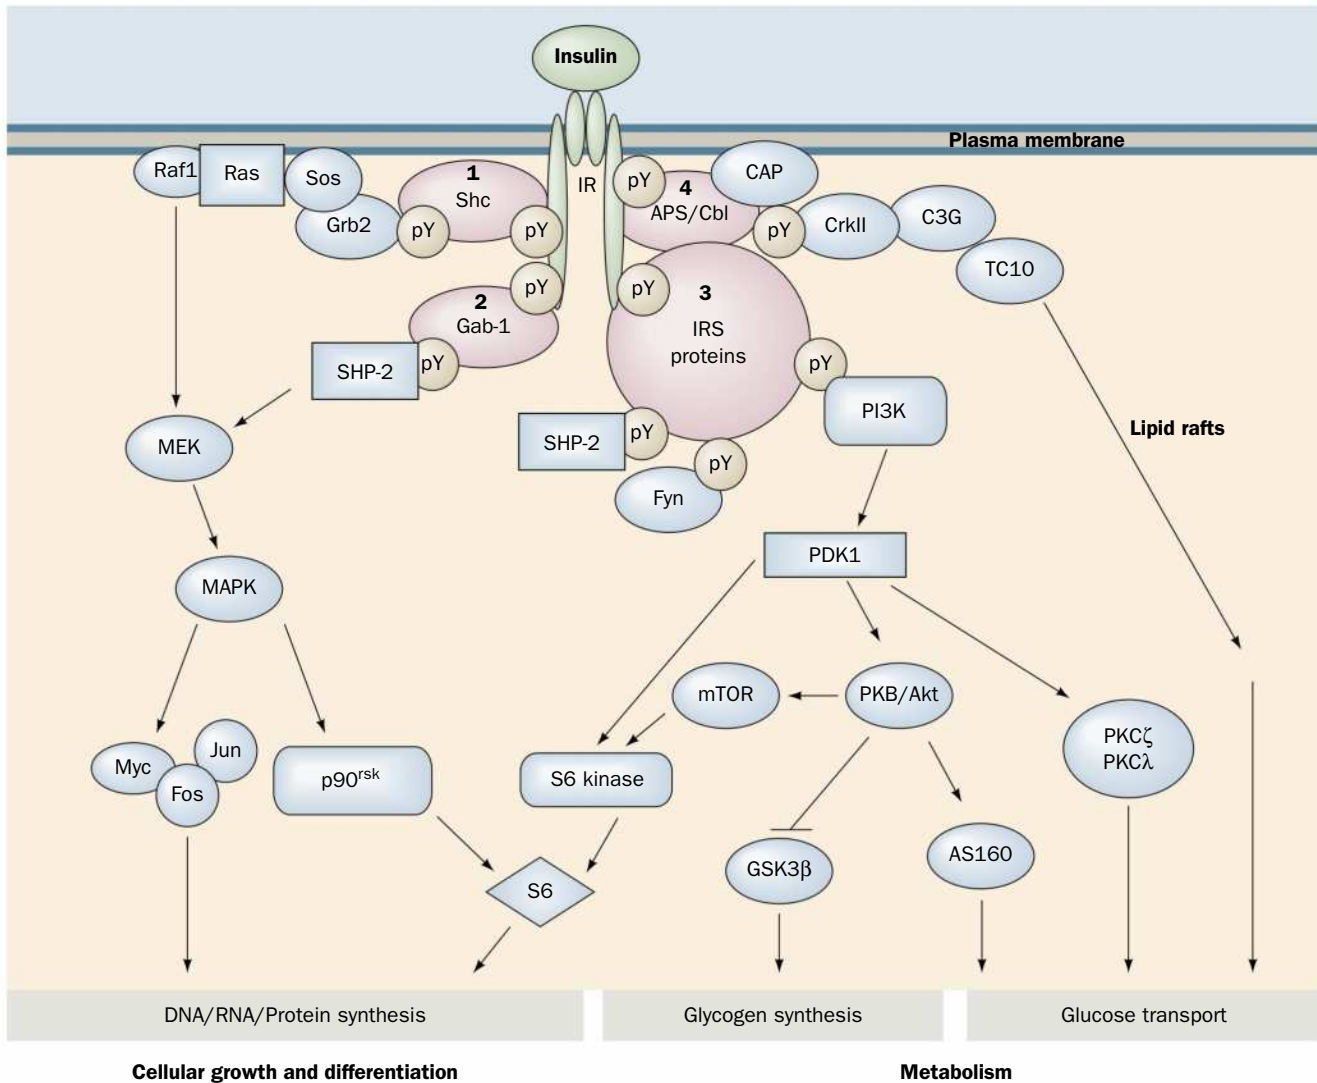

FIG. 13-31 A coarse outline of insulin signal transduction. The binding of insulin to the insulin receptor (**IR**) induces tyrosine phosphorylations (pY) that lead to the activation of MAPK via activation of Shc (**1**) and Gab-1 (**2**). The MAPK cascade regulates the expression of genes involved in cellular growth and differentiation. Phosphorylation of IRS proteins (**3**) activates the PI3K cascade, which leads to changes in the phosphorylation states of several enzymes, so as to stimulate glycogen synthesis as well as other metabolic pathways. The PI3K cascade also participates in the control of vesicle trafficking, leading to the translocation of the GLUT4 glucose transporter to the cell surface and thus increasing the rate of glucose transport into the cell. Glucose transport control is also exerted by the APS/Cbl system (**4**) in

a PI3K-independent manner involving lipid rafts (Section 9-4C). Other symbols: Myc, Fos, and Jun (transcription factors), **SHP-2** (an SH2-containing protein tyrosine phosphatase), **CAP** (Cbl-associated protein), **C3G** [a guanine nucleotide exchange factor (GEF)], **CrkII** (an SH2/SH3-containing adaptor protein), PDK1 (phosphoinositide-dependent protein kinase-1), **PKB** (protein kinase B, also named **Akt**), **GSK3β** (glycogen synthase-3β, which is inhibited by phosphorylation by PKB), **mTOR** (for mammalian target of rapamycin, a PI3K-related protein kinase; rapamycin is an immunosuppressant), **S6** (a protein subunit of the eukaryotic ribosome's small subunit whose phosphorylation stimulates translation), and PKCζ and PKCλ (atypical isoforms of protein kinase C). [After Zick, Y., *Trends Cell Biol.* **11**, 437 (2001).]

pathways. For example, the **insulin signaling system** (Fig. 13-31), although not yet fully elucidated, is clearly highly complex. Upon binding insulin, the insulin receptor autophosphorylates itself at several Tyr residues (Section 13-2A) and then Tyr-phosphorylates its target proteins, thereby activating several signaling pathways that control a diverse array of effects:

1. Phosphorylation of the adaptor protein **Shc**, which generates a binding site for Grb2's SH2 domain, results in stimulation of a MAP kinase cascade (Section 13-2B), ultimately affecting growth and differentiation.
2. Phosphorylation of **Gab-1** (**Grb2-associated binder-1**) similarly activates the MAP kinase cascade.
3. Phosphorylation of insulin receptor substrate (IRS) proteins (Section 13-2A) activates enzymes known as **phosphoinositide 3-kinases (PI3Ks)**. These enzymes add a phosphoryl group to the 3'-OH group of a phosphatidylinositol,

often the 4,5-bisphosphate shown in Fig. 13-25. The 3-phosphorylated lipid activates **phosphoinositide-dependent protein kinase-1 (PDK1)** that in turn initiates cascades leading to glycogen synthesis (Section 16-3C) and the translocation of the glucose transporter GLUT4 to the surface of insulin-responsive cells (Section 22-2), as well as affecting cell growth and differentiation.

4. Phosphorylation of the **APC/Cbl** complex (APC for adaptor protein containing plekstrin homology and Src homology-2 domains; Cbl is an SH2/SH3-binding docking protein that is a proto-oncogene product) leads to the stimulation of **TC10** (a monomeric G protein) and to the PI3K-independent regulation of glucose transport involving the participation of lipid rafts (Section 9-4C).

Thus, by activating multiple pathways, a hormone such as insulin can trigger a variety of physiological effects that would not be possible in a one hormone–one target regulatory system.

Understanding a Complex System Requires an Integrative Approach. The predominant approach in science is reductionist: the effort to understand a system in terms of its component parts. Thus chemists and biochemists explain the properties of molecules in terms of the properties of their component atoms, cell biologists explain the nature of cells in terms of the properties of their component macromolecules, and biologists explain the characteristics of multicellular organisms in terms of the properties of their component cells. However, complex systems have **emergent properties** that are not readily predicted from an understanding of their component parts (i.e., the whole is greater than the sum of its parts). Indeed, life itself is an emergent property that arises from the numerous chemical reactions that occur in a cell.

To elucidate the emergent properties of a complex system, an integrative approach is required. For signal transduction systems, such an approach would entail determining how each of the components of each signaling pathway in a cell interacts with all of the other such components under the conditions that each of these components experiences within its local environment. Yet, existing techniques for doing so are crude at best. Moreover, these systems are by no means static but vary, over multiple time scales, in response to cellular and organismal programs. Consequently, the means for understanding the holistic performance of cellular signal transduction systems are only in their earliest stages of development. Such an understanding is likely to have important biomedical consequences since many diseases, including cancer, diabetes, and a variety of neurological disorders, are caused by malfunctions of signal transduction systems.

CHECKPOINT

- Describe how ligand binding to a receptor leads to the production of IP₃ and DAG and the release of Ca²⁺.
- Which components of the phosphoinositide signaling system are soluble and which are associated with the membrane?
- How does calmodulin activate target proteins?
- Describe how PKC activity requires membrane components.
- Describe the mechanisms that limit signaling by the phosphoinositide pathway.
- Compare Figures 13-7, 13-23, and 13-24. What do all these pathways have in common? How do they differ?
- How do biological signaling systems support the idea that the whole is greater than the sum of its parts?

Summary

1 Hormones

- Hormones produced by endocrine glands and other tissues regulate diverse physiological processes. The polypeptide hormones insulin and glucagon control fuel metabolism; fight-or-flight responses are governed by epinephrine and norepinephrine binding to α - and β -adrenergic receptors; steroid hormones regulate sexual development and function; and growth hormone stimulates growth directly and indirectly.
- Hormone signals interact with target tissues by binding to receptors that transduce the signal to the interior of the cell.

2 Receptor Tyrosine Kinases

- On ligand binding, receptor tyrosine kinases such as the insulin receptor undergo autophosphorylation. This activates them to phosphorylate their target proteins, in some cases triggering a kinase cascade.
- One growth-promoting pathway involves the monomeric G protein Ras and leads to altered gene expression.

- Protein–protein interactions in signaling pathways may require SH2 and SH3 domains.
- Protein kinases share a common structure that often includes activation by displacement of an autoinhibitory segment.
- The effects of protein kinases are reversed by the activity of protein phosphatases.

3 Heterotrimeric G Proteins

- The G-protein–coupled receptors (GPCRs) have seven transmembrane helices. On agonist binding, these receptors undergo a conformational change that activates an associated heterotrimeric G protein.
- The G protein exchanges GDP for GTP and dissociates. G _{α} and G _{$\beta\gamma$} units may activate or inhibit targets such as adenylyl cyclase, which produces the cAMP activator of protein kinase A (PKA).
- Signaling activity is limited by the destruction of the second messenger.

4 The Phosphoinositide Pathway

- In the phosphoinositide pathway, the hormone receptor is associated with a G protein whose activation in turn activates phospholipase C. This enzyme catalyzes the hydrolysis of phosphatidylinositol-4,5-bisphosphate to yield two second messengers.
- The soluble inositol-1,4,5-trisphosphate (IP₃) second messenger opens Ca²⁺ channels, causing a rise in intracellular Ca²⁺ that acti-

vates protein kinases via the binding of the Ca²⁺-calmodulin complex. The lipid second messenger diacylglycerol (DAG) activates protein kinase C.

- Signaling pathways are complex systems in which a single extracellular signal can elicit multiple intracellular events, some of which may also be triggered by other signaling pathways.

Problems

EXERCISES

1. Would the pancreatic hormone somatostatin require a receptor on the surface of or in the cytosol of a target cell?
2. Retinoic acid (a derivative of vitamin A; Section 9-1F) is a hormone that mediates immune system function. Would retinoic acid require a receptor on the surface of a target cell?
3. What biochemical changes are required to convert tyrosine to (a) norepinephrine and (b) epinephrine?
4. The anabolic steroid methandrostenolone is shown here. (a) How does it differ structurally from testosterone? (b) Why might such drugs be administered to burn victims?

5. Estimate the binding affinity of a ligand for its receptor from the following data:

[Ligand] (μM)	Fractional saturation, Y
1	0.20
2	0.36
4	0.54
6	0.62
8	0.70

6. Calculate the binding affinity of a ligand for its receptor from the following data:

[Free ligand] (mM)	[Bound ligand] (mM)
0.6	2
1.5	4
3.0	6
6.0	8
15.0	10

7. Some bacterial signaling systems involve kinases that transfer a phosphoryl group to a His side chain. Draw the phospho-His side chain.
8. Why might a compound resembling ADP function as an inhibitor of a protein kinase?
9. Explain why a protein tyrosine phosphatase would include an SH₂ domain in addition to its phosphatase domain.
10. A growth factor that acts through a receptor tyrosine kinase stimulates cell division. Predict the effect of a viral protein that inhibits the corresponding protein tyrosine phosphatase.
11. Retroviruses bearing oncogenes will infect cells from their corresponding host animal but will usually not transform them to cancer cells. Yet these retroviruses will readily transform immortalized cells derived from the same organism. Explain.
12. Trastuzumab (Herceptin; Section 7-3) is an antibody that binds to the extracellular domain of the growth factor receptor HER2. Explain why trastuzumab would be an effective treatment for cancer in which cells overexpress HER2.
13. How does the presence of the poorly hydrolyzable GTP analog GTPγS (in which an O atom on the terminal phosphate is replaced by an S atom) affect cAMP production by adenylate cyclase?
14. *Mycobacterium tuberculosis* is an intracellular bacterium that causes tuberculosis. The *M. tuberculosis* genome includes 17 genes encoding adenylate cyclase, whereas free-living bacteria typically have just one AC gene. Why might it be an advantage for *M. tuberculosis* to generate high adenylate cyclase activity?
15. One of the toxins produced by *Bacillus anthracis* (the cause of anthrax) is known as EF, or edema factor (edema is the abnormal buildup of extracellular fluid). EF, which enters mammalian host cells, is a calmodulin-activated adenylate cyclase. Explain how this toxin causes edema.
16. Another *B. anthracis* toxin is lethal factor, LF, a protease that cleaves members of the MAPK kinase family so that they cannot bind to their downstream MAPK targets in white blood cells. Explain how LF inhibits activation of the immune system during *B. anthracis* infection.
17. Diacylglycerol is a substrate for the enzyme diacylglycerol kinase. What is the product of this reaction?
18. Explain why activation of diacylglycerol kinase would limit signaling by the phosphoinositide pathway.
19. Lithium ion, which is used to treat bipolar disorder, interferes with the phosphoinositide signaling pathway by inhibiting enzymes such as inositol monophosphatase and inositol polyphosphate 1-phosphatase. Predict the effect of Li⁺ on the supply of cellular inositol, a precursor of phosphatidylinositol and PIP₂.

20. The SHP-2 protein participates in insulin signaling through its indirect activation by the insulin receptor (Fig. 13-31), a receptor tyrosine kinase. Yet SHP-2 is a protein tyrosine phosphatase. Is this a paradox? Explain.

CHALLENGE QUESTIONS

21. Hormone A binds to its receptor with a K_L of $5 \mu\text{M}$. In the presence of $2.5 \mu\text{M}$ compound B and $2.0 \mu\text{M}$ hormone A, $1.0 \mu\text{M}$ of A remains unbound. Calculate the binding affinity of B for the hormone receptor.

22. Propranolol binds to β -adrenergic receptors with a K_L of $8.9 \times 10^{-9} \text{M}$. What concentration of propranolol would be required to achieve a 50% reduction in the binding of the receptor agonist isoproterenol if the agonist concentration is 10nM and its dissociation constant for the receptor is $4.8 \times 10^{-8} \text{M}$?

23. An insulin receptor substrate (IRS) contains a so-called pleckstrin homology (PH) domain that binds to the inositol head group of membrane lipids, a phosphotyrosine-binding (PTB) domain that differs from an SH2 domain, and six to eight Tyr residues that may be phosphorylated. Explain how each of these features contributes to signal transduction.

24. Predict the effect on cell growth of an Sos mutation that decreased its affinity for Ras.

25. Would the following alterations to Src be oncogenic? Explain. (a) The deletion or inactivation of the SH3 domain. (b) The mutation of Tyr 416 to Phe.

26. Would the following alterations to Src be oncogenic? Explain. (a) The mutation of Tyr 527 to Phe. (b) The replacement of Src residues 249 to 253 with the sequence APTMP.

27. Explain why mutations of the Arg residue in G_{sa} that is ADP-ribosylated by cholera toxin are oncogenic mutations.

28. Why doesn't cholera toxin cause cancer?

29. Phosphatidylethanolamine and PIP_2 containing identical fatty acyl residues can be hydrolyzed with the same efficiency by a certain

phospholipase C. Will the hydrolysis products of the two lipids have the same effect on protein kinase C? Explain.

30. How does pertussis toxin inhibit phospholipase C?

31. The white blood cells known as T lymphocytes respond to antigens that bind specifically to the T cell receptor, which consists of an antigen-binding $\alpha\beta$ transmembrane protein as well as a set of transmembrane signal-transducing proteins known as CD3 that are targets of NRTKs. The cytoplasmic domains of the CD3 proteins are positively charged and, in the absence of antigen, interact with the intracellular surface of the plasma membrane in such a way that buries several of their Tyr residues in the lipid bilayer. Antigen binding to the T cell receptor leads to a localized influx of Ca^{2+} ions. (a) Explain how a high concentration of Ca^{2+} could promote phosphorylation and activation of the CD3 proteins. (b) Would this phenomenon make the T lymphocyte more or less responsive to the antigen?

32. The diagnosis of some lymphomas (blood cell cancers) includes cytogenetic analysis, which involves examining a patient's cells for chromosomal abnormalities. Chromosomes are visible by light microscopy only during cell division. Cells removed from a patient's bone marrow may be treated with phorbol myristate acetate (PMA) prior to microscopic examination. What is the purpose of the PMA?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 G Protein–Coupled Receptors and Receptor Tyrosine Kinases

Exercise 2 Biosignaling and the KEGG Database

MORE TO EXPLORE The sense of smell, that is, the detection of odorant molecules, is mediated by G protein-coupled receptors. Are the number of such receptors in the human nose enough to detect all possible odors? Following ligand binding to one of these receptors, what happens in the cell? How is the presence of the odorant transmitted from an olfactory cell to the brain?

CHAPTER 14

Introduction to Metabolism

Chapter Contents

1 Overview of Metabolism

- A Nutrition Involves Food Intake and Use
- B Vitamins and Minerals Assist Metabolic Reactions
- C Metabolic Pathways Consist of Series of Enzymatic Reactions
- D Thermodynamics Dictates the Direction and Regulatory Capacity of Metabolic Pathways
- E Metabolic Flux Must Be Controlled

2 “High-Energy” Compounds

- A ATP Has a High Phosphoryl Group-Transfer Potential
- B Coupled Reactions Drive Endergonic Processes
- C Some Other Phosphorylated Compounds Have High Phosphoryl Group-Transfer Potentials
- D Thioesters Are Energy-Rich Compounds

3 Oxidation–Reduction Reactions

- A NAD^+ and FAD Are Electron Carriers
- B The Nernst Equation Describes Oxidation–Reduction Reactions
- C Spontaneity Can Be Determined by Measuring Reduction Potential Differences

4 Experimental Approaches to the Study of Metabolism

- A Labeled Metabolites Can Be Traced
- B Studying Metabolic Pathways Often Involves Perturbing the System
- C Systems Biology Has Entered the Study of Metabolism

HAWOONG JEONG, UNIVERSITY OF NOTRE DAME / Science Source Images

Modern approaches to understanding metabolism include the use of network theory to probe the functional importance of interacting cellular components, such as the yeast proteins shown here.

Understanding the chemical compositions and three-dimensional structures of biological molecules is not sufficient to understand how they are assembled into organisms or how they function to sustain life. We must therefore examine the reactions in which biological molecules are built and broken down. We must also consider how free energy is consumed in building cellular materials and carrying out cellular work and how free energy is generated from organic or other sources. **Metabolism**, the overall process through which living systems acquire and use free energy to carry out their various functions, is traditionally divided into two parts:

1. **Catabolism**, or degradation, in which nutrients and cell constituents are broken down to salvage their components and/or to make energy available.
2. **Anabolism**, or biosynthesis, in which biomolecules are synthesized from simpler components.

In general, catabolic reactions carry out the exergonic oxidation of nutrient molecules. The free energy thereby released is used to drive such endergonic processes as anabolic reactions, the performance of mechanical work, and the active transport of molecules against concentration gradients. Exergonic and endergonic processes are often coupled through the intermediate synthesis of a “high-energy” compound such as ATP. This simple principle underlies many of the chemical reactions presented in the following chapters. In this chapter, we introduce the general features of metabolic reactions and the roles of ATP and other compounds as energy carriers. Because many metabolic reactions are also oxidation–reduction reactions, we review the thermodynamics of these processes. Finally, we examine some approaches to studying metabolic reactions.

1 Overview of Metabolism

KEY CONCEPTS

- Different organisms use different strategies for capturing free energy from their environment and can be classified by their requirement for oxygen.
- Mammalian nutrition involves the intake of macronutrients (proteins, carbohydrates, and lipids) and micronutrients (vitamins and minerals).
- A metabolic pathway is a series of enzyme-catalyzed reactions, often located in a specific part of a cell.
- The flux of material through a metabolic pathway varies with the activities of the enzymes that catalyze irreversible reactions.
- These flux-controlling enzymes are regulated by allosteric mechanisms, covalent modification, substrate cycling, and changes in gene expression.

A bewildering array of chemical reactions occur in any living cell. Yet the principles that govern metabolism are the same in all organisms, a result of their common evolutionary origin and the constraints of the laws of thermodynamics. In fact, many of the specific reactions of metabolism are common to all organisms, with variations due primarily to differences in the sources of the free energy that supports them.

A Nutrition Involves Food Intake and Use

Nutrition, the intake and utilization of food, affects health, development, and performance. Food supplies the energy that powers life processes and provides the raw materials to build and repair body tissues. The nutritional requirements of an organism reflect its source of metabolic energy. For example, some prokaryotes are **autotrophs** (Greek: *autos*, self + *trophos*, feeder), which can synthesize all their cellular constituents from simple molecules such as H₂O, CO₂, NH₃, and H₂S. There are two possible free energy sources for this process. **Chemolithotrophs** (Greek: *lithos*, stone) obtain their energy through the oxidation of inorganic compounds such as NH₃, H₂S, or even Fe²⁺:

Photoautotrophs do so via photosynthesis, a process in which light energy powers the transfer of electrons from inorganic donors to CO₂ to produce carbohydrates, (CH₂O)_n, which are later oxidized to release free energy. **Heterotrophs** (Greek: *hetero*, other) obtain free energy through the oxidation of organic compounds (carbohydrates, lipids, and proteins) and hence ultimately depend on autotrophs for those substances.

Organisms can be further classified by the identity of the oxidizing agent for nutrient breakdown. **Obligate aerobes** (which include animals) must use O₂, whereas **anaerobes** employ oxidizing agents such as sulfate or nitrate. **Facultative anaerobes**, such as *E. coli*, can grow in either the presence or the absence of O₂. **Obligate anaerobes**, in contrast, are poisoned by the presence of O₂. Their metabolisms are thought to resemble those of the earliest life-forms, which arose more than 3.5 billion years ago when the earth's atmosphere lacked O₂. Most of our discussion of metabolism will focus on aerobic processes.

Animals are obligate **aerobic** heterotrophs, whose nutrition depends on a balanced intake of the **macronutrients** proteins, carbohydrates, and lipids. These are broken down by the digestive system to their component amino acids, monosaccharides, fatty acids, and glycerol—the major nutrients involved in cellular metabolism—which are then transported by the circulatory system to the tissues. The metabolic utilization of the latter substances also requires the intake of O₂ and water, as well as **micronutrients** composed of **vitamins** and **minerals**.

TABLE 14-1 Characteristics of Common Vitamins

Vitamin	Coenzyme Product	Reaction Mediated	Human Deficiency Disease
Water-Soluble			
Biotin (B ₇)	Biocytin	Carboxylation	<i>a</i>
Pantothenic acid (B ₅)	Coenzyme A	Acyl transfer	<i>a</i>
Cobalamin (B ₁₂)	Cobalamin coenzymes	Alkylation	Pernicious anemia
Riboflavin (B ₂)	Flavin coenzymes	Oxidation–reduction	<i>a</i>
—	Lipoic acid	Acyl transfer	<i>a</i>
Nicotinamide (niacin; B ₃)	Nicotinamide coenzymes	Oxidation–reduction	Pellagra
Pyridoxine (B ₆)	Pyridoxal phosphate	Amino group transfer	<i>a</i>
Folic acid (B ₉)	Tetrahydrofolate	One-carbon group transfer	Megaloblastic anemia
Thiamine (B ₁)	Thiamine pyrophosphate	Aldehyde transfer	Beriberi
Ascorbic acid (C)	Ascorbate	Hydroxylation	Scurvy
Fat-Soluble			
Vitamin A		Vision	Night blindness
Vitamin D		Ca ²⁺ absorption	Rickets
Vitamin E		Antioxidant	<i>a</i>
Vitamin K		Blood clotting	Hemorrhage

^aNo specific name; deficiency in humans is rare or unobserved.

TABLE 14-2 Major Essential Minerals and Trace Elements

Major Minerals	Trace Elements
Sodium	Iron
Potassium	Copper
Chlorine	Zinc
Calcium	Selenium
Phosphorus	Iodine
Magnesium	Chromium
Sulfur	Fluorine

? Which of the elements listed here occur as covalently bonded components of biological molecules?

B Vitamins and Minerals Assist Metabolic Reactions

Vitamins are organic molecules that an animal is unable to synthesize and must therefore obtain from its diet. Vitamins can be divided into two groups: **water-soluble vitamins** and **fat-soluble vitamins**. Table 14-1 lists many common vitamins and the types of reactions or processes in which they participate (we will consider the structures of these substances and their reaction mechanisms in the appropriate sections of the text).

Table 14-2 lists the essential minerals and trace elements necessary for metabolism. They participate in metabolic processes in many ways. Mg²⁺, for example, is involved in nearly all reactions that involve ATP and other nucleotides, including the synthesis of DNA, RNA, and proteins. Zn²⁺ is a cofactor in a variety of enzymes, including carbonic anhydrase (Section 11-3C). Ca²⁺, in addition to being the major mineral component of bones and teeth, is a vital participant in signal transduction processes (Section 13-4).

 **Most Water-Soluble Vitamins Are Converted to Coenzymes.** Many coenzymes (Section 11-1C) were discovered as growth factors for microorganisms or as substances that cure nutritional deficiency diseases in humans and/or animals. For example, the NAD⁺ component **nicotinamide**, or its carboxylic acid analog **nicotinic acid (niacin; Fig. 14-1)**, relieves the ultimately fatal

FIG. 14-1 The structures of nicotinamide and nicotinic acid. These vitamins form the redox-active components of the nicotinamide coenzymes NAD⁺ and NADP⁺ (compare with Fig. 11-4).

dietary deficiency disease in humans known as **pellagra**. Pellagra (Italian: *pelle*, skin + *agra*, sour), which is characterized by dermatitis, diarrhea, and dementia, was endemic in the rural southern United States in the early twentieth century. Most animals, including humans, can synthesize nicotinamide from the amino acid tryptophan. However, the corn (maize)-rich diet that was prevalent in the rural South contained little available nicotinamide or tryptophan from which to synthesize it. (Corn actually contains significant quantities of niacin but in a form that requires treatment with base before it can be intestinally absorbed. The Mexican Indians, who domesticated the corn plant but did not suffer from pellagra, customarily soak corn meal in lime water—dilute $\text{Ca}(\text{OH})_2$ solution—before using it to make their staple food, tortillas.) Dietary supplementation with nicotinamide or niacin has all but eliminated pellagra in the developed world.

The water-soluble vitamins in the human diet are all coenzyme precursors. In contrast, the fat-soluble vitamins, with the exception of vitamin K (Section 9-1F), are not components of coenzymes, although they are also required in small amounts in the diets of many higher animals.

🌱 The distant ancestors of humans probably had the ability to synthesize the various vitamins, as do many modern plants and microorganisms. Yet since vitamins are normally available in the diets of animals, which all eat other organisms, or are synthesized by the bacteria that normally inhabit their digestive systems, it seems likely that the superfluous cellular machinery to synthesize them was lost through evolution. For example, vitamin C (ascorbic acid) is required in the diets of only humans, apes, and guinea pigs (Section 6-1C and Box 6-2) because, in what is apparently a recent evolutionary loss, they lack a key enzyme for ascorbic acid biosynthesis.

C Metabolic Pathways Consist of Series of Enzymatic Reactions

Metabolic pathways are series of connected enzymatic reactions that produce specific products. Their reactants, intermediates, and products are referred to as **metabolites**. There are around 4000 known metabolic reactions, each catalyzed by a distinct enzyme. The types of enzymes and metabolites in a given cell vary with the identity of the organism, the cell type, its nutritional status, and its developmental stage. Many metabolic pathways are branched and interconnected, so delineating a pathway from a network of thousands of reactions is somewhat arbitrary and is driven by tradition as much as by chemical logic.

In general, degradative and biosynthetic pathways are related as follows (Fig. 14-2): In degradative pathways, the major nutrients, referred to as complex metabolites, are exergonically broken down into simpler products. The free energy released in the degradative process is conserved by the synthesis of ATP

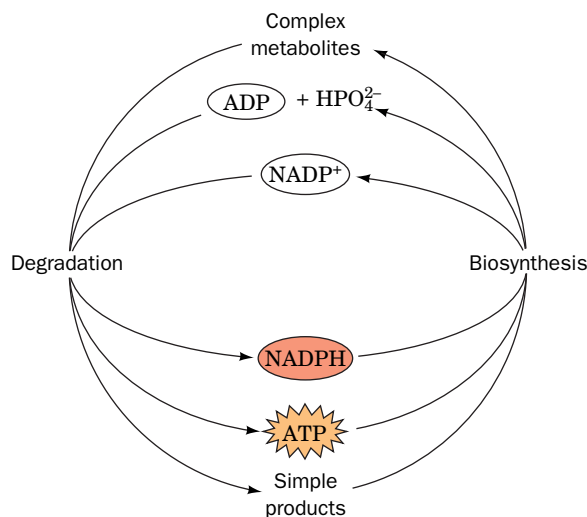

FIG. 14-2 Roles of ATP and NADPH in metabolism. ATP and NADPH, generated through the degradation of complex metabolites such as carbohydrates, lipids, and proteins, are sources of free energy for biosynthetic and other reactions.

from $\text{ADP} + \text{P}_i$ or by the reduction of a coenzyme such as NADP^+ (Fig. 11-4) to NADPH . ATP and NADPH are the major free energy sources for biosynthetic reactions. We will consider the thermodynamic properties of ATP and NADPH later in this chapter.

A striking characteristic of degradative metabolism is that *the pathways for the catabolism of a large number of diverse substances (carbohydrates, lipids, and proteins) converge on a few common intermediates*, in many cases, a two-carbon acetyl unit linked to **coenzyme A** to form **acetyl-coenzyme A (acetyl-CoA; Section 14-2D)**. These intermediates are then further metabolized in a central oxidative pathway. **Figure 14-3** outlines the breakdown of various foodstuffs to their monomeric units and then to acetyl-CoA. This is followed by the oxidation of the acetyl carbons to CO_2 by the **citric acid cycle** (Chapter 17). When one substance is **oxidized** (loses electrons), another must be **reduced** (gain electrons; Box 14-1). The citric acid cycle thus produces the reduced coenzymes NADH and FADH_2 (Section 14-3A), which then pass their electrons to O_2 to produce H_2O in the processes of **electron transport** and **oxidative phosphorylation** (Chapter 18).

Biosynthetic pathways carry out the opposite process. *Relatively few metabolites serve as starting materials for a host of varied products*. In the next several chapters, we discuss many catabolic and anabolic pathways in detail.

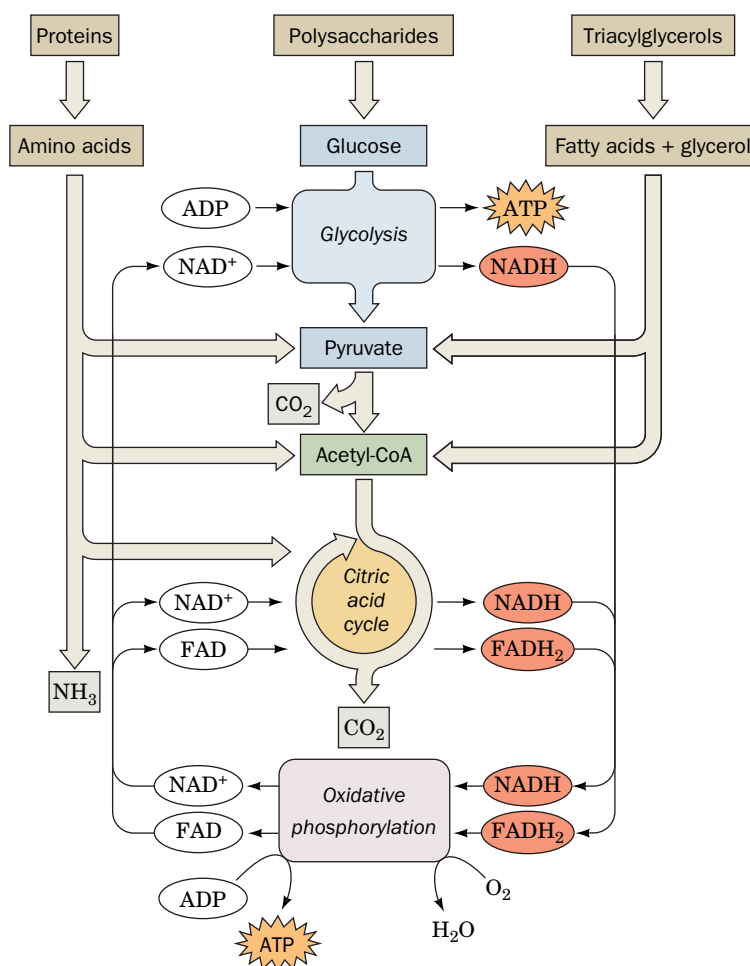

FIG. 14-3 Overview of catabolism. Complex metabolites such as carbohydrates, proteins, and lipids are degraded first to their monomeric units, chiefly glucose, amino acids, fatty acids, and glycerol, and then to the common intermediate, acetyl-CoA. The acetyl group is oxidized to CO_2 via the citric acid cycle with concomitant reduction of NAD^+ and FAD to NADH and FADH_2 . Reoxidation of NADH and FADH_2 by O_2 during electron transport and oxidative phosphorylation yields H_2O and ATP .

? Identify the three major waste products of catabolism.

Box 14-1 Perspectives in Biochemistry Oxidation States of Carbon

The carbon atoms in biological molecules can assume different oxidation states depending on the atoms to which they are bonded. For example, a carbon atom bonded to less electronegative hydrogen atoms is more reduced than a carbon atom bonded to highly electronegative oxygen atoms.

The simplest way to determine the oxidation number (and hence the oxidation state) of a particular carbon atom is to examine each of its bonds and assign the electrons to the more electronegative atom. In a C—O bond, both electrons “belong” to O; in a C—H bond, both electrons “belong” to C; and in a C—C bond, each carbon “owns” one electron. An atom’s oxidation number is the number of valence electrons on the free atom (4 for carbon) minus the number of its lone pair and assigned electrons. For example, the oxidation number of carbon in CO₂ is 4 – (0 + 0) = +4, and the oxidation number of carbon in CH₄ is 4 – (0 + 8) = –4. Keep in mind, however, that oxidation numbers are only accounting devices; actual atomic charges are much closer to neutrality.

The following compounds are listed according to the oxidation state of the highlighted carbon atom. In general, the more oxidized compounds have fewer electrons per C atom and are richer in oxygen, and the more reduced compounds have more electrons per C atom and are richer in hydrogen. But note that not all reduction events (gain of electrons) or oxidation events (loss of electrons) are associated with bonding to oxygen. For example, when an alkane is converted to an alkene, the formation of a carbon–carbon double bond involves the loss of electrons and therefore is an oxidation reaction although no oxygen is involved. Knowing the oxidation number of a carbon atom is seldom required. However, it is useful to be able to determine whether the oxidation state of a given atom increases or decreases during a chemical reaction.

Compound	Formula	Oxidation Number
Carbon dioxide	O=C=O	+4 (most oxidized)
Acetic acid	$\text{H}_3\text{C}-\overset{\text{O}}{\parallel}{\text{C}}-\text{OH}$	+3
Carbon monoxide	:C≡O:	+2
Formic acid	$\text{H}-\overset{\text{O}}{\parallel}{\text{C}}-\text{OH}$	+2
Acetone	$\text{H}_3\text{C}-\overset{\text{O}}{\parallel}{\text{C}}-\text{CH}_3$	+2
Acetaldehyde	$\text{H}_3\text{C}-\overset{\text{O}}{\parallel}{\text{C}}-\text{H}$	+1
Formaldehyde	$\text{H}-\overset{\text{O}}{\parallel}{\text{C}}-\text{H}$	0
Acetylene	HC≡CH	–1
Ethanol	$\text{H}_3\text{C}-\overset{\text{H}}{\underset{\text{H}}{\mid}}{\text{C}}-\text{OH}$	–1
Ethene	$\text{H}_2\text{C}=\overset{\text{H}}{\underset{\text{H}}{\mid}}{\text{C}}$	–2
Ethane	$\text{H}_3\text{C}-\overset{\text{H}}{\underset{\text{H}}{\mid}}{\text{C}}-\text{H}$	–3
Methane	$\text{H}-\overset{\text{H}}{\underset{\text{H}}{\mid}}{\text{C}}-\text{H}$	–4 (least oxidized)

Enzymes Catalyze the Reactions of Metabolic Pathways. With a few exceptions, the interconversions of metabolites in degradative and biosynthetic pathways are catalyzed by enzymes. In the absence of enzymes, the reactions would occur far too slowly to support life. In addition, the specificity of enzymes guarantees the efficiency of metabolic reactions by preventing the formation of useless or toxic by-products. Most importantly, enzymes provide a mechanism for coupling an endergonic chemical reaction (which would not occur on its own) with an energetically favorable reaction, as discussed below.

We will see examples of reactions catalyzed by all six classes of enzymes introduced in Section 11-1A. These reactions fall into four major types: **oxidations and reductions** (catalyzed by oxidoreductases), **group-transfer reactions** (catalyzed by transferases and hydrolases), **eliminations**, **isomerizations**, and

rearrangements (catalyzed by isomerases and mutases), and **reactions that make or break carbon–carbon bonds** (catalyzed by hydrolases, lyases, and ligases).

Metabolic Pathways Occur in Specific Cellular Locations. The compartmentation of the eukaryotic cytoplasm allows different metabolic pathways to operate in different locations. For example, electron transport and oxidative phosphorylation occur in the mitochondria, whereas **glycolysis** (a carbohydrate degradation pathway) and fatty acid biosynthesis occur in the cytosol. **Figure 14-4** shows the major metabolic functions of eukaryotic organelles. Metabolic processes in prokaryotes, which lack organelles, may be localized to particular areas of the cytosol.

The synthesis of metabolites in specific membrane-bounded compartments in eukaryotic cells requires mechanisms to transport these substances between compartments. Accordingly, transport proteins (Chapter 10) are essential components of many metabolic processes. For example, a transport protein is required to move ATP, which is generated in the mitochondria, to the cytosol, where most of it is consumed (Section 18-1B).

In multicellular organisms, compartmentation is carried a step further to the level of tissues and organs. The mammalian liver, for example, is largely responsible for the synthesis of glucose from noncarbohydrate precursors (**gluconeogenesis**; Section 16-4) so as to maintain a relatively constant level of glucose in the circulation, whereas adipose tissue is specialized for storage of triacylglycerols. The interdependence of the metabolic functions of the various organs is the subject of Chapter 22.

FIG. 14-4 Metabolic functions of eukaryotic organelles. Degradative and biosynthetic processes may occur in specialized compartments in the cell, or may involve several compartments.

? Without looking at the figure, summarize the major function of each cellular compartment. Identify which compartments carry out degradative versus synthetic processes.

An intriguing manifestation of specialization of tissues and subcellular compartments is the existence of **isozymes**, enzymes that catalyze the same reaction but are encoded by different genes and have different kinetic or regulatory properties. For example, we have seen that mammals have three isozymes of glycogen phosphorylase, those expressed in muscle, brain, and liver (Section 12-3B). Similarly, vertebrates possess two homologs of the enzyme **lactate dehydrogenase**: the M type, which predominates in tissues subject to anaerobic conditions such as skeletal muscle and liver, and the H type, which predominates in aerobic tissues such as heart muscle. Lactate dehydrogenase catalyzes the interconversion of **pyruvate**, a product of glycolysis, and **lactate** (Section 15-3A). The M-type isozyme appears mainly to function in the reduction by NADH of pyruvate to lactate, whereas the H-type enzyme appears to be better adapted to catalyze the reverse reaction.

The existence of isozymes allows for the testing of various illnesses. For example, heart attacks cause the death of heart muscle cells, which consequently rupture and release H-type LDH into the blood. A blood test indicating the presence of H-type LDH is therefore diagnostic of a heart attack.

D Thermodynamics Dictates the Direction and Regulatory Capacity of Metabolic Pathways

Knowing the location of a metabolic pathway and enumerating its substrates and products does not necessarily reveal how that pathway functions as part of a larger network of interrelated biochemical processes. It is also necessary to appreciate how fast end product can be generated by the pathway, as well as how pathway activity is regulated as the cell's needs change. Conclusions about a pathway's output and its potential for regulation can be gleaned from information about the thermodynamics of each enzyme-catalyzed step.

Recall from Section 1-3D that the free energy change ΔG of a biochemical process, such as the reaction

is related to the standard free energy change (ΔG°) and the concentrations of the reactants and products (Eq. 1-15):

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[C][D]}{[A][B]} \right) \quad [14-1]$$

At equilibrium, $\Delta G = 0$ and the equation becomes

$$\Delta G^\circ = -RT \ln K_{\text{eq}} \quad [14-2]$$

Thus, the value of ΔG° can be calculated from the equilibrium constant and vice versa (see Sample Calculation 14-1).

When the reactants are present at values close to their equilibrium values, $[C]_{\text{eq}}[D]_{\text{eq}}/[A]_{\text{eq}}[B]_{\text{eq}} \approx K_{\text{eq}}$, and $\Delta G \approx 0$. This is the case for many metabolic reactions, which are said to be **near-equilibrium reactions**. Because their ΔG values are close to zero, they can be relatively easily reversed by changing the ratio of products to reactants. When the reactants are in excess of their equilibrium concentrations, the net reaction proceeds in the forward direction until the excess reactants have been converted to products and equilibrium is attained. Conversely, when products are in excess, the net reaction proceeds in the reverse direction to convert products to reactants until the equilibrium concentration ratio is again achieved. *Enzymes that catalyze near-equilibrium reactions tend to act quickly to restore equilibrium concentrations, and the net rates of such reactions are effectively controlled by the relative concentrations of substrates and products.*

SAMPLE CALCULATION 14-1

Calculate the equilibrium constant for the hydrolysis of glucose-1-phosphate at 37°C, using the information in Table 14-3 (see Section 14-2A).

ΔG° for the reaction

is $-20.9 \text{ kJ} \cdot \text{mol}^{-1}$. At equilibrium, $\Delta G = 0$ and Eq. 14-1 becomes

$$\Delta G^\circ = -RT \ln K$$

(Eq. 14-2). Therefore,

$$K = e^{-\Delta G^\circ/RT}$$

$$K = e^{-(-20,900 \text{ J} \cdot \text{mol}^{-1})/(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K})}$$

$$K = 3.3 \times 10^3$$

WPLS See Sample Calculation Videos.

GATEWAY CONCEPT Le Châtelier's Principle

Recall from Chapter 1 that adding or removing components from a reaction at equilibrium causes the reaction to proceed in one direction or the other until a new equilibrium is established.

GATEWAY CONCEPT Free Energy Change

You can think of the free energy change (ΔG) for a reaction in terms of an urge or a force pushing the reactants toward equilibrium. The larger the free energy change, the farther the reaction is from equilibrium and the stronger is the tendency for the reaction to proceed. At equilibrium, of course, the reactants undergo no net change and $\Delta G = 0$.

Other metabolic reactions function far from equilibrium; that is, they are irreversible. This is because an enzyme catalyzing such a reaction has insufficient catalytic activity (the rate of the reaction it catalyzes is too slow) to allow the reaction to come to equilibrium under physiological conditions. Reactants therefore accumulate in large excess of their equilibrium amounts, making $\Delta G \ll 0$. Changes in substrate concentrations therefore have relatively little effect on the rate of an irreversible reaction; the enzyme is essentially saturated. Only changes in the activity of the enzyme—through allosteric interactions, for example—can significantly alter the rate. The enzyme is therefore analogous to a dam on a river: *It controls the flow of substrate through the reaction by varying its activity, much as a dam controls the flow of a river by varying the opening of its floodgates.*

Understanding the **flux** (rate of flow) of metabolites through a metabolic pathway requires knowledge of which reactions are functioning near equilibrium and which are far from it. Most enzymes in a metabolic pathway operate near equilibrium and therefore have net rates that vary with their substrate concentrations. However, certain enzymes that operate far from equilibrium are strategically located in metabolic pathways. This has several important implications:

- 1. Metabolic pathways are irreversible.** A highly exergonic reaction (one with $\Delta G \ll 0$) is irreversible; that is, it goes to completion. If such a reaction is part of a multistep pathway, it confers directionality on the pathway; that is, it makes the entire pathway irreversible.
- 2. Every metabolic pathway has a first committed step.** Although most reactions in a metabolic pathway function close to equilibrium, there is generally an irreversible (exergonic) reaction early in the pathway that “commits” its product to continue down the pathway (likewise, water that has gone over a dam cannot spontaneously return).
- 3. Catabolic and anabolic pathways differ.** If a metabolite is converted to another metabolite by an exergonic process, free energy must be supplied to convert the second metabolite back to the first. This energetically “uphill” process requires a different pathway for at least one of the reaction steps.

The existence of independent interconversion routes, as we will see, is an important property of metabolic pathways because it allows independent control of the two processes. If metabolite 2 is required by the cell, it is necessary to “turn off” the pathway from 2 to 1 while “turning on” the pathway from 1 to 2. Such independent control would be impossible without different pathways.

E Metabolic Flux Must Be Controlled**GATEWAY CONCEPT The Steady State**

Although many reactions are near equilibrium, an entire metabolic pathway—and the cell’s metabolism as a whole—never reaches equilibrium. This is because materials and energy are constantly entering and leaving the system, which is in a steady state. Metabolic pathways proceed, as if trying to reach equilibrium (Le Châtelier’s principle), but they cannot get there because new reactants keep arriving and products do not accumulate.

Living organisms are thermodynamically open systems that tend to maintain a steady state rather than reaching equilibrium (Section 1-3E). This is strikingly demonstrated by the observation that, over a 40-year time span, a normal human adult consumes literally tons of nutrients and imbibes more than 20,000 L of water but does so without major weight change. *The flux of intermediates through a metabolic pathway in a steady state is more or less constant; that is, the rates of synthesis and breakdown of each pathway intermediate maintain it at a constant concentration.* A steady state far from equilibrium is thermodynamically efficient, because only a nonequilibrium process ($\Delta G \neq 0$) can perform useful work. Indeed, living systems that have reached equilibrium are dead.

Since a metabolic pathway is a series of enzyme-catalyzed reactions, it is easiest to describe the flux of metabolites through the pathway by considering its

reaction steps individually. The flux of metabolites, J , through each reaction step is the rate of the forward reaction, v_f , less that of the reverse reaction, v_r :

$$J = v_f - v_r \quad [14-3]$$

At equilibrium, by definition, there is no flux ($J = 0$), although v_f and v_r may be quite large. In reactions that are far from equilibrium, $v_f \gg v_r$, the flux is essentially equal to the rate of the forward reaction ($J \approx v_f$).

For the pathway as a whole, flux is set by the rate-determining step of the pathway. By definition, this step is the pathway's slowest step, which is often the first committed step of the pathway. In some pathways, flux control is distributed over several enzymes, all of which help determine the overall rate of flow of metabolites through the pathway. Because a rate-determining step is slow relative to other steps in the pathway, its product is removed by succeeding steps in the pathway before it can equilibrate with reactant. Thus, *the rate-determining step functions far from equilibrium and has a large negative free energy change*. In an analogous manner, a dam creates a difference in water levels between its upstream and downstream sides, and a large negative free energy change results from the hydrostatic pressure difference. The dam can release water to generate electricity, varying the water flow according to the need for electrical power.

Reactions that function near equilibrium respond rapidly to changes in substrate concentration. For example, upon a sudden increase in the concentration of a reactant for a near-equilibrium reaction, the enzyme catalyzing it would increase the net reaction rate to rapidly achieve the new equilibrium level. Thus, a series of near-equilibrium reactions downstream from the rate-determining step all have the same flux. Likewise, the flux of water in a river is the same at all points downstream from a dam.

In practice, it is often possible to identify flux control points for a pathway by identifying reactions that have large negative free energy changes. The relative insensitivity of the rates of these nonequilibrium reactions to variations in the concentrations of their substrates permits the establishment of a steady state flux of metabolites through the pathway. Of course, flux through a pathway must vary in response to the organism's requirements to reach a new steady state. Altering the rates of the rate-determining steps can alter the flux of material through the entire pathway, often by an order of magnitude or more.

Cells use several mechanisms to control flux through the rate-determining steps of metabolic pathways:

1. **Allosteric control.** Many enzymes are allosterically regulated (Section 12-3A) by effectors that are often substrates, products, or coenzymes of the pathway but not necessarily of the enzyme in question. For example, in negative feedback regulation, the product of a pathway inhibits an earlier step in the pathway:

Thus, as we have seen, CTP, a product of pyrimidine biosynthesis, inhibits ATCase, which catalyzes the rate-determining step in the pathway (Fig. 12-11).

2. **Covalent modification.** Many enzymes that control pathway fluxes have specific sites that may be enzymatically phosphorylated and dephosphorylated (Section 12-3B) or covalently modified in some other way. Such enzymatic modification processes, which are themselves subject to control by external signals such as hormones (Section 13-1), greatly alter the activities of the modified enzymes. The signaling methods involved in such flux control mechanisms are discussed in Chapter 13.

3. **Substrate cycles.** If v_f and v_r represent the rates of two opposing non-equilibrium reactions that are catalyzed by different enzymes, v_f and v_r may be independently varied.

CHECKPOINT

- Describe the differences between autotrophs and heterotrophs.
- Use the words obligate, facultative, aerobic, anaerobic, autotroph, and heterotroph to describe the metabolism of a human, oak tree, *E. coli*, and *Methanococcus jannaschii* (an organism that lives in deepwater anoxic sediments).
- List the categories of macronutrients and micronutrients required for mammalian metabolism and provide examples of each.
- What is the relationship between vitamins and coenzymes?
- Explain the roles of ATP and NADPH in catabolic and anabolic reactions.
- Give some reasons why enzymes are essential for the operation of metabolic pathways.
- Why might different tissues express different isozymes?
- How are free energy changes and equilibrium constants related?
- Explain the metabolic significance of reactions that function near equilibrium and reactions that function far from equilibrium.
- Discuss the mechanisms by which the flux through a metabolic pathway can be controlled. Which mechanisms can rapidly alter flux?

For example, flux ($v_f - v_r$) can be increased not just by accelerating the forward reaction but by slowing the reverse reaction. The flux through such a **substrate cycle**, as we will see in Section 15-4, is more sensitive to the concentrations of allosteric effectors than is the flux through a single unopposed nonequilibrium reaction.

4. **Genetic control.** Enzyme concentrations, and hence enzyme activities, may be altered by protein synthesis in response to metabolic needs. The processes of transcribing a gene to messenger RNA and then translating the RNA to a polypeptide chain offer numerous points for regulation. Mechanisms of genetic control of enzyme concentrations are a major concern of Part V of this text.

Mechanisms 1 to 3 can respond rapidly (within seconds or minutes) to external stimuli and are therefore classified as “short-term” control mechanisms. Mechanism 4 responds more slowly to changing conditions (within hours or days in higher organisms) and is therefore regarded as a “long-term” control mechanism.

Control of most metabolic pathways involves several nonequilibrium steps. Hence, the flux of material through a pathway that supplies intermediates for use by an organism may depend on multiple effectors whose relative importance reflects the overall metabolic demands of the organism at a given time. Thus, a metabolic pathway is part of a **supply-demand process**.

2 “High-Energy” Compounds

KEY CONCEPTS

- Organisms capture the free energy released on degradation of nutrients as “high-energy” compounds such as ATP, whose subsequent breakdown is used to power otherwise endergonic reactions.
- The “high energy” of ATP is related to the large negative free energy change for hydrolysis of its phosphoanhydride bonds.
- ATP hydrolysis can be coupled to an endergonic reaction such that the net reaction is favorable.
- Phosphoryl groups are transferred from compounds with high phosphoryl group-transfer potentials to those with low phosphoryl group-transfer potentials.
- The thioester bond in acetyl-CoA is a “high-energy” bond.

The complete oxidation of a metabolic fuel such as glucose

releases considerable energy ($\Delta G^\circ = -2850 \text{ kJ} \cdot \text{mol}^{-1}$). The complete oxidation of palmitate, a typical fatty acid,

is even more exergonic ($\Delta G^\circ = -9781 \text{ kJ} \cdot \text{mol}^{-1}$). Oxidative metabolism proceeds in a stepwise fashion, so the released free energy can be recovered in a manageable form at each exergonic step of the overall process. *These “packets” of energy are conserved by the synthesis of a few types of “high-energy” intermediates whose subsequent exergonic breakdown drives endergonic processes.* These intermediates therefore form a sort of free energy “currency” through which free energy-producing reactions such as glucose oxidation or fatty acid oxidation “pay for” the free energy-consuming processes in biological systems (Box 14-2).

The cell uses several forms of energy currency, including phosphorylated compounds such as the nucleotide ATP (the cell’s primary energy currency), compounds that contain thioester bonds, and reduced coenzymes such as NADH. Each of these represents a source of free energy that the cell can use in various ways, including the synthesis of ATP. We will first examine ATP and then discuss the properties of other forms of energy currency.

GATEWAY CONCEPT Energy Transformation

Energy cannot be created or destroyed, but it can be transformed. The metabolic reactions that occur in cells convert one form of energy to another. Most often, the energy of chemical bonds is involved, but cells can also deal with thermal energy, light energy, mechanical energy, electrical energy, the energy of concentration gradients, and so on.

Box 14-2 Pathways of Discovery

Fritz Lipmann and “High-Energy” Compounds

Fritz Albert Lipmann (1899–1986) Among the many scientists who fled Europe for the United States in the 1930s was Fritz Lipmann, a German-born physician-turned-biochemist. During the first part of the twentieth century, scientists were interested primarily in the structures and compositions of biological molecules, so not much was known about their biosynthesis. Lipmann’s contribution to

this field centers on his understanding of “energy-rich” phosphates and other “active” compounds.

Lipmann began his research career by studying creatine phosphate, a compound that could provide energy for muscle contraction. He, like many of his contemporaries, was puzzled by the absence of an obvious link between this phosphorylated compound and the known metabolic activity of a contracting muscle, namely, converting glucose to lactate. One link was discovered by Otto Warburg (Box 15-1), who showed that one of the steps of glycolysis was accompanied by the incorporation of inorganic phosphate. The resulting acyl phosphate (1,3-bisphosphoglycerate) could then react with ADP to form ATP.

Lipmann wondered whether other phosphorylated compounds might behave in a similar manner. Because the purification of such labile (prone to degradation) compounds from whole cells was impractical, Lipmann synthesized them himself. He was able to show that cell extracts used synthetic acetyl phosphate to produce ATP. Lipmann went on to propose that cells contain two classes of phosphorylated compounds, which he termed “energy-poor” and “energy-rich,” by which he meant compounds with low and high negative free energies of hydrolysis (the “squiggle,” ~, which is still used, was his symbol for an “energy-rich” bond). Lipmann described a sort of “phosphate current”

in which photosynthesis or breakdown of food molecules generates “energy-rich” phosphates that lead to the synthesis of ATP. The ATP, in turn, can power mechanical work such as muscle contraction or drive biosynthetic reactions.

Until this point (1941), biochemists studying biosynthetic processes were largely limited to working with whole animals or relatively intact tissue slices. Lipmann’s insight regarding the role of ATP freed researchers from their cumbersome and poorly reproducible experimental systems. Biochemists could simply add ATP to their cell-free preparations to reconstitute the biosynthetic process.

Lipmann was intrigued by the discovery that a two-carbon group, an “active acetate,” served as a precursor for the synthesis of fatty acids and steroids. Was acetyl phosphate also the “active acetate”? This proved not to be the case, although Lipmann was able to show that the addition of a two-carbon unit to another molecule (acetylation) required acetate, ATP, and a heat-stable factor present in pigeon liver extracts. He isolated and determined the structure of this factor, which he named coenzyme A. For this seminal discovery, Lipmann was awarded the 1953 Nobel Prize in Physiology or Medicine.

Even after “high-energy” thioesters (as in acetyl-CoA) came on the scene, Lipmann remained a staunch advocate of “high-energy” phosphates. For example, he realized that carbamoyl phosphate ($\text{H}_2\text{N}-\text{COO}-\text{PO}_3^{2-}$) could function as an “active” carbamoyl group donor in biosynthetic reactions. He also helped identify more obscure compounds, mixed anhydrides between phosphate and sulfate, as “active” sulfates that function as sulfate group donors.

A ATP Has a High Phosphoryl Group-Transfer Potential

The “high-energy” intermediate adenosine triphosphate (ATP; Fig. 14-5) occurs in all known life-forms. ATP consists of an **adenosine** moiety (adenine + ribose) to which three phosphoryl ($-\text{PO}_3^{2-}$) groups are sequentially linked via a **phosphoester** bond followed by two **phosphoanhydride** bonds.

The biological importance of ATP rests in the large free energy change that accompanies cleavage of its phosphoanhydride bonds. This occurs when either a phosphoryl group is transferred to another compound, leaving ADP, or a nucleotidyl (AMP) group is transferred, leaving **pyrophosphate** ($\text{P}_2\text{O}_7^{4-}$; PP $_i$). When the acceptor is water, the process is known as hydrolysis:

Most biological group-transfer reactions involve acceptors other than water. However, knowing the free energy of hydrolysis of various phosphoryl compounds allows us to calculate the free energy of transfer of phosphoryl groups to other acceptors by determining the difference in free energy of hydrolysis of the phosphoryl donor and acceptor.

The ΔG° values for hydrolysis of several phosphorylated compounds of biochemical importance are tabulated in Table 14-3. The negatives of these values are often referred to as **phosphoryl group-transfer potentials**; they are a measure of the tendency of phosphorylated compounds to transfer their phosphoryl groups to water. Note that ATP has an intermediate phosphate group-transfer potential. Under standard conditions, the compounds above ATP in Table 14-3 can spontaneously transfer a phosphoryl group to ADP to form ATP, which can, in turn, spontaneously transfer a phosphoryl group to the appropriate groups to form the compounds listed below it. Note that a favorable free energy change for a reaction does not indicate how quickly the reaction occurs. Despite their high group-transfer potentials, ATP and related phosphoryl compounds are **kinetically stable** and do not react at a significant rate unless acted upon by an appropriate enzyme.

What Is the Nature of the “Energy” in “High-Energy” Compounds? Bonds whose hydrolysis proceeds with large negative values of ΔG° (customarily less than -25 kJ \cdot mol $^{-1}$) are often referred to as “**high-energy**” bonds or “**energy-rich**” bonds and are frequently symbolized by the squiggle (\sim). Thus, ATP can be represented as AR $-\text{P}\sim\text{P}\sim\text{P}$, where A, R, and P symbolize adenylyl, ribosyl, and phosphoryl groups, respectively. Yet the phosphoester bond joining the adenosyl group of ATP to its α -phosphoryl group appears to be not greatly different in electronic character from the “high-energy” bonds bridging its α - and β - and its β - and γ -phosphoryl groups. In fact, none of these bonds has any unusual properties, so the term “high-energy” bond is somewhat of a misnomer (in any case, it should not be confused with the term “bond energy,” which is defined as the energy required to break, not hydrolyze, a covalent bond). Why, then, are the phosphoryl group-transfer reactions of ATP so exergonic? Several factors appear to be responsible for the “high-energy” character of phosphoanhydride bonds such as those in ATP (Fig. 14-6):

1. The resonance stabilization of a phosphoanhydride bond is less than that of its hydrolysis products. This is because a phosphoanhydride’s two strongly electron-withdrawing groups must compete for the lone pairs of electrons of its bridging oxygen atom, whereas this competition is absent in the hydrolysis products. In other words, the electronic requirements of the phosphoryl groups are less satisfied in a phosphoanhydride than in its hydrolysis products.
2. Of perhaps greater importance is the destabilizing effect of the electrostatic repulsions between the charged groups of a phosphoanhydride compared to those of its hydrolysis products. In the physiological pH range, ATP has three to four negative charges whose mutual electrostatic repulsions are partially relieved by ATP hydrolysis.

3. Another destabilizing influence, which is difficult to assess, is the smaller solvation energy of a phosphoanhydride compared to that of its hydrolysis products. Some estimates suggest that this factor provides the dominant thermodynamic driving force for the hydrolysis of phosphoanhydrides.

Of course, the free energy change for any reaction, including phosphoryl group transfer from a “high-energy” compound, depends in part on the concentrations of the reactants and products (Eq. 14-1). Furthermore, because ATP and its hydrolysis products are ions, ΔG also depends on pH and ionic strength (Box 14-3).

B Coupled Reactions Drive Endergonic Processes

The hydrolysis of a “high-energy” compound, while releasing considerable free energy, is not in itself a useful reaction. However, the exergonic reactions of “high-energy” compounds can be coupled to endergonic processes to drive them to completion. The thermodynamic explanation for the coupling of an exergonic and an endergonic process is based on the additivity of free energy. Consider the following two-step reaction pathway:

If $\Delta G_1 \geq 0$, Reaction 1 will not occur spontaneously. However, if ΔG_2 is sufficiently exergonic so $\Delta G_1 + \Delta G_2 < 0$, then although the equilibrium concentration of D in Reaction 1 will be relatively small, it will be larger than that in Reaction 2. As Reaction 2 converts D to products, Reaction 1 will operate in the forward direction to replenish the equilibrium concentration of D. The highly exergonic Reaction 2 therefore “drives” or “pulls” the endergonic Reaction 1, and the two reactions are said to be coupled through their common intermediate, D. That these coupled reactions proceed spontaneously can also be seen by summing Reactions 1 and 2 to yield the overall reaction where $\Delta G_3 = \Delta G_1 + \Delta G_2 < 0$. As long as the overall pathway is exergonic, it will operate in the forward direction.

To illustrate this concept, let us consider two examples of phosphoryl group-transfer reactions. The initial step in the metabolism of glucose is its conversion to **glucose-6-phosphate** (Section 15-2A). Yet the direct reaction of glucose and

FIG. 14-6 Resonance and electrostatic stabilization in a phosphoanhydride and its hydrolytic products. The competing resonances (curved arrows from the central O) and charge-charge repulsions (zigzag lines) between phosphoryl groups decrease the stability of a phosphoanhydride relative to its hydrolysis products.

GATEWAY CONCEPT Resonance

Resonance refers to the delocalization of electrons in a chemical structure. Compounds are stabilized by resonance, which can be roughly assessed by the number of different ways to draw the structure.

Box 14-3 Perspectives in Biochemistry ATP and ΔG

The standard conditions reflected in $\Delta G^{\circ'}$ values never occur in living organisms. Furthermore, other compounds that are present at high concentrations and that can potentially interact with the substrates and products of a metabolic reaction may dramatically affect ΔG values. For example, Mg^{2+} ions in cells partially neutralize the negative charges on the phosphate groups in ATP and its hydrolysis products, thereby diminishing the electrostatic repulsions that make ATP hydrolysis so exergonic. Similarly, changes in pH alter the ionic character of phosphorylated compounds and therefore alter their free energies.

In a given cell, the concentrations of many ions, coenzymes, and metabolites vary with both location and time, often by several orders of magnitude. Intracellular ATP concentrations are maintained within a relatively narrow range, usually 2–10 mM, but the concentrations of ADP and P_i are more variable. Consider a typical cell with $[ATP] = 3.0$ mM, $[ADP] = 0.8$ mM, and $[P_i] = 4.0$ mM. Using Eq. 14-1, the actual free energy of ATP hydrolysis at 37°C is calculated as follows:

$$\begin{aligned} \Delta G &= \Delta G^{\circ'} + RT \ln \left(\frac{[ADP][P_i]}{[ATP]} \right) \\ &= -30.5 \text{ kJ} \cdot \text{mol}^{-1} + (8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K}) \\ &\quad \ln \left(\frac{(0.8 \times 10^{-3} \text{ M})(4.0 \times 10^{-3} \text{ M})}{(3.0 \times 10^{-3} \text{ M})} \right) \\ &= -30.5 \text{ kJ} \cdot \text{mol}^{-1} - 17.6 \text{ kJ} \cdot \text{mol}^{-1} \\ &= -48.1 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$

This value is even greater than the standard free energy of ATP hydrolysis. However, because of the difficulty in accurately measuring the concentrations of particular chemical species in a cell or organelle, the ΔG s for most *in vivo* reactions are little more than estimates. For the sake of consistency, we will, for the most part, use $\Delta G^{\circ'}$ values in this textbook.

FIG. 14-7 Some coupled reactions involving ATP. (a) The phosphorylation of glucose to form glucose-6-phosphate and ADP. (b) The phosphorylation of ADP by phosphoenolpyruvate to form ATP and pyruvate. Each reaction has been conceptually decomposed into a direct phosphorylation step (half-reaction 1) and a step in which ATP is hydrolyzed (half-reaction 2). Both half-reactions proceed in the direction that makes the overall reaction exergonic ($\Delta G < 0$).

? In theory, would the transfer of a phosphoryl group from phosphoenolpyruvate to glucose be spontaneous? Would the transfer of a phosphoryl group from glucose-6-phosphate to pyruvate be spontaneous?

P_i is thermodynamically unfavorable ($\Delta G^{\circ\prime} = +13.8 \text{ kJ} \cdot \text{mol}^{-1}$; Fig. 14-7a). In cells, however, this reaction is coupled to the exergonic cleavage of ATP (for ATP hydrolysis, $\Delta G^{\circ\prime} = -30.5 \text{ kJ} \cdot \text{mol}^{-1}$), so the overall reaction is thermodynamically favorable ($\Delta G^{\circ\prime} = +13.8 - 30.5 = -16.7 \text{ kJ} \cdot \text{mol}^{-1}$). ATP can be similarly regenerated ($\Delta G^{\circ\prime} = +30.5 \text{ kJ} \cdot \text{mol}^{-1}$) by coupling its synthesis from ADP and P_i to the even more exergonic cleavage of **phosphoenolpyruvate** ($\Delta G^{\circ\prime} = -61.9 \text{ kJ} \cdot \text{mol}^{-1}$; Fig. 14-7b and Section 15-2J).

Note that the half-reactions shown in Fig. 14-7 do not actually occur as written in an enzyme active site. **Hexokinase**, the enzyme that catalyzes the formation of glucose-6-phosphate (Fig. 14-7a), does not catalyze ATP hydrolysis but instead catalyzes the transfer of a phosphoryl group from ATP directly to glucose. Likewise, **pyruvate kinase**, the enzyme that catalyzes the reaction shown in Fig. 14-7b, does not add a free phosphoryl group to ADP but transfers a phosphoryl group from phosphoenolpyruvate to ADP to form ATP.

Phosphoanhydride Hydrolysis Drives Some Biochemical Processes. The free energy of the phosphoanhydride bonds of “high-energy” compounds such as ATP can be used to drive reactions even when the phosphoryl groups are not transferred to another organic compound. For example, ATP hydrolysis (i.e., phosphoryl group transfer directly to H_2O) provides the free energy for the operation of molecular chaperones (Section 6-5B), muscle contraction (Section 7-2B), and transmembrane active transport (Section 10-3). In these processes, proteins undergo conformational changes in response to binding ATP. *The exergonic hydrolysis of ATP and release of ADP and P_i renders these changes irreversible and thereby drives the processes forward.* GTP hydrolysis functions similarly to drive some of the reactions of signal transduction (Section 13-3B) and protein synthesis (Section 27-4).

In the absence of an appropriate enzyme, phosphoanhydride bonds are stable; that is, they hydrolyze quite slowly, despite the large amount of free energy released by these reactions. This is because these hydrolysis reactions have unusually high free energies of activation (ΔG^\ddagger ; Section 11-2). Consequently, *ATP hydrolysis is thermodynamically favored but kinetically disfavored*. For example, consider the reaction of glucose with ATP that yields glucose-6-phosphate (Fig. 14-7a). ΔG^\ddagger for the nonenzymatic transfer of a phosphoryl group from ATP to glucose is greater than that for ATP hydrolysis, so the hydrolysis reaction predominates (although neither reaction occurs at a biologically significant rate). However, in the presence of the appropriate enzyme, **hexokinase** (Section 15-2A), glucose-6-phosphate is formed far more rapidly than ATP is hydrolyzed. This is because the catalytic influence of the enzyme reduces the activation energy for phosphoryl group transfer from ATP to glucose to less than the activation energy for ATP hydrolysis. This example underscores the point that a thermodynamically favored reaction ($\Delta G < 0$) may not occur at a significant rate in a living system in the absence of a specific enzyme that catalyzes the reaction (i.e., lowers ΔG^\ddagger to increase the rate of product formation; Box 12-2).

Inorganic Pyrophosphatase Catalyzes Additional Phosphoanhydride Bond Cleavage. Although many reactions involving ATP yield ADP and P_i (**orthophosphate cleavage**), others yield AMP and PP_i (**pyrophosphate cleavage**). In these latter cases, the PP_i is rapidly hydrolyzed to 2 P_i by **inorganic pyrophosphatase** ($\Delta G^{\circ'} = -19.2 \text{ kJ} \cdot \text{mol}^{-1}$) so that *the pyrophosphate cleavage of ATP ultimately consumes two "high-energy" phosphoanhydride bonds*. The attachment of amino acids to tRNA molecules for protein synthesis is an example of this phenomenon (Fig. 14-8 and Section 27-2B). The two steps of the reaction are readily reversible because the free energies of hydrolysis of the bonds formed are comparable to that of ATP hydrolysis. The overall reaction is driven to completion by the irreversible hydrolysis of PP_i . Nucleic acid biosynthesis from nucleoside triphosphates also releases PP_i (Sections 25-1 and 26-1). The standard free energy changes of these reactions are around 0, so the subsequent hydrolysis of PP_i is also essential for the synthesis of nucleic acids.

C Some Other Phosphorylated Compounds Have High Phosphoryl Group-Transfer Potentials

"High-energy" compounds other than ATP are essential for energy metabolism, in part because they help maintain a relatively constant level of cellular ATP. *ATP is continually being hydrolyzed and regenerated*. Indeed, experimental

FIG. 14-8 Pyrophosphate cleavage in the synthesis of an aminoacyl-tRNA. (1) In the first reaction step, the amino acid is **adenylated** by ATP. (2) In the second step, a tRNA molecule displaces the AMP moiety to form an aminoacyl-tRNA. (3) The exergonic hydrolysis of pyrophosphate ($\Delta G^{\circ'} = -19.2 \text{ kJ} \cdot \text{mol}^{-1}$) drives the reaction forward.

? Write the net reaction for this process.

FIG. 14-9 Position of ATP relative to “high-energy” and “low-energy” phosphate compounds. Phosphoryl groups flow from the “high-energy” donors, via the ATP–ADP system, to “low-energy” acceptors.

evidence indicates that the metabolic half-life of an ATP molecule varies from seconds to minutes, depending on the cell type and its metabolic activity. For instance, brain cells have only a few seconds supply of ATP (which partly accounts for the rapid deterioration of brain tissue by oxygen deprivation). An average person at rest consumes and regenerates ATP at a rate of ~ 3 mol (1.5 kg) per hour and as much as an order of magnitude faster during strenuous activity.

Just as ATP drives endergonic reactions through the exergonic process of phosphoryl group transfer and phosphoanhydride hydrolysis, *ATP itself can be regenerated by coupling its formation to a more highly exergonic metabolic process.* As Table 14-3 indicates, in the thermodynamic hierarchy of phosphoryl-transfer agents, ATP occupies the middle rank. ATP can therefore be formed from ADP by direct transfer of a phosphoryl group from a “high-energy” compound (e.g., phosphoenolpyruvate; Fig. 14-7b and Section 15-2J). Such a reaction is referred to as a **substrate-level phosphorylation**. Other mechanisms generate ATP indirectly, using the energy supplied by transmembrane proton concentration gradients. In oxidative metabolism, this process is called **oxidative phosphorylation** (Section 18-3), whereas in photosynthesis, it is termed **photophosphorylation** (Section 19-2D).

The flow of energy from “high-energy” phosphate compounds to ATP and from ATP to “low-energy” phosphate compounds is diagrammed in Fig. 14-9. These reactions are catalyzed by enzymes known as **kinases**, which transfer phosphoryl groups from ATP to other compounds or from phosphorylated compounds to ADP. We will revisit these processes in our discussions of carbohydrate metabolism in Chapters 15 and 16.

The compounds whose phosphoryl group-transfer potentials are greater than that of ATP have additional stabilizing effects. For example, the hydrolysis of **acyl phosphates** (mixed phosphoric–carboxylic anhydrides), such as **acetyl phosphate** and **1,3-bisphosphoglycerate**,

is driven by the same competing resonance and differential solvation effects that influence the hydrolysis of phosphoanhydrides (Fig. 14-6). Apparently, these effects are more pronounced for acyl phosphates than for phosphoanhydrides, as the rankings in Table 14-3 indicate.

In contrast, compounds such as glucose-6-phosphate and **glycerol-3-phosphate**,

which are below ATP in Table 14-3, have no significantly different resonance stabilization or charge separation compared to their hydrolysis products. Their free energies of hydrolysis are therefore much less than those of the preceding “high-energy” compounds.

The high phosphoryl group-transfer potentials of **phosphoguanidines**, such as **phosphocreatine** and **phosphoarginine**, largely result from the competing

resonances in the **guanidino** group, which are even more pronounced than they are in the phosphate group of phosphoanhydrides:

Consequently, phosphocreatine can transfer its phosphoryl group to ADP to form ATP.

Phosphocreatine Provides a "High-Energy" Reservoir for ATP Formation. Muscle and nerve cells, which have a high ATP turnover, rely on phosphoguanidines to regenerate ATP rapidly. In vertebrates, phosphocreatine is synthesized by the reversible phosphorylation of creatine by ATP catalyzed by **creatine kinase**:

Note that this reaction is endergonic under standard conditions; however, *the intracellular concentrations of its reactants and products are such that it operates close to equilibrium* ($\Delta G \approx 0$). Accordingly, when the cell is in a resting state, so [ATP] is relatively high, the reaction proceeds with net synthesis of phosphocreatine, whereas at times of high metabolic activity, when [ATP] is low, the equilibrium shifts so as to yield net synthesis of ATP from phosphocreatine and ADP. *Phosphocreatine thereby acts as an ATP "buffer" in cells that contain creatine kinase.* A resting vertebrate skeletal muscle normally has sufficient phosphocreatine to supply its free energy needs for several minutes (but for only a few seconds at maximum exertion). In the muscles of some invertebrates, such as lobsters, phosphoarginine performs the same function. These phosphoguanidines are collectively named **phosphagens**.

Nucleoside Triphosphates Are Freely Interconverted. Many biosynthetic processes, such as the synthesis of proteins and nucleic acids, require nucleoside triphosphates other than ATP. For example, RNA synthesis requires the ribonucleotides CTP, GTP, and UTP, along with ATP, and DNA synthesis requires dCTP, dGTP, dTTP, and dATP (Section 3-1). All these nucleoside triphosphates (**NTPs**) are synthesized from ATP and the corresponding nucleoside diphosphate (**NDP**) in a reaction catalyzed by the nonspecific enzyme **nucleoside diphosphate kinase**:

The $\Delta G^{\circ'}$ values for these reactions are nearly 0, as might be expected from the structural similarities among the NTPs. These reactions are driven by the depletion of the NTPs through their exergonic utilization in subsequent reactions.

Other kinases reversibly convert nucleoside monophosphates to their diphosphate forms at the expense of ATP. One of these phosphoryl group-transfer reactions is catalyzed by **adenylate kinase**:

This enzyme is present in all tissues, where it functions to maintain equilibrium concentrations of the three nucleotides. When AMP accumulates, it is converted to ADP, which can be used to synthesize ATP through substrate-level phosphorylation, oxidative phosphorylation, or photophosphorylation. The reverse reaction helps restore cellular ATP because rapid consumption of ATP increases the level of ADP.

The X-ray structure of adenylate kinase, determined by Georg Schulz, reveals that, in the reaction catalyzed by the enzyme, two ~30-residue domains of the enzyme close over the substrates (Fig. 14-10), thereby tightly binding them and preventing water from entering the active site (which would lead to hydrolysis rather than phosphoryl group transfer). The movement of one of the domains depends on the presence of four invariant charged residues. Interactions between those groups and the bound substrates apparently trigger the rearrangements around the substrate-binding site (Fig. 14-10b).

Once the adenylate kinase reaction is complete, the tightly bound products must be rapidly released to maintain the enzyme's catalytic efficiency. Yet since the reaction is energetically neutral (the net number of phosphoanhydride bonds is unchanged), another source of free energy is required for rapid product release. Comparison of the X-ray structures of unliganded adenylate kinase and adenylate kinase in complex with the bisubstrate model compound Ap_5A (AMP and ATP connected by a fifth phosphate) show how the enzyme avoids the kinetic trap of tight-binding substrates and products: On binding substrate, a portion of the protein remote from the active site increases its chain mobility and thereby consumes some of the free energy of substrate binding. The region "resolidifies" when the binding site is opened and the products are released. This mechanism is thought to act as an "energetic counterweight" to help adenylate kinase maintain a high reaction rate.

D Thioesters Are Energy-Rich Compounds

The ubiquity of phosphorylated compounds in metabolism is consistent with their early evolutionary appearance. Yet phosphate is (and was) scarce in the abiotic world, which suggests that other kinds of molecules might have served as energy-rich compounds even before metabolic pathways became specialized for phosphorylated compounds. One candidate for a primitive "high-energy" compound is the **thioester**, which offers as its main recommendation its occurrence in the central

FIG. 14-10 Conformational changes in *E. coli* adenylate kinase on binding substrate. (a) The unliganded enzyme. (b) The enzyme with the bound bisubstrate analog Ap_5A . The Ap_5A is shown in stick form (C green, N blue, O red, and P yellow). The protein's cyan and blue domains undergo extensive conformational changes on ligand binding,

whereas the remainder of the protein (*magenta*), whose orientation is the same in Parts *a* and *b*, largely maintains its conformation. [Based on X-ray structures by Georg Schulz, Institut für Organische Chemie und Biochemie, Freiburg, Germany. PDBids (a) 4AKE and (b) 1AKE.]

FIG. 14-11 The chemical structure of **acetyl-CoA**. The thioester bond is drawn with a ~ to indicate that it is a “high-energy” bond (has a high negative free energy of hydrolysis). In CoA, the acetyl group is replaced by hydrogen.

metabolic pathways of all known organisms. Notably, the thioester bond is involved in substrate-level phosphorylation, an ATP-generating process that is independent of—and presumably arose before—oxidative phosphorylation.

The thioester bond appears in modern metabolic pathways as a reaction intermediate (involving a Cys residue in an enzyme active site) and in the form of acetyl-CoA (Fig. 14-11), the common product of carbohydrate, fatty acid, and amino acid catabolism. **Coenzyme A (CoASH or CoA)** consists of a β -mercaptoethylamine group bonded through an amide linkage to the vitamin **pantothenic acid**, which, in turn, is attached to a 3'-phosphoadenosine moiety via a pyrophosphate bridge. The acetyl group of acetyl-CoA is bonded as a thioester to the sulfhydryl portion of the β -mercaptoethylamine group. *CoA thereby functions as a carrier of acetyl and other acyl groups* (the A of CoA stands for “acetylation”). Thioesters also take the form of acyl chains bonded to a phosphopantetheine residue that is linked to a Ser OH group in a protein (Section 20-4C) rather than to 3'-phospho-AMP, as in CoA.

Acetyl-CoA is a “high-energy” compound. The ΔG° for the hydrolysis of its thioester bond is $-31.5 \text{ kJ} \cdot \text{mol}^{-1}$, which makes this reaction slightly ($1 \text{ kJ} \cdot \text{mol}^{-1}$) more exergonic than ATP hydrolysis. The hydrolysis of thioesters is more exergonic than that of ordinary esters because the thioester is less stabilized by resonance. This destabilization is a result of the large atomic radius of S, which reduces the electronic overlap between C and S compared to that between C and O.

The formation of a thioester bond in a metabolic intermediate conserves a portion of the free energy of oxidation of a metabolic fuel. That free energy can then be used to drive an exergonic process. In the citric acid cycle, for example, cleavage of a thioester (**succinyl-CoA**) releases sufficient free energy to synthesize GTP from GDP and P_i (Section 17-3E).

CHECKPOINT

- What kinds of molecules do cells use as energy currency?
- Why is ATP a “high-energy” compound?
- Describe the ways an exergonic process can drive an endergonic process.
- Why is the activity of inorganic pyrophosphatase metabolically indispensable?
- Explain how cellular ATP is replenished by phosphagens.
- What are the cellular roles of nucleoside diphosphate kinase and adenylate kinase?

3 Oxidation–Reduction Reactions

KEY CONCEPTS

- The electron carriers NAD^+ and FAD accept electrons from reduced metabolites and transfer them to other compounds.
- The Nernst equation describes the thermodynamics of oxidation–reduction reactions.
- The reduction potential describes the tendency for an oxidized compound to gain electrons (become reduced); the change in reduction potential for a reaction describes the tendency for a given oxidized compound to accept electrons from a given reduced compound.
- Free energy and reduction potential are negatively related: the greater the reduction potential, the more negative the free energy and the more favorable the reaction.

As metabolic fuels are oxidized to CO_2 , electrons are transferred to molecular carriers that, in aerobic organisms, ultimately transfer the electrons to molecular oxygen. The process of electron transport results in a transmembrane proton concentration gradient that drives ATP synthesis (oxidative phosphorylation; Section 18-3). Even obligate anaerobes, which do not carry out oxidative phosphorylation, rely on the oxidation of substrates to drive ATP synthesis. In fact, oxidation–reduction reactions (also known as **redox reactions**) supply living things with most of their free energy. In this section, we examine the thermodynamic basis for the conservation of free energy during substrate oxidation.

A NAD^+ and FAD Are Electron Carriers

Two of the most widely occurring electron carriers are the nucleotide coenzymes nicotinamide adenine dinucleotide (NAD^+) and **flavin adenine dinucleotide (FAD)**. The nicotinamide portion of NAD^+ (and its phosphorylated counterpart NADP^+ ; Fig. 11-4) is the site of reversible reduction, which formally occurs as the transfer of a hydride ion (H^- ; a proton with two electrons) as indicated in Fig. 14-12. The terminal electron acceptor in aerobic organisms, O_2 , can accept only unpaired electrons (because each of its two available lowest energy molecular orbitals is already occupied by one electron); that is, electrons must be transferred to O_2 one at a time. Electrons that are removed from metabolites as pairs (e.g., with the two-electron reduction of NAD^+) must be transferred to other carriers that can undergo both two-electron and one-electron redox reactions. FAD (Fig. 14-13) is such a coenzyme.

The conjugated ring system of FAD can accept one or two electrons to produce the stable radical (semiquinone) $\text{FADH}\cdot$ or the fully reduced (hydroquinone) FADH_2 (Fig. 14-14). The change in the electronic state of the ring system on reduction is reflected in a color change from brilliant yellow (in FAD) to pale yellow (in FADH_2). The metabolic functions of NAD^+ and FAD demand

FIG. 14-12 Reduction of NAD^+ to NADH . R represents the ribose–pyrophosphoryl–adenosine portion of the coenzyme. Only the nicotinamide ring is affected by reduction, which is formally represented here as occurring by hydride transfer.

FIG. 14-13 Flavin adenine dinucleotide (FAD). Adenosine (red) is linked to riboflavin (black) by a pyrophosphoryl group (green). The riboflavin portion of FAD is also known as vitamin B₂.

? Locate the base, ribose, and phosphate groups of this dinucleotide.

that they undergo reversible reduction so that they can accept electrons, pass them on to other electron carriers, and thereby be regenerated to participate in additional cycles of oxidation and reduction.

Humans cannot synthesize the flavin moiety of FAD but, rather, must obtain it from their diets, for example, in the form of riboflavin (vitamin B₂; Fig. 14-13). Nevertheless, riboflavin deficiency is quite rare in humans, in part because of the tight binding of flavin prosthetic groups to their apoenzymes. The symptoms of riboflavin deficiency, which are associated with general malnutrition or bizarre diets, include an inflamed tongue, lesions in the corner of the mouth, and dermatitis.

B The Nernst Equation Describes Oxidation–Reduction Reactions

Oxidation–reduction reactions resemble other types of group-transfer reactions except that the “groups” transferred are electrons, which are passed from an **electron donor** (reductant or **reducing agent**) to an **electron acceptor** (oxidant or **oxidizing agent**).

For example, in the reaction

Cu⁺, the reductant, is oxidized to Cu²⁺ while Fe³⁺, the oxidant, is reduced to Fe²⁺.

Redox reactions can be divided into two **half-reactions**, such as

whose sum is the whole reaction above. These particular half-reactions occur during the oxidation of cytochrome *c* oxidase in the mitochondrion (Section 18-2F). Note that for electrons to be transferred, both half-reactions must occur simultaneously. In fact, the electrons are the two half-reactions’ common intermediate.

A half-reaction consists of an electron donor and its conjugate electron acceptor; in the oxidative half-reaction shown above, Cu⁺ is the electron donor and Cu²⁺ is its conjugate electron acceptor. Together these constitute a **redox couple** or **conjugate redox pair** analogous to a conjugate acid–base pair (HA and A[−]; Section 2-2B). An important difference between redox pairs and acid–base pairs, however, is that *the two half-reactions of a redox reaction, each*

FIG. 14-14 Reduction of FAD to FADH₂. R represents the ribitol–pyrophosphoryl–adenosine portion of the coenzyme. The conjugated ring system of FAD can undergo two sequential one-electron reductions or a two-electron transfer that bypasses the **semiquinone** state.

FIG. 14-15 An electrochemical cell. The half-cell undergoing oxidation (here $\text{Cu}^+ \rightarrow \text{Cu}^{2+} + e^-$) passes the liberated electrons through the wire to the half-cell undergoing reduction (here $e^- + \text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$). Electroneutrality in the two half-cells is maintained by the transfer of ions through the electrolyte-containing salt bridge.

GATEWAY CONCEPT Oxidation–Reduction Reactions

For one substance to be reduced (gain electrons), another substance must be oxidized (lose electrons). In other words, an electron donor and an electron acceptor must appear on each side of an equilibrium expression. In oxidation–reduction reactions, the electrons remain associated with molecules; free electrons do not float around inside cells.

consisting of a conjugate redox pair, can be physically separated to form an **electrochemical cell** (Fig. 14-15). In such a device, each half-cell takes place in its separate **half-cell**, and electrons are passed between half-cells as an electric current in the wire connecting their two electrodes. A salt bridge is necessary to complete the electrical circuit by providing a conduit for ions to migrate and thereby maintain electrical neutrality.

The free energy of an oxidation–reduction reaction is particularly easy to determine by simply measuring the voltage difference between its two half-cells. Consider the general reaction

in which n electrons per mole of reactants are transferred from reductant (B_{red}) to oxidant ($\text{A}_{\text{ox}}^{n+}$). The free energy of this reaction is expressed as

$$\Delta G = \Delta G^{\circ'} + RT \ln \left(\frac{[\text{A}_{\text{red}}][\text{B}_{\text{ox}}^{n+}]}{[\text{A}_{\text{ox}}^{n+}][\text{B}_{\text{red}}]} \right) \quad [14-4]$$

Under reversible conditions,

$$\Delta G = -w' = -w_{\text{el}} \quad [14-5]$$

where w' is non-pressure–volume work. In this case, w' is equivalent to w_{el} , the electrical work required to transfer the n moles of electrons through the **electrical potential difference**, $\Delta \mathcal{E}$ [where the units of \mathcal{E} are volts (V), the number of joules (J) of work required to transfer 1 coulomb (C) of charge]. This, according to the laws of electrostatics, is

$$w_{\text{el}} = n\mathcal{F}\Delta \mathcal{E} \quad [14-6]$$

where \mathcal{F} , the **faraday**, is the electrical charge of 1 mol of electrons ($1 \mathcal{F} = 96,485 \text{ C} \cdot \text{mol}^{-1} = 96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1}$), and n is the number of moles of electrons transferred per mole of reactant converted. Thus, substituting Eq. 14-6 into Eq. 14-5,

$$\Delta G = -n\mathcal{F}\Delta \mathcal{E} \quad [14-7]$$

Combining Eqs. 14-4 and 14-7, and making the analogous substitution for ΔG° , yields the **Nernst equation**:

$$\Delta \mathcal{E} = \Delta \mathcal{E}^{\circ} - \frac{RT}{n\mathcal{F}} \ln \left(\frac{[\text{A}_{\text{red}}][\text{B}_{\text{ox}}^{n+}]}{[\text{A}_{\text{ox}}^{n+}][\text{B}_{\text{red}}]} \right) \quad [14-8]$$

which was originally formulated in 1881 by Walther Nernst. Here, \mathcal{E} is the **reduction potential**, the tendency for a substance to undergo reduction (gain electrons). $\Delta \mathcal{E}$, the **electromotive force (emf)**, can be described as the “electron pressure” that the electrochemical cell exerts. The quantity \mathcal{E}° , the reduction

potential when all components are in their standard states, is called the **standard reduction potential**. If these standard states refer to biochemical standard states (Section 1-3D), then \mathcal{E}° is replaced by \mathcal{E}' . Note that a positive $\Delta\mathcal{E}$ in Eq. 14-7 results in a negative ΔG ; in other words, a positive $\Delta\mathcal{E}$ indicates a spontaneous reaction, one that can do work.

C Spontaneity Can Be Determined by Measuring Reduction Potential Differences

Equation 14-7 shows that the free energy change of a redox reaction can be determined by directly measuring its change in reduction potential with a voltmeter (Fig. 14-15). Such measurements make it possible to determine the order of spontaneous electron transfers among a set of electron carriers such as those of the electron-transport pathway that mediates oxidative phosphorylation in cells.

Any redox reaction can be divided into its component half-reactions:

where, by convention, both half-reactions are written as reductions. These half-reactions can be assigned reduction potentials, \mathcal{E}_A and \mathcal{E}_B , in accordance with the Nernst equation:

$$\mathcal{E}_A = \mathcal{E}'_A - \frac{RT}{n\mathcal{F}} \ln \left(\frac{[A_{\text{red}}]}{[A_{\text{ox}}^{n+}]} \right) \quad [14-9]$$

$$\mathcal{E}_B = \mathcal{E}'_B - \frac{RT}{n\mathcal{F}} \ln \left(\frac{[B_{\text{red}}]}{[B_{\text{ox}}^{n+}]} \right) \quad [14-10]$$

For the overall redox reaction involving the two half-reactions, the difference in reduction potential, $\Delta\mathcal{E}'$, is defined as

$$\Delta\mathcal{E}' = \mathcal{E}'_{(e^- \text{ acceptor})} - \mathcal{E}'_{(e^- \text{ donor})} \quad [14-11]$$

Thus, when the reaction proceeds with A as the electron acceptor and B as the electron donor, $\Delta\mathcal{E}' = \mathcal{E}'_A - \mathcal{E}'_B$ and $\Delta\mathcal{E} = \mathcal{E}_A - \mathcal{E}_B$.

Standard Reduction Potentials Are Used to Compare Electron Affinities. Reduction potentials, like free energies, must be defined with respect to some arbitrary standard, in this case, the hydrogen half-reaction

in which H^+ is in equilibrium with $\text{H}_2(\text{g})$ that is in contact with a Pt electrode. This half-cell is arbitrarily assigned a standard reduction potential \mathcal{E}° of 0 V ($1\text{ V} = 1\text{ J} \cdot \text{C}^{-1}$) at pH 0, 25°C, and 1 atm. Under the biochemical convention, where the standard state is pH 7.0, the hydrogen half-reaction has a standard reduction potential \mathcal{E}' of -0.421 V .

When $\Delta\mathcal{E}$ is positive, ΔG is negative (Eq. 14-7), indicating a spontaneous process. In combining two half-reactions under standard conditions, the direction of spontaneity therefore involves the reduction of the redox couple with the more positive standard reduction potential. In other words, *the more positive the standard reduction potential, the higher the affinity of the redox couple's oxidized form for electrons; that is, the greater the tendency for the redox couple's oxidized form to accept electrons and thus become reduced.*

Biochemical Half-Reactions Are Physiologically Significant. The biochemical standard reduction potentials (\mathcal{E}') of some biochemically important half-reactions

are listed in **Table 14-4**. The oxidized form of a redox couple with a large positive standard reduction potential has a high affinity for electrons and is a strong electron acceptor (oxidizing agent), whereas its conjugate reductant is a weak electron donor (reducing agent). For example, O_2 is the strongest oxidizing agent in Table 14-4, whereas H_2O , which tightly holds its electrons, is the table's weakest reducing agent. The converse is true of half-reactions with large negative standard reduction potentials.

Since electrons spontaneously flow from low to high reduction potentials, they are transferred, under standard conditions, from the reduced products in any half-reaction in Table 14-4 to the oxidized reactants of any half-reaction above it (see Sample Calculation 14-2). However, such a reaction may not occur at a measurable rate in the absence of a suitable enzyme. Note that Fe^{3+} ions of the various cytochromes listed in Table 14-4 have significantly different reduction potentials.

TABLE 14-4 Standard Reduction Potentials of Some Biochemically Important Half-Reactions

Half-Reaction	\mathcal{E}' (V)
$\frac{1}{2}O_2 + 2H^+ + 2e^- \rightleftharpoons H_2O$	0.815
$NO_3^- + 2H^+ + 2e^- \rightleftharpoons NO_2^- + H_2O$	0.42
Cytochrome $a_3(Fe^{3+}) + e^- \rightleftharpoons$ cytochrome $a_3(Fe^{2+})$	0.385
$O_2 + 2H^+ + 2e^- \rightleftharpoons H_2O_2$	0.295
Cytochrome $a(Fe^{3+}) + e^- \rightleftharpoons$ cytochrome $a(Fe^{2+})$	0.29
Cytochrome $c(Fe^{3+}) + e^- \rightleftharpoons$ cytochrome $c(Fe^{2+})$	0.235
Cytochrome $c_1(Fe^{3+}) + e^- \rightleftharpoons$ cytochrome $c_1(Fe^{2+})$	0.22
Cytochrome $b(Fe^{3+}) + e^- \rightleftharpoons$ cytochrome $b(Fe^{2+})(mitochondrial)$	0.077
Ubiquinone + $2H^+ + 2e^- \rightleftharpoons$ ubiquinol	0.045
Fumarate $^- + 2H^+ + 2e^- \rightleftharpoons$ succinate $^-$	0.031
$FAD + 2H^+ + 2e^- \rightleftharpoons FADH_2$ (in flavoproteins)	-0.040
Oxaloacetate $^- + 2H^+ + 2e^- \rightleftharpoons$ malate $^-$	-0.166
Pyruvate $^- + 2H^+ + 2e^- \rightleftharpoons$ lactate $^-$	-0.185
Acetaldehyde + $2H^+ + 2e^- \rightleftharpoons$ ethanol	-0.197
$FAD + 2H^+ + 2e^- \rightleftharpoons FADH_2$ (free coenzyme)	-0.219
$S + 2H^+ + 2e^- \rightleftharpoons H_2S$	-0.23
Lipoic acid + $2H^+ + 2e^- \rightleftharpoons$ dihydrolipoic acid	-0.29
$NAD^+ + H^+ + 2e^- \rightleftharpoons NADH$	-0.315
$NADP^+ + H^+ + 2e^- \rightleftharpoons NADPH$	-0.320
Cysteine disulfide + $2H^+ + 2e^- \rightleftharpoons$ 2 cysteine	-0.340
Acetoacetate $^- + 2H^+ + 2e^- \rightleftharpoons$ β -hydroxybutyrate $^-$	-0.346
$H^+ + e^- \rightleftharpoons \frac{1}{2}H_2$	-0.421
$SO_4^{2-} + 2H^+ + 2e^- \rightleftharpoons SO_3^{2-} + H_2O$	-0.515
Acetate $^- + 3H^+ + 2e^- \rightleftharpoons$ acetaldehyde + H_2O	-0.581

? Are electrons more likely to move from ubiquinol to acetaldehyde or from ethanol to ubiquinone?

SAMPLE CALCULATION 14-2

Calculate $\Delta G^{\circ'}$ for the oxidation of NADH by FAD.

Combining the relevant half-reactions gives

Next, calculate the electromotive force ($\Delta \mathcal{E}^{\circ'}$) from the standard reduction potentials given in Table 14-4, using one of the following methods.

Method 1

According to Eq. 14-11,

$$\Delta \mathcal{E}^{\circ'} = \mathcal{E}^{\circ'}_{(e^- \text{ acceptor})} - \mathcal{E}^{\circ'}_{(e^- \text{ donor})}$$

Since FAD ($\mathcal{E}^{\circ'} = -0.219 \text{ V}$) is the electron acceptor, and NADH ($\mathcal{E}^{\circ'} = -0.315 \text{ V}$) is the electron donor,

$$\Delta \mathcal{E}^{\circ'} = (-0.219 \text{ V}) - (-0.315 \text{ V}) = +0.096 \text{ V}$$

Method 2

Write the net reaction as a sum of the two relevant half-reactions. For FAD, the half-reaction is the same as the reductive half-reaction given in Table 14-4, and its $\mathcal{E}^{\circ'}$ value is -0.219 V . For NADH, which undergoes oxidation rather than reduction, the half-reaction is the reverse of the one given in Table 14-4, and its $\mathcal{E}^{\circ'}$ value is $+0.315 \text{ V}$, the reverse of the reduction potential given in the table. The two half-reactions are added to give the net oxidation–reduction reaction, and the $\mathcal{E}^{\circ'}$ values are also added:

Next, use Eq. 14-7 to calculate $\Delta G^{\circ'}$. Because two moles of electrons are transferred for every mole of NADH oxidized to NAD^+ , $n = 2$.

$$\Delta G^{\circ'} = -n\mathcal{F}\Delta \mathcal{E}^{\circ'}$$

$$\Delta G^{\circ'} = -(2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(0.096 \text{ V}) = -18.5 \text{ kJ} \cdot \text{mol}^{-1}$$

WPLS See Sample Calculation Videos.

This indicates that *the protein components of redox enzymes play active roles in electron-transfer reactions by modulating the reduction potentials of their bound redox-active centers.*

Electron-transfer reactions are of great biological importance. For example, in the mitochondrial electron-transport chain (Section 18-2), electrons are passed from NADH along a series of electron acceptors of increasing reduction potential (including ubiquinone and others listed in Table 14-4) to O_2 . ATP is generated from ADP and P_i by coupling its synthesis to this free energy cascade. *NADH thereby functions as an energy-rich electron-transfer coenzyme.* In fact, the oxidation by O_2 of one NADH to NAD^+ supplies sufficient free energy to generate almost three ATPs. NAD^+ is an electron acceptor in many exergonic metabolite oxidations. In serving as the electron donor in ATP synthesis, it fulfills its cyclic role as a free energy conduit in a manner analogous to ATP (Fig. 14-9).

CHECKPOINT

- What are the metabolic roles of the coenzymes NAD^+ and FAD?
- Explain why NADH and FADH_2 are a type of energy currency in the cell.
- Explain the terms of the Nernst equation.
- When two half-reactions are combined, how can you predict which compound will be oxidized and which will be reduced?
- How is $\Delta \mathcal{E}$ related to ΔG ?

4 Experimental Approaches to the Study of Metabolism

KEY CONCEPTS

- Metabolic pathways are often studied by tracing metabolites labeled with radionuclides or NMR-active isotopes.
- The steps of a pathway can be identified by examining how metabolic inhibitors and genetic defects lead to the accumulation of pathway intermediates.
- DNA microarrays and proteomics techniques are used to determine the genetic expression of metabolic enzymes.
- A cell's metabolic activity is reflected in its metabolome.

A metabolic pathway can be understood at several levels:

1. In terms of the sequence of reactions by which a specific nutrient is converted to end products, and the energetics of the conversions.
2. In terms of the mechanisms by which each intermediate is converted to its successor. Such an analysis requires the isolation and characterization of the specific enzymes that catalyze each reaction.
3. In terms of the control mechanisms that regulate the flow of metabolites through the pathway. These mechanisms include the interorgan relationships that adjust metabolic activity to the needs of the entire organism.

Elucidating a metabolic pathway on all these levels is a complex process, often requiring contributions from a variety of disciplines.

The outlines of the major metabolic pathways have been known for decades, although in many cases, the enzymology behind various steps of the pathways remains unclear. Likewise, the mechanisms that regulate pathway activity under different physiological conditions are not entirely understood. These areas are of great interest because of their potential to yield information that could be useful in improving human health and curing metabolic diseases. Understanding the metabolic alterations that occur in cancer is a particularly active area of research. In addition, the metabolisms of microorganisms hold the promise of novel biological materials and enzymatic processes that can be exploited for the environmentally sensitive production of industrial materials, foods, and therapeutic drugs.

Early metabolic studies used whole organisms—often yeast, but also mammals. For example, Frederick Banting and Charles Best established the role of the pancreas in diabetes in 1921; they surgically removed that organ from dogs and observed that the animals then developed the disease (Box 22-2). Techniques for studying metabolic processes have since become more refined, progressing from whole-organ preparations and thin tissue slices to cultured cells and isolated organelles. The most recent approaches include identifying genes, their protein products, and the metabolites that appear as a result of their activities.

A Labeled Metabolite Can Be Traced

A metabolic pathway in which one compound is converted to another can be followed by tracing a specifically labeled metabolite. Franz Knoop formulated this technique in 1904 to study fatty acid oxidation. He fed dogs fatty acids chemically labeled with phenyl groups and isolated the phenyl-substituted end products from the dogs' urine. From the differences in these products, depending on whether the phenyl-substituted starting material contained odd or even numbers of carbon atoms, Knoop deduced that fatty acids are degraded in two-carbon units (Section 20-2). Modern biochemists use a similar approach, often introducing compounds tagged with a fluorescent group that can be traced within a tissue sample or even in a single cell (Table 14-5).

Chemical labeling has the disadvantage that the chemical properties of labeled metabolites differ from those of normal metabolites. This problem is largely

TABLE 14-5 Some Fluorescent Markers Used in Biochemistry

Fluorophore	Excitation maximum (nm) ^a	Emission maximum (nm)
Aminocoumarin	350	445
Fluorescein	495	519
Cy3	550	570
Phycoerythrin	565	578
Texas Red (sulforhodamine)	589	615
Cy5	650	670

^aA fluorophore (fluorescent group), becomes excited on absorption of one wavelength of light and emits light of a longer (lower energy) wavelength.

eliminated by labeling molecules with isotopes. *The fate of an isotopically labeled atom in a metabolite can therefore be elucidated by following its progress through the metabolic pathway of interest.* The advent of isotopic labeling and tracing techniques in the 1940s revolutionized the study of metabolism. Some of the most common radioactive isotopes (**radionuclides**) used in biochemistry are listed in **Table 14-6**, along with their half-lives and the type of radioactivity emitted by the spontaneously disintegrating atomic nuclei. Radioactive compounds can be detected by their ability to expose photographic film. Alternatively, β particles and γ rays can excite fluorescent compounds, and the emitted light can be measured.

One of the early advances in metabolic understanding resulting from the use of isotopic tracers was the demonstration, by David Shemin and David Rittenberg in 1945, that the nitrogen atoms of heme (Fig. 7-2) are derived from glycine rather than from ammonia, glutamic acid, proline, or leucine (Section 21-6A). They showed this by feeding rats the ¹⁵N-labeled nutrients, isolating the heme in their blood, and analyzing it by mass spectrometry for ¹⁵N content. Only when the rats were fed [¹⁵N] glycine did the heme contain ¹⁵N. This technique was also used with the radioactive isotope ¹⁴C to demonstrate that all of cholesterol's carbon atoms are derived from acetyl-CoA (Section 20-7A). Radioactive isotopes have become virtually indispensable for establishing the metabolic origins of complex metabolites. Whole-body scanning techniques, often used to locate sites of tumor growth, also use radioactive compounds, such as 2-deoxy-2-[¹⁸F]fluoro-D-glucose, that are taken up by cells.

TABLE 14-6 Some Radioactive Isotopes Used in Biochemistry

Radionuclide	Half-Life	Type of Radiation ^a
³ H	12.31 years	β

Another method for tracing the fates of labeled metabolites is nuclear magnetic resonance (NMR), which detects specific isotopes, including ^1H , ^{13}C , ^{15}N , and ^{31}P , by their characteristic nuclear spins. Since the NMR spectrum of a particular nucleus varies with its immediate environment, it is possible to identify the peaks corresponding to specific atoms even in relatively complex mixtures. The development of magnets large enough to accommodate animals and humans, and to localize spectra to specific organs, has made it possible to study metabolic pathways noninvasively by NMR techniques. For example, ^{31}P NMR can be used to study energy metabolism in muscle by monitoring the levels of phosphorylated compounds such as ATP, ADP, and phosphocreatine.

Isotopically labeling specific atoms of metabolites with ^{13}C (which is only 1.10% naturally abundant) permits the metabolic progress of the labeled atoms to be followed by ^{13}C NMR. **Figure 14-16** shows *in vivo* ^{13}C NMR spectra of a rat liver before and after an injection of D-[1- ^{13}C]glucose. The ^{13}C can be seen entering the liver and then being incorporated into glycogen (the storage form of glucose; Section 16-2).

B Studying Metabolic Pathways Often Involves Perturbing the System

Many of the techniques used to elucidate the intermediates and enzymes of metabolic pathways involve perturbing the system in some way and observing how

FIG. 14-16 The conversion of [1- ^{13}C]glucose to glycogen as observed by localized *in vivo* ^{13}C NMR. (a) The natural abundance ^{13}C NMR spectrum of the liver of a live rat. Note the resonance corresponding to C1 of glycogen. (b) The ^{13}C NMR spectrum of the liver of the same rat ~5 min after it was intravenously injected with 100 mg of [1- ^{13}C]glucose (90% enriched). The resonances of the C1 atom of both the α and β anomers of glucose are clearly distinguishable from each other and from the resonance of the C1 atom of glycogen. (c) The ^{13}C NMR spectrum of the liver of the same rat ~30 min after the [1- ^{13}C]glucose injection. The C1 resonances of both the α - and β -glucose anomers are much reduced while the C1 resonance of glycogen has increased. [After Reo, N.V., Siegfried, B.A., and Acherman, J.J.H., *J. Biol. Chem.* **259**, 13665 (1984).]

this affects the activity of the pathway. One way to perturb a pathway is to add certain substances, called **metabolic inhibitors**, that block the pathway at specific points, thereby causing the preceding intermediates to build up. This approach was used in elucidating the conversion of glucose to ethanol in yeast by glycolysis (Section 15-2). Similarly, the addition of substances that block electron transfer at different sites was used to deduce the sequence of electron carriers in the mitochondrial electron-transport chain (Section 18-2B).

Genetic Defects Also Cause Metabolic Intermediates to Accumulate. Archibald Garrod's realization, in the early 1900s, that human genetic diseases are the consequence of deficiencies in specific enzymes also contributed to the elucidation of metabolic pathways. For example, upon the ingestion of either phenylalanine or tyrosine, individuals with the largely harmless inherited condition known as **alcaptonuria**, but not normal subjects, excrete **homogentisic acid** in their urine (Box 21-2). This is because the liver of alcaptonurics lacks an enzyme that catalyzes the breakdown of homogentisic acid (Fig. 14-17).

Genetic Manipulation Alters Metabolic Processes. Early studies of metabolism led to the astounding discovery that *the basic metabolic pathways in most organisms are essentially identical*. This metabolic uniformity has greatly facilitated the study of metabolic reactions. Thus, although a mutation that inactivates or deletes an enzyme in a pathway of interest may be unknown in higher organisms, it can be readily generated in a rapidly reproducing microorganism through the use of **mutagens** (chemical agents that induce genetic changes; Section 25-4A), X-rays, or, more recently, through genetic engineering techniques (Section 3-5). The desired mutants, which cannot synthesize the pathway's end product, can be identified by their requirement for that product in their culture medium.

Higher organisms that have been engineered to lack particular genes (i.e., gene "knockouts"; Section 3-5D) are useful, particularly in cases in which the absence of a single gene product results in a metabolic defect but is not lethal. Genetic engineering techniques have advanced to the point that it is possible to selectively "knock out" a gene only in a particular tissue. This approach is necessary in cases in which a gene product is required for development and therefore cannot be entirely deleted. In the opposite approach, techniques for constructing transgenic animals make it possible to express genes in tissues in which they were not originally present.

C Systems Biology Has Entered the Study of Metabolism

Metabolism has traditionally been studied by hypothesis-driven research: isolating individual enzymes and metabolites and assembling them into metabolic pathways as guided by experimentally testable hypotheses. A new approach, **systems biology**, has emerged with the advent of complete genome sequences; the development of rapid and sensitive techniques for analyzing large numbers of gene transcripts, proteins, and metabolites all at once; and the development of new computational and mathematical tools. Systems biology is discovery-based: collecting and integrating enormous amounts of data in searchable databases so the properties and dynamics of entire biological networks can be analyzed. As a result, our understanding of the path from genotype to phenotype has expanded. In addition to the central dogma (Section 3-3B) that a single gene composed of DNA is transcribed to mRNA which is translated to a single protein that influences metabolism, we can explore these levels of gene expression in more detail. For example, we can assess the **genome**, **transcriptome** (the entire collection of RNA transcribed by a cell), **proteome** (the complete set of proteins synthesized by a cell in response to changing conditions), and **metabolome** (the cell's collection of metabolic intermediates) as well as

FIG. 14-17 Pathway for phenylalanine degradation. Alcaptonurics lack the enzyme that breaks down homogentisate; therefore, this intermediate accumulates and is excreted in the urine.

? What type of chemical change occurs at each step shown here?

FIG. 14-18 The relationship between genotype and phenotype. The path from genetic information (genotype) to metabolic function (phenotype) has several steps. Portions of the genome are transcribed to produce the transcriptome, which directs the synthesis of the proteome, whose various activities are responsible for synthesizing and degrading the components of the metabolome.

? What techniques would you use to quantify or identify the molecules at each level?

their interrelationships (Fig. 14-18). The term **bibliome** (Greek: *biblion*, book) has even been coined to denote the systematic incorporation of preexisting information about reaction mechanisms and metabolic pathways. Dozens of pathways are catalogued in Internet-accessible databases that list the structures and names of the intermediates and the enzymes that catalyze their interconversion, along with links to gene sequences and three-dimensional protein structures (see Bioinformatics Project 8). Two examples of such databases are the Kyoto Encyclopedia of Genes and Genomes (KEGG) Pathway Database: <http://www.genome.jp/kegg>; and BRENDA (BRaunschweig ENzyme DAtabase): www.brenda-enzymes.org/. In the following paragraphs we discuss some of the emerging technologies used in systems biology.

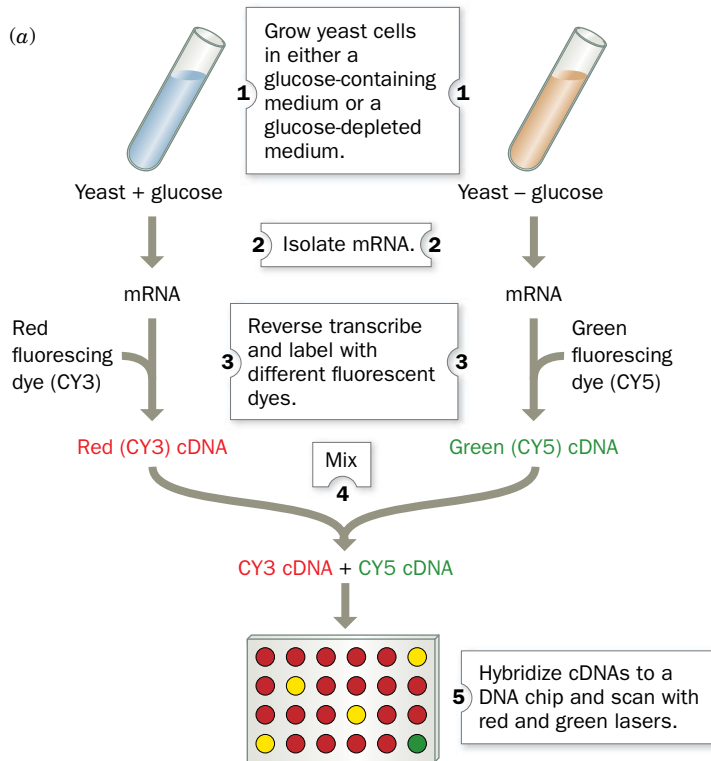

Genomics Examines the Entire Complement of an Organism's DNA Sequences.

The overall metabolic capabilities of an organism are encoded by its genome (its entire complement of genes). In theory, it should be possible to reconstruct a cell's metabolic activities from its DNA sequences. At present, this can be done only in a general sense. For example, the sequenced genome of *Vibrio cholerae*, the bacterium that causes cholera, reveals a large repertoire of genes encoding transport proteins and enzymes for catabolizing a wide range of nutrients. This is consistent with the complicated lifestyle of *V. cholerae*, which can live on its own, in association with zooplankton, or in the human gastrointestinal tract (where it causes cholera). Of course, a simple catalog of an organism's genes does not reveal how the genes function. Thus, some genes are expressed continuously at high levels, whereas others are expressed rarely—for example, only when the organism encounters a particular metabolite.

DNA Microarrays Help Create an Accurate Picture of Gene Expression. Creating an accurate picture of gene expression is the goal of **transcriptomics**, the study of a cell's transcriptome. Identifying and quantifying all the transcripts from a single cell type reveals which genes are active. Cells transcribe thousands of genes at once, so this study requires the use of new techniques, including DNA microarray technology.

DNA microarrays or **DNA chips** are made by depositing numerous (up to several hundred thousand) different DNA segments of known gene sequences in a precise array on a solid support such as a coated glass surface. These DNAs are often PCR-amplified cDNA clones derived from mRNAs (PCR is discussed in Section 3-5C) or their robotically synthesized counterparts. The mRNAs extracted from cells, tissues, or other biological sources grown under differing conditions are then reverse-transcribed to cDNA, labeled with a fluorescent dye (a different color for each growth condition), and allowed to hybridize with the DNAs on the DNA microarray. After the unhybridized cDNA is washed away, the resulting fluorescence intensity and color at each site on the DNA microarray indicates how much cDNA (and therefore how much mRNA) has bound to a particular complementary DNA sequence for each growth condition. **Figure 14-19** shows a DNA chip that indicates the changes in yeast gene expression when yeast grown on glucose have depleted their glucose supply.

PROCESS DIAGRAM

FIG. 14-19 DNA chips. (a) Schematic diagram of an experiment showing the differences in yeast gene expression in the presence and absence of glucose: (1) Yeast cells are grown in medium containing glucose and in glucose-depleted medium. (2) mRNA is isolated from each population of yeast. (3) Reverse transcriptase copies the mRNA to cDNA, incorporating a red fluorescent dye into the cDNA from the cells grown in glucose, and a green fluorescent dye for the cells harvested after glucose depletion. (4) The cDNAs are mixed. (5) The labeled cDNAs hybridize with DNA segments immobilized on a gene chip, and the bound red and green fluorescent cDNAs are detected. (b) An

~6000-gene array DNA chip containing most of the genes from baker's yeast, one per spot. The red and green spots, respectively, reveal those genes that are transcriptionally activated by the presence or absence of glucose, whereas the yellow spots (*red plus green*) indicate genes whose expression is unaffected by the level of glucose. (c) A DNA microarray assembly. It protects its enclosed DNA chip and provides a convenient hybridization chamber. Interrogation requires a specialized fluorescence measurement device. (Part a): **WPLS See the Animated Process Diagrams.**

Differences in the expression of particular genes have been correlated with many developmental processes or growth patterns. For example, DNA microarrays have been used to profile the patterns of gene expression in tumor cells because different types of tumors synthesize different types and amounts of

FIG. 14-20 The relative transcriptional activities of the genes in hepatocellular carcinoma (HCC) tumors as determined using DNA microarrays. The data are presented in matrix form, with each column representing one of 156 tissue samples [82 HCC tumors (the most common human liver cancer and among the five leading causes of cancer deaths in the world) and 74 nontumor liver tissues] and each row representing one of 3180 genes (those of the ~17,400 genes on the DNA microarray with the greatest variation in transcriptional activity among the various tissue samples). The data are arranged to group the genes, as well as the tissue samples, on the basis of similarities of their expression patterns. The color of each cell indicates the expression level of the corresponding gene in the corresponding tissue relative to its mean expression level in all the tissue samples, with bright red, black, and bright green indicating expression levels of 4, 1, and 1/4 times that of the mean for that gene (as indicated on the scale below). The dendrogram at the top of the matrix indicates the similarities in expression patterns among the various tissue samples.

proteins (Fig. 14-20). This information is useful in choosing how best to treat a cancer. Similarly, analyzing the gene expression patterns in white blood cells, which are easily obtained, can reveal whether a patient is suffering from a viral versus a bacterial infection; this information can prevent the unnecessary administration of antibiotics when the infection is viral.

Proteomics Studies All the Cell's Proteins. Unfortunately, the correlation between the amount of a particular mRNA and the amount of its protein product is imperfect. This is because the various mRNAs and their corresponding proteins are synthesized and degraded at different rates. Furthermore, many proteins are posttranslationally modified, sometimes in several different ways (e.g., by phosphorylation or glycosylation). Consequently, the number of unique proteins in a cell exceeds the number of unique mRNAs.

A more reliable way than transcriptomics to assess gene expression is to examine a cell's proteome. This **proteomics** approach requires that the proteins first be separated, usually by two-dimensional (2D) gel electrophoresis (a technique that separates proteins by isoelectric point in one direction and by mass in the perpendicular direction; Section 5-2D). Individual proteins are then identified by using tandem mass spectrometry to obtain amino acid sequence information (Section 5-3D) and correlating it with protein sequence databases. Because many peptides are generated from a single protein, the technique enables the redundant and unambiguous identification of that protein from the database. In this way we can catalog all the proteins that are contained in a cell or tissue under a given set of conditions.

Can we compare all the proteins synthesized by a cell under two different sets of conditions as is done for mRNA? The answer is yes, by using different isotopically labeled reagents that are either contained in the growth medium (e.g., deuterated amino acids) or that are reacted with the cell extract. The proteins are then purified and analyzed by tandem mass spectrometry. A hope for the future is that samples from diseased and normal subjects can be compared in this manner to find previously undetected protein markers that would allow early diagnosis of various diseases.

Metabolomics Analyzes All of a Cell's Metabolites. In order to describe a cell's functional state (its phenotype) we need, in addition to the cell's genome, transcriptome, and proteome, a quantitative description of all of the metabolites it contains under a given set of conditions, its metabolome. However, a cell or tissue contains thousands of metabolites with vastly different properties, so that identifying and quantifying all these substances is a daunting task, requiring many different analytical tools. Consequently, this huge undertaking is often subdivided. For example, **lipidomics** is the subsection of **metabolomics** aimed at characterizing all lipids in a cell under a particular set of conditions, including how these lipids influence membrane structure, cell signaling, gene expression, cell-cell interactions, and so on. For example, a panel of 10 lipid metabolites in blood has been used to predict the development of cognitive impairment in Alzheimer's disease. Another application of metabolomics is the comparison of the different types of cancers. Although all cells contain the same "core" metabolites, their patterns of use yield different profiles that could be exploited to inhibit cancer growth.

CHECKPOINT

- How are isotopically labeled compounds used to study metabolism?
- Which of the isotopes listed in Table 14-6 could be used to specifically label a protein? A nucleic acid?
- Explain how the buildup of a metabolite when an enzyme is blocked can shed light on the steps of a metabolic pathway.
- Describe how information about an organism's genome can be used to assess and manipulate its metabolic activities.
- What is the difference between hypothesis-driven and discovery-based research?
- Describe the "central dogma" in the "-omics" era.
- Summarize the relationships among an organism's metabolome, proteome, transcriptome, and genome.
- Why might transcriptomic and proteomic analyses reveal different information about the metabolic activity of a particular tissue?

Summary

1 Overview of Metabolism

- The free energy released from catabolic oxidation reactions is used to drive endergonic anabolic reactions.
- Nutrition is the intake and utilization of food to supply free energy and raw materials.
- Heterotrophic organisms obtain their free energy from compounds synthesized by chemolithotrophic or photoautotrophic organisms.
- Food contains proteins, carbohydrates, fats, water, vitamins, and minerals.
- Metabolic pathways are sequences of enzyme-catalyzed reactions that occur in different cellular locations.
- Near-equilibrium reactions are freely reversible, whereas reactions that function far from equilibrium serve as regulatory points and render metabolic pathways irreversible.
- Flux through a metabolic pathway is controlled by regulating the activities of the enzymes that catalyze its rate-determining steps.

2 “High-Energy” Compounds

- The free energy of the “high-energy” compound ATP is made available through cleavage of one or both of its phosphoanhydride bonds.
- An exergonic reaction such as ATP or PP_i hydrolysis can be coupled to an endergonic reaction to make it more favorable.
- Substrate-level phosphorylation is the synthesis of ATP from ADP by phosphoryl group transfer from another compound.

- The common product of carbohydrate, lipid, and protein catabolism, acetyl-CoA, is a “high-energy” thioester.

3 Oxidation–Reduction Reactions

- The coenzymes NAD^+ and FAD are reversibly reduced during the oxidation of metabolites.
- The Nernst equation relates the electromotive force of a redox reaction to the standard reduction potentials and concentrations of the electron donors and acceptors.
- Electrons flow spontaneously from the reduced member of a redox couple with the lower reduction potential to the oxidized member of a redox couple with the higher reduction potential.

4 Experimental Approaches to the Study of Metabolism

- Studies of metabolic pathways determine the order of metabolic transformations, their enzymatic mechanisms, their regulation, and their relationships to metabolic processes in other tissues.
- Metabolic pathways are studied using isotopic and fluorescent tracers, enzyme inhibitors, natural and engineered mutations, DNA microarrays, and proteomics techniques.
- Systems biology endeavors to quantitatively describe the properties and dynamics of biological networks as a whole through the integration of genomic, transcriptomic, proteomic, and metabolomic information.

Key Terms

metabolism 442	vitamin 443	pyrophosphate cleavage 457	electrochemical cell 464
catabolism 442	mineral 443	substrate-level phosphorylation 458	ΔG 464
anabolism 442	metabolite 445	oxidative phosphorylation 458	\mathcal{F} 464
nutrition 443	oxidation 446	photophosphorylation 458	Nernst equation 464
autotrophy 443	reduction 446	kinase 458	\mathcal{E}' 465
chemolithotroph 443	isozyme 449	phosphagen 459	systems biology 471
photoautotroph 443	near-equilibrium reaction 449	reducing agent 463	genomics 471
heterotroph 443	flux 450	oxidizing agent 463	transcriptomics 472
anaerobic 443	substrate cycle 452	half-reaction 463	DNA microarray 472
aerobic 443	“high-energy” intermediate 453	redox couple 463	proteomics 474
macronutrient 443	orthophosphate cleavage 457	conjugate redox pair 463	metabolomics 474
micronutrient 443			

Problems

EXERCISES

1. Explain why a heterotrophic organism may require vitamins, whereas an autotroph does not.
2. Methanogens are prokaryotes that produce methane according to the net equation

Some bacteria consume methane according to the net equation

- (a) Classify these two types of bacteria as autotrophic or heterotrophic.
- (b) Explain why the two types of bacteria are often found associated with each other.

3. A strain of bacteria isolated from an alkaline lake with a high concentration of arsenic is able to incorporate As into biological molecules. What class of molecules is most likely to contain As as part of its structure?
4. Explain why cadmium and mercury are toxic to most organisms.
5. Rank the following compounds in order of increasing oxidation state.

6. In the partial reactions shown below, is the reactant undergoing oxidation or reduction?

7. Citrate synthase catalyzes the reaction

The standard free energy change for the reaction is $-31.5 \text{ kJ} \cdot \text{mol}^{-1}$. (a) Calculate the equilibrium constant for this reaction at 37°C . (b) Would you expect this reaction to serve as a control point for its pathway (the citric acid cycle)?

8. Choose the best definition for a near-equilibrium reaction:

- Always operates with a favorable free energy change.
- Has a free energy change near zero.
- Is usually a control point in a metabolic pathway.
- Operates very slowly *in vivo*.

9. Use the data in Table 2-4 to estimate the net charge of an ATP molecule *in vivo*.

10. Nearly all enzymes that require a nicotinamide cofactor use either NAD^+/NADH or $\text{NADP}^+/\text{NADPH}$ (Figure 11-3) but not both. Compare the net charge of each cofactor.

11. Assuming 100% efficiency of energy conservation, how many moles of ATP can be synthesized under standard conditions by the complete oxidation of 1 mol of glucose?

12. Assuming 100% efficiency of energy conservation, how many moles of ATP can be synthesized under standard conditions by the complete oxidation of 1 mol of palmitate?

13. The reaction for "activation" of a fatty acid (RCOO^-),

has $\Delta G^{\circ'} = +4.6 \text{ kJ} \cdot \text{mol}^{-1}$. What is the thermodynamic driving force for this reaction?

14. The reaction catalyzed by malate dehydrogenase,

has a $\Delta G^{\circ'}$ value of $+29.7 \text{ kJ} \cdot \text{mol}^{-1}$. (a) Would this reaction occur spontaneously in a cell? (b) How does the citrate synthase reaction (described in Problem 7) promote the malate dehydrogenase reaction in the cell? What is the overall change in free energy for the two reactions?

15. List the following substances in order of their increasing oxidizing power: (a) acetoacetate, (b) cytochrome *b* (Fe^{3+}), (c) NAD^+ , (d) SO_4^{2-} , and (e) pyruvate.

16. Is the reduced form of cytochrome *c* more likely to give up its electron to oxidized cytochrome *a* or cytochrome *b*?

17. Under standard conditions, will the following reaction proceed spontaneously as written?

18. Under standard conditions, will the following reaction proceed spontaneously as written?

19. Would gene chips containing bacterial DNA segments be useful for monitoring gene expression in a mammalian cell?

20. Why do DNA chips often contain segments derived from cDNA rather than genomic DNA segments?

21. Biochemists studying cellular activity can quantify RNA sequences by converting them to DNA sequences that can be amplified via PCR (Section 3-5C), and they can quantify proteins by engineering the corresponding genes to include green fluorescent protein (Box 4-3). Explain why metabolites cannot be assessed using these same approaches.

22. Researchers have noted that different patients respond differently to the cholesterol-lowering statin drugs. They have attempted to link the adverse side effects of drugs to genetic variations such as single-nucleotide polymorphisms (SNPs; Section 3-4E). What other information could the researchers gather in order to identify genes that play a role in a patient's response to a statin drug?

CHALLENGE QUESTIONS

23. A certain metabolic reaction takes the form $\text{A} \rightarrow \text{B}$. Its standard free energy change is $7.5 \text{ kJ} \cdot \text{mol}^{-1}$. (a) Calculate the equilibrium constant for the reaction at 25°C . (b) Calculate ΔG at 37°C when the concentration of A is 0.5 mM and the concentration of B is 0.1 mM. Is the reaction spontaneous under these conditions? (c) How might the reaction proceed in the cell?

24. Cells carry out anabolic as well as catabolic pathways, with some enzymes functioning in both types of pathways. (a) Explain why these enzymes catalyze near-equilibrium reactions. (b) Explain why opposing anabolic and catabolic pathways must have different enzymes for at least one of the steps.

25. Does the magnitude of the free energy change for ATP hydrolysis increase or decrease as the pH increases from 5 to 6?

26. The $\Delta G^{\circ'}$ for hydrolytically removing a phosphoryl group from ATP is about twice as large as the $\Delta G^{\circ'}$ for hydrolytically removing a phosphoryl group from AMP ($-14 \text{ kJ} \cdot \text{mol}^{-1}$). Explain the discrepancy.

27. Predict whether creatine kinase will operate in the direction of ATP synthesis or phosphocreatine synthesis at 25°C when $[\text{ATP}] = 4 \text{ mM}$, $[\text{ADP}] = 0.15 \text{ mM}$, $[\text{phosphocreatine}] = 2.5 \text{ mM}$, and $[\text{creatine}] = 1 \text{ mM}$.

28. If intracellular $[\text{ATP}] = 5 \text{ mM}$, $[\text{ADP}] = 0.5 \text{ mM}$, and $[\text{P}_i] = 1.0 \text{ mM}$, calculate the concentration of AMP at pH 7 and 25°C under the condition that the adenylate kinase reaction is at equilibrium.

29. Some proteins contain internal thioesters, which form when a Cys side chain condenses with a Gln side chain a few residues away. Draw this structure.

30. The thioester described in Problem 29 reacts readily with compounds with the formula ROH or RNH_2 . Draw the resulting ester and amide reaction products.

31. In a mixture of NAD^+ , NADH, ubiquinone, and ubiquinol, which compound will be oxidized? Which will be reduced?

32. Aerobic organisms transfer electrons from reduced fuel molecules to O_2 , forming H_2O . Some anaerobic organisms use nitrate (NO_3^-) as an acceptor for electrons from reduced fuel molecules. Use the information in Table 14-4 to explain why aerobic organisms can harvest more free energy from a fuel molecule than can a nitrate-using anaerobe.

33. Write a balanced equation for the oxidation of ubiquinol by cytochrome *c*. Calculate $\Delta G^{\circ'}$ and $\Delta \mathcal{E}^{\circ'}$ for the reaction.

34. Under standard conditions, is the oxidation of free FADH_2 by ubiquinone sufficiently exergonic to drive the synthesis of ATP?

35. A hypothetical three-step metabolic pathway consists of intermediates W, X, Y, and Z and enzymes A, B, and C. Deduce the order of the enzymatic steps in the pathway from the following information:

- Compound Q, a metabolic inhibitor of enzyme B, causes Z to build up.
- A mutant in enzyme C requires Y for growth.
- An inhibitor of enzyme A causes W, Y, and Z to accumulate.
- Compound P, a metabolic inhibitor of enzyme C, causes W and Z to build up.

36. A certain metabolic pathway can be diagrammed as

where A, B, C, and D are the intermediates, and X, Y, and Z are the enzymes that catalyze the reactions. The physiological free energy changes for the reactions are

(a) Which reaction is likely to be a major regulatory point for the pathway? (b) If your answer in Part a was in fact the case, in the presence of an inhibitor that blocks the activity of enzyme Z, would the concentrations of A, B, C, and D increase, decrease, or not be affected?

BIOINFORMATICS www.wiley.com/college/voet

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Metabolism and the BRENDA and KEGG Databases

Exercise 2 Cofactor Chemistry

Extended Exercises Bioinformatics projects are available on the book companion site (www.wiley.com/college/voet), as well as in WileyPLUS Learning Space.

Project 8 Metabolic Enzymes, Microarrays, and Proteomics

- 1. Metabolic Enzymes.** Use the KEGG and Enzyme Structure databases to obtain information about dihydrofolate reductase.
- 2. Microarrays.** Learn about microarray technology and its use in studying disease.

3. Proteomics. Review some methods and their limitations.

4. Teaching and Learning Resources for Proteomics.

5. Two-Dimensional Gel Electrophoresis. Obtain data about dihydrofolate reductase from the Swiss-2D PAGE resource.

Project 9 Metabolomics Databases and Tools

- 1. The Metabolomics Society.** Learn about biomarkers—how they are identified, followed analytically, and used to assess disease states.
- 2. The Human Metabolome Database.** See how an individual metabolite (UDP-glucose) is followed by NMR and mass spectrometry and follow links to the many pathways that involve UDP-glucose.
- 3. The PubChem Project.** Explore one of the newest databases at NCBI, which contains information about the chemical properties and biological activities of small molecule metabolites.

CASE STUDY www.wiley.com/college/voet

Case 16 Allosteric Regulation of ATCase

Focus concept: An enzyme involved in nucleotide synthesis is subject to regulation by a variety of combinations of nucleotides.

Prerequisites: Chapters 7, 12, and 14

- Properties of allosteric enzymes
- Basic mechanisms involving regulation of metabolic pathways

MORE TO EXPLORE Access the Human Metabolome Database (<http://www.hmdb.ca/>) and search for information on uric acid. In what metabolic pathway is uric acid an intermediate? Does the pathway differ among species? What compounds are the precursors of uric acid? To which compounds can uric acid be converted? What is the normal concentration of uric acid in body fluids? How do diseases affect uric acid levels?

CHAPTER 15

Glucose Catabolism

Chapter Contents

1 Overview of Glycolysis

2 The Reactions of Glycolysis

- A Hexokinase Uses the First ATP
- B Phosphoglucose Isomerase Converts Glucose-6-Phosphate to Fructose-6-Phosphate
- C Phosphofructokinase Uses the Second ATP
- D Aldolase Converts a 6-Carbon Compound to Two 3-Carbon Compounds
- E Triose Phosphate Isomerase Interconverts Dihydroxyacetone Phosphate and Glyceraldehyde-3-Phosphate
- F Glyceraldehyde-3-Phosphate Dehydrogenase Forms the First “High-Energy” Intermediate
- G Phosphoglycerate Kinase Generates the First ATP
- H Phosphoglycerate Mutase Interconverts 3-Phosphoglycerate and 2-Phosphoglycerate
- I Enolase Forms the Second “High-Energy” Intermediate
- J Pyruvate Kinase Generates the Second ATP

3 Fermentation: The Anaerobic Fate of Pyruvate

- A Homolactic Fermentation Converts Pyruvate to Lactate
- B Alcoholic Fermentation Converts Pyruvate to Ethanol and CO₂
- C Fermentation Is Energetically Favorable

4 Regulation of Glycolysis

- A Phosphofructokinase Is the Major Flux-Controlling Enzyme of Glycolysis in Muscle
- B Substrate Cycling Fine-Tunes Flux Control

5 Metabolism of Hexoses Other than Glucose

- A Fructose Is Converted to Fructose-6-Phosphate or Glyceraldehyde-3-Phosphate
- B Galactose Is Converted to Glucose-6-Phosphate
- C Mannose Is Converted to Fructose-6-Phosphate

6 The Pentose Phosphate Pathway

- A Oxidative Reactions Produce NADPH in Stage 1
- B Isomerization and Epimerization of Ribulose-5-Phosphate Occur in Stage 2
- C Stage 3 Involves Carbon–Carbon Bond Cleavage and Formation
- D The Pentose Phosphate Pathway Must Be Regulated

Eye of Science/Photo Researchers, Inc.

The protozoan *Trypanosoma brucei* (purple), which causes trypanosomiasis, or sleeping sickness, relies almost entirely on glucose catabolism to extract free energy while it travels through the bloodstream. Although the parasite is a eukaryote, it differs enough from its host that its glycolytic enzymes offer targets for developing drugs that will not affect human enzymes.

Glucose is a major source of metabolic energy in many cells. The fermentation (anaerobic breakdown) of glucose to ethanol and CO₂ by yeast has been exploited for many centuries in baking and brewing. However, scientific investigation of the chemistry of this catabolic pathway began only in the mid-19th century with the demonstration, by Louis Pasteur, that fermentation is carried out by microorganisms. Nearly a century would pass before the complete pathway was elucidated. During that interval, several important features of the pathway came to light:

1. In 1897, Eduard Buchner showed that a cell-free extract of yeast could ferment glucose. This discovery refuted the then widely held belief that fermentation, and every other biological process, was mediated by some sort of “vital force” inherent in living matter and thereby brought fermentation within the province of chemistry.
2. In 1905, Arthur Harden and William Young discovered that phosphate is required for glucose fermentation. They also discovered that a cell-free yeast extract can be separated, by dialysis, into two fractions that are both required for fermentation: a nondialyzable heat-labile fraction they named **zymase**; and a dialyzable, heat-stable fraction they called **cozymase**. It was eventually shown by others that zymase is a mixture of enzymes and that cozymase is a mixture of coenzymes such as NAD⁺, ATP, and ADP, as well as metal ions.
3. Certain reagents, such as iodoacetic acid and fluoride ion, inhibit the formation of pathway products, thereby causing pathway intermediates to accumulate. Different substances caused the buildup of different intermediates and thereby revealed the sequence of molecular interconversions.
4. Studies of how different organisms break down glucose indicated that, with few exceptions, all of them do so in the same way.

Box 15-1 Pathways of Discovery Otto Warburg and Studies of Metabolism

Otto Warburg (1883–1970) One of the great figures in biochemistry—by virtue of his own contributions and his influence on younger researchers—is the German biochemist Otto Warburg. His long career spanned a period during which studies of whole organisms and crude extracts gave way to molecular explanations of biological structure and function. Like others of

his generation, he earned a doctorate in chemistry at an early age and went on to obtain a medical degree, although he spent the remainder of his career in scientific research rather than in patient care. He became interested primarily in three subjects related to the chemistry of oxygen and carbon dioxide: respiration, photosynthesis, and cancer.

One of Warburg's first accomplishments was to develop a technique for studying metabolic reactions in thin slices of animal tissue. This method produced more reliable results than the alternative practice of chopping or mincing tissues (such manipulations tend to release lysosomal enzymes that degrade enzymes and other macromolecules). Warburg was also largely responsible for refining manometry, the measurement of gas pressure, as a technique for analyzing the consumption and production of O_2 and CO_2 by living tissues.

Warburg received a Nobel prize in 1931 for his discovery of the catalytic role of iron porphyrins (heme groups) in biological oxidation (the subject was the reaction carried out by the enzyme complex now known as cytochrome *c* oxidase; Section 18-2F). Warburg also identified nicotinamide as an active part of some enzymes. In 1944, he was offered

a second Nobel prize for his work with enzymes, but he was unable to accept the award, owing to Hitler's decree that Germans could not accept Nobel prizes. In fact, Warburg's apparent allegiance to the Nazi regime incensed some of his colleagues in other countries and may have contributed to their resistance to some of his more controversial scientific pronouncements. In any case, Warburg was not known for his warm personality. He was never a teacher and tended to recruit younger research assistants who were expected to move on after a few years. Nevertheless, several of these individuals went on to win their own Nobel prizes.

In addition to the techniques he developed, which were widely adopted, and a number of insights into enzyme action, Warburg formulated some wide-reaching theories about the growth of cancer cells. He showed that cancer cells could live and develop even in the absence of oxygen. Moreover, he came to believe that anaerobiosis triggered the development of cancer, and he rejected the notion that viruses could cause cancer, a principle that had already been demonstrated in animals but not in humans. In the eyes of many, Warburg was guilty of equating the absence of evidence with the evidence of absence in the matter of virus-induced human cancer. Nevertheless, Warburg's observations of cancer cell metabolism, which is generally characterized by a high rate of glycolysis, were sound. Even today, the oddities of tumor metabolism offer opportunities for chemotherapy. Warburg's dedication to his research in cancer and other areas is revealed by the fact that he continued working in his laboratory until just a few days before his death at age 87.

Warburg, O., On the origin of cancer cells, *Science* **123**, 309–314 (1956).

The efforts of many investigators came to fruition in 1940, when the complete pathway of glucose breakdown was described. This pathway, which is named **glycolysis** (Greek: *glykus*, sweet + *lysis*, loosening), is alternately known as the **Embden–Meyerhof–Parnas pathway** to commemorate the work of Gustav Embden, Otto Meyerhof, and Jacob Parnas in its elucidation. The discovery of glycolysis came at a time when other significant inroads were being made in the area of metabolism (e.g., Box 15-1).

Glycolysis, which is among the most completely understood biochemical pathways, is a sequence of 10 enzymatic reactions in which one molecule of glucose is converted to two molecules of the three-carbon compound pyruvate with the concomitant generation of 2 ATP. It plays a key role in energy metabolism by providing a significant portion of the free energy used by most organisms and by preparing glucose and other compounds for further oxidative degradation. Thus, it is fitting that we begin our discussion of specific metabolic pathways by considering glycolysis. We examine the sequence of reactions by which glucose is degraded, along with some of the relevant enzyme mechanisms. We will then examine the features that influence glycolytic flux and the ultimate fate of its products. Finally, we will discuss the catabolism of other hexoses and the **pentose phosphate pathway**, an alternative pathway for glucose catabolism that functions to provide biosynthetic precursors.

1 Overview of Glycolysis

KEY CONCEPTS

- Glycolysis involves the breakdown of glucose to pyruvate while using the free energy released in the process to synthesize ATP from ADP and P_i .
- The 10-reaction sequence of glycolysis is divided into two stages: energy investment and energy recovery.

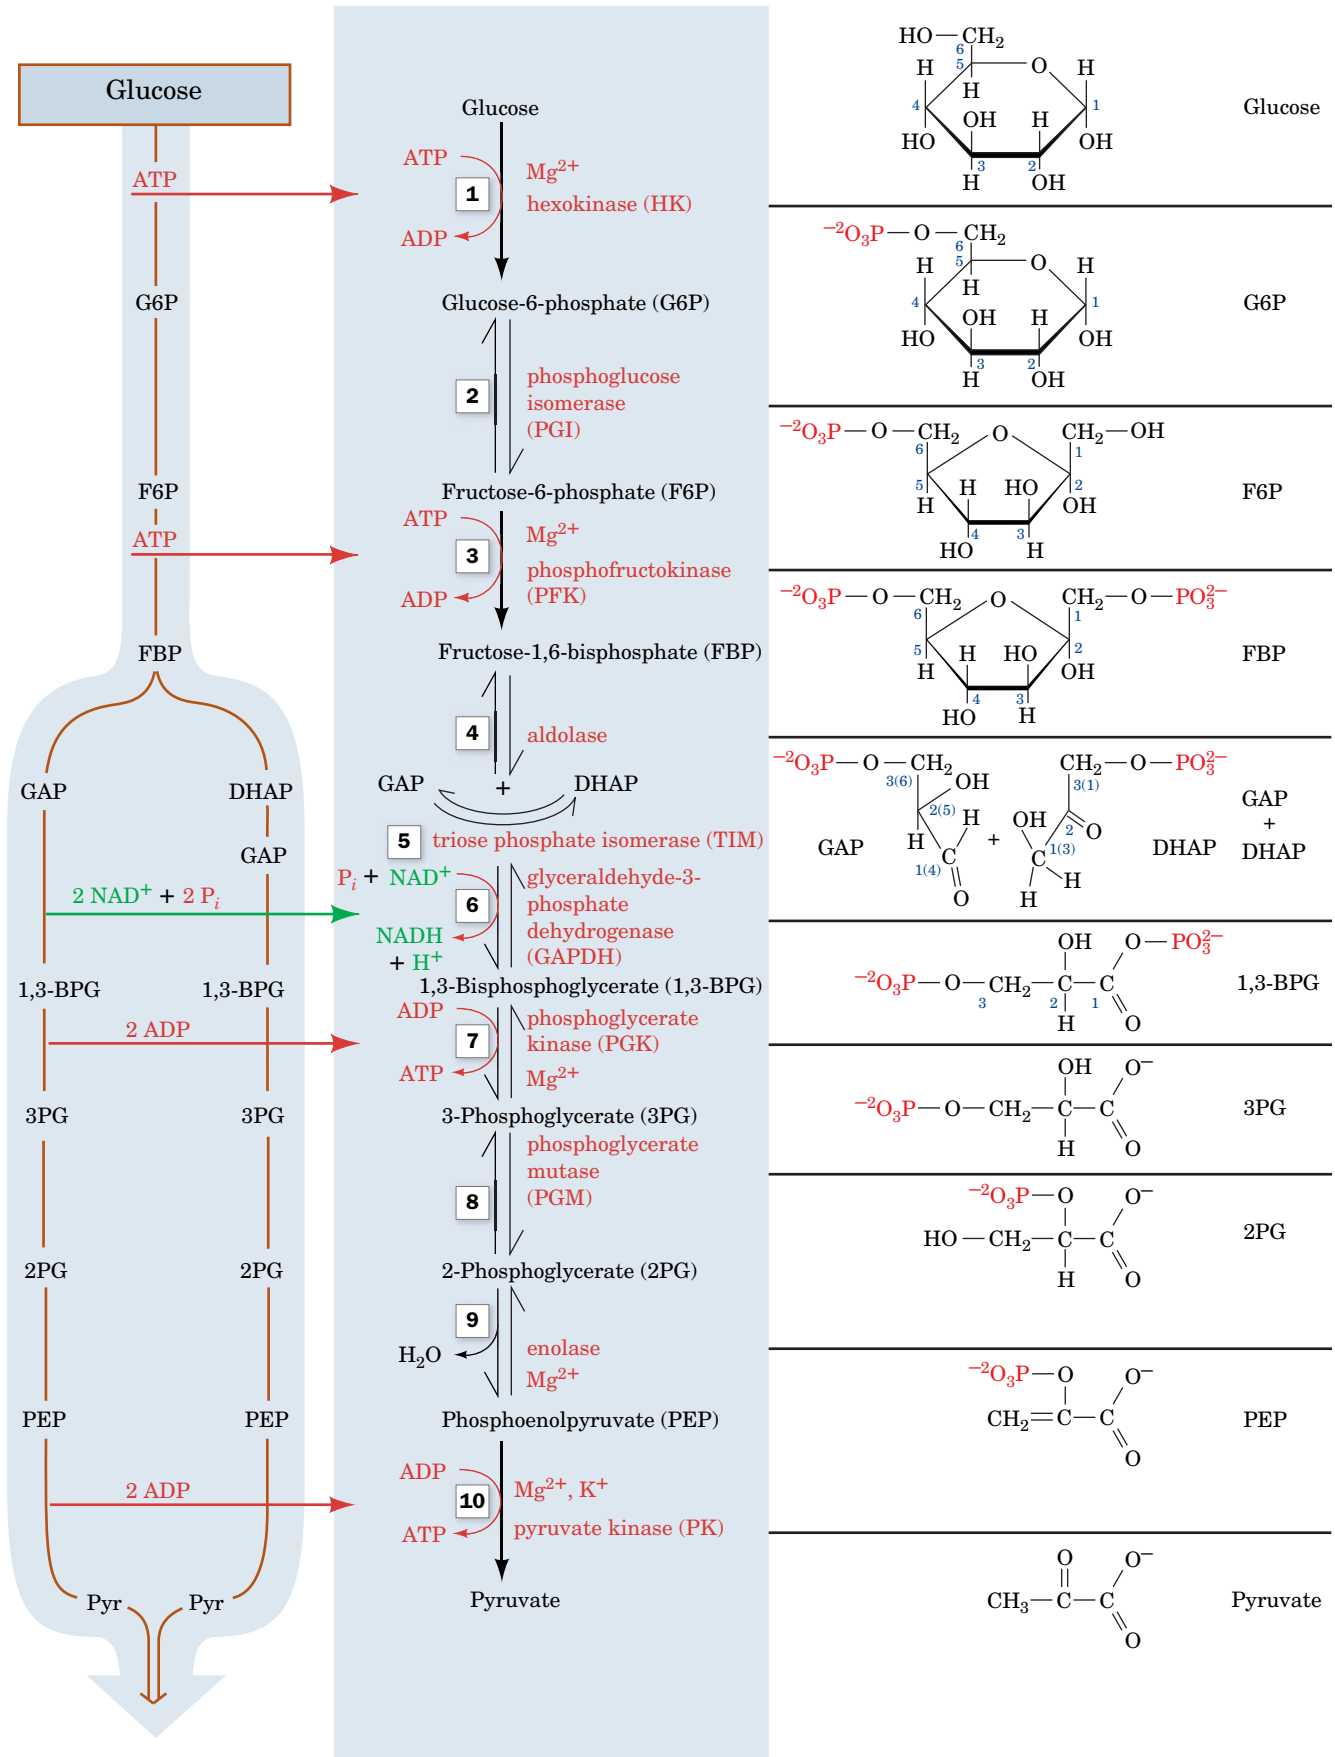

FIG. 15-1 Glycolysis. In its first stage (Reactions 1–5), one molecule of glucose is converted to two glyceraldehyde-3-phosphate (GAP) molecules in a series of reactions that consumes 2 ATP. In the second stage of glycolysis (Reactions 6–10), the two glyceraldehyde-3-phosphate

molecules are converted to two pyruvate molecules, generating 4 ATP and 2 NADH. **WPLS** See the Animated Figures.

? Without looking at the text, write the overall equation for glycolysis.

Before beginning our detailed discussion of glycolysis, let us first take a moment to survey the overall pathway as it fits in with animal metabolism as a whole. Glucose usually appears in the blood as a result of the breakdown of polysaccharides (e.g., liver glycogen or dietary starch and glycogen) or from its synthesis from noncarbohydrate precursors (**gluconeogenesis**; Section 16-4). Glucose enters most cells by specific carriers that transport it from the exterior of the cell into the cytosol (Section 10-2E). The enzymes of glycolysis are located in the cytosol, where they are only loosely associated, if at all, with each other or with other cell structures.

Glycolysis converts glucose to two C₃ units (pyruvate). The free energy released in the process is harvested to synthesize ATP from ADP and P_i. Thus, glycolysis is a pathway of chemically coupled phosphorylation reactions (Section 14-2B). The 10 reactions of glycolysis are diagrammed in **Fig. 15-1** (opposite). Note that ATP is used early in the pathway to synthesize phosphorylated compounds (Reactions 1 and 3) but is later resynthesized twice over (Reactions 7 and 10). Glycolysis can therefore be divided into two stages:

Stage I Energy investment (Reactions 1–5). In this preparatory stage, the hexose glucose is phosphorylated and cleaved to yield two molecules of the triose **glyceraldehyde-3-phosphate**. This process consumes 2 ATP.

Stage II Energy recovery (Reactions 6–10). The two molecules of glyceraldehyde-3-phosphate are converted to pyruvate, with concomitant generation of 4 ATP. Glycolysis therefore has a net “profit” of 2 ATP per glucose: Stage I consumes 2 ATP; Stage II produces 4 ATP.

The phosphoryl groups that are initially transferred from ATP to the hexose do not immediately result in “high-energy” compounds. However, subsequent enzymatic transformations convert these “low-energy” products to compounds with high phosphoryl group-transfer potentials, which are capable of phosphorylating ADP to form ATP. The overall reaction is

Hence, the NADH formed in the process must be continually reoxidized to keep the pathway supplied with its primary oxidizing agent, NAD⁺. In Section 15-3, we examine how organisms do so under aerobic or anaerobic conditions.

CHECKPOINT

- What happens during the two phases of glycolysis?
- How many ATP are invested and how many are recovered from each molecule of glucose that follows the glycolytic pathway?
- Compare the oxidation states of glucose and pyruvate. Explain why glycolysis generates NADH.

2 The Reactions of Glycolysis

KEY CONCEPTS

- The 10 steps of glycolysis can be described in terms of their substrates, products, and enzymatic mechanisms.
- Glycolytic enzymes catalyze phosphorylation reactions, isomerizations, carbon-carbon bond cleavage, and dehydration.
- ATP is consumed in Steps 1 and 3 but regenerated in Steps 7 and 10 for a net yield of 2 ATP per glucose.
- For each glucose, 2 NADH are produced in Step 6.

In this section, we examine the reactions of glycolysis more closely, describing the properties of the individual enzymes and their mechanisms. As we study the individual glycolytic enzymes, we will encounter many of the catalytic mechanisms described in Section 11-3.

WileyPLUS Learning Space

See **Guided Exploration**
Glycolysis Overview

A Hexokinase Uses the First ATP

Reaction 1 of glycolysis is the transfer of a phosphoryl group from ATP to glucose to form **glucose-6-phosphate (G6P)** in a reaction catalyzed by **hexokinase**.

(a)

A kinase is an enzyme that transfers phosphoryl groups between ATP and a metabolite (Section 14-2C). The metabolite that serves as the phosphoryl group acceptor is indicated in the prefix of the kinase name. Hexokinase is a ubiquitous, relatively nonspecific enzyme that catalyzes the phosphorylation of hexoses such as D-glucose, D-mannose, and D-fructose. Liver cells also contain the isozyme **glucokinase**, which catalyzes the same reaction but which is primarily involved in maintaining blood glucose levels (Section 22-1D).

The second substrate for hexokinase, as for other kinases, is an Mg^{2+} -ATP complex. In fact, uncomplexed ATP is a potent competitive inhibitor of hexokinase. Although we do not always explicitly mention the participation of Mg^{2+} , it is essential for kinase activity. The Mg^{2+} shields the negative charges of the ATP's α - and β - or β - and γ -phosphate oxygen atoms, making the γ -phosphorus atom more accessible for nucleophilic attack by the C6-OH group of glucose:

(b)

Comparison of the X-ray structures of yeast hexokinase and the glucose-hexokinase complex indicates that *glucose induces a large conformational change in hexokinase* (Fig. 15-2). The two lobes that form its active site cleft swing together by up to 8 Å to engulf the glucose in a manner that suggests the closing of jaws. *This movement places the ATP close to the —C6H₂OH group of glucose and excludes water from the active site (catalysis by proximity effects; Section 11-3D)*. If the catalytic and reacting groups were in the proper position for reaction while the enzyme was in the open position (Fig. 15-2a), ATP hydrolysis (i.e., phosphoryl group transfer to water, which is thermodynamically favored; Fig. 14-7a) would almost certainly be the dominant reaction.

Clearly, the substrate-induced conformational change in hexokinase is responsible for the enzyme's specificity. In addition, the active site polarity is reduced by exclusion of water, thereby facilitating the nucleophilic reaction. Other kinases have the same deeply clefted structure as hexokinase and undergo conformational changes on binding their substrates (e.g., protein kinase A, Fig. 13-21; adenylate kinase, Fig. 14-10).

B Phosphoglucose Isomerase Converts Glucose-6-Phosphate to Fructose-6-Phosphate

Reaction 2 of glycolysis is the conversion of G6P to **fructose-6-phosphate (F6P)** by **phosphoglucose isomerase (PGI)**.

FIG. 15-2 Substrate-induced conformational changes in yeast hexokinase. The enzyme is represented by a transparent molecular surface with its backbone shown as a purple or yellow ribbon. (a) Free hexokinase. Note its prominent bilobal appearance. (b) Hexokinase in complex with glucose drawn in space-filling form with C green and O red. In the enzyme-substrate complex, the two domains have swung together by a 17° rotation to engulf the substrate. [Based on an X-ray structure by Igor Polikarpov, Instituto de Física de São Carlos, Brazil. PDBids 1IG8 and 3B8A.]

Glucose-6-phosphate (G6P)

Fructose-6-phosphate (F6P)

This is the isomerization of an aldose to a ketose.

Since G6P and F6P both exist predominantly in their cyclic forms, the reaction requires ring opening followed by isomerization and subsequent ring closure (the interconversions of cyclic and linear forms of hexoses are shown in Fig. 8-3).

A proposed reaction mechanism for the PGI reaction involves general acid–base catalysis by the enzyme (Fig. 15-3):

Step 1 The substrate binds.

Step 2 An enzymatic acid, probably the ϵ -amino group of a conserved Lys residue, catalyzes ring opening.

PROCESS DIAGRAM

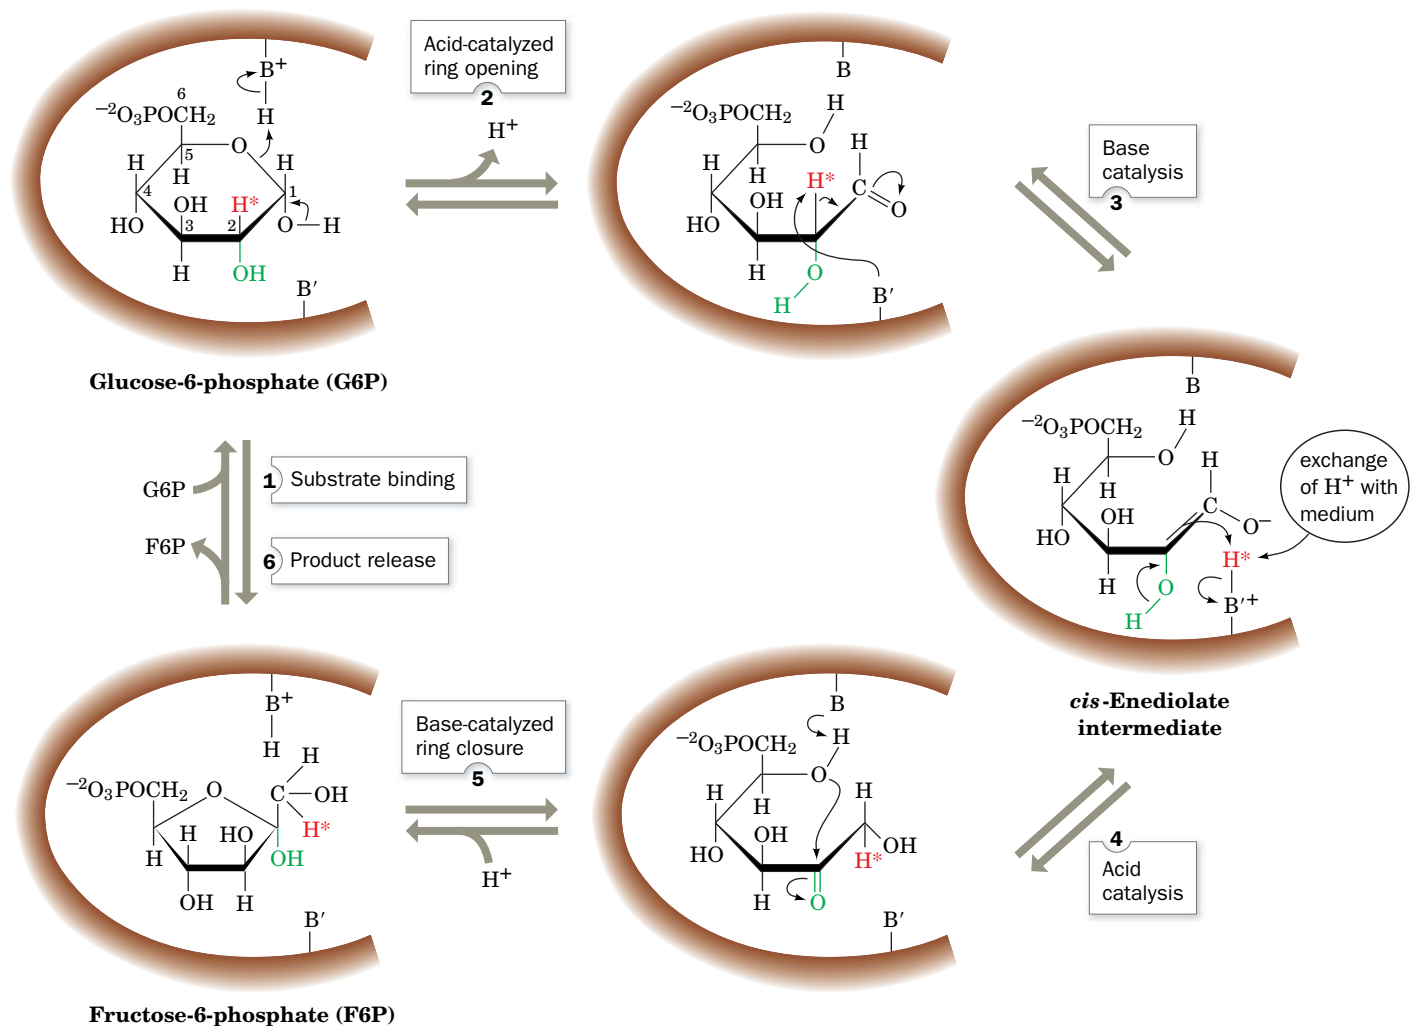

FIG. 15-3 The reaction mechanism of phosphoglucose isomerase. The active site catalytic residues, BH^+ and B' , are thought to be Lys and His, respectively. **WPLS** See the Animated Process Diagrams.

? Which steps of the mechanism would be slowed by a change in pH?

- Step 3** A base, thought to be a His imidazole group, abstracts the acidic proton from C2 to form a *cis*-enediolate intermediate (the proton is acidic because it is α to a carbonyl group).
- Step 4** The proton is replaced on C1 in an overall proton transfer. Protons abstracted by bases rapidly exchange with solvent protons. Nevertheless, Irwin Rose confirmed this step by demonstrating that $[2\text{-}^3\text{H}]\text{G6P}$ is occasionally converted to $[1\text{-}^3\text{H}]\text{F6P}$ by intramolecular proton transfer before the ^3H has had a chance to exchange with the medium.
- Step 5** The ring closes to form the product, which is subsequently released to yield free enzyme, thereby completing the catalytic cycle.

C Phosphofructokinase Uses the Second ATP

In Reaction 3 of glycolysis, **phosphofructokinase (PFK)** phosphorylates F6P to yield **fructose-1,6-bisphosphate (FBP or F1,6P)**.

(The product is a *bis*phosphate rather than a *diphosphate* because its two phosphate groups are not attached directly to each other.)

The PFK reaction is similar to the hexokinase reaction. The enzyme catalyzes the nucleophilic attack by the C1-OH group of F6P on the electrophilic γ -phosphorus atom of the Mg^{2+} -ATP complex.

Phosphofructokinase plays a central role in control of glycolysis because it catalyzes one of the pathway's rate-determining reactions. In many organisms, the activity of PFK is enhanced allosterically by several substances, including AMP, and inhibited allosterically by several other substances, including ATP and citrate. The regulatory properties of PFK are examined in Section 15-4A.

D Aldolase Converts a 6-Carbon Compound to Two 3-Carbon Compounds

Aldolase catalyzes Reaction 4 of glycolysis, the cleavage of FBP to form the two trioses **glyceraldehyde-3-phosphate (GAP)** and **dihydroxyacetone phosphate (DHAP)**:

PROCESS DIAGRAM

FIG. 15-4 The mechanism of base-catalyzed aldol cleavage. Aldol condensation occurs by the reverse mechanism. **WPLS** See the Animated Process Diagrams.

? Identify the aldehyde and alcohol in the aldol.

Note that at this point in the pathway, the atom numbering system changes. Atoms 1, 2, and 3 of glucose become atoms 3, 2, and 1 of DHAP, thus reversing order. Atoms 4, 5, and 6 become atoms 1, 2, and 3 of GAP.

Reaction 4 is an **aldol cleavage (retro aldol condensation)** whose nonenzymatic base-catalyzed mechanism is shown in **Fig. 15-4**. The **enolate** intermediate is stabilized by resonance, as a result of the electron-withdrawing character of the carbonyl oxygen atom. Note that aldol cleavage between C3 and C4 of FBP requires a carbonyl at C2 and a hydroxyl at C4. Hence, the “logic” of Reaction 2 in the glycolytic pathway, the isomerization of G6P to F6P, is clear. Aldol cleavage of G6P would yield products of unequal carbon chain length, while *aldol cleavage of FBP results in two interconvertible C₃ compounds that can therefore enter a common degradative pathway.*

Aldol cleavage is catalyzed by stabilizing its enolate intermediate through increased electron delocalization. In animals and plants, the reaction occurs as follows (**Fig. 15-5**):

- Step 1** The substrate FBP binds to the enzyme.
- Step 2** The FBP carbonyl group reacts with the ϵ -amino group of the active site Lys to form an iminium cation, that is, a protonated Schiff base.
- Step 3** The C3–C4 bond is cleaved, forming an enamine intermediate and releasing GAP. The iminium ion is a better electron-withdrawing group than the oxygen atom of the precursor carbonyl group. Thus, catalysis occurs because the enamine intermediate (**Fig. 15-5, Step 3**) is more stable than the corresponding enolate intermediate of the base-catalyzed aldol cleavage reaction (**Fig. 15-4, Step 2**).
- Step 4** Protonation and tautomerization of the enamine yield the iminium cation from the Schiff base.
- Step 5** Hydrolysis of the iminium cation releases DHAP and regenerates the free enzyme.

E Triose Phosphate Isomerase Interconverts Dihydroxyacetone Phosphate and Glyceraldehyde-3-Phosphate

Only one of the products of the aldol cleavage reaction, GAP, continues along the glycolytic pathway (**Fig. 15-1**). However, DHAP and GAP are ketose–aldose isomers (like F6P and G6P). They are interconverted by an isomerization reaction with an **enediol** (or **enediolate**) **intermediate**. **Triose phosphate**

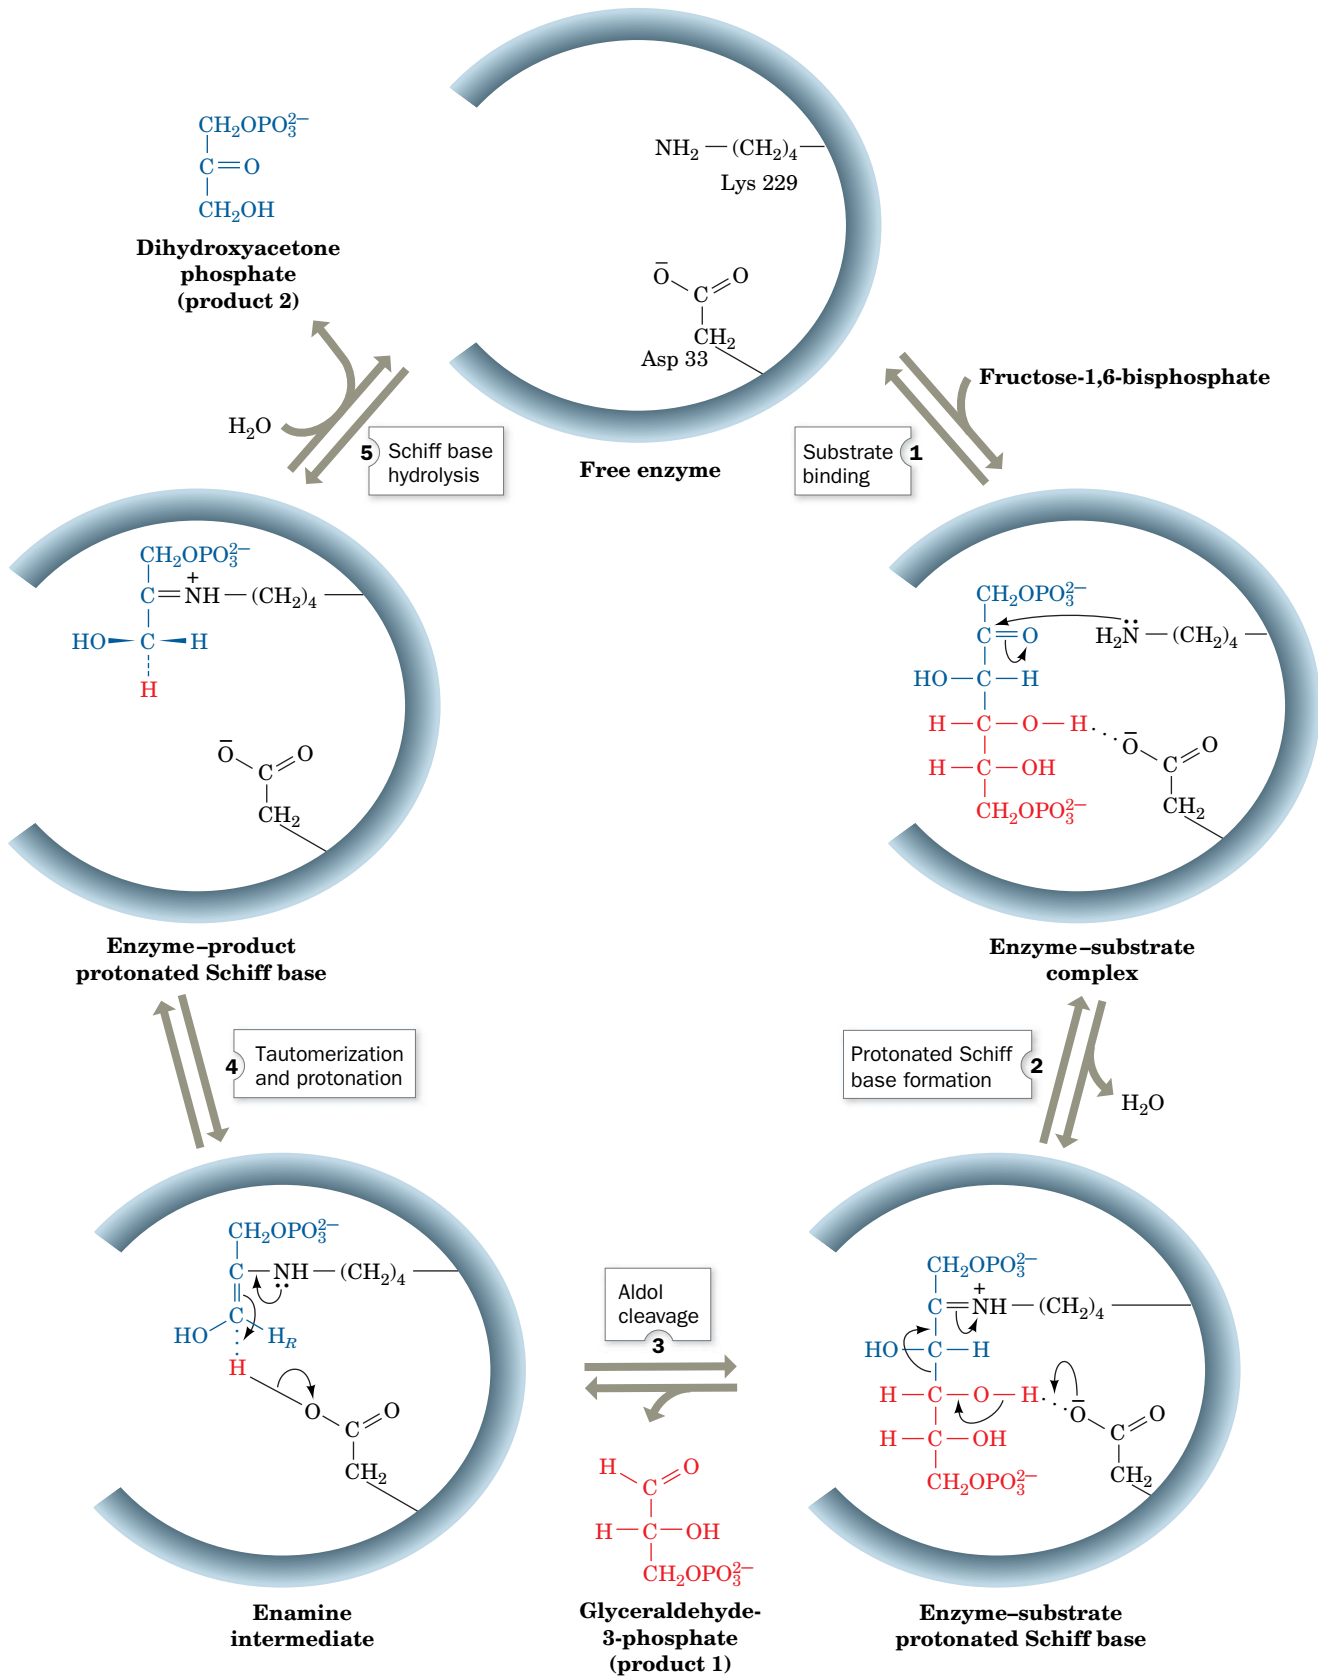

FIG. 15-5 The enzymatic mechanism of aldolase. See the text for details. **WPLS** See the Animated Process Diagrams.

isomerase (TIM) catalyzes this process in Reaction 5 of glycolysis, the final reaction of Stage I:

Support for this reaction scheme comes from the use of the transition state analogs **phosphoglycohydroxamate** and **2-phosphoglycolate**, stable compounds whose geometry resembles that of the proposed enediol or enediolate intermediate:

Enzymes catalyze reactions by binding the transition state complex more tightly than the substrate (Section 11-3E), and, in fact, phosphoglycohydroxamate and 2-phosphoglycolate bind 155- and 100-fold more tightly to TIM than does either GAP or DHAP.

Glu 165 and His 95 Act as General Acids and Bases. Mechanistic considerations suggest that the conversion of GAP to the enediol intermediate is catalyzed by a general base, which abstracts a proton from C2 of GAP, and by a general acid, which protonates its carbonyl oxygen atom. X-Ray studies reveal that the Glu 165 side chain of TIM is ideally situated to abstract the C2 proton from GAP (Fig. 15-6). In fact, the mutagenic replacement of Glu 165 by Asp, which X-ray studies show withdraws the carboxylate group only $\sim 1 \text{ \AA}$ farther away from the substrate than its position in the wild-type enzyme, reduces TIM's catalytic activity 1000-fold. X-Ray studies similarly indicate that His 95 is hydrogen bonded to and hence is properly positioned to protonate GAP's carbonyl oxygen. The positively charged side chain of Lys 12 is thought to electrostatically stabilize the negatively charged transition state in the reaction. In the conversion of the enediol intermediate to DHAP, Glu 165 acts as a general acid to protonate C1 and His 95 acts as a general base to abstract the proton from the OH group, thereby restoring the catalytic groups to their initial protonation states.

FIG. 15-6 Ribbon diagram of yeast TIM in complex with its transition state analog **2-phosphoglycolate**. A single subunit of this homodimeric enzyme is viewed roughly along the axis of its α/β barrel. The enzyme's flexible loop is cyan, and the side chains of the catalytic Lys, His, and Glu residues are purple, magenta, and red, respectively. The 2-phosphoglycolate is represented by a space-filling model colored according to atom type (C green, O red, P orange). [Based on an X-ray structure by Gregory Petsko, Brandeis University. PDBid 2YPI.]

? Explain why the cyan portion of the polypeptide must be flexible.

**Methylglyoxal**

A Flexible Loop Closes over the Active Site. The comparison of the X-ray structure of TIM (Fig. 6-30c) with that of the enzyme–2-phosphoglycolate complex reveals that when substrate binds to TIM, a conserved 10-residue loop closes over the active site like a hinged lid, in a movement that involves main chain shifts of $>7 \text{ \AA}$ (Fig. 15-6). A four-residue segment of the loop makes a hydrogen bond with the phosphate group of the substrate. Mutagenic excision of these four residues does not significantly distort the protein, so substrate binding is not greatly impaired. However, the catalytic power of the mutant enzyme is reduced 10^5 -fold, and it binds phosphoglycohydroxamate only weakly. Evidently, loop closure preferentially stabilizes the enzymatic reaction's enediol-like transition state.

Loop closure in the TIM reaction also supplies a striking example of the so-called **stereoelectronic control** that enzymes can exert on a reaction. In solution, the enediol intermediate readily breaks down with the elimination of the phosphate at C3 to form the toxic compound **methylglyoxal** (at left). On the enzyme's surface, however, that reaction is prevented because the phosphate group is held by the flexible loop in a position that disfavors phosphate elimination. In the mutant enzyme lacking the flexible loop, the enediol is able to escape: $\sim 85\%$ of the enediol intermediate is released into solution where it rapidly decomposes to methylglyoxal and P_i . Thus, the flexible loop closure ensures that substrate is efficiently transformed to product.

 **α/β Barrel Enzymes May Have Evolved by Divergent Evolution.** TIM was the first protein found to contain an α/β barrel (also known as a TIM barrel), a cylinder of eight parallel β strands surrounded by eight parallel α helices (Fig. 6-30c). This striking structural motif has since been found in numerous different proteins, essentially all of which are enzymes (including the glycolytic enzymes aldolase, enolase, and pyruvate kinase). Intriguingly, the active sites of nearly all known α/β barrel enzymes are located in the mouth of the barrel at the end that contains the C-terminal ends of the β strands, although there is no obvious structural rationale for this. Despite the fact that few of these proteins exhibit significant sequence similarity, it has been postulated that all of them have evolved from a common ancestor (divergent evolution). However, it has also been argued that the α/β barrel is a particularly stable arrangement that nature has independently discovered on several occasions (convergent evolution).

FIG. 15-7 Schematic diagram of the first stage of glycolysis. In this series of five reactions, a hexose is phosphorylated, isomerized, phosphorylated again, and then cleaved to two interconvertible triose phosphates. Two ATP are consumed in the process.

? Without looking at the text, name the enzyme that catalyzes each step.

Triose Phosphate Isomerase Is a Catalytically Perfect Enzyme. Jeremy Knowles demonstrated that TIM has achieved **catalytic perfection**. By this it is meant that the rate of the bimolecular reaction between enzyme and substrate is diffusion controlled, so product formation occurs as rapidly as enzyme and substrate can collide in solution. Any increase in TIM's catalytic efficiency therefore would not increase its reaction rate.

GAP and DHAP are interconverted so efficiently that the concentrations of the two metabolites are maintained at their equilibrium values: $K = [\text{GAP}]/[\text{DHAP}] = 4.73 \times 10^{-2}$. At equilibrium, $[\text{DHAP}] \gg [\text{GAP}]$. However, under the steady state conditions in a cell, GAP is consumed in the succeeding reactions of the glycolytic pathway. As GAP is siphoned off in this manner, more DHAP is converted to GAP to maintain the equilibrium ratio. In effect, DHAP follows GAP into the second stage of glycolysis, so a single pathway accounts for the metabolism of both products of the aldolase reaction.

Taking Stock of Glycolysis So Far. At this point in the glycolytic pathway, one molecule of glucose has been transformed into two molecules of GAP. This completes the first stage of glycolysis (Fig. 15-7). Note that 2 ATP have been consumed in generating the phosphorylated intermediates. This energy investment has not yet paid off, but with a little chemical artistry, the “low-energy” GAP can be converted to “high-energy” compounds whose free energies of hydrolysis can be coupled to ATP synthesis in the second stage of glycolysis.

F Glyceraldehyde-3-Phosphate Dehydrogenase Forms the First “High-Energy” Intermediate

Reaction 6 of glycolysis is the oxidation and phosphorylation of GAP by NAD^+ and P_i as catalyzed by **glyceraldehyde-3-phosphate dehydrogenase (GAPDH)**; (Fig. 6-31).

This is the first instance of the chemical artistry alluded to above. *In this reaction, aldehyde oxidation, an exergonic reaction, drives the synthesis of the “high-energy” acyl phosphate 1,3-bisphosphoglycerate (1,3-BPG).* Recall that acyl phosphates are compounds with high phosphoryl group-transfer potential (Section 14-2C).

Several key enzymological experiments have contributed to the elucidation of the GAPDH reaction mechanism:

1. GAPDH is inactivated by alkylation with stoichiometric amounts of iodoacetate. The presence of **carboxymethylcysteine** in the hydrolysate of the resulting alkylated enzyme (Fig. 15-8a) suggests that GAPDH has an active site Cys sulfhydryl group.
2. GAPDH quantitatively transfers ^3H from C1 of GAP to NAD^+ (Fig. 15-8b), thereby establishing that this reaction occurs via direct hydride transfer.

FIG. 15-8 Reactions that were used to elucidate the enzymatic mechanism of GAPDH. (a) The reaction of iodoacetate with an active site Cys residue. (b) Quantitative tritium transfer from substrate to NAD^+ . (c) The enzyme-catalyzed exchange of ^{32}P from phosphate to acetyl phosphate.

3. GAPDH catalyzes exchange of ^{32}P between P_i and the product analog **acetyl phosphate** (Fig. 15-8c). Such isotope exchange reactions are indicative of an acyl–enzyme intermediate; that is, the acetyl group forms a covalent complex with the enzyme, similar to the acyl–enzyme intermediate in the serine protease reaction mechanism (Section 11-5C).

David Trentham has proposed a mechanism for GAPDH based on this information and the results of kinetic studies (Fig. 15-9):

- Step 1** GAP binds to the enzyme.
Step 2 The essential sulfhydryl group, acting as a nucleophile, attacks the aldehyde to form a **thiohemiacetal**.
Step 3 The thiohemiacetal undergoes oxidation to an **acyl thioester** by direct hydride transfer to NAD^+ . This intermediate, which has been isolated, has a large free energy of hydrolysis. Thus, *the energy of aldehyde oxidation has not been dissipated but has been conserved through the synthesis of the thioester and the reduction of NAD^+ to NADH .*

PROCESS DIAGRAM

FIG. 15-9 The enzymatic mechanism of GAPDH. See the text for details. **WPLS** See the Animated Process Diagrams.

Step 4 P_i binds to the enzyme–thioester–NADH complex.

Step 5 The thioester intermediate undergoes nucleophilic attack by P_i to form the “high-energy” mixed anhydride 1,3-BPG product (an acyl phosphate), which then dissociates from the enzyme followed by replacement of NADH by another molecule of NAD^+ to regenerate the active enzyme.

6 Phosphoglycerate Kinase Generates the First ATP

Reaction 7 of the glycolytic pathway yields ATP together with **3-phosphoglycerate (3PG)** in a reaction catalyzed by **phosphoglycerate kinase (PGK)**.

(Note that this enzyme is called a “kinase” because the reverse reaction is phosphoryl group transfer from ATP to 3PG.)

PGK (Fig. 15-10) is conspicuously bilobal in appearance. The Mg^{2+} –ADP-binding site is located on one domain, ~ 10 Å from the 1,3-BPG-binding site, which is on the other domain. Physical measurements suggest that, on substrate binding, the two domains of PGK swing together to permit the substrates to react in a water-free environment, as occurs in hexokinase (Section 15-2A). Indeed, the appearance of PGK is remarkably similar to that of hexokinase (Fig. 15-2), although the structures of the proteins are otherwise unrelated.

The GAPDH and PGK Reactions Are Coupled. As described in Section 14-2B, a slightly unfavorable reaction can be coupled to a highly favorable reaction so both reactions proceed in the forward direction. In the case of the sixth and seventh

FIG. 15-10 X-Ray structure of yeast phosphoglycerate kinase (PGK) in complex with 3PG and ATP. The enzyme is represented by a transparent molecular surface with its embedded ribbon diagram colored with the N-terminal domain yellow and the C-terminal domain purple. The Mg^{2+} –ATP and 3PG are drawn in space-filling form colored according to atom type (ATP C green, 3PG C cyan, N blue, O red, P orange, and Mg^{2+} pale green). Note the similar overall appearance of PGK and hexokinase (Fig. 15-2). [Based on an X-ray structure by Herman Watson, University of Bristol, U.K. PDBid 3PGK.]

reactions of glycolysis, *1,3-BPG* is the common intermediate whose consumption in the *PGK* reaction “pulls” the *GAPDH* reaction forward. The energetics of the overall reaction pair are

Although the *GAPDH* reaction is endergonic, the strongly exergonic nature of the transfer of a phosphoryl group from *1,3-BPG* to *ADP* makes the overall synthesis of *NADH* and *ATP* from *GAP*, P_i , NAD^+ , and *ADP* favorable. This production of *ATP*, which does not involve O_2 , is an example of substrate-level phosphorylation. The subsequent oxidation by O_2 of the *NADH* produced in this reaction generates additional *ATP* by oxidative phosphorylation, as we will see in Section 18-3.

H Phosphoglycerate Mutase Interconverts 3-Phosphoglycerate and 2-Phosphoglycerate

In Reaction 8 of glycolysis, *3PG* is converted to **2-phosphoglycerate (2PG)** by **phosphoglycerate mutase (PGM)**:

FIG. 15-11 The active site region of yeast phosphoglycerate mutase (dephospho form). The substrate, *3PG*, which is drawn in ball-and-stick form with C green, O red, and P orange, binds to an ionic pocket whose side chains are drawn in stick form with C green, N blue, and O red. His 8 is phosphorylated in the active enzyme. [Based on an X-ray structure by Jennifer Littlechild, University of Exeter, U.K. PDBid 1QHF.]

? Identify the ionic groups in the substrate binding pocket.

A **mutase** catalyzes the transfer of a functional group from one position to another on a molecule. This more or less energetically neutral reaction is necessary preparation for the next reaction in glycolysis, which generates a “high-energy” phosphoryl compound.

At first sight, the reaction catalyzed by phosphoglycerate mutase appears to be a simple intramolecular phosphoryl group transfer. This is not the case, however. The active enzyme has a phosphoryl group at its active site, attached to His 8.

The phosphoryl group is transferred to the substrate to form a bisphospho intermediate. This intermediate then rephosphorylates the enzyme to form the product and regenerate the active phosphoenzyme. The enzyme’s X-ray structure shows the proximity of His 8 to the substrate (**Fig. 15-11**).

Catalysis by phosphoglycerate mutase occurs as follows (**Fig. 15-12**):

- Step 1** *3PG* binds to the phosphoenzyme in which His 8 is phosphorylated.
- Step 2** The enzyme’s phosphoryl group is transferred to the substrate, resulting in an intermediate 2,3-bisphosphoglycerate–enzyme complex.
- Step 3** The enzyme is rephosphorylated by the substrate’s 3-phospho group.
- Step 4** Release of the product *2PG* regenerates the phosphoenzyme.

PROCESS DIAGRAM

FIG. 15-12 A proposed reaction mechanism for phosphoglycerate mutase. The active form of the enzyme contains a phospho-His residue at the active site. See the text for details. **WPLS** See the Animated Process Diagrams.

The phosphoryl group of 3PG therefore ends up on C2 of the next 3PG to undergo reaction.

Occasionally, 2,3-bisphosphoglycerate (2,3-BPG) formed in Step 2 of the reaction dissociates from the dephosphoenzyme, leaving it in an inactive form. Trace amounts of 2,3-BPG must therefore always be available to regenerate the active phosphoenzyme by the reverse reaction. 2,3-BPG also specifically binds to deoxyhemoglobin, thereby decreasing its oxygen affinity (Section 7-1D). Consequently, erythrocytes require much more 2,3-BPG (5 mM) than the trace amounts that are used to prime phosphoglycerate mutase (Box 15-2).

I Enolase Forms the Second “High-Energy” Intermediate

In Reaction 9 of glycolysis, 2PG is dehydrated to **phosphoenolpyruvate (PEP)** in a reaction catalyzed by **enolase**:

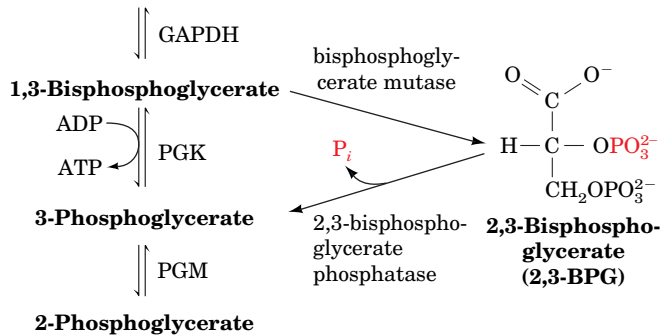

Synthesis of 2,3-Bisphosphoglycerate in Erythrocytes and Its Effect on the Oxygen Carrying Capacity of the Blood

The specific binding of 2,3-bisphosphoglycerate (2,3-BPG) to deoxyhemoglobin decreases the oxygen affinity of hemoglobin (Section 7-1D). Erythrocytes synthesize and degrade 2,3-BPG by a detour from the glycolytic pathway.

Glyceraldehyde 3-phosphate

Bisphosphoglycerate mutase catalyzes the transfer of a phosphoryl group from C1 to C2 of 1,3-BPG. The resulting 2,3-BPG is hydrolyzed to 3PG by **2,3-bisphosphoglycerate phosphatase**. The 3PG then continues through the glycolytic pathway.

The level of available 2,3-BPG regulates hemoglobin's oxygen affinity. Consequently, inherited defects of glycolysis in erythrocytes alter the ability of the blood to carry oxygen, as is indicated by the oxygen-saturation curve of its hemoglobin.

For example, in hexokinase-deficient erythrocytes, the concentrations of all the glycolytic intermediates are low (since hexokinase catalyzes the first step of glycolysis), thereby resulting in a diminished 2,3-BPG concentration and an increased hemoglobin oxygen affinity

(green curve). Conversely, a deficiency in pyruvate kinase (which catalyzes the final reaction of glycolysis; Fig. 15-1) decreases hemoglobin's oxygen affinity (purple curve) through an increase in 2,3-BPG concentration resulting from this blockade. Thus, although erythrocytes, which lack nuclei and other organelles, have only a minimal metabolism, this metabolism is physiologically significant.

[Oxygen-saturation curves after Delivoria-Papadopoulos, M., Oski, F.A., and Gottlieb, A.J., *Science* **165**, 601 (1969).]

The enzyme forms a complex with a divalent cation such as Mg^{2+} before the substrate binds. Fluoride ion inhibits glycolysis by blocking enolase activity (F^- was one of the metabolic inhibitors used in elucidating the glycolytic pathway). In the presence of P_i , F^- blocks substrate binding to enolase by forming a bound complex with Mg^{2+} at the enzyme's active site. Enolase's substrate, 2PG, therefore builds up, and, through the action of PGM, 3PG also builds up.

J Pyruvate Kinase Generates the Second ATP

In Reaction 10 of glycolysis, its final reaction, **pyruvate kinase (PK)** couples the free energy of PEP cleavage to the synthesis of ATP during the formation of pyruvate:

Assessing Stage II of Glycolysis. The energy investment of the first stage of glycolysis (2 ATP consumed) is doubly repaid in the second stage of glycolysis because two phosphorylated C₃ units are transformed to two pyruvates with the coupled synthesis of 4 ATP. This process is shown schematically in Fig. 15-15.

The overall reaction of glycolysis, as we have seen, is

Let us consider each of the three products of glycolysis:

- 1. ATP.** The initial investment of 2 ATP per glucose in Stage I and the subsequent generation of 4 ATP by substrate-level phosphorylation (two for each GAP that proceeds through Stage II) give a net yield of 2 ATP per glucose. In some tissues and organisms for which glucose is the primary metabolic fuel, ATP produced by glycolysis satisfies most of the cell's energy needs.
- 2. NADH.** During its catabolism by the glycolytic pathway, glucose is oxidized to the extent that two NAD⁺ are reduced to two NADH. As described in Section 14-3C, reduced coenzymes such as NADH represent a source of free energy that can be recovered by their subsequent oxidation. Under aerobic conditions, electrons pass from reduced coenzymes through a series of electron carriers to the final oxidizing agent, O₂, in a process known as **electron transport** (Section 18-2). The free energy of electron transport drives the synthesis of ATP from ADP (**oxidative phosphorylation**; Section 18-3). In aerobic organisms, this sequence of events also serves to regenerate oxidized NAD⁺ that can participate in further rounds of catalysis mediated by GAPDH. Under anaerobic conditions,

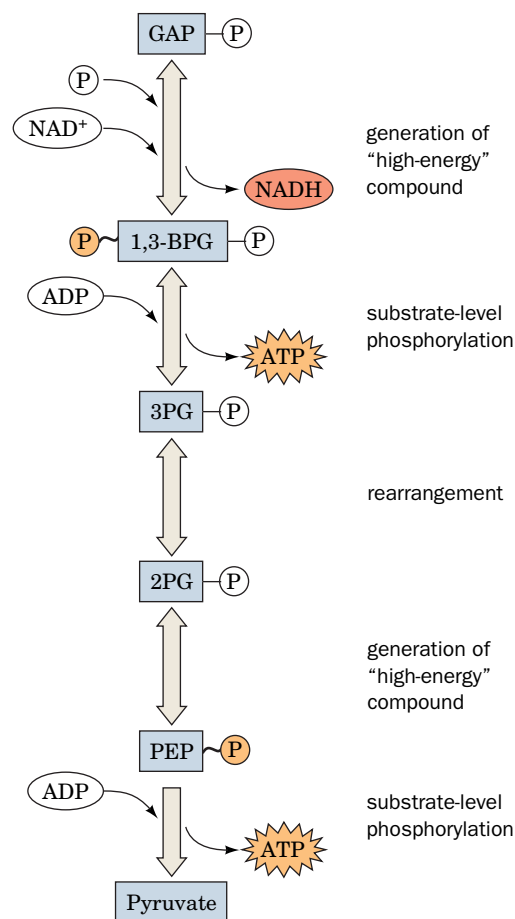

FIG. 15-15 Schematic diagram of the second stage of glycolysis. In this series of five reactions, GAP undergoes phosphorylation and oxidation, followed by molecular rearrangements so that both phosphoryl groups have sufficient free energy to be transferred to ADP to produce ATP. Two molecules of GAP are converted to pyruvate for every molecule of glucose that enters Stage I of glycolysis.

? Without looking at the text, name the enzyme that catalyzes each step.

NADH must be reoxidized by other means to keep the glycolytic pathway supplied with NAD^+ (Section 15-3).

- Pyruvate.** The two pyruvate molecules produced through the partial oxidation of each glucose are still relatively reduced molecules. Under aerobic conditions, complete oxidation of the pyruvate carbon atoms to CO_2 is mediated by the citric acid cycle (Chapter 17). The energy released in that process drives the synthesis of much more ATP than is generated by the limited oxidation of glucose by the glycolytic pathway alone. In anaerobic metabolism, pyruvate is metabolized to a lesser extent to regenerate NAD^+ , as we will see in the following section.

CHECKPOINT

- Write the reactions of glycolysis, showing the structural formulas of the intermediates and the names of the enzymes that catalyze the reactions.
- Summarize the types of catalytic mechanisms involved. Do any glycolytic enzymes require cofactors?
- Explain the chemical logic of converting glucose to fructose before aldolase splits the sugar in two.
- Why is triose phosphate isomerase considered to be catalytically perfect?
- How does phosphorylation differ between the kinase-catalyzed reactions and the reaction catalyzed by GAPDH?
- What compounds with high phosphate group-transfer potential are synthesized during glycolysis?
- Explain the chemical logic of dehydrating 2-phosphoglycerate before its phosphoryl group is transferred.
- Explain how chemical coupling of endergonic and exergonic reactions is used to generate ATP during glycolysis.
- Which products of glycolysis are reduced molecules that the cell can oxidize to recover free energy?

3 Fermentation: The Anaerobic Fate of Pyruvate

KEY CONCEPTS

- NADH, a substrate for the GAPDH reaction, must be reoxidized for glycolysis to continue.
- In muscle, pyruvate is reduced to lactate to regenerate NAD^+ .
- Yeast decarboxylates pyruvate to produce CO_2 and ethanol, in a process that requires the cofactor TPP.

The three common metabolic fates of pyruvate produced by glycolysis are outlined in Fig. 15-16.

- Under aerobic conditions, the pyruvate is completely oxidized via the citric acid cycle to CO_2 and H_2O .
- Under anaerobic conditions, pyruvate must be converted to a reduced end product in order to reoxidize the NADH produced by the GAPDH reaction. This occurs in two ways:
 - Under anaerobic conditions in muscle, pyruvate is reduced to **lactate** to regenerate NAD^+ in a process known as **homolactic fermentation** (a fermentation is an anaerobic biological process).
 - In yeast and certain other microorganisms, pyruvate is decarboxylated to yield CO_2 and **acetaldehyde**, which is then reduced by NADH to yield NAD^+ and ethanol. This process is known as **alcoholic fermentation**.

Thus, in aerobic glycolysis, NADH acts as a “high-energy” compound, whereas in anaerobic glycolysis, its free energy of oxidation is dissipated as heat.

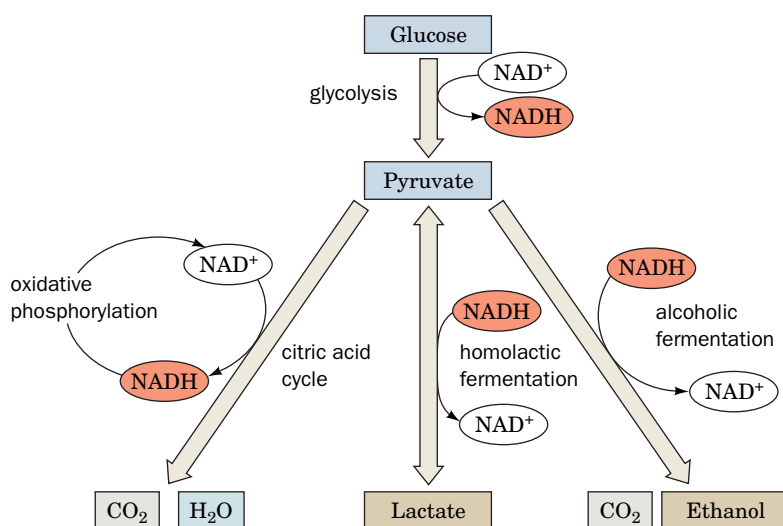

FIG. 15-16 Metabolic fate of pyruvate. Under aerobic conditions (*left*), the pyruvate carbons are oxidized to CO_2 by the citric acid cycle and the electrons are eventually transferred to O_2 to yield H_2O in oxidative phosphorylation. Under anaerobic conditions in muscle, pyruvate is reversibly converted to lactate (*middle*), whereas in yeast, it is converted to CO_2 and ethanol (*right*).

A Homolactic Fermentation Converts Pyruvate to Lactate

In muscle, during vigorous activity, when the demand for ATP is high and oxygen is in short supply, ATP is synthesized largely via anaerobic glycolysis, which rapidly generates ATP, rather than through the slower process of oxidative phosphorylation. Under these conditions, **lactate dehydrogenase (LDH)** catalyzes the oxidation of NADH by pyruvate to yield NAD^+ and lactate.

This reaction is often classified as Reaction 11 of glycolysis. The lactate dehydrogenase reaction is freely reversible, so *pyruvate and lactate concentrations are readily equilibrated*.

In the proposed mechanism for pyruvate reduction by LDH, a hydride ion is stereospecifically transferred from C4 of NADH to C2 of pyruvate with concomitant transfer of a proton from the imidazolium moiety of His 195:

Both His 195 and Arg 171 interact electrostatically with the substrate to orient pyruvate (or lactate, in the reverse reaction) in the enzyme active site.

The overall process of anaerobic glycolysis in muscle can be represented as

Lactate represents a sort of dead end for anaerobic glucose metabolism. The lactate can be either exported from the cell or converted back to pyruvate. Much of the lactate produced in skeletal muscle cells is carried by the blood to the liver, where it is used to synthesize glucose (Section 22-1F).

Contrary to widely held belief, it is not lactate buildup in the muscle per se that causes muscle fatigue and soreness, but the accumulation of glycolytically generated acid (muscles can maintain their workload in the presence of high lactate concentrations if the pH is kept constant).

B Alcoholic Fermentation Converts Pyruvate to Ethanol and CO_2

Under anaerobic conditions in yeast, NAD^+ for glycolysis is regenerated in a process that has been valued for thousands of years: the conversion of pyruvate to ethanol and CO_2 . Ethanol is, of course, the active ingredient of wine and spirits (more recently it has become an agriculturally renewable fuel); CO_2 so produced leavens bread.

Yeast (Fig. 15-17) produces ethanol and CO_2 via two consecutive reactions (Fig. 15-18):

FIG. 15-17 An electron micrograph of yeast cells.

TPP's catalytically active functional group is the **thiazolium ring**. The C2-H atom of this group is relatively acidic because of the adjacent positively charged quaternary nitrogen atom, which electrostatically stabilizes the carbanion formed when the proton dissociates. This dipolar carbanion (or **ylid**) is the active form of the coenzyme. Pyruvate decarboxylase operates as follows (Fig. 15-20):

- Step 1** The ylid form of TPP, a nucleophile, attacks the carbonyl carbon of pyruvate.
- Step 2** CO₂ departs, generating a resonance-stabilized carbanion adduct in which the thiazolium ring of the coenzyme acts as an electron sink.
- Step 3** The carbanion is protonated.
- Step 4** The TPP ylid is eliminated to form acetaldehyde and regenerate the active enzyme.

This mechanism has been corroborated by the isolation of the **hydroxyethylthiamine pyrophosphate** intermediate.

 **Vitamin B₁ Deficiency Causes Beriberi and Wernicke-Korsakoff syndrome.** The ability of TPP's thiazolium ring to add to carbonyl groups and act as an electron sink makes it the coenzyme most utilized in α-keto acid decarboxylation reactions. Such reactions occur in all organisms, not just yeast. Consequently thiamine (vitamin B₁), which is neither synthesized nor stored in

PROCESS DIAGRAM

FIG. 15-20 The reaction mechanism of pyruvate decarboxylase. See the text for details. **WPLS** See the Animated Process Diagrams.

significant quantities by the tissues of most vertebrates, is required in their diets. Thiamine deficiency in humans results in an ultimately fatal condition known as **beriberi** (Sinhalese for weakness) that is characterized by neurological disturbances causing pain, paralysis, and atrophy (wasting) of the limbs and/or edema (accumulation of fluid in tissues and body cavities).

Beriberi was particularly prevalent in the late eighteenth and early nineteenth centuries in the rice-consuming areas of Asia after the introduction of steam-powered milling machines that polished the rice grains to remove their coarse but thiamine-containing outer layers (the previously used milling procedures were less efficient and hence left sufficient thiamine on the grains). Parboiling rice before milling, a process common in India, causes the rice kernels to absorb nutrients from their outer layers, thereby decreasing the incidence of beriberi. Once thiamine deficiency was recognized as the cause of beriberi, enrichment procedures were instituted so that today it has ceased to be a problem except in areas undergoing famine. However, beriberi occasionally develops in chronic alcoholics due to their penchant for drinking but not eating and because ethanol inhibits thiamine uptake by the gastrointestinal tract.

Another manifestation of thiamine deficiency is **Wernicke-Korsakoff syndrome**, a life-threatening condition characterized by dementia (confusion and severe memory loss), ataxia (unsteady stance and gait), and eye abnormalities resulting from the atrophy of several regions of the brain.

Reduction of Acetaldehyde and Regeneration of NAD^+ . Yeast alcohol dehydrogenase (**YADH**), the enzyme that converts acetaldehyde to ethanol, is a tetramer, each subunit of which binds one Zn^{2+} ion. The Zn^{2+} polarizes the carbonyl group of acetaldehyde to stabilize the developing negative charge in the transition state of the reaction.

This facilitates the stereospecific transfer of a hydrogen from NADH to acetaldehyde.

Mammalian liver alcohol dehydrogenase (**LADH**) metabolizes the alcohols anaerobically produced by the intestinal flora as well as those from external sources (the direction of the alcohol dehydrogenase reaction varies with the relative concentrations of ethanol and acetaldehyde). Mammalian LADH is a dimer with significant amino acid sequence similarity to YADH, although LADH subunits each contain a second Zn^{2+} ion that presumably has a structural role.

C Fermentation Is Energetically Favorable

Thermodynamics permits us to dissect the process of fermentation into its component parts and to account for the free energy changes that occur. This enables us to calculate the efficiency with which the free energy of glucose catabolism is used in the synthesis of ATP. For homolactic fermentation,

For alcoholic fermentation,

Skeletal muscle consists of both **slow-twitch** (Type I) and **fast-twitch** (Type II) **fibers**. Fast-twitch fibers, so called because they predominate in muscles capable of short bursts of rapid activity, are nearly devoid of mitochondria (where oxidative phosphorylation occurs). Consequently, they must obtain nearly all of their ATP through anaerobic glycolysis, for which they have a particularly large capacity. Muscles designed to contract slowly and steadily, in contrast, are enriched in slow-twitch fibers that are rich in mitochondria and obtain most of their ATP through oxidative phosphorylation.

Fast- and slow-twitch fibers were originally known as white and red fibers, respectively, because otherwise pale-colored muscle tissue, when enriched with mitochondria, takes on the red color characteristic of their heme-containing cytochromes. However, fiber color is an imperfect indicator of muscle physiology.

In a familiar example, the flight muscles of migratory birds such as ducks and geese, which need a continuous energy supply, are rich in slow-twitch fibers. Therefore, these birds have dark breast meat. In contrast, the flight muscles of less ambitious fliers, such as chickens and turkeys, which are used only for short bursts (often to escape danger), consist mainly of fast-twitch fibers that form white meat. In humans, the muscles of sprinters are relatively rich in fast-twitch fibers, whereas distance runners have a greater proportion of slow-twitch fibers (although their muscles have the same color).

Each of these processes is coupled to the net formation of 2 ATP, which requires $\Delta G^{\circ} = +61 \text{ kJ} \cdot \text{mol}^{-1}$ of glucose consumed. Dividing ΔG° of ATP formation by that of lactate formation indicates that homolactic fermentation is 31% “efficient”; that is, 31% of the free energy released by the process under standard biochemical conditions is sequestered in the form of ATP. The rest is dissipated as heat, thereby making the process irreversible. Likewise, alcoholic fermentation is 26% efficient under biochemical standard state conditions. *Under physiological conditions, where the concentrations of reactants and products differ from those of the standard state, these reactions have thermodynamic efficiencies of >50%.*

Anaerobic fermentation uses glucose in a profligate manner compared to oxidative phosphorylation: Fermentation results in the production of 2 ATP per glucose, whereas oxidative phosphorylation yields up to 32 ATP per glucose (Section 18-3C). This accounts for Pasteur’s observation that yeast consume far more sugar when growing anaerobically than when growing aerobically (the **Pasteur effect**). However, *the rate of ATP production by anaerobic glycolysis can be up to 100 times faster than that of oxidative phosphorylation. Consequently, when tissues such as muscle are rapidly consuming ATP, they regenerate it almost entirely by anaerobic glycolysis.* (Homolactic fermentation does not really “waste” glucose since the lactate can be aerobically reconverted to glucose by the liver; Section 22-1F.) Certain muscles are specialized for the rapid production of ATP by glycolysis (Box 15-3).

CHECKPOINT

- Describe the three possible fates of pyruvate.
- Compare homolactic and alcoholic fermentation in terms of the products and the cofactors required.
- What is the role of TPP in decarboxylation?
- Compare the ATP yields and rates of ATP production for anaerobic and aerobic degradation of glucose.

4 Regulation of Glycolysis

KEY CONCEPTS

- Enzymes that function with large negative free energy changes are candidates for flux-control points.
- Phosphofructokinase, the major regulatory point for glycolysis in muscle, is allosterically inhibited by ATP and activated by AMP and ADP.
- Substrate cycling allows the rate of glycolysis to respond rapidly to changing needs.

TABLE 15-1 ΔG° and ΔG for the Reactions of Glycolysis in Heart Muscle^a

Reaction	Enzyme	ΔG° (kJ · mol ⁻¹)	ΔG (kJ · mol ⁻¹)
1	Hexokinase	-20.9	-27.2
2	PGI	+2.2	-1.4
3	PFK	-17.2	-25.9
4	Aldolase	+22.8	-5.9
5	TIM	+7.9	~0

10	PK	-23.0	-13.9

^aCalculated from data in Newsholme, E.A. and Start, C., *Regulation in Metabolism*, p. 97, Wiley (1973).

Under steady state conditions, glycolysis operates continuously in most tissues, although the glycolytic flux must vary to meet the needs of the organism. Elucidation of the flux control mechanisms of a given pathway, such as glycolysis, commonly involves three steps:

1. Identification of the rate-determining step(s) of the pathway by measuring the *in vivo* ΔG for each reaction. Enzymes that operate far from equilibrium are potential control points (Section 14-1D).
2. *In vitro* identification of allosteric modifiers of the enzymes catalyzing the rate-determining reactions. The mechanisms by which these compounds act are determined from their effects on the enzymes' kinetics.
3. Measurement of the *in vivo* levels of the proposed regulators under various conditions to establish whether the concentration changes are consistent with the proposed control mechanism.

Let us examine the thermodynamics of glycolysis in muscle tissue with an eye toward understanding its control mechanisms (keep in mind that different tissues control glycolysis in different ways). **Table 15-1** lists the standard free energy changes (ΔG°) and the actual physiological free energy change (ΔG) associated with each reaction in the pathway. It is important to realize that the free energy changes associated with the reactions under standard conditions may differ dramatically from the actual values *in vivo*.

Only three reactions of glycolysis, those catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase, function with large negative free energy changes in heart muscle under physiological conditions (**Fig. 15-21**). These non-equilibrium reactions of glycolysis are candidates for flux-control points. The other glycolytic reactions function near equilibrium: Their forward and reverse rates are much faster than the actual flux through the pathway. Consequently, these equilibrium reactions are very sensitive to changes in the concentration of pathway intermediates and readily accommodate changes in flux generated at the rate-determining step(s) of the pathway.

A Phosphofructokinase Is the Major Flux-Controlling Enzyme of Glycolysis in Muscle

In vitro studies of hexokinase, phosphofructokinase, and pyruvate kinase indicate that each is controlled by a variety of compounds. Yet when the G6P source for glycolysis is glycogen, rather than glucose, as is often the case in skeletal muscle, the hexokinase reaction is not required (glycogen is broken down to

FIG. 15-21 Diagram of free energy changes in glycolysis. This “waterfall” diagram illustrates the actual free energy changes for the glycolytic reactions in heart muscle (Table 15-1). Reactions 1, 3, and 10 are irreversible. The other reactions operate near equilibrium and can mediate flux in either direction.

? Explain why each reaction is represented by a downward step in this diagram.

GATEWAY CONCEPT Metabolic Flux

The glycolytic pathway can be considered to be a sort of pipe, with an entrance for glucose molecules and an exit for pyruvate molecules. The control points for the pathway are like one-way valves that prevent backflow and limit the amount of material passing through. Between those control points, intermediates can move in either direction. The pipe never runs dry because the pyruvate gets used up and more glucose is always available. In addition, intermediates can enter or leave the pathway at any point. Even the simplest cells contain many copies of each glycolytic enzyme, acting on a pool of millions of substrate molecules, so their collective behavior is what we refer to when we discuss flux through the pathway.

FIG. 15-22 X-Ray structure of PFK from *E. coli*. Two subunits of the tetrameric enzyme are shown in ribbon form (the other two subunits, which have been omitted for clarity, are related to those shown by a twofold rotation about the vertical axis). Each subunit binds its products, FBP (near the center of each subunit) and Mg^{2+} -ADP (lower right and upper left), together with its activator Mg^{2+} -ADP (upper right and lower left, in the rear), all in space-filling form with atoms colored according to type (ADP C green, FBP C cyan, N blue, O red, P orange, and Mg purple). Note the close proximity of the product ADP's β -phosphate group to the phosphoryl group at FBP's 1-position, the group that PFK transfers from ATP to F6P. [Based on an X-ray structure by Philip Evans, Cambridge University. PDBid 1PFK.]

G6P; Section 16-1). Pyruvate kinase catalyzes the last reaction of glycolysis and is therefore unlikely to be the primary point for regulating flux through the entire pathway. Evidently, PFK, an elaborately regulated enzyme functioning far from equilibrium, is the major control point for glycolysis in muscle under most conditions.

PFK (Fig. 15-22) is a tetrameric enzyme with two conformational states, R and T, that are in equilibrium. ATP is both a substrate and an allosteric inhibitor of phosphofructokinase. Other compounds, including ADP, AMP, and **fructose-2,6-bisphosphate (F2,6P)**, reverse the inhibitory effects of ATP and are therefore activators of PFK. Each PFK subunit has two binding sites for ATP: a substrate site and an inhibitor site. The substrate site binds ATP equally well in either conformation, but the inhibitor site binds ATP almost exclusively in the T state. The other substrate of PFK, F6P, preferentially binds to the R state. Consequently, at high concentrations, ATP acts as an allosteric inhibitor of PFK by binding to the T state, thereby shifting the $T \rightleftharpoons R$ equilibrium in favor of the T state and thus decreasing PFK's affinity for F6P (this is similar to the action of 2,3-BPG in decreasing the affinity of hemoglobin for O_2 ; Section 7-1D).

In graphical terms, high concentrations of ATP shift the curve of PFK activity versus [F6P] to the right and make it even more sigmoidal (cooperative) (Fig. 15-23). For example, when [F6P] = 0.5 mM (the dashed line in Fig. 15-23), the enzyme is nearly maximally active, but in the presence of 1 mM ATP, the activity drops to 15% of its original level, a nearly sevenfold decrease. An activator such as AMP or ADP counters the effect of ATP by binding to R-state PFK, thereby shifting the $T \rightleftharpoons R$ equilibrium toward the R state. (Actually, the most potent allosteric effector of PFK is F2,6P, which we discuss in Section 16-4C.)

Allosterism in Phosphofructokinase Involves Arg and Glu Side Chains. The X-ray structures of PFK from several organisms have been determined in both the R and the T states by Philip Evans. The R state of PFK is stabilized by the binding of its substrate F6P. In the R state of *Bacillus stearothermophilus* PFK,

FIG. 15-23 PFK activity versus F6P concentration. The various conditions are as follows: purple, no inhibitors or activators; green, 1 mM ATP; and red, 1 mM ATP + 0.1 mM AMP. [After data from Mansour, T.E. and Ahlfors, C.E., *J. Biol. Chem.* **243**, 2523–2533 (1968).] **WPLS** See the Animated Figures.

? At what substrate concentrations is the enzyme best able to regulate glycolytic flux?

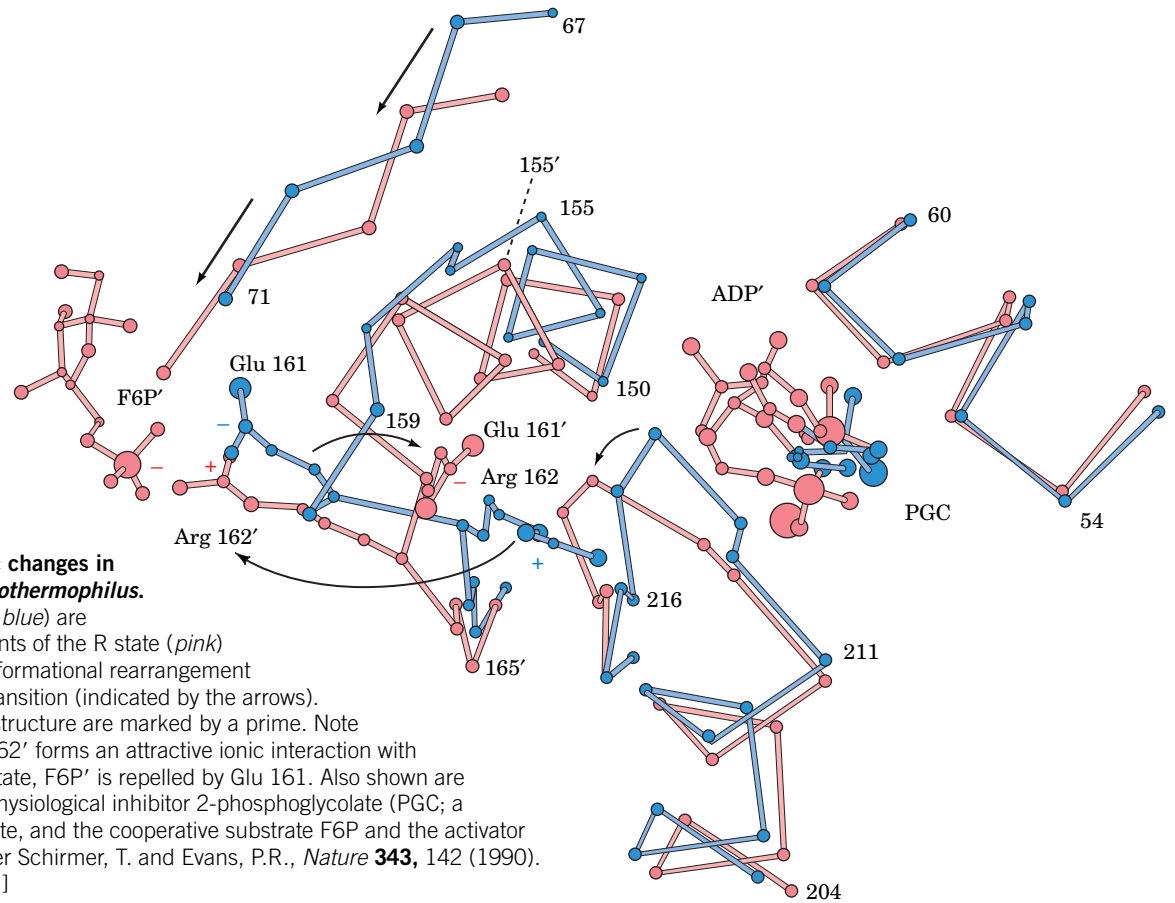

FIG. 15-24 Allosteric changes in PFK from *Bacillus stearothermophilus*.

Segments of the T state (blue) are superimposed on segments of the R state (pink) that undergo a large conformational rearrangement on the T→R allosteric transition (indicated by the arrows). Residues of the R-state structure are marked by a prime. Note that in the R state, Arg 162' forms an attractive ionic interaction with F6P', whereas in the T state, F6P' is repelled by Glu 161. Also shown are bound ligands: the nonphysiological inhibitor 2-phosphoglycolate (PGC; a PEP analog) for the T state, and the cooperative substrate F6P and the activator ADP for the R state. [After Schirmer, T. and Evans, P.R., *Nature* **343**, 142 (1990). PDBids 4PFK and 6PFK.]

the side chain of Arg 162 forms an ion pair with the phosphoryl group of an F6P bound in the active site of another subunit (Fig. 15-24). However, Arg 162 is located at the end of a helical turn that unwinds on transition to the T state. The positively charged side chain of Arg 162 thereby swings away and is replaced by the negatively charged side chain of Glu 161. As a consequence, the doubly negative phosphoryl group of F6P has a greatly diminished affinity for the T-state enzyme. The unwinding of this helical turn, which is obligatory for the R → T transition, is prevented by the binding of the activator ADP to its effector site on the enzyme. Presumably, ATP can bind to this site only when the helical turn is in its unwound conformation (the T state).

AMP Overcomes the ATP Inhibition of PFK. Direct allosteric regulation of PFK by ATP may at first appear to be the means by which glycolytic flux is controlled. After all, when [ATP] is high as a result of low metabolic demand, PFK is inhibited and flux through glycolysis is low; conversely when [ATP] is low, flux through the pathway is high and ATP is synthesized to replenish the pool. Consideration of the physiological variation in ATP concentration, however, indicates that the situation must be more complex. The metabolic flux through glycolysis may vary by 100-fold or more, depending on the metabolic demand for ATP. However, *measurements of [ATP] in vivo at various levels of metabolic activity indicate that [ATP] varies <10% between rest and vigorous exertion.* Yet there is no known allosteric mechanism that can account for a 100-fold change in flux of a nonequilibrium reaction with only a 10% change in effector concentration. Thus, some other mechanism(s) must be responsible for controlling glycolytic flux.

The inhibition of PFK by ATP is relieved by AMP as well as ADP. This results from AMP's preferential binding to the R state of PFK. If a PFK solution

containing 1 mM ATP and 0.5 mM F6P is brought to 0.1 mM in AMP, the activity of PFK rises from 15 to 50% of its maximal activity, a threefold increase (Fig. 15-23).

The [ATP] decreases by only 10% in going from a resting state to one of vigorous activity because it is buffered by the action of two enzymes: creatine kinase and adenylate kinase (Section 14-2C). Adenylate kinase catalyzes the reaction

which rapidly equilibrates the ADP resulting from ATP hydrolysis in muscle contraction with ATP and AMP.

In muscle, [ATP] is ~50 times greater than [AMP] and ~10 times greater than [ADP]. Consequently, a change in [ATP] from, for example, 1.0 to 0.9 mM, a 10% decrease, can result in a 100% increase in [ADP] from (0.1 to 0.2 mM) as a result of the adenylate kinase reaction, and a >400% increase in [AMP] (from 0.02 to ~0.1 mM). Therefore, a metabolic signal consisting of a decrease in [ATP] too small to relieve PFK inhibition is amplified significantly by the adenylate kinase reaction, which increases [AMP] by an amount that produces a much larger increase in PFK activity.

B Substrate Cycling Fine-Tunes Flux Control

Even a finely tuned allosteric mechanism like that of PFK can account for only a fraction of the 100-fold alterations in glycolytic flux. Additional control may be achieved by substrate cycling. Recall from Section 14-1D that only a near-equilibrium reaction can undergo large changes in flux because, in a near-equilibrium reaction, $v_f - v_r \approx 0$ (where v_f and v_r are the forward and reverse reaction rates) and hence a small change in v_f will result in a large fractional change in $v_f - v_r$. However, this is not the case for the PFK reaction because, for such nonequilibrium reactions, v_r is negligible.

Nevertheless, such equilibrium-like conditions may be imposed on a non-equilibrium reaction if a second enzyme (or series of enzymes) catalyzes the regeneration of its substrate from its product in a thermodynamically favorable manner. This can be diagrammed as

Since two different enzymes catalyze the forward (f) and reverse (r) reactions, v_f and v_r may be independently varied and v_r is no longer negligible compared to v_f . Note that the forward process (e.g., formation of FBP from F6P) and the reverse process (e.g., breakdown of FBP to F6P) *must* be carried out by different enzymes since the laws of thermodynamics would otherwise be violated (i.e., for a single reaction, the forward and reverse reactions cannot simultaneously be favorable).

Under physiological conditions, the reaction catalyzed by PFK:

is highly exergonic ($\Delta G = -25.9 \text{ k} \cdot \text{mol}^{-1}$). Consequently, the back reaction has a negligible rate compared to the forward reaction. **Fructose-1,6-bisphosphatase (FBPase)**, however, which is present in many mammalian tissues (and which is an essential enzyme in gluconeogenesis; Section 16-4B), catalyzes the exergonic hydrolysis of FBP ($\Delta G = -8.6 \text{ kJ} \cdot \text{mol}^{-1}$).

FIG. 15-25 Substrate cycling in the regulation of PFK. (a) In resting muscle, both enzymes in the F6P/FBP substrate cycle are active, and glycolytic flux is low. (b) In active muscle, PFK activity increases while FBPase activity decreases. This dramatically increases the flux through PFK and therefore results in high glycolytic flux.

Note that the combined reactions catalyzed by PFK and FBPase result in net ATP hydrolysis:

Such a set of opposing reactions (Section 14-1E) is known as a **substrate cycle** because it cycles a substrate to an intermediate and back again. When this set of reactions was discovered, it was referred to as a **futile cycle** since its net result seemed to be the useless consumption of ATP.

Eric Newsholme has proposed that substrate cycles are not at all “futile” but, rather, have a regulatory function. *The combined effects of allosteric effectors on the opposing reactions of a substrate cycle can produce a much greater fractional effect on pathway flux ($v_f - v_r$) than is possible through allosteric regulation of a single enzyme.* For example, the allosteric effector F2,6P activates the PFK reaction while inhibiting the FBPase reaction (this regulatory mechanism is important for balancing glycolysis and gluconeogenesis in liver cells; Section 16-4C).

Substrate cycling does not increase the maximum flux through a pathway. On the contrary, it functions to decrease the minimum flux. In a sense, the substrate is put into a “holding pattern.” In the PFK/FBPase example (Fig. 15-25), the cycling of substrate appears to be the energetic “price” that a muscle must pay to be able to change rapidly from a resting state (where $v_f - v_r$ is small), in which substrate cycling is maximal, to one of sustained high activity (where $v_f - v_r$ is large). The rate of substrate cycling itself may be under hormonal or neuronal control so as to increase the sensitivity of the metabolic system under conditions when high activity (fight or flight) is anticipated.

Substrate cycling and other mechanisms that control PFK activity *in vivo* are part of larger systems that regulate all the cell’s metabolic activities. At one time, it was believed that because PFK is the controlling enzyme of glycolysis, increasing its level of expression via genetic engineering would increase flux through glycolysis. However, this is not the case, because the *activity* of PFK, whatever its concentration, is ultimately controlled by factors that reflect the cell’s demand for the products supplied by glycolysis and all other metabolic pathways.

 **Substrate Cycling Is Related to Thermogenesis and Obesity.** Many animals, including adult humans, are thought to generate much of their body heat, particularly when it is cold, through substrate cycling in muscle and liver, a process known as **nonshivering thermogenesis** (the muscle contractions of shivering or any other movement also produce heat). Substrate cycling is stimulated by thyroid hormones (which stimulate metabolism in most tissues) as is indicated, for example, by the observation that rats lacking a functional thyroid gland do not survive at 5°C. Chronically obese individuals tend to have lower than normal metabolic rates, which is probably due, in part, to a reduced rate of nonshivering thermogenesis. Such individuals therefore tend to be cold sensitive. Indeed, whereas normal individuals increase their rate of thyroid hormone activation on exposure to cold, genetically obese animals and obese humans fail to do so.

CHECKPOINT

- Which glycolytic enzymes are potential control points?
- Describe the mechanisms that control phosphofructokinase activity.
- Why is ATP alone not an effective allosteric regulator of enzyme activity?
- What is the metabolic advantage of a substrate cycle? What is its cost?

5 Metabolism of Hexoses Other than Glucose

KEY CONCEPT

- The commonly available hexoses fructose, galactose, and mannose are converted to glycolytic intermediates for further metabolism.

Together with glucose, the hexoses fructose, galactose, and mannose are prominent metabolic fuels. After digestion, these monosaccharides enter the bloodstream, which carries them to various tissues. Fructose, galactose, and mannose are converted to glycolytic intermediates that are then metabolized by the glycolytic pathway (Fig. 15-26).

A Fructose Is Converted to Fructose-6-Phosphate or Glyceraldehyde-3-Phosphate

Fructose is a major fuel source in diets that contain large amounts of fruit or sucrose (a disaccharide of fructose and glucose; Section 8-2A). There are two pathways for the metabolism of fructose; one occurs in muscle and the other occurs in liver. This dichotomy results from the different enzymes present in these tissues.

Fructose metabolism in muscle differs little from that of glucose. Hexokinase (Section 15-2A), which converts glucose to G6P, also phosphorylates fructose, yielding F6P (Fig. 15-27, left). The entry of fructose into glycolysis therefore involves only one reaction step.

Liver contains a hexokinase homolog known as **glucokinase**, which phosphorylates only glucose (Section 22-1D). Fructose metabolism in liver must therefore differ from that in muscle. In fact, liver converts fructose to glycolytic intermediates through a pathway that involves seven enzymes (Fig. 15-27, right):

- Fructokinase** catalyzes the phosphorylation of fructose by ATP at C1 to form **fructose-1-phosphate**. Neither hexokinase nor PFK can phosphorylate fructose-1-phosphate at C6 to form the glycolytic intermediate FBP.
- Aldolase (Section 15-2D) has several isozymic forms. Muscle contains Type A aldolase, which is specific for FBP. Liver, however, contains Type B aldolase, for which fructose-1-phosphate is also a substrate (Type B aldolase is sometimes called **fructose-1-phosphate aldolase**). In liver, fructose-1-phosphate therefore undergoes an aldol cleavage:

$$\text{Fructose-1-phosphate} \rightleftharpoons \text{dihydroxyacetone phosphate} + \text{glyceraldehyde}$$
- Direct phosphorylation of **glyceraldehyde** by ATP through the action of **glyceraldehyde kinase** forms the glycolytic intermediate GAP.
- Alternatively, glyceraldehyde is converted to the glycolytic intermediate DHAP, beginning with its NADH-dependent reduction to glycerol as catalyzed by alcohol dehydrogenase.
- Glycerol kinase** catalyzes ATP-dependent phosphorylation to produce **glycerol-3-phosphate**.
- DHAP is produced by NAD^+ -dependent oxidation catalyzed by **glycerol phosphate dehydrogenase**.
- The DHAP is then converted to GAP by triose phosphate isomerase.

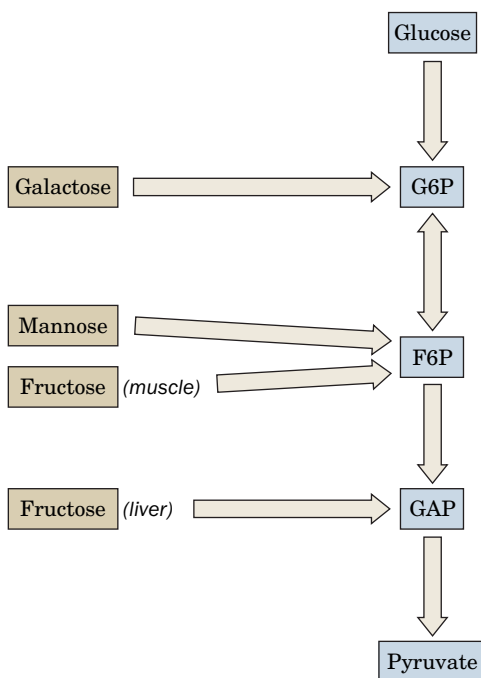

FIG. 15-26 Entry of other hexoses into glycolysis. Fructose (in muscle) and mannose are converted to F6P; liver fructose is converted to GAP; and galactose is converted to G6P.

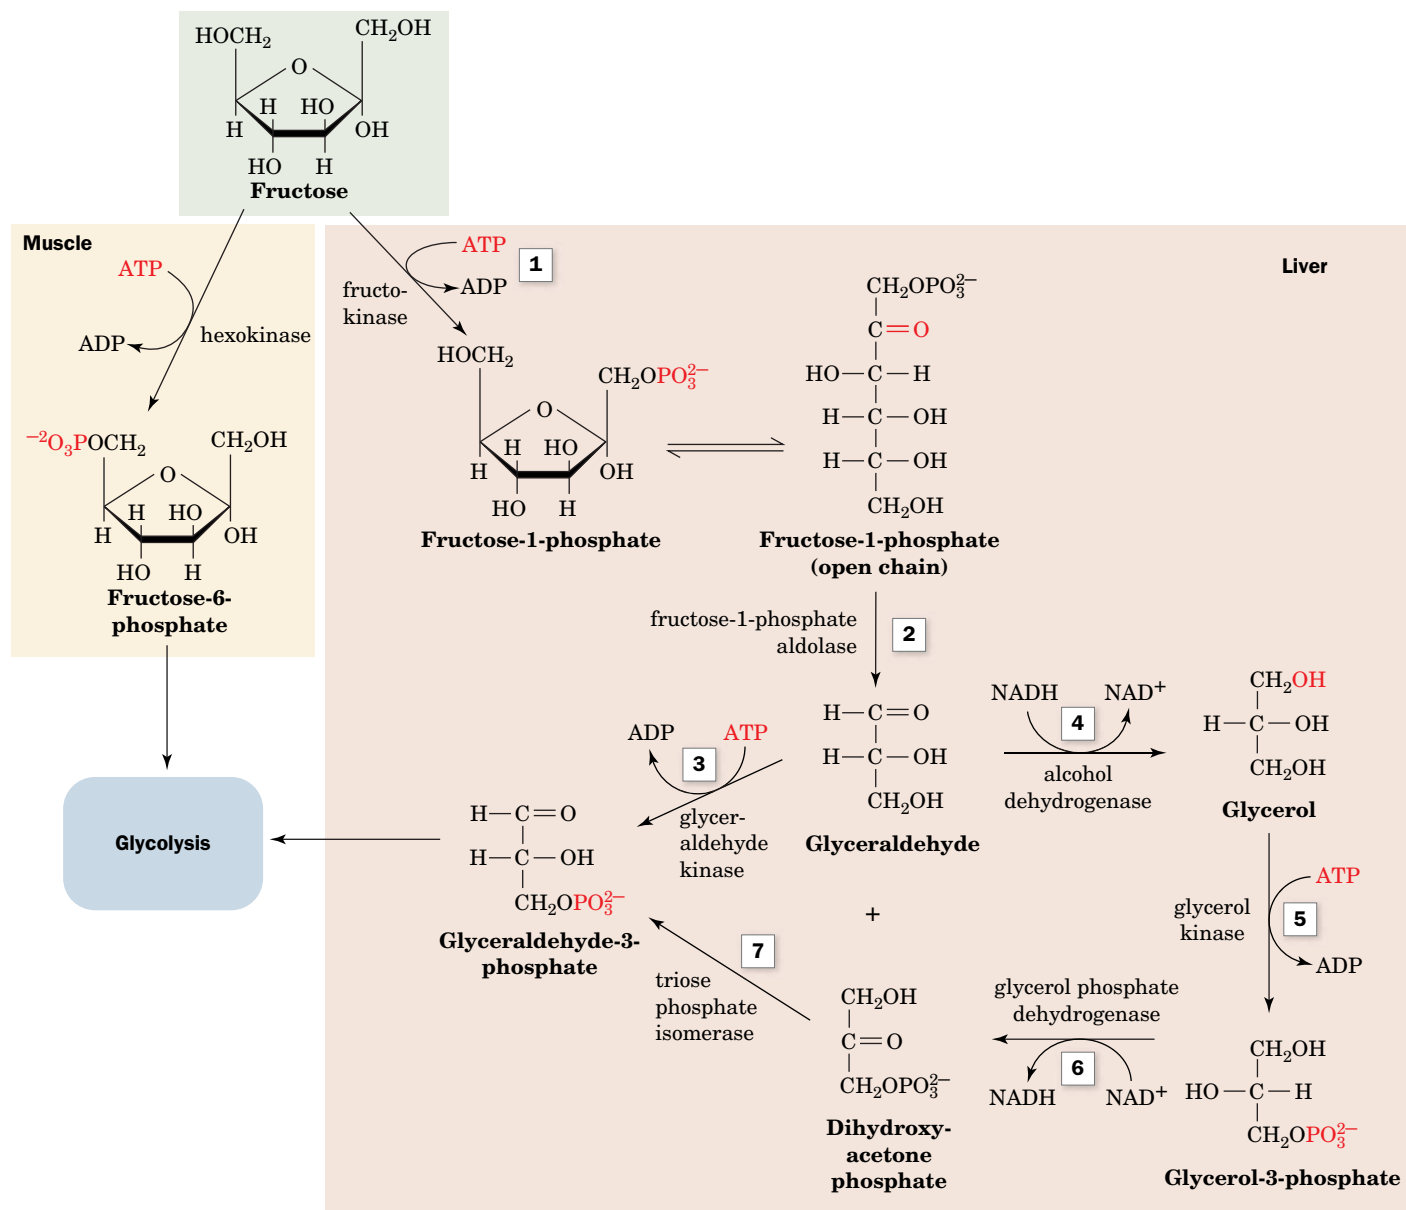

FIG. 15-27 The metabolism of fructose. In muscle (*left*), the conversion of fructose to the glycolytic intermediate F6P involves only one enzyme, hexokinase. In liver (*right*), seven enzymes participate in the conversion of fructose to glycolytic intermediates.

? Write an equation for the conversion of fructose to GAP in the liver.

The two pathways leading from glyceraldehyde to GAP have the same net cost: Both consume ATP, and although NADH is oxidized in Reaction 4, it is reduced again in Reaction 6. The longer pathway, however, produces glycerol 3-phosphate, which (along with DHAP) can become the glycerol backbone of glycerophospholipids and triacylglycerols (Section 20-6A).

Is Excess Fructose Harmful? The consumption of fructose in the United States has increased at least 10-fold in the last quarter century, in large part due to the use of high-fructose corn syrup as a sweetener in soft drinks and other foods. Fructose has a sweeter taste than sucrose (Box 8-2) and is inexpensive to produce. One possible hazard of excessive fructose intake is that fructose catabolism in liver bypasses the PFK-catalyzed step of glycolysis and thereby avoids a major metabolic control point. This could potentially disrupt fuel metabolism so

that glycolytic flux is directed toward lipid synthesis in the absence of a need for ATP production. This hypothesis suggests a link between the increase in both fructose consumption and the recently increasing incidence of obesity in the United States.

At the opposite extreme are individuals with **fructose intolerance**, which results from a deficiency in Type B aldolase. In the absence of the aldolase, fructose-1-phosphate may accumulate enough to deplete the liver's store of P_i . Under these conditions, [ATP] drops, which causes liver damage. In addition, the increased [fructose-1-phosphate] inhibits both **glycogen phosphorylase** (an essential enzyme in the breakdown of glycogen to glucose; Section 16-1A) and fructose-1,6-bisphosphatase (an essential enzyme in gluconeogenesis; Section 16-4B), thereby causing severe **hypoglycemia** (low levels of blood glucose), which can reach life-threatening proportions. However, fructose intolerance is self-limiting: Individuals with the condition rapidly develop a strong distaste for anything sweet.

B Galactose Is Converted to Glucose-6-Phosphate

Galactose is obtained from the hydrolysis of lactose (a disaccharide of galactose and glucose; Section 8-2A) in dairy products. Galactose and glucose are epimers that differ only in their configuration at C4.

Although hexokinase phosphorylates glucose, fructose, and mannose, it does not recognize galactose. An epimerization reaction must therefore occur before galactose enters glycolysis. This reaction takes place after the conversion of galactose to its **uridine diphosphate** derivative (the role of UDP-sugars and other nucleotidyl-sugars is discussed in more detail in Section 16-5). The entire pathway converting galactose to a glycolytic intermediate requires four reactions (**Fig. 15-28**):

- Galactose is phosphorylated at C1 by ATP in a reaction catalyzed by **galactokinase**.
- Galactose-1-phosphate uridylyl transferase** transfers the uridylyl group of UDP-glucose to **galactose-1-phosphate** to yield **glucose-1-phosphate (G1P)** and **UDP-galactose** by the reversible cleavage of UDP-glucose's pyrophosphoryl bond.
- UDP-galactose-4-epimerase** converts UDP-galactose back to UDP-glucose. This enzyme has an associated NAD^+ , which suggests that the reaction involves the sequential oxidation and reduction of the hexose C4 atom:

- G1P is converted to the glycolytic intermediate G6P by the action of **phosphoglucomutase** (Section 16-1C).

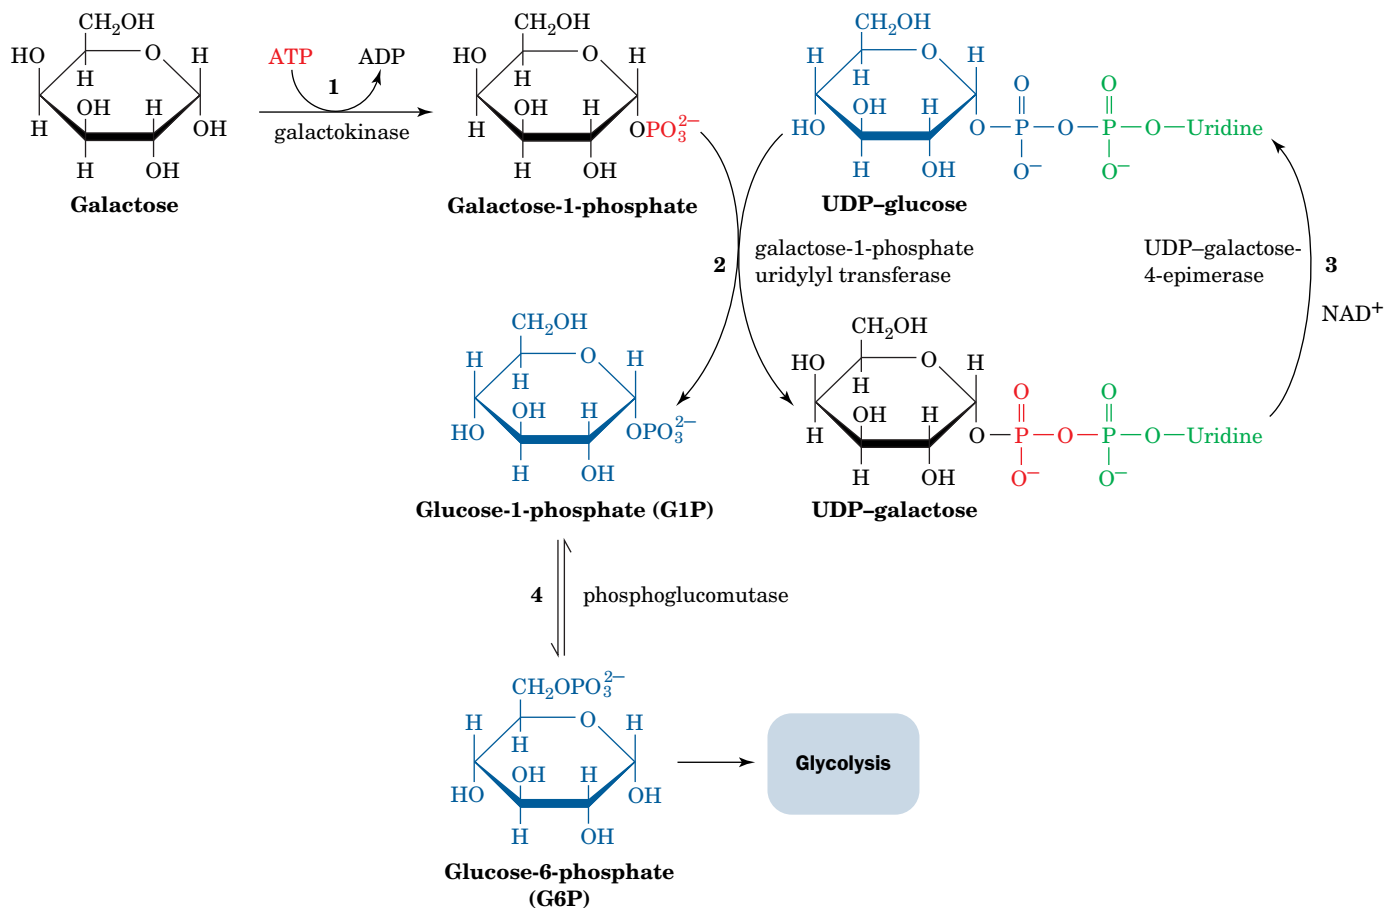

FIG. 15-28 The metabolism of galactose. Four enzymes participate in the conversion of galactose to the glycolytic intermediate G6P.

Individuals with Galactosemia Cannot Metabolize Galactose. Galactosemia

is a genetic disease characterized by the inability to convert galactose to glucose. Its symptoms include failure to thrive, mental retardation, and, in some instances, death from liver damage. Most cases of galactosemia involve a deficiency in the enzyme catalyzing Reaction 2 of the interconversion, galactose-1-phosphate uridylyl transferase. Formation of UDP-galactose from galactose-1-phosphate is thus prevented, leading to a buildup of toxic metabolic by-products. For example, the increased galactose concentration in the blood results in a higher galactose concentration in the lens of the eye, where the sugar is reduced to **galactitol**.

The presence of this sugar alcohol in the lens eventually causes cataract formation (clouding of the lens).

Galactosemia is treated by a galactose-free diet. Except for the mental retardation, this reverses all symptoms of the disease. The galactosyl units that are essential for the synthesis of glycoproteins (Section 8-3C) and glycolipids

FIG. 15-29 The metabolism of mannose. Two enzymes are required to convert mannose to the glycolytic intermediate F6P.

(Section 9-1D) can be synthesized from glucose by a reversal of the epimerase reaction. These syntheses therefore do not require dietary galactose.

C Mannose Is Converted to Fructose-6-Phosphate

Mannose, a product of digestion of polysaccharides and glycoproteins, is the C2 epimer of glucose.

Mannose enters the glycolytic pathway after its conversion to F6P via a two-reaction pathway (Fig. 15-29):

CHECKPOINT

- Describe how fructose, galactose, and mannose enter the glycolytic pathway.
- Which glycolytic enzymes are used by these tributary pathways?

1. Hexokinase recognizes mannose and converts it to **mannose-6-phosphate**.
2. **Phosphomannose isomerase** then converts this aldose to the glycolytic intermediate F6P in a reaction whose mechanism resembles that of phosphoglucose isomerase (Section 15-2B).

6 The Pentose Phosphate Pathway

KEY CONCEPTS

- The pentose phosphate pathway consists of three stages, in which NADPH is produced, pentoses undergo isomerization, and glycolytic intermediates are recovered.
- The pathway provides NADPH for reductive biosynthesis and ribose-5-phosphate for nucleotide biosynthesis in the quantities that the cell requires.

ATP is the cell's "energy currency"; its exergonic cleavage is coupled to many otherwise endergonic cell functions. *Cells also have a second currency, reducing power.* Many endergonic reactions, notably the reductive biosynthesis of fatty acids (Section 20-4) and cholesterol (Section 20-7A), require NADPH in addition to ATP. Despite their close chemical resemblance, *NADPH and NADH are not metabolically interchangeable.* Whereas cells capture the free energy of metabolite oxidation as NADH to synthesize ATP (oxidative phosphorylation), cells capture free energy as NADPH for reductive biosynthesis. This differentiation is possible because the dehydrogenases involved in oxidative and reductive metabolism are highly specific for their respective coenzymes. Indeed, cells normally maintain their $[\text{NAD}^+]/[\text{NADH}]$ ratio near 1000, which favors metabolite oxidation, while keeping their $[\text{NADP}^+]/[\text{NADPH}]$ ratio near 0.01, which favors reductive biosynthesis.

NADPH is generated by the oxidation of glucose-6-phosphate via an alternative pathway to glycolysis, the pentose phosphate pathway (also called the **hexose monophosphate shunt**; Fig. 15-30). Tissues most heavily involved in lipid biosynthesis (liver, mammary gland, adipose tissue, and adrenal cortex) are rich in pentose phosphate pathway enzymes. Indeed, some 30% of the glucose oxidation in liver occurs via the pentose phosphate pathway rather than glycolysis.

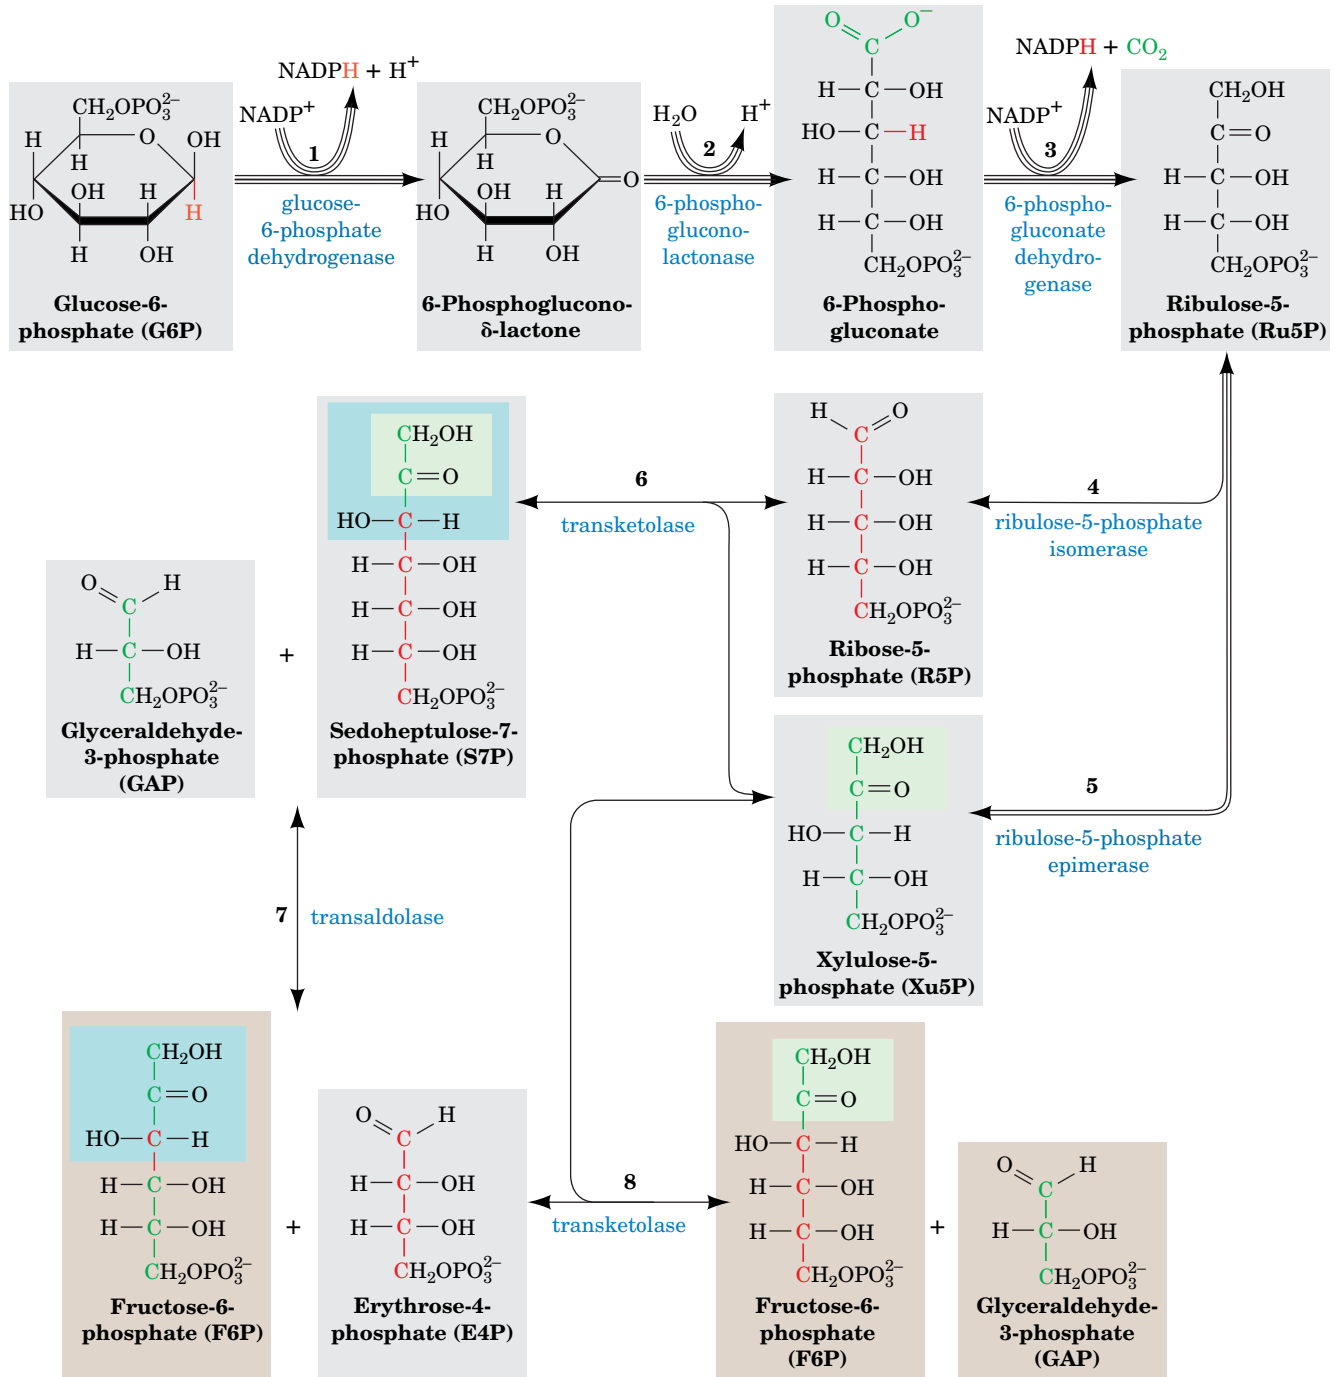

FIG. 15-30 The pentose phosphate pathway. The number of lines in an arrow represents the number of molecules reacting in one turn of the pathway so as to convert 3 G6P to 3 CO_2 , 2 F6P, and 1 GAP. For the sake of clarity, sugars from Reaction 3 onward are shown in their linear forms. The carbon skeleton of R5P and the atoms derived from it are drawn in red, and those from Xu5P are drawn in green. The C_2

units transferred by transketolase are shaded in green, and the C_3 units transferred by transaldolase are shaded in blue. Double-headed arrows indicate reversible reactions.

? How many different types of reactions occur in this pathway?

The overall reaction of the pentose phosphate pathway is

However, the pathway can be considered to have three stages:

Stage 1 Oxidative reactions (Fig. 15-30, Reactions 1–3), which yield NADPH and **ribulose-5-phosphate (Ru5P)**:

Stage 2 Isomerization and epimerization reactions (Fig. 15-30, Reactions 4 and 5), which transform Ru5P either to **ribose-5-phosphate (R5P)** or to **xylulose-5-phosphate (Xu5P)**:

Stage 3 A series of C—C bond cleavage and formation reactions (Fig. 15-30, Reactions 6–8) that convert two molecules of Xu5P and one molecule of R5P to two molecules of F6P and one molecule of GAP.

The reactions of Stages 2 and 3 are freely reversible, so the products of the pathway vary with the needs of the cell (see below). In this section, we discuss the three stages of the pentose phosphate pathway and how the pathway is controlled.

A Oxidative Reactions Produce NADPH in Stage 1

G6P is considered the starting point of the pentose phosphate pathway. This metabolite may arise through the action of hexokinase on glucose (Reaction 1 of glycolysis; Section 15-2A) or from glycogen breakdown (which produces G6P directly; Section 16-1). Only the first three reactions of the pentose phosphate pathway are involved in NADPH production (Fig. 15-30):

1. **Glucose-6-phosphate dehydrogenase (G6PD)** catalyzes net transfer of a hydride ion to NADP^+ from C1 of G6P to form **6-phosphoglucono- δ -lactone**:

G6P, a cyclic hemiacetal with C1 in the aldehyde oxidation state, is thereby oxidized to a cyclic ester (lactone). The enzyme is specific for NADP^+ and is strongly inhibited by NADPH.

2. **6-Phosphogluconolactonase** increases the rate of hydrolysis of 6-phosphoglucono- δ -lactone to **6-phosphogluconate** (the nonenzymatic reaction occurs at a significant rate).
3. **6-Phosphogluconate dehydrogenase** catalyzes the oxidative decarboxylation of 6-phosphogluconate, a β -hydroxy acid, to Ru5P and

FIG. 15-31 The 6-phosphogluconate dehydrogenase reaction. Oxidation of the OH group forms an easily decarboxylated β -keto acid (although the proposed intermediate has not been isolated).

CO₂ (Fig. 15-31). This reaction is thought to proceed via the formation of a β -keto acid intermediate. The keto group presumably facilitates decarboxylation by acting as an electron sink.

Formation of Ru5P completes the oxidative portion of the pentose phosphate pathway. *It generates two molecules of NADPH for each molecule of G6P that enters the pathway.*

B Isomerization and Epimerization of Ribulose-5-Phosphate Occur in Stage 2

Ru5P is converted to R5P by **ribulose-5-phosphate isomerase** (Fig. 15-30, Reaction 4) or to Xu5P by **ribulose-5-phosphate epimerase** (Fig. 15-30, Reaction 5). These isomerization and epimerization reactions, like the reaction catalyzed by triose phosphate isomerase (Section 15-2E), are thought to occur via enediolate intermediates.

The relative amounts of R5P and Xu5P produced from Ru5P depend on the needs of the cell. For example, R5P is an essential precursor in the biosynthesis of nucleotides (Chapter 23). Accordingly, R5P production is relatively high (in fact, the entire pentose phosphate pathway activity may be elevated) in rapidly dividing cells, in which the rate of DNA synthesis is increased. If the pathway is being used solely for NADPH production, Xu5P and R5P are produced in a 2:1 ratio for conversion to glycolytic intermediates in the third stage of the pentose phosphate pathway as is discussed below.

C Stage 3 Involves Carbon–Carbon Bond Cleavage and Formation

How is a five-carbon sugar transformed to a six-carbon sugar such as F6P? The rearrangements of carbon atoms in the third stage of the pentose phosphate pathway are easier to follow by considering the stoichiometry of the pathway. Every three G6P molecules that enter the pathway yield three Ru5P molecules in Stage 1. These three pentoses are then converted to one R5P and two Xu5P (Fig. 15-30, Reactions 4 and 5). The conversion of these three C₅ sugars to two C₆ sugars and one C₃ sugar involves a remarkable “juggling act” catalyzed by two enzymes, **transaldolase** and **transketolase**. These enzymes have mechanisms that involve the generation of stabilized carbanions and their addition to the electrophilic centers of aldehydes.

Transketolase Catalyzes the Transfer of C₂ Units. Transketolase, which has a thiamine pyrophosphate cofactor (TPP; Section 15-3B), catalyzes the transfer of

a C₂ unit from Xu5P to R5P, yielding GAP and **sedoheptulose-7-phosphate (S7P)**; Fig. 15-30, Reaction 6). The reaction intermediate is a covalent adduct between Xu5P and TPP (Fig. 15-32). The X-ray structure of the dimeric enzyme shows that the TPP binds in a deep cleft between the subunits so that residues from both subunits participate in its binding, just as in pyruvate decarboxylase (another TPP-requiring enzyme; Fig. 15-19). In fact, the structures are so similar that the enzymes likely diverged from a common ancestor.

Transaldolase Catalyzes the Transfer of C₃ Units. Transaldolase catalyzes the transfer of a C₃ unit from S7P to GAP yielding **erythrose-4-phosphate (E4P)** and F6P (Fig. 15-30, Reaction 7). The reaction occurs by aldol cleavage (Section 15-2D), which begins with the formation of a Schiff base

PROCESS DIAGRAM

FIG. 15-32 Mechanism of transketolase. Transketolase (represented by E) uses the coenzyme TPP to stabilize the carbanion formed on cleavage of the C2—C3 bond of Xu5P. The reaction occurs in 4 steps as shown. **WPLS** See the Animated Process Diagrams.

FIG. 15-33 Mechanism of transaldolase. Transaldolase contains an essential Lys residue that facilitates an aldol cleavage reaction as follows: (1) The ε-amino group of Lys forms a Schiff base with the carbonyl group of S7P; (2) a Schiff base-stabilized C3 carbanion is formed in an aldol cleavage reaction between C3 and C4 that eliminates E4P; (3) the

enzyme-bound resonance-stabilized carbanion adds to the carbonyl C atom of GAP, forming F6P linked to the enzyme via a Schiff base; (4) the Schiff base hydrolyzes, regenerating active enzyme and releasing F6P. **WPLS** See the Animated Process Diagrams.

between an ε-amino group of an essential Lys residue and the carbonyl group of S7P (Fig. 15-33).

A Second Transketolase Reaction Yields Glyceraldehyde-3-Phosphate and a Second Fructose-6-Phosphate Molecule. In a second transketolase reaction, a C₂ unit is transferred from a second molecule of Xu5P to E4P to form GAP and another molecule of F6P (Fig. 15-30, Reaction 8). The third stage of the pentose phosphate pathway thus transforms two molecules of Xu5P and one of R5P to two molecules of F6P and one molecule of GAP. To summarize, a series of carbon-carbon bond formations and cleavages convert three C₅ sugars to two C₆ sugars and one C₃ sugar. Here, the number to the left of each reaction is keyed to the corresponding reaction in Fig. 15-30.

NADPH is required for several reductive processes in addition to biosynthesis. For example, erythrocytes require a plentiful supply of reduced **glutathione (GSH)**, a Cys-containing tripeptide (Section 4-3B).

Glutathione (GSH)
(γ -L-glutamyl-L-cysteinylglycine)

A major function of GSH in the erythrocyte is to reductively eliminate H_2O_2 and organic hydroperoxides, which are reactive oxygen metabolites that can oxidize hemoglobin's Fe(II) to Fe(III) to form methemoglobin (Section 7-1A) and cleave the C—C bonds in the phospholipid tails of cell membranes. The unchecked buildup of peroxides results in premature cell lysis. Peroxides are eliminated by reaction with glutathione, catalyzed by **glutathione peroxidase**:

Organic hydroperoxide

GSSG represents oxidized glutathione (two GSH molecules linked through a disulfide bond between their sulfhydryl groups). Reduced

GSH is subsequently regenerated by the reduction of GSSG by NADPH as catalyzed by **glutathione reductase**:

A steady supply of NADPH is therefore vital for erythrocyte integrity.

The erythrocytes in individuals who are deficient in glucose-6-phosphate dehydrogenase (G6PD) are particularly sensitive to oxidative damage, although clinical symptoms may be absent. This enzyme deficiency, which is common in African, Asian, and Mediterranean populations, came to light through investigations of the sometimes fatal hemolytic anemia that is induced in these individuals when they ingest drugs such as the antimalarial compound **primaquine**

Primaquine

or eat **fava beans (broad beans, *Vicia faba*)**, a staple Middle Eastern vegetable. Primaquine stimulates peroxide formation, thereby increasing the demand for NADPH to a level that the mutant cells cannot meet. Certain toxic glycosides present in small amounts in fava beans have the same effect, producing a condition known as **favism**.

CHECKPOINT

- Write the net equation for the pentose phosphate pathway.
- Summarize the reactions of each stage of the pathway.
- Compare the transketolase and transaldolase reactions in terms of substrates, products, mechanism, and cofactor requirement.
- How does flux through the pentose phosphate pathway change in response to the need for NADPH or ribose-5-phosphate?

D The Pentose Phosphate Pathway Must Be Regulated

The principal products of the pentose phosphate pathway are R5P and NADPH. The transaldolase and transketolase reactions convert excess R5P to glycolytic intermediates when the metabolic need for NADPH exceeds that of R5P in nucleotide biosynthesis. The resulting GAP and F6P can be consumed through glycolysis and oxidative phosphorylation or recycled by gluconeogenesis (Section 16-4) to form G6P.

When the need for R5P outstrips the need for NADPH, F6P and GAP can be diverted from the glycolytic pathway for use in the synthesis of R5P by reversal of the transaldolase and transketolase reactions. The relationship between glycolysis and the pentose phosphate pathway is diagrammed in **Fig. 15-34**.

Flux through the pentose phosphate pathway and thus the rate of NADPH production is controlled by the rate of the glucose-6-phosphate dehydrogenase reaction (Fig. 15-30, Reaction 1). The activity of the enzyme, which catalyzes the pathway's first committed step ($\Delta G = -17.6 \text{ kJ} \cdot \text{mol}^{-1}$ in liver), is regulated by the NADP^+ concentration (i.e., regulation by substrate availability). When the cell consumes NADPH, the NADP^+ concentration rises, increasing the rate of the G6PD reaction and thereby stimulating NADPH regeneration. In some tissues, the amount of enzyme synthesized also appears to be under hormonal control. A deficiency in G6PD is the most common clinically significant enzyme defect of the pentose phosphate pathway (Box 15-4). Wernicke-Korsakoff syndrome (Section 15-3B) is caused by the reduced activity of transketolase. Consequently, individuals with a mutant form of transketolase that binds TPP with 10% percent of the normal affinity are subject to Wernicke-Korsakoff syndrome with even moderately thiamine-deficient diets.

The major reason for low enzymatic activity in affected cells appears to be an accelerated rate of breakdown of the mutant enzyme. This explains why patients with relatively mild forms of G6PD deficiency react to primaquine with hemolytic anemia but recover within a week despite continued primaquine treatment. Mature erythrocytes lack a nucleus and protein synthesizing machinery and therefore cannot synthesize new enzyme molecules to replace degraded ones (they likewise cannot synthesize new membrane components, which is why they are so sensitive to membrane damage in the first place). The initial primaquine treatments result in the lysis of old red blood cells whose defective G6PD has been largely degraded. Lysis products stimulate the release of young cells that contain more enzyme and are therefore better able to cope with primaquine stress.

It is estimated that more than 400 million people are deficient in G6PD, which makes this condition the most common human enzyme deficiency. Indeed, ~400 G6PD variants have been reported and at least 140 of them have been characterized at the molecular level. G6PD is active in a dimer-tetramer equilibrium. Many of the mutation sites in individuals with the most severe G6PD deficiency are at the dimer interface, shifting the equilibrium toward the inactive and unstable monomer.

The high prevalence of defective G6PD in malarial areas of the world suggests that such mutations confer resistance to the malarial parasite, *Plasmodium falciparum*. Indeed, erythrocytes with G6PD deficiency appear to be less suitable hosts for plasmodia than normal cells. Thus, like the sickle-cell trait (Section 7-1E), a defective G6PD confers a selective advantage on individuals living where malaria is endemic.

The G6PD deficiency affects primarily erythrocytes, in which the lack of a nucleus prevents replacement of the unstable mutant enzyme. However, the importance of NADPH in cells other than erythrocytes

has been demonstrated through the development of mice in which the G6PD gene has been knocked out. All the cells in these animals are extremely sensitive to oxidative stress, even though they contain other mechanisms for eliminating reactive oxygen species.

Dr. Gopal Murti/Photo Researchers

Photo of red blood cells containing intracellular *Plasmodium falciparum* (the malarial parasite), here seen as yellow bodies (named schizonts), which generate the small red cells (called merozoites).

FIG. 15-34 Relationship between glycolysis and the pentose phosphate pathway. The pentose phosphate pathway, which begins with G6P produced in Step 1 of glycolysis, generates NADPH for use in reductive reactions and R5P for nucleotide synthesis. Excess R5P is converted to glycolytic intermediates by a sequence of reactions that can operate in reverse to generate additional R5P, if needed.

? Which portions of the pathways would be most active in a cell just before and just after cell division?

Summary

1 Overview of Glycolysis

Glycolysis is a sequence of 10 enzyme-catalyzed reactions by which one molecule of glucose is converted to two molecules of pyruvate, with the net production of 2 ATP and the reduction of 2 NAD⁺ to 2 NADH.

2 The Reactions of Glycolysis

In the first stage of glycolysis, glucose is phosphorylated by hexokinase, isomerized by phosphoglucose isomerase (PGI), phosphorylated by phosphofructokinase (PFK), and cleaved by aldolase to yield the trioses glyceraldehyde-3-phosphate (GAP) and dihydroxyacetone phosphate (DHAP), which are interconverted by triose phosphate isomerase (TIM). These reactions consume 2 ATP per glucose.

In the second stage of glycolysis, GAP is oxidatively phosphorylated by glyceraldehyde-3-phosphate dehydrogenase (GAPDH), dephosphorylated by phosphoglycerate kinase (PGK) to produce ATP, isomerized by phosphoglycerate mutase (PGM), dehydrated by enolase, and dephosphorylated by pyruvate kinase to produce a second ATP and pyruvate. This stage produces 4 ATP per glucose for a net yield of 2 ATP per glucose.

3 Fermentation: The Anaerobic Fate of Pyruvate

Under anaerobic conditions, pyruvate is reduced to regenerate NAD⁺ for glycolysis. In homolactic fermentation, pyruvate is reversibly reduced to lactate.

In alcoholic fermentation, pyruvate is decarboxylated by a thiamine pyrophosphate (TPP)-dependent mechanism, and the resulting acetaldehyde is reduced to ethanol.

Problems

EXERCISES

1. Which of the 10 reactions of glycolysis are (a) phosphorylations, (b) isomerizations, (c) oxidation-reductions, (d) dehydrations, and (e) carbon-carbon bond cleavages?

2. When the pathogen *Salmonella typhimurium* infects mammalian cells, the host cell protease **caspase-1** is enabled to cleave and thereby activate signaling proteins that instigate the immune response. The targets of caspase-1 also include aldolase and enolase. What effect would this have on the infected cell and why might this be advantageous to the organism?

3. The reversible reaction shown here is part of the Calvin cycle, a pathway in photosynthetic organisms. Which glycolytic reaction does this reaction resemble and what type of enzyme catalyzes it?

4 Regulation of Glycolysis

The glycolytic reactions catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase are metabolically irreversible.

Phosphofructokinase is the primary flux control point for glycolysis. ATP inhibition of this allosteric enzyme is relieved by AMP and ADP, whose concentrations change more dramatically than those of ATP.

The opposing reactions of the fructose-6-phosphate (F6P)/fructose-1,6-bisphosphate (FBP) substrate cycle allow large changes in glycolytic flux.

5 Metabolism of Hexoses Other than Glucose

Fructose, galactose, and mannose are enzymatically converted to glycolytic intermediates for catabolism.

6 The Pentose Phosphate Pathway

In the pentose phosphate pathway, glucose-6-phosphate (G6P) is oxidized and decarboxylated to produce two NADPH, CO₂, and ribulose-5-phosphate (Ru5P).

Depending on the cell's needs, ribulose-5-phosphate may be isomerized to ribose-5-phosphate (R5P) for nucleotide synthesis or converted, via ribose-5-phosphate and xylulose-5-phosphate (Xu5P), to fructose-6-phosphate and glyceraldehyde-3-phosphate, which can re-enter the glycolytic pathway.

4. Step 4 of the pentose phosphate pathway converts ribulose-5-phosphate to ribose-5-phosphate. Which glycolytic reaction does this reaction resemble and what type of enzyme catalyzes it?

5. The aldolase reaction can proceed in reverse as an enzymatic aldol condensation. If the enzyme were not stereospecific, how many different products would be obtained?

6. Bacterial aldolase does not form a Schiff base with the substrate. Instead, it has a divalent Zn²⁺ ion in the active site. How does the ion facilitate the aldolase reaction?

7. Identify the intermediate in the phosphoglucomutase reaction.

8. The compound you identified in Problem 7 is a metabolic regulator. Predict its effect on (a) hexokinase and (b) PFK.

9. The pyruvate → lactate reaction in animals is reversible, but the pyruvate → ethanol fermentation in yeast is irreversible. Explain.

10. The half-reactions involved in the lactate dehydrogenase (LDH) reaction and their standard reduction potentials are

Calculate ΔG at pH 7.0 for the LDH-catalyzed reduction of pyruvate under the following conditions:

(a) [lactate]/[pyruvate] = 1 and [NAD⁺]/[NADH] = 1

(b) [lactate]/[pyruvate] = 160 and [NAD⁺]/[NADH] = 160

(c) $[\text{lactate}]/[\text{pyruvate}] = 1000$ and $[\text{NAD}^+]/[\text{NADH}] = 1000$

(d) Discuss the effect of the concentration ratios in Parts a–c on the direction of the reaction.

11. Why is it possible for the ΔG values in Table 15-1 to differ from the ΔG° values?

12. If a reaction has a ΔG° value of at least $-30.5 \text{ kJ} \cdot \text{mol}^{-1}$, sufficient to drive the synthesis of ATP ($\Delta G^\circ = 30.5 \text{ kJ} \cdot \text{mol}^{-1}$), can it still drive the synthesis of ATP *in vivo* when its ΔG is only $-10 \text{ kJ} \cdot \text{mol}^{-1}$? Explain.

13. Although it is not the primary flux-control point for glycolysis, pyruvate kinase is subject to allosteric regulation. What is the metabolic importance of regulating flux through the pyruvate kinase reaction?

14. What is the advantage of activating pyruvate kinase with fructose-1,6-bisphosphate?

15. Tumor cells, which tend to grow rapidly, typically express high levels of the glycolytic enzymes. Explain the advantage of high glycolytic flux for these cells.

16. The pyruvate kinase isozyme in cancerous cells has low activity compared to the isozymes in other tissues. What effect would this have on the cells and how does it promote tumor growth?

17. Compare the ATP yield of three glucose molecules that enter glycolysis and are converted to pyruvate with that of three glucose molecules that proceed through the pentose phosphate pathway such that their carbon skeletons (as two F6P and one GAP) reenter glycolysis and are metabolized to pyruvate.

18. If G6P is labeled at its C2 position, where will the label appear in the products of the pentose phosphate pathway?

19. Draw the enediolate intermediate of the ribulose-5-phosphate isomerase reaction ($\text{Ru5P} \rightarrow \text{R5P}$).

20. Draw the enediolate intermediate of the ribulose-5-phosphate epimerase reaction ($\text{Ru5P} \rightarrow \text{Xu5P}$).

21. Describe the lengths of the products of the transketolase reaction when the two substrates are both five-carbon sugars.

22. Describe the products of the transketolase reaction when the substrates are a five-carbon aldose and a six-carbon ketose. Does it matter which of the substrates binds to the enzyme first?

CHALLENGE QUESTIONS

23. Arsenate (AsO_4^{3-}), a structural analog of phosphate, can act as a substrate for any reaction in which phosphate is a substrate. Arsenate esters, unlike phosphate esters, are kinetically as well as thermodynamically unstable and hydrolyze almost instantaneously. Write a balanced overall equation for the conversion of glucose to pyruvate in the presence of ATP, ADP, NAD^+ , and either (a) phosphate or (b) arsenate. (c) Why is arsenate a poison?

24. The enzyme phosphoglucomutase interconverts glucose-1-phosphate and glucose-6-phosphate. Why is this enzyme likely to include a side chain such as Ser in its active site?

25. You combine 0.2 g of yeast, 0.2 g of sucrose and 10 mL of water, place the mixture inside an uninflated balloon, then tie off the opening of the balloon. (a) Explain what you would observe over the next hour. (b) What would you observe if you added iodoacetate to the mixture? (c) What would you observe if the mixture contained lactose rather than sucrose?

26. Nerve cells require a source of free energy to transport vesicles containing neurotransmitters along the length of the axon, where mitochondria are scarce. Explain why it makes sense that glyceraldehyde-3-phosphate dehydrogenase is located on the surface of some transport vesicles.

27. ΔG° for the aldolase reaction is $22.8 \text{ kJ} \cdot \text{mol}^{-1}$. In the cell at 37°C , $[\text{DHAP}]/[\text{GAP}] = 5.5$. Calculate the equilibrium ratio of $[\text{FBP}]/[\text{GAP}]$ when $[\text{GAP}] = 10^{-4} \text{ M}$.

28. The catalytic behavior of liver and brain phosphofructokinase-1 (PFK-1) was observed in the presence of AMP, P_i , and fructose-

2,6-bisphosphate. The following table lists the concentrations of each effector required to achieve 50% of the maximal velocity. Compare the response of the two isozymes to the three effectors and discuss the possible implications of their different responses.

PFK-1 isozyme	$[\text{P}_i]$	$[\text{AMP}]$	$[\text{F2,6P}]$
Liver	200 μM	10 μM	0.05 μM
Brain	350 μM	75 μM	4.5 μM

29. Consider the pathway for catabolizing galactose. What are the potential control points for this pathway?

30. Yeast take up and metabolize galactose, using the pathway outlined in Fig. 15-28. Galactose-1-phosphate, an intermediate of this pathway, inhibits phosphoglucomutase. Can this explain why galactose catabolism is much slower than glucose catabolism in yeast?

31. (a) Describe how glycerol enters the glycolytic pathway. (b) What is the ATP yield for the conversion of glycerol to pyruvate?

32. Some organisms can anaerobically convert glycerol to pyruvate. Could homolactic or alcoholic fermentation regenerate sufficient NAD^+ to support this pathway?

33. Explain why some tissues continue to produce CO_2 in the presence of high concentrations of fluoride ion, which inhibits glycolysis.

34. Some bacteria catabolize glucose by the **Entner–Doudoroff pathway**, a variant of glycolysis in which glucose-6-phosphate is converted to 6-phosphogluconate (as in the pentose phosphate pathway) and then to **2-keto-3-deoxy-6-phosphogluconate (KDPG)**.

KDPG

Next, an aldolase acts on KDPG. (a) Draw the structures of the products of the KDPG aldolase reaction. (b) Describe how these reaction products are further metabolized by glycolytic enzymes. (c) What is the ATP yield when glucose is metabolized to pyruvate by the Entner–Doudoroff pathway? How does this compare to the ATP yield of glycolysis?

35. A proposed pathway for ascorbic acid (vitamin C) biosynthesis in plants takes the form

Match each of the following enzymes to one of the pathway steps.

- galactose dehydrogenase
- GDP-mannose-3,5-epimerase
- phosphoglucose isomerase
- phosphomannose isomerase
- phosphomannose mutase

36. For enzymes a–e in Problem 35, identify their closest counterparts described in Chapter 15.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Hexokinase Structure and Ligand Binding

Exercise 2 Glycolysis and the KEGG Database

CASE STUDIES www.wiley.com/college/voet

Case 18 Purification of Phosphofructokinase 1-C

Focus concept: The purification of the C isozyme of PFK-1 is presented and the kinetic properties of the purified enzyme are examined.

Prerequisites: Chapters 5, 12, and 15

- Protein purification techniques
- Enzyme kinetics and inhibition
- The glycolytic pathway

Case 20 NAD⁺-Dependent Glyceraldehyde-3-Phosphate Dehydrogenase from *Thermoproteus tenax*

Focus concept: Glycolytic enzymes from *T. tenax* are regulated in an unusual manner.

Prerequisites: Chapters 7, 12, and 15

- The glycolytic pathway
- Enzyme kinetics and inhibition
- The cooperative nature of regulated enzymes

MORE TO EXPLORE Plant cell walls, which contain significant amounts of cellulose, are a source of glucose that can be converted to ethanol by microbial fermentation. Outline the metabolic pathways involved in the conversion of cellulose to ethanol. In order for the production of cellulosic biofuels to become economically viable, what steps of the process must be optimized? Why are genetically engineered organisms part of this effort?

Glycogen particles, which consist of several enormous branched polymers of glucose residues, are stained green in this electron micrograph of salamander liver. In all animals, glycogen is a key form of stored metabolic energy that is built up and broken down according to the needs of the body.

Glycogen (in animals, fungi, and bacteria) and starch (in plants) function to stockpile glucose for later metabolic use. In animals, a constant supply of glucose is essential for tissues such as the brain and red blood cells, which depend almost entirely on glucose as an energy source (other tissues can also oxidize fatty acids or amino acids for energy; Sections 20-2 and 21-4). The mobilization of glucose from glycogen stores, primarily in the liver, provides a constant supply of glucose (~5 mM in blood) to all tissues. When glucose is plentiful, such as immediately after a meal, glycogen synthesis accelerates. Yet the liver's capacity to store glycogen is sufficient to supply the brain with glucose for only about half a day. Under fasting conditions, most of the body's glucose needs are met by **gluconeogenesis** (literally, new glucose synthesis) from noncarbohydrate precursors such as amino acids. Not surprisingly, the regulation of glucose synthesis, storage, mobilization, and catabolism by glycolysis (Section 15-2) or the pentose phosphate pathway (Section 15-6) is elaborate and is sensitive to the immediate and long-term energy needs of the organism.

The importance of glycogen for glucose storage is plainly illustrated by the effects of deficiencies of the enzymes that release stored glucose. **McArdle's disease**, for example, is an inherited condition whose major symptom is painful muscle cramps on exertion. The muscles in afflicted individuals lack the enzyme required for glycogen breakdown to yield glucose. Although glycogen is synthesized normally, it cannot supply fuel for glycolysis to keep up with the demand for ATP.

Figure 16-1 summarizes the metabolic uses of glucose. Glucose-6-phosphate (G6P), a key branch point, is derived from free glucose through the action of hexokinase (Section 15-2A) or is the product of glycogen breakdown or gluconeogenesis. G6P has several possible fates: It can be used to synthesize glycogen; it can be catabolized via glycolysis to yield ATP and carbon atoms (as acetyl-CoA) that are further oxidized by the citric acid cycle; and it can be shunted through the pentose phosphate pathway to generate NADPH and/or ribose-5-phosphate. In the liver and kidney, G6P can be converted to glucose for export to other tissues via the bloodstream.

The opposing processes of glycogen synthesis and degradation, and of glycolysis and gluconeogenesis, are reciprocally regulated; that is, one is largely turned on while the other is largely turned off. In this chapter, we examine the enzymatic steps of glycogen metabolism and gluconeogenesis, paying particular attention to the regulatory mechanisms that ensure efficient operation of opposing metabolic pathways.

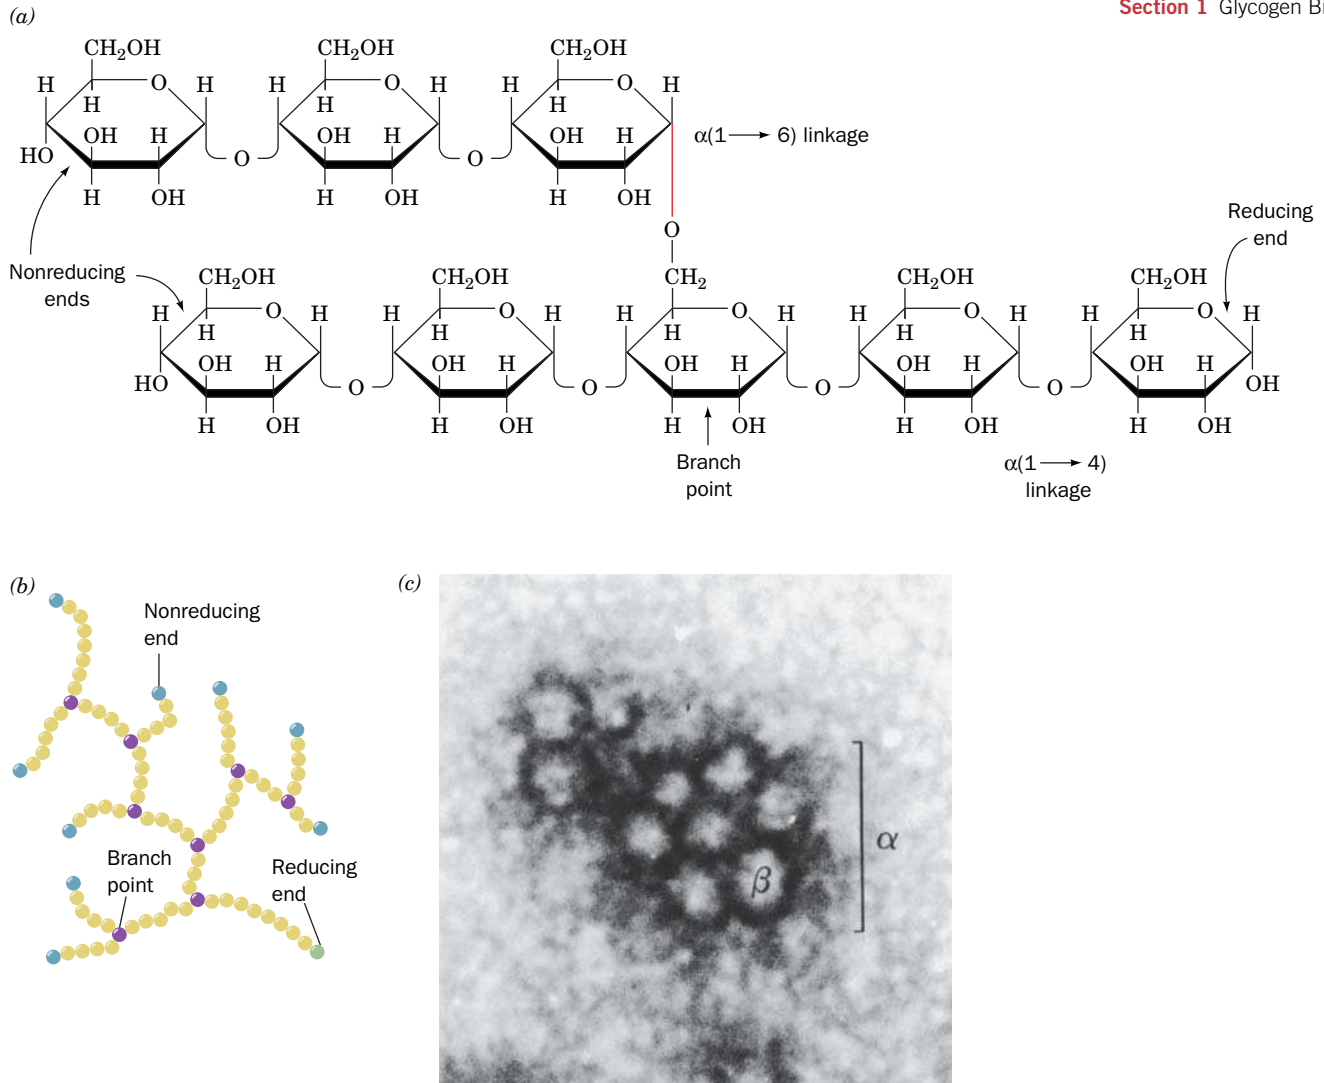

FIG. 16-2 The structure of glycogen. (a) Molecular formula. In the actual molecule, there are ~12 residues per chain. (b) Schematic diagram of glycogen's branched structure. Note that the molecule has many nonreducing ends but only one reducing end. *In vivo*, the reducing end is covalently linked to the protein glycogenin. (c) Electron micrograph of a glycogen granule from rat skeletal muscle. Each granule (labeled α) consists of several spherical glycogen molecules (β) and associated proteins. - 2. Glycogen debranching enzyme** removes glycogen's branches, thereby making additional glucose residues accessible to glycogen phosphorylase.
- 3. Phosphoglucomutase** converts G1P to G6P, which has several metabolic fates (Fig. 16-1).

Several key features of glycogen metabolism were discovered by the team of Carl and Gerty Cori (Box 16-1).

A Glycogen Phosphorylase Degrades Glycogen to Glucose-1-Phosphate

Glycogen phosphorylase is a dimer of identical 842-residue (97-kD) subunits that catalyzes the rate-controlling step in glycogen breakdown. It is regulated both by allosteric interactions and by covalent modification (phosphorylation

Box 16-1 Pathways of Discovery Carl and Gerty Cori and Glucose Metabolism

Carl F. Cori (1896–1984)
Gerty T. Cori (1896–1957)

A lifelong collaboration commenced with the marriage of Carl and Gerty Cori in 1920. Although the Coris began their professional work in Austria, they fled the economic and social hardships of Europe in 1922 and moved to Buffalo, New York. They later made their way to Washington University School of Medicine in St. Louis, where Carl served as chair of the pharmacology department and, later, chair of the biochemistry department. Despite her role as an equal partner in their research work, Gerty officially remained a research associate.

The Coris' research focused primarily on the metabolism of glucose. One of their first discoveries was the connection between glucose metabolism in muscle and glycogen metabolism in the liver. The "Cori cycle"

(Section 22-1F) describes how lactate produced by glycolysis in active muscle is transported to the liver, where it is used to synthesize glucose that is stored as glycogen until needed.

After describing the interorgan movement of glucose in intact animals, the Coris turned their attention to the metabolic fate of glucose, specifically, the intermediates and enzymes of glucose metabolism. In 1936, using a preparation of minced frog muscle, the Coris found glucose in the form of a phosphate ester (called the Cori ester, now known as glucose-1-phosphate). They traced the presence of the Cori ester to the activity of a phosphorylase (glycogen phosphorylase). This was a notable discovery, because the enzyme used phosphate, rather

than water, to split glucose residues from the ends of glycogen chains. Even more remarkably, the enzyme could be made to work in reverse to elongate a glycogen polymer by adding glucose residues (from glucose-1-phosphate). For the first time, a large biological molecule could be synthesized *in vitro*.

During the 1940s, the Coris unraveled many of the secrets of glycogen phosphorylase. For example, they found that the enzyme exists in two forms, one that requires the activator AMP and one that is active in the absence of an allosteric activator. Although it was not immediately appreciated that the differences between the two forms resulted from the presence of covalently bound phosphate, this work laid the foundation for subsequent research on enzyme regulation through phosphorylation and dephosphorylation.

Carl and Gerty Cori also described phosphoglucomutase, the enzyme that converts glucose-1-phosphate to glucose-6-phosphate so that it can participate in other pathways of glucose metabolism. Over time, the Cori lab became a magnet for scientists interested in purifying and characterizing other enzymes of glucose metabolism.

Perhaps because of their experience with discrimination and — especially for Gerty — the lack of equal opportunity, the Cori lab welcomed a more diverse group of scientists than was typical of labs of that era. The Coris received the 1947 Nobel Prize in Physiology or Medicine. Several of their junior colleagues, Arthur Kornberg (see Box 25-1), Severo Ochoa, Luis Leloir, Earl Sutherland, Christian de Duve, and Edwin G. Krebs, later earned Nobel prizes of their own, quite possibly reflecting the work ethic, broad view of science and medicine, and meticulous work habits instilled by Carl and Gerty Cori.

and dephosphorylation). Phosphorylase's allosteric inhibitors (ATP, G6P, and glucose) and its allosteric activator (AMP) interact differently with the phospho and dephosphoenzymes, resulting in an extremely sensitive regulation process. The structure of glycogen phosphorylase as well as its regulation by phosphorylation are discussed in Section 12-3B.

An ~30-Å-long crevice on the surface of the phosphorylase monomer connects the glycogen storage site to the active site (Fig. 12-15). *Since this crevice can accommodate four or five sugar residues in a chain but is too narrow to admit branched oligosaccharides, it provides a clear physical rationale for the inability of phosphorylase to cleave glycosyl residues closer than five units from a branch point.* Presumably, the glycogen storage site increases the catalytic efficiency of phosphorylase by permitting it to phosphorylate many glucose residues on the same glycogen particle without having to dissociate and reassociate completely between catalytic cycles.

Phosphorylase binds the cofactor **pyridoxal-5'-phosphate (PLP; at left)**, which it requires for activity. This prosthetic group, a **vitamin B₆** derivative, is covalently linked to the enzyme via a Schiff base (imine) formed between its aldehyde group and the ε-amino group of Lys 680. PLP also occurs in a variety of enzymes involved in amino acid metabolism, where PLP's conjugated ring system functions catalytically to delocalize electrons (Sections 21-2A and 21-4A). In phosphorylase, however, only the phosphate group participates in catalysis, where it acts as a general acid–base catalyst. Phosphorolysis of glycogen

Pyridoxal-5'-phosphate (PLP)

proceeds by a Random mechanism (Section 12-1D) involving an enzyme $\cdot P_i \cdot$ glycogen ternary complex. An oxonium ion intermediate forms during C1—O1 bond cleavage, similar to the transition state that forms in the reaction catalyzed by lysozyme (Section 11-4B). The phosphorylase reaction mechanism is diagrammed in Fig. 16-3, which shows how PLP's phosphate group functions as a general acid–base catalyst.

PROCESS DIAGRAM

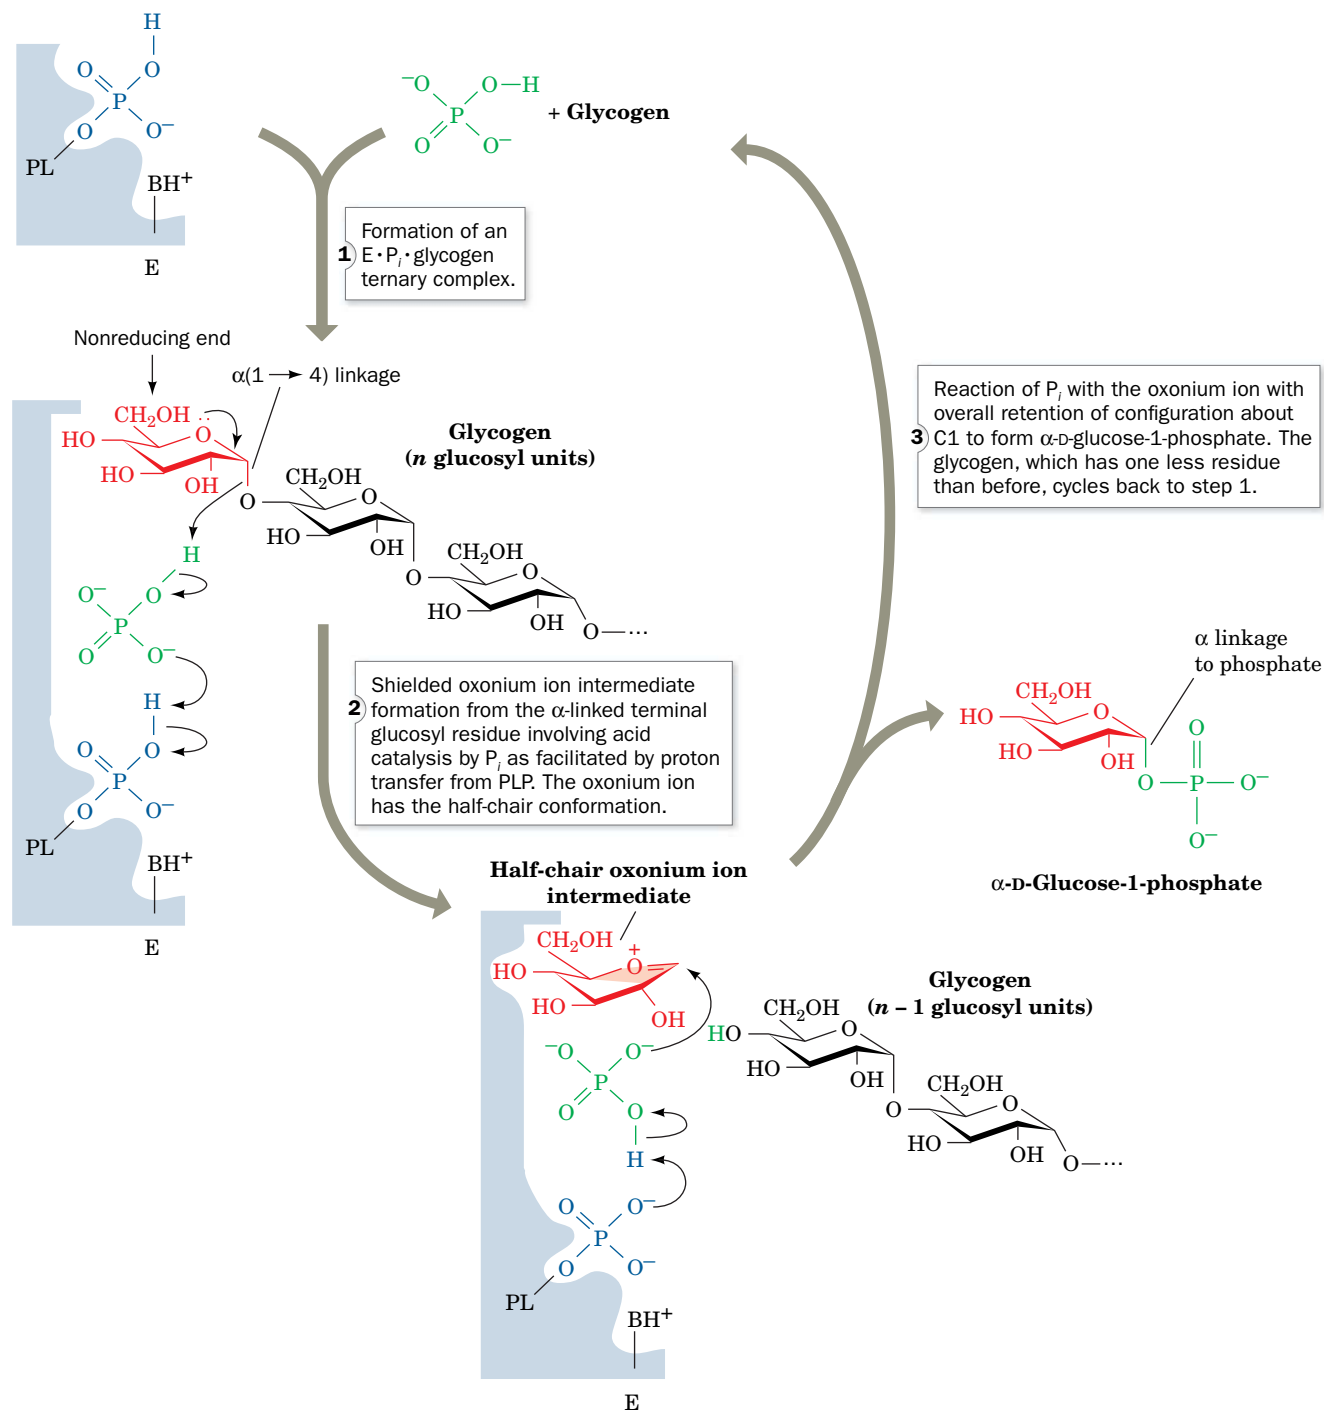

FIG. 16-3 The reaction mechanism of glycogen phosphorylase. PL is an enzyme-bound pyridoxal group; BH⁺ is a positively charged amino acid side chain, probably that of Lys 568, necessary for maintaining PLP electrical neutrality. The reaction occurs via a shielded oxonium ion intermediate and involves acid catalysis by P_i as facilitated by proton transfer from PLP. **WPLS** See the Animated Process Diagrams.

Glycogen Phosphorylase Undergoes Conformational Changes. The structural differences between the active (R) and inactive (T) conformations of phosphorylase (Fig. 12-16) are fairly well understood in terms of the symmetry model of allostereism (Section 7-1D). The T-state enzyme has a buried active site and hence a low affinity for its substrates, whereas the R-state enzyme has an accessible catalytic site and a high-affinity phosphate-binding site.

AMP promotes phosphorylase's T (*inactive*) \rightarrow R (*active*) conformational shift by binding to the R state of the enzyme at its allosteric effector site. This conformational change results in increased access of the substrate to the active site by disordering a loop of residues (282–286) that otherwise block the active site. The conformational change also causes the Arg 569 side chain, which is located in the active site near the PLP and the P_i -binding site, to rotate in a way that increases the enzyme's binding affinity for its anionic P_i substrate (Fig. 12-16).

ATP also binds to the allosteric effector site, but in the T state, so that it inhibits rather than promotes the T \rightarrow R conformational shift. This is because the β - and γ -phosphate groups of ATP prevent the alignment of its ribose and α -phosphate groups that are required for the conformational changes elicited by AMP.

Phosphorylation and dephosphorylation alter enzymatic activity in a manner reminiscent of allosteric regulation. The phosphate group has a double negative charge (a property not shared by naturally occurring amino acid residues) and its covalent attachment to Ser 14 causes dramatic tertiary and quaternary changes as the N-terminal segment moves to allow the phospho-Ser to ion pair with two cationic Arg residues. *The presence of the Ser 14-phosphoryl group causes conformational changes similar to those triggered by AMP binding, thereby shifting the enzyme's T \rightleftharpoons R equilibrium in favor of the R state.* This accounts for the observation that phosphorylase *b* (the unphosphorylated enzyme) requires AMP for activity and that the *a* form (the phosphorylated enzyme) is active without AMP. We return to the regulation of phosphorylase activity when we discuss the mechanisms that balance glycogen synthesis against glycogen degradation (Section 16-3).

B Glycogen Debranching Enzyme Acts as a Glucosyltransferase

Phosphorolysis proceeds along a glycogen branch until it approaches to within four or five residues of an $\alpha(1 \rightarrow 6)$ branch point, leaving a "limit branch." Glycogen debranching enzyme acts as an $\alpha(1 \rightarrow 4)$ **transglycosylase** (glycosyltransferase) by transferring an $\alpha(1 \rightarrow 4)$ -linked trisaccharide unit from a limit branch of glycogen to the nonreducing end of another branch (Fig. 16-4). This reaction forms a new $\alpha(1 \rightarrow 4)$ linkage with three more units available for phosphorylase-catalyzed phosphorolysis. The $\alpha(1 \rightarrow 6)$ bond linking the remaining glycosyl residue in the branch to the main chain is hydrolyzed (not phosphorolyzed) by the same debranching enzyme to yield glucose and debranched glycogen. About 10% of the residues in glycogen (those at the branch points) are therefore converted to glucose rather than G1P. *Debranching enzyme has separate active sites for the transferase and the $\alpha(1 \rightarrow 6)$ -glucosidase reactions.* The presence of two independent catalytic activities on the same enzyme no doubt improves the efficiency of the debranching process.

The maximal rate of the glycogen phosphorylase reaction is much greater than that of the glycogen debranching reaction. Consequently, the outermost branches of glycogen, which constitute nearly half of its residues, are degraded in muscle in a few seconds under conditions of high metabolic demand. Glycogen degradation beyond this point requires debranching and hence occurs more slowly. This, in part, accounts for the fact that a muscle can sustain its maximum exertion for only a few seconds.

FIG. 16-4 The reactions catalyzed by **debranching enzyme**. The enzyme transfers the terminal three $\alpha(1 \rightarrow 4)$ -linked glucose residues from a “limit branch” of glycogen to the non-reducing end of another branch. The $\alpha(1 \rightarrow 6)$ bond of the residue remaining at the branch point is hydrolyzed by further action of debranching enzyme to yield free glucose. The newly elongated branch is subject to degradation by glycogen phosphorylase.

? List the number and type of the monosaccharides produced by the complete degradation of the molecule shown here.

C Phosphoglucomutase Interconverts Glucose-1-Phosphate and Glucose-6-Phosphate

Phosphorylase converts the glucosyl units of glycogen to G1P, which, in turn, is converted by phosphoglucomutase to G6P. The phosphoglucomutase reaction is similar to that catalyzed by phosphoglycerate mutase (Section 15-2H). A phosphoryl group is transferred from the active phosphoenzyme to G1P, forming **glucose-1,6-bisphosphate (G1,6P)**, which then rephosphorylates the enzyme to yield G6P (Fig. 16-5; this near-equilibrium reaction also functions in reverse). An important difference between this enzyme and phosphoglycerate mutase is

PROCESS DIAGRAM

FIG. 16-5 The mechanism of phosphoglucomutase. **WPLS** See the Animated Process Diagrams.

? Explain why this reaction is freely reversible.

Glycogen storage diseases are inherited disorders that affect glycogen metabolism, producing glycogen that is abnormal in either quantity or quality. Studies of the genetic defects that underlie these diseases have helped elucidate the complexities of glycogen metabolism (e.g., McArdle's disease). Conversely, the biochemical characterization of the pathways affected by a genetic disease often leads to useful strategies for its treatment. The table on p. 531 lists the enzyme deficiencies associated with each type of glycogen storage disease.

Glycogen storage diseases that mainly affect the liver generally produce **hepatomegaly** (enlarged liver) and **hypoglycemia** (low blood sugar), whereas glycogen storage diseases that affect the muscles cause muscle cramps and weakness. Both types of disease may also cause cardiovascular and renal disturbances.

Type I: Glucose-6-Phosphatase Deficiency (von Gierke's Disease).

Glucose-6-phosphatase catalyzes the final step leading to the release of glucose into the bloodstream by the liver. Deficiency of the enzyme results in an increase of intracellular [G6P], which leads to a large accumulation of glycogen in the liver and kidney (because G6P activates glycogen synthase) and to an inability to increase blood glucose concentration in response to the hormones glucagon or epinephrine. The symptoms of Type I glycogen storage disease include severe hepatomegaly and hypoglycemia and a general failure to thrive. Treatment of the disease has included drug-induced inhibition of glucose uptake by the liver (to increase blood [glucose]), continuous intragastric feeding overnight (again to increase blood [glucose]), surgical transposition of the portal vein, which ordinarily feeds the liver directly from the intestines (to allow this glucose-rich blood to reach peripheral tissues before it reaches the liver), and liver transplantation.

Type II: α -1,4-Glucosidase Deficiency (Pompe's Disease). α -1,4-Glucosidase deficiency is the most devastating of the glycogen storage diseases. It results in a large accumulation of glycogen of normal structure in the lysosomes of all cells and causes death by cardiorespiratory failure, usually before the age of 1 year. α -1,4-Glucosidase is not involved in the main pathways of glycogen metabolism. It occurs in lysosomes, where it hydrolyzes maltose (a glucose disaccharide) and other linear oligosaccharides, as well as the outer branches of glycogen, thereby yielding free glucose. Normally, this alternative pathway of

glycogen metabolism is not quantitatively important, and its physiological significance is unknown.

Type III: Amylo-1,6-Glucosidase (Debranching Enzyme) Deficiency (Cori's Disease).

In Cori's disease, glycogen of abnormal structure containing very short outer chains accumulates in both liver and muscle since, in the absence of debranching enzyme, the glycogen cannot be further degraded. The resulting hypoglycemia is not as severe as in von Gierke's disease (Type I) and can be treated with frequent feedings and a high-protein diet (to offset the loss of amino acids used for gluconeogenesis). For unknown reasons, the symptoms of Cori's disease often disappear at puberty.

Type IV: Amylo-(1,4 \rightarrow 1,6)-Transglycosylase (Branching Enzyme) Deficiency (Andersen's Disease).

Andersen's disease is one of the most severe glycogen storage diseases; victims rarely survive past the age of 4 years. Liver glycogen is present in normal concentrations, but it contains long unbranched chains that greatly reduce its solubility. The abnormal glycogen leads to tissue swelling and scarring (cirrhosis) and eventually liver failure.

Type V: Muscle Phosphorylase Deficiency (McArdle's Disease).

The symptoms of McArdle's disease, painful muscle cramps on exertion, typically do not appear until early adulthood and can be prevented by avoiding strenuous exercise. This condition affects glycogen metabolism in muscle but not in liver, which contains normal amounts of a different phosphorylase isozyme.

Type VI: Liver Phosphorylase Deficiency (Hers' Disease). Patients with a deficiency of liver glycogen phosphorylase have symptoms similar to those with mild forms of Type I glycogen storage disease. The hypoglycemia in this case results from the inability of liver glycogen phosphorylase to respond to the need for circulating glucose.

Type VII: Muscle Phosphofructokinase Deficiency (Tarui's Disease).

The result of a deficiency of the glycolytic enzyme PFK in muscle is an abnormal buildup of the glycolytic metabolites G6P and F6P. High concentrations of G6P increase the activities of glycogen synthase and UDP-glucose pyrophosphorylase (G6P is in equilibrium with G1P, which is a substrate for UDP-glucose pyrophosphorylase, an enzyme required for glycogen synthesis) so that glycogen accumulates in

that the phosphoryl group in phosphoglucomutase is covalently bound to a Ser hydroxyl group rather than to a His imidazole nitrogen.

Glucose-6-Phosphatase Generates Glucose in the Liver. The G6P produced by glycogen breakdown can continue along the glycolytic pathway or the pentose phosphate pathway (note that the glucose is already phosphorylated, so that the ATP-consuming hexokinase-catalyzed phosphorylation of glucose is bypassed). In the liver, G6P is also made available for use by other tissues. Because G6P cannot exit the cell, it is first hydrolyzed by **glucose-6-phosphatase (G6Pase)**:

muscle. Other symptoms are similar to those of muscle phosphorylase deficiency since PFK deficiency prevents glycolysis from keeping up with the ATP demand in contracting muscle.

Type VIII: X-Linked Phosphorylase Kinase Deficiency. Some individuals with symptoms of Type VI glycogen storage disease have normal phosphorylase enzymes but a defective phosphorylase kinase, which results in their inability to convert phosphorylase *b* to phosphorylase *a*. The α subunit of phosphorylase kinase is encoded by a gene on the X chromosome, so Type VIII disease is X-linked rather than autosomal recessive, as are the other glycogen storage diseases.

Type IX: Phosphorylase Kinase Deficiency. Phosphorylase kinase deficiency, an autosomal recessive disease, results from a mutation

in one of the genes that encode the β , γ , and δ subunits of phosphorylase kinase. Because different tissues contain different phosphorylase kinase isozymes, the symptoms and severity of the disease vary according to the affected organs. Techniques for identifying genetic lesions are therefore more reliable than clinical symptoms for diagnosing a particular glycogen storage disease.

Type 0: Liver Glycogen Synthase Deficiency. Liver glycogen synthase deficiency is the only disease of glycogen metabolism in which there is a deficiency rather than an overabundance of glycogen. The activity of liver glycogen synthase is extremely low in individuals with Type 0 disease, who exhibit hyperglycemia after meals and hypoglycemia at other times. Some individuals, however, are asymptomatic, which suggests that there may be multiple forms of this autosomal recessive disorder.

Hereditary Glycogen Storage Diseases

Type	Enzyme Deficiency	Tissue	Common Name	Glycogen Structure
I	Glucose-6-phosphatase	Liver	von Gierke's disease	Normal
II	α -1,4-Glucosidase	All lysosomes	Pompe's disease	Normal
III	Amylo-1,6-glucosidase (debranching enzyme)	All organs	Cori's disease	Outer chains missing or very short
IV	Amylo-(1,4 \rightarrow 1,6)-transglycosylase (branching enzyme)	Liver, probably all organs	Andersen's disease	Very long unbranched chains
V	Glycogen phosphorylase	Muscle	McArdle's disease	Normal
VI	Glycogen phosphorylase	Liver	Hers' disease	Normal
VII	Phosphofructokinase	Muscle	Tarui's disease	Normal
VIII	Phosphorylase kinase	Liver	X-Linked phosphorylase kinase deficiency	Normal
IX	Phosphorylase kinase	All organs		Normal
0	Glycogen synthase	Liver		Normal, deficient in quantity

Although G6P is produced in the cytosol, G6Pase resides in the endoplasmic reticulum (ER) membrane. Consequently G6P must be imported into the ER by a **G6P translocase** before it can be hydrolyzed. The resulting glucose and P_i are then returned to the cytosol via specific transport proteins. A defect in any of the components of this G6P hydrolysis system results in **type I glycogen storage disease** (Box 16-2). Glucose leaves the liver cell via a specific glucose transporter named **GLUT2** and is carried by the blood to other tissues. Muscle and other tissues lack G6Pase and therefore retain their G6P.

CHECKPOINT

- List the metabolic sources and fates of G6P.
- Describe the structure of a glycogen molecule. What is the advantage of its branched structure?
- List the three enzymes involved in glycogen degradation and describe the type of reactions they catalyze.
- List the activators and inhibitors of glycogen phosphorylase. How does phosphorylation affect its activity?

2 Glycogen Synthesis

KEY CONCEPTS

- Liver glycogen synthesis involves a series of conversions from glucose to glucose-6-phosphate, to UDP-glucose, and finally to glycogen.
- UDP-glucose is an activated molecule.
- Glycogen is extended from a primer built on and by the protein glycogenin.

The $\Delta G^{\circ'}$ for the glycogen phosphorylase reaction is $+3.1 \text{ kJ} \cdot \text{mol}^{-1}$, but under physiological conditions, glycogen breakdown is exergonic ($\Delta G^{\circ'} = -5$ to $-8 \text{ kJ} \cdot \text{mol}^{-1}$). The synthesis of glycogen from G1P under physiological conditions is therefore thermodynamically unfavorable without free energy input. Consequently *glycogen synthesis and breakdown must occur by separate pathways*. This recurrent metabolic strategy—that biosynthetic and degradative pathways of metabolism are different—is particularly important when both pathways must operate under similar physiological conditions. This situation is thermodynamically impossible if one pathway is just the reverse of the other.

It was not thermodynamics, however, that led to recognition of the separation of synthetic and degradative pathways for glycogen, but McArdle's disease. Individuals with the disease lack muscle glycogen phosphorylase activity and therefore cannot break down glycogen. Yet their muscles contain moderately high quantities of normal glycogen. Clearly, glycogen synthesis does not require glycogen phosphorylase. In this section, we describe the three enzymes that participate in glycogen synthesis: **UDP-glucose pyrophosphorylase**, **glycogen synthase**, and **glycogen branching enzyme**. The opposing reactions of glycogen synthesis and degradation are diagrammed in **Fig. 16-6**.

A UDP-Glucose Pyrophosphorylase Activates Glucosyl Units

Since the direct conversion of G1P to glycogen and P_i is thermodynamically unfavorable (positive ΔG) under physiological conditions, glycogen biosynthesis requires an exergonic step. This is accomplished, as Luis Leloir discovered in 1957, by combining G1P with uridine triphosphate (UTP) in a reaction catalyzed by UDP-glucose pyrophosphorylase (**Fig. 16-7**). The product of this reaction, **uridine diphosphate glucose (UDP-glucose or UDPG)**, is an “activated” compound that can donate a glucosyl unit to the growing glycogen chain. The formation of UDPG itself has $\Delta G^{\circ'} \approx 0$ (it is a phosphoanhydride exchange reaction),

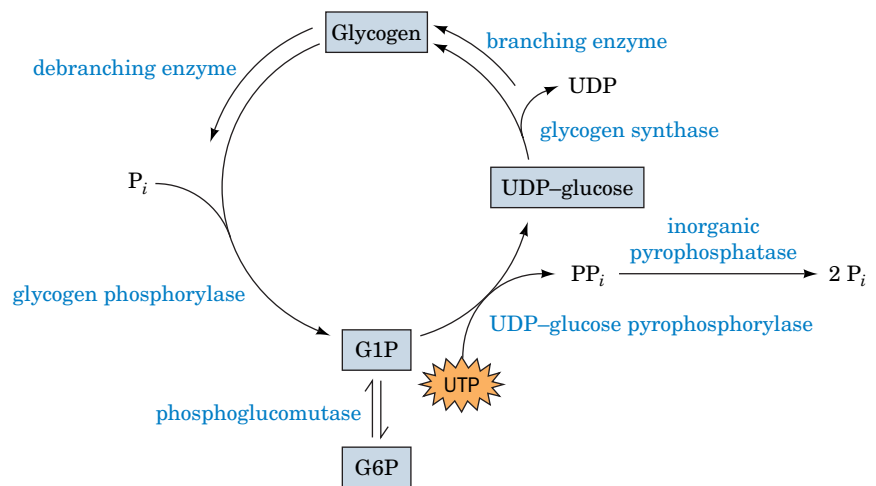

FIG. 16-6 Opposing pathways of glycogen synthesis and degradation. The exergonic process of glycogen breakdown is reversed by a process that uses UTP to generate a UDP-glucose intermediate.

FIG. 16-7 The reaction catalyzed by UDP-glucose pyrophosphorylase. This enzyme, which is named for its reverse reaction, catalyzes a phosphoanhydride exchange reaction. The reaction is driven to completion by PP_i hydrolysis. **WPLS** See the Animated Process Diagrams.

? Identify the “high-energy” bonds that are broken and formed.

but the subsequent exergonic hydrolysis of PP_i by the omnipresent enzyme inorganic pyrophosphatase makes the overall reaction exergonic.

This is an example of the common biosynthetic strategy of cleaving a nucleoside triphosphate to form PP_i . The free energy of PP_i hydrolysis can then be used to drive an otherwise unfavorable reaction to completion (Section 14-2B); the near total elimination of the PP_i by the highly exergonic (irreversible) pyrophosphatase reaction prevents the reverse of the PP_i -producing reaction from occurring.

B Glycogen Synthase Extends Glycogen Chains

In the next step of glycogen synthesis, the glycogen synthase reaction, the glucosyl unit of UDPG is transferred to the C4-OH group on one of glycogen's

nonreducing ends to form an $\alpha(1 \rightarrow 4)$ glycosidic bond. The ΔG° for the glycogen synthase reaction

is $-13.4 \text{ kJ} \cdot \text{mol}^{-1}$, making the overall reaction spontaneous under the same conditions that glycogen breakdown by glycogen phosphorylase is also spontaneous. However, glycogen synthesis does have an energetic price. Combining the first two reactions of glycogen synthesis gives

Thus, *one molecule of UTP is cleaved to UDP for each glucose residue incorporated into glycogen.* The UTP is replenished through a phosphoryl-transfer reaction mediated by nucleoside diphosphate kinase (Section 14-2C):

so that UTP consumption is energetically equivalent to ATP consumption.

The transfer of a glucosyl unit from UDPG to a growing glycogen chain involves the formation of a glucosyl oxonium ion by the elimination of UDP, a good leaving group (Fig. 16-8). The enzyme is inhibited by **1,5-gluconolactone** (*at left*), an analog that mimics the oxonium ion's half-chair geometry. The same analog inhibits both glycogen phosphorylase (Section 16-1A) and lysozyme (Section 11-4), which have similar mechanisms.

Human muscle glycogen synthase is a homotetramer of 737-residue subunits (the liver isozyme has 703-residue subunits). Like glycogen phosphorylase, it has two enzymatically interconvertible forms; in this case, however, the phosphorylated *b* form is less active, and the original (dephosphorylated) *a* form is more active. (Note: For enzymes subject to covalent modification, “*a*” refers to the more active form and “*b*” refers to the less active form.)

Glycogen synthase is under allosteric control; it is strongly inhibited by physiological concentrations of ATP, ADP, and P_i . In fact, the phosphorylated

FIG. 16-8 The reaction catalyzed by glycogen synthase. This reaction involves a glucosyl oxonium ion intermediate.

enzyme is almost totally inactive *in vivo*. The dephosphorylated enzyme, however, can be activated by G6P, so the cell's glycogen synthase activity varies with [G6P] and the fraction of the enzyme in its dephosphorylated form. The mechanistic details of the interconversion of phosphorylated and dephosphorylated forms of glycogen synthase are complex and are not as well understood as those of glycogen phosphorylase (for one thing, glycogen synthase has multiple phosphorylation sites). We discuss the regulation of glycogen synthase further in Section 16-3B.

Glycogenin Primes Glycogen Synthesis. Glycogen synthase cannot simply link together two glucose residues; it can only extend an already existing $\alpha(1 \rightarrow 4)$ -linked glucan chain. How, then, is glycogen synthesis initiated? In the first step of this process, a 349-residue protein named **glycogenin**, acting as a glycosyltransferase, attaches a glucose residue donated by UDPG to the OH group of its Tyr 194. Glycogenin then extends the glucose chain by up to seven additional UDPG-donated glucose residues to form a glycogen “primer.” Only at this point does glycogen synthase commence glycogen synthesis by extending the primer. Analysis of glycogen granules suggests that each glycogen molecule is associated with only one molecule each of glycogenin and glycogen synthase.

C Glycogen Branching Enzyme Transfers Seven-Residue Glycogen Segments

Glycogen synthase generates only $\alpha(1 \rightarrow 4)$ linkages to yield α -amylose. Branching to form glycogen is accomplished by a separate enzyme, **amylo-(1,4 \rightarrow 1,6)-transglycosylase (branching enzyme)**, which is distinct from glycogen debranching enzyme (Section 16-1B). A branch is created by transferring a 7-residue segment from the end of a chain to the C6-OH group of a glucose residue on the same or another glycogen chain (Fig. 16-9). Each transferred

FIG. 16-9 The branching of glycogen.

Branches are formed by transferring a 7-residue terminal segment from an $\alpha(1 \rightarrow 4)$ -linked glucan chain to the C6-OH group of a glucose residue on the same or another chain.

CHECKPOINT

- Why must opposing biosynthetic and degradative pathways differ in at least one enzyme?
- List the three enzymes involved in glycogen synthesis and describe the types of reactions they catalyze.
- What is the free energy source for glycogen synthesis?
- Describe the role of glycogenin.

segment must come from a chain of at least 11 residues, and the new branch point must be at least 4 residues away from other branch points. The branching pattern of glycogen has been optimized by evolution for the efficient storage and mobilization of glucose (Box 16-3).

3 Control of Glycogen Metabolism

KEY CONCEPTS

- The opposing processes of glycogen breakdown and synthesis are reciprocally regulated by allosteric interactions and the covalent modification of key enzymes.
- Glycogen metabolism is ultimately under the control of hormones such as insulin, glucagon, and epinephrine.

If glycogen synthesis and breakdown proceed simultaneously, all that is accomplished is the wasteful hydrolysis of UTP. Glycogen metabolism must therefore be controlled according to cellular needs. *The regulation of glycogen metabolism involves allosteric control as well as hormonal control by covalent modification of the pathway's regulatory enzymes.*

A Glycogen Phosphorylase and Glycogen Synthase Are under Allosteric Control

As we saw in Sections 14-1E and 15-4B, the net flux, J , of reactants through a step in a metabolic pathway is the difference between the forward and reverse reaction velocities, v_f and v_r . However, the flux varies dramatically with substrate concentration as the reaction approaches equilibrium ($v_f \approx v_r$). The flux through a near-equilibrium reaction is therefore all but uncontrollable. *Precise flux control of a pathway is possible when an enzyme functioning far from equilibrium is opposed by a separately controlled enzyme. Then, v_f and v_r vary independently and v_r can be larger or smaller than v_f , allowing control of both rate and direction.* Exactly this situation occurs in glycogen metabolism through the opposition of the glycogen phosphorylase and glycogen synthase reactions.

Both glycogen phosphorylase and glycogen synthase are under allosteric control by effectors that include ATP, G6P, and AMP. Muscle glycogen phosphorylase is activated by AMP and inhibited by ATP and G6P. Glycogen synthase, on the other hand, is activated by G6P. This suggests that when there is high demand for ATP (low [ATP], low [G6P], and high [AMP]), glycogen phosphorylase is stimulated and glycogen synthase is inhibited, which favors glycogen breakdown. Conversely, when [ATP] and [G6P] are high, glycogen synthesis is favored.

In vivo, this allosteric scheme is superimposed on an additional control system based on covalent modification. For example, phosphorylase *a* is active even without AMP stimulation (Section 16-1A), and glycogen synthase is essentially inactive (Section 16-2B) unless it is dephosphorylated and G6P is present. *Thus, covalent modification (phosphorylation and dephosphorylation) of glycogen phosphorylase and glycogen synthase provides a more sophisticated control system that modulates the responsiveness of the enzymes to their allosteric effectors.*

B Glycogen Phosphorylase and Glycogen Synthase Undergo Control by Covalent Modification

The interconversion of the *a* and *b* forms of glycogen synthase and glycogen phosphorylase is accomplished through enzyme-catalyzed phosphorylation and dephosphorylation (Section 12-3B), a process that is under hormonal control (Section 13-2). **Enzymatically interconvertible enzyme systems** can therefore respond to a greater number of effectors than simple allosteric systems.

Box 16-3 Perspectives in Biochemistry Optimizing Glycogen Structure

The function of glycogen in animal cells is to store the metabolic fuel glucose and to release it rapidly when needed. Glucose must be stored as a polymer, because glucose itself could not be stored without a drastic increase in intracellular osmotic pressure (Section 2-1D). It has been estimated that the total concentration of glucose residues stored as glycogen in a liver cell is ~0.4 M, whereas the concentration of glycogen is only ~10 nM. This huge difference mitigates osmotic stress.

To fulfill its biological function, the glycogen polymer must store the largest amount of glucose in the smallest possible volume while maximizing both the amount of glucose available for release by glycogen phosphorylase and the number of nonreducing ends (to maximize the rate at which glucose residues can be mobilized). These criteria must be met by optimizing just two variables: the degree of branching and chain length.

In a glycogen molecule, shown schematically here,

the glycogen chains, beginning with the innermost chain attached to glycogenin (G), each have two branches (the outermost chains are unbranched). The entire molecule is roughly spherical and is organized in tiers. There are an estimated 12 tiers in mature glycogen (only 4 are shown above).

With two branches per chain, the number of chains in a given tier is twice the number of the preceding tier, and the outermost tier contains about half of the total glucose residues (regardless of the number of tiers). When the degree of branching increases, for example, to three branches per chain, the proportion of residues in the outermost tier increases, but so does the density of glucose residues. This severely limits the maximum size of the glycogen particle and the number of glucose residues it can accommodate. Thus, glycogen has around two branches per chain.

Mathematical analysis of the other variable, chain length, yields an optimal value of 13, which is in good agreement with the actual length of glycogen chains in cells (8–14 residues). Consider the two simplified glycogen molecules shown below, which contain the same number of glucose residues (the same total length of line segments) and the same branching pattern:

The molecule with the shorter chains packs more glucose in a given volume and has more points for phosphorylase attack, but only about half the amount of glucose can be released before debranching must occur (debranching is much slower than phosphorolysis). In the less dense molecule, the longer chains increase the number of residues that can be continuously phosphorylated; however, there are fewer points of attack. Thirteen residues is apparently a compromise for mobilizing the largest amount of glucose in the shortest time.

Amylopectin (Section 8-2C), which is chemically similar to glycogen, is a much larger molecule and has longer chains. Amylose lacks branches altogether. Evidently, starch, unlike glycogen, is not designed for rapid mobilization of metabolic fuel.

[Figures adapted from Meléndez-Hevia, E., Waddell, T.G., and Shelton, E.D., *Biochem. J.* **295**, 477–483 (1993).]

Furthermore, a set of kinases and phosphatases linked in cascade fashion has enormous potential for signal amplification and flexibility in response to different metabolic signals. Note that the correlation between phosphorylation and enzyme activity varies with the enzyme. For example, glycogen phosphorylase is activated by phosphorylation ($b \rightarrow a$), whereas glycogen synthase is inactivated by phosphorylation ($a \rightarrow b$). Conversely, dephosphorylation inactivates glycogen phosphorylase and activates glycogen synthase.

Glycogen Phosphorylase Is Activated by Phosphorylation. The cascade that governs the enzymatic interconversion of glycogen phosphorylase involves three enzymes (Fig. 16-10):

1. **Phosphorylase kinase**, which specifically phosphorylates Ser 14 of glycogen phosphorylase *b*.
2. **Protein kinase A (PKA)**; Section 13-3C), which phosphorylates and thereby activates phosphorylase kinase.
3. **Phosphoprotein phosphatase-1 (PP1)**; Section 13-2D), which dephosphorylates and thereby deactivates both glycogen phosphorylase *a* and phosphorylase kinase.

Phosphorylase *b* is sensitive to allosteric effectors, but phosphorylase *a* is much less so, as discussed in Section 12-3B (Fig. 12-17). In the resting cell, the concentrations of ATP and G6P are high enough to inhibit phosphorylase *b*. The level of phosphorylase activity is therefore largely determined by the fraction of enzyme present as phosphorylase *a*. The steady state fraction of phosphorylated enzyme depends on the relative activities of phosphorylase kinase, PKA, and PP1. Recall that PKA is activated by **cAMP**, a second messenger that is made by **adenylate cyclase** on hormone-stimulated activation of a heterotrimeric **G protein** (Section 13-3C). Let us examine the factors that regulate the activities of phosphorylase kinase and PP1 before we return to the regulation of glycogen synthase activity.

Phosphorylase Kinase Is Activated by Phosphorylation and by Ca^{2+} . Phosphorylase kinase is a 1300-kD protein with four nonidentical subunits, known as α , β , γ , and δ . The γ subunit contains the catalytic site, and the other three subunits have regulatory functions. *Phosphorylase kinase is maximally activated by Ca^{2+} and by the phosphorylation of its α and β subunits by PKA.*

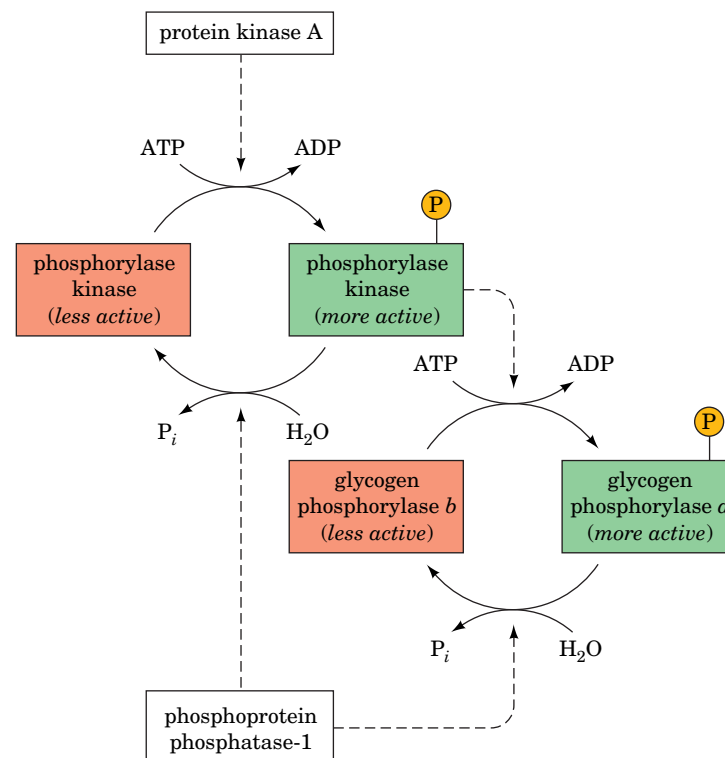

FIG. 16-10 The glycogen phosphorylase interconvertible enzyme system. Conversion of phosphorylase *b* (the less active form) to phosphorylase *a* (the more active form) is accomplished through phosphorylation catalyzed by phosphorylase kinase, which is itself subject to activation through phosphorylation by protein kinase A (PKA). Both glycogen phosphorylase *a* and phosphorylase kinase are dephosphorylated by phosphoprotein phosphatase-1.

FIG. 16-11 X-Ray structure of the γ subunit of rabbit muscle phosphorylase kinase in complex with ATP and a substrate analog. The N-terminal domain is pink, the C-terminal domain is cyan, the activation loop is light blue, and the heptapeptide substrate analog is orange, with its residue to be phosphorylated (Ser) white. The ATP is shown in space-filling form and the side chains of the catalytically essential Arg 148, Asp 149, and Glu 182 are shown in stick form, all colored according to atom type (C green, N blue, O red, and P yellow). [After an X-ray structure by Louise Johnson, Oxford University, U.K. PDBid 2PHK.]

? Compare this structure to the structures of the C subunit of protein kinase A (Fig. 13-21) and the tyrosine kinase domain of the insulin receptor (Fig. 13-5).

The 386-residue γ subunit of phosphorylase kinase is 36% identical in sequence to the PKA C subunit (Fig. 13-21) and has a similar structure (Fig. 16-11). The γ subunit is not subject to phosphorylation, as are many other protein kinases, because the Ser, Thr, or Tyr residue that is phosphorylated to activate those other kinases is replaced by a Glu residue in the γ subunit. The negative charge of the Glu is thought to mimic the presence of a phosphate group and interact with a conserved Arg residue near the active site. However, full catalytic activity of the γ subunit is prevented by an autoinhibitory C-terminal segment, which binds to and blocks the kinase's active site, much like the R subunit blocks the activity of the C subunit of protein kinase A. An inhibitory segment in the β subunit may also block the activity of the γ subunit.

Autoinhibition of phosphorylase kinase is relieved by PKA-catalyzed phosphorylation of both the α and β subunits. This presumably causes the β inhibitor segment to move aside (the way in which phosphorylation of the α subunit modulates the enzyme's behavior is not understood). However, full activity of the γ subunit also requires Ca^{2+} binding to the δ subunit, which is **calmodulin (CaM)**; Section 13-4B; CaM functions both as a free-floating protein and as a subunit of other proteins). Ca^{2+} concentrations as low as 10^{-7} M activate phosphorylase kinase by inducing a conformational change in CaM that causes it to bind to and extract the γ subunit's autoinhibitor segment from its catalytic site (Fig. 13-29).

The conversion of glycogen phosphorylase *b* to glycogen phosphorylase *a* through the action of phosphorylase kinase increases the rate of glycogen breakdown. The physiological significance of the Ca^{2+} trigger for this activation is that muscle contraction is also triggered by a transient increase in the level of cytosolic Ca^{2+} (Section 7-2B). The rate of glycogen breakdown in muscle is thereby linked to the rate of contraction. This is critical because glycogen breakdown provides fuel for glycolysis to generate the ATP required for muscle contraction. Since Ca^{2+} release occurs in response to nerve impulses, whereas the phosphorylation of phosphorylase kinase ultimately occurs in response to the presence of certain hormones, these two signals act synergistically in muscle cells to stimulate glycogenolysis.

Phosphoprotein Phosphatase-1 Is Inhibited by Phosphoprotein Inhibitor-1. A steady state for many phosphorylated enzymes is maintained by a balance between phosphorylation, as catalyzed by a corresponding kinase, and hydrolytic dephosphorylation, as catalyzed by a phosphatase. Phosphoprotein phosphatase-1 (PP1) removes the phosphoryl groups from glycogen phosphorylase *a* and the α and β subunits of phosphorylase kinase (Fig. 16-10), as well as those of other proteins involved in glycogen metabolism (see below).

PP1 is controlled differently in muscle and in liver. In muscle, the catalytic subunit of PP1 (called **PP1c**) is active only when it is bound to glycogen through its glycogen-binding **G_M subunit**. The activity of PP1c and its affinity for the G_M subunit are regulated by phosphorylation of the G_M subunit at two separate

FIG. 16-12 Regulation of phosphoprotein phosphatase-1 in muscle. The antagonistic effects of insulin and epinephrine on glycogen metabolism in muscle occur through their effects on the

phosphoprotein phosphatase-1 catalytic subunit, PP1c, via its glycogen-bound G_M subunit. Green circles and dashed arrows indicate activation.

? Is the effect of insulin consistent with its role as a signal of fuel abundance?

sites (Fig. 16-12). Phosphorylation of site 1 by an **insulin-stimulated protein kinase** (a homolog of PKA and the γ subunit of phosphorylase kinase) activates PP1c, whereas phosphorylation of site 2 by PKA (which can also phosphorylate site 1) causes PP1c to be released into the cytoplasm, where it cannot dephosphorylate the glycogen-bound enzymes of glycogen metabolism.

In the cytosol, phosphoprotein phosphatase-1 is also inhibited by its binding to the protein **phosphoprotein phosphatase inhibitor 1**. The latter protein provides yet another example of control by covalent modification: It too is activated by PKA and deactivated by phosphoprotein phosphatase-1 (Fig. 16-13, lower left). The concentration of cAMP therefore controls the fraction of an enzyme in its phosphorylated form, not only by increasing the rate at which it is phosphorylated, but also by decreasing the rate at which it is dephosphorylated. In the case of glycogen phosphorylase, an increase in [cAMP] not only increases the enzyme's rate of activation, but also decreases its rate of deactivation.

In liver, PP1 is also bound to glycogen, but through the intermediacy of a glycogen-binding subunit named G_L. In contrast to G_M, G_L is not subject to control via phosphorylation. The activity of the PP1 · G_L complex is controlled by its binding to phosphorylase *a*. Both the R and T forms of phosphorylase *a* strongly bind PP1, but only in the T state is the Ser 14 phosphoryl group accessible for hydrolysis (in the R state, the Ser 14 phosphoryl group is buried at the dimer interface; Fig. 12-16). Consequently, when phosphorylase *a* is in its active R form, it effectively sequesters PP1. However, under conditions where phosphorylase *a* shifts to the T state (see below), PP1 hydrolyzes the now exposed Ser 14 phosphoryl group, thereby converting phosphorylase *a* to phosphorylase *b*, which has only a low affinity for the PP1 · G_L complex. One effect of phosphorylase *a* dephosphorylation, therefore, is to relieve the inhibition of PP1. Since liver cells contain 10 times more glycogen phosphorylase than PP1, the phosphatase is not released until more than ~90% of the glycogen phosphorylase is in the *b* form. Only then can PP1 dephosphorylate its other target proteins, including glycogen synthase.

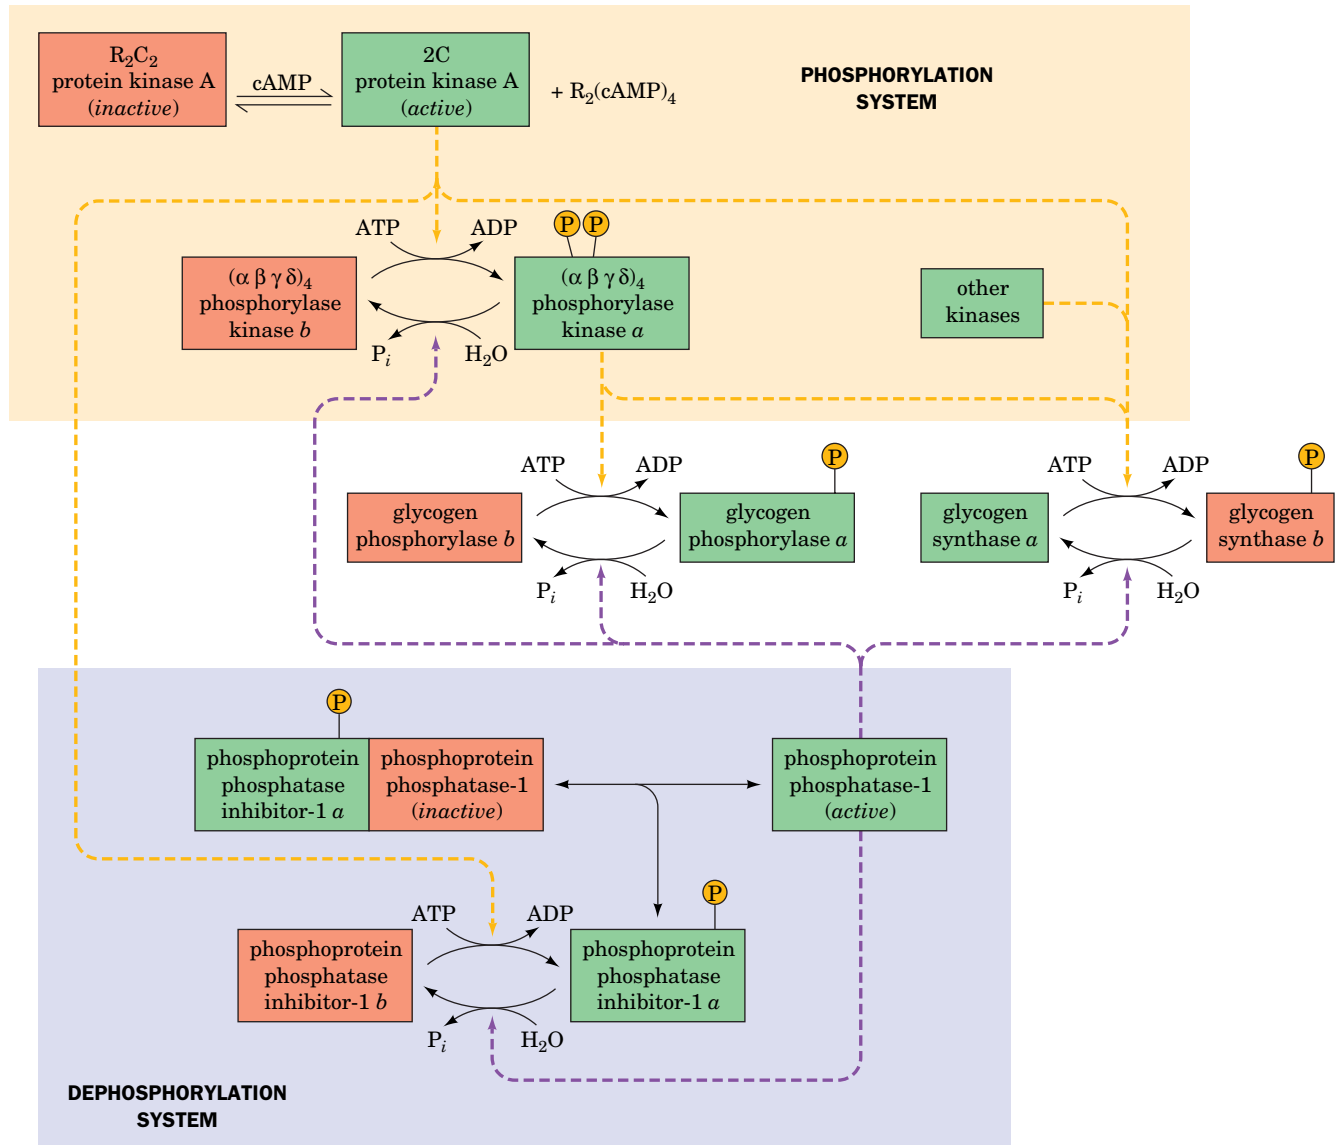

FIG. 16-13 The major phosphorylation and dephosphorylation systems that regulate glycogen metabolism in muscle. Activated enzymes are shaded green, and deactivated enzymes are shaded red.

Dashed arrows indicate facilitation of a phosphorylation or dephosphorylation reaction. **WPLS** See the Animated Figures.

Glucose is an allosteric inhibitor of phosphorylase *a* (Fig. 12-17). Consequently, when the concentration of glucose is high, phosphorylase *a* converts to its T form, thereby leading to its dephosphorylation and the dephosphorylation of glycogen synthase. Glucose is therefore thought to be important in the control of glycogen metabolism in the liver.

Glycogen Synthase Is Elaborately Regulated. Phosphorylase kinase, which activates glycogen phosphorylase, also phosphorylates and thereby inactivates glycogen synthase. Eight other protein kinases, including PKA, phosphorylase kinase, and **glycogen synthase kinase 3 β** (GSK3 β ; Fig. 13-31) are known to at least partially deactivate human muscle glycogen synthase by phosphorylating one or more of the nine Ser residues on each of its subunits (Fig. 16-13). The reason for this elaborate regulation of glycogen synthase is unclear.

The balance between net synthesis and degradation of glycogen as well as the rates of these processes depend on the relative activities of glycogen synthase and glycogen phosphorylase. To a large extent, the rates of the phosphorylation and dephosphorylation of these enzymes control glycogen synthesis and

Epinephrine and norepinephrine, which are often called the “fight or flight” hormones, are released into the bloodstream by the adrenal glands in response to stress. There are two types of receptors for these hormones: the **β -adrenergic receptor**, which is linked to the adenylate cyclase system, and the **α -adrenergic receptor**, whose second messenger causes intracellular $[Ca^{2+}]$ to increase (Section 13-4A). Muscle cells, which have the β -adrenergic receptor (Fig. 16-14), respond to epinephrine by breaking down glycogen for glycolysis, thereby generating ATP and helping the muscles cope with the stress that triggered the epinephrine release.

Liver cells respond to epinephrine directly and indirectly. Epinephrine promotes the release of glucagon from the pancreas, and glucagon binding to its receptor on liver cells stimulates glycogen breakdown as described above. Epinephrine also binds directly to both α - and β -adrenergic receptors on the surfaces of liver cells (Fig. 16-14). Binding to the β -adrenergic receptor results in increased intracellular $[cAMP]$, which leads to glycogen breakdown. Epinephrine binding to the α -adrenergic receptor stimulates an increase in intracellular $[Ca^{2+}]$, which reinforces the cells’ response to $cAMP$ (recall that phosphorylase kinase, which activates glycogen phosphorylase and inactivates glycogen synthase, is fully active only when phosphorylated and in the presence of increased $[Ca^{2+}]$). In addition, glycogen synthase is inactivated through phosphorylation catalyzed by several Ca^{2+} -dependent protein kinases.

Insulin and Epinephrine Are Antagonists. Insulin is released from the pancreas in response to high levels of circulating glucose (e.g., immediately after a meal). Hormonal stimulation by insulin increases the rate of glucose transport into the many types of cells that have both insulin receptors and insulin-sensitive glucose

FIG. 16-14 Hormonal control of glycogen metabolism. Epinephrine binding to β -adrenergic receptors on liver and muscle cells increases intracellular $[cAMP]$, which promotes glycogen degradation to G6P for glycolysis (in muscle) or to glucose for export (in liver). The liver responds similarly to glucagon. Epinephrine binding to α -adrenergic

receptors on liver cells leads to increased cytosolic $[Ca^{2+}]$, which also promotes glycogen degradation. When circulating glucose is plentiful, insulin stimulates glucose uptake and glycogen synthesis in muscle cells. The liver responds both to insulin and directly to increased glucose by increasing glycogen synthesis.

? Explain why a given hormone elicits different responses in different tissues.

CHECKPOINT

- Summarize the effects of AMP and G6P on glycogen phosphorylase and glycogen synthase.
- Summarize the effects of phosphorylation and dephosphorylation on glycogen phosphorylase and glycogen synthase.
- Why does a phosphorylation/dephosphorylation system allow more sensitive regulation of a metabolic process than a simple allosteric system?
- Draw a simple diagram, similar to Fig. 16-13, showing how a kinase and a phosphatase can regulate the activities of two enzymes that catalyze opposing processes.

transporters called **GLUT4** on their surfaces (e.g., muscle and fat cells, but not liver and brain cells). In addition, [cAMP] decreases, causing glycogen metabolism to shift from glycogen breakdown to glycogen synthesis (Fig. 16-14). The mechanism of insulin action is very complex (Sections 13-4D and 22-2), but one of its target enzymes appears to be PP1. As outlined in Fig. 16-12, insulin activates insulin-stimulated protein kinase in muscle to phosphorylate site 1 on the glycogen-binding G_M subunit of PP1 so as to activate this protein and thus dephosphorylate the enzymes of glycogen metabolism. The storage of glucose as glycogen is thereby promoted through the inhibition of glycogen breakdown and the stimulation of glycogen synthesis.

In liver, insulin stimulates glycogen synthesis as a result of the inhibition of glycogen synthase kinase 3β (GSK 3β ; Fig. 13-31). This action decreases the phosphorylation of glycogen synthase, thus increasing its activity. In addition, it is thought that glucose itself may be a messenger to which the glycogen metabolism system responds. *Glucose inhibits phosphorylase a by binding to the enzyme's inactive T state and thereby shifting the $T \rightleftharpoons R$ equilibrium toward the T state* (Fig. 12-17). This conformational shift exposes the Ser 14 phosphoryl group to dephosphorylation. An increase in glucose concentration therefore promotes inactivation of glycogen phosphorylase *a* through its conversion to phosphorylase *b*. The subsequent release of phosphoprotein phosphatase-1 activates glycogen synthase. Thus when glucose is plentiful, the liver stores the excess as glycogen.

4 Gluconeogenesis

KEY CONCEPTS

- The liver and kidney can synthesize glucose from lactate, pyruvate, and amino acids.
- Gluconeogenesis is mostly the reverse of glycolysis with the pyruvate kinase reaction bypassed by the pyruvate carboxylase and phosphoenolpyruvate carboxykinase reactions, and the phosphofructokinase and hexokinase reactions bypassed by phosphatase reactions.
- Glycolysis and gluconeogenesis are reciprocally regulated by allosteric effects, phosphorylation, and changes in enzyme synthesis rates.

When dietary sources of glucose are not available and when the liver has exhausted its supply of glycogen, glucose is synthesized from noncarbohydrate precursors by **gluconeogenesis**. In fact, gluconeogenesis provides a substantial fraction of the glucose produced in fasting humans, even within a few hours of eating. Gluconeogenesis occurs in liver and, to a lesser extent, in kidney.

The noncarbohydrate precursors that can be converted to glucose include the glycolysis products lactate and pyruvate, citric acid cycle intermediates, and the carbon skeletons of most amino acids. First, however, all these substances must be converted to the four-carbon compound **oxaloacetate** (at left), which itself is a citric acid cycle intermediate (Section 17-1). The only amino acids that cannot be converted to oxaloacetate in animals are leucine and lysine because their breakdown yields only acetyl-CoA (Section 21-4E) and because *there is no pathway in animals for the net conversion of acetyl-CoA to oxaloacetate*. Likewise, fatty acids cannot serve as glucose precursors in animals because most fatty acids are degraded completely to acetyl-CoA (Section 20-2). However, fatty acid breakdown generates much of the ATP that powers gluconeogenesis.

For convenience, we consider gluconeogenesis to be the pathway by which pyruvate is converted to glucose. Most of the reactions of gluconeogenesis are glycolytic reactions that proceed in reverse (Fig. 16-15). However, the glycolytic enzymes hexokinase, phosphofructokinase, and pyruvate kinase catalyze reactions with large negative free energy changes. These reactions must therefore be

Oxaloacetate

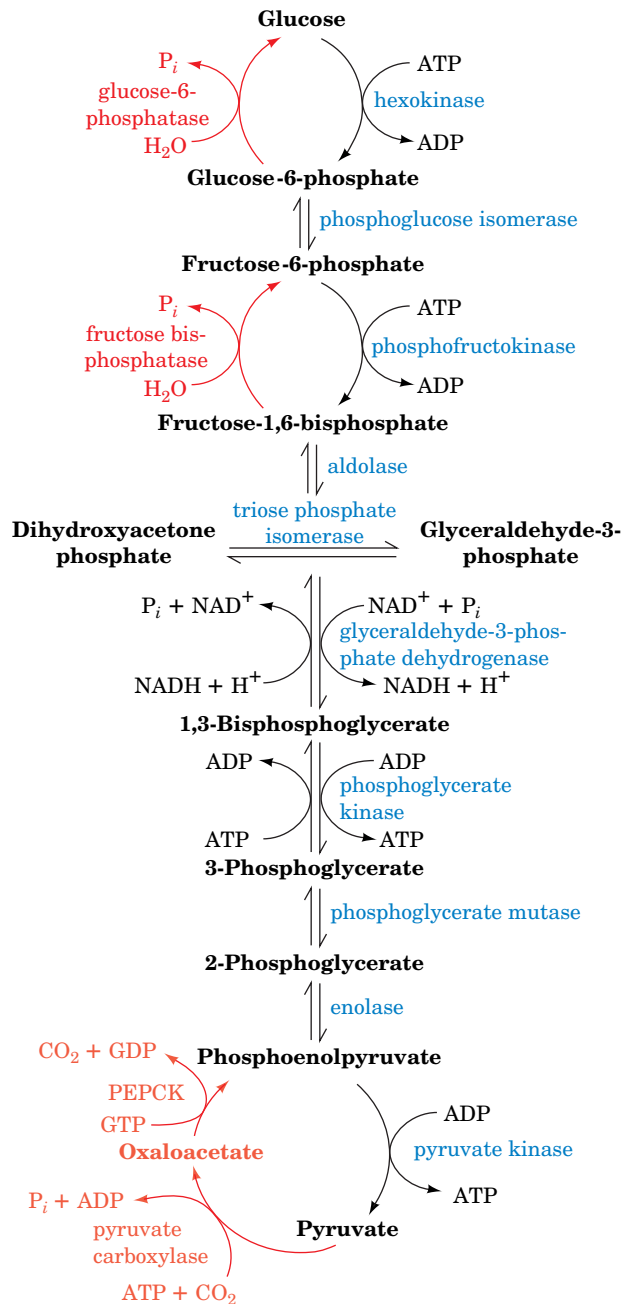

FIG. 16-15 Comparison of the pathways of gluconeogenesis and glycolysis. The red arrows represent the steps that are catalyzed by different enzymes in gluconeogenesis. The other seven reaction steps of gluconeogenesis are catalyzed by glycolytic enzymes that function near equilibrium. **WPLS** See the Animated Figures.

? Identify the irreversible steps of glycolysis and gluconeogenesis.

replaced in gluconeogenesis by reactions that make glucose synthesis thermodynamically favorable.

A Pyruvate Is Converted to Phosphoenolpyruvate in Two Steps

We begin our examination of the reactions unique to gluconeogenesis with the conversion of pyruvate to phosphoenolpyruvate (PEP). Because this step is the reverse of the highly exergonic reaction catalyzed by pyruvate kinase (Section 15-2J), it requires free energy input. This is accomplished by first converting the pyruvate to oxaloacetate. Oxaloacetate is a “high-energy” intermediate because its

FIG. 16-16 The conversion of pyruvate to phosphoenolpyruvate (PEP). This process requires (1) pyruvate carboxylase to convert

pyruvate to oxaloacetate and (2) PEP carboxykinase (PEPCK) to convert oxaloacetate to PEP.

? What is the cost, in ATP equivalents, of adding a one-carbon group to pyruvate and then removing it?

exergonic decarboxylation provides the free energy necessary for PEP synthesis. The process requires two enzymes (**Fig. 16-16**):

1. **Pyruvate carboxylase** catalyzes the ATP-driven formation of oxaloacetate from pyruvate and HCO_3^- .
2. **PEP carboxykinase (PEPCK)** converts oxaloacetate to PEP in a reaction that uses GTP as a phosphoryl-group donor.

Pyruvate Carboxylase Has a Biotin Prosthetic Group. Pyruvate carboxylase is a tetrameric protein of identical ~ 1160 -residue subunits, each of which has a **biotin** prosthetic group. Biotin (**Fig. 16-17a**) functions as a CO_2 carrier by forming a carboxyl substituent at its **ureido group** (**Fig. 16-17b**). Biotin is covalently bound to an enzyme Lys residue to form a **biocytin** (alternatively, **biotinyllysine**) residue (**Fig. 16-17b**). The biotin ring system is therefore at the end of a 14-Å-long flexible arm. Biotin, which was first identified in 1935 as a growth factor in yeast, is an essential human nutrient. Its nutritional deficiency is rare, however, because it occurs in many foods and is synthesized by intestinal bacteria.

The pyruvate carboxylase reaction occurs in two phases (**Fig. 16-18**):

Phase I The cleavage of ATP to ADP acts to dehydrate bicarbonate via the formation of a “high-energy” carboxyphosphate intermediate. The reaction of the resulting CO_2 with biotin is exergonic. The biotin-bound carboxyl group is therefore “activated” relative to bicarbonate and can be transferred to another molecule without further free energy input.

Phase II The activated carboxyl group is transferred from carboxybiotin to pyruvate in a three-step reaction to form oxaloacetate.

These two reaction phases occur on different subsites of the same enzyme; the 14-Å arm of biocytin transfers the biotin ring between the two sites.

Oxaloacetate is both a precursor for gluconeogenesis and an intermediate of the citric acid cycle (Section 17-3). When the citric acid cycle substrate acetyl-CoA accumulates, it allosterically activates pyruvate carboxylase, thereby

FIG. 16-17 Biotin and carboxybiotinyl-enzyme. (a) Biotin consists of an imidazolidine ring that is cis-fused to a tetrahydrothiophene ring bearing a valerate side chain. Positions 1, 2, and 3 constitute a ureido group. (b) Biotin is covalently attached to carboxylases by an amide

linkage between its valeryl carboxyl group and an ϵ -amino group of an enzyme Lys side chain. The carboxybiotinyl-enzyme forms when N1 of the biotin ureido group is carboxylated.

increasing the amount of oxaloacetate that can participate in the citric acid cycle. When citric acid cycle activity is low, oxaloacetate instead enters the gluconeogenic pathway.

PEP Carboxykinase Catalyzes the Formation of PEP. PEPCK, a monomeric ~610-residue enzyme, catalyzes the GTP-requiring decarboxylation/phosphorylation of oxaloacetate to form PEP and GDP (Fig. 16-19). Note that the CO₂ that carboxylates pyruvate to yield oxaloacetate is eliminated in the formation of PEP.

FIG. 16-19 The PEPCK mechanism. Decarboxylation of oxaloacetate (a β-keto acid) forms a resonance-stabilized enolate anion whose oxygen atom attacks the γ-phosphoryl group of GTP, forming PEP and GDP.

The favorable decarboxylation reaction drives the formation of the enol that GTP phosphorylates. *Oxaloacetate can therefore be considered as “activated” pyruvate, with CO₂ and biotin facilitating the activation at the expense of ATP.*

Gluconeogenesis Requires Metabolite Transport between Mitochondria and Cytosol. The generation of oxaloacetate from pyruvate or citric acid cycle intermediates occurs only in the mitochondrion, whereas the enzymes that convert PEP to glucose are cytosolic. The cellular location of PEPCK varies: In some species, it is mitochondrial; in some, it is cytosolic; and in some (including humans) it is equally distributed between the two compartments. In order for gluconeogenesis to occur, either oxaloacetate must leave the mitochondrion for conversion to PEP or the PEP formed there must enter the cytosol.

PEP is transported across the mitochondrial membrane by specific membrane transport proteins. There is, however, no such transport system for oxaloacetate. *In species with cytosolic PEPCK, oxaloacetate must first be converted either to aspartate (Fig. 16-20, Route 1) or to malate (Fig. 16-20, Route 2), for which mitochondrial transport systems exist.* The difference between the two routes involves the transport of NADH **reducing equivalents** (in the transport of reducing equivalents, the electrons—but not the electron carrier—cross the membrane). The **malate dehydrogenase** route (Route 2) results in the transport of reducing equivalents from the mitochondrion to the cytosol, since it uses mitochondrial NADH and produces cytosolic NADH. The **aspartate aminotransferase** route (Route 1) does not involve NADH. Cytosolic NADH is required for gluconeogenesis, so, under most conditions, the route through malate is a necessity. However, when the gluconeogenic precursor is lactate, its oxidation to pyruvate generates cytosolic NADH, and either transport system can then be used. All the reactions shown in Fig. 16-20 are freely reversible, so

FIG. 16-20 The transport of PEP and oxaloacetate from the mitochondrion to the cytosol. PEP is directly transported between the compartments. Oxaloacetate, however, must first be converted either to aspartate through the action of aspartate aminotransferase (Route 1) or to malate by malate dehydrogenase (Route 2). Route 2 involves the mitochondrial oxidation of NADH followed by the cytosolic reduction of NAD⁺ and therefore also transfers NADH reducing equivalents from the mitochondrion to the cytosol. **WPLS** See the Animated Figures.

? Explain why malate and aspartate are both considered to be gluconeogenic precursors.

that under appropriate conditions, the malate–aspartate shuttle system also operates to transport NADH reducing equivalents into the mitochondrion for oxidative phosphorylation (Section 18-1B). Liver has a variation of Route 1 in which aspartate entering the cytosol is deaminated via the urea cycle before undergoing a series of reactions that yield oxaloacetate (Section 21-3A).

B Hydrolytic Reactions Bypass Irreversible Glycolytic Reactions

The route from PEP to fructose-1,6-bisphosphate (FBP) is catalyzed by the enzymes of glycolysis operating in reverse. However, *the glycolytic reactions catalyzed by phosphofructokinase (PFK) and hexokinase are endergonic in the gluconeogenesis direction and hence must be bypassed by different gluconeogenic enzymes*. FBP is hydrolyzed by **fructose-1,6-bisphosphatase (FBPase)**. The resulting fructose-6-phosphate (F6P) is isomerized to G6P, which is then hydrolyzed by glucose-6-phosphatase, the same enzyme that converts glycogen-derived G6P to glucose (Section 16-1C) and which is present only in liver and kidney. Note that these two hydrolytic reactions release P_i rather than reversing the $ATP \rightarrow ADP$ reactions that occur at this point in the glycolytic pathway.

The net energetic cost of converting two pyruvate molecules to one glucose molecule by gluconeogenesis is six ATP equivalents: two each at the steps catalyzed by pyruvate carboxylase, PEPCK, and phosphoglycerate kinase (Fig. 16-15). Since the energetic profit of converting one glucose molecule to two pyruvate molecules via glycolysis is two ATP (Section 15-1), the energetic cost of the futile cycle in which glucose is converted to pyruvate and then resynthesized is four ATP equivalents. Such free energy losses are the thermodynamic price that must be paid to maintain the independent regulation of two opposing pathways.

Although glucose is considered the endpoint of the gluconeogenic pathway, it is possible for pathway intermediates to be directed elsewhere—for example, through the transketolase and transaldolase reactions of the pentose phosphate pathway (Section 15-6C) to produce ribose-5-phosphate. The G6P produced by gluconeogenesis may not be hydrolyzed to glucose but may instead be converted to G1P for incorporation into glycogen.

C Gluconeogenesis and Glycolysis Are Independently Regulated

The opposing pathways of gluconeogenesis and glycolysis, like glycogen synthesis and degradation, do not proceed simultaneously *in vivo*. Instead, the pathways are reciprocally regulated to meet the needs of the organism. There are three substrate cycles and therefore three potential points for regulating glycolytic versus gluconeogenic flux (Fig. 16-21).

Fructose-2,6-Bisphosphate Activates Phosphofructokinase and Inhibits Fructose-1,6-Bisphosphatase. The net flux through the substrate cycle created by the opposing actions of PFK and FBPase (described in Section 15-4B) is determined by the concentration of fructose-2,6-bisphosphate (F2,6P).

β -D-Fructose-2,6-bisphosphate (F2,6P)

F2,6P, which is not a glycolytic intermediate, is an extremely potent allosteric activator of PFK and an inhibitor of FBPase.

The concentration of F2,6P in the cell depends on the balance between its rates of synthesis and degradation by **phosphofructokinase-2 (PFK-2)** and

GATEWAY CONCEPT How Cells Use ATP

When ATP (or another nucleoside triphosphate) is required to drive an endergonic process, it is not just a spectator; it must take part in the reaction. The participation of ATP involves the net hydrolysis of one or more of its phosphoanhydride bonds. If this reaction occurred in isolation, the free energy of the hydrolysis reaction would be lost as heat. But in cells, the exergonic bond-cleavage reaction is linked to the endergonic reaction in most cases through the transfer of a phosphate group from the nucleotide to another substance. As we have seen before, the ATP reaction is the price the cell pays to make an otherwise unfavorable reaction proceed.

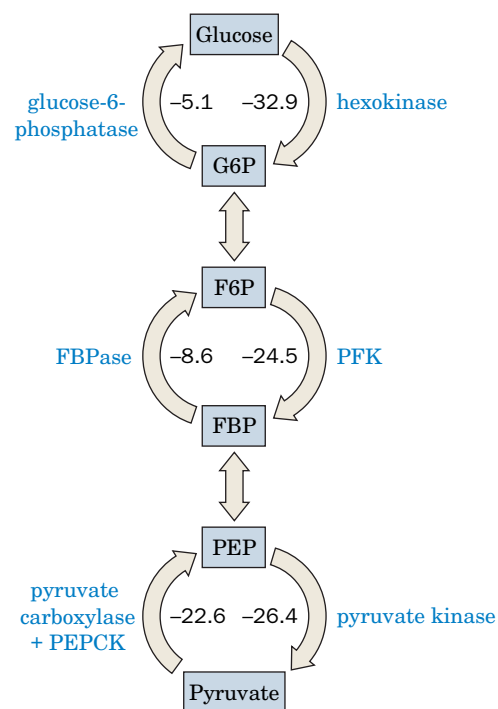

FIG. 16-21 Substrate cycles in glucose metabolism. The interconversions of glucose and G6P, F6P and FBP, and PEP and pyruvate are catalyzed by different enzymes in the forward and reverse directions so that all reactions are exergonic (the ΔG values for the reactions in liver are given in $\text{kJ} \cdot \text{mol}^{-1}$). [ΔG 's obtained from Newsholme, E.A. and Leech, A.R., *Biochemistry for the Medical Sciences*, p. 448, Wiley (1983).]

? Write a net equation for each of the three substrate cycles.

FIG. 16-22 The formation and degradation of β -D-fructose-2,6-bisphosphate (F2,6P). The enzymatic activities of phosphofructokinase-2 (PFK-2) and fructose bisphosphatase-2

(FBPase-2) occur on different domains of the same protein molecule. The phosphorylation of the liver enzyme inactivates PFK-2 while activating FBPase-2.

fructose bisphosphatase-2 (FBPase-2), respectively (Fig. 16-22). These enzyme activities are located on different domains of the same ~100-kD homodimeric protein (Fig. 16-23). The bifunctional enzyme is regulated by a variety of allosteric effectors and by phosphorylation and dephosphorylation as catalyzed by PKA and a phosphoprotein phosphatase. Thus, the balance between gluconeogenesis and glycolysis is under hormonal control.

For example, when [glucose] is low, glucagon stimulates the production of cAMP in liver cells. This activates PKA to phosphorylate the bifunctional enzyme at a specific Ser residue, which inactivates the enzyme's PFK-2 activity and activates its FBPase-2 activity. The net result is a decrease in [F2,6P], which shifts the balance between the PFK and FBPase reactions in favor of FBP hydrolysis and hence increases gluconeogenic flux (Fig. 16-24). The concurrent increases in gluconeogenesis and glycogen breakdown allow the liver to release glucose into the circulation. Conversely, when the blood [glucose] is high, cAMP levels decrease, and the resulting increase in [F2,6P] promotes glycolysis.

In muscle, which is not a gluconeogenic tissue, the F2,6P control system functions quite differently from that in liver due to the presence of different

FIG. 16-23 X-Ray structure of rat testis PFK-2/FBPase-2. The N-terminal PFK-2 domain is blue and the C-terminal FBPase-2 domain is yellow-green. The bound Mg^{2+} -AMPPNP, succinate, F6P, and P_i are shown in space-filling form colored according to atom type (AMPPNP C green, succinate C magenta, F6P C cyan, N blue, O red, Mg^{2+} light green, and P orange). The P_i , which occupies the binding site of the F2,6P's 2-phosphate group, is opposite the His 256 site (magenta) to which it would be transferred in the catalytic reaction. The succinate occupies the presumed F6P binding pocket of the PFK-2 domain. [Based on an X-ray structure by Kosaku Uyeda and Charles Hasemann, University of Texas Southwestern Medical Center. PDBid 2BIF.]

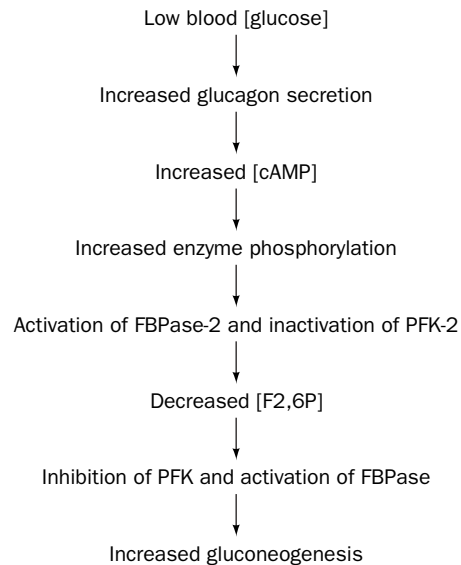

FIG. 16-24 Sequence of metabolic events linking low blood [glucose] to gluconeogenesis in liver.

? Compare this pathway to the effect of glucagon on liver glycogen metabolism (see Fig. 16-14). What is the outcome of each pathway?

PFK-2/FBPase-2 isozymes. For example, hormones that stimulate glycogen breakdown in heart muscle lead to phosphorylation of a site on the bifunctional enzyme that activates rather than inhibits PFK-2. The resulting increase in F2,6P stimulates glycolysis so that glycogen breakdown and glycolysis are coordinated. The skeletal muscle isozyme lacks a phosphorylation site altogether and is therefore not subject to cAMP-dependent control. Rather, the ratio of its PFK-2-to-FBPase-2 activity is allosterically increased by high [F6P], which is indicative of the need for an increased rate of glycolysis.

Other Allosteric Effectors Influence Gluconeogenic Flux. Acetyl-CoA activates pyruvate carboxylase (Section 16-4A), but there are no known allosteric effectors of PEPCK, which, together with pyruvate carboxylase, reverses the pyruvate kinase reaction. Pyruvate kinase, however, is allosterically inhibited in the liver by alanine, a major gluconeogenic precursor. Alanine is converted to pyruvate by the transfer of its amino group to an α -keto acid to yield a new amino acid and the α -keto acid pyruvate,

a process termed **transamination** (which is discussed in Section 21-2A). Liver pyruvate kinase is also inactivated by phosphorylation, further increasing gluconeogenic flux. Since phosphorylation also activates glycogen phosphorylase, the pathways of gluconeogenesis and glycogen breakdown both flow toward G6P, which is converted to glucose for export from the liver.

The activity of hexokinase (or glucokinase, the liver isozyme) is also controlled, as we will see in Section 22-1D. The activity of glucose-6-phosphatase is controlled as well but the process is complex and poorly understood.

The regulation of glucose metabolism occurs not only through allosteric effectors, but also through long-term changes in the amounts of enzymes synthesized. Pancreatic and adrenal hormones influence the rates of transcription and the stabilities of the mRNAs encoding many of the regulatory proteins of glucose metabolism. For example, insulin inhibits transcription of the gene for PEPCK, whereas high concentrations of intracellular cAMP promote the transcription of the genes for PEPCK, FBPase, and glucose-6-phosphatase, and repress transcription of the genes for glucokinase, PFK, and the PFK-2/FBPase-2 bifunctional enzyme.

CHECKPOINT

- What are the substrates for gluconeogenesis? What role do fatty acids play in gluconeogenesis?
- Describe the reactions of gluconeogenesis. Which reactions are not shared with glycolysis?
- Why is the malate–aspartate shuttle system important for gluconeogenesis?
- What is the net energy cost for synthesizing a molecule of glucose from two molecules of pyruvate?
- What are the potential control points for gluconeogenesis?
- Describe the role of fructose-2,6-bisphosphate in regulating gluconeogenesis and glycolysis.

5 Other Carbohydrate Biosynthetic Pathways

KEY CONCEPTS

- The formation of glycosidic bonds in carbohydrates requires the energy of activated nucleotide sugars.
- O-Linked oligosaccharides are synthesized by the sequential addition of sugars to a protein.
- N-Linked oligosaccharides are first assembled on a dolichol carrier.

The liver, by virtue of its mass and its metabolic machinery, is primarily responsible for maintaining a constant level of glucose in the circulation. Glucose produced by gluconeogenesis or from glycogen breakdown is released from the liver for use by other tissues as an energy source. Of course, glucose has other uses in the liver and elsewhere, for example, in the synthesis of lactose (Box 16-4).

Like sucrose in plants, lactose is a disaccharide that is synthesized for later use as a metabolic fuel, in this case, after digestion by very young mammals. Lactose, or milk sugar, is produced in the mammary gland by **lactose synthase**. In this reaction, the donor sugar is UDP-galactose, which is formed by the epimerization of UDP-glucose (Fig. 15-28). The acceptor sugar is glucose:

Thus, both saccharide units of lactose are ultimately derived from glucose.

Lactose synthase consists of two subunits:

1. **Galactosyltransferase**, the catalytic subunit, occurs in many tissues, where it catalyzes the reaction of UDP-galactose and *N*-acetylglucosamine to yield ***N*-acetylactosamine**, a constituent of many complex oligosaccharides.

2. **α -Lactalbumin**, a mammary gland protein with no catalytic activity, alters the specificity of galactosyltransferase so that it uses glucose as an acceptor, rather than *N*-acetylglucosamine, to form lactose instead of *N*-acetylactosamine.
