Synthesis of α -lactalbumin, whose sequence is ~37% identical to that of lysozyme (which also participates in reactions involving sugars), is triggered by hormonal changes at parturition (birth), thereby promoting lactose synthesis for milk production.

Nucleotide Sugars Power the Formation of Glycosidic Bonds. Glucose and other monosaccharides (principally mannose, *N*-acetylglucosamine, fucose, galactose, *N*-acetylneuraminic acid, and *N*-acetylgalactosamine) occur in glycoproteins and glycolipids. Formation of the glycosidic bonds that link sugars to each other and to other molecules requires free energy input under physiological conditions ($\Delta G^{\circ} = 16 \text{ kJ} \cdot \text{mol}^{-1}$). This free energy, as we have seen in glycogen synthesis (Section 16-2A), is acquired through the synthesis of a **nucleotide sugar** from a nucleoside triphosphate and a monosaccharide, thereby releasing PP_i , whose exergonic hydrolysis drives the reaction. The nucleoside diphosphate at the sugar's anomeric carbon atom is a good leaving group and thereby facilitates formation of a glycosidic bond to a second sugar in a reaction catalyzed by a glycosyltransferase (Fig. 16-25). In mammals, most glycosyl groups are donated by UDP-sugars, but fucose and mannose are carried by GDP, and sialic acid by CMP. In plants, starch is built from glucose units donated by **ADP-glucose**, and cellulose synthesis relies on ADP-glucose or **CDP-glucose**.

FIG. 16-25 Role of nucleotide sugars. These compounds are the glycosyl donors in oligosaccharide biosynthetic reactions as catalyzed by glycosyltransferases.

? What is the energetic cost of synthesizing the nucleotide sugar?

O-Linked Oligosaccharides Are Posttranslationally Formed. Nucleotide sugars are the donors in the synthesis of *O*-linked oligosaccharides and in the processing of the *N*-linked oligosaccharides of glycoproteins (Section 8-3C). *O*-Linked oligosaccharides are synthesized in the Golgi apparatus by the serial addition of monosaccharide units to a completed polypeptide chain (Fig. 16-26). Synthesis begins with the transfer, as catalyzed by **GalNAc transferase**, of *N*-acetylgalactosamine (GalNAc) from UDP–GalNAc to a Ser or Thr residue on the polypeptide. The location of the glycosylation site is thought to be specified only by the secondary or tertiary structure of the polypeptide. Glycosylation continues with the stepwise addition of sugars such as galactose, sialic acid, *N*-acetylglucosamine, and fucose. In each case, the sugar residue is transferred from its nucleotide sugar derivative by a corresponding glycosyltransferase.

N-Linked Oligosaccharides Are Constructed on Dolichol Carriers. The synthesis of *N*-linked oligosaccharides is more complicated than that of *O*-linked oligosaccharides. In the early stages of *N*-linked oligosaccharide synthesis, sugar residues are sequentially added to a lipid carrier, **dolichol pyrophosphate** (Fig. 16-27). **Dolichol** is a long-chain polyisoprenol containing 17 to 21 isoprene units in animals and 14 to 24 units in fungi and plants. It anchors the growing oligosaccharide to the endoplasmic reticulum membrane, where the initial glycosylation reactions take place.

Although nucleotide sugars are the most common monosaccharide donors in glycosyltransferase reactions, several mannosyl and glucosyl residues are transferred to growing dolichol-PP-oligosaccharides from their corresponding dolichol-P derivatives. Dolichol phosphate “activates” a sugar residue for subsequent transfer, as does a nucleoside diphosphate.

The construction of an *N*-linked oligosaccharide begins, as is described in Section 8-3C, by the synthesis of an oligosaccharide with the composition (*N*-acetylglucosamine)₂(mannose)₉(glucose)₃. This occurs on a dolichol carrier in a 12-step process catalyzed by a series of specific glycosyltransferases (Fig. 16-28). Note that some of these reactions take place on the luminal surface of the endoplasmic reticulum, whereas others occur on its cytoplasmic surface. Hence, on four occasions (Reactions 3, 5, 8, and 11 in Fig. 16-28), dolichol and its attached hydrophilic group are translocated, via unknown mechanisms, across the endoplasmic reticulum membrane. In the final steps of the process, the oligosaccharide is transferred to the Asn residue in a segment of sequence Asn-X-Ser/Thr (where X is any residue except Pro and only rarely Asp, Glu, Leu, or Trp) on a growing polypeptide chain. The resulting dolichol pyrophosphate is hydrolyzed to dolichol phosphate and P_i, a process similar to the pyrophosphatase cleavage of PP_i to 2 P_i. Further processing of the oligosaccharide takes place, as described in Section 8-3C, first in the endoplasmic reticulum and then in the Golgi apparatus (Fig. 8-19), where certain monosaccharide residues are trimmed away by specific glycosylases and others are added by specific nucleotide sugar–requiring glycosyltransferases.

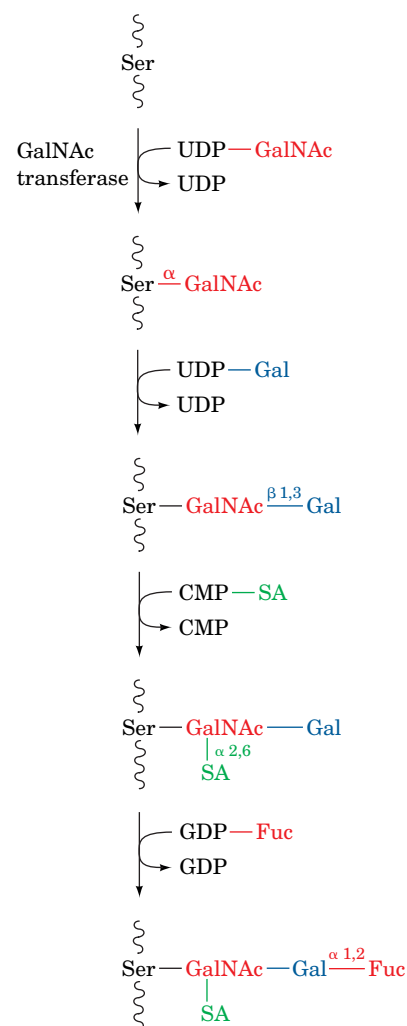

FIG. 16-26 Synthesis of an *O*-linked oligosaccharide chain. This pathway shows the proposed steps in the assembly of a carbohydrate moiety in canine submaxillary mucin. SA is sialic acid.

FIG. 16-27 Dolichol pyrophosphate glycoside. The carbohydrate precursors of *N*-linked glycosides are synthesized as oligosaccharides attached to dolichol, a long-chain polyisoprenol ($n = 14$ –24) in which the α -isoprene unit is saturated.

FIG. 16-28 The pathway of dolichol-PP-oligosaccharide synthesis. (1) Addition of *N*-acetylglucosamine-1-P and a second *N*-acetylglucosamine to dolichol-P. (2) Addition of five mannosyl residues from GDP-mannose in reactions catalyzed by five different mannosyltransferases. (3) Membrane translocation of dolichol-PP-(*N*-acetylglucosamine)₂(mannose)₅ to the lumen of the endoplasmic reticulum (ER). (4) Cytosolic synthesis of dolichol-P-mannose from GDP-mannose and dolichol-P. (5) Membrane translocation of dolichol-P-mannose to the lumen of the ER. (6) Addition of four mannosyl residues from dolichol-P-mannose in reactions catalyzed by four different

mannosyltransferases. (7) Cytosolic synthesis of dolichol-P-glucose from UDPG and dolichol-P. (8) Membrane translocation of dolichol-P-glucose to the lumen of the ER. (9) Addition of three glucosyl residues from dolichol-P-glucose. (10) Transfer of the oligosaccharide from dolichol-PP to the polypeptide chain at an Asn residue in the sequence Asn-X-Ser/Thr, releasing dolichol-PP. (11) Translocation of dolichol-PP to the cytoplasmic surface of the ER membrane. (12) Hydrolysis of dolichol-PP to dolichol-P. (13) Dolichol-P can also be formed by phosphorylation of dolichol by CTP. [Modified from Abeijon, C. and Hirschberg, C.B., *Trends Biochem. Sci.* 17, 34 (1992).] **WPLS** See the Animated Process Diagrams.

? Identify the reactions that are catalyzed by a translocase and those catalyzed by a transferase.

FIG. 16-29 The chemical structure of bacitracin. Note that this dodecapeptide has four *D*-amino acid residues and two unusual intrachain linkages. "Orn" represents the nonstandard amino acid ornithine (Fig. 21-9).

Bacitracin Interferes with the Dephosphorylation of Dolichol Pyrophosphate. A number of compounds block the actions of specific glycosylation enzymes, including **bacitracin** (Fig. 16-29), a cyclic polypeptide that is a widely used antibiotic. Bacitracin forms a complex with dolichol pyrophosphate that inhibits its dephosphorylation (Fig. 16-28, Reaction 12), thereby preventing the synthesis of glycoproteins from dolichol-linked oligosaccharide precursors. Bacitracin is clinically useful because it inhibits bacterial cell wall synthesis (which also involves dolichol-linked oligosaccharides) but does not affect animal cells since it cannot cross cell membranes (bacterial cell wall synthesis is an extracellular process).

CHECKPOINT

- List some of the synthetic pathways that use nucleotide sugars.
- Explain the group transfer reaction of glycosidic bond formation by describing the attacking nucleophile, the atom attacked, and the leaving group.
- Compare the synthesis of *O*- and *N*-linked oligosaccharides.
- Explain why a lipid, dolichol, is involved in glycoprotein synthesis.
- Describe the types of enzymatic reactions that occur during the synthesis of *N*-linked oligosaccharides.

Summary

1 Glycogen Breakdown

- Glycogen breakdown requires three enzymes. Glycogen phosphorylase converts the glucosyl units at the nonreducing ends of glycogen to glucose-1-phosphate (G1P).
- Debranching enzyme transfers an $\alpha(1\rightarrow4)$ -linked trisaccharide to a nonreducing end and hydrolyzes the $\alpha(1\rightarrow6)$ linkage.
- Phosphoglucomutase converts G1P to glucose-6-phosphate (G6P). In liver, G6P is hydrolyzed by glucose-6-phosphatase to glucose for export to the tissues.

2 Glycogen Synthesis

- Glycogen synthesis requires a different pathway in which G1P is activated by reaction with UTP to form UDP-glucose.
- Glycogen synthase adds glucosyl units to the nonreducing ends of a growing glycogen molecule that has been primed by glycogenin.
- Branching enzyme removes an $\alpha(1\rightarrow4)$ -linked 7-residue segment and reattaches it through an $\alpha(1\rightarrow6)$ linkage to form a branched chain.

3 Control of Glycogen Metabolism

- Glycogen metabolism is controlled in part by allosteric effectors such as AMP, ATP, and G6P. Covalent modification of glycogen phosphorylase and glycogen synthase shifts their $T \rightleftharpoons R$ equilibria and therefore alters their sensitivity to allosteric effectors.
- The ratio of phosphorylase *a* (more active) to phosphorylase *b* (less active) depends on the activity of phosphorylase kinase, which is regulated by the activity of protein kinase A (PKA), a cAMP-dependent enzyme, and on the activity of phosphoprotein phosphatase-1 (PP1).

Glycogen phosphorylase is activated by phosphorylation, whereas glycogen synthase is activated by dephosphorylation.

- Hormones such as glucagon, epinephrine, and insulin control glycogen metabolism. Hormone signals that generate cAMP as a second messenger or that elevate intracellular Ca^{2+} , which binds to the calmodulin subunit of phosphorylase kinase, promote glycogen breakdown. Insulin stimulates glycogen synthesis in part by activating phosphoprotein phosphatase-1.

4 Gluconeogenesis

- Compounds that can be converted to oxaloacetate can subsequently be converted to glucose. The conversion of pyruvate to glucose by gluconeogenesis requires enzymes that bypass the three exergonic steps of glycolysis: Pyruvate carboxylase and PEP carboxykinase (PEPCK) bypass pyruvate kinase, fructose-1,6-bisphosphatase (FBPase) bypasses phosphofructokinase, and glucose-6-phosphatase bypasses hexokinase.
- Gluconeogenesis is regulated by changes in enzyme synthesis and by allosteric effectors, including fructose-2,6-bisphosphate (F2,6P), which inhibits FBPase and activates phosphofructokinase (PFK) and whose synthesis depends on the phosphorylation state of the bifunctional enzyme phosphofructokinase-2/fructose bisphosphatase-2 (PFK-2/FBPase-2).

5 Other Carbohydrate Biosynthetic Pathways

- Formation of glycosidic bonds requires nucleotide sugars.
- *O*-Linked oligosaccharides are synthesized by adding monosaccharides to a protein.
- *N*-Linked oligosaccharides are assembled on a dolichol carrier and then transferred to a protein.

Problems

EXERCISES

1. Explain why the glycogen phosphorylase reaction ($\Delta G^{\circ} = 3.1 \text{ kJ} \cdot \text{mol}^{-1}$) is exergonic in the cell.
2. Glucose binds to glycogen phosphorylase and competitively inhibits the enzyme. What is the physiological advantage of this?

3. Phosphoglucokinase catalyzes the phosphorylation of the C6-OH group of G1P. Why is this enzyme important for the normal function of phosphoglucomutase?
4. Glucose-6-phosphatase is located inside the endoplasmic reticulum. Describe the probable symptoms of a defect in G6P transport across the endoplasmic reticulum membrane.

5. Individuals with McArdle's disease often experience a "second wind" resulting from cardiovascular adjustments that allow glucose mobilized from liver glycogen to fuel muscle contraction. Explain why the amount of ATP derived in the muscle from circulating glucose is less than the amount of ATP that would be obtained by mobilizing the same amount of glucose from muscle glycogen.

6. A sample of glycogen from a patient with liver disease is incubated with P_i , normal glycogen phosphorylase, and normal debranching enzyme. The ratio of G1P to glucose formed in the reaction mixture is 100. What is the patient's most probable enzymatic deficiency?

7. Calculations based on the volume of a glucose residue and the branching pattern of cellular glycogen indicate that a glycogen molecule could have up to 28 branching tiers before becoming impossibly dense. What are the advantages of such a molecule and why is it not found *in vivo*?

8. Subjects who consumed a meal containing a high amylose:amylopectin ratio showed a lower increase in blood glucose levels than subjects who consumed a meal with a low amylose:amylopectin ratio. Explain.

9. Many diabetics do not respond to insulin because of a deficiency of insulin receptors on their cells. How does this affect (a) the levels of circulating glucose immediately after a meal and (b) the rate of glycogen synthesis in muscle?

10. Why does it make metabolic sense for the same hormone signal to stimulate glycogenolysis and inhibit glycolysis in the liver while stimulating both glycogenolysis and glycolysis in muscles?

11. Comparisons of wolf and dog DNA reveal that dogs have 4 to 30 amylase genes, whereas wolves have only 2. Why might additional amylase genes have played a role in the domestication of wolves (the ancestors of modern dogs) when humans began farming about 10,000 years ago?

12. Some archaeobacteria produce an enzyme with two active sites: one catalyzes the dephosphorylation of fructose-1,6-bisphosphate, and one catalyzes the condensation of dihydroxyacetone phosphate and glyceraldehyde-3-phosphate. Explain the advantage of combining these catalytic activities in a single bifunctional enzyme.

13. Write the balanced equation for the sequential conversion of glucose to pyruvate and of pyruvate to glucose.

14. Write the balanced equation for the catabolism of six molecules of G6P by the pentose phosphate pathway followed by conversion of ribulose-5-phosphate back to G6P by gluconeogenesis.

15. Indicate the energy yield or cost, in ATP equivalents, for the following processes:

- (a) glycogen (3 residues) \rightarrow 6 pyruvate
- (b) 3 glucose \rightarrow 6 pyruvate
- (c) 6 pyruvate \rightarrow 3 glucose

16. In the Cori cycle, the lactate product of glycolysis in muscle is transformed back into glucose by the liver. (a) List the enzymes involved in the lactate \rightarrow glucose pathway. (b) What is the net gain/loss of ATP for one round of the Cori cycle (glucose \rightarrow lactate \rightarrow glucose)?

17. Predict the effect of a fructose-1,6-bisphosphatase deficiency on blood glucose levels (a) before and (b) after a 24-hour fast.

18. Explain why an individual with a fructose-1,6-bisphosphatase deficiency would have elevated levels of pyruvate in the blood.

19. The growth of new blood vessels, called angiogenesis, can be triggered by anoxia (lack of oxygen) and involves the rapid proliferation of endothelial cells, which form the vessel walls. These cells exhibit extremely high levels of the enzyme PFK-2. Explain the advantage of PFK-2 activity in these cells.

20. In angiogenic endothelial cells, pyruvate is converted to lactate (generating 2 ATP per glucose) rather than being completely oxidized (which would generate \sim 32 ATP by oxidative phosphorylation). Explain why angiogenic cells generate ATP anaerobically.

21. The cells that line the mammalian intestine produce glycoproteins with *O*-linked oligosaccharides. Some of the glycoproteins remain anchored to the cell surface and some are released into the intestinal space.

In a healthy animal, numerous microbial species (the microbiome) live in the intestine. These organisms produce fucosidase, an enzyme that hydrolyzes glycosidic bonds involving fucose. (a) Why is this enzyme useful to the microorganisms? (b) Pathogenic (disease-causing) bacteria typically lack fucosidase. How does this help prevent the growth of pathogens in the intestine, particularly during an illness when the human host stops eating?

22. In germ-free mice, which harbor no intestinal bacteria, the *O*-linked oligosaccharides of intestinal glycoproteins tend to lack a terminal fucose residue (see Fig. 16-26). (a) What enzyme is not produced in normal quantities in these mice? (b) What monosaccharides tend to appear at the ends of *O*-linked oligosaccharides in these animals?

CHALLENGE QUESTIONS

23. One molecule of dietary glucose can be oxidized through glycolysis and the citric acid cycle to generate a maximum of 32 molecules of ATP. Calculate the fraction of this energy that is lost when the glucose is stored as glycogen before it is catabolized.

24. The free energy of hydrolysis of an $\alpha(1\rightarrow4)$ glycosidic bond is $-15.5 \text{ kJ} \cdot \text{mol}^{-1}$, whereas that of an $\alpha(1\rightarrow6)$ glycosidic bond is $-7.1 \text{ kJ} \cdot \text{mol}^{-1}$. Use these data to explain why glycogen debranching includes three reactions [breaking and re-forming $\alpha(1\rightarrow4)$ bonds and hydrolyzing $\alpha(1\rightarrow6)$ bonds], whereas glycogen branching requires only two reactions [breaking $\alpha(1\rightarrow4)$ bonds and forming $\alpha(1\rightarrow6)$ bonds].

25. (a) What amino acid, other than alanine, can be converted by transamination to a gluconeogenic precursor? (b) Calculate the cost, in ATP equivalents, of converting two molecules of this amino acid to one molecule of glucose.

26. The pathways of carbohydrate metabolism described in Chapters 15 and 16 include two reactions involving the transfer of one-carbon groups. (a) Name the enzymes and the pathways where these reactions occur. (b) What cofactors are required for the transfer reactions?

27. The pathways outlined in this chapter include steps that involve cleavage of a nucleoside triphosphate. Which of these reactions is/are phosphoryl group transfer?

28. The pathways outlined in this chapter include steps that involve cleavage of a nucleoside triphosphate. Which of these cleavage reactions is/are not phosphoryl group transfer?

29. Would you expect the allosteric regulator AMP to increase or decrease liver fructose-1,6-bisphosphatase activity?

30. Explain why it makes metabolic sense for acetyl-CoA, which is not a substrate for gluconeogenesis, to activate pyruvate carboxylase.

31. Fill in the blanks in the following diagram representing sucrose synthesis in plants.

32. Starch synthase in plants contains a single active site that accommodates ADP-glucose. However, cellulose synthase may contain two UDP-glucose-binding active sites. Given the structural differences between starch and cellulose, explain why two substrate-binding sites would promote efficient cellulose synthesis. [Hint: See Fig. 8-9.]

33. A mature glycogen particle typically has 12 tiers of branches with 2 branches per tier and 13 residues per branch. How many glucose residues are in such a particle?

34. The V_{\max} of muscle glycogen phosphorylase is much larger than that of the liver enzyme. Discuss the functional significance of this phenomenon.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Glycogen Phosphorylase Structure and Activity

Exercise 2 Glucagon Control of Glycogen and Glucose Metabolism

CASE STUDIES www.wiley.com/college/voet

Case 22 Carrier-Mediated Uptake of Lactate in Rat Hepatocytes

Focus concept: The structural characteristics of the lactate transport protein in hepatocytes are determined.

Prerequisites: Chapters 10, 15, and 16

- Transport proteins
- Major carbohydrate metabolic pathways including glycolysis and gluconeogenesis

Case 26 The Role of Specific Amino Acids in the Peptide Hormone Glucagon in Receptor Binding and Signal Transduction

Focus concept: Amino acid side chains important in glucagon binding and signal transduction are identified.

Prerequisites: Chapters 4, 13, and 16

- Amino acid structure
- Signal transduction via G proteins

MORE TO EXPLORE Use the Online Mendelian Inheritance in Man (OMIM) database (<http://www.ncbi.nlm.nih.gov/omim>) to explore one of the glycogen storage diseases described in Box 16-2. At what age is the disease typically noticed? What are the clinical symptoms? How is a diagnosis made? How is the disease treated? Are there variant forms of the disease, and what is the genetic basis for the variation?

Michael P. Gadomski/Photo Researchers, Inc.

The metabolic activity of this germinating seed is geared to generate the energy and carry out the biosynthetic reactions necessary for growth. Among the most active pathways in this and most organisms is the citric acid cycle, a series of reactions that participate in both catabolic and anabolic processes.

In the preceding two chapters, we examined the catabolism of glucose and its biosynthesis, storage, and mobilization. Although glucose is a source of energy for nearly all cells, it is not the only metabolic fuel, nor is glycolysis the only energy-yielding catabolic pathway. Cells that rely exclusively on glycolysis to meet their energy requirements actually waste most of the chemical potential energy of carbohydrates. When glucose is converted to lactate or ethanol, a relatively reduced product leaves the cell. If the end product of glycolysis is instead further oxidized, the cell can recover considerably more energy.

The oxidation of an organic compound requires an electron acceptor, such as NO_3^- , SO_4^{2-} , Fe^{3+} , or O_2 , all of which are exploited as oxidants in different organisms. In aerobic organisms, the electrons produced by oxidative metabolism are ultimately transferred to O_2 . Oxidation of metabolic fuels is carried out by the citric acid cycle, a sequence of reactions that arose sometime after levels of atmospheric oxygen became significant, about 3 billion years ago. As the reduced carbon atoms of metabolic fuels are oxidized to CO_2 , electrons are transferred to electron carriers that are subsequently reoxidized by O_2 . In this chapter, we examine the oxidation reactions of the citric acid cycle itself. In the following chapter, we examine the fate of the electrons and see how their energy is used to drive the synthesis of ATP.

FIG. 17-1 Overview of oxidative fuel metabolism. Acetyl groups derived from carbohydrates, amino acids, and fatty acids enter the citric acid cycle, where they are oxidized to CO_2 . **WPLS** See the Animated Figures.

It is sometimes convenient to think of the citric acid cycle as an addendum to glycolysis. Pyruvate derived from glucose can be split into CO_2 and a two-carbon fragment that enters the cycle for oxidation as acetyl-CoA (Fig. 17-1). However, it is really misleading to think of the citric acid cycle as merely a continuation of carbohydrate catabolism. *The citric acid cycle is a central pathway for recovering energy from several metabolic fuels, including carbohydrates, fatty acids, and amino acids, that are broken down to acetyl-CoA for oxidation.* In fact, under some conditions, the principal function of the citric acid cycle is to recover energy from fatty acids. We will also see that the citric acid cycle supplies the reactants for a variety of biosynthetic pathways.

We begin this chapter with an overview of the citric acid cycle. Next, we explore how acetyl-CoA, its starting compound, is formed from pyruvate. After discussing the reactions catalyzed by each of the enzymes of the cycle, we consider the regulation of these enzymes. Finally, we examine the links between citric acid cycle intermediates and other metabolic processes.

1 Overview of the Citric Acid Cycle

KEY CONCEPT

- The citric acid cycle is a multistep catalytic process that converts acetyl groups derived from carbohydrates, fatty acids, and amino acids to CO_2 , and produces NADH, FADH_2 , and GTP.

The **citric acid cycle** (Fig. 17-2) is an ingenious series of eight reactions that oxidizes the acetyl group of acetyl-CoA to two molecules of CO_2 in a manner that conserves the liberated free energy in the reduced compounds NADH and FADH_2 . The cycle is named after the product of its first reaction, **citrate**. One complete round of the cycle yields two molecules of CO_2 , three NADH, one FADH_2 , and one “high-energy” compound (GTP or ATP).

The citric acid cycle first came to light in the 1930s, when Hans Krebs, building on the work of others, proposed a circular reaction scheme for the interconversion of certain compounds containing two or three carboxylic acid groups (that is, di- and tricarboxylates). At the time, many of the citric acid cycle intermediates were already well known as plant products: **citrate** from citrus fruit, **aconitate** from monkshood (*Aconitum*), **succinate** from amber (succinum), **fumarate** from the herb *Fumaria*, and **malate** from apple (*Malus*). Two other intermediates, **α -ketoglutarate** and **oxaloacetate**, are known by their chemical names because they were synthesized before they were identified in living organisms. Krebs was the first to show how the metabolism of these compounds was linked to the oxidation of metabolic fuels. His discovery of the citric acid cycle, in 1937, ranks as one of the most important achievements of metabolic chemistry (Box 17-1). Although the enzymes and intermediates of the citric acid cycle are now well established, many investigators continue to explore the molecular mechanisms of the enzymes and how the enzymes are regulated for optimal performance under varying metabolic conditions in different organisms.

Before we examine each of the reactions in detail, we should emphasize some general features of the citric acid cycle:

- The circular pathway, which is also called the **Krebs cycle** or the **tricarboxylic acid (TCA) cycle**, oxidizes acetyl groups from many

WileyPLUS Learning Space

See Guided Exploration
Citric cycle overview

FIG. 17-2 The reactions of the citric acid cycle. The reactants and products of this catalytic cycle are boxed. The pyruvate → acetyl-CoA reaction (*top*) supplies the cycle's substrate via carbohydrate metabolism but is not considered to be part of the cycle. An isotopic label at C4 of oxaloacetate (*) becomes C1 of alpha-ketoglutarate and is

released as CO₂ in Reaction 4. An isotopic label at C1 of acetyl-CoA (‡) becomes C5 of alpha-ketoglutarate and is scrambled in Reaction 5 between C1 and C4 of succinate (1/2‡). **WPLS** See the Animated Figures.

? Without looking at the text, write an equation for the citric acid cycle.

sources, not just pyruvate. Because it accounts for the major portion of carbohydrate, fatty acid, and amino acid oxidation, the citric acid cycle is often considered the “hub” of cellular metabolism.

2. The net reaction of the citric acid cycle is

The oxaloacetate that is consumed in the first step of the citric acid cycle is regenerated in the last step of the cycle. Thus, *the citric acid cycle acts as a multistep catalyst that can oxidize an unlimited number of acetyl groups.*

3. In eukaryotes, all the enzymes of the citric acid cycle are located in the mitochondria, so all substrates, including NAD^+ and GDP, must be generated in the mitochondria or be transported into mitochondria from the

Box 17-1 Pathways of Discovery

Hans Krebs and the Citric Acid Cycle

Hans Krebs (1900–1981) Hans Krebs worked in Otto Warburg’s laboratory from 1926 until 1930 and later declared that he had learned more from Warburg (see Box 15-1) than from any other teacher. Krebs applied Warburg’s tissue-slice technique to the study of biosynthetic reactions (Warburg himself was interested primarily in oxidative and degradative reactions). Over a period of years, Krebs investigated synthetic pathways for urea,

uric acid, and purines, as well as oxidative pathways. He was forced to leave his native Germany for England in 1933, but unlike many other German emigrant scientists, he was able to bring much of his laboratory equipment with him. In England, Krebs continued to work on a series of metabolic reactions that he named the citric acid cycle.

The cycle was discovered not through sudden inspiration but through a series of careful experiments spanning the years 1932 to 1937. Krebs became interested in the “combustion” phase of fuel use, namely, what occurs after the fermentation of glucose to lactate. Until the 1930s, the mechanism of glucose oxidation and its relationship to cellular respiration (oxygen uptake) was a mystery. Krebs understood that the stoichiometry of the overall process ($\text{glucose} + 6 \text{ O}_2 \rightarrow 6 \text{ CO}_2 + 6 \text{ H}_2\text{O}$) required a multistep pathway. He was also aware that other researchers had examined the ability of muscle tissue to rapidly oxidize various dicarboxylates (α -ketoglutarate, succinate, and malate) and a tricarboxylate (citrate), but none of these substances had a clear relationship to any foodstuffs.

In 1935, Albert Szent-Györgyi found that cellular respiration was dramatically accelerated by small amounts of succinate, fumarate, malate, or oxaloacetate. In fact, the addition of any of these compounds stimulated O_2 uptake and CO_2 production far in excess of what would be expected for their oxidation. In other words, the compounds acted catalytically to boost the combustion of other compounds in the cell. At about the same time, Carl Martius and Franz Knoop showed that citrate could be converted to α -ketoglutarate. Soon, Krebs had an entire sequence of reactions for converting citrate to oxaloacetate: citrate \rightarrow aconitate \rightarrow isocitrate \rightarrow α -ketoglutarate \rightarrow succinate \rightarrow fumarate \rightarrow malate \rightarrow oxaloacetate. However, for this sequence of reactions to work catalytically, it must repeatedly return to its starting point; that is, the

first compound must be regenerated. And there was still no obvious link to glucose metabolism!

Krebs believed that citrate and the other intermediates were involved in glucose combustion because they appeared to burn at the same rate as foodstuffs and were the only substances that did so. In addition, earlier work had shown that the three-carbon compound malonate not only blocks the conversion of succinate to fumarate, it blocks all combustion by living cells. In 1937, Martius and Knoop provided Krebs with a key piece of information: Oxaloacetate and pyruvate could be converted to citrate in the presence of hydrogen peroxide.

Krebs now had the missing link: Pyruvate is a product of glucose metabolism, and its reaction with oxaloacetate to form citrate closed off the linear series of reactions to form a cycle. The idea of a circular pathway was not new to Krebs. He and Kurt Henseleit had elucidated the four-step urea cycle in 1932 (Section 21-3). Krebs quickly showed that the reaction of pyruvate with oxaloacetate to form citrate took place in living tissue and that the rates of citrate synthesis and breakdown were high enough to account for the observed fuel combustion in a variety of tissue types.

Remarkably, Krebs’ initial report on the citric acid cycle was rejected by *Nature*, a leading journal, before being accepted for publication in the less prestigious *Enzymologia*. In his report, Krebs established the major outlines of the pathway, although some details were later revised. For example, the mechanism of citrate formation (which involves acetyl-CoA rather than pyruvate) and the participation of succinyl-CoA in the cycle were not immediately appreciated. Coenzyme A was not discovered until 1945, and only in 1951 was acetyl-CoA shown to be the intermediate that condenses with oxaloacetate to form citrate. Work by Krebs and others established that the citric acid cycle plays a major role in the oxidation of amino acids and fatty acids. In fact, the pathway accounts for approximately two-thirds of the energy derived from metabolic fuels. Krebs also recognized the role of the citric acid cycle in supplying precursors for synthetic reactions.

[Krebs, H.A. and Johnson, W.A., The role of citric acid in intermediate metabolism in animal tissues, *Enzymologia* **4**, 148–156 (1937).]

CHECKPOINT

- Explain why the citric acid cycle is considered to be the hub of cellular metabolism.
- What are the substrates and products of the net reaction corresponding to one turn of the citric acid cycle?

cytosol. Similarly, all the products of the citric acid cycle must be consumed in the mitochondria or transported into the cytosol.

4. The carbon atoms of the two molecules of CO_2 produced in one round of the cycle are not the two carbons of the acetyl group that began the round (Fig. 17-2). These acetyl carbon atoms are lost in subsequent rounds of the cycle. However, the net effect of each round of the cycle is the oxidation of one acetyl group to 2CO_2 .
5. Citric acid cycle intermediates are precursors for the biosynthesis of other compounds (e.g., oxaloacetate for gluconeogenesis; Section 16-4).
6. The oxidation of an acetyl group to 2CO_2 requires the transfer of four pairs of electrons. The reduction of 3NAD^+ to 3NADH accounts for three pairs of electrons; the reduction of FAD to FADH_2 accounts for the fourth pair. Much of the free energy of oxidation of the acetyl group is conserved in these reduced coenzymes. Energy is also recovered as GTP (or ATP). In Section 18-3C, we will see that approximately 10 ATP are formed when the four pairs of electrons are eventually transferred to O_2 .

2 Synthesis of Acetyl-Coenzyme A

KEY CONCEPTS

- Pyruvate dehydrogenase is a multienzyme complex that catalyzes a five-part reaction in which pyruvate releases CO_2 and the remaining acetyl group becomes linked to coenzyme A.
- The reaction sequence requires the cofactors TPP, lipoamide, coenzyme A, FAD, and NAD^+ .

Acetyl groups enter the citric acid cycle as part of the “high-energy” compound acetyl-CoA (recall that thioesters have high free energies of hydrolysis; Section 14-2D). Although acetyl-CoA can also be derived from fatty acids (Section 20-2) and certain amino acids (Section 21-4), we focus here on the production of acetyl-CoA from pyruvate derived from carbohydrates.

As we saw in Section 15-3, the end product of glycolysis under anaerobic conditions is lactate or ethanol. However, under aerobic conditions, when the NADH generated by glycolysis is reoxidized in the mitochondria, the final product is pyruvate. A transport protein imports pyruvate along with H^+ (i.e., a pyruvate- H^+ symport) into the mitochondrion for further oxidation.

A Pyruvate Dehydrogenase Is a Multienzyme Complex

Multienzyme complexes are groups of noncovalently associated enzymes that catalyze two or more sequential steps in a metabolic pathway. Virtually all organisms contain multienzyme complexes, which represent a step forward in the evolution of catalytic efficiency because they offer the following advantages:

1. Enzymatic reaction rates are limited by the frequency with which enzymes collide with their substrates (Section 11-3D). When a series of reactions occurs within a multienzyme complex, the distance that substrates must diffuse between active sites is minimized, thereby enhancing the reaction rate.
2. The channeling (passing) of metabolic intermediates between successive enzymes in a metabolic pathway reduces the opportunity for these intermediates to react with other molecules, thereby minimizing side reactions.
3. The reactions catalyzed by a multienzyme complex can be coordinately controlled.

FIG. 17-3 Electron micrographs of the *E. coli* pyruvate dehydrogenase multienzyme complex. (a) The intact complex. (b) The dihydrolipoyl transacetylase (E2) core complex.

Acetyl-CoA is formed from pyruvate through oxidative decarboxylation by a multienzyme complex named **pyruvate dehydrogenase**. This complex contains multiple copies of three enzymes: **pyruvate dehydrogenase (E1)**, **dihydrolipoyl transacetylase (E2)**, and **dihydrolipoyl dehydrogenase (E3)**.

The *E. coli* pyruvate dehydrogenase complex is an ~4600-kD particle with a diameter of about 300 Å (Fig. 17-3a). The core of the particle is made of 24 E2 proteins arranged in a cube (Figs. 17-3b and 17-4a), which is surrounded by 24 E1 proteins and 12 E3 proteins (Fig. 17-4b,c). In mammals, yeast, and some bacteria, the pyruvate dehydrogenase complex is even larger and more complicated, although it catalyzes the same reactions using homologous enzymes and similar mechanisms. In these ~10,000-kD complexes, the largest known multienzyme complexes, the E2 core consists of 60 subunits arranged with dodecahedral symmetry [Fig. 17-5; a dodecahedron is a regular polyhedron with *I* symmetry (Fig. 6-34c) that has 20 vertices and 12 pentagonal faces] surrounded by a shell consisting of ~45 E1 $\alpha_2\beta_2$ heterotetramers and ~9 E3 homodimers. E1 and E3 competitively bind to mutually exclusive sites on E2 in a random distribution. Mammalian complexes, in addition, contain ~12 copies of **E3 binding protein**, which facilitates the binding of E3 to the E2 core, and several copies of a kinase and a phosphatase that function to regulate the activity of the complex (Section 17-4A).

FIG. 17-5 Model of the *Bacillus stearothermophilus* pyruvate dehydrogenase complex. This ~500-Å-diameter cutaway surface diagram is based on cryoelectron microscopic images of a complex consisting of a core of 60 E2 subunits (gray-green) surrounded by an outer shell of 60 E1 subunits (purple) separated by an ~90-Å-wide annular gap. Three full-length E2 subunits are schematically represented in red, green, and yellow to indicate their catalytic domains (embedded in the E2 core), their peripheral subunit-binding domains (embedded in the E3 shell) that bind the E1 (and E3) subunits, and their lipoyl domains, all connected by flexible polypeptide linkers (Section 17-2B). Here, the red lipoyl domain is shown visiting an E1 active site (white dot), whereas the green and yellow lipoyl domains occupy intermediate positions in the annular region between the E2 core and E1 shell. In a normal pyruvate dehydrogenase complex, E3 subunits would take the place of some of the E1 subunits. Indeed, a complex of 60 E3 subunits and 60 E2 subunits closely resembles the E1–E2 complex.

FIG. 17-4 Structural organization of the *E. coli* pyruvate dehydrogenase multienzyme complex. (a) The dihydrolipoyl transacetylase (E2) core. The 24 E2 proteins (green spheres) associate as trimers at the corners of a cube. (b) The 24 pyruvate dehydrogenase (E1) proteins (orange spheres) form dimers that associate with the E2 core (shaded cube) along its 12 edges. The 12 dihydrolipoyl dehydrogenase (E3) proteins (purple spheres) form dimers that attach to the six faces of the E2 cube. (c) Parts a and b combined form the entire 60-subunit complex.

B The Pyruvate Dehydrogenase Complex Catalyzes Five Reactions

The pyruvate dehydrogenase complex catalyzes five sequential reactions with the overall stoichiometry

Five different coenzymes are required: thiamine pyrophosphate (TPP; Section 15-3B), **lipoamide**, coenzyme A (Fig. 14-11), FAD (Fig. 14-13), and NAD^+ (Fig. 11-4). The coenzymes and their mechanistic functions are listed in **Table 17-1**. The sequence of reactions catalyzed by the pyruvate dehydrogenase complex is as follows (**Fig. 17-6**):

1. Pyruvate dehydrogenase (E1), a TPP-requiring enzyme, decarboxylates pyruvate with the formation of a hydroxyethyl-TPP intermediate:

This reaction is identical to that catalyzed by yeast pyruvate decarboxylase (Fig. 15-20). Recall (Section 15-3B) that the ability of TPP's thiazolium ring to add to carbonyl groups and act as an electron sink makes it the coenzyme most utilized in α -keto acid decarboxylation reactions.

2. Unlike pyruvate decarboxylase, however, pyruvate dehydrogenase does not convert the hydroxyethyl-TPP intermediate into acetaldehyde

TABLE 17-1 The Coenzymes and Prosthetic Groups of Pyruvate Dehydrogenase

Cofactor	Location	Function
Thiamine pyrophosphate (TPP)	Bound to E1	Decarboxylates pyruvate, yielding a hydroxyethyl-TPP carbanion
Lipoic acid	Covalently linked to a Lys on E2 (lipoamide)	Accepts the hydroxyethyl carbanion from TPP as an acetyl group
Coenzyme A (CoA)	Substrate for E2	Accepts the acetyl group from lipoamide
Flavin adenine dinucleotide (FAD)	Bound to E3	Reduced by lipoamide
Nicotinamide adenine dinucleotide (NAD^+)	Substrate for E3	Reduced by FADH_2

FIG. 17-6 The five reactions of the pyruvate dehydrogenase multienzyme complex. E1 (pyruvate dehydrogenase) contains TPP and catalyzes Reactions 1 and 2. E2 (dihydrolipoyl transacetylase) contains lipoamide and catalyzes Reaction 3. E3 (dihydrolipoyl

dehydrogenase) contains FAD and a redox-active disulfide and catalyzes Reactions 4 and 5.

? What type of reaction occurs in each of the five steps?

and TPP. Instead, the hydroxyethyl group is transferred to the next enzyme, dihydrolipoyl transacetylase (E2), which contains a lipoamide group. Lipoamide consists of **lipoic acid** linked via an amide bond to the ϵ -amino group of a Lys residue (Fig. 17-7). The reactive center of lipoamide is a cyclic disulfide that can be reversibly reduced to yield **dihydrolipoamide**. The hydroxyethyl group derived from pyruvate attacks the lipoamide disulfide, and TPP is eliminated, thus regenerating

FIG. 17-7 Interconversion of lipoamide and dihydrolipoamide. Lipoamide consists of lipoic acid covalently joined to the ϵ -amino group of a Lys residue via an amide bond.

active E1. The hydroxyethyl carbanion is oxidized to an acetyl group as the lipoamide disulfide is reduced:

3. E2 then catalyzes a transesterification reaction in which the acetyl group is transferred to CoA, yielding acetyl-CoA and dihydrolipoamide-E2:

4. Acetyl-CoA has now been formed, but the lipoamide group of E2 must be regenerated. Dihydrolipoyl dehydrogenase (E3) reoxidizes dihydrolipoamide to complete the catalytic cycle of E2. Oxidized E3 contains a reactive Cys—Cys disulfide group and a tightly bound FAD. The oxidation of dihydrolipoamide is a disulfide interchange reaction:

5. Finally, reduced E3 is reoxidized. The sulfhydryl groups are reoxidized by a mechanism in which FAD funnels electrons to NAD^+ , yielding NADH :

The X-ray structure of dihydrolipoyl dehydrogenase together with mechanistic information indicate that the reaction catalyzed by dihydrolipoamide

The toxicity of arsenic has been known since ancient times. As(III) compounds such as **arsenite** (AsO_3^{3-}) and **organic arsenicals** are toxic because they bind to sulfhydryl compounds (including lipoamide) that can form bidentate adducts:

Arsenite

Dihydro-
lipoamideOrganic
arsenical

The inactivation of lipoamide-containing enzymes by arsenite, especially the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes, brings respiration to a halt. However, organic arsenicals are more toxic to microorganisms than they are to humans, apparently because of differences in the sensitivities of their various enzymes to the compounds. This differential toxicity is the basis for the early twentieth century use of organic arsenicals in the treatment of **syphilis** (a bacterial disease) and **trypanosomiasis** (a parasitic disease). These compounds were actually the first antibiotics, although, not surprisingly, they produced severe side effects.

Arsenic is often suspected as a poison in untimely deaths. It was long thought that Napoleon Bonaparte died from arsenic

poisoning while in exile on the island of St. Helena, a suspicion that is strongly supported by the recent finding that a lock of his hair contains high levels of arsenic. But was it murder or environmental pollution? Arsenic-containing dyes were used in wallpaper at the time, and it was eventually determined that in damp weather, fungi convert the arsenic to a volatile compound. Surviving samples of the wallpaper from Napoleon's room in fact contain arsenic. Napoleon's arsenic poisoning may therefore have been unintentional.

Napoleon Bonaparte.

Photo Researchers

Charles Darwin.

Charles Darwin may also have been an unwitting victim of chronic arsenic poisoning. In the years following his epic voyage on the *Beagle*, Darwin was plagued by eczema, vertigo, headaches, gout, and nausea—all symptoms of arsenic poisoning. Fowler's solution, a widely used nineteenth century "tonic," contained 10 mg of arsenite per mL. Many individuals, quite possibly Darwin himself, took this "medication" for years.

3 Enzymes of the Citric Acid Cycle

KEY CONCEPTS

- The eight enzymes of the citric acid cycle catalyze condensation, isomerization, oxidation–reduction, phosphorylation, and hydration reactions.
- Two reactions produce CO_2 , one reaction produces GTP, and four reactions generate the reduced coenzymes NADH or FADH_2 .

In this section, we discuss the eight enzymes of the citric acid cycle. The elucidation of the mechanisms for each of these enzymes is the result of an enormous amount of experimental work. Even so, there remain questions about the mechanistic details of the enzymes and their regulatory properties.

A Citrate Synthase Joins an Acetyl Group to Oxaloacetate

Citrate synthase catalyzes the condensation of acetyl-CoA and oxaloacetate. This initial reaction of the citric acid cycle is the point at which carbon atoms (from carbohydrates, fatty acids, and amino acids) are “fed into the furnace” as acetyl-CoA. The citrate synthase reaction proceeds with an Ordered Sequential kinetic mechanism in which oxaloacetate binds before acetyl-CoA.

FIG. 17-9 Conformational changes in citrate synthase. (a) The open conformation. (b) The closed, substrate-binding conformation. In both forms, the homodimeric protein is viewed along its twofold axis and is represented by its transparent molecular surface with its polypeptide chains drawn in worm form colored in rainbow order from their N-termini (*blue*) to their C-termini (*red*). The reaction product citrate, which is bound to both enzymatic forms, and coenzyme A, which is also bound to the closed form, are shown in space-filling form

with citrate C cyan, CoA C green, N blue, O red, and P orange. The large conformational shift between the open and closed forms entails 18° rotations of the small domains (*upper left and lower right*) relative to the large domains resulting in relative interatomic movements of up to 15 Å. [Based on X-ray structures by James Remington and Robert Huber, Max-Planck-Institut für Biochemie, Martinsried, Germany. PDBids 1CTS and 2CTS.]

X-Ray studies show that the free enzyme (a homodimer) is in an “open” form, with two domains that form a cleft containing the substrate-binding site (Fig. 17-9a). When substrate binds, the smaller domain undergoes a remarkable 18° rotation, which closes the cleft (Fig. 17-9b). The existence of the “open” and “closed” forms explains the enzyme’s Ordered Sequential kinetic behavior. *The conformational change generates the acetyl-CoA binding site and seals the oxaloacetate binding site so that solvent cannot reach the bound substrate.* We have seen similar conformational changes in adenylate kinase (Fig. 14-10) and hexokinase (Fig. 15-2), which prevent ATP hydrolysis.

In the reaction mechanism proposed by James Remington, three ionizable side chains of citrate synthase participate in catalysis (Fig. 17-10):

1. The enol of acetyl-CoA is generated in the rate-limiting step of the reaction when Asp 375 (a base) removes a proton from the methyl group. His 274 forms a hydrogen bond with the enolate oxygen.
2. **Citryl-CoA** is formed in a concerted acid–base catalyzed step, in which the acetyl-CoA enolate (a nucleophile) attacks oxaloacetate. His 320 (an acid) donates a proton to oxaloacetate’s carbonyl group. The citryl-CoA intermediate remains bound to the enzyme. Citrate synthase is one of the few enzymes that directly forms a carbon–carbon bond without the assistance of a metal ion cofactor.

FIG. 17-10 The mechanism of the citrate synthase reaction. His 274 and His 320 in their neutral forms and Asp 375 have been implicated as general acid–base catalysts. [Mostly after Remington, J.S., *Curr. Opin. Struct. Biol.* **2**, 732 (1992).] **WPLS** See the Animated Process Diagrams.

? Would citrate synthase activity be more sensitive to a slight increase in pH or a slight decrease in pH?

- Citryl-CoA is hydrolyzed to citrate and CoA. This hydrolysis provides the reaction's thermodynamic driving force ($\Delta G^{\circ} = -31.5 \text{ kJ} \cdot \text{mol}^{-1}$). We will see later why this reaction requires such a large, seemingly wasteful, expenditure of free energy.

B Aconitase Interconverts Citrate and Isocitrate

Aconitase catalyzes the reversible isomerization of citrate and **isocitrate**, with **cis-aconitate** as an intermediate:

The reaction begins with a dehydration step in which a proton and an OH group are removed. Since citrate has two carboxymethyl groups substituent to its central C atom, it is prochiral rather than chiral. Thus, although water might conceivably be eliminated from either of the two carboxymethyl arms, aconitase removes water only from citrate's lower (*pro-R*) arm (i.e., such that the product molecule has the *R* configuration; Box 4-2).

Aconitase contains a **[4Fe–4S] iron–sulfur cluster** (an arrangement of four iron atoms and four sulfur atoms, Section 18-2C) that presumably coordinates

the OH group of citrate to facilitate its elimination. Iron–sulfur clusters normally participate in redox processes; aconitase is an intriguing exception.

The second stage of the aconitase reaction is rehydration of the double bond of *cis*-aconitate to form isocitrate. Although addition of water across the double bond of *cis*-aconitate could potentially yield four stereoisomers, aconitase catalyzes the stereospecific addition of OH[−] and H⁺ to produce only one isocitrate stereoisomer. The ability of an enzyme to differentiate its substrate's *pro-R* and *pro-S* groups was not appreciated until 1948, when Alexander Ogston pointed out that aconitase can distinguish between the two —CH₂COO[−] groups of citrate when it is bound to the enzyme (Section 11-1B).

Aconitase Functions as an Iron Sensor. Nature is opportunistic in that it often finds more than one use for a protein, a phenomenon dubbed moonlighting (after the practice of taking a second job, often at night, when the moon often shines). Aconitase is such a multifunctional protein. Cells require a balanced amount of iron. Too little and their many iron-containing proteins will lose function, whereas too much is toxic, particularly to the liver, heart, and pancreas, causing a life-threatening condition known as **hemochromatosis**. Dietary iron is transported through bloodstream by the protein **transferrin**, enters cells through receptor-mediated endocytosis (Section 20-1B) in which the receptor is **transferrin receptor**, and any excess iron is stored by the protein **ferritin**. When a cell has insufficient iron, its aconitase is inactivated through the loss of its [4Fe–4S] iron–sulfur cluster. The resulting protein, which undergoes extensive conformational changes to become known as **iron regulatory protein-1 (IRP1)**, binds to specific sequences on the mRNAs encoding the transferrin receptor and ferritin. This inhibits the degradation of the transferrin receptor mRNA, resulting in an increased rate of synthesis of transferrin receptor, whereas it blocks the translation of the ferritin mRNA. A cell's rate of iron uptake is thereby increased, whereas its amount of ferritin-bound iron is decreased.

C NAD⁺-Dependent Isocitrate Dehydrogenase Releases CO₂

Isocitrate dehydrogenase catalyzes the oxidative decarboxylation of isocitrate to α-ketoglutarate (also known as **2-oxoglutarate**). This reaction produces the first CO₂ and NADH of the citric acid cycle. Note that this CO₂ began the citric acid cycle as a component of oxaloacetate, not of acetyl-CoA (Fig. 17-2). (Mammalian tissues also contain an isocitrate dehydrogenase isozyme that uses NADP⁺ as a cofactor.)

NAD⁺-dependent isocitrate dehydrogenase, which also requires a Mn²⁺ or Mg²⁺ cofactor, catalyzes the oxidation of a secondary alcohol (isocitrate) to a ketone (**oxalosuccinate**) followed by the decarboxylation of the carboxyl group β to the ketone (Fig. 17-11). Mn²⁺ helps polarize the newly formed carbonyl group. The isocitrate dehydrogenase reaction mechanism is similar to that of phosphogluconate dehydrogenase in the pentose phosphate pathway (Section 15-6A).

The oxalosuccinate intermediate of the isocitrate dehydrogenase reaction exists only transiently, and its existence was therefore difficult to confirm.

FIG. 17-11 The reaction mechanism of isocitrate dehydrogenase. Oxalosuccinate is shown in brackets because it does not dissociate from the enzyme.

However, an enzymatic reaction can be slowed by mutating catalytically important residues—in this case, Tyr 160 and Lys 230—to create kinetic “bottlenecks” so that reaction intermediates accumulate. Accordingly, crystals of the mutant isocitrate dehydrogenase were exposed to the substrate isocitrate and immediately visualized via X-ray crystallography using rapid measurement techniques that require the highly intense X-rays generated by a synchrotron. These studies revealed the oxalosuccinate intermediate in the active site of the enzyme.

D α -Ketoglutarate Dehydrogenase Resembles Pyruvate Dehydrogenase

α -Ketoglutarate dehydrogenase catalyzes the oxidative decarboxylation of an α -keto acid (α -ketoglutarate). This reaction produces the second CO_2 and NADH of the citric acid cycle:

Again, this CO_2 entered the citric acid cycle as a component of oxaloacetate rather than of acetyl-CoA (Fig. 17-2). Thus, although each round of the citric acid cycle oxidizes two C atoms to CO_2 , the C atoms of the entering acetyl groups are not oxidized to CO_2 until subsequent rounds of the cycle.

The α -ketoglutarate dehydrogenase reaction chemically resembles the reaction catalyzed by the pyruvate dehydrogenase multienzyme complex. α -Ketoglutarate dehydrogenase is a multienzyme complex containing **α -ketoglutarate dehydrogenase (E1)**, **dihydrolipoyl transsuccinylase (E2)**, and **dihydrolipoyl dehydrogenase (E3)**. Indeed, this E3 is identical to the E3 of the pyruvate dehydrogenase complex (a third member of the **2-keto acid dehydrogenase** family of multienzyme complexes is **branched-chain α -keto acid dehydrogenase**, which participates in the degradation of isoleucine, leucine, and valine; Section 21-4). The reactions catalyzed by the α -ketoglutarate dehydrogenase complex occur by mechanisms identical to those of the pyruvate dehydrogenase complex. Again, the product is a “high-energy” thioester, in this case, **succinyl-CoA**.

E Succinyl-CoA Synthetase Produces GTP

Succinyl-CoA synthetase (also called **succinate thiokinase**) couples the cleavage of the “high-energy” succinyl-CoA to the synthesis of a “high-energy” nucleoside triphosphate (both names for the enzyme reflect the reverse reaction). Mammalian enzymes usually synthesize GTP from $\text{GDP} + \text{P}_i$, whereas plant and bacterial enzymes usually synthesize ATP from $\text{ADP} + \text{P}_i$. These reactions are nevertheless energetically equivalent since ATP and GTP are rapidly interconverted through the action of nucleoside diphosphate kinase (Section 14-2C):

How does succinyl-CoA synthetase couple the exergonic cleavage of succinyl-CoA ($\Delta G^{\circ'} = -32.6 \text{ kJ} \cdot \text{mol}^{-1}$) to the endergonic formation of a nucleoside triphosphate ($\Delta G^{\circ'} = +30.5 \text{ kJ} \cdot \text{mol}^{-1}$) from the corresponding nucleoside diphosphate and P_i ? This question was answered by an experiment with isotopically labeled ADP. In the absence of succinyl-CoA, the spinach enzyme catalyzes the transfer of the γ -phosphoryl group from ATP to [^{14}C]ADP, producing [^{14}C]ATP. Such an isotope-exchange reaction suggests the

participation of a phosphoryl-enzyme intermediate that mediates the reaction sequence

This information led to the isolation of a kinetically active phosphoryl-enzyme in which the phosphoryl group is covalently linked to the N3 position of a His residue. A three-step mechanism for succinyl-CoA synthetase is shown in Fig. 17-12.

1. Succinyl-CoA reacts with P_i to form **succinyl-phosphate** and CoA.
2. The phosphoryl group is then transferred from succinyl-phosphate to a His residue on the enzyme, releasing succinate.
3. The phosphoryl group on the enzyme is transferred to GDP, forming GTP.

Note that in each of these steps, *the energy of succinyl-CoA is conserved through the formation of "high-energy" compounds: first, succinyl-phosphate, then a 3-phospho-His residue, and finally GTP.* The process is reminiscent of passing a hot potato. The reaction catalyzed by succinyl-CoA synthetase is another example of substrate-level phosphorylation (ATP synthesis that does not directly depend on the presence of oxygen).

By this point in the citric acid cycle, one acetyl equivalent has been completely oxidized to two CO_2 . Two NADH and one GTP (equivalent to one ATP) have also been generated. To complete the cycle, succinate must be converted back to oxaloacetate. This is accomplished by the cycle's remaining three reactions.

PROCESS DIAGRAM

FIG. 17-12 The reaction catalyzed by succinyl-CoA synthetase. **WPLS** See the Animated Process Diagrams.

? Diagram this multi-reactant process using the Cleland notation (Section 12-1D).

F Succinate Dehydrogenase Generates FADH₂

Succinate dehydrogenase catalyzes the stereospecific dehydrogenation of succinate to fumarate:

This enzyme is strongly inhibited by malonate (*at left*), a structural analog of succinate and a classic example of a competitive inhibitor. When Krebs was formulating his theory of the citric acid cycle, the inhibition of cellular respiration by malonate provided one of the clues that succinate plays a catalytic role in oxidizing substrates and is not just another substrate (Box 17-1).

Succinate dehydrogenase contains an FAD prosthetic group that is covalently linked to the enzyme via a His residue (Fig. 17-13; in most other FAD-containing enzymes, the FAD is held tightly but noncovalently). In general, FAD functions biochemically to oxidize alkanes (such as succinate) to alkenes (such as fumarate), whereas NAD⁺ participates in the more exergonic oxidation of alcohols to aldehydes or ketones (e.g., in the reaction catalyzed by isocitrate dehydrogenase). The dehydrogenation of succinate produces FADH₂, which must be reoxidized before succinate dehydrogenase can undertake another catalytic cycle. The reoxidation of FADH₂ occurs when its electrons are passed to the mitochondrial electron transport chain, which we will examine in Section 18-2. Succinate dehydrogenase is the only membrane-bound enzyme of the citric acid cycle (the others occupy the inner compartment of the mitochondrion, its so-called **matrix**; Section 18-1A), so it is positioned to funnel electrons directly into the electron transport machinery of the mitochondrial membrane.

FIG. 17-13 The covalent attachment of FAD to a His residue of succinate dehydrogenase. R represents the ADP moiety.

G Fumarase Produces Malate

Fumarase (fumarate hydratase) catalyzes the hydration of the double bond of fumarate to form malate. The hydration reaction proceeds via a carbanion transition state. OH⁻ addition occurs before H⁺ addition:

H Malate Dehydrogenase Regenerates Oxaloacetate

Malate dehydrogenase catalyzes the final reaction of the citric acid cycle, the regeneration of oxaloacetate. The hydroxyl group of malate is oxidized in an NAD⁺-dependent reaction:

Transfer of the hydride ion to NAD^+ occurs by the same mechanism used for hydride ion transfer in lactate dehydrogenase and alcohol dehydrogenase (Section 15-3). X-Ray crystallographic comparisons of the NAD^+ -binding domains of these three enzymes indicate that they are remarkably similar, consistent with the proposal that all NAD^+ -binding domains evolved from a common ancestor.

The $\Delta G^{\circ'}$ value for the malate dehydrogenase reaction is $+29.7 \text{ kJ} \cdot \text{mol}^{-1}$; therefore, the concentration of oxaloacetate at equilibrium (and under cellular conditions) is very low relative to malate. Recall, however, that the reaction catalyzed by citrate synthase, the first reaction of the citric acid cycle, is highly exergonic ($\Delta G^{\circ'} = -31.5 \text{ kJ} \cdot \text{mol}^{-1}$) because of the cleavage of the thioester bond of acetyl-CoA. We can now understand the necessity for such a seemingly wasteful process. It allows citrate formation to be exergonic even at the low oxaloacetate concentrations present in cells and thus helps keep the citric acid cycle rolling.

4 Regulation of the Citric Acid Cycle

KEY CONCEPTS

- The need for energy regulates the citric acid cycle capacity at the pyruvate dehydrogenase step and at the three rate-controlling steps of the cycle.
- Regulatory mechanisms depend on substrate availability, product inhibition, covalent modification, and allosteric effects.

The capacity of the citric acid cycle to generate energy for cellular needs is closely regulated. The availability of substrates, the need for citric acid cycle intermediates as biosynthetic precursors, and the demand for ATP all influence the operation of the cycle. There is some evidence that the enzymes of the citric acid cycle are physically associated, which might contribute to their coordinated regulation. Before we examine the various mechanisms for regulating the citric acid cycle, let us briefly consider the energy-generating capacity of the cycle.

The oxidation of one acetyl group to two molecules of CO_2 is a four-electron pair process (but keep in mind that it is not the carbon atoms of the incoming acetyl group that are oxidized). For every acetyl-CoA that enters the cycle, three molecules of NAD^+ are reduced to NADH, which accounts for three of the electron pairs, and one molecule of FAD is reduced to FADH_2 , which accounts for the fourth electron pair. In addition, one GTP (or ATP) is produced (Fig. 17-14).

The electrons carried by NADH and FADH_2 are funneled into the electron-transport chain, which culminates with the reduction of O_2 to H_2O . The energy of electron transport is conserved in the synthesis of ATP by oxidative phosphorylation (Section 18-3). For every NADH that passes its electrons on, approximately 2.5 ATP are produced from $\text{ADP} + \text{P}_i$. For every FADH_2 , approximately 1.5 ATP are produced. Thus, one turn of the citric acid cycle ultimately generates approximately 10 ATP. We will see in Section 18-3C why these values are only approximations.

When glucose is converted to two molecules of pyruvate by glycolysis, two molecules of ATP are generated and two molecules of NAD^+ are reduced (Section 15-1). The NADH molecules yield approximately 5 molecules of ATP on passing their electrons to the electron-transport chain. When the two pyruvate molecules are converted to two acetyl-CoA by the pyruvate dehydrogenase

CHECKPOINT

- Draw the structures of the eight intermediates of the citric acid cycle and name the enzymes that catalyze their interconversions.
- Which steps of the citric acid cycle release CO_2 as a product? Which steps produce NADH or FADH_2 ? Which step produces GTP?
- Write the net equations for oxidation of pyruvate, the acetyl group of acetyl-CoA, and glucose to CO_2 and H_2O .

GATEWAY CONCEPT Metabolic Flux

In cells, the citric acid cycle runs continually as a variable-speed, multistep catalyst that converts two-carbon acetyl groups into 2 CO_2 and transforms the energy of the acetyl groups into the free energy of ATP and reduced cofactors. Cells can control both the rate of flow and the overall capacity of the cycle, much like a highway where the speed limit and number of vehicles can be increased or decreased.

FIG. 17-14 Products of the citric acid cycle. For every two carbons that are oxidized to CO_2 , electrons are recovered in the form of three NADH and one FADH_2 . One GTP (or ATP) is also produced.

? Identify the number of carbons in each intermediate.

complex, the two molecules of NADH produced in that process also eventually give rise to ~5 ATP. Two turns of the citric acid cycle (one for each acetyl group) generate ~20 ATP. Thus, one molecule of glucose can potentially yield ~32 molecules of ATP under aerobic conditions, when the citric acid cycle is operating. In contrast, only 2 molecules of ATP are produced per glucose molecule under anaerobic conditions.

A Pyruvate Dehydrogenase Is Regulated by Product Inhibition and Covalent Modification

Given the large amount of ATP that can potentially be generated from carbohydrate catabolism via the citric acid cycle, it is not surprising that the entry of acetyl units derived from carbohydrate sources is regulated. The decarboxylation of pyruvate by the pyruvate dehydrogenase complex is irreversible, and since there are no other pathways in mammals for the synthesis of acetyl-CoA from pyruvate, it is crucial that the reaction be precisely controlled. Two regulatory systems are used:

1. **Product inhibition by NADH and acetyl-CoA.** These compounds compete with NAD⁺ and CoA for binding sites on their respective enzymes. They also drive the reversible transacetylase (E2) and dihydrolipoyl dehydrogenase (E3) reactions backward (Fig. 17-6). High [NADH]/[NAD⁺] and [acetyl-CoA]/[CoA] ratios therefore maintain E2 in the acetylated form, incapable of accepting the hydroxyethyl group from the TPP on E1. This, in turn, ties up the TPP on the E1 subunit in its hydroxyethyl form, decreasing the rate of pyruvate decarboxylation.
2. **Covalent modification by phosphorylation/dephosphorylation of E1.** In eukaryotes, the products of the pyruvate dehydrogenase reaction, NADH and acetyl-CoA, also activate the **pyruvate dehydrogenase kinase** associated with the enzyme complex.

FIG. 17-15 Covalent modification of eukaryotic pyruvate dehydrogenase. E1 is inactivated by the specific phosphorylation of one of its Ser residues in a reaction catalyzed by pyruvate dehydrogenase kinase. This phosphoryl group is hydrolyzed through the action of pyruvate dehydrogenase phosphatase, thereby reactivating E1.

? Would the kinase or the phosphatase be more active when the cell's need for ATP is low?

The resulting phosphorylation of a specific dehydrogenase Ser residue inactivates the pyruvate dehydrogenase complex (Fig. 17-15). Insulin, the hormone that signals fuel abundance, reverses the inactivation by activating **pyruvate dehydrogenase phosphatase**, which removes the phosphate groups from pyruvate dehydrogenase. Recall that insulin also activates glycogen synthesis by activating phosphoprotein phosphatase (Section 16-3B). Thus, in response to increases in blood [glucose], insulin promotes the synthesis of acetyl-CoA as well as glycogen.

Other regulators of the pyruvate dehydrogenase system include pyruvate and ADP, which inhibit pyruvate dehydrogenase kinase, and Ca^{2+} , which inhibits pyruvate dehydrogenase kinase and activates pyruvate dehydrogenase phosphatase. In contrast to the glycogen metabolism control system (Section 16-3B), pyruvate dehydrogenase activity is unaffected by cAMP.

B Three Enzymes Control the Rate of the Citric Acid Cycle

To understand how a metabolic pathway is controlled, we must identify the enzymes that catalyze its rate-determining steps, the *in vitro* effectors of the enzymes, and the *in vivo* concentrations of these substances. *A proposed mechanism of flux control must operate within the physiological concentration ranges of the effectors.*

Identifying the rate-determining steps of the citric acid cycle is more difficult than it is for glycolysis because most of the cycle's metabolites are present in both mitochondria and cytosol and we do not know their distribution between these two compartments (recall that identifying a pathway's rate-determining steps requires determining the ΔG of each of its reactions from the concentrations of its substrates and products). However, we will assume that the compartments are in equilibrium and use the total cell concentrations of these substances to estimate their mitochondrial concentrations. **Table 17-2** gives the standard free energy changes for the eight citric acid cycle enzymes and estimates of the physiological free energy changes for the reactions in heart muscle or liver tissue. We can see that *three of the enzymes are likely to function far from equilibrium under physiological conditions (negative ΔG): citrate synthase, NAD^+ -dependent isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase.* These are therefore the rate-determining enzymes of the cycle.

In heart muscle, where the citric acid cycle is active, the flux of metabolites through the citric acid cycle is proportional to the rate of cellular oxygen consumption. *Because oxygen consumption, NADH reoxidation, and ATP production are tightly coupled (Section 18-3), the citric acid cycle must be regulated by feedback mechanisms that coordinate NADH production with energy expenditure.* Unlike the rate-limiting enzymes of glycolysis and glycogen metabolism, which regulate flux by elaborate systems of allosteric control, substrate cycles, and covalent modification, the regulatory enzymes of the citric acid cycle seem to control flux primarily by three simple mechanisms: (1) substrate availability, (2) product inhibition, and (3) competitive feedback inhibition by intermediates further along the cycle. Some of the major regulatory mechanisms are diagrammed

TABLE 17-2 Standard Free Energy Changes ($\Delta G'^{\circ}$) and Physiological Free Energy Changes (ΔG) of Citric Acid Cycle Reactions

Reaction	Enzyme	$\Delta G'^{\circ}$ ($\text{kJ} \cdot \text{mol}^{-1}$)	ΔG ($\text{kJ} \cdot \text{mol}^{-1}$)
1	Citrate synthase	-31.5	Negative
2	Aconitase	~5	~0
3	Isocitrate dehydrogenase	-21	Negative
4	α -Ketoglutarate dehydrogenase	-33	Negative
5	Succinyl-CoA synthetase	-2.1	~0
6	Succinate dehydrogenase	+6	~0
7	Fumarase	-3.4	~0
8	Malate dehydrogenase	+29.7	~0

FIG. 17-16 Regulation of the citric acid cycle. This diagram of the citric acid cycle, which includes the pyruvate dehydrogenase reaction, indicates points of inhibition (red octagons) and the pathway intermediates that function as inhibitors (dashed red arrows). ADP and Ca^{2+} (green dots) are activators. **WPLS** See the Animated Figures.

? Identify the enzymes that are regulated by product inhibition and by feedback inhibition.

in Fig. 17-16. There is no single flux-control point in the citric acid cycle; rather, flux control is distributed among several enzymes.

Perhaps the most crucial regulators of the citric acid cycle are its substrates, acetyl-CoA and oxaloacetate, and its product, NADH. Both acetyl-CoA and oxaloacetate are present in mitochondria at concentrations that do not saturate citrate synthase. The metabolic flux through the enzyme therefore varies with substrate concentration and is controlled by substrate availability. We have already seen that the production of acetyl-CoA from pyruvate is regulated by the activity of pyruvate dehydrogenase. The concentration of oxaloacetate, which is in equilibrium with malate, fluctuates with the $[\text{NADH}]/[\text{NAD}^+]$ ratio according to the equilibrium expression

$$K = \frac{[\text{oxaloacetate}] [\text{NADH}]}{[\text{malate}] [\text{NAD}^+]}$$

If, for example, the muscle workload and respiration rate increase, mitochondrial $[\text{NADH}]$ decreases. The consequent increase in $[\text{oxaloacetate}]$ stimulates the citrate synthase reaction, which controls the rate of citrate formation.

Aconitase functions close to equilibrium, so the rate of citrate consumption depends on the activity of NAD^+ -dependent isocitrate dehydrogenase, which is strongly inhibited *in vitro* by its product NADH. Citrate synthase is also inhibited by NADH but is less sensitive than isocitrate dehydrogenase to changes in $[\text{NADH}]$.

Other instances of product inhibition in the citric acid cycle are the inhibition of citrate synthase by citrate (citrate competes with oxaloacetate) and the inhibition of α -ketoglutarate dehydrogenase by NADH and succinyl-CoA.

Succinyl-CoA also competes with acetyl-CoA in the citrate synthase reaction (competitive feedback inhibition). This interlocking system helps keep the citric acid cycle coordinately regulated and the concentrations of its intermediates within reasonable bounds.

Additional Regulatory Mechanisms. *In vitro* studies of citric acid cycle enzymes have identified a few allosteric activators and inhibitors. ADP is an allosteric activator of isocitrate dehydrogenase, whereas ATP inhibits the enzyme. Ca^{2+} , in addition to its many other cellular functions, regulates the citric acid cycle at several points. It activates pyruvate dehydrogenase phosphatase (Fig. 17-15), which in turn activates the pyruvate dehydrogenase complex to produce acetyl-CoA. Ca^{2+} also activates both isocitrate dehydrogenase and α -ketoglutarate dehydrogenase (Fig. 17-16). Thus Ca^{2+} , the signal that stimulates muscle contraction, also stimulates the production of the ATP to fuel it.

The Enzymes of the Citric Acid Cycle Are Organized into a Metabolon. Considerable efficiency can be gained by organizing the enzymes of a metabolic pathway such that the enzymes catalyzing its sequential steps interact to channel intermediates between them. Indeed, we saw this to be the case with the pyruvate dehydrogenase multienzyme complex (Section 17-2A). The advantages of such an assembly, termed a **metabolon**, include the protection of labile (reactive) intermediates and the increase of their local concentration for more efficient catalysis. Considerable effort has been expended to obtain evidence for such interactions in the major metabolic pathways, including glycolysis and the citric acid cycle. Since citric acid cycle intermediates must be available for use in other metabolic pathways, any complexes between citric acid cycle enzymes are likely to be weak and therefore unable to withstand the laboratory manipulations necessary to isolate them, particularly dilution from the highly concentrated protein solution in the mitochondrial matrix (mitochondrial architecture is discussed in Section 18-1A). Nevertheless, there is now considerable evidence that at least several of the citric acid cycle enzymes associate in supramolecular complexes—that is, as metabolons—that are associated with the matrix side of the inner mitochondrial membrane, in which succinate dehydrogenase is anchored.

CHECKPOINT

- How much ATP can be generated from glucose when the citric acid cycle is operating?
- Which steps of the citric acid cycle regulate flux through the cycle?
- Describe the role of ADP, Ca^{2+} , acetyl-CoA, and NADH in regulating pyruvate dehydrogenase and the citric acid cycle.

5 Reactions Related to the Citric Acid Cycle

KEY CONCEPTS

- The citric acid cycle provides metabolites for gluconeogenesis, fatty acid synthesis, and amino acid synthesis.
- Citric acid cycle intermediates can be replenished by other pathways.
- Some organisms use the glyoxylate cycle, a variant of the citric acid cycle, for the net conversion of acetyl-CoA to oxaloacetate.

At first glance, a metabolic pathway appears to be either catabolic, with the release and conservation of free energy, or anabolic, with a requirement for free energy. The citric acid cycle is catabolic, of course, because it involves degradation and is a major free-energy conservation system in most organisms. Cycle intermediates are required in only catalytic amounts to maintain the degradative function of the cycle. However, several biosynthetic pathways use citric acid cycle intermediates as starting materials for anabolic reactions. The citric acid cycle is therefore **amphibolic** (both anabolic and catabolic). In this section, we examine some of the reactions that feed intermediates into the citric acid cycle or draw them off; we also examine the **glyoxylate cycle**, a variation of the citric acid cycle that occurs only in plants and converts acetyl-CoA to oxaloacetate. Some

FIG. 17-17 Amphibolic functions of the citric acid cycle. The diagram indicates the positions at which intermediates are drawn off by cataplerotic reactions for use in anabolic pathways (*red arrows*) and the points where anaplerotic reactions replenish cycle intermediates (*green arrows*). Reactions involving amino acid transamination and deamination are reversible, so their direction varies with metabolic demand. **WPLS** See the Animated Figures.

? Which reactions predominate when the cell's need for ATP increases?

of the reactions that use and replenish citric acid cycle intermediates are summarized in Fig. 17-17.

A Other Pathways Use Citric Acid Cycle Intermediates

Reactions that utilize and therefore drain citric acid cycle intermediates are called **cataplerotic reactions** (emptying; Greek: *cata*, down + *plerotikos*, to fill). These reactions serve not only to synthesize important products but also to avoid the inappropriate buildup of citric acid cycle intermediates in the mitochondrion, for example, when there is a high rate of breakdown of amino acids to citric acid cycle intermediates. Cataplerotic reactions occur in the following pathways:

- 1. Glucose biosynthesis** (gluconeogenesis) utilizes oxaloacetate (Section 16-4). Because gluconeogenesis takes place in the cytosol, oxaloacetate must be converted to malate or aspartate for transport out of the mitochondrion (Fig. 16-20). Since the citric acid cycle is a cyclic pathway, any of its intermediates can be converted to oxaloacetate and used for gluconeogenesis.
- 2. Fatty acid biosynthesis** is a cytosolic process that requires acetyl-CoA. Acetyl-CoA is generated in the mitochondrion and is not transported across the mitochondrial membrane. *Cytosolic acetyl-CoA is therefore generated by the breakdown of citrate, which can cross the membrane, in a reaction catalyzed by ATP-citrate lyase* (Section 20-4A). This reaction uses the free energy of ATP to “undo” the citrate synthase reaction:

- 3. Amino acid biosynthesis** uses α -ketoglutarate and oxaloacetate as starting materials. For example, α -ketoglutarate is converted to glutamate by reductive amination catalyzed by a **glutamate dehydrogenase** that utilizes either NADH or NADPH:

Oxaloacetate undergoes transamination with alanine to produce aspartate and pyruvate (Section 21-2A):

B Some Reactions Replenish Citric Acid Cycle Intermediates

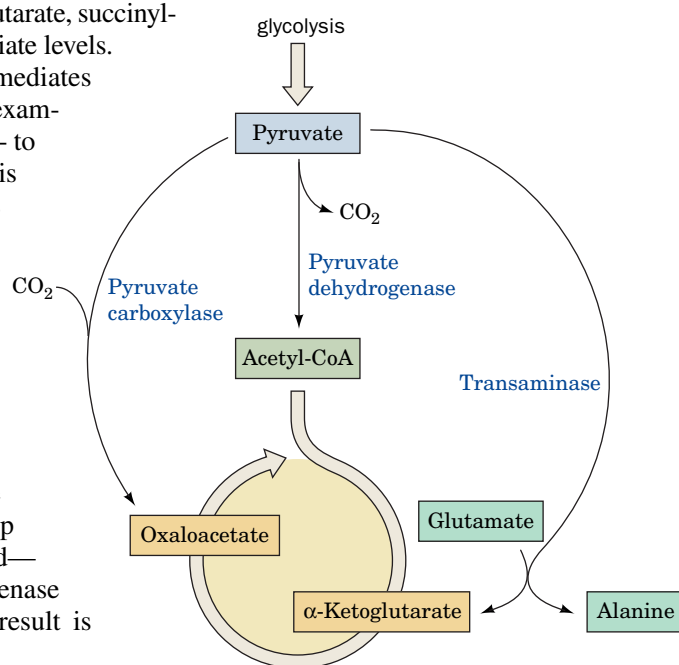

In aerobic organisms, the citric acid cycle is the major source of free energy, and hence the catabolic function of the citric acid cycle cannot be interrupted: Cycle intermediates that have been siphoned off must be replenished. The replenishing reactions are called **anaplerotic reactions** (filling up; Greek: *ana*, up + *plero-tikos*, to fill). The most important of these reactions is catalyzed by pyruvate carboxylase, which produces oxaloacetate from pyruvate:

(This is also one of the first steps of gluconeogenesis; Section 16-4A). Pyruvate carboxylase “senses” the need for more citric acid cycle intermediates through its activator, acetyl-CoA. *Any decrease in the rate of the cycle caused by insufficient oxaloacetate or other intermediates allows the concentration of acetyl-CoA to rise.* This activates pyruvate carboxylase, which replenishes oxaloacetate. The reactions of the citric acid cycle convert the oxaloacetate to citrate, α -ketoglutarate, succinyl-CoA, and so on, until all the intermediates are restored to appropriate levels.

An increase in the concentrations of citric acid cycle intermediates supports increased flux of acetyl groups through the cycle. For example, flux through the citric acid cycle may increase as much as 60- to 100-fold in muscle cells during intense exercise. Not all of this increase is due to elevated concentrations of cycle intermediates (which only increase about fourfold), because other regulatory mechanisms (as described in Section 17-4B) also promote flux through the rate-controlling steps of the cycle.

During exercise, some of the pyruvate generated by increased glycolytic flux is directed toward oxaloacetate synthesis as catalyzed by pyruvate carboxylase. Pyruvate can also accept an amino group from glutamate (a transamination reaction) to generate alanine (the amino acid counterpart of pyruvate) and the citric acid cycle intermediate α -ketoglutarate (the ketone counterpart of glutamate). Both of these mechanisms help the citric acid cycle efficiently catabolize the acetyl groups derived—also from pyruvate—by the reactions of the pyruvate dehydrogenase complex. These reactions are summarized at right. The end result is increased production of ATP to power muscle contraction.

The citric acid cycle is ubiquitous in aerobic organisms and plays a central role in energy metabolism in these cells. However, an eight-step catalytic cycle such as the citric acid cycle is unlikely to have arisen all at once and must have evolved from a simpler set of enzyme-catalyzed reactions. Clues to its origins can be found by examining the metabolism of cells that resemble early life-forms. Such organisms emerged before significant quantities of atmospheric oxygen became available some 3 billion years ago. These cells may have used sulfur as their terminal oxidizing agent, reducing it to H_2S . Their modern-day counterparts are anaerobic autotrophs that harvest free energy by pathways that are independent of the pathways that oxidize carbon-containing compounds. These organisms therefore do not use the citric acid

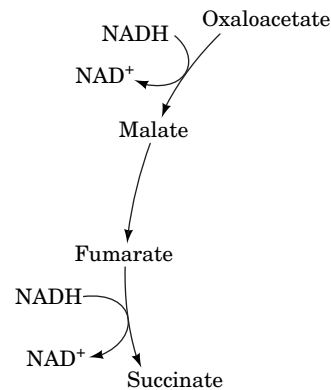

cycle to generate reduced cofactors that are subsequently oxidized by molecular oxygen. However, all organisms must synthesize the small molecules from which they can build proteins, nucleic acids, carbohydrates, and lipids.

The task of divining an organism's metabolic capabilities has been facilitated through bioinformatics. By comparing the sequences of prokaryotic genomes and assigning functions to various homologous genes, it is possible to reconstruct the central metabolic pathways for the organisms. This approach has been fruitful because many "housekeeping" genes, which encode enzymes that make free energy and molecular building blocks available to the cell, are highly conserved among different species and hence are relatively easy to recognize.

Genomic analysis reveals that many prokaryotes lack the citric acid cycle. However, these organisms do contain genes for some citric acid cycle enzymes. The last four reactions of the cycle, leading from succinate to oxaloacetate, appear to be the most highly conserved. This pathway fragment constitutes a mechanism for accepting electrons that are released during sugar fermentation. For example, the reverse of this pathway could regenerate NAD^+ from the $NADH$ produced by the glyceraldehyde-3-phosphate dehydrogenase step of glycolysis.

Methanococcus jannaschii, an organism without a citric acid cycle.

Other metabolites that feed into the citric acid cycle are succinyl-CoA, a product of the degradation of odd-chain fatty acids (Section 20-2E) and certain amino acids (Section 21-4), and α -ketoglutarate and oxaloacetate, which are formed by the reversible transamination of certain amino acids, as indicated above. The links between the citric acid cycle and other metabolic pathways offer some clues to its evolution (Box 17-3).

C The Glyoxylate Cycle Shares Some Steps with the Citric Acid Cycle

Plants, bacteria, and fungi, but not animals, possess enzymes that mediate the net conversion of acetyl-CoA to oxaloacetate, which can be used for gluconeogenesis. In plants, these enzymes constitute the glyoxylate cycle (Fig. 17-18), which operates in two cellular compartments: the mitochondrion and the **glyoxysome**, a membrane-bounded plant organelle that is a specialized peroxisome. Most of the enzymes of the glyoxylate cycle are the same as those of the citric acid cycle.

The resulting succinate could then be used as a starting material for the biosynthesis of other compounds.

Many archaeal cells have a **pyruvate:ferredoxin oxidoreductase** that converts pyruvate to acetyl-CoA (but without producing NADH). In a primitive cell, the resulting acetyl groups could have condensed with oxaloacetate (by the action of a citrate synthase), eventually giving rise to an oxidative sequence of reactions resembling the first few steps of the modern citric acid cycle.

The α -ketoglutarate produced in this way can be converted to glutamate and other amino acids.

The reductive and oxidative branches of the citric acid cycle outlined so far function in modern bacterial cells such as *E. coli* cells when they are growing anaerobically, suggesting that similar pathways could have filled the metabolic needs of early cells. The evolution of a complete citric acid cycle in which the two branches are linked and both proceed in an oxidative (clockwise) direction would have required an enzyme such as α -ketoglutarate:ferredoxin reductase (a homolog of pyruvate:ferredoxin oxidoreductase) to link α -ketoglutarate and succinate.

Interestingly, a primitive citric acid cycle that operated in the reverse (counterclockwise) direction could have provided a route for fixing CO_2 (that is, incorporating CO_2 into biological molecules).

The genes encoding enzymes that catalyze the steps of such a pathway have been identified in several modern autotrophic bacteria. This reductive pathway, which occurs in some deeply rooted archaeal species, possibly predates the CO_2 -fixing pathway used in some photosynthetic bacteria and in the chloroplasts of green plants (Section 19-3A).

The glyoxylate cycle consists of five reactions (Fig. 17-18):

- Reactions 1 and 2.** Glyoxysomal oxaloacetate is condensed with acetyl-CoA to form citrate, which is isomerized to isocitrate as in the citric acid cycle. Since the glyoxysome contains no aconitase, Reaction 2 presumably takes place in the cytosol.
- Reaction 3.** Glyoxysomal **isocitrate lyase** cleaves the isocitrate to succinate and **glyoxylate** (hence the cycle's name).
- Reaction 4.** **Malate synthase**, a glyoxysomal enzyme, condenses glyoxylate with a second molecule of acetyl-CoA to form malate.
- Reaction 5.** Glyoxysomal malate dehydrogenase catalyzes the oxidation of malate to oxaloacetate by NAD^+ .

The glyoxylate cycle therefore results in the net conversion of two acetyl-CoA to succinate instead of to four molecules of CO_2 as would occur in the citric acid cycle. The succinate produced in Reaction 3 is transported to the mitochondrion where it enters the citric acid cycle and is converted to malate, which has two

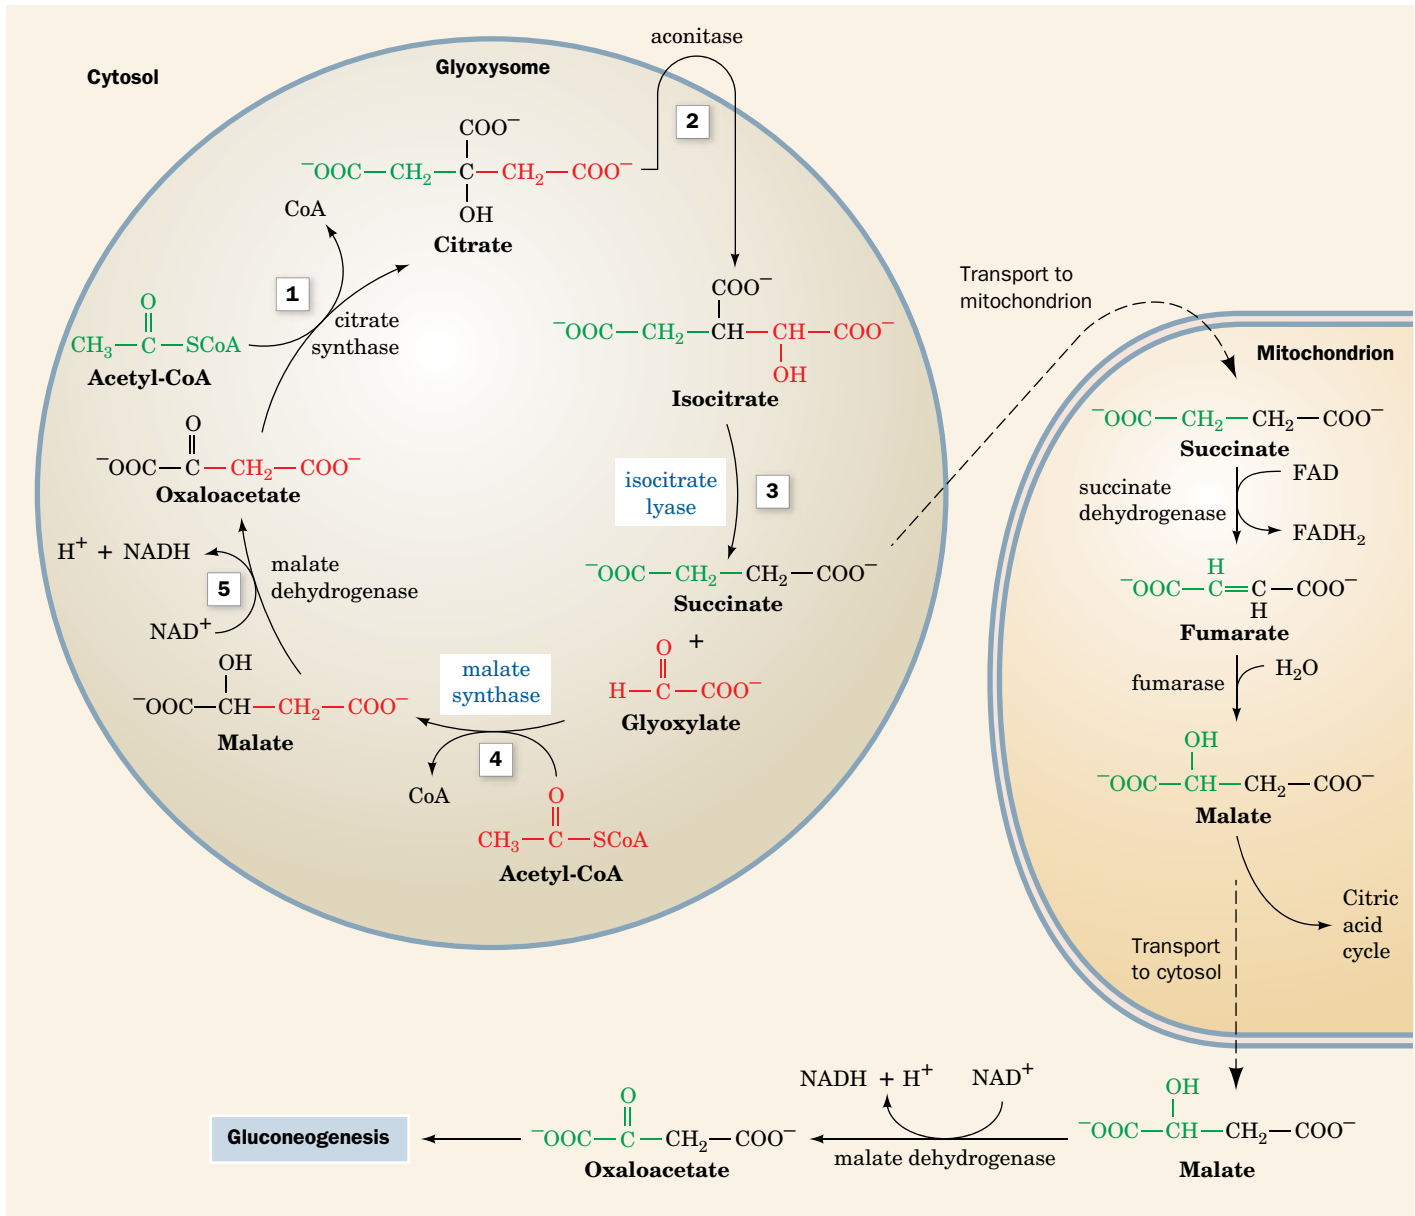

FIG. 17-18 The glyoxylate cycle. The cycle results in the net conversion of two acetyl-CoA to succinate in the glyoxysome, which can be converted to malate in the mitochondrion, where it can be converted to oxaloacetate for use in gluconeogenesis. Isocitrate lyase and malate synthase, enzymes unique to glyoxysomes (which occur only in plants), are indicated in blue. **(1)** Glyoxysomal citrate synthase catalyzes the condensation of oxaloacetate with acetyl-CoA to form citrate. **(2)** Cytosolic aconitase catalyzes the conversion of citrate to isocitrate. **(3)** Isocitrate lyase catalyzes the cleavage of isocitrate to succinate and glyoxylate. **(4)** Malate synthase catalyzes the condensation of glyoxylate with

acetyl-CoA to form malate. **(5)** Glyoxysomal malate dehydrogenase catalyzes the oxidation of malate to oxaloacetate, completing the cycle. Succinate is transported to the mitochondrion, where it is converted to malate via the citric acid cycle. This malate is transported to the cytosol, where malate dehydrogenase catalyzes its oxidation to oxaloacetate, which can then be used in gluconeogenesis. Alternatively, malate can continue in the citric acid cycle, making the glyoxylate cycle anaplerotic.

? Which steps of the citric acid cycle are bypassed by the glyoxylate cycle?

alternative fates: (1) It can be converted to oxaloacetate in the mitochondrion, continuing the citric acid cycle and thereby making the glyoxylate cycle an anaplerotic process (Section 17-5B); or (2) it can be transported to the cytosol, where it is converted to oxaloacetate for entry into gluconeogenesis.

The overall reaction of the glyoxylate cycle can be considered to be the formation of oxaloacetate from two molecules of acetyl-CoA:

Isocitrate lyase and malate synthase do not occur in animals. In plants, these enzymes enable germinating seeds to convert their stored triacylglycerols, through acetyl-CoA, to glucose. It had long been assumed that this was a requirement of germination. However, a mutant of *Arabidopsis thaliana* (an oilseed plant) lacking isocitrate lyase, and hence unable to convert lipids to carbohydrates, nevertheless germinated. This process was inhibited only when the mutant plants were subjected to low light conditions. Therefore, it now appears that the glyoxylate cycle's importance in seedling growth is its anaplerotic function in providing four-carbon units to the citric acid cycle, which can then oxidize the triacylglycerol-derived acetyl-CoA.

Organisms that lack the glyoxylate pathway cannot undertake the net synthesis of glucose from acetyl-CoA. This is the reason humans cannot convert fats (that is, fatty acids, which are catabolized to acetyl-CoA) to carbohydrates (that is, glucose).

Some human pathogens use the glyoxylate cycle, sometimes to great advantage. For example, *Mycobacterium tuberculosis*, which causes tuberculosis, can persist for years in the lung without being attacked by the immune system. During this period, the bacterium subsists largely on lipids, using the citric acid cycle to produce precursors for amino acid synthesis and using the glyoxylate cycle to produce carbohydrate precursors. Drugs that are designed to inhibit the bacterial isocitrate lyase can therefore potentially limit the pathogen's survival. The virulence of the yeast *Candida albicans*, which often infects immunosuppressed individuals, may also depend on activation of the glyoxylate cycle when these yeast cells take up residence inside macrophages.

CHECKPOINT

- Explain how a catalytic cycle can supply precursors for other metabolic pathways without depleting its own intermediates.
- Which citric acid cycle intermediates can be directly used in gluconeogenesis? Which can be used for fatty acid synthesis? Which can be directly converted to amino acids?
- How does the cell replenish oxaloacetate, α -ketoglutarate, and succinyl-CoA?
- Describe the reactions of the glyoxylate cycle. Which two enzymes are unique to this pathway? What does the pathway accomplish?

Summary

1 Overview of the Citric Acid Cycle

- The eight enzymes of the citric acid cycle function in a multistep catalytic cycle to oxidize an acetyl group to two CO_2 molecules with the concomitant generation of three NADH, one FADH_2 , and one GTP.
- The free energy released when the reduced coenzymes ultimately reduce O_2 is used to generate ATP.

2 Synthesis of Acetyl-Coenzyme A

- Acetyl groups enter the citric acid cycle as acetyl-CoA. The pyruvate dehydrogenase multienzyme complex, which contains three types of enzymes and five types of coenzymes, generates acetyl-CoA from the glycolytic product pyruvate.
- The lipoyllysyl arm of E2 acts as a tether that swings reactive groups between enzymes in the complex.

3 Enzymes of the Citric Acid Cycle

- Citrate synthase catalyzes the condensation of acetyl-CoA and oxaloacetate in a highly exergonic reaction.
- Aconitase catalyzes the isomerization of citrate to isocitrate, and isocitrate dehydrogenase catalyzes the oxidative decarboxylation of isocitrate to α -ketoglutarate to produce the citric acid cycle's first CO_2 and NADH.
- α -Ketoglutarate dehydrogenase catalyzes the oxidative decarboxylation of α -ketoglutarate to produce succinyl-CoA and the citric acid cycle's second CO_2 and NADH.
- Succinyl-CoA synthetase couples the cleavage of succinyl-CoA to the synthesis of GTP (or in some organisms, ATP) via a phosphoryl-enzyme intermediate.

- The citric acid cycle's remaining three reactions, catalyzed by succinate dehydrogenase, fumarase, and malate dehydrogenase, regenerate oxaloacetate to continue the citric acid cycle.
- Neither of the CO_2 molecules released in a given turn of the citric acid cycle are derived from the acetyl group that entered the same turn of the cycle. Instead, they are derived from the oxaloacetate that was synthesized from the acetyl groups that entered previous turns of the cycle.

4 Regulation of the Citric Acid Cycle

- Entry of glucose-derived acetyl-CoA into the citric acid cycle is regulated at the pyruvate dehydrogenase step by product inhibition (by NADH and acetyl-CoA) and by covalent modification.
- The citric acid cycle itself is regulated at the steps catalyzed by citrate synthase, NAD^+ -dependent isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase.
- Regulation is accomplished mainly by substrate availability, product inhibition, and feedback inhibition.

5 Reactions Related to the Citric Acid Cycle

- Cataplerotic reactions deplete citric acid cycle intermediates. Some citric acid cycle intermediates are substrates for gluconeogenesis, fatty acid biosynthesis, and amino acid biosynthesis.
- Anaplerotic reactions, such as the pyruvate carboxylase reaction, replenish citric acid cycle intermediates.
- The glyoxylate cycle, which operates only in plants, bacteria, and fungi, requires the glyoxysomal enzymes isocitrate lyase and malate synthase. This variation of the citric acid cycle permits net synthesis of glucose from acetyl-CoA.

Problems

EXERCISES

- The CO_2 produced in one round of the citric acid cycle does not originate in the acetyl carbons that entered that round. If acetyl-CoA is labeled with ^{14}C at its carbonyl carbon, how many rounds of the cycle are required before $^{14}\text{CO}_2$ is released?
- If acetyl-CoA is labeled with ^{14}C at its methyl group, how many rounds of the cycle are required before $^{14}\text{CO}_2$ is released?
- List four possible metabolic fates for pyruvate in a mammalian cell. Indicate the type of reaction that occurs. What additional reaction occurs in yeast?
- Explain why metabolic acidosis (Box 2-2) may result from the accumulation of some citric acid cycle intermediates.
- Which one of the five steps of the pyruvate dehydrogenase complex reaction is most likely to be metabolically irreversible? Explain.
- Explain why an individual with a deficiency of pyruvate dehydrogenase phosphatase (PDP) is unable to tolerate exercise.
- Photosynthetic organisms use elaborate machinery to incorporate carbon (as CO_2) into glyceraldehyde-3-phosphate, which is used to synthesize glucose for later metabolism. However, one carbon is lost following glycolysis when the three-carbon pyruvate is converted to acetyl-CoA. The bacterial enzyme pyruvate-formate lyase (also known as formate C-acetyltransferase) catalyzes the reaction

How does this reaction help the cell avoid losing carbon?

- Does the pyruvate-formate lyase reaction described in Problem 7 lead to the production of ATP, as pyruvate processing to acetyl-CoA does?
- Some human brain cancer cells contain a mutated form of isocitrate dehydrogenase that has lost its normal activity and instead catalyzes the NADP^+ -dependent reduction of the carbonyl group of α -ketoglutarate. Draw the structure of the reaction product.
- The compound you identified in Problem 9 resembles glutamate and might therefore competitively inhibit glutamate transamination. How would this affect citric acid cycle activity?
- Malonate competes with succinate in the succinate dehydrogenase reaction. Explain why increasing the oxaloacetate concentration can overcome malonate inhibition.
- What citric acid cycle intermediates would accumulate in the presence of malonate?
- What is the $\Delta G^{\circ\prime}$ value for the portion of the citric acid cycle that converts malate and acetyl-CoA to citrate?
- Given the following information, calculate the physiological ΔG of the isocitrate dehydrogenase reaction at 25°C and $\text{pH } 7.0$: $[\text{NAD}^+]/[\text{NADH}] = 8$, $[\alpha\text{-ketoglutarate}] = 0.1 \text{ mM}$, and $[\text{isocitrate}] = 0.02 \text{ mM}$. Assume standard conditions for CO_2 ($\Delta G^{\circ\prime}$ is given in Table 17-2). Is this reaction a likely site for metabolic control?
- Calculate the ratio of [fumarate] to [succinate] under cellular conditions at 37°C .
- What is the ratio of [isocitrate] to [citrate] under cellular conditions at 37°C ?

- Explain why a deficiency of pyruvate carboxylase leads to lactic acidosis.
- How would a deficiency of pyruvate dehydrogenase activity affect blood pH?
- (a) Explain why obligate anaerobes contain some citric acid cycle enzymes. (b) Why don't these organisms have a complete citric acid cycle?
- The first organisms on earth may have been chemoautotrophs in which the citric acid cycle operated in reverse to "fix" atmospheric CO_2 in organic compounds. Complete a catalytic cycle that begins with the hypothetical overall reaction $\text{succinate} + 2 \text{CO}_2 \rightarrow \text{citrate}$.
- Helicobacter pylori*, which causes gastric ulcers, does not operate a citric acid cycle but contains many of the citric acid cycle enzymes. *H. pylori* can convert oxaloacetate to succinate for biosynthetic processes. Write an equation for this conversion.
- The malaria parasite *Plasmodium falciparum* does not carry out oxidative phosphorylation and therefore does not use the citric acid cycle to generate reduced cofactors. Instead, the parasite converts amino acid-derived α -ketoglutarate to succinate. Write an equation for the α -ketoglutarate \rightarrow succinate conversion that follows (a) the oxidative (clockwise) path of the citric acid cycle or (b) the reductive (counterclockwise) path of the cycle.

CHALLENGE QUESTIONS

- The branched-chain α -keto acid dehydrogenase complex, which participates in amino acid catabolism, contains the same three types of enzymes as are in the pyruvate dehydrogenase and the α -ketoglutarate dehydrogenase complexes. Draw the reaction product when valine is deaminated as in the glutamate \rightleftharpoons α -ketoglutarate reaction (Section 17-5A) and then is acted on by the branched-chain α -keto acid dehydrogenase.
- Which compounds would accumulate in an individual with beriberi (caused by thiamine deficiency)?
- Refer to Table 14-4 to explain why FAD rather than NAD^+ is used in the succinate dehydrogenase reaction.
- Certain microorganisms with an incomplete citric acid cycle decarboxylate α -ketoglutarate to produce **succinate semialdehyde**. A dehydrogenase then converts succinate semialdehyde to succinate.

These reactions can be combined with other standard citric acid cycle reactions to create a pathway from citrate to oxaloacetate. Compare the ATP and reduced cofactor yield of the standard and alternate pathways.

27. Why is it advantageous for citrate, the product of Reaction 1 of the citric acid cycle, to inhibit phosphofructokinase, which catalyzes the third reaction of glycolysis?

28. When blood [glucose] is high and a cell's energy needs are met, insulin stimulates glycogen synthesis. Is it counterproductive for insulin to also promote the conversion of pyruvate to acetyl-CoA? Explain.

29. The catabolism of several amino acids generates succinyl-CoA. Describe the series of reactions that are required to convert mitochondrial succinyl-CoA to cytosolic oxaloacetate that can be used for gluconeogenesis.

30. Many amino acids are broken down to intermediates of the citric acid cycle. (a) Why can't these amino acid "remnants" be directly oxidized to CO₂ by the citric acid cycle? (b) Explain why amino acids that are broken down to pyruvate can be completely oxidized by the citric acid cycle.

31. Anaplerotic reactions permit the citric acid cycle to supply intermediates to biosynthetic pathways while maintaining the proper levels of cycle intermediates. Write the equation for the net synthesis of citrate from pyruvate.

32. Although animals cannot synthesize glucose from acetyl-CoA, if a rat is fed ¹⁴C-labeled acetate, some of the label appears in glycogen extracted from its muscles. Explain.

33. Malate generated inside the mitochondrion is translocated to the cytosol, where it is a substrate for cytosolic malic enzyme, which catalyzes the following reaction:

Explain how the activity of malic enzyme, which appears to catalyze a catabolic process, can promote biosynthetic reactions in the cytosol.

34. The action of malic enzyme opposes the action of pyruvate carboxylase. (a) Diagram the substrate cycle formed by these enzymes plus a third enzyme. (b) Write the net equation for converting malate to pyruvate and back to malate. What does this accomplish for the cell?

35. The archaeobacterium *Haloarcula marismortui* can use acetate (which is converted to acetyl-CoA) as a precursor for carbohydrate synthesis, but it lacks isocitrate lyase and therefore cannot use the glyoxylate pathway. Instead, it converts isocitrate to α -ketoglutarate, which is then converted to the amino acid methylaspartate in two more

steps. This five-carbon compound is modified and broken down to release glyoxylate. Describe the three reactions that lead from isocitrate to methylaspartate.

Methylaspartate

36. Acetyl-CoA, in addition to providing 2-carbon groups to the citric acid cycle, is also the substrate of enzymes that add acetyl groups to proteins. Histone acetyltransferase adds an acetyl group to the ϵ -amino group of a Lys residue in histones, proteins that interact closely with DNA. Draw the structure of the acetylated Lys side chain and explain why acetylation would disrupt the interaction between the histone and the DNA.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1. Viewing and Analyzing the Pyruvate Dehydrogenase Complex

Exercise 2. The Citric Acid Cycle and the KEGG Database

CASE STUDY www.wiley.com/college/voet

Case 21 Characterization of Pyruvate Carboxylase from *Methanobacterium thermoautotrophicum*

Focus concept: Pyruvate carboxylase is discovered in a bacterium that was previously thought not to contain the enzyme.

Prerequisite: Chapter 17

- Citric acid cycle reactions and associated anaplerotic reactions
- Glyoxylate cycle reactions

MORE TO EXPLORE *Plasmodium falciparum*, the parasite that causes malaria, spends part of its life cycle inside erythrocytes, an environment that is rich in nutrients and oxygen. However, the parasite consumes very little oxygen. How does it generate most of its ATP? The parasite contains a pyruvate dehydrogenase, but this enzyme does not generate acetyl-CoA for the citric acid cycle. Where is the dehydrogenase located, and what is the resulting acetyl-CoA used for?

CHAPTER 18

Electron Transport and Oxidative Phosphorylation

Chapter Contents

1 The Mitochondrion

- A Mitochondria Contain a Highly Folded Inner Membrane
- B Ions and Metabolites Enter Mitochondria via Transporters

2 Electron Transport

- A Electron Transport Is an Exergonic Process
- B Electron Carriers Operate in Sequence
- C Complex I Accepts Electrons from NADH
- D Complex II Contributes Electrons to Coenzyme Q
- E Complex III Translocates Protons via the Q Cycle
- F Complex IV Reduces Oxygen to Water

3 Oxidative Phosphorylation

- A The Chemiosmotic Theory Links Electron Transport to ATP Synthesis
- B ATP Synthase Is Driven by the Flow of Protons
- C The P/O Ratio Relates the Amount of ATP Synthesized to the Amount of Oxygen Reduced
- D Oxidative Phosphorylation Can Be Uncoupled from Electron Transport

4 Control of Oxidative Metabolism

- A The Rate of Oxidative Phosphorylation Depends on the ATP and NADH Concentrations
- B Aerobic Metabolism Has Some Disadvantages

A network of mitochondria (purple) attached to microtubules (green) in a monkey kidney cell is visualized using a high-resolution fluorescence microscopic technique. The mitochondria, organelles that carry out most of the cell's oxidative metabolism, are highly dynamic structures that move, change shape, grow, and divide.

Xiaowei Zhuang Laboratory at Harvard University and Howard Hughes Medical Institute

Aerobic organisms consume oxygen and generate carbon dioxide in the process of oxidizing metabolic fuels. The complete oxidation of glucose ($C_6H_{12}O_6$), for example, by molecular oxygen

can be broken down into two half-reactions that the metabolic machinery carries out. In the first, glucose carbon atoms are oxidized:

and in the second, molecular oxygen is reduced:

We have already seen that the first half-reaction is mediated by the enzymatic reactions of glycolysis and the citric acid cycle (the breakdown of fatty acids—the other major type of metabolic fuel—also requires the citric acid cycle). In this chapter, we describe the pathway by which the electrons from reduced fuel molecules are transferred to molecular oxygen in eukaryotes. We also examine how the energy of fuel oxidation is conserved and used to synthesize ATP.

As we have seen, the 12 electron pairs released during glucose oxidation are not transferred directly to O_2 . Rather, they are transferred to the coenzymes NAD^+ and FAD to form 10 $NADH$ and 2 $FADH_2$ (Fig. 18-1) in the reactions catalyzed by the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (Section 15-2F), pyruvate dehydrogenase (Section 17-2B), and the citric acid cycle enzymes isocitrate dehydrogenase, α -ketoglutarate dehydrogenase, succinate dehydrogenase, and malate dehydrogenase (Section 17-3). *The electrons then pass into the mitochondrial electron-transport chain, a system of linked electron carriers.* The following events occur during the electron-transport process:

1. By transferring their electrons to other substances, the $NADH$ and $FADH_2$ are reoxidized to NAD^+ and FAD so that they can participate in additional substrate oxidation reactions.
2. The transferred electrons participate in the sequential oxidation–reduction of multiple **redox centers** (groups that undergo oxidation–reduction reactions) in four enzyme complexes before reducing O_2 to H_2O .

FIG. 18-1 The sites of electron transfer that form NADH and FADH₂ in glycolysis and the citric acid cycle.

? Point out the electron carriers that account for all 24 of the electrons derived from the oxidation of glucose to CO₂.

3. The transfer of electrons is coupled to the expulsion of protons from the mitochondrion, producing a proton gradient across the inner mitochondrial membrane. The free energy stored in this electrochemical gradient drives the synthesis of ATP from ADP and P_i through **oxidative phosphorylation**.

1 The Mitochondrion

KEY CONCEPTS

- A highly folded, protein-rich inner membrane separates the mitochondrial matrix from the outer membrane.
- Transport proteins are required to import reducing equivalents, ADP, and P_i into the mitochondria.

The mitochondrion (Greek: *mitos*, thread + *chondros*, granule) is the site of eukaryotic oxidative metabolism. Mitochondria contain pyruvate dehydrogenase, the citric acid cycle enzymes, the enzymes catalyzing fatty acid oxidation

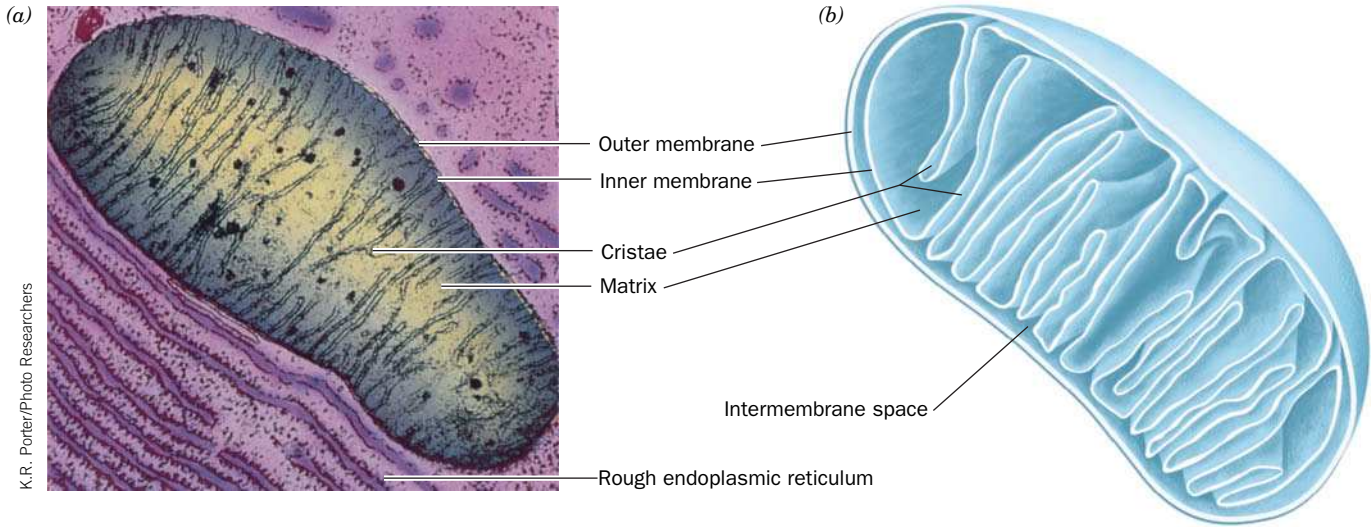

FIG. 18-2 The mitochondrion. (a) An electron micrograph of an animal mitochondrion. (b) Cutaway diagram of a mitochondrion.

(Section 20-2), and the enzymes and redox proteins involved in electron transport and oxidative phosphorylation. It is therefore with good reason that the mitochondrion is often described as the cell's “power plant.”

A Mitochondria Contain a Highly Folded Inner Membrane

Mitochondria vary in size and shape, depending on their source and metabolic state, but they are often ellipsoidal with dimensions of around $0.5 \times 1.0 \mu\text{m}$, about the size of a bacterium. A eukaryotic cell typically contains 800 to 2000 mitochondria, which occupy roughly one-fifth of its total cell volume. A mitochondrion is bounded by a smooth outer membrane and contains an extensively invaginated inner membrane (Fig. 18-2). The number of invaginations, called **cristae** (Latin: crests), reflects the type of cell and its respiratory activity. The large protein complexes mediating electron transport and oxidative phosphorylation are embedded in the inner mitochondrial membrane, so the respiration rate varies with membrane surface area.

The inner membrane divides the mitochondrion into two compartments, the **intermembrane space** and the internal **matrix**. The matrix is a gel-like solution that contains extremely high concentrations of the soluble enzymes of oxidative metabolism as well as substrates, nucleotide cofactors, and inorganic ions. The matrix also contains the mitochondrial genetic machinery—DNA, RNA, and ribosomes—that generates only 13 of the more than 1500 mitochondrial proteins. The remainder are encoded by nuclear genes and hence must be imported into the mitochondrion. The 13 mitochondrially encoded proteins (see below) are all exceptionally hydrophobic, which suggests that evolution could not find a way to efficiently import them. The remaining mitochondrial genes encode 22 tRNAs and two ribosomal RNAs, for a total of 37 genes in the mitochondrial genome (in humans, an $\sim 16,600$ -bp circular DNA that is inherited solely from the mother).

Two-dimensional electron micrographs of mitochondria such as Fig. 18-2a suggest that mitochondria are discrete kidney-shaped organelles. In fact, some mitochondria adopt a tubular shape that extends throughout the cytosol. Furthermore, mitochondria are highly variable structures. For example, the cristae may not resemble baffles and the intercrystal spaces may not communicate freely with the mitochondrion's intermembrane space. Electron microscopy-based three-dimensional image reconstruction methods have revealed that cristae can range in shape from simple tubular entities to more complicated lamellar assemblies that merge with the inner membrane via narrow tubular structures (Fig. 18-3). Evidently, cristae form microcompartments that restrict the diffusion of substrates

FIG. 18-3 Electron microscopy-based three-dimensional image reconstruction of a rat liver mitochondrion. The outer membrane (OM) is red, the inner membrane (IM) is yellow, and the cristae (C) are green. The arrowheads point to tubular regions of the cristae that connect them to the inner membrane and to each other.

and ions between the intercrystal and intermembrane spaces. This has important functional implications because it would result in a locally greater pH gradient across cristal membranes than across inner membranes that are not part of cristae, thereby significantly influencing the rate of oxidative phosphorylation (Section 18-3).

B Ions and Metabolites Enter Mitochondria via Transporters

Like bacterial outer membranes, the outer mitochondrial membrane contains porins, proteins that permit the free diffusion of molecules of up to 10 kD (Section 10-2B). *The intermembrane space is therefore equivalent to the cytosol in its concentrations of metabolites and ions.* The inner membrane, which is ~75% protein by mass, is considerably richer in proteins than is the outer membrane (Fig. 18-4). It is freely permeable only to O₂, CO₂, and H₂O and contains, in addition to respiratory chain proteins, numerous transport proteins that control the passage of metabolites such as ATP, ADP, pyruvate, Ca²⁺, and phosphate. *The controlled impermeability of the inner mitochondrial membrane to most ions and metabolites permits the generation of ion gradients across this barrier and results in the compartmentalization of metabolic functions between cytosol and mitochondria.*

Cytosolic Reducing Equivalents Are “Transported” into Mitochondria. The NADH produced in the cytosol by glycolysis must gain access to the mitochondrial electron-transport chain for aerobic oxidation. However, the inner mitochondrial membrane lacks an NADH transport protein. *Only the electrons from cytosolic NADH are transported into the mitochondrion by one of several ingenious “shuttle” systems.* We have already discussed the **malate–aspartate shuttle** (Fig. 16-20), in which, when run in reverse, cytosolic oxaloacetate is reduced to malate for transport into the mitochondrion. When malate is reoxidized in the matrix, it gives up the reducing equivalents that originated in the cytosol.

The **glycerophosphate shuttle** (Fig. 18-5) is expressed at variable levels in different animal tissues and is especially active in insect flight muscle (the tissue with the largest known sustained power output). In the first step of the shuttle

FIG. 18-4 Electron micrographs of the inner and outer mitochondrial membranes that have been split to expose the inner surfaces of their bilayer leaflets. Note that the inner membrane contains about twice the density of embedded particles as does the outer membrane. The particles are the portions of integral membrane proteins that were exposed when the bilayers were split.

FIG. 18-5 The glycerophosphate shuttle. The electrons of cytosolic NADH are transported to the mitochondrial electron-transport chain in three steps (shown in red as hydride transfers): (1) Cytosolic oxidation of NADH by dihydroxyacetone phosphate catalyzed by 3-phosphoglycerol dehydrogenase. (2) Oxidation of 3-phosphoglycerol by flavoprotein dehydrogenase with reduction of FAD to FADH₂. (3) Reoxidation of FADH₂ with passage of electrons into the electron-transport chain.

? Identify the component undergoing oxidation or reduction in each step.

mechanism, **3-phosphoglycerol dehydrogenase** catalyzes the oxidation of cytosolic NADH by dihydroxyacetone phosphate to yield NAD^+ , which re-enters glycolysis. The electrons of the resulting **3-phosphoglycerol** are then transferred to **flavoprotein dehydrogenase** to form FADH_2 . This enzyme, which is situated on the inner mitochondrial membrane's outer surface, supplies electrons directly to the electron-transport chain (Section 18-2D).

A Translocator Exchanges ADP and ATP. Most of the ATP generated in the **mitochondrial matrix** through oxidative phosphorylation is used in the cytosol. The inner mitochondrial membrane contains an **ADP-ATP translocator** (also called the **adenine nucleotide translocase**) that transports ATP out of the matrix in exchange for ADP produced in the cytosol by ATP-consuming reactions.

Several natural products inhibit the ATP-ADP translocator, including **atractyloside** (a poison produced by the Mediterranean thistle *Atractylis gummifera* that was known to the ancient Egyptians) and its derivative **carboxyatractyloside (CATR)**. In fact, the translocator has been purified by affinity chromatography (Section 5-2C) using atractyloside derivatives as affinity ligands.

R = H **Atractyloside**
R = COOH **Carboxyatractyloside (CATR)**

The ATP-ADP translocator, a dimer of identical ~ 300 -residue subunits, has characteristics similar to those of other transport proteins. Each subunit has one binding site for which ADP and ATP compete. It has two major conformations, one with its ATP-ADP binding site facing the matrix, and the other with this site facing the intermembrane space. In its X-ray structure in complex with CATR (Fig. 18-6), determined by Eva Pebay-Peyroula, each subunit's six transmembrane helices surround a deep, cone-shaped cavity open to the matrix that is occupied by the CATR.

The translocator must bind ligand to change from one conformation to the other at a physiologically reasonable rate. Thus it functions as an exchanger by importing one ADP for every ATP that is exported. In this respect, it differs from the glucose transporter (Fig. 10-13), which can change its conformation in the absence of ligand. Note that the export of ATP (net charge -4) and the import of ADP (net charge -3) results in the export of

FIG. 18-6 X-Ray structure of bovine heart ATP-ADP translocator in complex with carboxyatractyloside. (a) A subunit of the homodimeric protein, viewed from the plane of the inner membrane with the intermembrane space above, is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) and embedded in its semitransparent surface diagram. The carboxyatractyloside is drawn in space-filling form with C cyan, O red, and S yellow. Three cardiolipin molecules (Table 9-2) that cocrystallized with the protein are drawn in stick form with C green, O red, and P orange. (b) The molecular surface as viewed from the intermembrane space and colored according to its surface charge with blue positive, white neutral, and red negative. Note the deep, positively charged cavity in which the anionic ATP binds. [Based on an X-ray structure by Eva Pebay-Peyroula, Université Joseph Fourier, Grenoble, France. PDBid 2C3E.]

one negative charge per transport cycle. This **electrogenic** antiport is driven by the membrane potential difference, $\Delta\Psi$, across the inner mitochondrial membrane (positive outside), which is a consequence of the transmembrane proton gradient.

Phosphate Must Be Imported into the Mitochondrion. ATP is synthesized from ADP + P_i in the mitochondrion but is utilized in the cytosol. The P_i is returned to the mitochondrion by the **phosphate carrier**, an electroneutral P_i – H^+ symport that is driven by ΔpH . The transmembrane proton gradient generated by the electron-transport machinery of the inner mitochondrial membrane thus not only provides the thermodynamic driving force for ATP synthesis (Section 18-3), it also motivates the transport of the raw materials—ADP and P_i —required for the process.

CHECKPOINT

- Draw a simple diagram of a mitochondrion and identify its structural features.
- Describe how shuttle systems transport reducing equivalents into the mitochondria.
- Explain how the free energy of the proton gradient drives the transport of ATP, ADP, and P_i .

2 Electron Transport

KEY CONCEPTS

- The free energy of electron transport from NADH to O_2 drives the synthesis of approximately 2.5 ATP.
- Electron carriers are arranged in the mitochondrial membrane so that electrons travel from Complexes I and II via coenzyme Q to Complex III, and from there via cytochrome *c* to Complex IV.
- The L-shaped Complex I transfers electrons from NADH to CoQ via a series of iron–sulfur clusters and simultaneously translocates four protons to the intermembrane space.
- Complex II transfers electrons from succinate to the CoQ pool but does not contribute to the transmembrane proton gradient.
- Electrons from Complex III are transferred to cytochrome *c* and two protons are translocated during the operation of the Q cycle in Complex III.
- Complex IV accepts electrons from cytochrome *c* to reduce O_2 to H_2O and translocates four protons for every two electrons transferred.

The electron carriers that ferry electrons from NADH and $FADH_2$ to O_2 are associated with the inner mitochondrial membrane. Some of these redox centers are highly mobile, and others are less mobile components of integral membrane protein complexes. The sequence of electron carriers roughly reflects their relative reduction potentials, so that the overall process of electron transport is exergonic. We begin this section by examining the thermodynamics of electron transport. We then consider the molecular characteristics of the various electron carriers.

A Electron Transport Is an Exergonic Process

We can estimate the thermodynamic efficiency of electron transport by inspecting the standard reduction potentials of the redox centers. As we saw in our thermodynamic considerations of oxidation–reduction reactions (Section 14-3), an oxidized substrate's affinity for electrons increases with its standard reduction potential, \mathcal{E}' (Table 14-4 lists the standard reduction potentials of some biologically important half-reactions). The standard reduction potential difference, $\Delta\mathcal{E}'$, for a redox reaction involving any two half-reactions is expressed

$$\Delta\mathcal{E}' = \mathcal{E}'_{(e^- \text{ acceptor})} - \mathcal{E}'_{(e^- \text{ donor})}$$

For the reaction that occurs in mitochondria, that is, the oxidation of NADH by O_2 , the relevant half-reactions are

and

Since the O_2/H_2O half-reaction has the greater standard reduction potential (O_2 has a higher affinity for electrons than NAD^+), we write the $NADH$ half-reaction in reverse so that $NADH$ is the electron donor in the couple and O_2 the electron acceptor. The overall reaction is

so that

$$\Delta \mathcal{E}^{\circ'} = 0.815 \text{ V} - (-0.315 \text{ V}) = 1.130 \text{ V}$$

The standard free energy change for the reaction can then be calculated from Eq. 14-7:

$$\Delta G^{\circ'} = -n\mathcal{F}\Delta \mathcal{E}^{\circ'}$$

For $NADH$ oxidation, $\Delta G^{\circ'} = -218 \text{ kJ} \cdot \text{mol}^{-1}$. In other words, the oxidation of 1 mol of $NADH$ by O_2 (the transfer of 2 mol e^-) under standard biochemical conditions is associated with the release of 218 kJ of free energy.

Because the standard free energy required to synthesize 1 mol of ATP from $ADP + P_i$ is $30.5 \text{ kJ} \cdot \text{mol}^{-1}$, the oxidation of one mol of $NADH$ by O_2 is theoretically able to drive the formation of several moles of ATP. In mitochondria, the coupling of $NADH$ oxidation to ATP synthesis is achieved by an electron-transport chain in which electrons pass through three protein complexes. *This allows the overall free energy change to be broken into three smaller parcels, each of which contributes to ATP synthesis by oxidative phosphorylation. Oxidation of one $NADH$ results in the synthesis of approximately 2.5 ATP* (we will see later why the relationship is not strictly stoichiometric). The thermodynamic efficiency of oxidative phosphorylation is therefore $2.5 \times 30.5 \text{ kJ} \cdot \text{mol}^{-1} \times 100/218 \text{ kJ} \cdot \text{mol}^{-1} = 35\%$ under standard biochemical conditions. However, under physiological conditions in active mitochondria (where the reactant and product concentrations as well as the pH deviate from standard conditions), the thermodynamic efficiency is thought to be $\sim 70\%$. In comparison, the energy efficiency of a typical automobile engine is $< 30\%$.

B Electron Carriers Operate in Sequence

*Oxidation of $NADH$ and $FADH_2$ is carried out by the electron-transport chain, a series of four protein complexes containing redox centers with progressively greater affinities for electrons (increasing standard reduction potentials). Electrons travel through the chain from lower to higher standard reduction potentials (Fig. 18-7). Electrons are carried from **Complexes I and II** to **Complex III** by the lipid **coenzyme Q (CoQ or ubiquinone)**; so named because of its ubiquity in respiring organisms), and from **Complex III** to **Complex IV** by the small soluble protein **cytochrome c**.*

Complex I catalyzes oxidation of $NADH$ by CoQ:

$$\Delta \mathcal{E}^{\circ'} = 0.360 \text{ V} \quad \Delta G^{\circ'} = -69.5 \text{ kJ} \cdot \text{mol}^{-1}$$

Complex III catalyzes oxidation of CoQ (reduced) by cytochrome c:

$$\Delta \mathcal{E}^{\circ'} = 0.190 \text{ V} \quad \Delta G^{\circ'} = -36.7 \text{ kJ} \cdot \text{mol}^{-1}$$

Complex IV catalyzes oxidation of reduced cytochrome c by O_2 , the terminal electron acceptor of the electron-transport process:

$$\Delta \mathcal{E}^{\circ'} = 0.580 \text{ V} \quad \Delta G^{\circ'} = -112 \text{ kJ} \cdot \text{mol}^{-1}$$

As an electron pair successively traverses Complexes I, III, and IV, sufficient free energy is released at each step to power ATP synthesis.

WileyPLUS Learning Space

See Guided Exploration

Electron transport and oxidative phosphorylation overview.

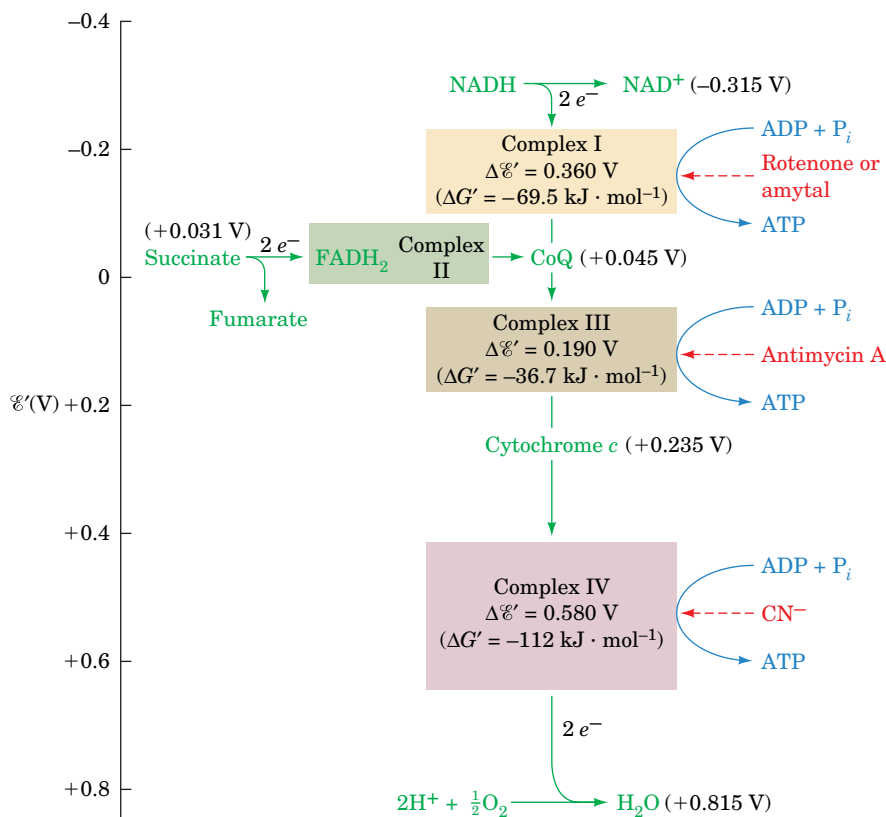

FIG. 18-7 Overview of electron transport in the mitochondrion. The standard reduction potentials of its most mobile components (green) are indicated, as are the points where sufficient free energy is released to synthesize ATP (blue) and the sites of action of several respiratory inhibitors (red). Complexes I, III, and IV do not directly synthesize ATP but sequester the free energy necessary to do so by pumping protons outside the mitochondrion to form a proton gradient.

? What is the approximate value of $\Delta\mathcal{E}'$ for the passage of electrons through Complexes I, III, and IV?

Complex II catalyzes the oxidation of FADH_2 by CoQ :

This redox reaction does not release sufficient free energy to synthesize ATP; it functions only to inject the electrons from FADH_2 into the electron-transport chain.

Inhibitors Reveal the Workings of the Electron-Transport Chain. The sequence of events in electron transport was elucidated largely through the use of specific inhibitors and later corroborated by measurements of the standard reduction potentials of the redox components. The rate at which O_2 is consumed by a suspension of mitochondria is a sensitive measure of the activity of the electron-transport chain. Compounds that inhibit electron transport, as judged by their effect on O_2 consumption, include **rotenone** (a plant toxin used by Amazonian Indians to poison fish and which is also used as an insecticide), **amytal** (a barbiturate), **antimycin A** (an antibiotic), and **cyanide**.

GATEWAY CONCEPT Oxidation–Reduction Reactions

When one substance is reduced (gains electrons), another substance must be oxidized (loses electrons). Electron carriers like NAD^+ and ubiquinone function as shuttles by accepting electrons (becoming reduced) and then passing them to another substance (returning to their oxidized forms). Because the carriers are constantly regenerated, electrons can continue to flow, following a path from higher free energy to lower free energy; that is, originating from substances with lower reduction potential and ending at substances with higher reduction potential.

Adding rotenone or amytal to a suspension of mitochondria blocks electron transport in Complex I; antimycin A blocks Complex III, and CN^- blocks electron transport in Complex IV (Fig. 18-7). Each of these inhibitors also halts O_2 consumption. Oxygen consumption resumes following addition of a substance whose electrons enter the electron-transport chain “downstream” of the block. For example, the addition of succinate to rotenone-blocked mitochondria restores electron transport and O_2 consumption. Experiments with inhibitors of electron transport thus reveal the points of entry of electrons from various substrates.

Each of the four respiratory complexes of the electron-transport chain consists of several protein components that are associated with a variety of redox-active prosthetic groups with successively increasing reduction potentials (Table 18-1). The complexes are all laterally mobile within the inner mitochondrial membrane and also apparently associate to form “supercomplexes” with variable composition, such as III_2IV_2 and $\text{I}_1\text{III}_2\text{IV}$ that resemble the metabolons formed by soluble enzymes (Section 17-4B). The dynamic organization of the complexes may allow the mitochondria to adapt to different sources of electrons in order to maximize the efficiency of electron transport under different conditions. In the following sections,

FIG. 18-8 The mitochondrial electron-transport chain. This diagram indicates the pathways of electron transfer (blue) and proton translocation (red). Electrons are transferred between Complexes I and III by the

membrane-soluble coenzyme Q (Q) and between Complexes III and IV by the water-soluble protein cytochrome c. Complex II transfers electrons from succinate to coenzyme Q. **WPLS** See the Animated Figures.

we examine the structures of Complexes I through IV and the molecules that transfer electrons between them. Their relationships are summarized in Fig. 18-8.

C Complex I Accepts Electrons from NADH

Complex I (NADH-coenzyme Q oxidoreductase), which passes electrons from NADH to CoQ, is the largest protein complex in the inner mitochondrial membrane. In mammals, it consists of 44 different subunits with a total mass of ~980 kD. Eukaryotes and many prokaryotes share 14 “core” subunits. In mammals, the 7 core subunits that comprise its transmembrane region (see below) are encoded by mitochondrial genes.

The X-ray structure of the 16-subunit *Thermus thermophilus* Complex I (Fig. 18-9a), determined by Leonid Sazanov, reveals an L-shaped protein with one arm embedded in the

FIG. 18-9 The X-ray structure of Complex I from the bacterium *T. thermophilus*. (a) The 536-kD protein as viewed parallel to the plane of the plasma membrane with the cytoplasm (equivalent to the mitochondrial matrix) above and the periplasm (intermembrane space) below. The 16 different subunits (subunits Nqo15 and Nqo16 are specific for thermophiles), which have a total of 64 transmembrane helices, are drawn in ribbon form in different colors with the 110-Å-long horizontal C-terminal helix of subunit Nqo12 magenta. The two [Fe-S] and seven [4Fe-4S] clusters in the peripheral (cytoplasmic) arm are drawn in space-filling form with S yellow and Fe red-brown. The bound

FMN, the entry point for the CoQ binding cavity (Q), the [4Fe-4S] cluster named N2, and the approximate position of the membrane are indicated. (b) The arrangement of the redox groups in Complex I as viewed from the back of Part a. The NADH, FMN, and ubiquinone (UQ) are drawn in stick form with NADH C magenta, FMN C green, UQ C violet, N blue, O red, and P orange. The center-to-center distances of neighboring redox centers are given in Ångströms (the shortest edge-to-edge distances are indicated in parentheses). Blue arrows represent the ~94-Å-long main path of electrons from FMN to ubiquinone. PDBid 4HEA.

plasma membrane (equivalent to the inner mitochondrial membrane in eukaryotes) and the other extending into the cytoplasm (the mitochondrial matrix in eukaryotes). Proton translocation occurs in the 7-subunit membrane-embedded arm of the complex, whereas redox reactions take place in its 9-subunit peripheral arm. Cryo-EM studies indicate that the ~ 30 supernumerary (non-core) proteins in the mammalian Complex I are distributed in a cagelike fashion about the periphery of the 14-subunit core, where they likely have assembly, stabilizing, and regulatory roles, and possibly function as scaffoldings for other enzymatic activities.

Complex I Contains Multiple Coenzymes. Complex I contains one molecule of **flavin mononucleotide (FMN)**, a redox-active prosthetic group that differs from FAD only by the absence of the AMP group) and eight (in mammals), or nine or ten (in prokaryotes), **iron-sulfur clusters** (Fig. 18-9b). Iron-sulfur clusters occur as the prosthetic groups of **iron-sulfur proteins** (also called **nonheme iron proteins**). The two most common types, designated **[2Fe-2S]** and **[4Fe-4S]** clusters (*at left*), consist of equal numbers of iron and sulfide (S²⁻) ions and are both coordinated to four protein Cys sulfhydryl groups. Note that the Fe atoms in both types of clusters are each coordinated by four S atoms, which are more or less tetrahedrally disposed around the Fe.

Iron-sulfur clusters can undergo one-electron oxidation and reduction. *The oxidized and reduced states of all iron-sulfur clusters differ by one formal charge regardless of their number of Fe atoms.* This is because the Fe atoms in each cluster form a conjugated system and thus can have oxidation states between the normal +2 and +3 values for individual Fe ions.

FMN and CoQ can each adopt three oxidation states (Fig. 18-10). They are capable of accepting and donating either one or two electrons because their semiquinone forms are stable (these semiquinones are stable **free radicals**, molecules with an unpaired electron). FMN is tightly bound to proteins; however, CoQ has a hydrophobic tail that makes it soluble in the inner mitochondrial membrane's lipid bilayer. In mammals, this tail consists of 10 C₅ isoprenoid units (Section 9-1F) and hence the coenzyme is designated **Q₁₀**. In other organisms, CoQ may have only 6 (Q₆) or 8 (Q₈) isoprenoid units.

Electrons Follow a Multistep Path through Complex I. The 140-Å-high peripheral arm of the *T. thermophilus* Complex I (Fig. 18-9a) contains all of the enzyme's prosthetic redox centers: an FMN, seven [4Fe-4S] clusters, and two [2Fe-2S] clusters (Fig. 18-9b). The FMN is located at the bottom of a solvent-exposed cavity that presumably forms the NADH-binding site. The CoQ-binding site is located at the top of a 30-Å-long and narrow chamber, ~ 15 Å above the membrane surface and 12 Å from [4Fe-4S] cluster N2. Thus, to accept electrons from N2, the CoQ must diffuse out of the lipid bilayer and move to the top of this chamber.

The transit of electrons from NADH to CoQ presumably occurs by a step-wise mechanism, according to the reduction potential of the various redox centers in Complex I (Table 18-1). This process involves the transient reduction of each group as it binds electrons and its reoxidation when it passes the electrons to the next group. The spatial arrangement of the groups indicates the likely path of the electrons (Fig. 18-9b). Note that redox centers do not need to come into contact in order to transfer an electron. An electron's quantum mechanical properties enable it to quickly (in the microsecond range) "tunnel" (jump) between protein-embedded redox groups that are separated by less than ~ 14 Å. Because electron transfer rates decrease exponentially with the distance between redox centers (they exhibit an ~ 10 -fold decrease for each 1.7 Å increase in distance), electron transfers over distances longer than ~ 14 Å always involve chains of redox centers.

NADH can participate in only a two-electron transfer reaction. In contrast, the Fe-S clusters, as well as the cytochromes of Complex III (see below) to

FIG. 18-10 The oxidation states of FMN and coenzyme Q. Both (a) FMN and (b) coenzyme Q form stable semiquinone free-radical states.

which reduced CoQ passes its electrons, are capable of only one-electron reactions. *FMN* and *CoQ*, which can transfer one or two electrons at a time, therefore provide an electron conduit between the two-electron donor *NADH* and the one-electron acceptors. Thus, *NADH* reduces *FMN* in a two-electron reaction (formally, a hydride transfer), which in turn passes these electrons, one by one, through the “wire” of Fe–S clusters, to the *CoQ*.

Complex I Translocates Four Protons in Each Reaction Cycle. *As electrons are transferred between the redox centers of Complex I, four protons are translocated from the matrix to the intermembrane space.* This proton pumping is driven by conformational changes induced by changes in the redox state of the protein (see below). The conformational changes alter the *pK* values of ionizable side chains so that protons are taken up or released as electrons are transferred. Coupling between electron transport in the peripheral arm and proton pumping in the transmembrane arm requires communication over distances of up to ~ 200 Å.

Because a proton is simply an atomic nucleus, it cannot be transported across a membrane in the same way as ions such as Na^+ and K^+ . However, a proton can be translocated by “hopping” along a chain of hydrogen-bonded groups in a

transmembrane channel, just as it “jumps” between hydrogen-bonded water molecules in solution (Fig. 2-15). Such an arrangement of hydrogen-bonded groups in the protein, which may include water molecules, has been described as a **proton wire**. Complex I contains four proton wires that each pump one proton across the membrane for every pair of electrons that passes from NADH to CoQ (see below).

Bacteriorhodopsin Is a Model Proton Pump. An instructive model for proton-translocating complexes is bacteriorhodopsin, an integral membrane protein from *Halobacterium salinarium* that contains seven transmembrane helical segments surrounding a central polar channel (Fig. 9-22). Bacteriorhodopsin is a light-driven proton pump: It obtains the free energy required for pumping protons through the absorbance of light by its retinal prosthetic group. The retinal is linked to the protein via a protonated Schiff base to the side chain of Lys 216.

On absorbing light, the all-*trans*-retinal isomerizes to its 13-*cis* configuration:

This structural change initiates a sequence of protein conformational adjustments that restore the system to its ground state over a period of ~10 ms. These conformational changes alter the pK's of several amino acid side chains (Fig. 18-11). Specifically, the pK of Asp 85 increases so it can receive a proton from the Schiff base. Asp 85 then transfers the proton to the extracellular medium via a hydrogen-bonded network that includes Arg 82, Glu 194, Glu 204, and several water molecules. Water molecules also move into position to form a hydrogen-bonded network that reprotonates the Schiff base with an intracellular proton via Asp 96, whose pK decreases. The net result is that a proton appears to move from the cytosol to the cell exterior (the proton that leaves the cytosol is not the same proton that enters the extracellular space).

The various amino acid side chains involved in proton transport in bacteriorhodopsin move by ~1 Å or less, but this is enough to alter their pK values and to sequentially make and break hydrogen bonds so as to allow a proton to pass along the proton wire. The vectorial (one-way) nature of the process arises from the unidirectional series of conformational changes made by the photoexcited retinal as it relaxes to its ground state. The transfer of electrons from NADH to CoQ in Complex I motivates a similar sequence of conformational and pK changes (see below).

CoQ Reduction Mechanically Drives Proton Translocation. How does electron transfer motivate proton pumping in Complex I? The membrane-embedded arm of Complex I contains three subunits, Nqo12, Nqo13, and Nqo14, that resemble known Na⁺/H⁺ antiporters, each of which are postulated to form a proton translocation channel. The antiporterlike subunits, all of which are distant from the CoQ

FIG. 18-11 Proton translocation in bacteriorhodopsin. The retinal prosthetic group in Schiff base linkage to Lys 216 of the seven-transmembrane helix protein is shown in purple. The side chains of amino acids that participate in light-driven proton translocation are shown in stick form with C gray, N blue, and O red. The arrows with their associated numbers indicate the order of proton-transfer steps during the photochemical cycle: (1) deprotonation of the Schiff base and protonation of Asp 85; (2) proton release to the extracellular surface; (3) reprotonation of the Schiff base and deprotonation of Asp 96; (4) reprotonation of Asp 96 from the cytoplasmic surface; and (5) deprotonation of Asp 85 and reprotonation of the proton release site. FIG. 18-12 Schematic diagram of the proposed mechanism coupling proton translocation to the reduction of CoQ in Complex I. The subunits forming the membrane arm are colored and viewed similarly to those in Fig. 18-9a. The proton translocation channels are indicated by black arrows. The hydrophilic chain of charged and polar residues is represented by red arrows with the red and blue circles symbolizing Glu and Lys/His residues, respectively. The blue arrows are indicative of conformational changes around cluster N2. Helix HL assists in coordinating the conformational changes by linking the discontinuous transmembrane helices of the three antiports (Nqo12–14).

binding site, are linked to it by a chain of charged and polar residues (Fig. 18-12), including a “river” of water molecules, a most unusual assembly for the interior of a membrane. Two of the helices in each of the antiporterlike subunits have centrally located kinks that provide them with the conformational flexibility to open and close the proton translocation channels. Many of the charged residues in the hydrophilic chain are associated with these kinks and are therefore postulated to participate in the proton translocation process. A fourth proposed proton translocation channel is more directly associated with the CoQ binding site.

The foregoing observations led Sazanov to postulate the mechanism for proton translocation by Complex I delineated in Fig. 18-12. CoQ appears to fit so snugly into its binding site that when it is reduced by cluster N2 to CoQ^{2-} , it remains unprotonated until it dissociates from the protein. The added negative charges electrostatically induce conformational changes around the CoQ binding site that are transmitted to the proton translocation channels by the hydrophilic chain and possibly by the 110-Å-long, membrane embedded, C-terminal helix of subunit Nqo12 (HL in Fig. 18-12). This mechanically drives the conformational changes that result in the pK changes responsible for proton translocation, much as the coupling rods of a steam locomotive link its pistons to its drive wheels. The entire process of NADH reduction, electron transport, CoQ reduction, and proton translocation occurs ~ 200 times per second, the turnover rate of Complex I.

D Complex II Contributes Electrons to Coenzyme Q

Complex II (**succinate–coenzyme Q oxidoreductase**), which contains the citric acid cycle enzyme succinate dehydrogenase (Section 17-3F), passes electrons from succinate to CoQ. Its redox groups include succinate dehydrogenase’s covalently bound FAD (Fig. 17-13) to which electrons are initially passed, one [4Fe–4S] cluster, a [3Fe–4S] cluster (essentially a [4Fe–4S] complex that lacks one Fe atom), one [2Fe–2S] cluster, and one **cytochrome b_{560}** (cytochromes are discussed in Box 18-1). All of its four subunits are encoded by nuclear genes.

The free energy for electron transfer from succinate to CoQ (Fig. 18-7) is insufficient to drive ATP synthesis. The complex is nevertheless important because it allows relatively high-potential electrons to enter the electron-transport chain by bypassing Complex I.

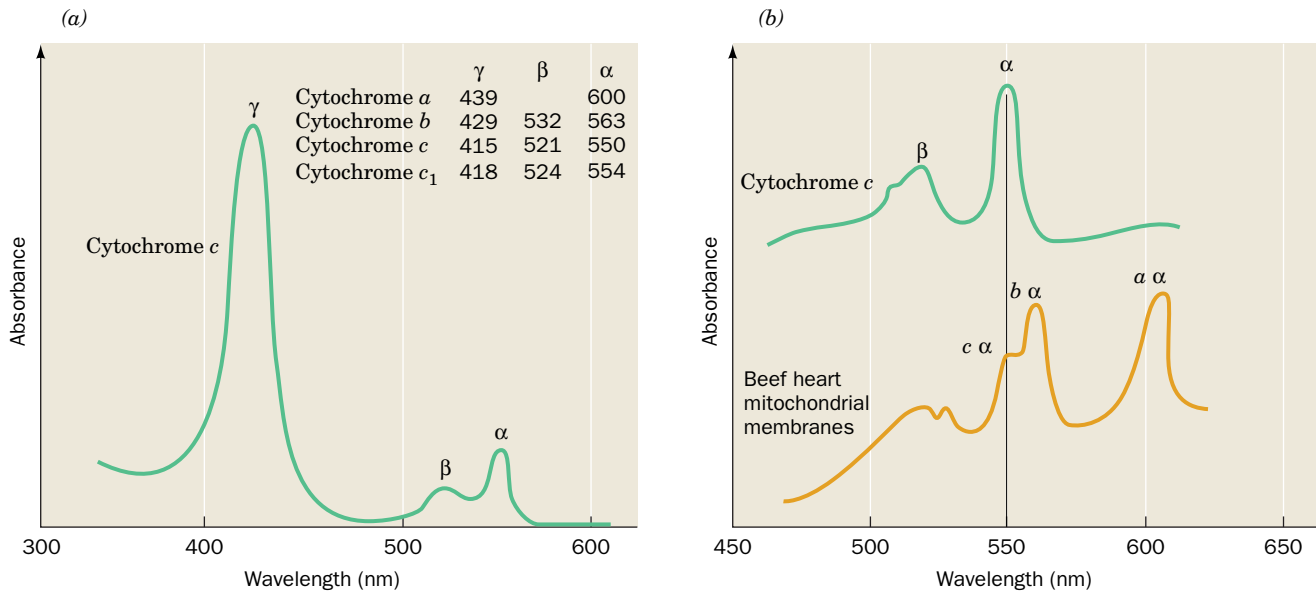

Note that Complexes I and II, despite their names, do not operate in series. But both accomplish the same result: the transfer of electrons to CoQ from reduced substrates (NADH or succinate). *CoQ, which diffuses in the lipid bilayer among the respiratory complexes, therefore serves as a sort of electron collector.* As we will see in Section 20-2C, the first step in fatty acid oxidation also generates electrons that enter the electron-transport chain at the level of CoQ. CoQ also

Cytochromes, whose function was elucidated in 1925 by David Keilin, are redox-active proteins that occur in all organisms except a few types of obligate anaerobes. These proteins contain heme groups that alternate between their Fe(II) and Fe(III) oxidation states during electron transport.

The heme groups of the reduced Fe(II) cytochromes have prominent visible absorption spectra consisting of three peaks: the α , β , and γ (**Soret**) bands. The spectrum for cytochrome *c* is shown in Fig. *a*. The wavelength of the α peak, which varies characteristically with the reduced cytochrome species (it is absent in oxidized cytochromes), is used to differentiate the various cytochromes in mitochondrial membranes (top right of Fig. *a* and Fig. *b*).

Each group of cytochromes contains a differently substituted heme group coordinated with the redox-active iron atom. The *b*-type cytochromes contain **protoporphyrin IX**, which also occurs in myoglobin and hemoglobin (Section 7-1A). The heme group of *c*-type cytochromes differs from protoporphyrin IX in that its vinyl groups have added Cys sulfhydryls across their double bonds to form thioether linkages to the protein. Heme *a* contains a long hydrophobic tail of isoprene units attached to the porphyrin, as well as a formyl group in place of a methyl substituent in hemes *b* and *c*. The axial ligands of the heme iron also vary with the cytochrome type. In cytochromes *a* and *b*, both ligands are His residues, whereas in cytochromes *c*, one is His and the other is the S atom of Met.

collects electrons from the FADH_2 produced by the glycerophosphate shuttle (Fig. 18-5) and from pyrimidine biosynthesis (Section 23-2A).

Complex II Contains a Linear Chain of Redox Cofactors. The X-ray structure of chicken mitochondrial Complex II has been determined (Fig. 18-13). Complex II is a mushroom-shaped homotrimer whose protomers each consist of two hydrophilic subunits, a flavoprotein (**Fp**) and an iron–sulfur subunit (**Ip**), that project into the mitochondrial matrix, and two hydrophobic membrane-anchor subunits, **CybL** and **CybS**, which each have three transmembrane helices and which collectively bind one *b*-type heme and one ubiquinone. All of them are encoded by nuclear genes. Fp binds both the substrate (whose binding site in the X-ray structure is occupied by the inhibitor oxaloacetate) and the FAD prosthetic group, whereas Ip binds the complex's three iron–sulfur clusters. The substrate- and ubiquinone-binding sites are connected by a $>40\text{-\AA}$ -long chain of redox centers with the sequence substrate—FAD—[2Fe–2S]—[4Fe–4S]—[3Fe–4S]—CoQ (top to bottom in Fig. 18-13). The heme *b*, which is not located in this direct electron-transfer pathway, apparently fine-tunes the system's electronic properties so as to suppress side reactions that form damaging **reactive oxygen species** such as H_2O_2 (Section 18-4B). The [2Fe–2S] cluster labeled N1a in Complex I (Fig. 18-9b) may have a similar role.

E Complex III Translocates Protons via the Q Cycle

Complex III (also known as **coenzyme Q–cytochrome *c* oxidoreductase** or **cytochrome *bc*₁**) passes electrons from reduced CoQ to cytochrome *c*. It contains two *b*-type cytochromes, one cytochrome *c*₁, and one [2Fe–2S] cluster in

Within each group of cytochromes, different heme group environments may be characterized by slightly different α peak wavelengths. For this reason, it is convenient to identify cytochromes by the wavelength (in nanometers) at which its α band absorbance is maximal (e.g., cytochrome b_{560} in Complex II). Cytochromes are also identified nondescriptively with either numbers or letters.

Reduced heme groups are highly reactive entities; they can transfer electrons over distances of 10 to 20 Å at physiologically significant rates. Hence cytochromes, in a sense, have the opposite function of

enzymes: Instead of persuading unreactive substrates to react, they must prevent their hemes from transferring electrons nonspecifically to other cellular components. This, no doubt, is why the hemes are almost entirely enveloped by protein. However, cytochromes must also provide a path for electron transfer to an appropriate partner. Since electron transfer occurs far more efficiently through bonds than through space, protein structure appears to be an important determinant of the rate of electron transfer between proteins.

which one of the Fe atoms is coordinated by two His residues rather than two Cys residues (and which is known as a **Rieske center** after its discoverer, John Rieske). Complex III from yeast mitochondria is a 419-kD homodimer whose protomers each consist of 9 subunits (11 in the 485-kD bovine heart mitochondrial Complex III). Its X-ray structure (Fig. 18-14) reveals a pear-shaped homodimer whose widest part extends ~ 75 Å into the mitochondrial matrix. The ~ 40 -Å-thick transmembrane portion consists of 12 transmembrane helices per protomer (14 in bovine heart Complex III), most of which are tilted with respect to the plane of the membrane. Eight of the helices belong to the **cytochrome *b*** subunit, which binds both *b*-type cytochrome hemes, b_{562} (or b_H , for high potential, which lies near the matrix) and b_{566} (or b_L , for low potential, which lies near the intermembrane space), and is the only subunit encoded by a mitochondrial gene. The cytochrome c_1 subunit is anchored by a single transmembrane helix, with its globular head, which contains a *c*-type heme, extending into the intermembrane space. The **iron-sulfur protein (ISP)**, which contains the Rieske center, is similarly anchored by a single transmembrane helix and extends into the intermembrane space. The two ISPs of the dimeric complex are intertwined so that the [2Fe-2S] cluster in the ISP of one protomer interacts with the cytochrome *b* and cytochrome c_1 subunits of the other protomer.

The Q cycle

Electrons from Coenzyme Q Follow Two Paths. Complex III functions to permit one molecule of CoQH_2 , a two-electron carrier, to reduce two molecules of cytochrome *c*, a one-electron carrier. This occurs by a surprising bifurcation of the flow of electrons from CoQH_2 to cytochrome c_1 and to cytochrome *b* (in which, as we shall see, the flow is cyclic). It is this so-called **Q cycle** that permits Complex III to pump protons from the matrix to the intermembrane space.

The essence of the Q cycle is that *CoQH*₂ undergoes a two-cycle reoxidation in which the semiquinone, CoQ^\cdot , is a stable intermediate. This involves two independent binding sites for coenzyme Q: Q_o , which binds CoQH_2 and is located between the Rieske [2Fe-2S] center and heme b_L in proximity to the intermembrane space; and Q_i , which binds both CoQ^\cdot and CoQ and is located near heme b_H in proximity to the matrix. In the first cycle (Fig. 18-15, top), CoQH_2 from Complex I (1 and 2) binds to the Q_o site, where it transfers one of its electrons to the ISP (3), releasing its two protons into the intermembrane space and yielding CoQ^\cdot . The ISP goes on to reduce cytochrome c_1 , whereas the CoQ^\cdot transfers its remaining electron to cytochrome b_L (4), yielding fully oxidized CoQ . Cytochrome b_L then reduces cytochrome b_H (6).

FIG. 18-14 X-Ray structure of yeast Complex III in complex with cytochrome *c* and the inhibitor stigmatellin.

The homodimeric complex is viewed from within the plane of the membrane with the intermembrane space above. The nine different subunits in each protomer, which collectively have 12 transmembrane helices, are differently colored with cytochrome *b* pale yellow, cytochrome c_1 light purple, the ISP tan, and cytochrome *c* pink. The portions of the protein that extend into the matrix are colored cyan and orange. The four different heme groups, the [2Fe-2S] cluster, and stigmatellin are drawn in space-filling form with heme C green, stigmatellin C magenta, N blue, O red, S yellow, and Fe red-brown. The horizontal lines delineate the inferred position of the membrane. Note that only one cytochrome *c* is bound to the homodimeric Complex III. [Based on an X-ray structure by Carola Hunte, Max Planck Institute for Biophysics, Frankfurt am Main, Germany. PDBid 1KY0.]

FIG. 18-15 The Q cycle. The Q cycle, which is mediated by Complex III, results in the translocation of H⁺ from the matrix to the intermembrane space as driven by the transport of electrons from cytochrome *b* to cytochrome *c*. The overall cycle is actually two cycles, the first requiring Reactions 1 through 7 and the second requiring Reactions 1 through 6 and 8. (1) Coenzyme QH₂ is supplied by Complex I on the matrix side of the membrane. (2) QH₂ diffuses to the cytosolic side of the membrane, where it binds in the Q_o site on the cytochrome *b* subunit of Complex III. (3) QH₂ reduces the Rieske iron-sulfur protein (ISP), forming Q• semiquinone and releasing 2 H⁺. The ISP goes on to reduce heme c₁. (4) Q• reduces heme b_L to form coenzyme Q. (5) Q diffuses to the matrix side, where, in Cycle 1 only, it binds in the Q_i site on cytochrome *b*. (6) Heme b_L reduces heme b_H. (7, Cycle 1 only) Q is reduced to Q• by heme b_H. (8, Cycle 2 only) Q• bound in the Q_i site is reduced to QH₂ by heme b_H. The net reaction is the transfer of two electrons from QH₂ to cytochrome c₁ and the translocation of four protons from the matrix to the intermembrane space. [After Trumpower, B.L., *J. Biol. Chem.* **265**, 11410 (1990).]

? Write an equation for Cycle 1 and Cycle 2.

The CoQ from Step 4 is released from the Q_o site and rebinds to the Q_i site (5), where it picks up the electron from cytochrome b_H (7), reverting to the semiquinone form, CoQ•. Thus, the reaction for the first cycle is

In the second cycle (Fig. 18-15, *bottom*), another CoQH₂ from Complex I repeats Steps 1 through 6: One electron reduces the ISP and then cytochrome c₁, and the other electron sequentially reduces cytochrome b_L and then cytochrome b_H. This second electron then reduces the CoQ• at the Q_i site produced in the first cycle (8), yielding CoQH₂. The protons consumed in this last step originate in the mitochondrial matrix. The reaction for the second cycle is therefore

For every two CoQH₂ that enter the Q cycle, one CoQH₂ is regenerated. The combination of both cycles, in which two electrons are transferred from CoQH₂ to cytochrome c₁, results in the overall reaction

How does the structure of Complex III support the operation of the Q cycle? First, X-ray studies provide direct evidence for the independent existence of the Q_o and Q_i sites. The antifungal agent **stigmatellin**,

which is known to inhibit electron flow from CoQH_2 to the ISP and to heme b_L (Steps 3 and 4 of both cycles), binds in a pocket within cytochrome b midway between the iron positions of the Rieske [$2\text{Fe}-2\text{S}$] center and heme b_L . Thus, this binding pocket is likely to overlap the Q_o site. Similarly, antimycin A (Section 18-2B), which has been shown to block electron flow from heme b_H to CoQ or CoQ^- (Step 7 of Cycle 1 and Step 8 of Cycle 2), binds in a pocket near heme b_H , thereby identifying this pocket as site Q_i .

The circuitous route of electron transfer in Complex III is tied to the ability of coenzyme Q to diffuse within the hydrophobic core of the membrane in order to bind to both the Q_o and Q_i sites. In fact, the mitochondrial membrane likely contains a pool of CoQ , CoQ^- , and CoQH_2 , so the ubiquinone molecule released from the Q_o site may not be the same one that rebinds to the Q_i site in Cycle 1 (Fig. 18-15).

X-Ray structures of cytochrome bc_1 also explain why Q_o -bound CoQ^- exclusively reduces heme b_L rather than the Rieske [$2\text{Fe}-2\text{S}$] cluster of the ISP, despite the greater reduction potential difference ($\Delta\mathcal{E}$) favoring the latter reaction (Table 18-1). The globular domain of the ISP can swing via an $\sim 20\text{-\AA}$ hinge motion between the Q_o site and cytochrome c_1 . Consequently, the ISP acquires an electron from CoQH_2 in the Q_o site and mechanically delivers it to the heme c_1 group. The CoQ^- product cannot reduce the ISP (after it has reduced cytochrome c_1) because the ISP has moved too far away for this to occur.

The net reaction for the Q cycle indicates that when CoQH_2 is oxidized, two reduced cytochrome c molecules and four protons appear on the outer side of the membrane. Proton transport by the Q cycle thus differs from the proton-pumping mechanism of Complexes I and IV (see below): In the Q cycle, a redox center itself (CoQ) is the proton carrier.

Cytochrome c Is a Soluble Electron Carrier. The electrons that flow to cytochrome c_1 are transferred to cytochrome c , which, unlike the other cytochromes of the respiratory electron-transport chain, is soluble in the intermembrane space. It shuttles electrons between the portions of Complexes III and IV that project above the outer surface of the inner mitochondrial membrane. The evolution and structure of cytochrome c are discussed in Sections 5-4A and 6-2D. Several highly conserved Lys residues in cytochrome c lie in a ring around the exposed edge of its otherwise buried heme group (Fig. 18-16). These positively charged residues constitute binding sites for complementary negatively charged groups on cytochrome c_1 and cytochrome c oxidase. Such interactions presumably serve to align redox groups for optimal electron transfer.

The X-ray structure shown in Fig. 18-14 reveals that the association between cytochrome bc_1 and cytochrome c is particularly tenuous, because its interfacial area (880 \AA^2) is significantly less than that exhibited by protein-protein complexes known to have low stability (typically $< 1600 \text{ \AA}^2$). Such a small interface is well suited for fast binding and release. This interface involves only two cytochrome c Lys residues, Lys 86 and Lys 79 (vertebrate numbering; Table 5-6), which, respectively, contact Glu 235 and Ala 164 of cytochrome c_1 . Other pairs of charged and often conserved residues surround the contact site but they are not

FIG. 18-16 Ribbon diagram of cytochrome c showing the Lys residues involved in intermolecular complex formation. Dark and light blue balls, respectively, mark the position of Lys residues whose ϵ -amino groups are strongly and less strongly protected by cytochrome c_1 or cytochrome c oxidase against acetylation. Note that the Lys residues form a ring around the heme (solid bar) on one face of the protein. [After Mathews, F.S., *Prog. Biophys. Mol. Biol.* **45**, 45 (1986).]

network involving amino acid side chains, the polypeptide backbone, and the propionate side chains of the heme groups.

Cytochrome *c* Oxidase Catalyzes a Four-Electron Redox Reaction. The reduction of O_2 to $2 H_2O$ by cytochrome *c* oxidase takes place at the cytochrome a_3 - Cu_B binuclear complex and requires the nearly simultaneous input of four electrons. However, the fully reduced $Fe(II)$ - $Cu(I)$ binuclear complex can readily contribute only three electrons to its bound O_2 in reaching its fully oxidized $Fe(IV)$ - $Cu(II)$ state [cytochrome a_3 assumes its $Fe(IV)$ or **ferryl** oxidation state during the reduction of O_2 ; see below]. What is the source of the fourth electron?

X-Ray structures of cytochrome *c* oxidase clearly indicate that the His 240 ligand of Cu_B is covalently bonded to the side chain of a conserved Tyr residue (Tyr 244; Fig. 18-18, *lower right*). This places the Tyr phenolic $-OH$ group close to the heme a_3 -ligated O_2 such that *Tyr 244 can supply the fourth electron by transiently forming a tyrosyl radical* ($TyrO\cdot$). Tyrosyl radicals have been implicated in several other enzyme-mediated redox processes, including the generation of O_2 from H_2O in photosynthesis (Section 19-2C) and in the **ribonucleotide reductase** reaction (which converts NDP to dNDP; Section 23-3A). In cytochrome *c* oxidase, the Tyr phenolic $-OH$ group is within hydrogen-bonding distance of the enzyme-bound O_2 and hence is a likely H^+ donor during $O-O$ bond cleavage. The formation of the covalent cross-link is expected to lower both the reduction potential and the pK of Tyr 244, thereby facilitating both radical formation and proton donation.

A proposed reaction sequence for cytochrome *c* oxidase, which was elucidated through the use of a variety of spectroscopic techniques, is shown in **Fig. 18-19**:

- 1 and 2.** The O (for oxidized) state binuclear complex [$Fe(III)_{a_3}-OH-H_2O-Cu(II)_B$], in which Tyr 244 is in its phenolate state ($Y-O^-$), is reduced by two consecutive one-electron transfers from cytochrome *c* via Cu_A and cytochrome *a*, each accompanied by the acquisition of a proton from the matrix and the release of an H_2O . This yields the R (for reduced) complex [$Fe(II) Cu(I)$] in which Tyr 244 has assumed its phenolic state ($Y-OH$).
- 3.** O_2 binds to the R state binuclear complex so as to ligand its $Fe(II)_{a_3}$ atom. It binds to the heme with much the same configuration it has in oxymyoglobin (Fig. 7-3). Tyr 244 remains in its phenolic state.
- 4.** Internal electron redistribution rapidly yields the oxyferryl complex [$Fe(IV)=O^{2-} HO^- -Cu(II)$] in which Tyr 244 has donated

FIG. 18-19 Proposed reaction sequence for cytochrome *c* oxidase. A total of four electrons ultimately donated by four cytochrome *c* molecules, together with four protons, are required to reduce O_2 to H_2O at the cytochrome a_3 - Cu_B binuclear complex. The numbered steps are discussed in the text. The entire reaction is extremely fast; it goes to completion in ~ 1 ms at room temperature. [Modified from Babcock, G.T., *Proc. Natl. Acad. Sci.* **96**, 12971 (1999).]

? How does Tyr 244 function in the reduction of O_2 ?

an electron and a proton to the complex and thereby assumed its neutral radical state ($Y-O\cdot$). This is known as the P state because it was once thought to be a *peroxy* compound.

5. A third one-electron transfer from cytochrome *c*, together with the acquisition of a proton from the matrix, converts Tyr 244 to its phenolate state ($Y-O^-$), yielding the F (for *ferryl*) state in which an H_2O remains liganded to $Cu(II)_B$.
6. A fourth and final electron transfer and proton acquisition again yields the O state [$Fe(III)_{a3}-OH^- H_2O-Cu(II)_B$], thereby completing the catalytic cycle.

Cytochrome *c* Oxidase Has Two Proton-Translocating Channels. The reaction catalyzed by cytochrome *c* oxidase contributes to the transmembrane proton gradient in two ways. First, four so-called **chemical** or **scalar** protons are taken up from the matrix during the reduction of O_2 by cytochrome *c* oxidase to yield $2 H_2O$, thereby depleting the matrix $[H^+]$. Second, the four-electron reduction reaction is coupled to the translocation of four so-called **pumped** or **vectorial** protons from the matrix to the intermembrane space, one each in steps 3, 4, 5, and 6 of Fig. 18-19. Note that for each turnover of the enzyme,

a total of eight positive charges are lost from the matrix, thus contributing to the membrane potential difference that drives ATP synthesis (Section 18-3).

X-Ray structures of cytochrome *c* oxidase reveal the presence of two channels that lead from the matrix to the vicinity of the O_2 -reducing center, which could potentially transport protons via a proton wire mechanism. The **K-channel** (so named because it contains an essential Lys residue) leads from the matrix side of the protein to Tyr 244, the residue that forms a free radical as described above. Since this channel does not appear to be connected to the intermembrane space, it is thought to supply the first two chemical protons for O_2 reduction (steps 1 and 2 of Fig. 18-19). The **D-channel** (named for a key Asp residue) extends from the matrix to the vicinity of the heme a_3-Cu_B center, where it connects to the so-called **exit channel**, which communicates with the intermembrane space. Apparently, the D-channel, in series with the exit channel, functions to pump vectorial protons from the matrix to the intermembrane space. Moreover, the D-channel also functions as a conduit for the other two chemical protons that are required for the reaction cycle (steps 5 and 6 of Fig. 18-19). Despite the foregoing, the mechanism that couples O_2 reduction to proton pumping in Complex IV remains largely an enigma.

CHECKPOINT

- Describe the route followed by electrons from glucose to O_2 .
- Write the net equation for electron transfer from NADH to O_2 .
- Assuming 100% efficiency, calculate the maximum amount of ATP that could be synthesized as a result.
- For each of the electron-transport complexes, write the relevant redox half-reactions.
- Position the four electron-transport complexes on a graph showing their relative reduction potentials, and indicate the path of electron flow.
- How did inhibitors reveal the order of electron transport?
- List the types of prosthetic groups in Complexes I, II, III, and IV and state whether they are one- or two-electron carriers.
- What does the Q cycle accomplish in each of its two rounds?
- Describe the different mechanisms for translocating protons during electron transport.
- What is the significance of the Tyr radical in cytochrome *c* oxidase?

3 Oxidative Phosphorylation

KEY CONCEPTS

- The chemiosmotic theory explains how a proton gradient links electron transport to ATP synthesis.
- ATP synthase consists of an F_1 component that catalyzes ATP synthesis by a binding change mechanism.
- The F_0 component of ATP synthase includes a *c*-ring whose rotation is driven by the dissipation of the proton gradient and drives conformational changes in the F_1 component.
- For every two electrons that enter the electron-transport chain as NADH and reduce one oxygen atom, approximately 2.5 ATP molecules are produced, giving a P/O ratio of 2.5.
- Agents that dissipate the proton gradient can uncouple electron transport and ATP synthesis.

The endergonic synthesis of ATP from ADP and P_i in mitochondria is catalyzed by an **ATP synthase** (also known as **Complex V**) that is driven by the electron-transport process. *The free energy released by electron transport through Complexes I–IV must be conserved in a form that the ATP synthase can use.* Such energy conservation is referred to as **energy coupling**.

The physical characterization of energy coupling proved to be surprisingly elusive; many sensible and often ingenious ideas failed to withstand the test of experimental scrutiny. For example, one theory—now abandoned—was that electron transport yields a “high-energy” intermediate, such as phosphoenolpyruvate (PEP) in glycolysis (Section 15-2J), whose subsequent breakdown drives ATP synthesis. No such intermediate has ever been identified. In fact, ATP synthesis is coupled to electron transport through the production of a transmembrane proton gradient during electron transport by Complexes I, III, and IV. In this section, we explore this coupling mechanism and the operation of ATP synthase.

A The Chemiosmotic Theory Links Electron Transport to ATP Synthesis

The **chemiosmotic theory**, proposed in 1961 by Peter Mitchell, spurred considerable controversy before becoming widely accepted (Box 18-2). Mitchell’s theory states that *the free energy of electron transport is conserved by pumping H^+ from the mitochondrial matrix to the intermembrane space to create an electrochemical H^+ gradient across the inner mitochondrial membrane. The electrochemical potential of this gradient is harnessed to synthesize ATP (Fig. 18-20).* Several key observations are explained by the chemiosmotic theory:

1. Oxidative phosphorylation requires an intact inner mitochondrial membrane.
2. The inner mitochondrial membrane is impermeable to ions such as H^+ , OH^- , K^+ , and Cl^- , whose free diffusion would discharge an electrochemical gradient.
3. Electron transport results in the transport of H^+ out of intact mitochondria (the intermembrane space is equivalent to the cytosol), thereby creating a measurable electrochemical gradient across the inner mitochondrial membrane.

FIG. 18-20 The coupling of electron transport and ATP synthesis. Electron transport (blue arrow) generates a proton electrochemical gradient across the inner mitochondrial membrane. H^+ is pumped out of the mitochondrion during electron transport (red arrows) and its exergonic return powers the synthesis of ATP (green

arrows). Note that the intermembrane space is topologically equivalent to the cytosol because the outer mitochondrial membrane is permeable to H^+ . **WPLS** See the Animated Figures.

? Write an equation to describe the chemical events shown here.

Peter Mitchell (1920–1992) One of the most dramatic paradigm shifts in biochemistry came about through the work of Peter Mitchell, whose chemiosmotic hypothesis linked biological electron transport to ATP synthesis. Mitchell was primarily a theoretical biochemist, although he also generated experimental data to support his hypothesis. He once compared the human mind to a garden planted with facts and ideas

that are constantly being rearranged. However, he promoted his own ideas, which were highly controversial, with great tenacity and very little flexibility.

Mitchell graduated from the University of Cambridge in 1942 and conducted research there, laying the groundwork for the chemiosmotic theory. Mitchell continued his work after 1955 at the University of Edinburgh. He was captivated by the idea of compartmentation in living cells and by the vectorial, or one-way, aspect of metabolic processes. Initially, he chose to study phosphate transport in bacteria because this process was linked both to metabolism and to transmembrane transport. He realized that the vectorial nature of membrane transport must be due to the presence of membrane-associated systems that were driven by chemical forces.

Mitchell also became interested in the respiratory chain, an idea formulated by David Keilin at Cambridge, because this too was a clearly vectorial biological phenomenon. Mitchell reasoned that there must be enzymes that, like transporters, convert a substrate on one side of a membrane to a product on the other side. Other researchers had already discovered that the activity of the respiratory chain generated a pH gradient. Mitchell's genius was to explain how the pH gradient could drive ATP synthesis. In his seminal paper of 1961, Mitchell proposed that the respiratory chain, associated with the cristae in the mitochondrion, generates a protonmotive force due to electrical and pH differences across the membrane. This force drives an ATPase, working in reverse, to catalyze the condensation of phosphate with ADP to produce ATP.

Mitchell's hypothesis, elegant as it was, met strong resistance from other biochemists for several reasons. First, chemiosmosis was a theoretical notion without direct experimental evidence. Second, the study of oxidative phosphorylation was dominated by a few powerful laboratories that were not inclined to welcome new theories. In particular, metabolic studies since the mid-1940s had been focused on the activities of soluble enzymes. Mitchell's theory was not a product of this classic biochemical approach but instead came through an understanding of membrane physiology. Furthermore, the prevailing theories about the

connection between electron transport and ATP synthesis centered on a phosphorylated compound as a high-energy intermediate. Fritz Lipmann (Box 14-2) had proposed that a high-energy phosphate group might become attached to some component of the respiratory chain. This hypothesis was later amended to invoke a soluble phosphorylated intermediate. The search for the elusive compound lasted some 20 years, and the investment of time and money may have made some researchers hesitant to abandon the theory in favor of Mitchell's seemingly outrageous proposal. In the meantime, a third theory was proposed, in which electron transport was coupled to ATP synthesis through protein conformational changes, with the observed pH gradient presumed to be simply a by-product of the process.

Mitchell's chemiosmotic hypothesis did not garner significant support until about 10 years after its publication. During this period of sometimes acrimonious debate, Mitchell became ill, moved to Cornwall, and renovated a manor house, part of which became a private laboratory, known as Glynn Research, that was funded by Mitchell's family fortune. Here, he and his lifelong collaborator, Jennifer Moyle, produced experimental evidence to support the chemiosmotic theory. Ultimately, Mitchell was proven correct by other researchers who demonstrated the proton-pumping activity of purified mitochondrial components reconstituted in liposomes. Mitchell was awarded a Nobel Prize in Chemistry in 1978.

Mitchell succeeded in changing the prevailing views of a central feature of aerobic metabolism, although it was a long battle. He later expressed sadness that his work was taken for granted, as if it had been "self-evident from the beginning." Oddly, Mitchell stubbornly resisted altering any of his own ideas. For example, he never wavered in his belief that protons participate directly in ADP phosphorylation in the active site of ATP synthase. And for many years, Mitchell refused to acknowledge proton pumping (as we now know occurs in Complexes I and IV). Instead, he insisted that the source of the proton gradient was a "redox loop" in which two electrons are transferred from the positive to the negative side of the membrane and combine with two protons to reduce a quinone to a quinol. The quinol then diffuses back across the bilayer to be reoxidized at the positive side, where the protons are released. The redox loop mechanism, which requires two "active sites," does occur during the Q cycle in mitochondrial Complex III and in certain bacterial systems, but it cannot account for the entire protonmotive force that is the heart of the chemiosmotic mechanism.

Mitchell, P., Coupling of phosphorylation to electron and hydrogen transfer by a chemiosmotic type of mechanism, *Nature* **191**, 144–148 (1961).

Prebble, J., Peter Mitchell and the ox phos wars, *Trends Biochem. Sci.* **27**, 209–212 (2002).

4. Compounds that increase the permeability of the inner mitochondrial membrane to protons, and thereby dissipate the electrochemical gradient, allow electron transport (from NADH and succinate oxidation) to continue but inhibit ATP synthesis; that is, they "uncouple" electron transport from oxidative phosphorylation. Conversely, increasing the acidity outside the inner mitochondrial membrane stimulates ATP synthesis.

An entirely analogous process occurs in bacteria, whose electron-transporting machinery is located in their plasma membranes (Box 18-3).

Electron Transport Generates a Proton Gradient. *Electron transport, as we have seen, causes Complexes I, III, and IV to transport protons across the inner mitochondrial membrane from the matrix, a region of low $[H^+]$, to the intermembrane space (which is in contact with the cytosol), a region of high $[H^+]$*

It comes as no surprise that aerobic bacteria (such as those pictured below), whose ancestors gave rise to mitochondria, use similar machinery to oxidize reduced coenzymes and conserve their energy in ATP synthesis. In bacteria, the components of the respiratory electron-transport chain are located in the plasma membrane, and protons are pumped from the cytosol to the outside of the plasma membrane. Protons flow back into the cell via an ATP synthase, whose catalytic component is oriented toward the cytosol. This is exactly the arrangement expected if bacteria and mitochondria are evolutionarily related.

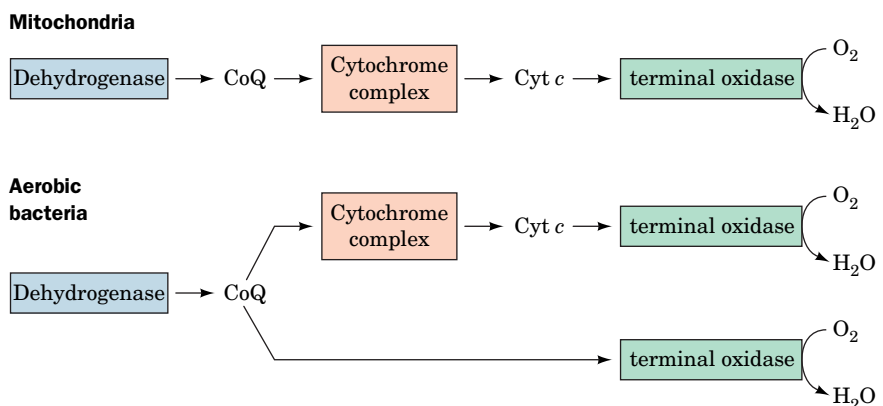

The oxidation of CoQH_2 is universal in aerobic organisms. In mitochondria, CoQ collects electrons donated by NADH (via Complex I), succinate (via Complex II), and fatty acids. In aerobic bacteria, CoQ is the collection point for electrons extracted by dehydrogenases specific for a wide variety of substrates. In bacteria, as in mitochondria, electrons flow from CoQ through cytochrome-based oxidoreductases before reaching O_2 (below, right). In some species, two protein complexes (analogous to mitochondrial Complexes III and IV) carry out this process. In other species, including *E. coli*, a single type of enzyme, **quinol oxidase**, uses the electrons donated by CoQ to reduce O_2 .

The advantage of a multicomplex electron-transport pathway is that it affords more opportunities for proton translocation across the bacterial membrane, so the ATP yield per electron is greater. However, the shorter electron-transport pathways may confer a selective advantage in the presence of toxins that inactivate the bacterial counterpart of mitochondrial Complex III. Multiple routes for electron transport probably also allow bacteria to adjust oxidative phosphorylation to the availability of different energy sources and to balance ATP synthesis against the regeneration of various reduced coenzymes. For example, in facultative anaerobic bacteria (which can grow in either the absence or presence of O_2), when energy needs are met through anaerobic fermentation, electron transport can be adjusted to regenerate NAD^+ without synthesizing ATP by oxidative phosphorylation.

A variety of cytochrome-containing protein complexes occur in bacterial plasma membranes. Some of these proteins represent more streamlined versions of the mitochondrial complexes since they lack the additional subunits encoded by the nuclear genome of eukaryotes. However, this is not a universal feature of respiratory complexes, and many bacterial proteins (e.g., **cytochrome d**) have no counterparts encoded by either the mitochondrial or nuclear genomes.

Staphylococcus aureus.

(Fig. 18-8). The free energy sequestered by the resulting electrochemical gradient (also called the **protonmotive force; pmf**) powers ATP synthesis.

The free energy change of transporting a proton from one side of the membrane to the other has a chemical as well as an electrical component, since H^+ is an ion (Section 10-1). ΔG is therefore expressed by Eq. 10-3, which in terms of pH is

$$\Delta G = 2.3 RT [\text{pH} (\textit{side 1}) - \text{pH} (\textit{side 2})] + Z\mathcal{F}\Delta\Psi \quad [18-1]$$

where Z is the charge on the proton (including sign), \mathcal{F} is the Faraday constant, and $\Delta\Psi$ is the membrane potential. The sign convention for $\Delta\Psi$ is that when a proton is transported from a negative region to a positive region, $\Delta\Psi$ is positive. Since the pH outside the mitochondrion (*side 2*) is less than the pH of the matrix (*side 1*), the export of protons from the mitochondrial matrix (against the proton gradient) is an endergonic process.

SAMPLE CALCULATION 18-1

Calculate the free energy change for transporting a proton out of the mitochondrial matrix when the matrix pH is 8 and the cytosolic pH is 7. Assume that $\Delta\Psi = 0.168$ V (inside negative) and $T = 37^\circ\text{C}$.

Use Equation 18-1:

$$\Delta G = 2.3 RT [\text{pH}(\text{side } 1) - \text{pH}(\text{side } 2)] + Z\mathcal{F}\Delta\Psi$$

$$\begin{aligned}\Delta G &= 2.3(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K})(8 - 7) + \\ &\quad (1)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(0.168 \text{ V}) \\ &= 5900 \text{ J} \cdot \text{mol}^{-1} + 16,200 \text{ J} \cdot \text{mol}^{-1} \\ &= 22,100 \text{ J} \cdot \text{mol}^{-1} = 22.1 \text{ kJ} \cdot \text{mol}^{-1}\end{aligned}$$

WPLS See Sample Calculation Videos

The measured membrane potential across the inner membrane of a liver mitochondrion, for example, is 0.168 V (inside negative). The pH of its matrix is 0.75 units higher than that of its intermembrane space. ΔG for proton transport out of this mitochondrial matrix is therefore $21.5 \text{ kJ} \cdot \text{mol}^{-1}$ (see Sample Calculation 18-1). Because formation of the proton gradient is an endergonic process, discharge of the gradient is exergonic. This free energy is harnessed by ATP synthase to drive the phosphorylation of ADP.

An ATP molecule's estimated physiological free energy of synthesis, around $+40$ to $+50 \text{ kJ} \cdot \text{mol}^{-1}$, is too large for ATP synthesis to be driven by the passage of a single proton back into the mitochondrial matrix; at least two protons are required. In fact, most experimental measurements (which are difficult to quantitate precisely) indicate that around three protons are required per ATP synthesized.

B ATP Synthase Is Driven by the Flow of Protons

ATP synthase, also known as **proton-pumping ATP synthase** and **F_1F_0 -ATPase**, is a multisubunit transmembrane protein with a total molecular mass of 450 kD. Efraim Racker discovered that mitochondrial ATP synthase is composed of two functional units, F_0 and F_1 . F_0 is a water-insoluble transmembrane protein containing as many as eight different types of subunits. F_1 is a water-soluble peripheral membrane protein, composed of five types of subunits, that is easily and reversibly dissociated from F_0 by treatment with urea. Solubilized F_1 hydrolyzes ATP but cannot synthesize it (hence the name ATPase).

Electron micrographs of the inner mitochondrial membrane reveal that its matrix surface is studded with molecules of ATP synthase whose F_1 component is connected to the membrane-embedded F_0 component by a protein stalk, thereby giving F_1 a lollipop-like appearance (Fig. 18-21). Similar entities have been observed lining the inner surface of the bacterial plasma membrane and in chloroplasts (Section 19-2D).

The F_1 Component Has Pseudo-Threefold Symmetry. The F_1 component of mitochondrial ATP synthase has the subunit composition $\alpha_3\beta_3\gamma\delta\epsilon$. The X-ray structure of the 3440-residue (371-kD) F_1 subunit from bovine heart mitochondria, determined by John Walker and Andrew Leslie, reveals that it consists of a 100-Å-high and 100-Å-wide spheroid that is mounted on a 50-Å-long stem

FIG. 18-21 Electron micrograph of mitochondrial cristae. The “lollipops” projecting into the matrix are the F_1 components of ATP synthase.

FIG. 18-22 X-Ray structure of F_1 -ATP synthase from bovine heart mitochondria. (a) The protein is drawn as a semitransparent ribbon viewed parallel to the membrane with the matrix above. The α , β , γ , δ , and ϵ subunits are pink, yellow, blue, orange, and green, respectively. Bound nucleotides are shown in space-filling form with ATP C green, ADP C cyan, N blue, O red, and P orange. (b) The

structure in Part a rotated 90° about the horizontal axis such that the protein is viewed along its pseudo-three-fold axis from the matrix. The δ and ϵ subunits have been deleted for clarity. [Based on an X-ray structure by Andrew Leslie and John Walker, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1E79.]

(Fig. 18-22a). The α and β subunits, which are 20% identical in sequence and have nearly identical folds, are arranged alternately, like the segments of an orange, around the upper portion of a 114-Å-long α helix formed by the γ subunit (Fig. 18-22b). The lower portion of the helix forms an antiparallel coiled coil with the N-terminal segment of the γ subunit. This coiled coil, along with the δ and ϵ subunits that are wrapped around it, links F_1 to F_0 .

The cyclic arrangement and structural similarities of F_1 's α and β subunits give it both pseudo-threefold and pseudo-sixfold rotational symmetry (Fig. 18-22b). Nevertheless, the protein is asymmetric due to the presence of the γ subunit but, more importantly, because each pair of α and β subunits adopts a different conformation, each with a different substrate affinity. Although the α subunits can bind ADP or ATP, only the β subunits catalyze ATP synthesis. Thus one β subunit (designated β_{DP}) binds a molecule of the substrate ADP, the second (β_{TP}) binds the product ATP, and the third (β_E) has an empty and distorted binding site. These conformational states are labeled in Figure 18-22b, although β_{TP} contains a bound ADP rather than ATP in this model.

The F_0 Component Includes a Transmembrane Ring. The F_0 component of bacterial and mitochondrial F_1F_0 -ATPases consists of multiple subunits. In *E. coli*, three transmembrane subunits—*a*, *b*, and *c*—form an $a_1b_2c_{12}$ complex. Mitochondrial F_0 contains additional subunits whose functions are unclear. The *c* subunits, each of which contains two α helices, associate to form a ring that is embedded in the membrane. Studies of F_0 from different species indicate that the

FIG. 18-23 A composite model of the *E. coli* F₁F₀-ATPase. The model is based on the X-ray structure of the *E. coli* F₁ subunit (PDBid 1JNV), which resembles that of bovine F₁ (Fig. 18-22), and X-ray and NMR structures of δ and the transmembrane segment of the *b* protein from *E. coli* (PDBids 2A7U and 1B9U). The structures of *a* and the so-called hinge region of *b* are unknown.

number of *c* subunits varies from 8 to 15. The cryo-EM structure of the *T. thermophilus* ATPase at 10 Å resolution suggests that its highly hydrophobic *a* subunit consists largely of a bundle of eight transmembrane helices. The mitochondrial homolog of the *a* subunit, together with an associated minor subunit, are encoded by mitochondrial genes.

In *E. coli*, the two *b* subunits plus the δ protein (which, due to confusing nomenclature, is not a counterpart of the eukaryotic δ protein) form a peripheral stalk that links the *a* subunit of F₀ to the top of F₁. In vertebrates, this stalk consists of at least four proteins. **Figure 18-23** shows a composite model of the *E. coli* ATP synthase, based on X-ray and NMR structures of its various components, which of course resemble their mitochondrial counterparts. The *c*-ring is largely embedded in the membrane, with the ϵ subunit (the counterpart of the mitochondrial δ subunit) forming extensive contacts with the top of the *c*-ring and the γ subunit of F₁. The γ subunit passes through the center of the $\alpha_3\beta_3$ assembly.

ATP Is Synthesized by the Binding Change Mechanism. The proton-translocating ATP synthase must be able to do three things:

1. Translocate protons, which is carried out by F₀.
2. Catalyze formation of the phosphoanhydride bond of ATP, which is carried out by F₁.
3. Couple the dissipation of the proton gradient with ATP synthesis, which requires interaction of F₁ and F₀.

Considerable evidence supports a mechanism for ATP formation proposed by Paul Boyer. According to this **binding change mechanism**, F₁ has three interacting catalytic protomers ($\alpha\beta$ units), each in a different conformational state: one that binds substrates and products loosely (L state), one that binds them tightly (T state), and one that does not bind them at all (open or O state). *The free energy released on proton translocation is harnessed to interconvert these three states.* The phosphoanhydride bond of ATP is synthesized only in the T state, and

FIG. 18-24 The binding change mechanism for ATP synthase.

F_1 has three chemically identical but conformationally distinct interacting $\alpha\beta$ protomers: O, the open conformation, has very low affinity for ligands and is catalytically inactive; L binds ligands loosely and is catalytically inactive; T binds ligands tightly and is catalytically active. ATP synthesis occurs in three steps: (1) ADP and P_i bind to site L. (2) An energy-dependent conformational change converts binding site L to T, T to O, and O to L. (3) ATP is synthesized at site T and ATP is

released from site O. The enzyme returns to its initial state after two more passes of the reaction sequence. The free energy that drives the conformational change is transmitted to the catalytic $\alpha_3\beta_3$ assembly via the rotation of the $\gamma\delta$ assembly ($\gamma\epsilon$ in *E. coli*), here represented by the centrally located asymmetric object (green). [After Cross, R.L., *Annu. Rev. Biochem.* **50**, 687 (1980).] **WPLS See the Animated Figures.**

? How far does the γ subunit rotate during the reaction shown here?

ATP is released only in the O state. The reaction involves three steps (Fig. 18-24):

1. ADP and P_i bind to the loose (L) binding site (β_{DP} in Fig. 18-22b).
2. A free energy-driven conformational change converts the L site to a tight (T) binding site (β_{TP}) that catalyzes the formation of ATP. This step also involves conformational changes of the other two protomers that convert the ATP-containing T site to an open (O) site (β_E) and convert the O site to an L site.
3. ATP is synthesized at the T site on one subunit while ATP dissociates from the O site on another subunit. The reaction forming ATP is essentially at equilibrium under the conditions at the enzyme's active site. The free energy supplied by the proton flow primarily facilitates the release of the newly synthesized ATP from the enzyme; that is, it drives the $T \rightarrow O$ transition, thereby disrupting the enzyme-ATP interactions that had previously promoted the spontaneous formation of ATP from $ADP + P_i$ in the T site.

FIG. 18-25 The mitochondrial $F_1 \alpha_3\beta_3$ assembly viewed from the matrix.

The protein surface is colored according to its electrical potential, with positive potentials blue, negative potentials red, and neutral potentials white. Note the absence of charge on the inner surface of the sleeve. The portion of the γ subunit's C-terminal helix that contacts the sleeve is similarly devoid of charge. [From Abrahams, J.P., Leslie, A.G.W., Lutter, R., and Walker, J.E., *Nature* **370**, 621 (1994). PDBid 1BMF.]

How is the free energy of proton transfer coupled to the synthesis of ATP? The cyclic nature of the binding change mechanism led Boyer to propose that *the binding changes are driven by the rotation of the catalytic assembly, $\alpha_3\beta_3$, with respect to other portions of the F_1F_0 -ATPase.* This hypothesis is supported by the X-ray structure of F_1 . Thus, the closely fitting nearly circular arrangement of the α and β subunits' inner surface about the γ subunit's helical C-terminus is reminiscent of a cylindrical bearing rotating in a sleeve. Indeed, the contacting hydrophobic surfaces in this assembly are devoid of the hydrogen-bonding and ionic interactions that would interfere with their free rotation (Fig. 18-25); that is, the bearing and sleeve appear to be "lubricated." Moreover, the central cavity in the $\alpha_3\beta_3$ assembly (Figs. 18-22b and 18-23) would permit the passage of the γ subunit's N-terminal helix within the core of the particle during rotation. Finally, the conformational differences between F_1 's three catalytic sites appear to be correlated with the position of the γ subunit. *Apparently the γ subunit, which rotates within the fixed $\alpha_3\beta_3$ assembly, acts as a molecular camshaft in linking the proton gradient-driven F_0 engine to the conformational changes in the catalytic sites of F_1 .*

The F_1F_0 -ATPase Is a Rotary Engine. The proposed rotation of the $\alpha_3\beta_3$ assembly with respect to the γ subunit engendered by the binding change mechanism has led to the model of the F_1F_0 -ATPase diagrammed in Fig. 18-26. A rotational engine must have both a rotor (which rotates) and a stator (which is stationary). In the F_1F_0 -ATPase, the rotor is proposed to be an assembly of the c -ring with the γ and (*E. coli*) ϵ subunits, whereas the ab_2 unit and the (*E. coli*) δ subunit together

FIG. 18-26 Model of the *E. coli* F₁F₀-ATPase. The $\gamma\epsilon$ -c₁₂ ring complex is the rotor and the $ab_2\alpha_3\beta_3\delta$ complex is the stator. Rotational motion is imparted to the rotor by the passage of protons from the outside (periplasmic space, *bottom*; equivalent to the mitochondrial intermembrane space) to the inside (cytoplasm, *top*; equivalent to the mitochondrial matrix). Protons entering from the outside bind to a c subunit where it interacts with the a subunit, and exit to the inside after the c-ring has made a nearly full rotation as indicated (*black arrows*), so that the c subunit again contacts the a subunit. The b₂δ complex presumably functions to prevent the α₃β₃ assembly from rotating with the γ subunit. [After a drawing by Richard Cross, State University of New York, Syracuse, New York.]

? Which parts of the complex rotate and which remain stationary?

with the α₃β₃ spheroid form the stator. The rotation of the c-ring in the membrane relative to the stationary a subunit is driven by the migration of protons from the outside to the inside as we discuss below (here “outside” refers to the mitochondrial intermembrane space or the bacterial exterior, whereas “inside” refers to the mitochondrial matrix or the bacterial cytoplasm). The b₂δ assembly presumably functions to hold the α₃β₃ spheroid in position while the γ subunit rotates inside it.

In the model for proton-driven rotation of the F₀ subunit that is diagrammed in Fig. 18-26, protons from the outside enter a hydrophilic channel between the a subunit and the c-ring, where they bind to a c subunit. The c-ring then rotates nearly a full turn (while protons bind to successive c subunits as they pass this input channel) until the subunit reaches a second hydrophilic channel between the a subunit and the c-ring that opens into the inside, where the proton is released (in an alternative model, the protons are released through putative channels between the C-terminal helices of adjacent c subunits, channels that are occluded when the a and c subunits are in contact). Thus, the F₁F₀-ATPase, which generates 3 ATP per turn and (at least in *E. coli*) has 12 c subunits in its F₀ assembly, ideally forms $3/12 = 0.25$ ATP for every proton it passes from outside to inside.

How does the passage of protons through this system induce the rotation of the c-ring and hence the synthesis of ATP? Each c subunit consists of two α helices of different lengths that are connected by a four-residue polar loop and arranged in an antiparallel coiled coil. Protons most likely bind to Asp 61 of each c subunit, an invariant residue whose protonation and deprotonation alter the subunit’s conformation (Fig. 18-27). Evidently, when a c subunit binds a proton as it passes the input channel, its conformation changes, which causes it to mechanically push against the a subunit so as to induce the c-ring to rotate in the direction indicated in Fig. 18-26. This process is augmented by the interaction between Asp 61 on the c subunit and the invariant Arg 210 on the a subunit.

FIG. 18-27 NMR structure of the c subunit of *E. coli* F₁F₀-ATPase. (a) At pH 8, Asp 61 (D61) is deprotonated. (b) At pH 5, D61 is protonated. Selected side chains are shown to aid in the comparison of the two structures. Note that the C-terminal helix in the pH 8 structure is rotated 140° clockwise, as viewed from the top of the drawing, relative to that in the pH 5 structure. PDBid 1COV.

The blue arrow indicates the observed direction of rotation of the fluorescently labeled actin filament that was linked to the c -ring. (b) The rotation of a 3.6- μm -long actin filament in the presence of 5 mM ATP as seen in successive video images taken through a fluorescence microscope.

GATEWAY CONCEPT Energy Transformation

Energy can neither be created nor destroyed, but it can be transformed. In oxidative phosphorylation, the free energy of reduced cofactors, representing the free energy derived from the breakdown of metabolic fuels, is used to generate a proton gradient. The free energy of the gradient is then transformed to the mechanical energy of ATP synthase, which sequesters chemical energy in the form of ATP.

These two residues have been shown to become juxtaposed at some point during the c -ring's rotation cycle. It has therefore been proposed that the electrostatic attraction between the cationic Arg 210 and the anionic Asp 61 helps rotate the c -ring so as to bring the two residues into opposition but, as this occurs, Asp 61 becomes protonated, thereby forcing the c -ring to continue its rotation.

The rotation of the $\gamma\epsilon$ - c -ring rotor with respect to the $ab_2\alpha_3\beta_3\delta$ stator has been ingeniously demonstrated by Masamitsu Futai (Fig. 18-28a). The $\alpha_3\beta_3$ spheroid of *E. coli* F_1F_0 -ATPase was fixed, head down, to a glass surface as follows. Six consecutive His residues (a so-called **His tag**) were mutagenically appended to the N-terminus of the α subunit, which is located at the top of the $\alpha_3\beta_3$ spheroid as it is drawn in Fig. 18-22a. The His-tagged assembly was applied to a glass surface coated with horseradish peroxidase (which, like most proteins, sticks to glass) conjugated with Ni^{2+} -nitroloacetic acid [Ni^{2+} - $\text{N}(\text{CH}_2\text{COOH})_3$, which tightly binds His tags], thereby binding the F_1F_0 -ATPase to the surface with its F_0 side facing away from the surface. The Glu 2 residues of this assembly's c subunits, which are located on the side of the c -ring facing away from F_1 , had been mutagenically replaced by Cys residues, which were then covalently linked to biotin (Section 16-4A). A fluorescently labeled and biotinylated (at one end) filament of the muscle protein **actin** (Section 7-2C) was then attached to the c subunit through the addition of a bridging molecule of **streptavidin**, a bacterial protein that avidly binds biotin to each of four binding sites.

The *E. coli* F_1F_0 -ATPase can work in reverse, that is, it can pump protons from the inside to the outside at the expense of ATP hydrolysis (this enables the bacterium to maintain its proton gradient under anaerobic conditions, which it uses to drive various processes). Thus, the foregoing preparation was observed under a fluorescence microscope as a 5 mM ATP solution was infused over it. *Many of the actin filaments were seen to rotate (Fig. 18-28b), and always in a counterclockwise direction when viewed looking down on the glass surface (from the outside).* This would permit the γ subunit to sequentially interact with the β subunits in the direction

(Figs. 18-22a and 18-24), the direction expected for ATP hydrolysis. Similar experiments revealed that the γ subunit rotates mostly in increments of 120° , with a slight pause after 80° . Presumably, electrostatic interactions between the γ and β subunits of F_1 act as a catch that temporarily holds the γ subunit in place. As the c -ring rotates, strain builds up and causes the γ subunit to snap to the next β subunit. In addition, when a magnetic bead was instead attached to the γ subunit of immobilized F_1 -ATPase and an external magnetic field was rotated in the clockwise direction so as to force the γ subunit to follow, ATP was synthesized from $\text{ADP} + \text{P}_i$.

C The P/O Ratio Relates the Amount of ATP Synthesized to the Amount of Oxygen Reduced

ATP synthesis is tightly coupled to the proton gradient; that is, ATP synthesis requires the discharge of the proton gradient, and the proton gradient cannot be discharged without the synthesis of ATP. The proton gradient is established through the activity of the electron-transporting complexes of the inner mitochondrial membrane. Therefore, it is possible to express the amount of ATP synthesized in terms of substrate molecules oxidized. Experiments with isolated mitochondria show that the oxidation of NADH is associated

with the synthesis of approximately 3 ATP, and the oxidation of FADH_2 with approximately 2 ATP. Oxidation of the nonphysiological compound **tetramethyl-*p*-phenylenediamine**,

which donates an electron pair directly to Complex IV, yields approximately 1 ATP. These stoichiometric relationships are called **P/O ratios** because they relate the amount of ATP synthesized (P) to the amount of oxygen reduced (O).

Experimentally determined P/O ratios are compatible with the chemiosmotic theory and the known structure of ATP synthase. The flow of two electrons through Complexes I, III, and IV results in the translocation of 10 protons into the intermembrane space (Fig. 18-8). Influx of these 10 protons through the F_1F_0 -ATPase, which contains 8 *c* subunits in eukaryotes, results in approximately one complete rotation of the *c*-ring- γ subunit rotor relative to the $\alpha_3\beta_3$ spheroid, enough to drive the synthesis of ~ 3 ATP. Electrons that enter the electron-transport chain as FADH_2 at Complex II bypass Complex I and therefore lead to the transmembrane movement of only 6 protons, enough to synthesize ~ 2 ATP (corresponding to approximately two-thirds of a full rotation of the ATP synthase rotary engine). The transit of two electrons through Complex IV alone contributes 2 protons to the gradient, enough for ~ 1 ATP (around one-third of a rotation).

In actively respiring mitochondria, *P/O ratios are almost certainly not integral numbers*. This is also consistent with the chemiosmotic theory. Oxidation of a physiological substrate contributes to the transmembrane proton gradient at several points, but the gradient is tapped mainly at a single point, the F_1F_0 -ATPase. Therefore, the number of protons translocated out of the mitochondrion by any component of the electron-transport chain need not be an integral multiple of the number of protons required to synthesize ATP from $\text{ADP} + \text{P}_i$. Moreover, the proton gradient is dissipated to some extent by the nonspecific leakage of protons back into the matrix and by the consumption of protons for other purposes, such as the transport of P_i into the matrix (Section 18-1B). Taking P_i transport into account gives a stoichiometry of four protons consumed per ATP synthesized from $\text{ADP} + \text{P}_i$. Thus, as Peter Hinkle has experimentally demonstrated, the P/O ratios above are actually closer to 2.5, 1.5, and 1. Consequently, the number of ATPs that are synthesized per molecule of glucose oxidized is $2.5 \text{ ATP/NADH} \times 10 \text{ NADH/glucose} + 1.5 \text{ ATP/FADH}_2 \times 2 \text{ FADH}_2/\text{glucose} + 2 \text{ ATP/glucose from the citric acid cycle} + 2 \text{ ATP/glucose from glycolysis} = 32 \text{ ATP/glucose}$ (see Section 17-4).

D Oxidative Phosphorylation Can Be Uncoupled from Electron Transport

Electron transport (the oxidation of NADH and FADH_2 by O_2) and oxidative phosphorylation (the proton gradient-driven synthesis of ATP) are normally tightly coupled. *This coupling depends on the impermeability of the inner mitochondrial membrane, which allows an electrochemical gradient to be established across the membrane by H^+ translocation during electron transport.* Virtually the only way for H^+ to re-enter the matrix is through the F_0 portion of ATP synthase. In the resting state, when oxidative phosphorylation is minimal, the electrochemical gradient across the inner mitochondrial membrane builds up to the extent that it prevents further proton pumping and therefore inhibits electron

FIG. 18-29 Action of 2,4-dinitrophenol. A proton-transferring ionophore such as DNP uncouples oxidative phosphorylation from electron transport by discharging the electrochemical proton gradient generated by electron transport.

CHECKPOINT

- Summarize the chemiosmotic theory.
- Explain why an intact, impermeable mitochondrial membrane is essential for ATP synthesis.
- Describe the overall structure of the F_1 and F_0 components of ATP synthase. Which parts move? Which are stationary? Which are mostly stationary but undergo conformational changes?
- Summarize the steps of the binding change mechanism.
- Describe how protons move from the intermembrane space into the matrix. How is proton translocation linked to ATP synthesis?
- Explain why the P/O ratio for a given substrate is not necessarily an integer.
- Explain how oxidative phosphorylation is linked to electron transport and how the two processes can be uncoupled.
- Summarize the energy transformations that occur in converting the free energy of glucose to the free energy of ATP.

? Why must the pK of DNP be close to neutral?

transport. When ATP synthesis increases, the electrochemical gradient dissipates, allowing electron transport to resume.

Over the years, compounds such as **2,4-dinitrophenol (DNP)** have been found to “uncouple” electron transport and ATP synthesis. DNP is a lipophilic weak acid that readily passes through membranes in its neutral, protonated state. In a pH gradient, it binds protons on the acidic side of the membrane, diffuses through the membrane, and releases the protons on the membrane’s alkaline side, thereby acting as a proton-transferring ionophore (Section 10-2A) and dissipating the gradient (Fig. 18-29). The chemiosmotic theory provides a rationale for understanding the action of such **uncouplers**. *The presence in the inner mitochondrial membrane of an agent that increases its permeability to H^+ uncouples oxidative phosphorylation from electron transport by providing a route for the dissipation of the proton electrochemical gradient that does not require ATP synthesis.* Uncoupling therefore allows electron transport to proceed unchecked even when ATP synthesis is inhibited. Consequently, in the 1920s, DNP was used as a “diet pill,” a practice that was effective in inducing weight loss but often caused fatal side effects. Under physiological conditions, *the dissipation of an electrochemical H^+ gradient, which is generated by electron transport and uncoupled from ATP synthesis, produces heat* (see Box 18-4).

4 Control of Oxidative Metabolism

KEY CONCEPTS

- The rate of oxidative phosphorylation is coordinated with the cell’s other oxidative pathways.
- Although aerobic metabolism is efficient, it leads to the production of reactive oxygen species.

An adult woman requires some 1500 to 1800 kcal (6300–7500 kJ) of metabolic energy per day. This corresponds to the free energy of hydrolysis of over 200 mol of ATP to ADP and P_i . Yet the total amount of ATP present in the body at any one time is <0.1 mol; obviously, this sparse supply of ATP must be continually recycled. As we have seen, when carbohydrates serve as the energy supply and aerobic conditions prevail, this recycling involves glycogenolysis, glycolysis, the citric acid cycle, and oxidative phosphorylation.

Box 18-4 Perspectives in Biochemistry
Uncoupling in Brown Adipose Tissue Generates Heat

Heat generation is the physiological function of **brown adipose tissue (brown fat)**. This tissue is unlike typical (white) adipose tissue in that it contains numerous mitochondria whose cytochromes cause its brown color. Newborn mammals that lack fur, such as humans, as well as hibernating mammals, all contain brown fat in their neck and upper back that generates heat by **nonshivering thermogenesis**. Other sources of heat are the ATP hydrolysis that occurs during muscle contraction (in shivering or any other movement) and the operation of ATP-hydrolyzing substrate cycles (see Section 15-4B).

The mechanism of heat generation in brown fat involves the regulated uncoupling of oxidative phosphorylation. Brown fat mitochondria contain a proton channel known as **uncoupling protein (UCP1)**, also called **thermogenin**; see below). In cold-adapted animals, UCP1 constitutes up to 15% of the protein in the inner mitochondrial membranes of brown fat. The flow of protons through UCP1 is inhibited by physiological concentrations of purine nucleotides (ADP, ATP, GDP, GTP), but this inhibition can be overcome by free fatty acids.

Thermogenesis in brown fat mitochondria is under hormonal control (see diagram). Norepinephrine (**1**; noradrenaline) induces the

production of the second messenger cAMP (**2**) and thereby activates protein kinase A (**3**; Section 13-3C). The kinase then activates **hormone-sensitive triacylglycerol lipase (4)** by phosphorylating it. The activated lipase hydrolyzes triacylglycerols (**5**) to yield free fatty acids that counteract the inhibitory effect of the purine nucleotides on UCP1 (**6**). The resulting flow of protons through UCP1 dissipates the proton gradient across the inner mitochondrial membrane. This allows substrate oxidation to proceed (and generate heat) without the synthesis of ATP.

Adult humans have relatively little brown fat, but the mitochondria of ordinary adipose tissue and muscle appear to contain uncoupling proteins known as **UCP2** and **UCP3**. These proteins may help regulate metabolic rates, and variations in UCP levels or activity might explain why some people seem to have a “fast” or “slow” metabolism. UCPs are being studied as targets for treating obesity, since increasing the activity of UCPs could uncouple respiration from ATP synthesis, thus permitting stored metabolic fuels (especially fat) to be metabolized.

Of course, the need for ATP is not constant. There is a 100-fold change in the rate of ATP consumption between sleep and vigorous activity. *The activities of the pathways that produce ATP are under strict coordinated control so that ATP is never produced more rapidly than necessary.* We have already discussed the control mechanisms of glycolysis, glycogenolysis, and the citric acid cycle (Sections 15-4, 16-3, and 17-4). In this section, we discuss the mechanisms that control the rate of oxidative phosphorylation.

A The Rate of Oxidative Phosphorylation Depends on the ATP and NADH Concentrations

In our discussions of metabolic pathways, we have seen that most of their reactions function close to equilibrium. The few irreversible reactions constitute potential control points of the pathways and usually are catalyzed by regulatory enzymes that are under allosteric control. In the case of oxidative phosphorylation, the pathway from NADH to cytochrome *c* functions near equilibrium:

and hence

$$K_{\text{eq}} = \left(\frac{[\text{NAD}^+]}{[\text{NADH}]} \right)^{1/2} \frac{[c^{2+}]}{[c^{3+}]} \frac{[\text{ATP}]}{[\text{ADP}][\text{P}_i]}$$

This pathway is therefore readily reversed by the addition of its product, ATP. However, *the cytochrome *c* oxidase reaction (the terminal step of the electron-transport chain) is irreversible and is therefore a potential control site.* Cytochrome *c* oxidase, in contrast to most regulatory enzyme systems, appears to be controlled primarily by the availability of one of its substrates, reduced cytochrome *c* (c^{2+}). Since c^{2+} is in equilibrium with the rest of the coupled oxidative phosphorylation system, the concentration of c^{2+} ultimately depends on the intramitochondrial ratios of $[\text{NADH}]/[\text{NAD}^+]$ and $[\text{ATP}]/[\text{ADP}][\text{P}_i]$ (the latter quantity is known as the **ATP mass action ratio**). We can see, by rearranging the foregoing equilibrium expression,

$$\frac{[c^{2+}]}{[c^{3+}]} = \left(\frac{[\text{NADH}]}{[\text{NAD}^+]} \right)^{1/2} \frac{[\text{ADP}][\text{P}_i]}{[\text{ATP}]} K_{\text{eq}}$$

that the higher the $[\text{NADH}]/[\text{NAD}^+]$ ratio and the lower the ATP mass action ratio, the higher the concentration of reduced cytochrome *c* and thus the higher the cytochrome *c* oxidase activity.

How is this system affected by changes in physical activity? In an individual at rest, the rate of ATP hydrolysis to ADP and P_i is minimal and the ATP mass action ratio is high; the concentration of reduced cytochrome *c* is therefore low and the rate of oxidative phosphorylation is minimal. Increased activity results in hydrolysis of ATP to ADP and P_i , thereby decreasing the ATP mass action ratio and increasing the concentration of reduced cytochrome *c*. This results in an increase in the rate of electron transport and ADP phosphorylation.

The concentrations of ATP, ADP, and P_i in the mitochondrial matrix depend on the activities of the transport proteins that import these substances from the cytosol. Thus, the ADP-ATP translocator and the P_i transporter may play a part in regulating oxidative phosphorylation. There is also some evidence that Ca^{2+} stimulates the electron-transport complexes and possibly ATP synthase itself. This is consistent with the many other instances in which Ca^{2+} directly stimulates oxidative metabolic processes.

Mitochondria contain an 84-residue protein, called **IF₁**, that functions to regulate ATP synthase. In actively respiring mitochondria, in which the matrix

pH is relatively high, F_1 exists as an inactive tetramer. However, below pH 6.5, the protein dissociates into dimers and in this form inhibits the ATPase activity of the F_1 component by binding to the interface between its α_{DP} and β_{DP} subunits so as to trap the ATP bound to the β_{DP} subunit. This appears to be a mechanism to prevent ATP hydrolysis when respiratory activity (and therefore the proton gradient) is temporarily interrupted by lack of O_2 . Otherwise, the F_1F_0 -ATPase would reverse its direction of rotation as driven by the hydrolysis of ATP (then generated by glycolysis), thus depriving the cell of its remaining energy resources.

Pathways of Oxidative Metabolism Are Coordinately Controlled. The primary sources of the electrons that enter the mitochondrial electron-transport chain are glycolysis, fatty acid degradation, and the citric acid cycle. For example, 10 molecules of NAD^+ are converted to NADH per molecule of glucose oxidized (Fig. 18-1). Not surprisingly, the control of glycolysis and the citric acid cycle is coordinated with the demand for oxidative phosphorylation. An adequate supply of electrons to feed the electron-transport chain is provided by regulation of the control points of glycolysis and the citric acid cycle (phosphofruktokinase, pyruvate dehydrogenase, citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase) by adenine nucleotides or NADH or both, as well as by certain metabolites (Fig. 18-30).

One particularly interesting regulatory effect is the inhibition of phosphofruktokinase (PFK) by citrate. When demand for ATP decreases, [ATP] increases and [ADP] decreases. Because isocitrate dehydrogenase is activated by ADP and α -ketoglutarate dehydrogenase is inhibited by ATP, the citric acid cycle slows down. This causes the citrate concentration to build up. Citrate leaves the mitochondrion via a specific transport system and, *once in the cytosol, acts to restrain further carbohydrate breakdown by inhibiting PFK*. The citrate concentration also builds up when the acetyl-CoA concentration increases, which occurs, as we will see in Chapter 20, during the oxidation of fatty acids. The inhibition of glycolysis by fatty acid oxidation is called the **glucose–fatty acid cycle** or **Randle cycle** (after its discoverer, Phillip Randle) although it is not, in fact, a cycle. The Randle cycle allows fatty acids to be utilized as the major fuel for oxidative metabolism in heart muscle, while conserving glucose for organs such as the brain, which require it.

B Aerobic Metabolism Has Some Disadvantages

Not all organisms carry out oxidative phosphorylation. However, those that do are able to extract considerably more energy from a given amount of a metabolic fuel. This principle is illustrated by the Pasteur effect (Section 15-3C): When anaerobically growing yeast are exposed to oxygen, their glucose consumption drops precipitously. An analogous effect is observed in mammalian muscle; the concentration of lactic acid (the anaerobic product of muscle glycolysis; Section 15-3A) drops dramatically when cells switch to aerobic metabolism. These effects are easily understood by

FIG. 18-30 The coordinated control of glycolysis and the citric acid cycle. The diagram shows the effects of ATP, ADP, AMP, P_i , Ca^{2+} , and the $[NADH]/[NAD^+]$ ratio (the vertical arrows indicate increases in this ratio). Here a green dot signifies activation and a red octagon represents inhibition. [After Newsholme, E. A. and Leech, A. R., *Biochemistry for the Medical Sciences*, pp. 316, 320, Wiley (1983).] **WPLS** See the Animated Figures.

examining the stoichiometries of anaerobic and aerobic breakdown of glucose (Section 17-4):

Anaerobic glycolysis:

Aerobic metabolism of glucose:

Thus, *aerobic metabolism is up to 16 times more efficient than anaerobic glycolysis in producing ATP.*

Aerobic metabolism has its drawbacks, however. Many organisms and tissues depend exclusively on aerobic metabolism and suffer irreversible damage during oxygen deprivation (Box 18-5). Oxidative metabolism is also accompanied by the production of low levels of reactive oxygen metabolites that, over time, may damage cellular components. Evidently, the organisms that have existed during the last 3 billion years (the period in which the earth's atmosphere has contained significant amounts of O_2) exhibit physiological and biochemical adaptations that permit them to take advantage of the oxidizing power of O_2 while minimizing the potential dangers of oxygen itself.

Partial Oxygen Reduction Produces Reactive Oxygen Species. Although the four-electron reduction of O_2 by cytochrome *c* oxidase is nearly always orchestrated with great rapidity and precision, *O_2 is occasionally only partially reduced, yielding oxygen species that readily react with a variety of cellular components.* Complexes I, II, and III also occasionally generate these **reactive oxygen species (ROS)**, presumably by leaking electrons. The best known ROS is the **superoxide radical**:

The superoxide radical is a precursor of other reactive species. Protonation of O_2^- yields HO_2^\cdot , a much stronger oxidant than O_2^- . The most potent oxygen species in biological systems is probably the hydroxyl radical, which forms from the relatively harmless hydrogen peroxide (H_2O_2):

The hydroxyl radical also forms through the reaction of superoxide with H_2O_2 :

Although most free radicals are extremely short-lived (the half-life of O_2^- is 1×10^{-6} s, and that of $\cdot\text{OH}$ is 1×10^{-9} s), they readily extract electrons from other molecules, converting them to free radicals and thereby initiating a chain reaction.

The random nature of free-radical attacks makes it difficult to characterize their reaction products, but all classes of biological molecules are susceptible to oxidative damage caused by free radicals. The oxidation of polyunsaturated lipids in cells may disrupt the structures of biological membranes, and oxidative damage to DNA may result in point mutations. Enzyme function may also be compromised through radical reactions with amino acid side chains. Because the mitochondrion is the site of the bulk of the cell's oxidative metabolism, its lipids, DNA, and proteins probably bear the brunt of free radical-related damage.

 Several degenerative diseases, including **Parkinson's**, **Alzheimer's**, and **Huntington's diseases**, are associated with oxidative damage to mitochondria. Such observations have led to the free-radical theory of aging, which holds that *free-radical reactions arising during the course of normal oxidative metabolism are at least partially responsible for the aging process.* In fact, individuals with congenital defects in their mitochondrial DNA suffer from a variety of symptoms typical of old age, including neuromotor difficulties, deafness, and dementia. Their genetic defects may make their mitochondria all the

As outlined in Box 7-1, organisms larger than 1 mm thick require circulatory systems to deliver nutrients to cells and dispose of cellular wastes. In addition, the circulatory fluid in most larger organisms contains proteins specialized for oxygen transport (e.g., hemoglobin). The sophistication of oxygen-delivery systems and their elaborate regulation are consistent with their essential nature and their long period of evolution.

What happens during oxygen deprivation? Consider two common causes of human death, **myocardial infarction** (heart attack) and **stroke**, which result from interruption of the blood (O_2) supply to a portion of the heart or the brain, respectively. In the absence of O_2 , a cell, which must then rely only on glycolysis for ATP production, rapidly depletes its stores of phosphocreatine (a source of rapid ATP production; Section 14-2C) and glycogen. As the rate of ATP production falls below the level required by membrane ion pumps for maintaining proper intracellular ion concentrations, osmotic balance is disrupted so that the cell and its membrane-enveloped organelles begin to swell. The resulting overstretched membranes become permeable, thereby leaking their enclosed contents. For this reason, a useful diagnostic criterion for myocardial infarction is the presence in the blood of heart-specific enzymes, such as the H-type isozyme of lactate dehydrogenase (Section 14-1C) and creatine kinase, which leak out of necrotic (dead) heart tissue. Moreover, the decreased intracellular pH that accompanies anaerobic glycolysis (because of lactic acid production) permits the released lysosomal enzymes (which are active only at acidic pH) to

degrade the cell contents. Thus, O_2 deprivation leads not only to cessation of cellular activity but to irreversible cell damage and cell death. Rapidly respiring tissues, such as the heart and brain, are particularly susceptible to damage by oxygen deprivation.

CNRI/Photo Researchers

Necrotic tissue resulting from a heart attack.

more susceptible to the reactive oxygen species generated by the electron-transport machinery.

Cells Are Equipped with Antioxidant Mechanisms. **Antioxidants** destroy oxidative free radicals such as O_2^- and $\cdot OH$. In 1969, Irwin Fridovich discovered that the enzyme **superoxide dismutase (SOD)**, which is present in nearly all cells, catalyzes the conversion of O_2^- to H_2O_2 .

Mitochondrial and bacterial SOD are both Mn-containing tetramers; eukaryotic cytosolic SOD is a dimer containing copper and zinc ions. The rate of nonenzymatic superoxide breakdown is $\sim 2 \times 10^5 M^{-1} \cdot s^{-1}$, whereas the rate of the Cu,Zn-SOD-catalyzed reaction is $\sim 2 \times 10^9 M^{-1} \cdot s^{-1}$. This rate enhancement, which is close to the diffusion-controlled limit (Section 12-1B), is apparently accomplished by electrostatic guidance of the negatively charged superoxide substrate into the enzyme's active site (Fig. 18-31). The active-site Cu ion lies at the bottom of a deep pocket in each enzyme subunit. A hydrogen-bonded network of Glu 123, Glu 133, Lys 136, and Thr 137 at the entrance to the pocket facilitates the diffusion of O_2^- to a site between the Cu ion and Arg 143.

SOD is considered a first-line defense against reactive oxygen species. The H_2O_2 produced in the reaction, which can potentially react to yield

FIG. 18-31 Electrostatic effects in human Cu,Zn-superoxide dismutase. In this cross section of the active site channel of Cu,Zn-SOD, the molecular surface is represented by a dot surface that is colored according to charge: red, most negative; yellow, negative; green, neutral; light blue, positive; dark blue, most positive. The electrostatic field vectors are represented by similarly colored arrows. The Cu and Zn ions at the active site are represented by orange and silver dotted spheres. The O_2^- -binding site is located between the Cu ion and the side chain of Arg 143.

other reactive oxygen species, is degraded to water and oxygen by enzymes such as **catalase**, which catalyzes the reaction

and glutathione peroxidase (Box 15-4), which uses glutathione (GSH) as the reducing agent:

The latter enzyme also catalyzes the breakdown of organic hydroperoxides. Some types of glutathione peroxidase require Se for activity; this is one reason why Se appears to have antioxidant activity.

Other potential antioxidants are plant-derived compounds such as ascorbate (vitamin C; Section 6-1C) and α -tocopherol (vitamin E; Section 9-1F). These compounds may help protect plants from oxidative damage during photosynthesis, a process in which H_2O is oxidized to O_2 . Their efficacy as antioxidants in humans, however, is unproven.

CHECKPOINT

- How do the ATP mass action ratio and the F_1 protein regulate ATP synthesis?
- What control mechanisms link glycolysis, the citric acid cycle, and oxidative phosphorylation?
- Describe the advantages and disadvantages of oxygen-based metabolism.
- How do cells minimize oxidative damage?

Summary

1 The Mitochondrion

- Electrons from the reduced coenzymes NADH and FADH_2 pass through a series of redox centers in the electron-transport chain before reducing O_2 .
- During electron transfer, protons are translocated out of the mitochondrion to form an electrochemical gradient whose free energy drives ATP synthesis.
- The mitochondrion contains soluble and membrane-bound enzymes for oxidative metabolism.
- Reducing equivalents are imported from the cytosol via a shuttle system. Specific transporters mediate the transmembrane movements of ADP, ATP, and P_i .

2 Electron Transport

- Electrons flow from redox centers with more negative reduction potentials to those with more positive reduction potentials. Inhibitors have been used to reveal the sequence of electron carriers and the points of entry of electrons into the electron-transport chain.
- Electron transport is mediated by one-electron carriers (Fe-S clusters, cytochromes, and Cu ions) and two-electron carriers (CoQ, FMN, FAD).
- Complex I transfers two electrons from NADH to CoQ while translocating four protons to the intermembrane space.
- Complex II transfers electrons from succinate through FAD to CoQ.
- Complex III transfers two electrons from CoQH_2 to two molecules of cytochrome *c*. The concomitant operation of the Q cycle translocates four protons to the intermembrane space.

- Complex IV reduces O_2 to $2 \text{H}_2\text{O}$ using four electrons donated by four cytochrome *c* and four protons from the matrix. Two protons are translocated to the intermembrane space for every two electrons that reduce oxygen.

3 Oxidative Phosphorylation

- As explained by the chemiosmotic theory, protons translocated into the intermembrane space during electron transport through Complexes I, III, and IV establish an electrochemical gradient across the inner mitochondrial membrane.
- The influx of protons through the F_0 component of ATP synthase (F_1F_0 -ATPase) drives its F_1 component to synthesize ATP from $\text{ADP} + \text{P}_i$ via the binding change mechanism, a process that is mechanically driven by the F_0 -mediated rotation of F_1 's γ subunit with respect to its catalytic $\alpha_3\beta_3$ assembly.
- The P/O ratio, the number of ATPs synthesized per oxygen reduced, need not be an integral number.
- Agents that discharge the proton gradient can uncouple oxidative phosphorylation from electron transport.

4 Control of Oxidative Metabolism

- Oxidative phosphorylation is controlled by the ratio $[\text{NADH}]/[\text{NAD}^+]$ and by the ATP mass action ratio. Glycolysis and the citric acid cycle are coordinately regulated according to the need for oxidative phosphorylation.
- Aerobic metabolism is more efficient than anaerobic metabolism. However, aerobic organisms must guard against damage caused by reactive oxygen species.

Problems

EXERCISES

1. Explain why a liver cell mitochondrion contains fewer cristae than a mitochondrion from a heart muscle cell.
2. Certain genetic diseases caused by defective mitochondrial proteins are inherited only maternally, in contrast to most genetic diseases, in which either parent can pass on the defect. Explain.
3. How many ATPs are synthesized for every cytoplasmic NADH that participates in the glycerophosphate shuttle in insect flight muscle?
4. How many ATPs are synthesized for every cytoplasmic NADH reducing equivalent that is transferred into the matrix via the malate–aspartate shuttle?
5. Explain why defects in mitochondrial genes often produce symptoms such as lactic acidosis.
6. Deficiencies of the components of Complexes I, III, and IV tend to have severe physiological consequences, however, deficiencies of Complex II components tend to have mild effects. Explain.
7. Calculate ΔG° for the oxidation of free FADH₂ by O₂. What is the maximum number of ATPs that can be synthesized, assuming standard conditions and 100% conservation of energy?
8. Show that the free energy change for the succinate dehydrogenase reaction catalyzed by Complex II is insufficient to drive ATP synthesis under standard conditions.
9. Vitamin K (Section 9-1F) is the cofactor for an enzyme that posttranslationally modifies certain proteins. It also functions as an electron carrier in some prokaryotes and may play a similar role in mitochondria. At what point in the mitochondrial electron-transport chain would vitamin K act?
10. Pyocyanin from the bacterium *Pseudomonas aeruginosa*, which can cause fatal infections, contributes to the production of reactive oxygen species in the mammalian host. What component of the electron transport chain does pyocyanin resemble?

Pyocyanin

11. Cytochrome *c* may associate with cardiolipin (diphosphatidylglycerol) in the inner mitochondrial membrane. What sort of intermolecular forces are likely to be involved in this association?
12. Under certain conditions, cytochrome *c* can trigger apoptosis, or programmed cell death, by activating cytosolic proteins known as caspases. (a) Why doesn't cytochrome *c* trigger apoptosis in healthy cells? (b) What must happen in order for cytochrome *c* to activate the caspases?
13. Some anaerobic prokaryotes use nitrate (NO₃⁻) as the terminal electron acceptor for energy metabolism. Assuming 100% efficiency, how much ATP could be synthesized by the oxidation of NADH by nitrate?
14. Some anaerobic prokaryotes reduce elemental sulfur to H₂S. Assuming 100% efficiency, how much ATP could be synthesized by the oxidation of acetate by S under standard conditions?
15. Why is it possible for electrons to flow from a redox center with a more positive \mathcal{E}° to one with a more negative \mathcal{E}° within an electron-transfer complex?
16. A family of proteins known as cupredoxins contain a single redox-active Cu ion coordinated by a Cys, a Met, and two His residues. The reduction potentials of cupredoxins range from about 0.15 V to 0.68 V. What does this information reveal about the role of the protein component of the cupredoxins?
17. Bombarding a suspension of mitochondria with high-frequency sound waves (**sonication**) produces **submitochondrial particles** derived

from the inner mitochondrial membrane. These membranous vesicles seal inside out, so that the intermembrane space of the mitochondrion becomes the lumen of the submitochondrial particle. Diagram the process of electron transfer and oxidative phosphorylation in these particles.

18. For the experimental system described in Problem 17, and assuming all the substrates for oxidative phosphorylation are present in excess, does ATP synthesis increase or decrease with an increase in the pH of the fluid in which the submitochondrial particles are suspended?
19. Consider the mitochondrial ADP–ATP translocator and the P_i–H⁺ symport protein. How do the activities of the two transporters affect the electrochemical gradient across the mitochondrial membrane?
20. What thermodynamic force drives the transport of ADP and P_i into the mitochondrial matrix for ATP synthesis?
21. Dicyclohexylcarbodiimide (DCCD) is a reagent that reacts with Asp or Glu residues.

Dicyclohexylcarbodiimide (DCCD)

Explain why the reaction of DCCD with the *c* subunits of F₁F₀-ATPase blocks its ATP-synthesizing activity.

22. The antibiotic oligomycin B blocks proton transport through F₀. Explain why lactate concentrations build up in rats that have been treated with oligomycin B.
23. Explain why compounds such as DNP increase metabolic rates.
24. What is the advantage of hormones activating a lipase to stimulate nonshivering thermogenesis in brown fat rather than activating UCP1 directly (see Box 18-4)?
25. Describe the changes in [NADH]/[NAD⁺] and [ATP]/[ADP] that occur during the switch from anaerobic to aerobic metabolism. How do these ratios influence the activity of glycolysis and the citric acid cycle?
26. During cell signaling events that increase cytosolic calcium concentrations, Ca²⁺ enters the mitochondria via Ca²⁺ channels in the inner membrane. (a) Explain why it is necessary for these channels to be highly specific for Ca²⁺. (b) How would increased matrix [Ca²⁺] affect oxidative phosphorylation?
27. Activated neutrophils and macrophages (types of white blood cells) fight invading bacteria by releasing superoxide. These cells contain an **NADPH oxidase** that catalyzes the reaction

Explain why flux through the glucose-6-phosphate dehydrogenase reaction increases in these cells.

28. Mutations in SOD are associated with the neurodegenerative disease amyotrophic lateral sclerosis (ALS). Explain why researchers initially believed that loss of SOD activity would damage neurons.

CHALLENGE QUESTIONS

29. The O₂-consumption curve of a dilute, well-buffered suspension of mitochondria containing an excess of ADP and P_i takes the following form:

Sketch the curves obtained when (a) amytal is added at time $t = 1$ and (b) amytal is added at $t = 1$ and succinate is added at $t = 2$.

30. Sketch the O_2 -consumption curves obtained for the mitochondria in Problem 29 when (a) CN^- is added at $t = 1$ and succinate is added at $t = 2$ and (b) oligomycin (which binds to F_0 and prevents ATP synthesis) is added at $t = 1$ and DNP is added at $t = 2$.

31. The difference in pH between the internal and external surfaces of the inner mitochondrial membrane is 1.4 pH units (external side acidic). If the membrane potential is 0.06 V (inside negative), what is the free energy change on transporting 1 mol of protons across the membrane from outside to inside at 25°C?

32. For the mitochondrial membrane described in Problem 31, how many protons must be transported to provide enough free energy for the synthesis of 1 mol of ATP (assuming standard biochemical conditions)?

33. Nicotinamide nucleotide transhydrogenase (NNT) in the inner mitochondrial membrane catalyzes the reaction $NADH + NADP^+ \rightarrow NAD^+ + NADPH$ to generate the NADPH needed for certain reactions that help destroy reactive oxygen species. (a) Explain why the NNT reaction cannot be driven primarily by the difference in substrate reduction potentials ($\Delta\mathcal{E}$). (b) In fact, the NNT reaction is driven by proton translocation across the membrane (from outside to inside). How does operation of the transhydrogenase affect the efficiency of oxidative phosphorylation?

34. The antidiabetes drug metformin inhibits 3-phosphoglycerol dehydrogenase. How would this affect ATP production by mitochondria?

35. How do the P/O ratios for NADH differ in ATP synthases that contain 10 and 15 c subunits?

36. How many protons are required to synthesize one ATP by F_1F_0 -ATPase containing (a) 10 or (b) 15 c subunits?

37. During dietary restriction, amino acids may be used as metabolic fuels. In this process, glutamate is converted by glutamate dehydrogenase (Section 17-5A) to α -ketoglutarate. α -Ketoglutarate binds to the β subunit of ATP synthase and inhibits its catalytic activity. Predict the effect of increased α -ketoglutarate on oxygen consumption and the production of reactive oxygen species.

38. Is the information in Problem 37 consistent with the hypothesis that dietary restriction can slow the aging process?

39. In coastal marine environments, high concentrations of nutrients from terrestrial runoff often lead to algal blooms. When the nutrients are depleted, the algae die and sink and are degraded by other microorganisms. The algal die-off may be followed by a sharp drop in oxygen in the depths, which can kill fish and bottom-dwelling invertebrates. How do these “dead zones” form?

40. Chromium is most toxic and highly soluble in its oxidized Cr(VI) state but is less toxic and less soluble in its more reduced Cr(III) state. Efforts to detoxify Cr-contaminated groundwater have involved injecting chemical reducing agents underground. Another approach is bioremediation, which involves injecting molasses or cooking oil into the contaminated groundwater. Explain how these substances would promote the reduction of Cr(VI) to Cr(III).

41. (a) A simplistic interpretation of the Q cycle would predict that the proton pumping efficiency of cytochrome bc_1 would be reduced by no more than 50% in the presence of saturating amounts of antimycin A. Explain. (b) Indicate why cytochrome bc_1 is nearly 100% inhibited by antimycin A.

42. Certain unscrupulous operators offer, for a fee, to freeze recently deceased individuals in liquid nitrogen until medical science can cure the disease from which they died. What is the biochemical fallacy of this procedure?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Viewing and Analyzing Complexes I-IV

Exercise 2 Diversity of the Electron Transport Chain and the KEGG Database

CASE STUDIES www.wiley.com/college/voet

Case 24 Uncoupling Proteins in Plants

Focus concept: Uncoupling proteins in plants uncouple oxidative phosphorylation to generate heat in the developing plant.

Prerequisite: Chapter 18

- Electron transport and oxidative phosphorylation
- Mechanisms of uncoupling agents, such as 2,4-dinitrophenol

Case 27 Regulation of Sugar and Alcohol Metabolism in *Saccharomyces cerevisiae*

Focus concept: The regulation of carbohydrate metabolic pathways in yeast serves as a good model for regulation of the same pathways in multicellular organisms.

Prerequisites: Chapters 15, 16, 17, and 18

- The major pathways associated with carbohydrate metabolism, including glycolysis, the citric acid cycle, oxidative phosphorylation, pentose phosphate pathway, and gluconeogenesis
- The various fates of pyruvate via alcoholic fermentation and aerobic respiration

Case 33 Modification of Subunit c from Bovine Mitochondrial ATPase

Focus concept: Modification of Lys 43 in the mitochondrial ATPase, once thought to be the structural basis of Batten disease, has been found in bovine mitochondria, indicating that this modification is completely normal.

Prerequisites: Chapters 5 and 18

- Mechanism of ATP synthesis in oxidative phosphorylation
- Protein structure/function relationships

MORE TO EXPLORE Anaerobic organisms produce ATP by pathways that do not require molecular oxygen. However, all organisms carry out oxidation-reduction reactions in the normal course of metabolism. What compounds other than O_2 can serve as electron acceptors in anaerobes?

What is the fate of the resulting reduced compounds?

- C The Calvin Cycle Is Controlled Indirectly by Light
- D Photorespiration Competes with Photosynthesis

Courtesy of Josef Wiktor

Photosynthetic organisms grow wherever sunlight is available. These algae, which live within Arctic sea ice, convert solar energy to chemical energy that becomes food for other organisms.

The notion that plants obtain nourishment from such insubstantial things as light and air was not validated until the eighteenth century. Evidence that plants produce a vital substance—O₂—was not obtained until 1771, when Joseph Priestley noted that the air in a jar in which a candle had burned out could be “restored” by introducing a small plant into the jar. In the presence of sunlight, photosynthetic organisms consume CO₂ and H₂O and produce O₂ and “fixed” carbon in the form of carbohydrate:

Photosynthesis, in which light energy drives the reduction of carbon, is essentially the reverse of oxidative carbohydrate metabolism. Photosynthetically produced carbohydrates therefore serve as an energy source for the organism that produces them as well as for nonphotosynthetic organisms that directly or indirectly consume photosynthetic organisms. Moreover, photosynthesis, over the eons, generated all of the oxygen in the earth’s atmosphere (recall that the early earth’s atmosphere was devoid of O₂; Section 1-1A). It is estimated that photosynthesis annually fixes ~10¹¹ tons of carbon, which represents the storage of over 10¹⁸ kJ of energy. About half of this activity is carried out by **phytoplankton**, mainly **cyanobacteria** (formerly known as blue-green algae, although they are prokaryotes). The process by which light energy is converted to chemical energy has its roots early in evolution, and its complexity is consistent with its long history. Our discussion focuses first on purple photosynthetic bacteria, because of the relative simplicity of their photosynthetic machinery, and then on plants, whose chloroplasts are their site of photosynthesis.

Early in the twentieth century, it was mistakenly thought that light absorbed by photosynthetic pigments directly reduced CO₂, which then combined with water to form carbohydrate. In fact, photosynthesis in plants is a two-stage process in which light energy is harnessed to oxidize H₂O:

The electrons thereby obtained subsequently reduce CO₂:

The two stages of photosynthesis are traditionally referred to as the **light reactions** and **dark reactions**:

1. In the light reactions, specialized pigment molecules capture light energy and are thereby oxidized. A series of electron-transfer reactions, which

culminate with the reduction of NADP^+ to NADPH, generate a transmembrane proton gradient whose energy is tapped to synthesize ATP from $\text{ADP} + \text{P}_i$. The oxidized pigment molecules are reduced by H_2O , thereby generating O_2 .

2. The dark reactions use NADPH and ATP to reduce CO_2 and incorporate it into the three-carbon precursors of carbohydrates.

As we will see, both processes occur in the light and are therefore better described as light-dependent and light-independent reactions. After describing the chloroplast and its contents, we consider the light reactions and dark reactions in turn.

1 Chloroplasts

KEY CONCEPTS

- The chloroplast thylakoid membrane is the site of light absorption.
- Pigment molecules, some arranged in light-harvesting complexes, absorb visible light.

The site of photosynthesis in eukaryotes (algae and higher plants) is the **chloroplast**. Cells contain 1 to 1000 chloroplasts, which vary considerably in size and shape but are typically $\sim 5\text{-}\mu\text{m}$ -long ellipsoids. These organelles presumably evolved from photosynthetic bacteria.

A The Light Reactions Take Place in the Thylakoid Membrane

Like mitochondria, which they resemble in many ways, chloroplasts have a highly permeable outer membrane and a nearly impermeable inner membrane separated by a narrow intermembrane space (Fig. 19-1). The inner membrane encloses the **stroma**, a concentrated solution of enzymes, including those required for carbohydrate synthesis. The stroma also contains the DNA, RNA, and ribosomes involved in the synthesis of several chloroplast proteins.

FIG. 19-1 Chloroplast from corn. (a) An electron micrograph. (b) Schematic diagram.

? How do chloroplasts resemble mitochondria? How do they differ?

	R_1	R_2	R_3	R_4
Chlorophyll <i>a</i>	$-\text{CH}=\text{CH}_2$	$-\text{CH}_3$	$-\text{CH}_2-\text{CH}_3$	P
Chlorophyll <i>b</i>	$-\text{CH}=\text{CH}_2$	$-\text{C}(=\text{O})-\text{H}$	$-\text{CH}_2-\text{CH}_3$	P
Bacteriochlorophyll <i>a</i>	$-\text{C}(=\text{O})-\text{CH}_3$	$-\text{CH}_3^a$	$-\text{CH}_2-\text{CH}_3^a$	P or G
Bacteriochlorophyll <i>b</i>	$-\text{C}(=\text{O})-\text{CH}_3$	$-\text{CH}_3^a$	$=\text{CH}-\text{CH}_3^a$	P

^a No double bond between positions C3 and C4.

FIG. 19-2 Chlorophyll structures. The molecular formulas of chlorophylls *a* and *b* and bacteriochlorophylls *a* and *b* are compared to that of iron-protoporphyrin IX (heme). The isoprenoid phytol and geranylgeranyl tails presumably increase the chlorophylls' solubility in their nonpolar membrane environments.

The stroma, in turn, surrounds a third membranous compartment, the **thylakoid** (Greek: *thylakos*, a sac or pouch). The thylakoid is probably a single highly folded vesicle, although in most organisms it appears to consist of stacks of disk-like sacs named **grana** (singular, granum), which are interconnected by unstacked **stromal lamellae**. A chloroplast usually contains 10 to 100 grana. Thylakoid membranes arise from invaginations in the inner membrane of developing chloroplasts and therefore resemble mitochondrial cristae. The thylakoid membrane contains protein complexes involved in harvesting light energy, transporting electrons, and synthesizing ATP. In photosynthetic bacteria, the machinery for the light reactions is located in the plasma membrane, which often forms invaginations or multilamellar structures that resemble grana.

B Pigment Molecules Absorb Light

The principal photoreceptor in photosynthesis is **chlorophyll**. This cyclic tetrapyrrole, like the heme group of globins and cytochromes (Section 7-1A and Box 18-1), is derived biosynthetically from protoporphyrin IX. Chlorophyll molecules, however, differ from heme in several respects (Fig. 19-2). In chlorophyll, the central metal ion is Mg^{2+} rather than Fe(II) or Fe(III) , and a cyclopentanone

FIG. 19-3 Absorption spectra of various photosynthetic pigments. The chlorophylls have two absorption bands, one in the red (long wavelength) and one in the blue (short wavelength). Phycoerythrin absorbs blue and green light, whereas phycocyanin absorbs yellow light. Together, these pigments absorb most of the visible light in the solar spectrum. [After a drawing by Govindjee, University of Illinois.]

? What is the color of each pigment?

ring, Ring V, is fused to pyrrole Ring III. The major chlorophyll forms in plants and cyanobacteria, **chlorophyll a (Chl a)** and **chlorophyll b (Chl b)**, and the major forms in photosynthetic bacteria, **bacteriochlorophyll a (BChl a)** and **bacteriochlorophyll b (BChl b)**, also differ from heme and from each other in the degree of saturation of Rings II and IV and in the substituents of Rings I, II, and IV.

The highly conjugated chlorophyll molecules, along with other photosynthetic pigments, strongly absorb visible light (the most intense form of the solar radiation reaching the earth's surface; Fig. 19-3). The relatively small chemical differences among the various chlorophylls greatly affect their absorption spectra.

Light-Harvesting Complexes Contain Multiple Pigments. The primary reactions of photosynthesis, as is explained in Section 19-2B, take place at **photosynthetic reaction centers**. Yet photosynthetic assemblies contain far more chlorophyll molecules than are contained in reaction centers. This is because most chlorophyll molecules do not participate directly in photochemical reactions but function to gather light; that is, they act as **light-harvesting antennas**. These **antenna chlorophylls** pass the energy of absorbed **photons** (units of light) from molecule to molecule until it reaches a photosynthetic reaction center (Fig. 19-4).

Transfer of energy from the antenna system to a reaction center (**RC**) occurs in $<10^{-10}$ s with an efficiency of $>90\%$. This high efficiency depends on the chlorophyll molecules having appropriate spacings and relative orientations.

FIG. 19-4 Flow of energy through a photosynthetic antenna complex. The energy of an absorbed photon randomly migrates among the molecules of the antenna complex (*light green circles*) until it reaches a reaction center chlorophyll (*dark green circles*) or, less frequently, is reemitted (fluorescence).

Courtesy of Juergen Koepfle and Hartmut Michel, Max Planck Institute of Biophysics, Germany

FIG. 19-5 X-Ray structure of the light-harvesting complex LH-2 from *Rs. molischianum*. (a) View perpendicular to the photosynthetic membrane showing that the α subunits (blue; 56 residues) and the β subunits (magenta; 45 residues), as represented by their C_{α} backbones, are arranged in two concentric eightfold symmetric rings. Twenty-four bacteriochlorophyll *a* (BChl *a*; green) and eight lycopene (a carotenoid; yellow) molecules are sandwiched between the protein rings. (b) View from the plane of the membrane, using the same colors as in Part a, in which the α -helical portions of the proteins are

represented by cylinders and the Mg^{2+} ions are represented by white spheres. Note that eight of the BChl *a* molecules are bound near the top of the complex with their ring systems nearly parallel to the plane of the membrane, whereas the remaining sixteen BChl *a* molecules are bound near the bottom of the complex with their ring systems approximately perpendicular to the plane of the membrane. This arrangement, together with that of the lycopene molecules, presumably optimizes the light-absorbing and excitation-transmitting capability of the antenna system. PDBid 1L6H.

Even in bright sunlight, an RC directly intercepts only ~ 1 photon per second, a metabolically insignificant rate. Hence, a complex of antenna pigments, or **light-harvesting complex (LHC)**, is essential.

LHCs consist of arrays of membrane-bound hydrophobic proteins that each contain numerous, often symmetrically arranged pigment molecules. For example, **LH-2** from the purple photosynthetic bacterium *Rhodospirillum rubrum* is an integral membrane protein that consists of eight α subunits and eight β subunits arranged in two eightfold symmetric concentric rings between which are sandwiched 32 pigment molecules (Fig. 19-5). Other LHCs vary widely in their structure and complement of light-harvesting pigments. The number and arrangement of pigment molecules in each LHC have presumably been optimized for efficient energy transfer throughout the LHC. Indeed, the ring of 16 BChl *a* molecules in LH-2 (lower part of Fig. 19-5b) are so strongly coupled that they absorb radiation almost as a single unit.

Most LHCs contain other light-absorbing substances besides chlorophyll. These **accessory pigments** “fill in” the absorption spectra of the antenna complexes, covering the spectral regions where chlorophylls do not absorb strongly (Fig. 19-3). For example, **carotenoids**, which are linear polyenes such as **β -carotene**,

β -Carotene

are components of all green plants and many photosynthetic bacteria and are therefore the most common accessory pigments. They are largely responsible for the brilliant fall colors of deciduous trees as well as for the orange color of carrots (after which they are named).

Water-dwelling photosynthetic organisms additionally contain other types of accessory pigments. This is because light outside the wavelengths 450 to 550 nm (blue and green light) is absorbed almost completely by passage through more than 10 m of water. In red algae and cyanobacteria, Chl *a* therefore is replaced as an antenna pigment by a set of linear tetrapyrroles, notably the red **phycoerythrobilin** and the blue **phycocyanobilin** (their spectra when linked to protein are shown in Fig. 19-3).

Phycoerythrobilin and phycocyanobilin

CHECKPOINT

- Summarize the events of the light reactions and light-independent reactions.
- Describe the structure of the chloroplast.
- Why do photosynthetic organisms contain several types of pigment molecules?
- What is the function of light-harvesting complexes?

2 The Light Reactions

KEY CONCEPTS

- Absorbed light energy can be dissipated by internal conversion, fluorescence, exciton transfer, or photooxidation.
- The special pair of the purple bacterial photosynthetic reaction center undergoes photooxidation, and an electron-transport chain returns an electron to the special pair.
- In plants and in cyanobacteria, two photosystems, cytochrome *b₆f*, and mobile electron carriers form an electron-transport chain described by the Z-scheme.
- Photosystem II reduces its photooxidized special pair with electrons derived from water.
- Electrons traveling from photosystem II through the cytochrome *b₆f* complex undergo a Q cycle that generates a transmembrane proton gradient.
- Electrons liberated by photooxidation of photosystem I reduce NADP⁺ or return to the cytochrome *b₆f* complex, whose activity contributes to the proton gradient.
- ATP is produced by photophosphorylation.

Photosynthesis is a process in which electrons from excited chlorophyll molecules are passed through a series of acceptors that convert electronic energy to chemical energy. We can thus ask two questions: (1) What is the mechanism of energy transduction? and (2) How do photooxidized chlorophyll molecules regain their lost electrons?

A Light Energy Is Transformed to Chemical Energy

Electromagnetic radiation is propagated as discrete **quanta** (photons) whose energy *E* is given by **Planck's law**:

$$E = h\nu = \frac{hc}{\lambda}$$

where *h* is **Planck's constant** ($6.626 \times 10^{-34} \text{ J} \cdot \text{s}$), *c* is the speed of light in vacuum ($2.998 \times 10^8 \text{ m} \cdot \text{s}^{-1}$), *ν* is the frequency of the radiation, and *λ* is its wavelength.

FIG. 19-6 An energy diagram indicating the electronic states of chlorophyll and their most important modes of interconversion. The wiggly arrows represent the absorption of photons or their fluorescent emission. Excitation energy may also be dissipated in radiationless processes such as internal conversion (heat production) and chemical reactions. **WPLS** See the Animated Figures.

When a molecule absorbs a photon, one of its electrons is promoted from its ground (lowest energy) state molecular orbital to one of higher energy. However, a given molecule can absorb photons of only certain wavelengths because, as is required by the law of conservation of energy, the energy difference between the two states must exactly match the energy of the absorbed photon.

An electronically excited molecule can dissipate its excitation energy in several ways (**Fig. 19-6**):

- 1. Internal conversion**, a common mode of decay in which electronic energy is converted to the kinetic energy of molecular motion; that is, to heat. Many molecules relax in this manner to their ground states. Chlorophyll molecules, however, usually relax only to their lowest excited states. Consequently, the photosynthetically applicable excitation energy of a chlorophyll molecule that has absorbed a photon in its short-wavelength band, which corresponds to its second excited state, is no different than if it had absorbed a photon in its less energetic long-wavelength band.
- 2. Fluorescence**, in which an electronically excited molecule decays to its ground state by emitting a photon. A fluorescently emitted photon generally has a longer wavelength (lower energy) than that initially absorbed. Fluorescence accounts for the dissipation of only 3 to 6% of the light energy absorbed by living plants.
- 3. Exciton transfer** (also known as **resonance energy transfer**), in which an excited molecule directly transfers its excitation energy to nearby unexcited molecules with similar electronic properties. This process occurs through interactions between the molecular orbitals of the participating molecules. *Light energy is funneled to RCs through exciton transfer among antenna pigments.* The energy (excitation) is trapped at the RC chlorophylls because they have slightly lower excited state energies than the antenna chlorophylls (**Fig. 19-7**). This energy difference is lost as heat.
- 4. Photooxidation**, in which a light-excited donor molecule is oxidized by transferring an electron to an acceptor molecule, which is thereby reduced. This process occurs because the transferred electron is less tightly bound to the donor in its excited state than it is in the ground state. In photosynthesis, excited chlorophyll (Chl^*) is such a donor. *The energy of the absorbed photon is thereby chemically transferred to the photosynthetic reaction system.* Photooxidized chlorophyll, Chl^+ , a cationic free radical, eventually returns to its reduced state by oxidizing some other molecule.

FIG. 19-7 Excitation energy trapping by the photosynthetic reaction center. Light energy that has been passed among pigment molecules by exciton transfer is trapped by the reaction center chlorophyll because its lowest excited state has a lower energy than those of the antenna pigment molecules.

? Which part of this diagram represents heat energy?

(400–800 nm) does not penetrate; they require a near infrared–absorbing species of chlorophyll]. Each member of the special pair—here, P960—contacts another BChl molecule that, in turn, associates with a BPheo molecule. The menaquinone is close to the L subunit BPheo *b* (Fig. 19-9, *right*), whereas the ubiquinone associates with the M subunit BPheo *b* (Fig. 19-9, *left*). The Fe(II) is positioned between the menaquinone and the ubiquinone rings. Curiously, the two symmetry-related sets of prosthetic groups are not functionally equivalent; electrons are almost exclusively transferred through the L subunit (the right sides of Figs. 19-8 and 19-9). This effect is generally attributed to subtle structural and electronic differences between the L and M subunits.

Photon Absorption Rapidly Photooxidizes the Special Pair. The photochemical events mediated by the PbRC occur as follows:

1. The primary photochemical event of bacterial photosynthesis is the absorption of a photon by the special pair (e.g., P960). The excited electron is delocalized over both its BChl molecules.
2. P960*, the excited state of P960, has but a fleeting existence. Within ~ 3 picoseconds (ps; 10^{-12} s), P960* transfers an electron to the BPheo on the right in Fig. 19-9 to yield P960⁺ BPheo *b*⁻ (the intervening BChl group probably plays a role in conveying electrons, although it is not itself reduced; it is therefore known as the **accessory BChl**).
3. During the next 200 ps, the electron migrates to the menaquinone (or, in many species, the second ubiquinone), designated Q_A, to form the anionic semiquinone radical Q_A⁻. All these electron transfers, as diagrammed in Fig. 19-10, are to progressively lower energy states, which makes the process all but irreversible.

Rapid removal of the excited electron from the vicinity of P960⁺ is an essential feature of the PbRC; this prevents return of the electron to P960⁺, which would lead to the wasteful internal conversion of its excitation energy to heat. In fact, *electron transfer in the PbRC is so efficient that its overall quantum yield (ratio of molecules reacted to photons absorbed) is virtually 100%*. No man-made device has yet approached this level of efficiency.

FIG. 19-10 The photosynthetic electron-transport system of purple photosynthetic bacteria. Electrons liberated by the absorption of photons by P960 pass through BPheo *b* and Q_A before reaching Q_B, which exchanges with a pool of free ubiquinone. Electrons from QH₂ pass through cytochrome *bc*₁ to cytochrome *c*₂, which then reduces P960⁺. Note that two photons are required for the two-electron reduction of Q to QH₂ and that cytochrome *c*₂ carries one electron at a time back to the PbRC. The overall process is essentially irreversible because electrons are transferred to progressively lower energy states (more positive standard reduction potentials).

? Estimate the change in reduction potential of P960 that occurs when it absorbs light.

Electrons Are Returned to the Photooxidized Special Pair via an Electron-Transport Chain. Q_A^- , which occupies a hydrophobic pocket in the PbRC, transfers its excited electron to the more solvent-exposed ubiquinone, Q_B , to form Q_B^- (the Fe ion positioned between Q_A and Q_B does not directly participate in these redox reactions). Q_A never becomes fully reduced; it shuttles between its oxidized and semiquinone forms.

When the PbRC is excited again, it transfers a second electron to Q_B^- to form the fully reduced Q_B^{2-} . This anionic quinol takes up two protons from the cytoplasmic side of the plasma membrane to form Q_BH_2 . Thus, Q_B is a molecular transducer that converts two light-driven one-electron excitations to a two-electron chemical reduction.

The electrons taken up by Q_BH_2 are eventually returned to $P960^+$ via an electron-transport chain (Fig. 19-10). The details of this process are species dependent. The available redox carriers include a membrane-bound pool of ubiquinone molecules, a **cytochrome bc_1 complex**, and **cytochrome c_2** (whose structure is drawn in Fig. 6-32b). The electron-transport pathway leads from Q_BH_2 through the ubiquinone pool, with which Q_BH_2 exchanges, to cytochrome bc_1 , and then to cytochrome c_2 . The reduced cytochrome c_2 , which closely resembles mitochondrial cytochrome c , carries an electron back to $P960^+$. The PbRC is thereby reduced and prepared to absorb another photon.

Since electron transport in purple photosynthetic bacteria is a cyclic process (Fig. 19-10), it results in no net oxidation–reduction. However, when QH_2 transfers its electrons to cytochrome bc_1 , its protons are translocated across the plasma membrane. Cytochrome bc_1 is a transmembrane protein complex containing a [2Fe–2S] iron–sulfur protein, cytochrome c_1 , and a cytochrome b that contains two hemes, b_H and b_L (H and L for high and low potential). Note that cytochrome bc_1 is strikingly similar to the proton-translocating Complex III of mitochondria (which is also called cytochrome bc_1 ; Section 18-2E). In fact, electron transfer from QH_2 (a two-electron carrier) to the one-electron acceptor cytochrome c_2 occurs in a two-stage Q cycle, exactly as occurs in mitochondrial electron transport (Fig. 18-15). The net result is that for every two electrons transferred from QH_2 to cytochrome c_2 , four protons enter the periplasmic space. Thus, photon absorption by the PbRC generates a transmembrane H^+ gradient. Light-dependent synthesis of ATP is driven by the dissipation of this gradient (Section 19-2D).

C Two-Center Electron Transport Is a Linear Pathway That Produces O_2 and NADPH

In plants and cyanobacteria, *photosynthesis is a noncyclic process that uses the reducing power generated by the light-driven oxidation of H_2O to produce NADPH*. This multistep process involves two photosynthetic reaction centers (RCs) that each bear considerable resemblance to PbRCs. These RCs are **photosystem II (PSII)**, which oxidizes H_2O , and **photosystem I (PSI)**, which reduces $NADP^+$. Each photosystem is independently activated by light, with electrons flowing from PSII to PSI. *PSII and PSI therefore operate in electrical series to couple H_2O oxidation with $NADP^+$ reduction*.

Evidence for the existence of two photosystems came from observations that in the presence of both red light (which activates only PSI) and yellow-green light (which also activates PSII), plants produce O_2 (i.e., oxidize H_2O) at a greater rate than the sum of the rates for each light acting alone. The herbicide **3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU)**

3-(3,4-Dichlorophenyl)-1,1-dimethylurea (DCMU)

FIG. 19-11 A model of the thylakoid membrane. The electron-transport system consists of three protein complexes: PSII, the cytochrome b_6f complex, and PSI, which are electrically “connected” by the diffusion of the electron carriers plastoquinone (Q) and plastocyanin (PC). Light-driven transport of electrons (blue arrows) from H_2O to $NADP^+$ motivates the transport of protons (red arrows) into the thylakoid lumen. Additional protons are split off from water by the oxygen-evolving center (OEC), yielding O_2 . The resulting proton gradient powers the synthesis of ATP by the CF_1CF_0 proton-translocating ATP

synthase. The membrane also contains light-harvesting complexes (not shown) whose component pigments transfer their excitations to PSII and PSI. Fd represents ferredoxin. [After Ort, D.R. and Good, N.E., *Trends Biochem. Sci.* **13**, 469 (1988).]

? How many photon-absorption events are required to reduce $NADP^+$ to $NADPH$? How many protons are translocated across the thylakoid membrane during the process?

blocks electron flow from PSII to PSI so that even with adequate illumination (i.e., activation of both PSI and PSII), PSI is not supplied with electrons, PSII cannot be reoxidized, and photosynthetic oxygen production ceases.

The pathway of electron transport in the chloroplast is more elaborate than in purple photosynthetic bacteria. *The components involved in electron transport from H_2O to $NADPH$ are largely organized into three thylakoid membrane-bound particles (Fig. 19-11): PSII, a cytochrome b_6f complex, and PSI.* Electrons are transferred between the complexes via mobile electron carriers, much as occurs in the respiratory electron-transport chain. The ubiquinone analog **plastoquinone (Q)**, via its reduction to **plastoquinol (QH_2)**, links PSII to the cytochrome b_6f

FIG. 19-12 The Z-scheme of photosynthesis. Electrons ejected from P680 in PSII by the absorption of photons are replaced with electrons abstracted from H_2O by an Mn-containing complex (the oxygen-evolving center; OEC), thereby forming O_2 and 4H^+ . Each ejected electron passes through a chain of electron carriers to a pool of plastoquinone molecules (Q_{pool}). The resulting plastoquinol, in turn, reduces the cytochrome b_6f complex (green box) with the concomitant translocation of protons into the thylakoid lumen. Cytochrome b_6f then transfers the electrons to plastocyanin (PC). The plastocyanin

reduces photooxidized P700 in PSI. The electron ejected from P700, through the intermediacy of a chain of electron carriers, reduces NADP^+ to NADPH in noncyclic electron transport. Alternatively, the electron may return to the cytochrome b_6f complex in a cyclic process that translocates additional protons into the thylakoid lumen. The reduction potentials increase downward so that electrons flow spontaneously in this direction.

? Write a chemical equation for the Z-scheme.

complex, which, in turn, interacts with PSI through the mobile peripheral membrane protein **plastocyanin (PC)**.

Electrons eventually reach **ferredoxin-NADP⁺ reductase (FNR)**, where they are used to reduce NADP^+ . The oxidation of water and the passage of electrons through a Q cycle generate a transmembrane proton gradient, with the greater $[\text{H}^+]$ in the thylakoid lumen. The free energy of the proton gradient is tapped by chloroplast ATP synthase.

The various prosthetic groups of the photosynthetic apparatus of plants can be arranged in a diagram known as the **Z-scheme** (Fig. 19-12). As in other electron-transport systems, electrons flow from low to high reduction potentials. The zigzag nature of the Z-scheme reflects the two loci for photochemical events (one at PSII, one at PSI) that are required to drive electrons from H_2O to NADP^+ .

PSII Resembles the PbRC. PSII from the thermophilic cyanobacterium *Thermosynechococcus elongatus* consists of 19 subunits, 14 of which occupy the photosynthetic membrane. These transmembrane subunits include the reaction center proteins **D1 (PsbA)** and **D2 (PsbD)**, the chlorophyll-containing inner-antenna subunits **CP43 (PsbC)** and **CP47 (PsbB)**, and **cytochrome b_{559}** . Two-center photosynthesis (Z-scheme) overview

(a)

FIG. 19-13 X-Ray structure of PSII from *T. elongatus*. The PSII dimer is viewed from within the plane of the membrane. Its transmembrane subunits include D1 (yellow), D2 (orange), CP47 (red), CP43 (green), and cytochrome b_{559} (magenta). Other transmembrane subunits are colored light blue and blue-gray. Its extrinsic proteins are PsbO (dark blue), PsbU (purple), and PsbV (light green). The various cofactors are drawn in stick form with the chlorophylls of the D1/D2 reaction center light green, those of the antenna complexes dark green, pheophytins dark blue, hemes red, β -carotenes orange, Q_A and Q_B purple, and the nonheme Fe represented by a red sphere. The inferred position of the membrane is indicated by the light blue band. (b) View of a PSII protomer perpendicular to the membrane from the thylakoid lumen showing only the transmembrane portions of the complex and colored as in Part a. A portion of the other protomer in the PSII dimer is shown in muted colors with the dashed line indicating the region of monomer–monomer interactions. The pseudotwofold axis, which is perpendicular to the membrane and passes through the nonheme Fe, relates the transmembrane helices of the D1/D2 heterodimer, CP43 and CP47, and PsbI and PsbX as emphasized by the black lines encircling the subunits. PDBid 1S5L.

(b)

X-ray structure of this PSII (Fig. 19-13), independently determined by James Barber and So Iwata and by Wolfram Saenger, reveals that the ~ 340 -kD protein is a symmetric dimer, whose protomeric units each contain 35 transmembrane helices. Each protomer, which has pseudotwofold symmetry, binds 36 Chl a 's, 2 pheophytin a 's (Pheo a 's; Chl a with its Mg^{2+} replaced by two protons), 1 heme b , 1 heme c , 2 plastoquinones, 1 nonheme Fe, 7 all-trans carotenoids presumed to be β -carotene, 2 HCO_3^- ions, and 1 Mn_4CaO_5 complex known as the oxygen-evolving center (OEC). In higher plants, the PSII protomer contains ~ 25 subunits and forms an ~ 1000 -kD transmembrane supercomplex with several antenna proteins. The arrangement of the 5 transmembrane helices in both D1 and D2 resembles that in the L and M subunits of the PbRC (Fig. 19-8). Indeed, the two sets of subunits have similar sequences, thereby indicating that they arose from a common ancestor.

FIG. 19-14 The arrangement of electron-transfer cofactors in PSII from *T. elongatus*. The complex is viewed along the membrane plane with the thylakoid lumen below. The cofactors are colored as in Fig. 19-13 but with Mg^{2+} yellow, N blue, and O red. The phytol tails of the chlorophylls and pheophytins have been removed for clarity. The side chains of Tyr_Z (D1 Tyr 161) and D1 His 190 are yellow, and those of Tyr_D (D2 Tyr 160) and D2 His 189 are orange. The OEC is drawn in space-filling form with Mn purple, Ca^{2+} cyan, and O red. The numbers indicate the center-to-center distances, in Ångströms, between the cofactors spanned by the accompanying thin black lines. PDBid 1S5L.

? Compare this figure to Fig. 19-9 (which is drawn upside down relative to this figure).

The cofactors of PSII's RC (Fig. 19-14) are organized similarly to those of the bacterial system (Fig. 19-9): They have essentially the same components (with Chl *a*, Pheo *a*, and plastoquinone respectively replacing BChl *b*, BPheo *b*, and menaquinone) and are symmetrically organized along the complex's pseudotwofold axis. The two Chl *a* rings labeled P_{D1} and P_{D2} in Fig. 19-14 are positioned analogously to the BChl *b*'s of P960's "special pair" and are therefore presumed to form PSII's primary electron donor, **P680** (named after the wavelength at which its absorbance maximally decreases on photooxidation). The electron ejected from P680 follows a similar asymmetric course as that in the PbRC even though the two systems operate over different ranges of reduction potential (compare Figs. 19-10 and 19-12). As indicated in the central part of Fig. 19-12, the electron is transferred to a molecule of Pheo *a* (Pheo_{D1} in Fig. 19-14), probably via a Chl *a* molecule (Chl_{D1}), and then to a bound plastoquinone (Q_A). The electron is subsequently transferred to a second plastoquinone molecule, Q_B , which, after it receives a second electron in a like manner, takes up two protons at the stromal (cytoplasmic in cyanobacteria) surface of the thylakoid membrane. The resulting plastoquinol, Q_BH_2 , then exchanges with a membrane-bound pool of plastoquinone molecules. DCMU as well as many other commonly used herbicides compete with plastoquinone for the Q_B -binding site on PSII, which explains how they inhibit photosynthesis.

O₂ Is Generated by a Five-Stage Water-Splitting Reaction. The electron ejected by photooxidation of P680 is replaced by an electron derived from H₂O via the OEC. The OEC of PSII is also known as the **water-splitting enzyme** because it breaks down two water molecules to O₂, four protons, and four electrons. Insight into this process was garnered by Pierre Joliet and Bessel Kok, who analyzed the production of O₂ by dark-adapted chloroplasts that were exposed to a series of short flashes of light. O₂ was evolved with a peculiar oscillatory pattern (Fig. 19-15). There is virtually no O₂ evolved by the first two flashes. The third flash results in the maximum O₂ yield. Thereafter, the amount of O₂ produced peaks with every fourth flash until the oscillations damp out to a

FIG. 19-15 The O₂ yield per flash in dark-adapted spinach chloroplasts. Note that the yield peaks on the third flash and then on every fourth flash thereafter until the curve eventually damps out to its average value. [After Forbush, B., Kok, B., and McGloin, M.P., *Photochem. Photobiol.* **14**, 309 (1971).]

FIG. 19-16 Schematic mechanism of O_2 generation in chloroplasts. Four electrons are stripped, one at a time, in light-driven reactions ($S_0 \rightarrow S_4$), from two bound H_2O molecules. O_2 is released in the recovery step ($S_4 \rightarrow S_0$), which is light independent. Four of the five steps release protons into the thylakoid lumen.

steady state. This periodicity indicates that each OEC must undergo four light-dependent reactions—that is, four electron transfers—before releasing O_2 .

The OEC is thought to cycle through five different states, S_0 through S_4 (Fig. 19-16). O_2 is released in the transition between S_4 and S_0 . The observation that O_2 evolution peaks at the third rather than the fourth flash indicates that the OEC's resting state is predominantly S_1 rather than S_0 . The oscillations gradually damp out because a small fraction of the RCs fail to be excited or become doubly excited by a given flash of light, so that the RCs eventually lose synchrony. The complete reaction sequence releases a total of four water-derived protons into the inner thylakoid space in a stepwise manner. These protons contribute to the transmembrane proton gradient.

Since the OEC abstracts electrons from H_2O , its five states must have extraordinarily high reduction potentials (recall from Table 14-4 that the O_2/H_2O half-reaction has a standard reduction potential of 0.815 V). PSII must also stabilize the highly reactive intermediates for extended periods (as much as minutes) in close proximity to water.

The OEC, which is located at the luminal surface of the D1 subunit (Fig. 19-14), is a Mn_4CaO_5 complex in which the O atoms bridge neighboring Mn atoms. The structure of the OEC had been difficult to determine because it decomposes rapidly when exposed to the X-rays typically used to determine protein structures. This problem was overcome through the use of an **X-ray free-electron laser**, which produces an X-ray beam of such enormous intensity that it vaporizes anything in its path. However, the beam comes in pulses of only a few femtoseconds (fs; 10^{-15} s), so short that the atoms of a protein crystal can move no more than a fraction of an ångström during the pulse. Thus, the recorded diffraction pattern is that of the undisturbed crystal (a new crystal or a new portion of a crystal must be used after every X-ray pulse).

Fig. 19-17 shows the structure of the native OEC in its S_1 state in the X-ray structure of *Thermosynechococcus vulcanus* PSII, as determined, using an X-ray free-electron laser, by Masaki Yamamoto, Hideo Ago, and Jian-Ren Shen. Each of the OEC's four Mn ions is six-coordinated by O atoms and protein side chains (not shown in Fig. 19-17). The significantly longer Mn—O bonds involving O5 compared to the other bridging O atoms suggest that O5 is an OH^- ion rather than an oxygen dianion (O^{2-}). This further suggests that, in the S_0 state, O5 is part of a water molecule that releases a proton on transitioning to the S_1 state (Fig. 19-16).

Water-splitting, a reaction that is essential for sustaining most organisms, is driven by the excitation of the PSII RC. A variety of evidence indicates that the Mn ions in the OEC's five S states (Fig. 19-16) cycle through specific combinations of Mn(II), Mn(III), Mn(IV), and Mn(V) while abstracting protons and electrons from two H_2O molecules to yield O_2 , which is released into the thylakoid lumen. However, although several proposals for the chemical mechanism through which the OEC oxidizes water have been put forward, none has been experimentally verified.

The electrons abstracted from water by the OEC are relayed, one at a time, to $P680^+$ by an entity originally named Z (Fig. 19-12). Spectroscopic measurements have identified Z as a transient neutral tyrosyl radical ($TyrO\cdot$) located on D1 Tyr 161 (known as Tyr_Z), which is situated between the OEC and $P680$ (Fig. 19-14). Recall that a tyrosyl radical has also been implicated in the reduction of O_2 to $2 H_2O$ by cytochrome *c* oxidase (Complex IV) in the respiratory electron-transport chain (Section 18-2F).

FIG. 19-17 The structure of the OEC in its S_1 state from the thermophilic cyanobacterium *T. vulcanus*. The Mn_4CaO_5 complex is shown with Mn ions gray, the Ca^{2+} ion blue, O red except O5, which is yellow, and structural water oxygen atoms (W) orange. Distances between the metal ions and bridging oxygen atoms are given in ångströms. The proposed oxidation states of the Mn ions, as inferred from spectroscopic and structural data, are indicated in roman numerals. Interactions with protein side chains (mainly Asp, Glu, and His) are not shown. [Courtesy of Jian-Ren Shen, Okayama University, Japan. PDBid 4UB8.]

FIG. 19-18 X-Ray structure of the cytochrome b_6f complex from the thermophilic cyanobacterium *Mastigocladus laminosus*. A ribbon diagram of the dimeric complex is drawn on the left with cytochrome b_6 blue, subunit IV purple, cytochrome f red, the iron–sulfur protein (ISP) yellow, and the other subunits green. The inferred position of the lipid bilayer is indicated by a yellow band. The paths of electron and proton transfer through the complex and the distances, in angstroms, between redox centers are shown on the right. [Modified from a drawing by William A. Cramer and Janet Smith, Purdue University. PDBid 1UM3.]

? Compare this figure to Fig. 18-14 (which is upside down relative to this figure) and summarize the similarities and differences.

Electron Transport through the Cytochrome b_6f Complex Generates a Proton Gradient. From the plastoquinone pool, electrons pass through the cytochrome b_6f complex. This integral membrane assembly resembles cytochrome bc_1 , its purple bacterial counterpart (Section 19-2B), as well as Complex III of the mitochondrial electron-transport chain (Section 18-2E). Electron flow through the cytochrome b_6f complex occurs through a Q cycle (Fig. 18-15). Accordingly, two protons are translocated across the thylakoid membrane for every electron transported. The four electrons abstracted from 2 H_2O by the OEC therefore lead to the translocation of eight H^+ from the stroma to the thylakoid lumen. *Electron transport via the cytochrome b_6f complex generates much of the electrochemical proton gradient that drives the synthesis of ATP in chloroplasts.*

The X-ray structure of cytochrome b_6f (Fig. 19-18) was independently determined by Janet Smith and William Cramer and by Jean-Luc Polpot and Daniel Picot. Cytochrome b_6f is a dimer of ~ 109 -kD protomers, each containing four large subunits (18–32 kD) that have counterparts in cytochrome bc_1 : **cytochrome b_6** , a homolog of the N-terminal half of cytochrome b ; **subunit IV**, a homolog of the C-terminal half of cytochrome b ; **cytochrome f** (f for *feuille*, French for leaf), a c -type cytochrome that is a functional analog of cytochrome c_1 , although the two are unrelated in structure or sequence; and a Rieske iron–sulfur protein (ISP), which is also present in cytochrome bc_1 . In addition, cytochrome b_6f has four small hydrophobic subunits that have no equivalents in cytochrome bc_1 . Each protomer contains 13 transmembrane helices, four in cytochrome b_6 , three in subunit IV, and one each in the remaining subunits. Cytochrome b_6f binds cofactors that are the equivalents of all of those in cytochrome bc_1 : **heme f** , a c -type heme bound by cytochrome f ; a $[2Fe-2S]$ cluster bound by the ISP; hemes b_H and b_L ; a plastoquinone molecule that occupies either the Q_i site (the quinone-binding site at which fully reduced quinone is regenerated during the Q cycle; Section 18-2E) or the Q_o site. In addition, cytochrome b_6f binds several cofactors that have no counterparts in cytochrome bc_1 : a Chl a , a β -carotene, and, unexpectedly, a novel heme named **heme x** (alternatively, **heme c_i**), which is covalently linked to the protein via a single thioether bond to Cys 35 of cytochrome b_6 , and whose only axial ligand is a water molecule (compare with hemes a , b , and c in Box 18-1).

Plastocyanin Transports Electrons from Cytochrome b_6f to PSI. Electron transfer between cytochrome f , the terminal electron carrier of the cytochrome b_6f

FIG. 19-19 X-Ray structure of plastocyanin (PC) from poplar leaves. This 99-residue monomeric protein, a member of the family of **blue copper proteins**, folds into a β sandwich. Its Cu atom (*orange sphere*), which alternates between its Cu(I) and Cu(II) oxidation states, is tetrahedrally coordinated by the side chains of His 37, Cys 84, His 87, and Met 92, which are shown in stick form with C green, N blue, and S yellow. Seven conserved Asp and Glu residues that form a negatively charged patch on the protein's surface are red. [Based on an X-ray structure by Mitchell Guss and Hans Freeman, University of Sydney, Australia. PDBid 1PLC.]

complex, and PSI is mediated by plastocyanin (PC), a peripheral membrane protein located on the thylakoid luminal surface (Fig. 19-11). The Cu-containing redox center of this mobile monomer cycles between its Cu(I) and Cu(II) oxidation states. The X-ray structure of PC from poplar leaves shows that the Cu atom is coordinated with distorted tetrahedral geometry by a Cys, a Met, and two His residues (Fig. 19-19). Cu(II) complexes with four ligands normally adopt a square planar coordination geometry, whereas those of Cu(I) are usually tetrahedral. Evidently, the strain of Cu(II)'s protein-imposed tetrahedral coordination in PC promotes its reduction to Cu(I). This hypothesis accounts for PC's high standard reduction potential (0.370 V) compared to that of the normal Cu(II)/Cu(I) half-reaction (0.158 V) and illustrates how proteins can modulate the reduction potentials of their redox centers. In the case of plastocyanin, this facilitates electron transfer from the cytochrome *b₆f* complex to PSI.

The structures of cytochrome *f* and PC suggest how the proteins associate. Cytochrome *f*'s Lys 187, a member of a conserved group of five positively charged residues on the protein's surface, can be chemically cross-linked to Asp 44 on PC, which occupies a conserved negatively charged surface patch. Quite possibly the two proteins associate through electrostatic interactions, much like PC's functional analog cytochrome *c* interacts with its redox partners in the mitochondrial electron-transport chain (Section 18-2E).

The PSI RC Resembles Both the PSII RC and the PbRC. Cyanobacterial PSIs are trimers of protomers that each consist of at least 11 different protein subunits coordinating >100 cofactors. The X-ray structure of PSI from *T. elongatus* (Fig. 19-20), determined by Saenger, reveals that each of its 356-kD protomers contains nine transmembrane subunits (**PsaA, PsaB, PsaF, PsaI–M, and PsaX**) and three stromal (cytoplasmic in cyanobacteria) subunits (**PsaC–E**), which collectively bind 127 cofactors that comprise 30% of PSI's mass. The cofactors forming the PSI RC are all bound by the homologous subunits PsaA (755 residues) and PsaB (740 residues), whose 11 transmembrane helices each are arranged in a manner resembling those in the L and M subunits of the PbRC (Fig. 19-8) and the D1 and D2 subunits of PSII (Fig. 19-13), thus supporting the notion that all RCs arose from a common ancestor. PsaA and PsaB, together with other transmembrane subunits, also bind the cofactors of the core antenna system (see below).

Figure 19-21 indicates that PSI's RC consists of 6 Chl *a*'s and two molecules of **phylloquinone**,

which has the same phytol side chain as do chlorophylls (Fig. 19-2), all arranged in two pseudosymmetrically related branches, followed by three [4Fe-4S] clusters. The primary electron donor of this system, **P700**, consists of a pair of parallel

FIG. 19-20 X-Ray structure of PSI from *T. elongatus*. (a) View of the trimeric complex perpendicular to the membrane from its stromal side. The stromal subunits have been removed for clarity. PSI's threefold axis of symmetry is represented by the small black triangle. Different structural elements are shown for each of the three protomers (I, II, and III). I shows the arrangement of transmembrane helices (*cylinders*), which are differently colored for each subunit. The transmembrane helices of both PsaA (*blue*) and PsaB (*red*) are named a through k from their N- to C-termini. The six helices in extramembranous loop regions are drawn as spirals. II shows the transmembrane helices as cylinders with the stromal and luminal loop

regions drawn in ribbon form. III shows the transmembrane helices as cylinders together with all cofactors. The RC Chl *a*'s and quinones, drawn in stick form, are blue, the Fe and S atoms of the [4Fe-4S] clusters are drawn as orange and yellow spheres, the antenna system Chl *a*'s (whose side chains have been removed for clarity) are yellow, the carotenoids are black, and the bound lipids are light green. (b) One protomer as viewed parallel to the membrane along the arrow in Part a with the stroma above. The transmembrane subunits are colored as in Part a with the stromal subunits PsaC, PsaD, and PsaE pink, cyan, and light green. The vertical line and triangle mark the trimer's threefold axis of symmetry. PDBid 1JBO.

Chl *a*'s, A1 and B1, whose Mg²⁺ ions are separated by 6.3 Å, and thus resembles the special pair in the PbRC. A1 is followed in the left branch of Fig. 19-21 by two more Chl *a* rings, B2 and A3, and B1 is followed by A2 and B3 in the right branch. One or both of the third pair of Chl *a* molecules, A3 and B3, probably form the spectroscopically identified primary electron acceptor A₀ (right side of Fig. 19-12). The Mg²⁺ ions of A3 and B3 are each axially liganded by the S atoms of a Met residue rather than by His side chains (thereby forming the only known biological examples of Mg²⁺—S coordination). Electrons are passed from A3 and B3 to the phylloquinones, Q_k-A and Q_k-B, which almost certainly correspond to the spectroscopically identified electron acceptor A₁. Spectroscopic investigations indicate that, in contrast to the case for the PbRC, electrons pass through

? Compare this figure with Figs. 19-9 and 19-14.

FIG. 19-22 X-Ray structure of ferredoxin from *Peptococcus aerogenes*. This monomeric 54-residue protein contains two [4Fe–4S] clusters. The C_β atoms of the four Cys residues liganding each cluster are green, the Fe atoms are orange, and the S atoms are yellow. [Based on an X-ray structure by Elinor Adman, Larry Sieker, and Lyle Jensen, University of Washington. PDBid 1FDX.]

both branches of the PSI RC, although at different rates. Indeed, the PSI RC is most closely related to the RC of **green sulfur bacteria** (a second class of photosynthetic bacteria), which is a true homodimer.

Until this point, PSI's RC resembles those of PSII and purple photosynthetic bacteria. However, rather than the reduced forms of either Q_{K-A} or Q_{K-B} dissociating from PSI, both of the quinones directly pass their photoexcited electron to a chain of three spectroscopically identified [4Fe–4S] clusters designated F_X, F_A, and F_B (right side of Fig. 19-12). F_X, which lies on the pseudotwofold axis relating PsaA and PsaB, is coordinated by two Cys residues from each of the subunits. F_A and F_B are bound to the stromal subunit PsaC, which structurally resembles bacterial ferredoxins that contain two [4Fe–4S] clusters (Fig. 19-22). The observation that both branches of PSI's electron-transfer pathways are active, in contrast to only one active branch in PSII and the PbRC, is rationalized by the observation that the two quinones at the ends of each branch are functionally equivalent in PSI but functionally different in PSII and the PbRC.

PSI's core antenna system consists of 90 Chl *a* molecules and 22 carotenoids (Fig. 19-20a). The spatial distribution of these antenna Chl *a*'s resembles that in the core antenna subunits CP43 and CP47 of PSII (Fig. 19-13). Indeed, the N-terminal domains of PsaA and PsaB are similar in sequence to those of CP43 and CP47 and fold into similar structures containing six transmembrane helices each. The carotenoids, which are mostly β-carotenes, are deeply buried in the membrane, where they are in van der Waals contact with Chl *a* rings. This permits efficient energy transfer from photoexcited carotenoids to Chl *a*.

PSIs from higher plants are monomers rather than trimers, as are cyanobacterial PSIs. Nevertheless, the X-ray structure of PSI from peas reveals that the positions and orientations of the chlorophylls in both species of PSIs are nearly identical, a remarkable finding considering the >1 billion years since chloroplasts diverged from their cyanobacterial ancestors. However, pea PSI has four antenna proteins not present in cyanobacterial PSI that are arranged in a crescent-shaped transmembrane belt around one side of its RC and that collectively bind 56 chlorophyll molecules.

PSI-Activated Electrons May Reduce NADP⁺ or Motivate Proton Gradient Formation. *Electrons ejected from F_B in PSI may follow either of two alternative pathways* (Fig. 19-12):

1. Most electrons follow a noncyclic pathway by reducing an ~100-residue, [2Fe–2S]-containing, soluble protein called **ferredoxin (Fd)** (Fig. 19-22) that is located in the stroma. Reduced Fd, in turn, reduces NADP⁺ in a reaction mediated by the ~310-residue, monomeric, FAD-containing ferredoxin–NADP⁺ reductase (FNR, Fig. 19-23) to yield the final product of the chloroplast light reactions, NADPH. Two reduced Fd molecules successively deliver one electron each to the FAD of FNR, which thereby sequentially assumes the neutral semiquinone and fully reduced states before transferring the two electrons and a proton to the NADP⁺ via what is formally a hydride ion transfer.
2. Some electrons are returned from PSI, via cytochrome *b*₆, to the plastoquinone pool, thereby traversing a cyclic pathway

FIG. 19-23 X-Ray structure of pea ferredoxin–NADP⁺ reductase (FNR) in complex with FAD and NADP⁺. This 308-residue protein has two domains: The N-terminal domain (*gold*), which forms the FAD-binding site, folds into an anti-parallel β barrel, whereas the C-terminal domain (*magenta*), which provides the NADP⁺-binding site, forms a dinucleotide-binding fold (Section 6-2C). The FAD and NADP⁺ are shown in stick form with NADP⁺ C green, FAD C cyan, N blue, and P yellow. The flavin and nicotinamide rings are in opposition with C4 of the nicotinamide ring and C5 of the flavin ring 3.0 Å apart, an arrangement that is consistent with direct hydride transfer as also occurs in dihydrolipoyl dehydrogenase (Fig. 17-8). [Based on an X-ray structure by Andrew Karplus, Cornell University. PDBid 1QFY.]

that translocates protons across the thylakoid membrane. A mechanism that has been proposed for this process is that Fd transfers an electron to heme x of cytochrome b_6 (Fig. 19-18) rather than to FNR. Since heme x contacts heme b_L at the periphery of cytochrome b_6f 's Q_i site, an electron injected into heme x would be expected to reduce plastoquinone via a Q cycle-like mechanism (Fig. 18-15). Note that the cyclic pathway is independent of the action of PSII and hence does not result in the evolution of O_2 . This accounts for the observation that chloroplasts absorb more than eight photons per O_2 molecule evolved.

The cyclic electron flow presumably functions to increase the amount of ATP produced relative to that of NADPH and thus permits the cell to adjust the relative amounts of the two substances produced according to its needs. However, the mechanism that apportions electrons between the cyclic and noncyclic pathways is unknown. Fine-tuning of the light reactions also depends on the segregation of PSI and PSII in distinct portions of the thylakoid membrane (Box 19-1).

Box 19-1 Perspectives in Biochemistry

Segregation of PSI and PSII

Electron microscopy has revealed that the protein complexes of the thylakoid membrane have characteristic distributions (see figure).

1. PSI occurs mainly in the unstacked stromal lamellae, in contact with the stroma, where it has access to $NADP^+$.
2. PSII is located almost exclusively between the closely stacked grana, out of direct contact with the stroma.
3. Cytochrome b_6f is uniformly distributed throughout the membrane.

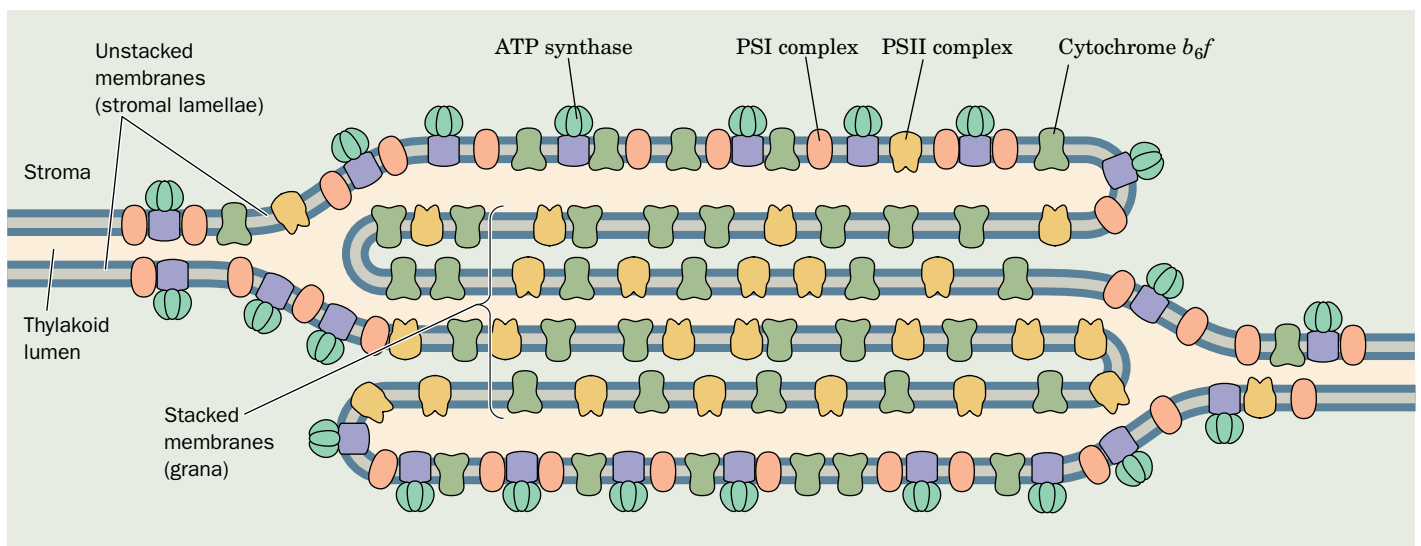

The high mobilities of plastoquinone and plastocyanin, the electron carriers that shuttle electrons between these particles, permit photosynthesis to proceed at a reasonable rate.

What function is served by the segregation of PSI and PSII? If the two photosystems were in close proximity, the higher excitation energy of PSII (P680 versus P700) would cause it to pass a large fraction of its absorbed photons to PSI via exciton transfer; that is, PSII would act as a light-harvesting antenna for PSI. The separation of the particles by around 100 Å eliminates this difficulty.

The physical separation of PSI and PSII also permits the chloroplast to respond to changes in illumination. The relative amounts of light

absorbed by the two photosystems vary with how the light-harvesting complexes are distributed between the stacked and unstacked portions of the thylakoid membrane. Under high illumination (normally direct sunlight, which contains a high proportion of short-wavelength blue light), PSII absorbs more light than PSI. PSI is then unable to take up electrons as fast as PSII can supply them, so the plastoquinone is predominantly in its reduced state. The reduced plastoquinone activates a protein kinase to phosphorylate specific Thr residues of the LHCs, which, in response, migrate to the unstacked regions of the thylakoid membrane, where they associate with PSI. A greater fraction of the incident light is thereby funneled to PSI.

Under low illumination (normally shady light, which contains a high proportion of long-wavelength red light), PSI takes up electrons faster than PSII can provide them so that plastoquinone predominantly assumes its oxidized form. The LHCs are consequently dephosphorylated and migrate to the stacked portions of the thylakoid membrane, where they associate with PSII. The chloroplast therefore maintains the balance between its two photosystems by a light-activated feedback mechanism.

FIG. 19-24 Electron micrograph of thylakoids. The CF₁ “lollipops” of their ATP synthases project from their stromal surfaces.

? Compare this electron micrograph with Fig. 18-21.

D The Proton Gradient Drives ATP Synthesis by Photophosphorylation

Chloroplasts generate ATP in much the same way as mitochondria, that is, by coupling the dissipation of a proton gradient to the enzymatic synthesis of ATP (Section 18-3). This light-dependent process is known as **photophosphorylation**. Like oxidative phosphorylation, it requires an intact thylakoid membrane and can be uncoupled from light-driven electron transport by compounds such as 2,4-dinitrophenol (Fig. 18-29).

Electron micrographs of thylakoid membrane stromal surfaces and bacterial plasma membrane inner surfaces reveal lollipop-shaped structures (Fig. 19-24). These closely resemble the F₁ units of the proton-translocating ATP synthase in mitochondria (Fig. 18-21). In fact, the chloroplast ATP synthase, which is also known as the CF₁CF₀ complex (C for chloroplast), is remarkably similar to the mitochondrial F₁F₀ complex. For example,

1. Both the F₀ and the CF₀ units are hydrophobic transmembrane proteins that contain a proton-translocating channel.
2. Both the F₁ and the CF₁ units are hydrophilic peripheral membrane proteins of subunit composition $\alpha_3\beta_3\gamma\delta\epsilon$, of which β is a reversible ATPase.
3. Both ATP synthases are inhibited by oligomycin and by dicyclohexylcarbodiimide (DCCD).

Clearly, proton-translocating ATP synthase must have evolved very early in the history of cellular life. Note, however, that whereas chloroplast ATP synthase translocates protons out of the thylakoid space into the stroma (Fig. 19-11), mitochondrial ATP synthase conducts them from the intermembrane space into the matrix space (Fig. 18-20). This is because the stroma is topologically analogous to the mitochondrial matrix.

Photosynthesis with Noncyclic Electron Transport Produces Around One ATP per Absorbed Photon. At saturating light intensities, chloroplasts generate proton gradients of ~ 3.5 pH units across their thylakoid membranes as a result of two processes:

1. The evolution of a molecule of O₂ from two H₂O molecules releases four protons into the thylakoid lumen.
2. The transport of the liberated four electrons through the cytochrome *b₆f* complex occurs with the translocation of eight protons from the stroma to the thylakoid lumen.

Altogether, ~ 12 protons enter the lumen per molecule of O₂ produced by noncyclic electron transport.

The thylakoid membrane, in contrast to the inner mitochondrial membrane, is permeable to ions such as Mg²⁺ and Cl⁻. Translocation of protons and electrons across the thylakoid membrane is consequently accompanied by the passage of these ions to maintain electrical neutrality (Mg²⁺ out and Cl⁻ in). This all but eliminates the membrane potential. *The electrochemical gradient in chloroplasts is therefore almost entirely a result of the pH (concentration) gradient.*

Chloroplast ATP synthase, according to most estimates, produces one ATP for every three protons it transports from the thylakoid lumen to the stroma. Noncyclic electron transport in chloroplasts therefore results in the production of $\sim 12/3 = 4$ molecules of ATP per molecule of O₂ evolved (cyclic electron

transport generates more ATP because more protons are translocated to the thylakoid lumen via the Q cycle mediated by cytochrome b_6f).

Noncyclic electron transport, of course, also yields NADPH (2 NADPH for every 4 electrons liberated from 2 H₂O by the OEC). Each NADPH has the free energy to produce 2.5 ATP (Section 18-3C; although NADPH is not used to drive ATP synthesis), for a total of 5 more ATP equivalents per O₂ produced. Consequently, a total of 9 ATP equivalents are generated per O₂ produced. A minimum of two photons is required for each electron traversing the system from H₂O to NADPH, that is, eight photons per O₂ produced. This is confirmed by experimental measurements which indicate that plants and algae require 8 to 10 photons of visible light to produce one molecule of O₂. Thus, the overall efficiency of the light reactions is 9 ATP/8–10 photons, or approximately one ATP per absorbed photon.

3 The Dark Reactions

KEY CONCEPTS

- The Calvin cycle carboxylates a pentose, converts the products to glyceraldehyde-3-phosphate, and regenerates the pentose, using the ATP and NADPH produced by the light reactions.
- The products of the Calvin cycle are converted to carbohydrates (glucose polymers).
- The Calvin cycle enzymes are more reactive in the light.
- Plants undergo photorespiration, which consumes O₂ and generates CO₂.

In the previous section we saw how plants harness light energy to generate ATP and NADPH. In this section we discuss how these products are used to synthesize carbohydrates and other substances from CO₂.

A The Calvin Cycle Fixes CO₂

The metabolic pathway by which plants incorporate CO₂ into carbohydrates was elucidated between 1946 and 1953 by Melvin Calvin, James Bassham, and Andrew Benson. They did so by tracing the metabolic fate of the radioactive label from ¹⁴CO₂ in cultures of algal cells. Some of Calvin's earliest experiments indicated that algae exposed to ¹⁴CO₂ for a minute or more synthesize a complex mixture of labeled metabolites, including sugars and amino acids. Analysis of the algae within 5 s of their exposure to ¹⁴CO₂, however, showed that the *first stable radioactive compound formed is 3-phosphoglycerate (3PG), which is initially labeled only in its carboxyl group*. This result immediately suggested that the 3PG was formed by the carboxylation of a C₂ compound. Yet no such precursor was found. The actual carboxylation reaction involves a pentose derived from **ribulose-5-phosphate (Ru5P; at right)**. The resulting C₆ product splits into two C₃ compounds, both of which turned out to be 3PG. ATP and NADPH, the products of the light reactions, are required to convert 3PG to glyceraldehyde-3-phosphate (GAP), which is used to synthesize carbohydrates as well as re-form Ru5P (Fig. 19-25). The entire pathway, which involves the carboxylation of a pentose, the formation of carbohydrate products, and the regeneration of the pentose, is known as the **Calvin cycle** or the **reductive pentose phosphate cycle**.

During the search for the carboxylation substrate, several other photosynthetic intermediates had been identified and their labeling patterns elucidated. For example, the hexose fructose-1,6-bisphosphate (FBP) is initially labeled only at its C3 and C4 positions but later becomes labeled to a lesser degree at its other atoms. A consideration of the flow of labeled carbon through the various tetrose, pentose, hexose, and heptose phosphates led, in what is a milestone of metabolic

CHECKPOINT

- How do molecules dissipate absorbed light energy? Which mechanism is most important for photosynthesis?
- Describe the events that occur after the special pair of P680 absorbs a photon.
- Explain why electron transport in purple photosynthetic bacteria follows a circular path.
- Describe the effect of photooxidation on the redox reactions summarized in the Z-scheme.
- What is the importance of the water-splitting reaction for photosynthesis?
- What does the Q cycle accomplish in bacterial and plant photosynthetic electron transport?
- What chloroplast protein is the functional counterpart of mitochondrial cytochrome c ?
- What are the implications of cyclic and non-cyclic electron transfer in PSI?
- Compare and contrast photophosphorylation and oxidative phosphorylation.
- Explain how the energy of one photon is transformed to the energy of one ATP.
- What is the relationship between the number of photons absorbed and the amount of O₂ produced?

Ribulose-5-phosphate (Ru5P)

FIG. 19-25 Overview of the dark reactions. The products of the light reactions, ATP and NADPH, are consumed in converting CO₂ into carbohydrates in a process called the Calvin cycle.

GATEWAY CONCEPT Energy Transformation

Energy can neither be created nor destroyed, but it can be transformed. In photosynthesis, light energy absorbed by the photosystems is transformed to the chemical energy of reduced cofactors. Some of this energy is used to generate a proton gradient that is then transformed to the mechanical energy of ATP synthase. Finally, chemical energy in the form of ATP and NADPH is transformed to the chemical energy of reduced carbon atoms in carbohydrates.

biochemistry, to the deduction of the Calvin cycle as is diagrammed in Fig. 19-26. The existence of many of its postulated reactions was eventually confirmed by *in vitro* studies using purified enzymes.

The Calvin Cycle Generates GAP from CO₂ via a Two-Stage Process. The Calvin cycle can be considered to have two stages:

- Stage 1.** The production phase (top line of Fig. 19-26), in which three molecules of Ru5P react with three molecules of CO₂ to yield six molecules of glyceraldehyde-3-phosphate (GAP) at the expense of nine ATP and six NADPH molecules. *The cyclic nature of the entire pathway makes this process equivalent to the synthesis of one GAP from three CO₂ molecules.* At this point, GAP can be bled off from the cycle for use in biosynthesis.
- Stage 2.** The recovery phase (bottom lines of Fig. 19-26), in which the carbon atoms of the remaining five GAPs are shuffled in a remarkable series of reactions, similar to those of the pentose phosphate pathway (Section 15-6), to re-form the three Ru5Ps with which the cycle began. This stage can be conceptually decomposed into four sets of reactions (with the numbers keyed to the corresponding reactions in Fig. 19-26):

The overall stoichiometry for the process is therefore

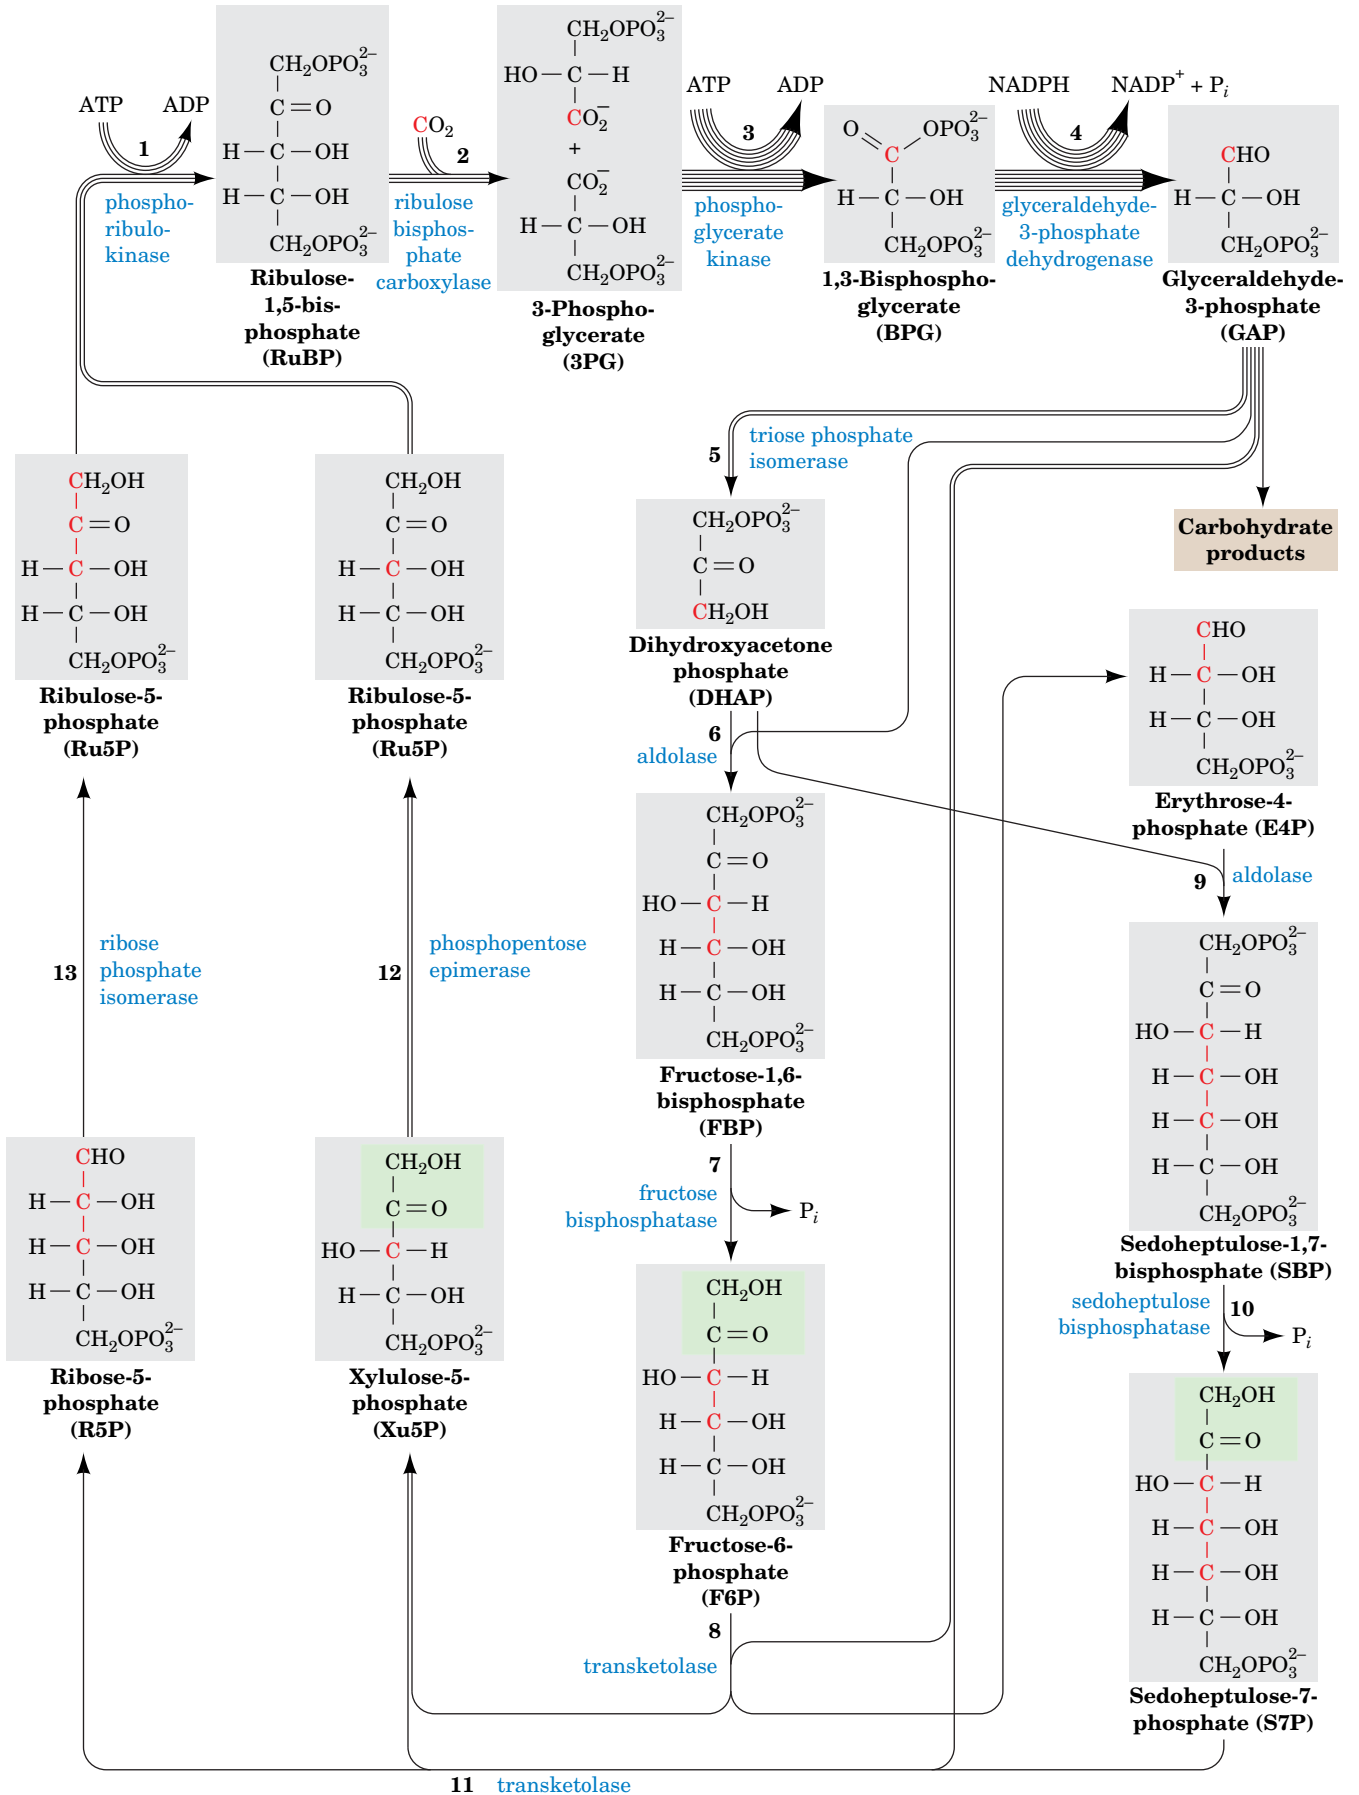

Note that this stage of the Calvin cycle occurs without further input of free energy (ATP) or reducing equivalents (NADPH).

The first reaction of the Calvin cycle is the phosphorylation of Ru5P by **phosphoribulokinase** to form **ribulose-1,5-bisphosphate (RuBP)**. Following the carboxylation of RuBP (Reaction 2; discussed below), the resulting 3PG is converted first to 1,3-bisphosphoglycerate (BPG) and then to GAP. The latter sequence is the reverse of two consecutive glycolytic reactions (Section 15-2G and 15-2F) except that the Calvin cycle reaction uses NADPH rather than NADH.

The second stage of the Calvin cycle begins with the reverse of a familiar glycolytic reaction, the isomerization of GAP to dihydroxyacetone phosphate (DHAP) by triose phosphate isomerase (Section 15-2E). Following this, DHAP is directed along two analogous paths: Reactions 6 to 8 or Reactions 9 to 11. Reactions 6 and 9 are aldolase-catalyzed aldol condensations in which DHAP is linked to an aldehyde. Reaction 6 is also the reverse of a glycolytic reaction (Section 15-2D). Reactions 7 and 10 are phosphate hydrolysis reactions that are catalyzed, respectively, by fructose biphosphatase (FBPase; Section 15-4B) and **sedoheptulose biphosphatase (SBPase)**. The remaining Calvin cycle reactions are catalyzed by enzymes that also participate in the pentose phosphate pathway. In Reactions 8 and 11, both catalyzed by transketolase, a C₂ keto unit (shaded

FIG. 19-26 The Calvin cycle. (*Opposite*) The number of lines in an arrow indicates the number of molecules reacting in that step for a single turn of the cycle that converts three CO₂ molecules to one GAP molecule. For the sake of clarity, the sugars are all shown in their linear forms, although the hexoses and heptoses predominantly exist in their cyclic forms. The ¹⁴C-labeling patterns generated in one turn of the cycle through the use of ¹⁴CO₂ are indicated in red. Note that two of the product Ru5Ps are labeled only at C3, whereas the third Ru5P is equally labeled at C1, C2, and C3. **WPLS See the Animated Figures.**

? Write the net equation for the process shown here.

green in Fig. 19-26) is transferred from a ketose to GAP to form xylulose-5-phosphate (Xu5P), leaving the aldoses erythrose-4-phosphate (E4P) in Reaction 8 and ribose-5-phosphate (R5P) in Reaction 11. The E4P produced by Reaction 8 feeds into Reaction 9. The Xu5Ps produced by Reactions 8 and 11 are converted to Ru5P by **phosphopentose epimerase** in Reaction 12. The R5P from Reaction 11 is also converted to Ru5P by **ribose phosphate isomerase** in Reaction 13, thereby completing a turn of the Calvin cycle. Only 3 of the 11 Calvin cycle enzymes—phosphoribulokinase, the carboxylation enzyme ribulose biphosphate carboxylase, and SBPase—have no equivalents in animal tissues.

RuBP Carboxylase Catalyzes CO₂ Fixation. The enzyme that catalyzes CO₂ fixation, ribulose biphosphate carboxylase (**RuBP carboxylase**), is arguably the world's most important enzyme since nearly all life on earth ultimately depends on its action. This protein, presumably as a consequence of its low catalytic efficiency ($k_{\text{cat}} \approx 3 \text{ s}^{-1}$), accounts for up to 50% of leaf proteins and is therefore the most abundant protein in the biosphere. RuBP carboxylase from higher plants and most photosynthetic microorganisms consists of eight large (L) subunits (477 residues in tobacco leaves) encoded by chloroplast DNA, and eight small (S) subunits (123 residues) specified by a nuclear gene (the RuBP carboxylase from certain photosynthetic bacteria is an L₂ dimer whose L subunit has 28% sequence identity with and is structurally similar to that of the L₈S₈ enzyme). X-Ray studies by Carl-Ivar Brändén and by David Eisenberg demonstrated that the L₈S₈ enzyme has the symmetry of a square prism (Fig. 19-27a,b). The L subunit is made of a β sheet domain and an α/β barrel domain that contains the enzyme's catalytic site (Fig. 19-27c). The function of the S subunit is unknown; attempts to show that it has a regulatory role, in analogy with other enzymes, have been unsuccessful.

The accepted mechanism of RuBP carboxylase, which was largely formulated by Calvin, is indicated in Fig. 19-28. Abstraction of the C3 proton of RuBP, the reaction's rate-determining step, generates an enediolate that nucleophilically

FIG. 19-27 X-Ray structure of tobacco RuBP carboxylase in complex with the transition state inhibitor 2-carboxyarabinitol-1,5-bisphosphate. The L₈S₈ protein has D_4 symmetry (the symmetry of a square prism; Fig. 6-34b). (a) Surface diagram viewed along the protein's fourfold axis and (b) along its twofold axis. Parts *a* and *b* are related by a 90° rotation about the horizontal axis. The elongated L subunits can be considered to associate as two interdigitated tetramers, with that extending from the top in Part *b* cyan and that extending from the bottom green. The S subunits, which form square tetramers that cap the top and bottom of the complex, are alternately yellow and orange. The 2-carboxyarabinitol-1,5-bisphosphate is drawn in stick form with C green, O red, and P orange. (c) Ribbon diagram of an L subunit oriented as is the central green subunit in Part *b* and colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The 2-carboxyarabinitol-1,5-bisphosphate is bound in the substrate-binding site at the mouth of the enzyme's α/β barrel. [Based on an X-ray structure by David Eisenberg, UCLA. PDBid 1RLC.]

FIG. 19-28 Mechanism of the RuBP carboxylase reaction. The reaction proceeds via an enediolate intermediate that nucleophilically attacks CO₂ to form a β-keto acid. This intermediate reacts with water to yield two molecules of 3PG. **WPLS** See the Animated Figures.

attacks CO₂. The resulting β-keto acid is rapidly attacked at its C3 position by H₂O to yield an adduct that splits, by a reaction similar to aldol cleavage, to yield the two product 3PG molecules. *The driving force for the overall reaction, which is highly exergonic ($\Delta G^{\circ'} = -35.1 \text{ kJ} \cdot \text{mol}^{-1}$), is provided by the cleavage of the β-keto acid intermediate to yield an additional resonance-stabilized carboxylate group.*

RuBP carboxylase activity requires Mg²⁺, which probably stabilizes developing negative charges during catalysis. The Mg²⁺ is, in part, bound to the enzyme by a catalytically important carbamate group (—NH—COO[−]) that is generated by the reaction of a nonsubstrate CO₂ with the ε-amino group of Lys 201. This essential reaction is catalyzed *in vivo* by the enzyme **RuBP carboxylase activase** in an ATP-driven process.

B Calvin Cycle Products Are Converted to Starch, Sucrose, and Cellulose

The overall stoichiometry of the Calvin cycle is

GAP, the primary product of photosynthesis, is used in a variety of biosynthetic pathways, both inside and outside the chloroplast. For example, it can be converted to fructose-6-phosphate by the further action of Calvin cycle enzymes and then to glucose-1-phosphate (G1P) by phosphoglucose isomerase and phosphoglucomutase (Section 16-1C). *G1P is the precursor of the higher order carbohydrates characteristic of plants.*

The polysaccharide α-amylase, a major component of starch (Section 8-2C), is synthesized in the chloroplast stroma as a temporary storage depot for glucose units. It is also synthesized as a long-term storage molecule elsewhere in the plant, including leaves, seeds, and roots. G1P is first activated by its reaction with ATP to form ADP-glucose as catalyzed by **ADP-glucose pyrophosphorylase**. **Starch synthase** then transfers the glucose residue to the nonreducing end of an

FIG. 19-29 Starch synthesis. ADP-glucose is formed from G1P and ATP in a phosphoanhydride exchange reaction (1). The PP_i product is rapidly hydrolyzed. ADP-glucose is the substrate for starch synthase (2), which adds the glucose residue to an existing polysaccharide, releasing ADP.

? What is the net cost of this reaction in ATP equivalents?

α-amyllose molecule, forming a new glycosidic linkage (Fig. 19-29). The overall reaction is driven by the exergonic hydrolysis of the PP_i released in the formation of ADP-glucose. A similar reaction sequence occurs in glycogen synthesis, which uses UDP-glucose (Section 16-2).

Sucrose, a disaccharide of glucose and fructose (Section 8-2A), is the major transport sugar for delivering carbohydrates to nonphotosynthesizing cells and hence is the major photosynthetic product of green leaves. Since sucrose is synthesized in the cytosol, either glyceraldehyde-3-phosphate or dihydroxyacetone phosphate is transported out of the chloroplast by an antiporter that exchanges phosphate for a triose phosphate. Two trioses combine to form fructose-6-phosphate (F6P) and subsequently glucose-1-phosphate (G1P), which is then activated by UTP to form UDP-glucose. Next, sucrose-6-phosphate is produced in a reaction catalyzed by **sucrose-phosphate synthase**. Finally, sucrose-6-phosphate is hydrolyzed by **sucrose-phosphate phosphatase** to yield sucrose (*at left*), which is then exported to other plant tissues.

Cellulose, which consists of long chains of β(1 → 4)-linked glucose units and is the major polysaccharide of plants, is also synthesized from UDP-glucose. Plant cell walls consist of nearly crystalline cables containing ~36 cellulose chains, all embedded in an amorphous matrix of other polysaccharides and lignin (Section 8-2B). Unlike starch in plants or glycogen in mammals, cellulose is synthesized by multisubunit enzyme complexes in the plant plasma membrane and extruded into the extracellular space.

C The Calvin Cycle Is Controlled Indirectly by Light

During the day, plants satisfy their energy needs via the light and dark reactions of photosynthesis. At night, however, like other organisms, they must use their nutritional reserves to generate ATP and NADPH through glycolysis, oxidative

TABLE 19-1 Standard and Physiological Free Energy Changes for the Reactions of the Calvin Cycle

Step ^a	Enzyme	ΔG° (kJ · mol ⁻¹)	ΔG (kJ · mol ⁻¹)
1	Phosphoribulokinase	-21.8	-15.9
2	Ribulose biphosphate carboxylase	-35.1	-41.0
3 + 4	Phosphoglycerate kinase + glyceraldehyde-3-phosphate dehydrogenase	+ 18.0	-6.7
5	Triose phosphate isomerase	-7.5	-0.8

phosphorylation, and the pentose phosphate pathway. Since the stroma contains the enzymes of glycolysis and the pentose phosphate pathway as well as those of the Calvin cycle, *plants must have a light-sensitive control mechanism to prevent the Calvin cycle from consuming this catabolically produced ATP and NADPH in a wasteful futile cycle.*

As we have seen, the control of flux in a metabolic pathway occurs at enzymatic steps that are far from equilibrium (large negative value of ΔG). Inspection of **Table 19-1** indicates that the three best candidates for flux control in the Calvin cycle are the reactions catalyzed by RuBP carboxylase, FBPase, and SBPase (Reactions 2, 7, and 10 of Fig. 19-26). In fact, the catalytic efficiencies of the three enzymes all vary *in vivo* with the level of illumination.

The activity of RuBP carboxylase responds to three light-dependent factors:

1. pH. On illumination, the pH of the stroma increases from ~ 7.0 to ~ 8.0 as protons are pumped from the stroma into the thylakoid lumen. RuBP carboxylase has a sharp pH optimum near pH 8.0.
2. $[\text{Mg}^{2+}]$. Recall that the light-induced influx of protons to the thylakoid lumen is accompanied by the efflux of Mg^{2+} to the stroma (Section 19-2D). This Mg^{2+} stimulates RuBP carboxylase.
3. The transition state analog **2-carboxyarabinitol-1-phosphate (CA1P)**.

2-Carboxyarabinitol-1-phosphate (CA1P)

Many plants synthesize this compound, which inhibits RuBP carboxylase, only in the dark. RuBP carboxylase activase facilitates the release of

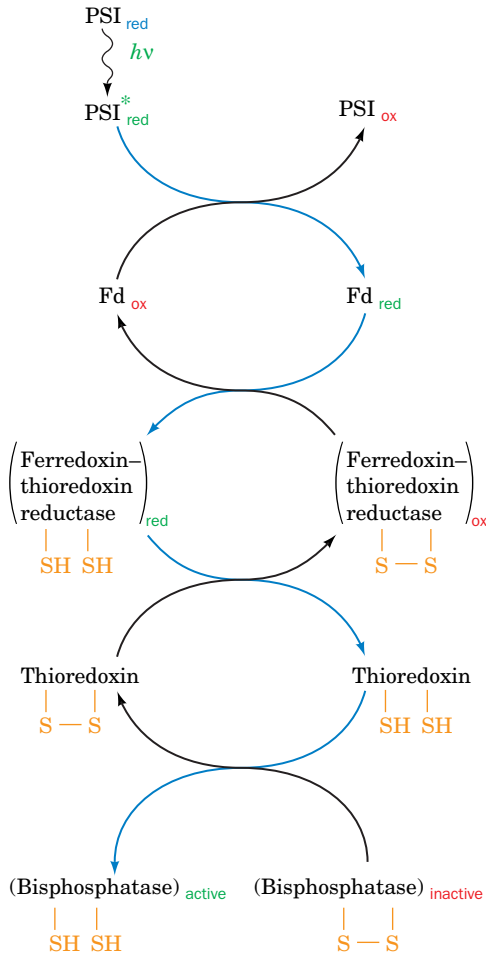

FIG. 19-30 The light-activation mechanism of FBPase and SBPase. Photoactivated PSI reduces soluble ferredoxin (Fd), which reduces ferredoxin–thioredoxin reductase, which, in turn, reduces the disulfide linkage of thioredoxin. Reduced thioredoxin reacts with the inactive bisphosphatases by disulfide interchange, thereby activating the flux-controlling Calvin cycle enzymes.

the tight-binding CA1P from RuBP carboxylase as well as catalyzing its carbamoylation (Section 19-3A).

FBPase and SBPase are also activated by increased pH and $[Mg^{2+}]$, and by NADPH as well. The effect of these factors is complemented by a second regulatory system that responds to the redox potential of the stroma. **Thioredoxin**, an ~ 105 -residue protein that occurs in many types of cells, contains a reversibly reducible disulfide group. Reduced thioredoxin activates both FBPase and SBPase by a disulfide interchange reaction (Fig. 19-30). The redox level of thioredoxin is maintained by a second disulfide-containing enzyme, **ferredoxin–thioredoxin reductase**, which directly responds to the redox state of the soluble ferredoxin in the stroma. This in turn varies with the illumination level. The thioredoxin system also deactivates phosphofructokinase (PFK), the main flux-generating enzyme of glycolysis (Section 15-4A). Thus, in plants, *light stimulates the Calvin cycle while deactivating glycolysis, whereas darkness has the opposite effect* (that is, the so-called dark reactions do not occur in the dark).

D Photorespiration Competes with Photosynthesis

It has been known since the 1960s that *illuminated plants consume O_2 and evolve CO_2 in a pathway distinct from oxidative phosphorylation. In fact, at low CO_2 and high O_2 levels, this **photorespiration** process can outstrip photosynthetic CO_2 fixation.* The basis of photorespiration was unexpected: O_2 competes with CO_2 as a substrate for RuBP carboxylase (RuBP carboxylase is therefore also called **RuBP carboxylase–oxygenase** or **RuBisCO**). In the oxygenase reaction, O_2 reacts with the enzyme's other substrate, RuBP, to form 3PG and **2-phosphoglycolate** (Fig. 19-31). The 2-phosphoglycolate is hydrolyzed to **glycolate** by **phosphoglycolate phosphatase** and, as described below, is partially oxidized to yield CO_2 by a series of enzymatic reactions that occur in the **peroxisome** and the mitochondrion. Thus, photorespiration is a seemingly wasteful process that undoes some of the work of photosynthesis. In this section we discuss the biochemical basis of photorespiration and how certain plants manage to evade its deleterious effects.

Photorespiration Dissipates ATP and NADPH. The photorespiration pathway is outlined in Fig. 19-32. Glycolate is exported from the chloroplast to the

FIG. 19-31 Probable mechanism of the oxygenase reaction catalyzed by RuBP carboxylase–oxygenase. Note the similarity of this mechanism to that of the carboxylase reaction catalyzed by the same enzyme (Fig. 19-28).

peroxisome (also called the glyoxysome; Section 17-5C), where it is oxidized by **glycolate oxidase** to glyoxylate and H_2O_2 . The H_2O_2 , a potentially harmful oxidizing agent, is converted to H_2O and O_2 by the heme-containing enzyme catalase (Section 18-4B). The glyoxylate can be converted to glycine in a transamination reaction, as is discussed in Section 21-2A, and exported to the mitochondrion. There, two molecules of glycine are converted to one molecule of serine and one of CO_2 . *This is the origin of the CO_2 generated by photorespiration.* The serine is transported back to the peroxisome, where a transamination reaction converts it to **hydroxypyruvate**. This substance is reduced to **glycerate** and phosphory-

FIG. 19-32 Photorespiration. This pathway metabolizes the phosphoglycolate produced by the RuBP carboxylase-catalyzed oxidation of RuBP. The reactions occur, as indicated, in the chloroplast, the peroxisome, the mitochondrion, and the cytosol. Note that two glycines are required to form serine + CO_2 .

? Write a chemical equation for photorespiration.

lated in the cytosol to 3PG, which reenters the chloroplast and is reconverted to RuBP in the Calvin cycle. *The net result of this complex photorespiration cycle is that some of the ATP and NADPH generated by the light reactions is uselessly dissipated and previously fixed CO₂ is lost.*

Although photorespiration has no known metabolic function, the RuBP carboxylases from the great variety of photosynthetic organisms so far tested all exhibit oxygenase activity, which is estimated to result in a 30% loss of photosynthetic efficiency. Yet, over the eons, the forces of evolution must have optimized the function of this important enzyme. Photorespiration may confer a selective advantage by protecting the photosynthetic apparatus from photooxidative damage when insufficient CO₂ is available to otherwise dissipate its absorbed light energy. This hypothesis is supported by the observation that when chloroplasts or leaf cells are brightly illuminated in the absence of both CO₂ and O₂, their photosynthetic capacity is rapidly and irreversibly lost. In addition, different types of photosynthetic organisms have evolved several strategies for minimizing photorespiration by concentrating CO₂ in the vicinity of rubisco.

C₄ Plants Concentrate CO₂. On a hot, bright day, when photosynthesis has depleted the level of CO₂ at the chloroplast and raised that of O₂, the rate of photorespiration approaches the rate of photosynthesis. This phenomenon is a major limitation on the growth of many plants (and is therefore an important agricultural problem that is being attacked through genetic engineering studies—none of which has yet been successful). However, *certain species of plants, such as sugarcane, corn, and most important weeds, have a metabolic cycle that concentrates CO₂ in their photosynthetic cells, thereby almost totally preventing photorespiration.* The leaves of plants that have this so-called **C₄ cycle** have a characteristic anatomy. Their fine veins are concentrically surrounded by a single layer of so-called **bundle-sheath cells**, which in turn are surrounded by a layer of **mesophyll cells**.

The C₄ cycle (Fig. 19-33) was elucidated in the 1960s by Marshall Hatch and Rodger Slack. It begins when mesophyll cells, which lack RuBP carboxylase, take up atmospheric CO₂ by condensing it as HCO₃⁻ with phosphoenolpyruvate

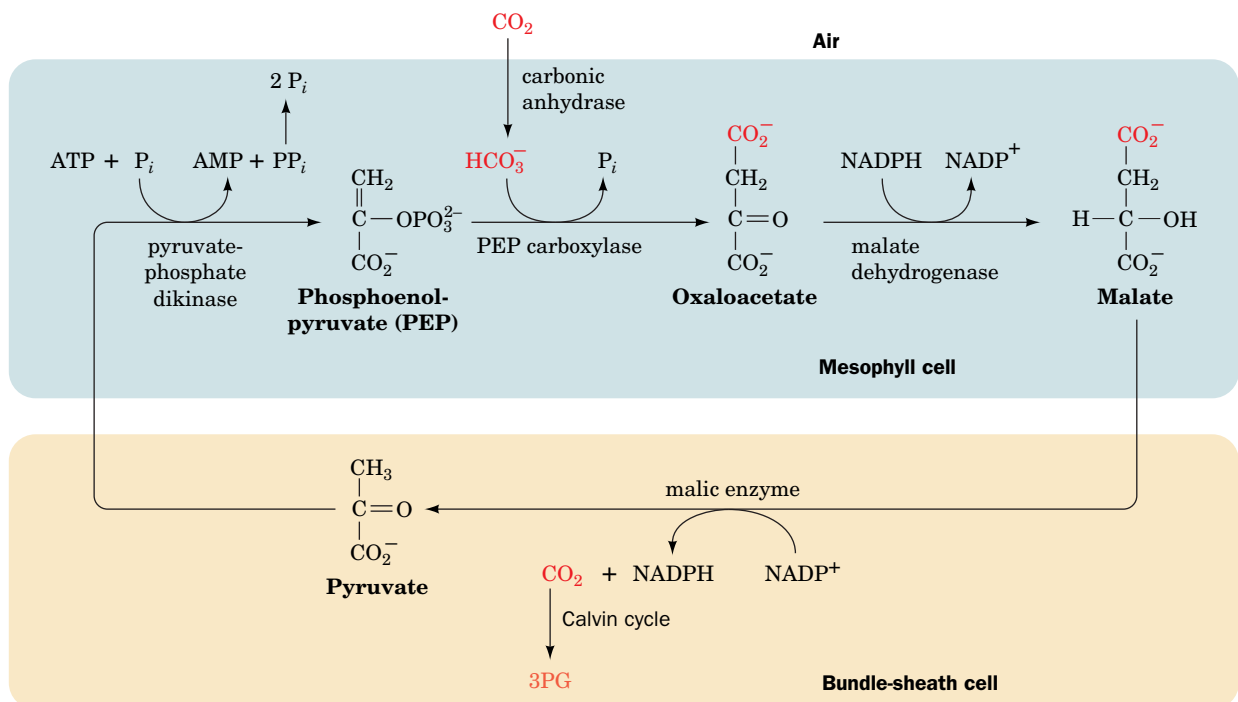

FIG. 19-33 The C₄ pathway. CO₂ is concentrated in the mesophyll cells and transported to the bundle-sheath cells for entry into the Calvin cycle.

(PEP) to yield oxaloacetate. The oxaloacetate is reduced by NADPH to malate, which is exported to the bundle-sheath cells (the name C_4 refers to these four-carbon acids). There, the malate is oxidatively decarboxylated by NADP to form CO_2 , pyruvate, and NADPH. The CO_2 , which has been concentrated by this process, enters the Calvin cycle. The pyruvate is returned to the mesophyll cells, where it is phosphorylated to regenerate PEP. The enzyme that mediates this reaction, **pyruvate-phosphate dikinase**, has the unusual action of simultaneously phosphorylating pyruvate and P_i with ATP's β and γ phosphoryl groups, respectively. *The C_4 pathway thereby concentrates CO_2 in the bundle-sheath cells at the expense of 2 ATP equivalents. Consequently, photosynthesis in C_4 plants consumes a total of 5 ATP per CO_2 fixed versus the 3 ATP required by the Calvin cycle alone.*

C_4 plants occur largely in tropical regions because they grow faster under hot and sunny conditions than other, so-called **C_3 plants** (so named because they initially fix CO_2 in the form of three-carbon acids). In cooler climates, where photorespiration is less of a burden, C_3 plants have the advantage because they require less energy to fix CO_2 .

CAM Plants Store CO_2 through a Variant of the C_4 Cycle. A variant of the C_4 cycle that separates CO_2 acquisition and the Calvin cycle in time rather than in space occurs in many desert-dwelling succulent plants. If these plants opened their stomata (pores in the leaves) by day to acquire CO_2 , as most plants do, they would lose unacceptable amounts of water by evaporation. To minimize this loss, these succulents absorb CO_2 only at night and use the reactions of the C_4 pathway (Fig. 19-33) to store it as malate. This process is known as **crassulacean acid metabolism (CAM)**, so named because it was first discovered in plants of the family Crassulaceae. The large amount of PEP necessary to store a day's supply of CO_2 is obtained by the breakdown of starch via glycolysis. During the course of the day, the malate is broken down to CO_2 , which enters the Calvin cycle, and pyruvate, which is used to resynthesize starch. CAM plants are thus able to carry out photosynthesis with minimal water loss.

CHECKPOINT

- Explain the relationship between the light and dark reactions.
- Summarize the two stages of the Calvin cycle.
- How many different types of reactions (e.g., phosphorylation, isomerization) occur in the Calvin cycle?
- Which Calvin cycle steps are similar to those of the pentose phosphate pathway?
- Describe the chemistry of the RuBP carboxylase reaction.
- Describe how GAP produced by the Calvin cycle is converted to sucrose, starch, and cellulose.
- How do pH, Mg^{2+} , and ferredoxin link the light reactions with control of the Calvin cycle?
- Compare the mechanisms of carboxylation and oxygenation of RuBP.
- What is the apparent advantage of photorespiration?
- How do plants minimize photorespiration?

Summary

1 Chloroplasts

- Photosynthesis is the process whereby light energy drives the reduction of CO_2 to yield carbohydrates. In plants and cyanobacteria, photosynthesis oxidizes water to O_2 .
- In plants, the photosynthetic machinery consists of protein complexes embedded in the thylakoid membrane and enzymes dissolved in the stroma of chloroplasts.
- Chlorophyll and other light-absorbing pigments are organized in light-harvesting complexes that funnel light energy to photosynthetic reaction centers (RCs).

2 The Light Reactions

- The purple bacterial photosynthetic reaction center (PbRC) undergoes photooxidation when it absorbs a photon. The excited electron passes through a series of electron carriers before reducing ubiquinone. The reduced ubiquinone is reoxidized by cytochrome bc_1 , which in the process translocates four protons from the cytosol to the periplasmic space via a Q cycle. The electron is then returned to the PbRC via an electron-transport chain resulting in no net oxidation–reduction.
- In plants and cyanobacteria, photosystems I and II (PSI and PSII) operate in electrical series in an arrangement known as the Z-scheme. The oxidation of water by the Mn-containing oxygen-evolving center (OEC) is driven by the photooxidation of PSII.

- The electrons released by the photooxidation of PSII are transferred, via plastoquinone, to the cytochrome b_6f complex, which mediates a proton-translocating Q cycle while passing the electrons to plastocyanin.
- The photooxidation of PSI drives the electrons obtained from plastocyanin to ferredoxin and then to $NADP^+$ to produce NADPH. In cyclic electron flow, however, electrons return to cytochrome b_6f , thereby bypassing the need for PSII photooxidation.
- The reaction centers of the PbRC, PSII, and PSI have similar structures and mechanisms and therefore appear to have arisen from a common ancestor.
- In photophosphorylation, the protons released by the oxidation of H_2O and proton translocation into the thylakoid lumen generate a transmembrane proton gradient that is tapped by chloroplast ATP synthase to drive the phosphorylation of ADP. A similar process occurs in purple photosynthetic bacteria.

3 The Dark Reactions

- The dark reactions use the ATP and NADPH produced in the light reactions to power the synthesis of carbohydrates from CO_2 . In the first phase of the Calvin cycle, CO_2 reacts with ribulose-1,5-bisphosphate (RuBP) to ultimately yield glyceraldehyde-3-phosphate (GAP). The remaining reactions of the cycle regenerate the RuBP acceptor of CO_2 .

• RuBP carboxylase, the key enzyme of the dark reactions, is regulated by pH, $[Mg^{2+}]$, and the inhibitory compound 2-carboxyarabinitol-1-phosphate (CAIP). The two bisphosphatases of the Calvin cycle are controlled by the redox state of the chloroplast via disulfide interchange reactions mediated in part by thioredoxin.

• Photorespiration, in which plants consume O_2 and evolve CO_2 , uses the ATP and NADPH produced by the light reactions. C_4 plants minimize the oxygenase activity of RuBP carboxylase (RuBisCO) by concentrating CO_2 in their photosynthetic cells. CAM plants use a related mechanism to conserve water.

Problems

EXERCISES

1. The net equation for oxidative phosphorylation can be written as

Write an analogous equation for the light reactions of photosynthesis.

2. Green sulfur bacteria use H_2S as an electron donor for photosynthesis. Write an equation that describes photosynthesis in these organisms.

3. The "red tide" is a massive proliferation of certain algal species that causes seawater to become visibly red. Describe the spectral characteristics of the dominant photosynthetic pigments in the algae.

4. Explain why the chlorophylls in light-harvesting complexes must absorb light of shorter wavelength than the light that would directly excite the special pair of PSI or PSII.

5. Calculate the energy of one mole of photons of red light ($\lambda = 700 \text{ nm}$).

6. How many moles of ATP could theoretically be synthesized under standard conditions using the energy of the photons in Problem 5?

7. The three electron-transporting complexes of the thylakoid membrane can be called plastocyanin-ferredoxin oxidoreductase, plastoquinone-plastocyanin oxidoreductase, and water-plastoquinone oxidoreductase. What are the common names of these enzymes and in what order do they act?

8. $H_2^{18}O$ is added to a suspension of chloroplasts capable of photosynthesis. Where does the label appear when the suspension is exposed to sunlight?

9. Describe the functional similarities between the purple bacterial photosynthetic reaction center and PSI.

10. Calculate the change in free energy for the transit of two electrons from the quinone pool to cytochrome c_2 in purple bacterial photosynthetic electron transport. Assume that the reduction potential of cytochrome c_2 is similar to those of other c -type cytochromes.

11. Estimate the change in free energy when P960 undergoes photooxidation.

12. Calculate $\Delta \mathcal{E}'$ and $\Delta G'$ for the light reactions in plants, that is, the four-electron oxidation of H_2O by $NADP^+$.

13. Although the net equation for photosynthesis indicates that the process can be measured in terms of either O_2 produced or CO_2 fixed, in practice, these measurements are not necessarily equivalent. Explain.

14. Why is it possible for chloroplasts to absorb much more than 8–10 photons per O_2 molecule evolved?

15. Predict the effect of adding myxothiazol, an inhibitor of electron transport in mitochondrial Complex III, to a suspension of chloroplasts exposed to light. Would either ATP or NADPH production be affected?

16. Why would "knocking out" a gene for a chloroplast fatty acid desaturase (an enzyme involved in synthesizing fatty acids containing three double bonds) increase the rate of photosynthesis at 40°C , a temperature at which photosynthesis is normally impaired?

17. Calculate the free energy change for moving a proton from the thylakoid lumen to the stroma when $\Delta\text{pH} = 3.4$, $\Delta\Psi = 0$, and $T = 25^\circ\text{C}$.

18. Chloroplast ATP synthase contains 14 c subunits. How many protons must be translocated to the thylakoid lumen to support the synthesis of one ATP?

19. Predict the effect of an uncoupler such as dinitrophenol (Fig. 18-29) on production of ATP in a chloroplast.

20. Predict the effect of an uncoupler such as dinitrophenol (Fig. 18-29) on production of NADPH in a chloroplast.

21. *Arabidopsis thaliana* chloroplasts contain a K^+ channel in the thylakoid stromal lamellae. Propose a function for this channel.

22. Would the activity of the *A. thaliana* K^+ channel described in Problem 21 increase or decrease in response to a rise in pH in the thylakoid lumen?

23. Chloroplasts are illuminated until the levels of the Calvin cycle intermediates reach a steady state. The light is then turned off. How does the level of RuBP vary after this point?

24. For the chloroplasts described in Problem 23, how does the level of 3PG vary after the light is turned off?

25. Cyanobacteria contain carboxysomes, which consist of a protein shell that encloses RuBP carboxylase and is permeable to small anions such as HCO_3^- . Explain why carbonic anhydrase is also a component of the carboxysome.

26. The shell of the cyanobacterial carboxysome described in Problem 25 is relatively impermeable to O_2 . Why would this be an advantage for the bacteria?

27. In an effort to increase the efficiency of photosynthesis in crop plants, researchers have genetically engineered tobacco plants (a model organism) to express cyanobacterial RuBP carboxylase, which has lower oxygenase activity. However, tobacco plant growth was not enhanced unless the plants were also engineered to express the cyanobacterial genes for bicarbonate transporters. Explain this observation.

28. Describe the effects of an increase in oxygen pressure on the dark reactions of photosynthesis.

29. The leaves of some species of desert plants taste sour in the early morning, but, as the day wears on, they become tasteless and then bitter. Explain.
30. Plants must obtain CO_2 but avoid the loss of H_2O by evaporation. What would be the effect of increased atmospheric $[\text{CO}_2]$ on photosynthesis? Would the effect be the same for C_3 and C_4 plants?
31. How might the increase in atmospheric $[\text{CO}_2]$ affect plants' water consumption?
32. C_4 plants collect CO_2 in mesophyll cells, which are close to the leaf surface, then transfer it to bundle-sheath cells, which are rich in RuBP carboxylase and surround the "veins" that deliver water to the leaf tissue. C_3 plants carry out the entire Calvin cycle in mesophyll cells and have relatively fewer bundle-sheath cells. Explain why C_4 plants have an advantage over C_3 plants under drought conditions.

CHALLENGE QUESTIONS

33. Chlorophyll *f*, which occurs in some species of cyanobacteria that grow under low illumination, has an absorption maximum of 706 nm, whereas other types of chlorophylls show absorption maxima at shorter wavelengths. Why is it advantageous for the cyanobacteria to produce chlorophyll *f*?
34. The cyanobacterium *Oscillatoria sancta* appears reddish-brown when grown under green light but alters its gene expression patterns and becomes blue-green when grown under red light. Explain this observation.
35. Use the solutions of Problems 19-5 and 19-12 to calculate how many moles of photons of red light ($\lambda = 700 \text{ nm}$) are theoretically required to drive the four-electron oxidation of H_2O by NADP^+ under standard conditions to produce one mole of O_2 .
36. Use the solution of Problem 19-12 to calculate how many moles of photons of UV light ($\lambda = 220 \text{ nm}$) would be required to drive the four-electron oxidation of H_2O by NADP^+ under standard conditions to produce one mole of O_2 .
37. Under conditions of very high light intensity, excess absorbed solar energy is dissipated by the action of photoprotective proteins in the thylakoid membrane. Explain why it is advantageous for these proteins to be activated by buildup of the proton gradient across the membrane.
38. Which of the mechanisms for dissipating light energy shown in Fig. 19-6 would best protect the photosystems from excess light energy?

39. Calculate the energy cost of the Calvin cycle combined with glycolysis and oxidative phosphorylation, that is, the ratio of the energy spent synthesizing starch from CO_2 and photosynthetically produced NADPH and ATP to the energy generated by the complete oxidation of starch. Assume that each NADPH is energetically equivalent to 2.5 ATP and that starch biosynthesis and breakdown are mechanistically identical to glycogen synthesis and breakdown.
40. Oil is a major energy-storage molecule in most seeds. During seed development in some plants, oil (triacylglycerols) is synthesized using acetyl-CoA derived from sucrose. The developing seed also contains RuBP carboxylase, although the Calvin cycle is not active. (a) How does the carboxylase maximize the efficiency of converting starch into oil? (b) The seeds that contain RuBP carboxylase are green, suggesting that they harvest some light energy. Explain why some energy collection would be useful in the developing seed.
41. One aspect of climate change is that average nighttime temperatures have increased more than average daytime temperatures have increased. Since the rates of metabolic processes, including photosynthesis and cellular respiration, depend on temperature, how might climate change affect plant growth?
42. Experiments to address the day-night discrepancy in warming (see Problem 41) indicate that climate change has inhibited plant growth in warm dry areas more than in cool wet areas. Explain this observation.
43. If a C_3 plant and a C_4 plant are placed together in a sealed illuminated box with sufficient moisture, the C_4 plant thrives while the C_3 plant sickens and eventually dies. Explain.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Viewing and Analyzing Photosystems I and II

Exercise 2 Photosynthesis and the KEGG Database

MORE TO EXPLORE Five distinct pathways for fixing CO_2 —that is, incorporating it into biological molecules—have been described. In what types of organisms do the different pathways occur? What is the free energy source for carbon fixation in each case? Which of the processes can be considered to be photosynthesis?

CHAPTER 20

Lipid Metabolism

Chapter Contents

1 Lipid Digestion, Absorption, and Transport

- A Triacylglycerols Are Digested before They Are Absorbed
- B Lipids Are Transported as Lipoproteins

2 Fatty Acid Oxidation

- A Fatty Acids Are Activated by Their Attachment to Coenzyme A
- B Carnitine Carries Acyl Groups across the Mitochondrial Membrane
- C β Oxidation Degrades Fatty Acids to Acetyl-CoA
- D Oxidation of Unsaturated Fatty Acids Requires Additional Enzymes
- E Oxidation of Odd-Chain Fatty Acids Yields Propionyl-CoA
- F Peroxisomal β Oxidation Differs from Mitochondrial β Oxidation

3 Ketone Bodies

4 Fatty Acid Biosynthesis

- A Mitochondrial Acetyl-CoA Must Be Transported into the Cytosol
- B Acetyl-CoA Carboxylase Produces Malonyl-CoA
- C Fatty Acid Synthase Catalyzes Seven Reactions
- D Fatty Acids May Be Elongated and Desaturated
- E Fatty Acids Are Esterified to Form Triacylglycerols

5 Regulation of Fatty Acid Metabolism

6 Synthesis of Other Lipids

- A Glycerophospholipids Are Built from Intermediates of Triacylglycerol Synthesis
- B Sphingolipids Are Built from Palmitoyl-CoA and Serine
- C C_{20} Fatty Acids Are the Precursors of Prostaglandins

7 Cholesterol Metabolism

- A Cholesterol Is Synthesized from Acetyl-CoA
- B HMG-CoA Reductase Controls the Rate of Cholesterol Synthesis
- C Abnormal Cholesterol Transport Leads to Atherosclerosis

Dr. Cecil H. Fox/Getty Images, Inc.

Excess cholesterol that accumulates in the walls of blood vessels causes inflammation and can trigger blood clots, leading to a heart attack or stroke. In this micrograph of a human aorta, the green shapes indicate the spaces that were occupied by needle-shaped cholesterol crystals.

Most cells contain a wide variety of lipids, but many of these structurally distinct molecules are functionally similar. For example, most cells can tolerate variations in the lipid composition of their membranes, provided that membrane fluidity, which is largely a property of their component fatty acid chains, is maintained (Section 9-2B).

Even greater variation is exhibited in the cellular content of lipids stored as energy reserves. Triacylglycerol stores are built up and gradually depleted in response to changing physiological demands. The camel's hump is a well-known example of a fat depot that supplies energy (the catabolism of the fat also generates water). Other organisms that undergo dramatic changes in body fat content are hibernating mammals and birds that migrate long distances without refueling. Lipid metabolism in those cases is notable for the sheer amount of material that flows through the few relatively simple biosynthetic and degradative pathways.

In this chapter, we acknowledge the central function of lipids in energy metabolism by first examining the absorption and transport of their component fatty acids and the oxidation of fatty acids to produce energy. The second part of this chapter examines the synthesis of fatty acids and other lipids, including glycerophospholipids, sphingolipids, and cholesterol.

1 Lipid Digestion, Absorption, and Transport

KEY CONCEPTS

- Triacylglycerols are broken down by lipases, and the products are absorbed by the intestine.
- Lipoproteins transport lipids between the intestines, liver, and other tissues.

Triacylglycerols (also called fats or triglycerides) constitute ~90% of dietary lipids and are the major form of metabolic energy storage in humans. Triacylglycerols consist of glycerol triesters of fatty acids such as palmitic and oleic acids

1-Palmitoyl-2,3-dioleoyl-glycerol

(the names and structural formulas of some biologically common fatty acids are listed in Table 9-1). The mechanisms for digesting, absorbing, and transporting triacylglycerols from the intestine to the tissues must accommodate their inherent hydrophobicity.

A Triacylglycerols Are Digested before They Are Absorbed

Since triacylglycerols are water insoluble, whereas digestive enzymes are water soluble, triacylglycerol digestion takes place at lipid–water interfaces. The rate of triacylglycerol digestion therefore depends on the surface area of the interface, which is greatly increased by the churning peristaltic movements of the intestine combined with the emulsifying action of **bile acids**. The bile acids (also called **bile salts**) are amphipathic detergent-like molecules that act to solubilize fat globules by dispersing them into micelles. Bile acids are cholesterol derivatives that are synthesized by the liver and secreted as glycine or **taurine** conjugates (Fig. 20-1) into the gallbladder for storage. From there, they are secreted into the small intestine, where lipid digestion and absorption mainly take place.

Lipases Act at the Lipid–Water Interface. Pancreatic **lipase (triacylglycerol lipase)** catalyzes the hydrolysis of triacylglycerols at their 1 and 3 positions to form sequentially **1,2-diacylglycerols** and **2-acylglycerols**, together with the Na^+ and K^+ salts of fatty acids (soaps). The enzymatic activity of pancreatic lipase greatly increases when it contacts the lipid–water interface, a phenomenon known as **interfacial activation**. Binding to the lipid–water interface requires mixed micelles of phosphatidylcholine and bile acids, as well as pancreatic **colipase**, a 90-residue protein that forms a 1:1 complex with lipase. The X-ray structures, determined by Christian Cambillau, of pancreatic lipase–colipase complexes reveal the structural basis of the interfacial activation of lipase as well

 $\text{R}_1 = \text{OH}$ $\text{R}_1 = \text{H}$ $\text{R}_2 = \text{OH}$ $\text{R}_2 = \text{NH}-\text{CH}_2-\text{COOH}$ $\text{R}_2 = \text{NH}-\text{CH}_2-\text{CH}_2-\text{SO}_3\text{H}$ **Cholic acid****Glycocholic acid****Taurocholic acid****Chenodeoxycholic acid****Glychenodeoxycholic acid****Taurochenodeoxycholic acid**

FIG. 20-1 Structures of the major bile acids and their glycine and taurine conjugates.

? How do these molecules differ from cholesterol?

FIG. 20-2 X-Ray structures of pancreatic lipase in complex with colipase. (a) In aqueous solution, and (b) cocrystallized with mixed micelles of phosphatidylcholine and bile salts. The lipase is drawn in ribbon form with its N-terminal domain (residues 1–336) cyan, its C-terminal domain (residues 337–449) green, the lid (residues 237–262) magenta, and the β 5 loop (residues 76–85) orange. The

colipase is yellow. A phosphatidylcholine molecule that is bound in the lipase active site in Part b is shown in stick form with C green, O red, and P orange. The micelles, which have irregular structures, are not visible. [Based on X-ray structures by Christian Cambillau, LCCMB-CNRS, Marseille, France. PDBids 1N8S and 1LPB.]

as how colipase and micelles help lipase bind to the lipid–water interface (Fig. 20-2).

The active site of the 449-residue pancreatic lipase, which is contained in the enzyme’s N-terminal domain (residues 1–336), contains a catalytic triad that closely resembles that in serine proteases (Section 11-5B; recall that ester hydrolysis is mechanistically similar to peptide hydrolysis). In the absence of lipid micelles, lipase’s active site is covered by a 26-residue helical “lid.” However, in the presence of the micelles, the lid undergoes a complex structural reorganization that exposes the active site. Simultaneously, a 10-residue loop, called the β 5 loop, changes conformation in a way that forms the active enzyme’s oxyanion hole and generates a hydrophobic surface near the entrance to the active site.

Colipase binds to the C-terminal domain of lipase (residues 337–449) such that the hydrophobic tips of its three loops extend from the complex. This creates a continuous hydrophobic plateau, extending >50 Å past the lipase active site, that presumably helps bind the complex to the lipid surface. Colipase also forms three hydrogen bonds to the opened lid, thereby stabilizing it in that conformation.

Other lipases, such as phospholipase A_2 (Fig. 9-6), also preferentially catalyze reactions at interfaces. Instead of changing its conformation, however, phospholipase A_2 contains a hydrophobic channel that provides the substrate with direct access from the phospholipid aggregate (micelle or membrane) surface to the bound enzyme’s active site (Fig. 20-3). Hence, on leaving its micelle to bind to the enzyme, the substrate need not become solvated and then desolvated. In contrast, soluble and dispersed phospholipids must first surmount those significant kinetic barriers in order to bind to the enzyme.

Bile Acids and Fatty Acid–Binding Protein Facilitate the Intestinal Absorption of Lipids. The mixture of fatty acids and mono- and diacylglycerols produced by lipid digestion is absorbed by the cells lining the small intestine (the intestinal mucosa). *Bile acids not only aid lipid digestion; they are essential for the absorption of the digestion products.* The micelles formed by the bile acids take up the nonpolar lipid degradation products so as to permit their transport across the unstirred aqueous boundary layer at the intestinal wall. The importance of this process is demonstrated in individuals with obstructed bile ducts: They absorb little of their ingested lipids but, rather, eliminate them in hydrolyzed form in their feces. Bile acids are likewise required for the efficient intestinal absorption of the lipid-soluble vitamins A, D, E, and K.

FIG. 20-3 Substrate binding to phospholipase A_2 . (a) Hypothetical model of phospholipase A_2 in complex with a micelle of lysophosphatidylethanolamine as shown in cross section. The protein is drawn in cyan, the phospholipid head groups are yellow, and their hydrocarbon tails are blue. The calculated atomic motions of the assembly are indicated through a series of superimposed images taken at 5-ps intervals. (b) Schematic diagram of a phospholipid contained in a micelle entering the hydrophobic phospholipid channel in phospholipase A_2 (red arrow).

? What amino acid side chains are likely to occur in the lipid-binding channel? On the surface of the protein where it contacts the micelle?

Inside the intestinal cells, fatty acids form complexes with **intestinal fatty acid-binding protein (I-FABP)**, a cytoplasmic protein that increases the effective solubility of the water-insoluble substances and also protects the cell from their detergent-like effects. The X-ray structure of rat I-FABP, determined by James Sacchettini, shows that this monomeric, 131-residue protein consists largely of 10 antiparallel β strands stacked in two approximately orthogonal β sheets (Fig. 20-4). A fatty acid molecule occupies a gap between two of the β strands, lying between the β sheets so that it is more or less parallel to the gapped β strands (a structure that has been dubbed a “ β -clam”). The fatty acid’s carboxyl group interacts with Arg 106, Gln 115, and two bound water molecules, whereas its tail is encased by the side chains of several hydrophobic, mostly aromatic residues.

B Lipids Are Transported as Lipoproteins

The fatty acid products of lipid digestion that are absorbed by the intestinal mucosa make their way to other tissues for catabolism or storage. But because they are only sparingly soluble in aqueous solution, lipids are transported by the circulation in complex with proteins.

Lipoproteins Are Complexes of Lipid and Protein. **Lipoproteins** are globular micelle-like particles that consist of a nonpolar core of triacylglycerols and cholesteryl esters surrounded by an amphiphilic coating of protein, phospholipid, and cholesterol. There are five classes of lipoproteins (Table 20-1), which vary in composition and physiological function.

Intestinal mucosal cells convert dietary fatty acids to triacylglycerols and package them, along with dietary cholesterol, into lipoproteins called **chylomicrons**. These particles are released into the intestinal lymph and are transported through the lymphatic vessels before draining into the large veins. (The lymphatic circulation serves to collect extracellular fluid that leaks out of blood vessels under high pressure.) The bloodstream then delivers chylomicrons throughout the body. Other lipoproteins known as **very low density lipoproteins (VLDL)**, **intermediate density lipoproteins (IDL)**, and **low density lipoproteins (LDL)** are synthesized by the liver to transport endogenous (internally produced) triacylglycerols and cholesterol from the liver to the tissues. **High density lipoproteins (HDL)** transport cholesterol and other lipids from the tissues back to the liver.

FIG. 20-4 X-Ray structure of rat intestinal fatty acid-binding protein in complex with palmitate. The protein is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The palmitate is drawn in space-filling form with C green and O red. [Based on an X-ray structure by James Sacchettini, Texas A&M University. PDBid 2IFB.]

TABLE 20-1 Characteristics of the Major Classes of Lipoproteins in Human Plasma

	Chylomicrons	VLDL	IDL	LDL	HDL
Density ($\text{g} \cdot \text{cm}^{-3}$)	<0.95	<1.006	1.006–1.019	1.019–1.063	1.063–1.210
Particle diameter (\AA)	750–12,000	300–800	250–350	180–250	50–120
Particle mass (kD)	400,000	10,000–80,000	5000–10,000	2300	175–360
% Protein ^a	1.5–2.5	5–10	15–20	20–25	40–55
% Phospholipids ^a	7–9	15–20	22	15–20	20–35
% Free cholesterol ^a	1–3	5–10	8	7–10	3–4
% Triacylglycerols ^b	84–89	50–65	22	7–10	3–5
% Cholesteryl esters ^b	3–5	10–15	30	35–40	12
Major apolipoproteins	A-I, A-II, B-48, C-I, C-II, C-III, E	B-100, C-I, C-II, C-III, E	B-100, C-I, C-II, C-III, E	B-100	A-I, A-II, C-I, C-II, C-III, D, E

^bCore lipids.

FIG. 20-5 Diagram of LDL, the major cholesterol carrier of the bloodstream. This spheroidal particle consists of some 1500 cholesteryl ester molecules surrounded by an amphiphilic coat of ~800 phospholipid molecules, ~500 cholesterol molecules, and a single 4536-residue molecule of apolipoprotein B-100.

? Explain why the protein must be amphiphilic.

Each lipoprotein contains just enough protein, phospholipid, and cholesterol to form an ~20-Å-thick monolayer of these substances on the particle surface (Fig. 20-5). Lipoprotein densities increase with decreasing particle diameter because the density of their outer coating is greater than that of their inner core. Thus, the HDL, which are the most dense of the lipoproteins, are also the smallest.

Apolipoproteins Coat Lipoprotein Surfaces. The protein components of lipoproteins are known as **apolipoproteins** or just **apoproteins**. At least nine apolipoproteins are distributed in different amounts in the human lipoproteins (Table 20-1). For example, LDL contain **apolipoprotein B-100 (apoB-100)**. This protein, a 4536-residue monomer (and thus one of the largest monomeric proteins known), has a hydrophobicity approaching that of integral membrane proteins. Each LDL particle contains only one molecule of apoB-100, which appears to cover at least half of the particle surface (Fig. 20-5).

Unlike apoB-100, the other apolipoproteins are water soluble and associate rather weakly with lipoproteins. These apolipoproteins also have a high helix content, which increases when they are incorporated into lipoproteins. Contact with a hydrophobic surface apparently favors formation of helices, which satisfy the hydrogen bonding potential of the protein's polar backbone groups. In addition, *the helices in apolipoproteins have hydrophilic and hydrophobic side chains on opposite sides of the helical cylinder, suggesting that lipoprotein α helices are amphipathic and float on phospholipid surfaces, much like logs on water.* The charged head groups of the lipids presumably bind to oppositely charged residues on the helix while the first few methylene groups of their fatty acyl chains associate with the nonpolar face of the helix.

Apolipoprotein A-I (apoA-I), which occurs in chylomicrons and HDL, is a 243-residue, 29-kD polypeptide. It consists largely of tandem 22-residue segments of similar sequence. The X-ray structure of a truncated apolipoprotein A-I (lacking residues 1–43) reveals that the polypeptide chain forms a pseudocontinuous α helix that is punctuated by kinks at Pro residues spaced about every 22 residues. Four monomers associate to form the structure shown in Fig. 20-6a. The size and twisted elliptical shape of the complex seem ideal for wrapping around an HDL particle. Figure 20-6b contains a helical wheel representation of a portion of apoA-I, illustrating the amphipathic nature of the helix.

(a)

(b)

Chylomicrons Are Delipidated in the Capillaries of Peripheral Tissues. Chylomicrons adhere to binding sites on the inner surface (endothelium) of the capillaries in skeletal muscle and adipose tissue. The chylomicron's component triacylglycerols are hydrolyzed through the action of the extracellular enzyme **lipoprotein lipase**. The tissues then take up the liberated monoacylglycerol and fatty acids. The chylomicrons shrink as their triacylglycerols are progressively hydrolyzed until they are reduced to cholesterol-

FIG. 20-6 Structure of human apolipoprotein A-I. (a) The X-ray structure of the D_2 -symmetric homotetramer with its four subunits, which lack their N-terminal 43 residues, drawn in different colors. The complex, which has a twisted ellipsoidal shape, is viewed along one of its twofold axes. [Based on an X-ray structure by David Borhani, Southern Research Institute, Birmingham, Alabama, and Christie Brouillette, University of Alabama Medical Center, Birmingham, Alabama. PDBid 1AV1.] (b) A helical wheel projection of the amphipathic α helix constituting residues 148 to 164 of apolipoprotein A-I (in a helical wheel representation, the side chain positions are projected down the helix axis onto a plane). Note the segregation of nonpolar and polar residues to different sides of the helix as well as the segregation of the basic residues to the outer edges of the polar surface, where they can interact with the anionic head groups of membrane lipids. Other apolipoprotein helices have similar polarity distributions. [After Kaiser, E.T., in Oxender, D.L. and Fox, C.F. (Eds.), *Protein Engineering*, p. 194, Liss (1987).]

FIG. 20-7 Plasma triacylglycerol and cholesterol transport in humans.

? Trace the path of dietary lipids from the stomach to other tissues. What functions does the liver perform?

enriched **chylomicron remnants**. The remnants dissociate from the capillary endothelium and re-enter the circulation to be taken up by the liver. *Chylomicrons therefore deliver dietary triacylglycerols to muscle and adipose tissue, and dietary cholesterol to the liver* (Fig. 20-7, blue arrows).

VLDL Are Gradually Degraded. Very low density lipoproteins (VLDL), which transport endogenous triacylglycerols and cholesterol, are also degraded by lipoprotein lipase in the capillaries of adipose tissue and muscle (Fig. 20-7). The released fatty acids are taken up by the cells and oxidized for energy or used to resynthesize triacylglycerols. The glycerol backbone of triacylglycerols is transported to the liver or kidneys and converted to the glycolytic intermediate dihydroxyacetone phosphate. Oxidation of this three-carbon unit, however, yields only a small fraction of the energy available from oxidizing the three fatty acyl chains of a triacylglycerol.

After giving up their triacylglycerols, the VLDL remnants, which have also lost some of their apolipoproteins, appear in the circulation first as IDL and then as LDL. About half of the VLDL, after degradation to IDL and LDL, are taken up by the liver.

Cells Take Up LDL by Receptor-Mediated Endocytosis. Animal cells acquire cholesterol, an essential component of cell membranes (Section 9-2B), either by synthesizing it or by taking up LDL, which are rich in cholesterol and cholesteryl esters. The latter process, as Michael Brown and Joseph Goldstein have demonstrated, occurs by **receptor-mediated endocytosis** (engulfment) of the LDL (**Fig. 20-8**). The LDL particles are sequestered by **LDL receptors**, cell-surface transmembrane glycoproteins that specifically bind apoB-100. LDL receptors cluster into **clathrin-coated pits**, which gather the cell-surface receptors that are destined for endocytosis while excluding other cell-surface proteins. The coated pits invaginate from the plasma membrane to form **clathrin-coated vesicles** (Section 9-4E). Then, after divesting themselves of their clathrin coats, the

FIG. 20-8 Receptor-mediated endocytosis of LDL. LDL receptor is synthesized on the endoplasmic reticulum (**a**), processed in the Golgi apparatus (**b**), and inserted into the plasma membrane (**c**), where it becomes a component of clathrin-coated pits (**d**). The apolipoprotein B-100 (apoB-100) component of LDL specifically binds to LDL receptors on clathrin-coated pits (**1**). These bud into the cell (**2**) to form clathrin-coated vesicles, whose clathrin coats depolymerize to form triskelions (**3**), which are recycled to the cell surface. The uncoated vesicles fuse with vesicles called endosomes (**4**), which have an internal pH of ~5.0. The acidity induces the LDL particle to dissociate from its receptor. The LDL accumulates in the vesicular portion of the endosome, whereas the LDL receptors concentrate in the membrane of an attached tubular structure, which then separates from the endosome

(**5**) and subsequently recycles the LDL receptors to the plasma membrane (**6**). The vesicular portion of the endosome fuses with a lysosome (**7**), yielding a **secondary lysosome** in which the apoB-100 component of the LDL and the cholesteryl esters are hydrolyzed. This releases cholesterol (**8**), which either is converted to cholesteryl esters through the action of **acyl-CoA:cholesterol acyltransferase (ACAT)** and sequestered in a droplet (**9**) or proceeds to the endoplasmic reticulum (**10**). Increased cholesterol concentration in the endoplasmic reticulum decreases the rate of synthesis of **HMG-CoA reductase** (the enzyme that catalyzes the rate-limiting step of cholesterol biosynthesis; Section 20-7B) and LDL receptors (*down arrows*), while increasing that of ACAT (*up arrow*). [After Brown, M.S. and Goldstein, J.L., *Curr. Topics Cell. Reg.* **26**, 7 (1985).] **WPLS See the Animated Figures.**

vesicles fuse with vesicles known as **endosomes**, whose internal pH is ~ 5.0 . Under these conditions, the LDL particle dissociates from its receptor. The receptors are recycled back to the cell surface, while the endosome with its enclosed LDL fuses with a lysosome. In the lysosome, LDL's apoB-100 is rapidly degraded to its component amino acids, and the cholesteryl esters are hydrolyzed to yield cholesterol and fatty acids.

Receptor-mediated endocytosis is a general mechanism whereby cells take up large molecules, each through a corresponding specific receptor. Many cell-surface receptors recycle between the plasma membrane and the endosomal compartment as does the LDL receptor, even in the absence of ligand. The LDL receptor cycles in and out of the cell membrane about every 10 minutes. New receptors are synthesized on the endoplasmic reticulum and travel via vesicles through the Golgi apparatus to the cell surface (Fig. 20-8; Section 9-4E). The intracellular concentration of free cholesterol controls the rate of LDL receptor synthesis (Section 20-7). However, defects in the LDL receptor system lead to abnormally high levels of circulating cholesterol with the attendant increased risk of heart disease (Section 20-7C).

HDL Transport Cholesterol from the Tissues to the Liver. HDL have essentially the opposite function of LDL: *They remove cholesterol from the tissues.* HDL are assembled in the plasma from components largely obtained through the degradation of other lipoproteins. *A circulating HDL particle acquires its cholesterol by extracting it from cell-surface membranes.* The cholesterol is then converted to cholesteryl esters by the HDL-associated enzyme **lecithin-cholesterol acyltransferase (LCAT)**, which is activated by apoA-I. HDL therefore function as cholesterol scavengers.

The liver is the only organ capable of disposing of significant quantities of cholesterol (by its conversion to bile acids; Fig. 20-1). About half of the VLDL, after their degradation to IDL and LDL, are taken up by the liver via LDL receptor-mediated endocytosis (Fig. 20-7). However, liver cells take up HDL by an entirely different mechanism: Rather than being engulfed and degraded, an HDL particle binds to a cell-surface receptor named **SR-BI** (for scavenger receptor class B type I) and selectively transfers its component lipids to the cell. The lipid-depleted HDL particle then dissociates from the cell and re-enters the circulation.

CHECKPOINT

- How do lipases access their substrates?
- Explain the purpose of bile acids and fatty acid-binding protein in the digestion and absorption of lipids.
- Describe the overall structure of lipoproteins. What distinguishes the different types?
- Summarize the roles of the various lipoproteins in transporting triacylglycerols and cholesterol.
- What is the importance of lipoprotein lipase?
- Describe the process of receptor-mediated endocytosis of LDL.

2 Fatty Acid Oxidation

KEY CONCEPTS

- Fatty acids to be degraded are linked to CoA in an ATP-dependent reaction.
- Fatty acyl groups are transported into the mitochondrion via a carnitine shuttle for oxidation.
- Each round of mitochondrial β oxidation produces FADH_2 , NADH, and acetyl-CoA.
- Additional enzymes are required to oxidize unsaturated fatty acids.
- The propionyl-CoA produced by the oxidation of odd-chain fatty acids is converted to succinyl-CoA.
- Peroxisomes oxidize long-chain fatty acids, producing H_2O_2 .

The triacylglycerols stored in adipocytes are mobilized in times of metabolic need by the action of **hormone-sensitive lipase** (Section 20-5). The free fatty acids are released into the bloodstream, where they bind to **serum albumin** (or just **albumin**). This soluble 585-residue monomeric protein, which comprises about half the protein in the blood serum, functions to transport a variety of non-polar substances, including many hormones and drugs. In the absence of albumin, the maximum solubility of fatty acids is $\sim 10^{-6}$ M; the effective solubility of fatty acids in complex with albumin is as high as 2 mM. Nevertheless, those rare individuals with **analbuminemia** (severely depressed levels of albumin) suffer no apparent adverse symptoms; evidently, their fatty acids are transported in complex with other serum proteins.

FIG. 20-9 Franz Knoop's classic experiment indicating that fatty acids are metabolically oxidized at their β -carbon atom. ω -Phenyl-labeled fatty acids containing an odd number of carbon atoms are oxidized to the phenyl-labeled C_1 product, benzoic acid, whereas those with an even number of carbon atoms are oxidized to the phenyl-labeled C_2 product, phenylacetic acid. These products are excreted

as their respective glycine amides, hippuric and phenylaceturic acids. The vertical arrows indicate the deduced sites of carbon oxidation. The intermediate C_2 products are oxidized to CO_2 and H_2O and were therefore not isolated.

? Identify the β carbon in each fatty acid.

Fatty acids are catabolized by an oxidative process that releases free energy. The biochemical strategy of fatty acid oxidation was understood long before the oxidative enzymes were purified. In 1904, Franz Knoop, in the first use of chemical labels to trace metabolic pathways, fed dogs fatty acids labeled at their ω (last) carbon atom by a benzene ring and isolated the phenyl-containing metabolic products from their urine. Dogs fed labeled odd-chain fatty acids excreted **hippuric acid**, the glycine amide of **benzoic acid**, whereas those fed labeled even-chain fatty acids excreted **phenylaceturic acid**, the glycine amide of **phenylacetic acid** (Fig. 20-9). Knoop therefore deduced that fatty acids are progressively degraded by two-carbon units and that the process involves the oxidation of the carbon atom β to the carboxyl group. Otherwise, the phenylacetic acid would be further oxidized to benzoic acid. Knoop's **β oxidation** hypothesis was only confirmed in the 1950s. The β -oxidation pathway is a series of enzyme-catalyzed reactions that operates in a repetitive fashion to progressively degrade fatty acids by removing two-carbon units.

A Fatty Acids Are Activated by Their Attachment to Coenzyme A

Before fatty acids can be oxidized, they must be "primed" for reaction in an ATP-dependent acylation reaction to form fatty acyl-CoA. The activation process is catalyzed by a family of at least three **acyl-CoA synthetases** (also called **thiokinases**) that differ in their chain-length specificities. These enzymes, which are associated with either the endoplasmic reticulum or the outer mitochondrial membrane, all catalyze the reaction

This reaction proceeds via an acyladenylate mixed anhydride intermediate that is attacked by the sulfhydryl group of CoA to form the thioester product (Fig. 20-10), thereby preserving the free energy of ATP hydrolysis in the "high-energy" thioester bond (Section 14-2D). The overall reaction is driven to completion by the exergonic hydrolysis of pyrophosphate catalyzed by inorganic pyrophosphatase.

B Carnitine Carries Acyl Groups across the Mitochondrial Membrane

Although fatty acids are activated for oxidation in the cytosol, they are oxidized in the mitochondrion, as Eugene Kennedy and Albert Lehninger established

FIG. 20-10 The mechanism of fatty acid activation catalyzed by acyl-CoA synthetase. Formation of acyl-CoA involves an intermediate acyladenylate mixed anhydride.

? Count the number of “high-energy” bonds that are broken and formed.

in 1950. We must therefore consider how fatty acyl-CoA is transported across the inner mitochondrial membrane. A long-chain fatty acyl-CoA cannot directly cross the inner mitochondrial membrane. Instead, its acyl portion is first transferred to **carnitine**, a compound that occurs in both plant and animal tissues.

This transesterification reaction has an equilibrium constant close to 1, which indicates that the *O*-acyl bond of **acyl-carnitine** has a free energy of hydrolysis similar to that of acyl-CoA's thioester bond. **Carnitine palmitoyl transferases I and II**, which can transfer a variety of acyl groups (not just palmitoyl groups), are located, respectively, on the external and internal surfaces of the inner mitochondrial membrane. The translocation process itself is mediated by a specific carrier protein that transports acyl-carnitine into the mitochondrion while transporting free carnitine in the opposite direction. The acyl-CoA transport system is diagrammed in **Fig. 20-11**.

FIG. 20-11 The transport of fatty acids into the mitochondrion. (1) The acyl group of a cytosolic acyl-CoA is transferred to carnitine, thereby releasing the CoA to its cytosolic pool. (2) The resulting acyl-carnitine is transported into the mitochondrial matrix by the carrier protein. (3) The acyl group is transferred to a CoA molecule from the mitochondrial pool. (4) The product carnitine is returned to the cytosol.

C β Oxidation Degrades Fatty Acids to Acetyl-CoA

The degradation of fatty acyl-CoA via β oxidation occurs in four reactions (Fig. 20-12):

1. Formation of a trans- α,β double bond through dehydrogenation by the flavoenzyme **acyl-CoA dehydrogenase (AD)**.
2. Hydration of the double bond by **enoyl-CoA hydratase (EH)** to form a **3-L-hydroxyacyl-CoA**.
3. NAD^+ -dependent dehydrogenation of the β -hydroxyacyl-CoA by **3-L-hydroxyacyl-CoA dehydrogenase (HAD)** to form the corresponding β -ketoacyl-CoA.
4. $\text{C}_\alpha\text{—C}_\beta$ cleavage in a thiolysis reaction with CoA as catalyzed by **β -ketoacyl-CoA thiolase (KT)**; also called just **thiolase** to form acetyl-CoA and a new acyl-CoA containing two fewer C atoms than the original one.

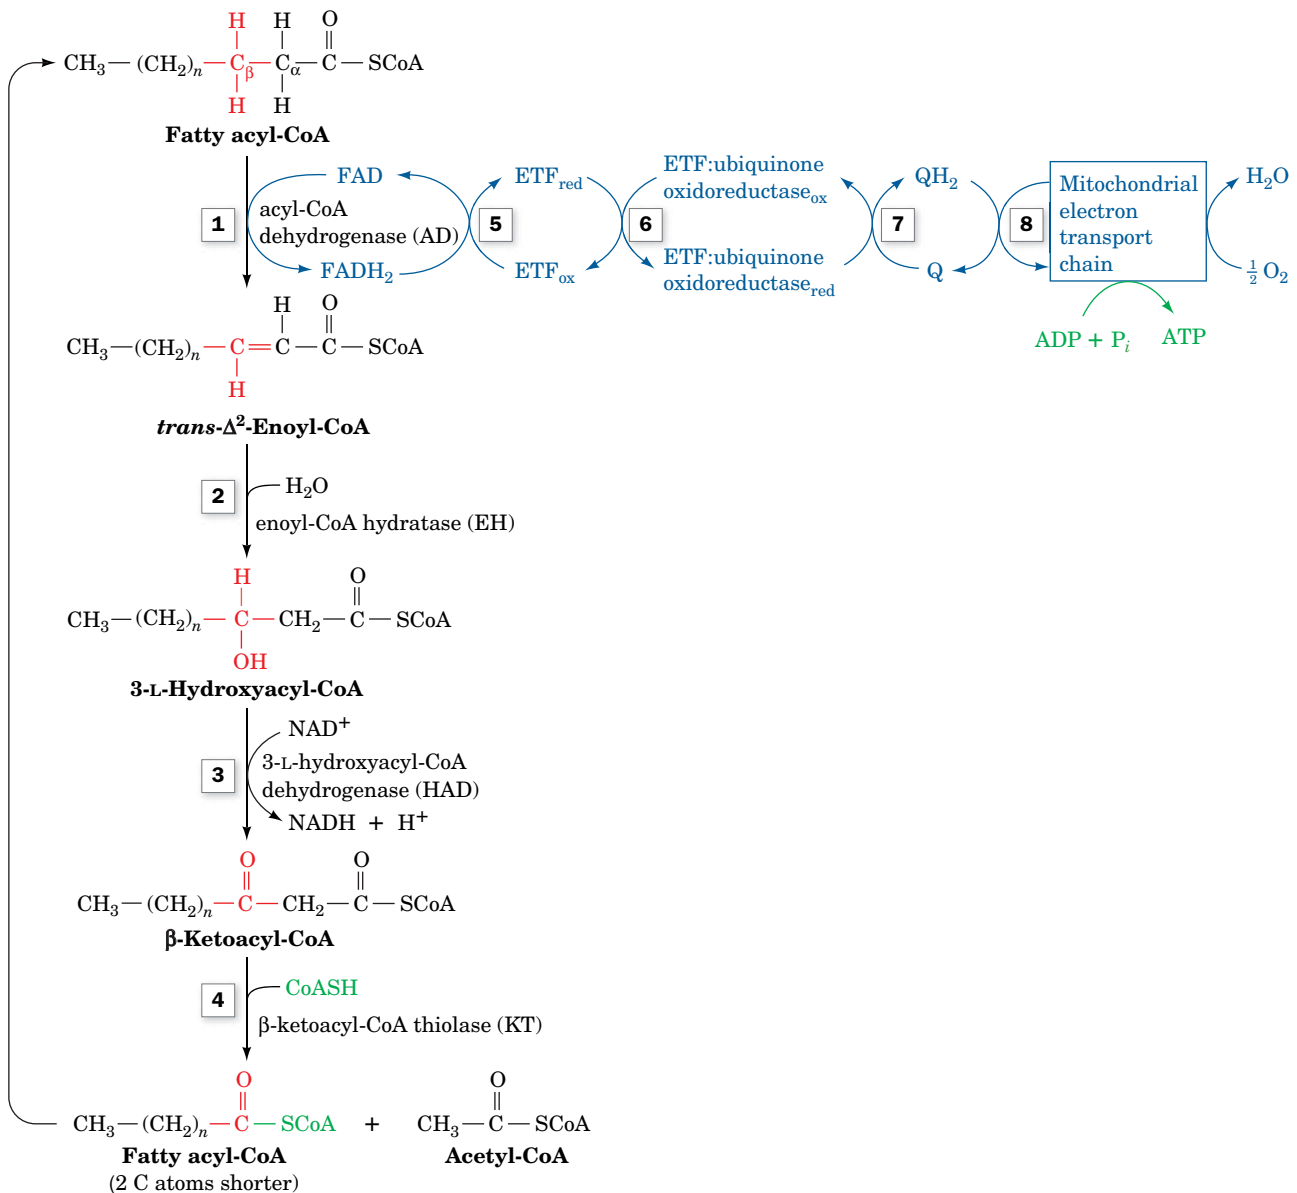

FIG. 20-12 The β -oxidation pathway of fatty acyl-CoA. Reactions 1–4 degrade fatty acyl-CoA to acetyl-CoA. Reactions 5–8 are electron transfers. **WPLS** See the Animated Figures.

? Describe the type of reaction that occurs at each step.

FIG. 20-13 Ribbon diagram of the active site region of medium-chain acyl-CoA dehydrogenase. The enzyme, from pig liver mitochondria, is a tetramer of identical 385-residue subunits, each of which binds an FAD prosthetic group (*green*) and an octanoyl-CoA substrate (whose octanoyl and CoA moieties are blue and white) in largely extended conformations. The octanoyl-CoA binds such that its C_{α} — C_{β} bond is sandwiched between the carboxylate group of Glu 376 (*red*) and the flavin ring (*green*), consistent with the proposal that Glu 376 is the general base that abstracts the α proton in the α,β dehydrogenation reaction catalyzed by the enzyme. [Based on an X-ray structure by Jung-Ja Kim, Medical College of Wisconsin. PDBid 3MDE.]

Acyl-CoA Dehydrogenase Is Linked to the Electron-Transport Chain. Mitochondria contain four acyl-CoA dehydrogenases, with specificities for short (C_4 to C_6), medium (C_6 to C_{10}), long (between medium and very long), and very long chain (C_{12} to C_{18}) fatty acyl-CoAs. The reaction catalyzed by these enzymes is thought to involve removal of a proton at C_{α} and transfer of a hydride ion equivalent from C_{β} to FAD (Fig. 20-12, Reaction 1). The X-ray structure of **medium-chain acyl-CoA dehydrogenase (MCAD)** in complex with **octanoyl-CoA**, determined by Jung-Ja Kim, clearly shows how the enzyme orients a basic group (Glu 376), the substrate C_{α} — C_{β} bond, and the FAD prosthetic group for reaction (Fig. 20-13).

⚡ A deficiency of MCAD has been identified in ~10% of cases of **sudden infant death syndrome (SIDS)**. Glucose is the principal metabolic fuel just after eating, but when the glucose level later decreases, the rate of fatty acid oxidation must correspondingly increase. The sudden death of infants lacking MCAD may be caused by the imbalance between glucose and fatty acid oxidation.

The $FADH_2$ resulting from the oxidation of the fatty acyl-CoA substrate is reoxidized by the mitochondrial electron-transport chain through a series of electron-transfer reactions. **Electron-transfer flavoprotein (ETF)** transfers an electron pair from $FADH_2$ to the flavo-iron-sulfur protein **ETF:ubiquinone oxidoreductase**, which in turn transfers an electron pair to the mitochondrial electron-transport chain by reducing coenzyme Q (CoQ; Fig. 20-12, Reactions 5–8). Reduction of O_2 to H_2O by the electron-transport chain beginning at the CoQ stage results in the synthesis of approximately 1.5 ATP per electron pair transferred (Section 18-3C).

Long-Chain Enoyl-CoAs Are Converted to Acetyl-CoA and a Shorter Acyl-CoA by Mitochondrial Trifunctional Protein. The product of acyl-CoA dehydrogenases are 2-enoyl-CoAs. Depending on their chain lengths, their processing is continued by one of three systems (Fig. 20-12): the short chain, medium chain, or long chain 2-enoyl-CoA hydratases (EHs), hydroxyacyl-CoA dehydrogenases (HADs), and 3-ketoacyl-CoA thiolases (KTs). The long chain (LC) versions of these enzymes are contained on one $\alpha_4\beta_4$ heterooctameric, trifunctional protein, located in the inner mitochondrial membrane. LCEH and LCHAD are contained on the α subunits while LCKT is located on the β subunits. The protein is therefore both a multifunctional protein (more than one enzyme activity on a single polypeptide chain) and a multienzyme complex (a complex of polypeptides catalyzing more than one reaction). The advantage of such a trifunctional enzyme is the ability to channel the intermediates toward the final product. Indeed, no long-chain hydroxyacyl-CoA or ketoacyl-CoA intermediates are released into solution by this system.

The Thiolase Reaction Occurs via Claisen Ester Cleavage. The fourth step of β oxidation is the thiolase reaction (Fig. 20-12, Reaction 4), which yields

acetyl-CoA and a new acyl-CoA that is two carbon atoms shorter than the one that began the cycle (Fig. 20-14):

1. An active site thiol group adds to the β -keto group of the substrate acyl-CoA.
2. Carbon-carbon bond cleavage yields a thioester between the acyl-CoA substrate and the active site thiol group, together with an acetyl-CoA carbanion intermediate that is stabilized by electron withdrawal into the thioester's carbonyl group. This type of reaction is known as a Claisen ester cleavage (the reverse of a Claisen condensation). The citric acid cycle enzyme citrate synthase also catalyzes a reaction that involves a stabilized acetyl-CoA carbanion intermediate (Section 17-3A).
3. An enzyme acidic group protonates the acetyl-CoA carbanion, yielding acetyl-CoA.
- 4 and 5. Finally, CoA displaces the enzyme thiol group from the enzyme-thioester intermediate, yielding an acyl-CoA that is shortened by two C atoms.

Fatty Acid Oxidation Is Highly Exergonic. The function of fatty acid oxidation is, of course, to generate metabolic energy. Each round of β oxidation produces one NADH, one FADH_2 , and one acetyl-CoA. Oxidation of acetyl-CoA via the citric acid cycle generates an additional FADH_2 and 3 NADH, which are reoxidized through oxidative phosphorylation to form ATP. Complete oxidation of a fatty acid molecule is therefore a highly exergonic process that yields numerous ATPs. For example, oxidation of palmitoyl-

CoA (which has a C_{16} fatty acyl group) involves seven rounds of β oxidation, yielding 7 FADH_2 , 7 NADH, and 8 acetyl-CoA. Oxidation of the 8 acetyl-CoA, in turn, yields 8 GTP, 24 NADH, and 8 FADH_2 . Since oxidative phosphorylation of the 31 NADH molecules yields 77.5 ATP and that of the 15 FADH_2 yields 22.5 ATP, subtracting the 2 ATP equivalents required for fatty acyl-CoA formation (Section 20-2A), the oxidation of one palmitate molecule has a net yield of 106 ATP.

D Oxidation of Unsaturated Fatty Acids Requires Additional Enzymes

Almost all unsaturated fatty acids of biological origin contain only *cis* double bonds, which most often begin between C_9 and C_{10} (referred to as a Δ^9 or 9-double bond; Table 9-1). Additional double bonds, if any, occur at three-carbon intervals and are therefore never conjugated. Two examples of unsaturated fatty acids are oleic acid and linoleic acid.

FIG. 20-14 Mechanism of action of β -ketoacyl-CoA thiolase. An active site Cys residue participates in the formation of an enzyme-thioester intermediate.

? Write an equation describing this reaction.

Note that one of the double bonds in linoleic acid is at an odd-numbered carbon atom and the other is at an even-numbered carbon atom. The double bonds in fatty acids such as linoleic acid pose three problems for the β -oxidation pathway that are solved through the actions of four additional enzymes (Fig. 20-15).

FIG. 20-15 The oxidation of unsaturated fatty acids. β oxidation of an unsaturated fatty acid such as linoleic acid presents three problems. The first problem, the presence of a β, γ double bond, seen in the left-hand pathway, is solved by the bond's conversion to a $\text{trans-}\alpha, \beta$ double bond. The second problem in the left-hand pathway, that a 2,4-dienoyl-CoA is a poor substrate for enoyl-CoA hydratase, is eliminated by the NADPH-dependent reduction of the Δ^4 bond by 2,4-dienoyl-CoA reductase to yield the β -oxidation substrate trans-2-enoyl-CoA . This step requires one enzyme in *E. coli* and two in mammals. The third problem, the isomerization of 2,5-dienoyl-CoA (originating from the oxidation of unsaturated fatty acids with double bonds at odd-numbered C atoms) to 3,5-dienoyl-CoA, is solved by converting the 3,5-dienoyl-CoA to 2,4-dienoyl-CoA, a substrate for 2,4-dienoyl-CoA reductase.

Problem 1: A β,γ Double Bond. The first enzymatic difficulty occurs after the third round of β oxidation: The resulting *cis*- β,γ double bond-containing enoyl-CoA is not a substrate for enoyl-CoA hydratase. **Enoyl-CoA isomerase**, however, converts the *cis*- Δ^3 double bond to the *trans*- Δ^2 form. The Δ^2 compound is the normal substrate of enoyl-CoA hydratase, so β oxidation can continue.

Problem 2: A Δ^4 Double Bond Inhibits Enoyl-CoA Hydratase. The next difficulty arises in the fifth round of β oxidation: The presence of a double bond at an even-numbered carbon atom results in the formation of 2,4-dienoyl-CoA, which is a poor substrate for enoyl-CoA hydratase. However, NADPH-dependent **2,4-dienoyl-CoA reductase** reduces the Δ^4 double bond. The *E. coli* reductase produces *trans*-2-enoyl-CoA, a normal substrate of β oxidation. The mammalian reductase, however, yields *trans*-3-enoyl-CoA, which, to proceed along the β -oxidation pathway, must first be isomerized to *trans*-2-enoyl-CoA by **3,2-enoyl-CoA isomerase**.

Problem 3: The Unanticipated Isomerization of 2,5-Enoyl-CoA by 3,2-Enoyl-CoA Isomerase. Mammalian 3,2-enoyl-CoA isomerase catalyzes a reversible reaction that interconverts Δ^2 and Δ^3 double bonds. A carbonyl group is stabilized by being conjugated to a Δ^2 double bond. However, the presence of a Δ^5 double bond (originating from an unsaturated fatty acid with a double bond at an odd-numbered C atom such as the Δ^9 double bond of linoleic acid) is likewise stabilized by being conjugated with a Δ^3 double bond. If a 2,5-enoyl-CoA is converted by 3,2-enoyl-CoA isomerase to 3,5-enoyl CoA, which occurs up to 20% of the time, another enzyme is necessary to continue the oxidation: **3,5-2,4-Dienoyl-CoA isomerase** isomerizes the 3,5 diene to a 2,4 diene, which is then reduced by 2,4-dienoyl-CoA reductase and isomerized by 3,2-enoyl-CoA isomerase as in Problem 2 above. After two more rounds of β oxidation, the *cis*- Δ^4 double bond originating from the *cis*- Δ^{12} double bond of linoleic acid is also dealt with as in Problem 2.

FIG. 20-16 Conversion of propionyl-CoA to succinyl-CoA.

? What type of reaction occurs at each step?

E Oxidation of Odd-Chain Fatty Acids Yields Propionyl-CoA

Most fatty acids, for reasons explained in Section 20-4, have even numbers of carbon atoms and are therefore completely converted to acetyl-CoA. Some plants and marine organisms, however, synthesize fatty acids with an odd number of carbon atoms. *The final round of β oxidation of these fatty acids yields propionyl-CoA, which is converted to succinyl-CoA for entry into the citric acid cycle.* Propionate and propionyl-CoA are also produced by the oxidation of the amino acids isoleucine, valine, and methionine (Section 21-4D).

The conversion of propionyl-CoA to succinyl-CoA involves three enzymes (**Fig. 20-16**):

1. The first reaction, catalyzed by **propionyl-CoA carboxylase**, requires a biotin prosthetic group and is driven by the hydrolysis of ATP to ADP + P_i . The reaction resembles that of pyruvate carboxylase (Fig. 16-18).
2. The (*S*)-methylmalonyl-CoA product of the carboxylase reaction is converted to the *R* form by **methylmalonyl-CoA racemase**.
3. (*R*)-Methylmalonyl-CoA is a substrate for **methylmalonyl-CoA mutase**, which catalyzes an unusual carbon skeleton rearrangement.

Methylmalonyl-CoA mutase uses a **5'-deoxyadenosylcobalamin** prosthetic group (**AdoCbl**; also called **coenzyme B₁₂**, a derivative of **cobalamin**, or **vitamin B₁₂**; Box 20-1). Dorothy Hodgkin determined the structure of this complex molecule (**Fig. 20-17**) in 1956 through X-ray crystallographic

FIG. 20-17 Structure of 5'-deoxyadenosylcobalamin.

? Identify the six Co ligands.

The existence of vitamin B₁₂ came to light in 1926 when George Minot and William Murphy discovered that **pernicious anemia**, an often fatal disease of the elderly characterized by decreased numbers of red blood cells, low hemoglobin levels, and progressive neurological deterioration, can be treated by the daily consumption of large amounts of raw liver. Nevertheless, the antipernicious anemia factor—vitamin B₁₂—was not isolated until 1948.

Vitamin B₁₂ is synthesized by neither plants nor animals but only by a few species of bacteria. Herbivores obtain their vitamin B₁₂ from the bacteria that inhabit their gut (in fact, some animals, such as rabbits, must periodically eat some of their feces to obtain sufficient amounts of this essential substance). Humans, however, obtain almost all their vitamin B₁₂ directly from their diet, particularly from meat. In the intestine, the glycoprotein **intrinsic factor**, which is secreted by the stomach, specifically binds vitamin B₁₂, and the protein–vitamin complex is

absorbed via a receptor in the intestinal mucosa. The complex dissociates and the liberated vitamin B₁₂ is transported to the bloodstream. At least three different plasma proteins, called **transcobalamins**, bind the vitamin and facilitate its uptake by the tissues.

Pernicious anemia is not usually a dietary deficiency disease but, rather, results from insufficient secretion of intrinsic factor, often due to an autoimmune attack against the cells that produce it. The normal human requirement for cobalamin is very small, $\sim 3 \mu\text{g} \cdot \text{day}^{-1}$, and the liver stores a 3- to 5-year supply of the vitamin. This accounts for the insidious onset of pernicious anemia and the fact that true dietary deficiency of vitamin B₁₂, even among strict vegetarians, is extremely rare. However, individuals with pernicious anemia must take massive quantities of vitamin B₁₂ because, in the absence of intrinsic factor, it is poorly absorbed. Patients whose stomach has been surgically removed, usually because of cancer, must also do so.

analysis combined with chemical degradation studies, a landmark achievement (Box 20-2).

5'-Deoxyadenosylcobalamin contains a hemelike **corrin** ring whose four pyrrole N atoms each ligand a six-coordinate Co ion. The fifth Co ligand in the free coenzyme is an N atom of a **5,6-dimethylbenzimidazole (DMB)** nucleotide that is covalently linked to the corrin D ring. The sixth ligand is a 5'-deoxyadenosyl group in which the deoxyribose C5' atom forms a covalent C—Co bond, *one of only two carbon–metal bonds known in biology* (the other is a C—Ni bond in the bacterial enzyme **carbon monoxide dehydrogenase**). In some cobalamin-dependent enzymes, the sixth ligand instead is a CH₃ group that likewise forms a C—Co bond. There are only about a dozen known cobalamin-dependent enzymes, which catalyze molecular rearrangements or methyl-group transfer reactions.

Methylmalonyl-CoA Mutase Has a Unique α/β Barrel. The X-ray structure of methylmalonyl-CoA mutase from *Propionibacterium shermanii*, an $\alpha\beta$ heterodimer, in complex with the substrate analog **2-carboxypropyl-CoA** (which lacks methylmalonyl-CoA's thioester oxygen atom) was determined by Philip Evans.

Box 20-2 Pathways of Discovery

Dorothy Crowfoot Hodgkin and the Structure of Vitamin B₁₂

Dorothy Crowfoot Hodgkin (1910–1994) The third woman to receive a Nobel Prize in Chemistry, after Marie Curie in 1911 and her daughter Irene Joliot-Curie in 1935, was Dorothy Crowfoot Hodgkin, who received the award in 1964 for determining the structures of biological molecules by X-ray crystallography. Hodgkin's career as a scientist is notable not only for her

accomplishments—elucidating the structures of sterols, penicillin, vitamin B₁₂, and insulin—but also for her contributions to the methodology of X-ray crystallography.

Hodgkin's fascination with crystals reportedly began at age 10 with a simple experiment involving alum. Her scientific tendencies were encouraged by her parents, particularly her mother, who was an accomplished amateur botanist. Hodgkin attributed her independent spirit to the fact that her parents were absent for long periods, as her father worked as an archaeologist in Egypt and the Middle East.

Hodgkin's formal training in crystallography took place at Oxford University during her undergraduate years and continued as she earned a doctorate under the guidance of J.D. Bernal at Cambridge University. Unlike many of his colleagues at the time, Bernal was generous in giving credit to his junior associates. Consequently, Hodgkin received recognition along with Bernal in 1934 when they

reported the first X-ray diffraction pattern of a protein, pepsin. Bernal and Hodgkin had thereby shown that proteins are not amorphous colloids but have discrete structures. They also advanced the field of macromolecular crystallography by noting the necessity of examining crystals surrounded by their mother liquor (the solution from which the molecules crystallize) rather than air-dried, as was standard procedure at the time.

After returning to Oxford, Hodgkin established her own laboratory, a challenging task for someone striking out in a new field, and even more difficult for a woman trying to balance work with marriage and motherhood in the late 1930s. At Oxford, Hodgkin undertook studies of crystallized cholesterol and other steroids, showing that calculations based on X-ray diffraction in three rather than two dimensions could disclose considerable information about molecular structure, including the stereochemistry of each carbon atom. Hodgkin also began studying crystals of insulin, although an atomic model of the 777-atom protein took 34 years to complete (the sequence of insulin, determined by Frederick Sanger, was not known until 1955; Box 5-1). During World War II, Hodgkin turned her attention to the structure of penicillin and used X-ray crystallography to elucidate its unexpected ring structure (three carbons and a nitrogen; Box 8-3). This discovery helped pave the way for the synthesis of penicillin and its derivatives. Hodgkin's work also marked the beginning of an electronic age in biochemical

FIG. 20-18 X-Ray structure of *P. shermanii* methylmalonyl-CoA mutase in complex with 2-carboxypropyl-CoA and AdoCbl. (a) The catalytically active α subunit in which the N-terminal domain is cyan, the β strands of its α/β barrel are orange, and the C-terminal domain is pink. The substrate analog 2-carboxypropyl-CoA (magenta) and AdoCbl (green) are drawn in space-filling form. The 2-carboxypropyl-CoA passes through the center of the α/β barrel and is oriented such that the methylmalonyl group of methylmalonyl-CoA would contact the corrin ring of the AdoCbl, which is sandwiched between the enzyme's N- and C-terminal domains. (b) The arrangement of the AdoCbl and 2-carboxypropyl-CoA molecules which, together with the side chain of

His 610, are represented in stick form colored according to atom type (2-carboxypropyl-CoA and His C green, AdoCbl C cyan, N blue, O red, P magenta, and S yellow). The corrin ring's Co atom is represented by a lavender sphere and the α/β barrel's β strands are represented by orange ribbons. The view is similar to that in Part a. Note that the DMB group (bottom) has swung away from the corrin ring (seen edgewise) to be replaced by the side chain of His 610 from the C-terminal domain and that the 5'-deoxyadenosyl group is unseen (due to disorder). [Based on an X-ray structure by Philip Evans, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 7REQ.]

Its AdoCbl cofactor is sandwiched between the catalytically active α subunit's two domains: a 559-residue N-terminal α/β barrel (TIM barrel, the most common enzymatic motif; Sections 6-2C and 15-2) and a 169-residue C-terminal α/β domain that resembles a Rossmann fold (Section 6-2C). The structure of the α/β barrel contains several surprising features (Fig. 20-18):

research, as she used one of the first analog computers from IBM to help with the required calculations.

In 1955, a visitor brought Hodgkin crystals of cyanocobalamin, whose deep-red color may have enticed Hodgkin to immediately examine their X-ray diffraction. The cobalamin structure, four times larger than that of penicillin, had not yet yielded its structural secrets to conventional chemical approaches. Hodgkin's success in determining the structure of cobalamin was the result of experience as well as intuition. She was reportedly able to discern features of molecular structure simply by examining the diffraction pattern. However, she also took advantage of powerful computers available to her collaborator Kenneth Trueblood at the University of California at Los Angeles, who, due to the great distance between them, communicated with her through letters and telegrams. Hodgkin bravely decided to use the cobalt atom naturally present in cobalamin to solve the "phase problem" that prevents the straightforward determination of X-ray structures (Box 7-2). Although others believed that the cobalt atom would not scatter X-rays strongly enough relative to the lighter atoms in the structure, Hodgkin was able to derive the necessary phase information and thus was spared having to produce cobalamin crystals containing a heavier atom.

Hodgkin and her collaborators identified the unusual porphyrin structure of cyanocobalamin, in which rings A and D are directly linked and ring A is fully saturated (Fig. 20-17). They subsequently identified

cobalamin, with its Co—C bond, as the first known biological organometallic compound. Hodgkin later determined the structure of the physiological form of vitamin B₁₂, adenosylcobalamin, in 1961. Now that the structure of the vitamin was known, it could be synthesized and used to treat pernicious anemia (Box 20-1). In addition to its obvious implications for human health, Hodgkin's work with cobalamin encouraged other researchers to pursue the structures of large compounds previously thought to be too complicated for crystallographic analysis. Hodgkin herself finally completed a three-dimensional model of insulin in 1969.

After receiving the Nobel prize in 1964, along with many other honors, Hodgkin became increasingly involved in international organizations, including the International Union of Crystallography and other groups dedicated to promoting scientific cooperation as a means for decreasing international tensions during the Cold War. Her own laboratory over the years hosted scientists from around the globe. By the end of her life, her efforts to foster international goodwill were no less notable than her accomplishments as a crystallographer.

Ferry, G., *Dorothy Hodgkin: A Life*, Cold Spring Harbor Laboratory Press (2000). Hodgkin, D.C., Kamper, J., Mackay, M., Pickworth, J., Trueblood, K.N. and White, J.G., Structure of vitamin B-12, *Nature* **178**, 64 (1956).

1. The active sites of nearly all α/β barrel enzymes are located at the C-terminal ends of the barrel's β strands. In methylmalonyl-CoA mutase, however, the AdoCbl is packed against the N-terminal ends of the barrel's β strands.
2. In free AdoCbl, the Co atom is axially liganded by an N atom of its DMB group and by the adenosyl residue's 5'-CH₂ group (Fig. 20-17). In the enzyme, however, the DMB has swung aside to bind in a separate pocket and has been replaced by the side chain of His 610 from the C-terminal domain. The adenosyl group is not visible in the structure due to disorder and hence has probably also swung aside.
3. In nearly all other α/β barrel-containing enzymes, the center of the barrel is occluded by large, often branched, hydrophobic side chains. In methylmalonyl-CoA mutase, however, the 2-carboxypropyl-CoA's pantotheine group binds in a narrow tunnel along the center of the α/β barrel to put the methylmalonyl group of an intact substrate in close proximity to the unliganded face of the cobalamin ring. The tunnel provides the only direct access to the active site cavity, thereby protecting the reactive free radical intermediates that are produced in the catalytic reaction from side reactions (see below). The tunnel is lined by small hydrophilic residues (Ser and Thr).

Methylmalonyl-CoA mutase's substrate-binding mode resembles that of several other AdoCbl-containing enzymes of known structure, which are collectively unique among α/β barrel-containing enzymes.

Methylmalonyl-CoA Mutase Stabilizes and Protects Free Radical Intermediates. The proposed methylmalonyl-CoA mutase reaction mechanism (Fig. 20-19) begins with the **homolytic cleavage** of the cobalamin C—Co bond; in other words, the C and Co atoms each acquire one of the electrons that formed the cleaved electron pair bond. (Note that a homolytic cleavage reaction is unusual in biology; most other biological bond-cleavage reactions occur via **heterolytic cleavage** in which the electron pair forming the cleaved bond is fully acquired by one of the separating atoms.) The Co ion therefore alternates between its Co(III) and Co(II) oxidation states and hence *functions as a reversible free radical generator*. The C—Co(III) bond is well suited to this function because it is inherently weak (dissociation energy 109 kJ · mol⁻¹) and is further weakened through steric interactions with the enzyme.

Spectroscopic measurements indicate that the Co atom in methylmalonyl-CoA mutase is in the Co(II) state, thereby confirming that it has no sixth ligand (as occurs during its catalytic cycle; Fig. 20-19). Protein-induced strain makes the His N—Co bond (the fifth ligand) extremely long (2.5 Å versus 1.9–2.0 Å in various other B₁₂-containing structures), which stabilizes the Co(II) species relative to Co(III) and thereby favors the formation of the adenosyl radical. The radical abstracts a hydrogen atom from the methylmalonyl-CoA substrate, thereby facilitating its rearrangement to succinyl-CoA through the intermediate formation of a cyclopropoxy radical.

Succinyl-CoA Is Not Directly Consumed by the Citric Acid Cycle. Methylmalonyl-CoA mutase catalyzes the conversion of a metabolite to a citric acid cycle intermediate other than acetyl-CoA. However, such C₄ intermediates are actually catalysts, not substrates, of the citric acid cycle. *In order for succinyl-CoA to undergo net oxidation by the citric acid cycle, it must first be converted to pyruvate and then to acetyl-CoA.* This is accomplished by converting succinyl-CoA to malate (Reactions 5–7 of the citric acid cycle; Fig. 17-2) followed by its

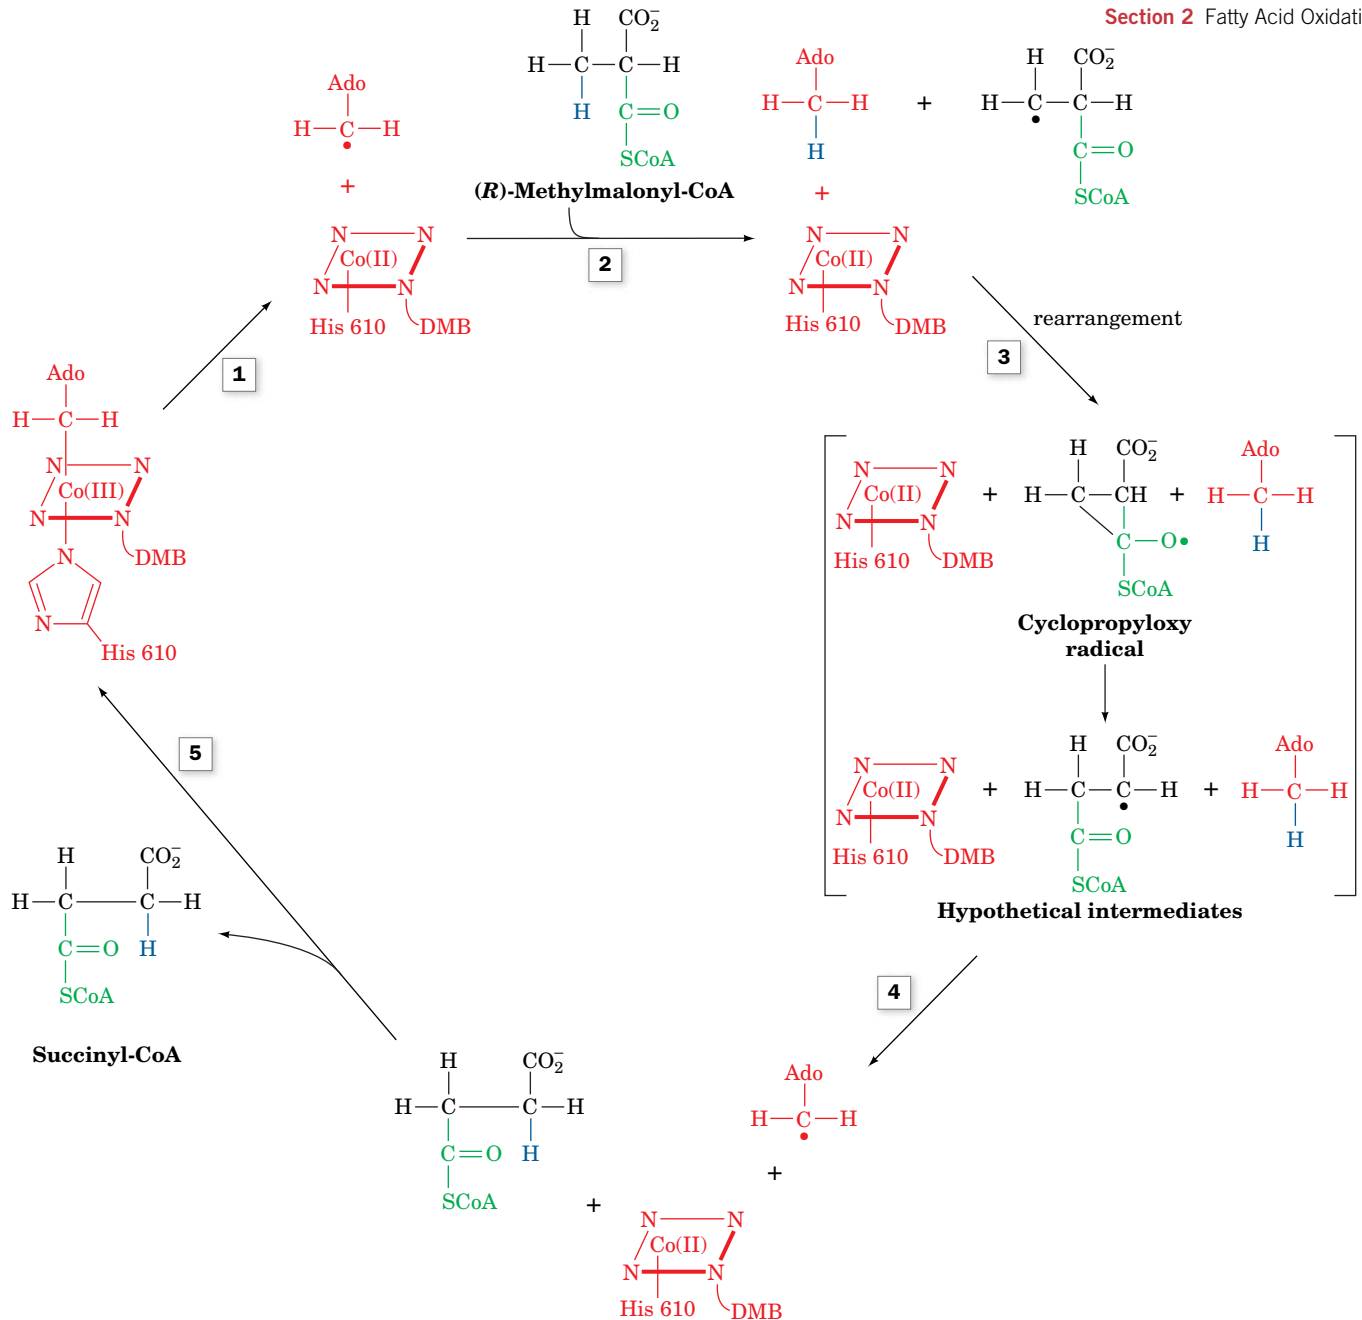

FIG. 20-19 Proposed mechanism of methylmalonyl-CoA mutase. (1) The homolytic cleavage of the C—Co(III) bond yields a 5'-deoxyadenosyl (Ado) radical and cobalamin in its Co(II) oxidation state. (2) The 5'-deoxyadenosyl radical abstracts a hydrogen atom from methylmalonyl-CoA, thereby generating a methylmalonyl-CoA radical.

(3) Carbon skeleton rearrangement yields a succinyl-CoA radical via a proposed cyclopropyloxy radical intermediate. (4) The succinyl-CoA radical abstracts a hydrogen atom from 5'-deoxyadenosine to regenerate the 5'-deoxyadenosyl radical. (5) The release of succinyl-CoA re-forms the coenzyme.

transport to the cytosol and oxidative decarboxylation to pyruvate and CO_2 by **malic enzyme**

FIG. 20-20 Electron micrograph of a peroxisome from rat liver surrounded by the rough endoplasmic reticulum. Peroxisomes are membrane-bounded organelles that perform a variety of metabolic functions, including the oxidation of very long chain fatty acids.

(this enzyme also functions in the C_4 cycle of photosynthesis; Fig. 19-33). Pyruvate is then completely oxidized via pyruvate dehydrogenase and the citric acid cycle.

F Peroxisomal β Oxidation Differs from Mitochondrial β Oxidation

In mammalian cells, the bulk of β oxidation occurs in the mitochondria, but **peroxisomes** (Fig. 20-20) also oxidize fatty acids, particularly those with very long chains or branched chains. In plants, fatty acid oxidation occurs exclusively in the peroxisomes and glyoxysomes (which are specialized peroxisomes). In addition to lipid catabolism, mammalian peroxisomes participate in the synthesis of certain lipids, including bile acids.

Peroxisomal β oxidation, which differs only slightly from mitochondrial β oxidation, shortens very long chain fatty acids (>22 carbon atoms), which are then fully degraded by the mitochondrial pathway. Very long chain fatty acids are transported into the peroxisomes by a mechanism that does not require carnitine, and are activated by a long chain acyl-CoA synthetase. Peroxisomal β oxidation results in the same chemical changes to fatty acids as in the mitochondrial pathway but requires only three enzymes:

1. Acyl-CoA oxidase catalyzes the reaction

The enzyme uses an FAD cofactor, but the abstracted electrons are transferred directly to O_2 to yield H_2O_2 (hydrogen peroxide; hence the name “peroxisome”) rather than passing through the electron-transport chain with its concomitant oxidative phosphorylation (Fig. 20-12, Reactions 5–8). Peroxisomal fatty acid oxidation therefore generates 1.5 fewer ATP per C_2 cycle than mitochondrial fatty acid oxidation. Catalase converts the H_2O_2 produced in the oxidase reaction to $\text{H}_2\text{O} + \text{O}_2$.

2. Peroxisomal enoyl-CoA hydratase and 3-L-hydroxyacyl-CoA dehydrogenase activities occur on a single polypeptide. The reactions catalyzed are identical to those of the mitochondrial system (Fig. 20-12, Reactions 2 and 3).
3. Peroxisomal thiolase catalyzes the final step of oxidation. This enzyme is almost inactive with acyl-CoAs of length C_8 or less, so peroxisomes incompletely oxidize fatty acids.

The peroxisome contains both a carnitine acetyltransferase and a transferase specific for longer chain acyl groups. Acyl-CoAs that have been chain-shortened by peroxisomal β oxidation are thereby converted to their carnitine esters. These substances, for the most part, passively diffuse out of the peroxisome to the mitochondrion, where they are oxidized further.

 **Zellweger syndrome**, an inherited disease whose symptoms include neurological problems, vision and hearing loss, and skeletal abnormalities causing distinctive facial features and ending in death by one year, is caused by the reduction or absence of functional peroxisomes. As a consequence, the very long chain and branched chain fatty acids that are normally degraded in the peroxisome accumulate in the body, which impairs the functioning of multiple organ systems.

X-Linked adrenoleukodystrophy (X-ALD) is caused by inherited defects in the peroxisomal transferase for very long chain fatty acids, the consequent accumulation of which causes adrenal gland failure and destroys the myelin sheath that electrically insulates the axons of many neurons (Fig. 9-8). Its varied neurological symptoms present (become evident) between the ages of 4 and 10 years and are usually fatal within 1 to 10 years. X-ALD has been successfully treated by bone marrow transplantation, although this does not improve adrenal function. Gene therapy with a gene encoding the normal peroxisomal transferase has also been successful in resolving the neurological symptoms of a small number of patients, although the levels of very long chain fatty acids in their blood remain high.

CHECKPOINT

- Describe the activation of fatty acids. What is the energy cost for the process?
- How do cytosolic acyl groups enter the mitochondrion for degradation?
- Summarize the chemical reactions that occur in each round of β oxidation. Explain why the process is called β oxidation.
- How is ATP recovered from the products of β oxidation?
- What additional steps are required to oxidize unsaturated and odd-chain fatty acids?
- What is unusual about the methylmalonyl-CoA mutase structure and the reaction it catalyzes?
- Describe the differences between peroxisomal and mitochondrial β oxidation.

3 Ketone Bodies

KEY CONCEPT

- Acetyl-CoA may be reversibly converted to ketone bodies in the liver to be used as fuel by other tissues.

The acetyl-CoA produced by oxidation of fatty acids can be further oxidized via the citric acid cycle. In liver mitochondria, however, a significant fraction of this acetyl-CoA has another fate. By a process known as **ketogenesis**, acetyl-CoA is converted to **acetoacetate** or **D-β-hydroxybutyrate**. These compounds together with acetone are somewhat inaccurately referred to as **ketone bodies**:

Ketone bodies are important metabolic fuels for many peripheral tissues, particularly heart and skeletal muscle. The brain, under normal circumstances, uses only glucose as its energy source (fatty acids are unable to pass through the blood–brain barrier), but during starvation, the small, water-soluble ketone bodies become the brain’s major fuel source (Section 22-4A).

Acetoacetate formation occurs in three reactions (Fig. 20-21):

- Two molecules of acetyl-CoA are condensed to **acetoacetyl-CoA** by thiolase (also called **acetyl-CoA acetyltransferase**) working in the reverse

FIG. 20-21 Ketogenesis. Acetoacetate is formed from acetyl-CoA in three steps. (1) Two molecules of acetyl-CoA condense to form acetoacetyl-CoA. (2) A Claisen ester condensation of the acetoacetyl-CoA with a third acetyl-CoA forms β-hydroxy-β-methylglutaryl-CoA (HMG-CoA). (3) HMG-CoA is degraded to acetoacetate and acetyl-CoA in a mixed aldol–Claisen ester cleavage.

FIG. 20-22 Metabolic conversion of ketone bodies to acetyl-CoA.

? Compare this pathway to the ketogenesis pathway. Which steps are similar?

CHECKPOINT

- What are ketone bodies?
- How are they synthesized and degraded?

direction from the way it does in the final step of β oxidation (Fig. 20-12, Reaction 4).

2. Condensation of the acetoacetyl-CoA with a third acetyl-CoA by **HMG-CoA synthase** forms **β -hydroxy- β -methylglutaryl-CoA (HMG-CoA)**. The mechanism of this reaction resembles the reverse of the thiolase reaction (Fig. 20-14) in that an active site thiol group forms an acyl-thioester intermediate.
3. HMG-CoA is degraded to acetoacetate and acetyl-CoA in a mixed aldol-Claisen ester cleavage by **HMG-CoA lyase**. The mechanism of this reaction is analogous to the reverse of the citrate synthase reaction (Fig. 17-10). HMG-CoA is also a precursor in cholesterol biosynthesis (Section 20-7A). HMG-CoA lyase is present only in liver mitochondria and therefore does not interfere with cholesterol synthesis in the cytoplasm.

Acetoacetate may be reduced to D- β -hydroxybutyrate by **β -hydroxybutyrate dehydrogenase**:

Acetoacetate, a β -keto acid, also undergoes relatively facile nonenzymatic decarboxylation to acetone and CO_2 . Indeed, in individuals with **ketosis**, a pathological condition in which acetoacetate is produced faster than it is metabolized (a symptom of diabetes; Section 22-4B), the breath has the characteristic sweet smell of acetone.

The liver releases acetoacetate and β -hydroxybutyrate, which are carried by the bloodstream to the peripheral tissues for use as alternative fuels. There, these products are converted to two acetyl-CoA as is diagrammed in Fig. 20-22. Succinyl-CoA, which acts as the CoA donor in this process, can also be converted to succinate with the coupled synthesis of GTP in the succinyl-CoA synthetase reaction of the citric acid cycle (Section 17-3E). The “activation” of acetoacetate bypasses this step and therefore “costs” the free energy of GTP hydrolysis.

4 Fatty Acid Biosynthesis

KEY CONCEPTS

- The tricarboxylate transport system transfers acetyl-CoA into the cytosol for fatty acid synthesis.
- Fatty acid synthesis begins with the carboxylation of acetyl-CoA to generate malonyl-CoA.
- Fatty acid synthase carries out seven reactions and lengthens a fatty acid two carbons at a time.
- Elongases and desaturases may modify fatty acids.
- Triacylglycerols are synthesized from glycerol and fatty acids.

Fatty acid biosynthesis occurs through condensation of C_2 units, the reverse of the β -oxidation process. Through isotopic labeling techniques, David Rittenberg and Konrad Bloch demonstrated, in 1945, that these condensation units are

FIG. 20-23 Comparison of fatty acid β oxidation and fatty acid biosynthesis. Differences occur in (1) cellular location, (2) acyl group carrier, (3) electron acceptor/donor, (4) stereochemistry of the

hydration/dehydration reaction, and (5) the form in which C_2 units are produced/donated. **WPLS** See the Animated Figures.

derived from acetic acid. Subsequent research showed that both acetyl-CoA and bicarbonate are required, and that a C_3 unit, **malonyl-CoA**, is an intermediate of fatty acid biosynthesis.

The pathway of fatty acid synthesis differs from that of fatty acid oxidation. This situation, as we saw for glycogen metabolism in Section 16-3, is typical of opposing biosynthetic and degradative pathways because it permits them both to be thermodynamically favorable and independently regulated under similar physiological conditions. **Figure 20-23** outlines fatty acid oxidation and synthesis with emphasis on the differences between the pathways, including the cellular locations of the pathways, the redox coenzymes, and the manner in which C_2 units are removed from or added to the fatty acyl chain.

A Mitochondrial Acetyl-CoA Must Be Transported into the Cytosol

Acetyl-CoA, the starting material for fatty acid synthesis, is generated in the mitochondrion by the oxidative decarboxylation of pyruvate as catalyzed by pyruvate dehydrogenase (Section 17-2B) as well as by the oxidation of fatty acids. When the demand for ATP is low, so the oxidation of acetyl-CoA via the citric acid cycle and oxidative phosphorylation is minimal, this mitochondrial acetyl-CoA may be stored for future use as fat. Fatty acid biosynthesis occurs in the cytosol, however, and the mitochondrial membrane is essentially impermeable to acetyl-CoA. *Acetyl-CoA enters the cytosol in the form of citrate via the tricarboxylate transport system (Fig. 20-24).* ATP-citrate lyase then catalyzes the reaction

which resembles the reverse of the citrate synthase reaction (Fig. 17-10) except that ATP hydrolysis is required to drive the synthesis of the thioester bond. Oxaloacetate is then reduced to malate by malate dehydrogenase. Malate is oxidatively decarboxylated to pyruvate by malic enzyme and returned in this form to the mitochondrion. This reaction involves the reoxidation of malate to

FIG. 20-24 The tricarboxylate transport system. The overall effect of this sequence of reactions is the transfer of acetyl groups from the mitochondrion to the cytosol.

? What is the energetic cost of this cycle?

oxaloacetate, a β -keto acid, which is then decarboxylated, a reaction reminiscent of the isocitrate dehydrogenase reaction in the citric acid cycle (Section 17-3C). The NADPH produced is used in the reductive reactions of fatty acid biosynthesis.

B Acetyl-CoA Carboxylase Produces Malonyl-CoA

Acetyl-CoA carboxylase (ACC) catalyzes the first committed step of fatty acid biosynthesis and one of its rate-controlling steps. The mechanism of this biotin-dependent enzyme is similar to those of propionyl-CoA carboxylase (Section 20-2E) and pyruvate carboxylase (Fig. 16-18). The reaction occurs in two steps, a CO₂ activation and a carboxylation:

The result is a three-carbon (malonyl) group linked as a thioester to CoA.

Mammalian acetyl-CoA carboxylase, a ~2350-residue polypeptide, is subject to allosteric and hormonal control. For example, citrate stimulates acetyl-CoA carboxylase and long chain fatty acyl-CoAs are feedback inhibitors of the enzyme. Fine-tuning of enzyme activity is accomplished through covalent modification. Acetyl-CoA carboxylase is a substrate for several kinases. It has six phosphorylation sites, but phosphorylation of only one (Ser 79) is clearly associated with enzyme inactivation. Ser 79 is phosphorylated by **AMP-dependent protein kinase (AMPK)** in a cAMP-independent pathway. However, glucagon as well as epinephrine, which act through protein kinase A (PKA; Section 16-3B), promote the phosphorylation of Ser 79, possibly by inhibiting its dephosphorylation (recall that this occurs in glycogen metabolism when the PKA-mediated phosphorylation of phosphoprotein phosphatase inhibitor-1 inhibits dephosphorylation; Fig. 16-13). Insulin, on the other hand, stimulates dephosphorylation of acetyl-CoA carboxylase and thereby activates the enzyme.

Mammalian Acetyl-CoA Carboxylase Has Two Major Isoforms. There are two major isoforms of ACC. **ACC1** occurs in adipose tissue and **ACC2** occurs in tissues that oxidize but do not synthesize fatty acids, such as heart muscle. Tissues that both synthesize and oxidize fatty acids, such as liver, contain both isoforms, which are homologous although the genes encoding them are located on different chromosomes. What is the function of ACC2? The product of the ACC-catalyzed reaction, malonyl-CoA, strongly inhibits the mitochondrial import of fatty acyl-CoA for fatty acid oxidation, the major control point for this process. Thus it appears that ACC2 has a regulatory function (Section 20-5).

The *E. coli* acetyl-CoA carboxylase, which is a multisubunit protein, is regulated by guanine nucleotides so that fatty acid synthesis is coordinated with cell growth. In prokaryotes, fatty acids serve primarily as phospholipid precursors, since these organisms do not synthesize triacylglycerols for energy storage.

C Fatty Acid Synthase Catalyzes Seven Reactions

The synthesis of fatty acids, mainly palmitic acid, from acetyl-CoA and malonyl-CoA involves seven enzymatic reactions. These reactions were first studied in cell-free extracts of *E. coli*, in which they are catalyzed by independent enzymes. Individual enzymes with these activities also occur in chloroplasts (plant fatty acid synthesis does not occur in the cytosol). In yeast, **fatty acid synthase** is a cytosolic, 2500-kD multifunctional enzyme with the composition $\alpha_6\beta_6$, whereas in animals it is a 534-kD multifunctional enzyme consisting of two identical polypeptide chains. Presumably, such proteins evolved by the joining of previously independent genes for the enzymes.

Although fatty acid synthesis begins with the synthesis of a CoA ester, malonyl-CoA, the growing fatty acid is anchored to **acyl-carrier protein (ACP; Fig. 20-25)**. ACP, like CoA, contains a phosphopantetheine group that forms a

FIG. 20-25 The phosphopantetheine group in acyl-carrier protein (ACP) and in CoA.

thioester with an acyl group. The phosphopantetheine phosphoryl group is esterified with a Ser OH group of ACP, whereas in CoA it is linked to AMP. In *E. coli*, ACP is a 10-kD polypeptide, whereas in animals it is part of the multifunctional fatty acid synthase.

The reactions catalyzed by mammalian fatty acid synthase are diagrammed in Fig. 20-26:

1. These are priming reactions in which the synthase is “loaded” with the precursors for the condensation reaction. In mammals, **malonyl/acetyl-CoA-ACP transacylase (MAT)** catalyzes two similar reactions at a single active site: An acetyl group originally linked as a thioester in acetyl-CoA is transferred to ACP (**1a**), and a malonyl group is transferred from malonyl-CoA to ACP (**1b**).
2. The **β -ketoacyl-ACP synthase (KS)**; also known as **condensing enzyme** first transfers the acetyl group from ACP to an enzyme Cys residue (**2a**). In the condensation reaction (**2b**), the malonyl-ACP is decarboxylated, and the resulting carbanion attacks the acetylthioester to form a four-carbon acetoacetyl-ACP. The decarboxylation reaction drives the condensation reaction:

- 3–5. Two reductions and a dehydration convert the β -keto group to an alkyl group. The coenzyme in both reductive steps is NADPH. In β oxidation, the analogs of Reactions 3 and 5, respectively, use NAD^+ and FAD (Fig. 20-12, Reactions 3 and 1). Moreover, Reaction 4 requires a D- β -hydroxyacyl substrate, whereas the analogous reaction in β oxidation forms the corresponding L isomer.

At this point, the acyl group, originally an acetyl group, has been elongated by a C_2 unit. This butyryl group is then transferred from ACP to the Cys—SH of the enzyme (a repeat of Reaction 2a) so that it can be extended by additional rounds of the fatty acid synthase reaction sequence. Note that the malonyl-CoA synthesized by the acetyl-CoA carboxylase reaction is decarboxylated in the condensation reaction. The formation of a C—C bond is an endergonic process requiring an activated precursor. Malonyl-ACP is a β -keto ester whose exergonic decarboxylation yields the acetyl-ACP carbanion required for C—C bond

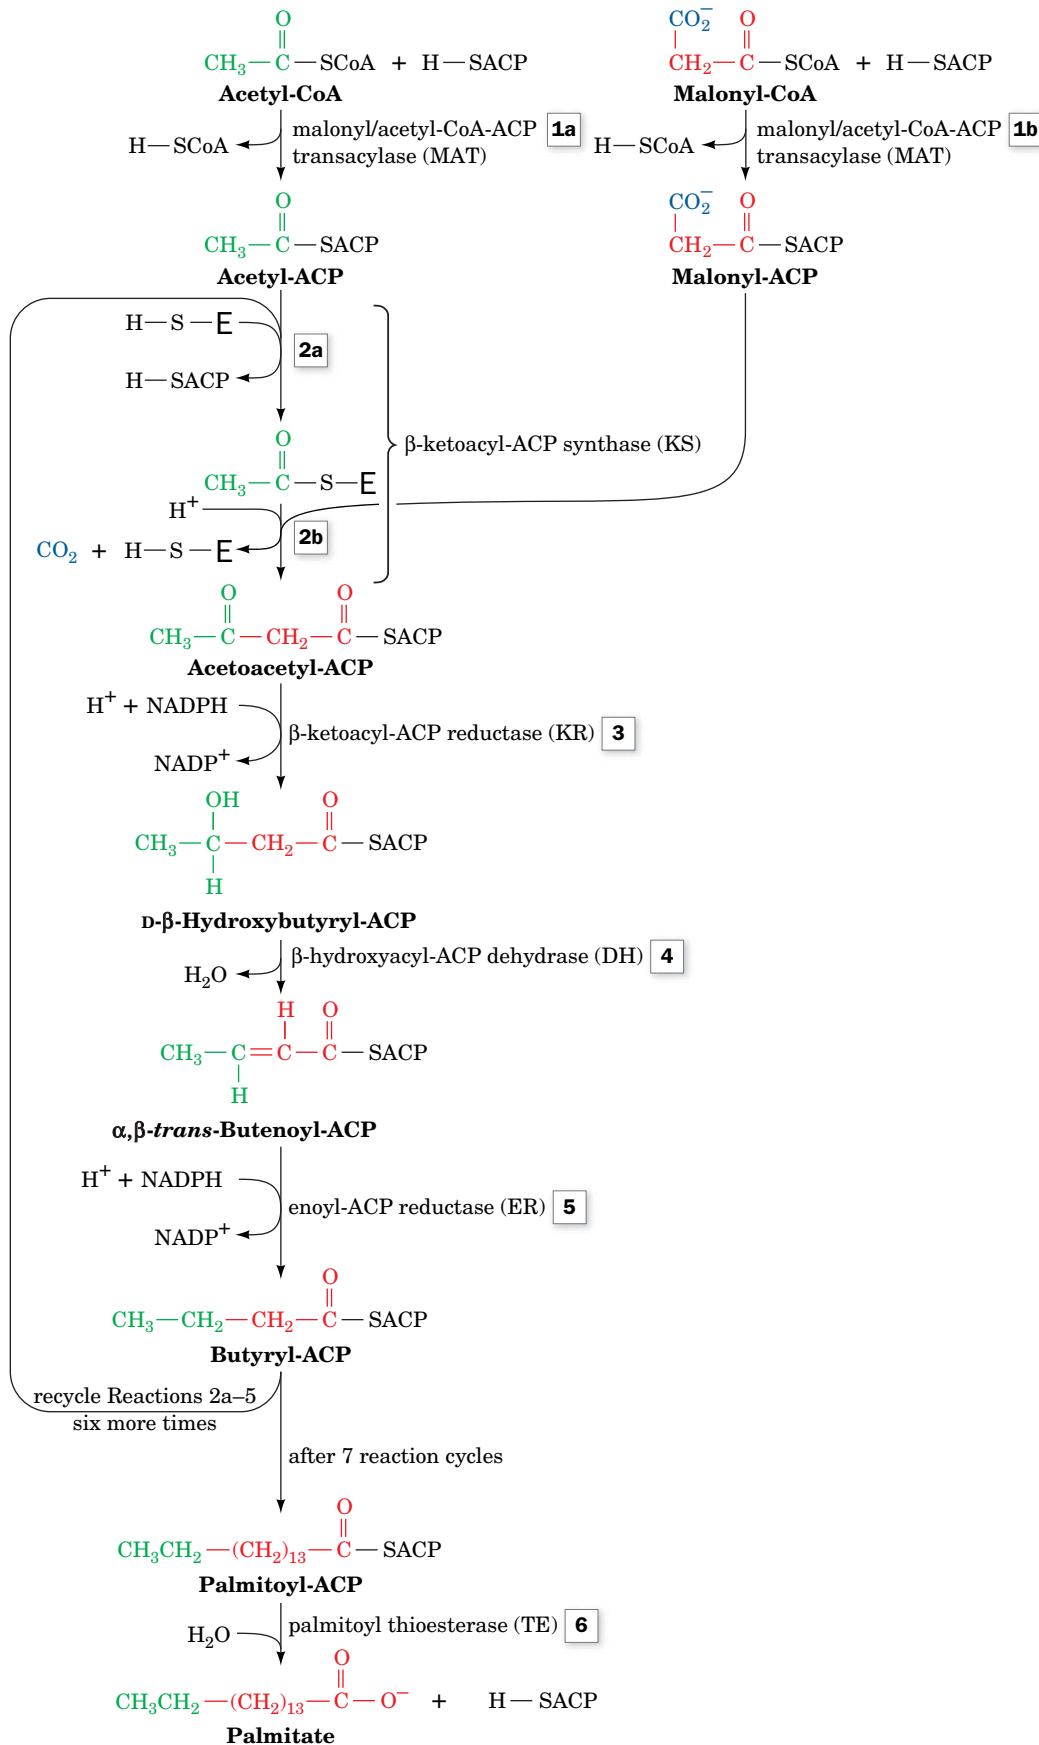

FIG. 20-26 Reaction sequence for the biosynthesis of fatty acids. In forming palmitate, the pathway is repeated for seven cycles of C₂ elongation followed by a final hydrolysis step. **WPLS** See the Animated Figures.

? Describe the type of reaction that occurs at each step.

formation. The free energy required for the overall reaction is supplied by the ATP hydrolysis in the acetyl-CoA carboxylase reaction, which generates the malonyl-CoA precursor of malonyl-ACP. This carboxylation–decarboxylation sequence is similar to the activation of pyruvate to oxaloacetate for conversion to phosphoenolpyruvate in gluconeogenesis (Section 16-4A).

In each reaction cycle, the ACP is “reloaded” with a malonyl group, and the acyl chain grows by two carbon atoms. Note that each new acetyl unit donated by malonyl-CoA adds to the growing acyl chain at its point of attachment to the enzyme. Thus, the fatty acid grows from its thioester end, not from its methyl end (likewise, fatty acids are catabolized from their thioester ends).

Seven cycles of elongation are required to form **palmitoyl-ACP**. The thioester bond is then hydrolyzed by **palmitoyl thioesterase (TE)**; (Fig. 20-26, Reaction 6), yielding palmitate, the normal product of the fatty acid synthase pathway, and regenerating the enzyme for a new round of synthesis.

The stoichiometry of palmitate synthesis is therefore

Since the 7 malonyl-CoA are derived from acetyl-CoA as follows:

the overall stoichiometry for palmitate biosynthesis is

The Two Halves of Fatty Acid Synthase Operate in Concert. In animals, the seven reactions of fatty acid synthesis are localized to six discrete active sites (MAT carries out two reactions, 1a and 1b). The order of the domains along the animal fatty acid synthase polypeptide chain is indicated in [Fig. 20-27a](#). Three of the domains besides ACP lack enzymatic activity: a linker domain (LD) that bridges the KS and MAT domains; a pseudo-methyltransferase (Ψ ME) domain, so named because it is homologous to the methyltransferase family; and a pseudo-ketoreductase (Ψ KR) domain, so named because it is a truncated form of the KR domain.

The two subunits of fatty acid synthase form an asymmetric X with two reaction chambers ([Fig. 20-27b](#)). The subunits associate via an extensive interface involving the KS, ER, and DH domains. However, the upper and lower portions of the X are only loosely connected. The lower portion of the X contains the enzyme’s two condensing activities, MAT and KS (which catalyze reactions 1 and 2 in [Fig. 20-26](#)), and the upper portion of the X contains the enzyme’s β -carbon modifying activities, DH, KR, and ER (which catalyze reactions 3–5 in [Fig. 20-26](#)). The C-terminal ACP and TE domains are flexibly tethered to the enzyme and are therefore unobserved.

Each of the two reaction chambers of the enzyme is lined by the full set of catalytic domains from one subunit, all of which must be visited by the long, flexible phosphopantetheine arm of an ACP. [The flexible lipoyllysyl arms of the pyruvate dehydrogenase multienzyme complex (Section 17-2B) perform a similar function in that enzyme.] The catalytic sites of the fatty acid synthase domains occur on both the front and back faces of the protein, and their distribution has no discernable relationship to the order of the reactions in the catalytic cycle. Mutational studies indicate that a single ACP domain can service active sites on both subunits. Apparently, the upper portion of the X can rotate 180° relative to the lower portion, a degree of flexibility that is consistent with the tenuous structure that joins the two halves of the enzyme. Because fatty acid synthase is a dimer, two fatty acids can be synthesized simultaneously. In some organisms,

multifunctional enzymes that resemble fatty acid synthase produce complex molecules (Box 20-3).

In well-nourished individuals, fatty acid synthesis proceeds at a low rate. However, certain tissues, particularly malignancies, express high levels of fatty acid synthase and produce fatty acids at a high rate. Consequently, inhibitors of fatty acid synthase may act as anticancer agents.

Polyketides are a family of >10,000 diverse and structurally complex natural products, many of which have antimicrobial, antitumor, and immunosuppressive properties. They are synthesized in bacteria, fungi, plants, and certain marine animals by the stepwise condensation of acetyl-CoA or propionyl-CoA with malonyl-CoA or methylmalonyl-CoA extender units. Each condensation reaction is driven by the decarboxylation of the extender unit and yields a β -keto functional group (e.g., an acetoacetyl group; this is why the ultimate product is called a polyketide). Palmitate is an example of a polyketide since it is formed by the condensation of one acetyl-CoA primer and seven malonyl-CoA extender units. Following each condensation reaction, the new β -keto group may be reduced, dehydrated, and reduced again, as with fatty acids, or may undergo only partial modification.

Polyketides are synthesized by multienzyme polypeptides that resemble eukaryotic fatty acid synthase but are often much larger. They include acyl-carrier domains plus an assortment of enzymatic units that can function in an iterative fashion, repeating the same elongation/modification steps (as in fatty acid synthesis), or in a sequential fashion so as to generate more heterogeneous types of polyketides.

For example, the soil bacterium *Saccharopolyspora erythraea* produces the polyketide **6-deoxyerythronolide B (6dEB)**, which is the precursor of the antibiotic **erythromycin A**. Synthesis requires a propionyl-CoA primer and six (*S*)-methylmalonyl-CoA extenders. The

enzyme **deoxyerythronolide B synthase (DEBS)**, a 2000-kD $\alpha_2\beta_2\gamma_2$ complex, contains 28 different active sites that function like an assembly line. Its three units (DEBS1, DEBS2, and DEBS3) each catalyze two elongation and modification steps (see the figure).

Module 4 resembles fatty acid synthase (it contains KS, AT, ACP, KR, DH, and ER). However, it does not contain TE because the elongation process is not complete after this phase. Module 3 contains only ACP, KS, and AT and passes its β -ketone condensation product to module 4 without further modification. Modules 1, 2, 5, and 6 contain only ACP, AT, KS, and KR, the sites necessary for the condensation and ketone reduction steps, thereby generating hydroxy products. The overall organization of the modules therefore creates a polyhydroxy chain with one keto group. The chain cyclizes through reaction of the terminal hydroxyl group with the thioester that anchored the growing chain to the synthase. As is the case for many polyketides, additional covalent modifications are required to generate a product with full biological activity. The modular nature of polyketide synthases and the variety of their reaction products make these enzymes appealing to genetic engineers trying to design enzymes that can synthesize novel compounds or more effective drugs.

An example of polyketide biosynthesis: the synthesis of erythromycin A. [After Pfeifer, B.A., Admiraal, S.J., Gramajo, H., Cane, D.E., and Khosla, C., *Science* **291**, 1790 (2001).]

D Fatty Acids May Be Elongated and Desaturated

Palmitate, a saturated C_{16} fatty acid, is converted to longer chain saturated and unsaturated fatty acids through the actions of **elongases** and **desaturases**. Elongases are present in both the mitochondria and the endoplasmic reticulum, but the mechanisms of elongation at the two sites differ. Mitochondrial elongation (a process independent of the fatty acid synthase pathway in the cytosol) occurs by the successive addition and reduction of acetyl units in a reversal of fatty acid oxidation; the only chemical difference between the two pathways occurs in the final reduction step in which NADPH takes the place of $FADH_2$ as the terminal redox coenzyme (Fig. 20-28). Elongation in the endoplasmic reticulum involves the successive condensations of malonyl-CoA with acyl-CoA. These reactions are each followed by NADPH-dependent reductions similar to those catalyzed by fatty acid synthase, the only difference being that the fatty acid is elongated as its CoA derivative rather than as its ACP derivative.

Unsaturated fatty acids are produced by **terminal desaturases**. Mammalian systems contain four terminal desaturases of broad chain-length specificities designated Δ^9 -, Δ^6 -, Δ^5 -, and Δ^4 -**fatty acyl-CoA desaturases**. These nonheme iron-containing enzymes catalyze the general reaction

where x is at least 5 and where $(\text{CH}_2)_x$ can contain one or more double bonds. The $(\text{CH}_2)_y$ portion of the substrate is always saturated. Double bonds are inserted between existing double bonds in the $(\text{CH}_2)_x$ portion of the substrate and the CoA group such that the new double bond is three carbon atoms closer to the CoA group than the next double bond (not conjugated to an existing double bond) and, in animals, never at positions beyond C9.

 **Certain Polyunsaturated Fatty Acids Must Be Obtained in the Diet.** A variety of unsaturated fatty acids can be synthesized by combinations of elongation and desaturation reactions. However, since palmitic acid is the shortest available fatty acid in animals, the above rules preclude the formation of the Δ^{12} double bond of linoleic acid ($\Delta^{9,12}$ -octadecadienoic acid; a polyunsaturated fatty acid), a required precursor of **prostaglandins** and other **eicosanoids** (Section 9-1F). *Linoleic acid must consequently be obtained in the diet (ultimately from plants that have Δ^{12} - and Δ^{15} -desaturases) and is therefore an essential fatty acid.* Indeed, animals maintained on a fat-free diet develop an ultimately fatal condition that is initially characterized by poor growth, poor wound healing, and dermatitis. Linoleic acid is also an important constituent of epidermal sphingolipids that function as the skin's water permeability barrier: Animals deprived of linoleic acid must drink far more water than those with an adequate diet.

FIG. 20-28 Mitochondrial fatty acid elongation. This process is the reverse of fatty acid oxidation (Fig. 20-12) except that the final reaction employs NADPH rather than $FADH_2$ as its redox coenzyme.

E Fatty Acids Are Esterified to Form Triacylglycerols

Triacylglycerols are synthesized from fatty acyl-CoA esters and glycerol-3-phosphate or dihydroxyacetone phosphate (Fig. 20-29). The initial step in this process is catalyzed either by **glycerol-3-phosphate acyltransferase** in mitochondria and the endoplasmic reticulum, or by **dihydroxyacetone phosphate acyltransferase** in the endoplasmic reticulum or peroxisomes. In the latter case, the product acyl-dihydroxyacetone phosphate is reduced to the corresponding **lysophosphatidic acid** by an NADPH-dependent reductase. The lysophosphatidic acid is converted to a triacylglycerol by the successive actions of **1-acylglycerol-3-phosphate acyltransferase**, **phosphatidic acid phosphatase**, and **diacylglycerol acyltransferase**. The intermediate phosphatidic acid and 1,2-diacylglycerol can also be converted to phospholipids by the pathways described in Section 20-6A. The

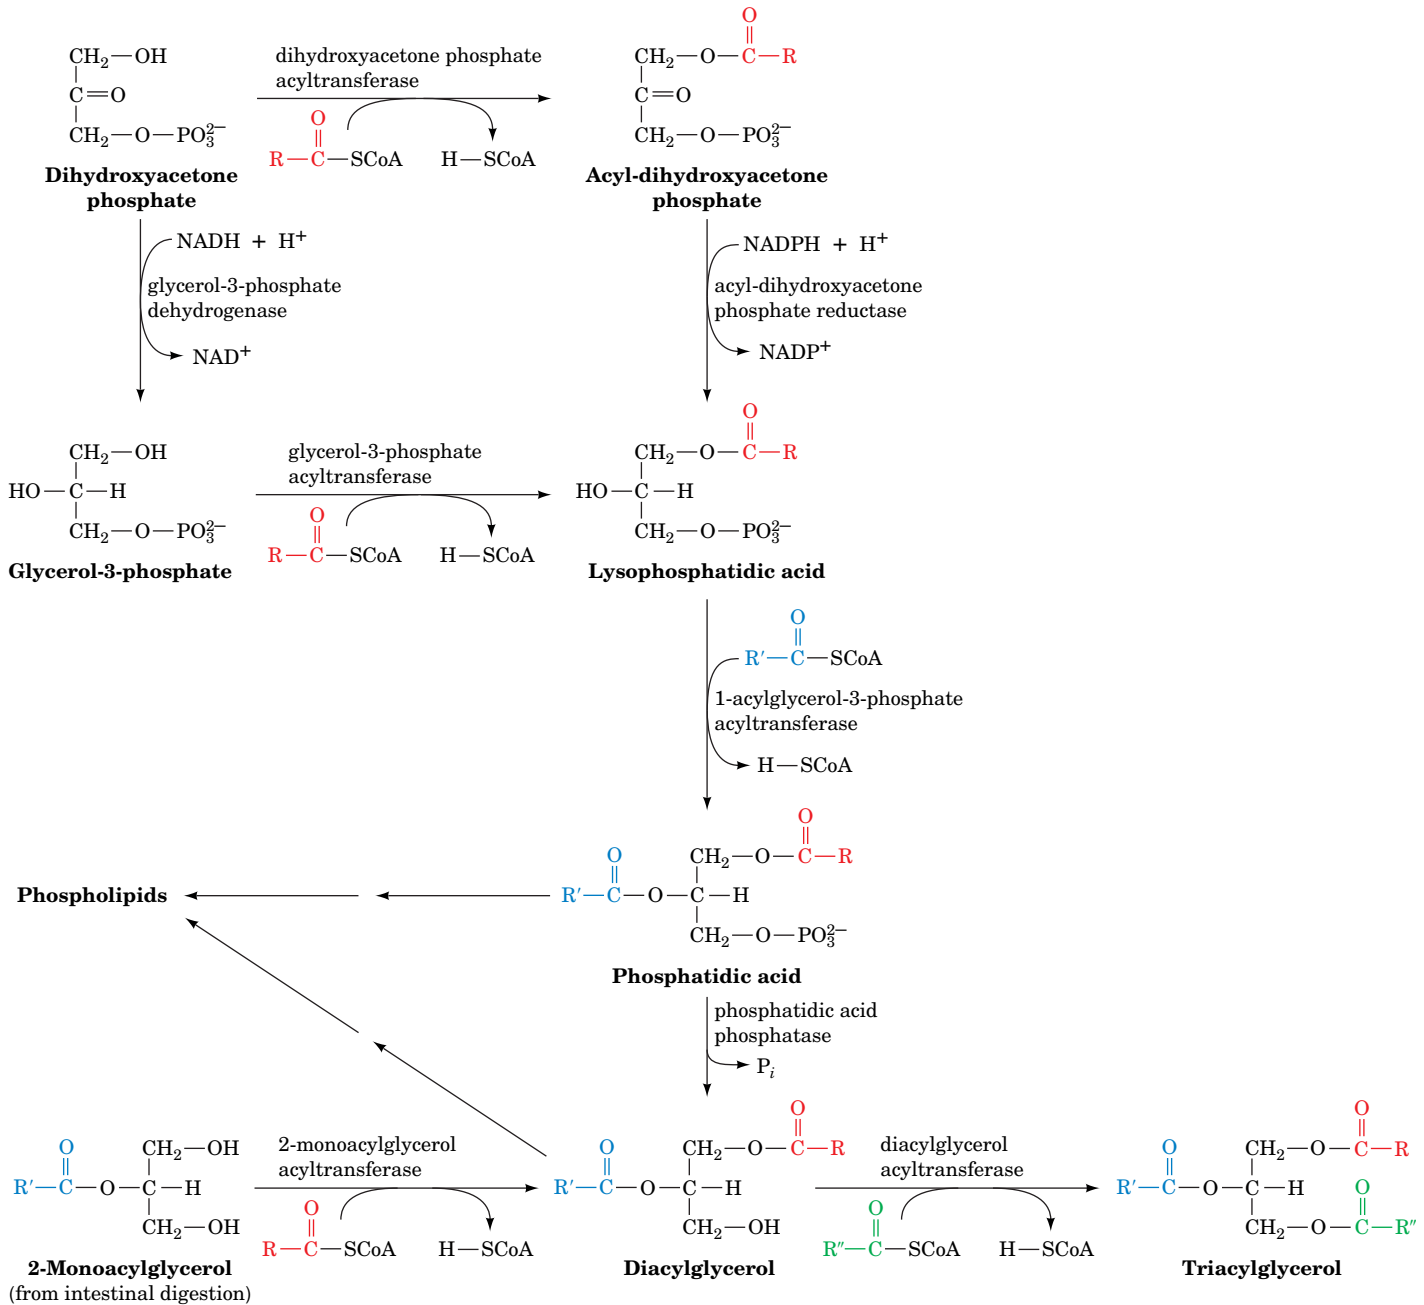

FIG. 20-29 The reactions of triacylglycerol biosynthesis.

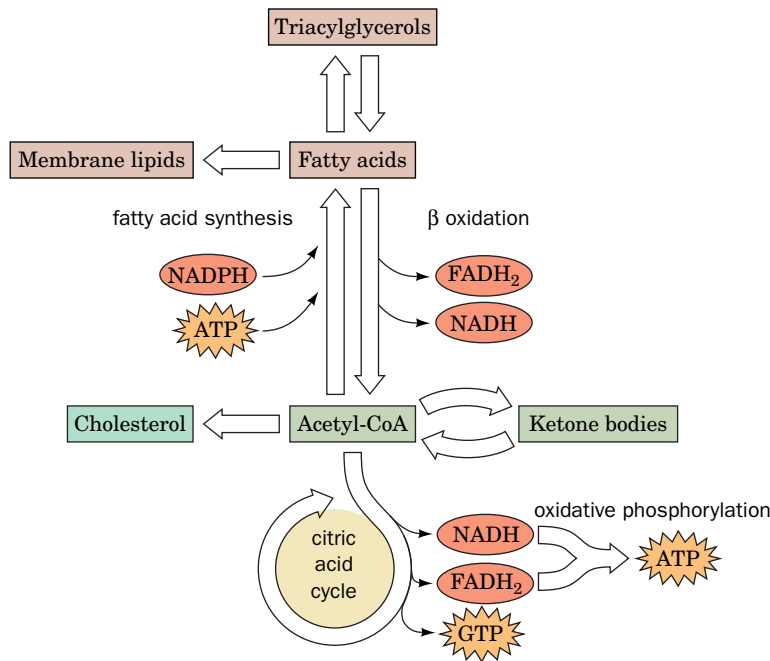

FIG. 20-30 A summary of lipid metabolism.

acyltransferases are not completely specific for particular fatty acyl-CoAs, either in chain length or degree of unsaturation, but in human adipose tissue triacylglycerols, palmitate tends to be concentrated at position 1 and oleate at position 2.

Glyceroneogenesis Is Important for Triacylglycerol Biosynthesis. The dihydroxyacetone phosphate used to make glycerol-3-phosphate for triacylglycerol synthesis comes either from glucose via the glycolytic pathway (Fig. 15-1) or from oxaloacetate via an abbreviated version of gluconeogenesis (Fig. 16-15) termed **glyceroneogenesis**. Glyceroneogenesis is necessary in times of starvation, since approximately 30% of the fatty acids that enter the liver during a fast are re-esterified to triacylglycerol and exported in VLDL (Section 20-1). Adipocytes also carry out glyceroneogenesis in times of starvation. They do not carry out gluconeogenesis but contain the gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK), which is upregulated when the glucose concentration is low and participates in the glyceroneogenesis required for triacylglycerol biosynthesis.

At this point, we can appreciate how triacylglycerols synthesized from fatty acids built from two-carbon acetyl units can be broken back down into acetyl units. In the liver, the resulting acetyl-CoA may be shunted to the formation of ketone bodies and later converted back to acetyl-CoA by another tissue. The acetyl-CoA can then either be used to build fatty acids that are stored as triacylglycerols or be oxidized by the citric acid cycle to generate considerable ATP by oxidative phosphorylation. As we will see, the flux of material in the direction of triacylglycerol synthesis or triacylglycerol degradation depends on the metabolic energy needs of the organism and the need for synthesis of other compounds, such as membrane lipids (Section 20-6) and cholesterol (Section 20-7A). These key features of lipid metabolism are summarized in [Fig. 20-30](#).

CHECKPOINT

- Compare the shuttle systems for transporting fatty acids into the mitochondria and acetyl-CoA into the cytosol.
- What is the role of ATP-citrate lyase in fatty acid synthesis?
- Describe the reactions that produce and consume malonyl-CoA during fatty acid synthesis.
- Why does it make metabolic sense for the cell to regulate the activity of acetyl-CoA carboxylase?
- Summarize the reactions catalyzed by fatty acid synthase and compare them to the reactions of fatty acid oxidation.
- Describe the role of multifunctional enzymes in both fatty acid synthesis and oxidation.
- What are the purposes of elongases and desaturases? Where are the enzymes located?
- Describe how newly synthesized fatty acids are incorporated into triacylglycerols.

5 Regulation of Fatty Acid Metabolism

KEY CONCEPT

- Fatty acid oxidation and synthesis are regulated by hormones and cellular factors.

Discussions of metabolic control are usually concerned with the regulation of metabolite flow through a pathway in response to the differing energy needs and

dietary states of an organism. In mammals, glycogen and triacylglycerols are sources of fuel for energy-requiring processes and are synthesized in times of plenty for future use. *Synthesis and breakdown of glycogen and triacylglycerols are processes that concern the whole organism, with its organs and tissues forming an interdependent network connected by the bloodstream.* The blood carries the metabolites responsible for energy production: triacylglycerols in the form of chylomicrons and VLDL, fatty acids as their albumin complexes, ketone bodies, amino acids, lactate, and glucose. As in glycogen metabolism (Section 16-3), *hormones such as insulin and glucagon regulate the rates of the opposing pathways of lipid metabolism and thereby control whether fatty acids will be oxidized or synthesized.* The major control mechanisms are summarized in **Fig. 20-31**.

Fatty acid oxidation is regulated largely by the concentration of fatty acids in the blood, which is, in turn, controlled by the hydrolysis rate of triacylglycerols in adipose tissue by **hormone-sensitive triacylglycerol lipase**. This enzyme is so named because it is susceptible to regulation by phosphorylation and dephosphorylation in response to hormonally controlled cAMP levels. Glucagon, epinephrine, and norepinephrine, which are released in times of metabolic need, increase adipose tissue cAMP concentrations. cAMP allosterically activates PKA (Section 13-3C), which, in turn, phosphorylates certain enzymes. Phosphorylation activates hormone-sensitive lipase, thereby stimulating lipolysis in adipose tissue, raising blood fatty acid levels, and ultimately activating the β -oxidation pathway in other tissues, such as liver and muscle. In liver, this process leads to the production of ketone bodies that are secreted into the bloodstream for use as an alternative fuel to glucose by peripheral tissues. PKA also inactivates acetyl-CoA carboxylase (Section 20-4B), so *cAMP-dependent phosphorylation simultaneously stimulates fatty acid oxidation and inhibits fatty acid synthesis.*

Insulin, a pancreatic hormone released in response to high blood glucose concentrations (the fed state), has the opposite effect of glucagon and epinephrine: It stimulates the formation of glycogen and triacylglycerols. Insulin decreases cAMP levels, leading to the dephosphorylation and thus the inactivation of hormone-sensitive lipase. This reduces the amounts of fatty acids available for oxidation. Insulin also activates acetyl-CoA carboxylase (Section 20-4B). *The glucagon:insulin ratio therefore determines the rate and direction of fatty acid metabolism.*

Another mechanism that inhibits fatty acid oxidation when fatty acid synthesis is stimulated is the inhibition of carnitine palmitoyl transferase I by malonyl-CoA. This inhibition keeps the newly synthesized fatty acids out of the mitochondria (Section 20-2B) and thus away from the β -oxidation system. In fact, heart muscle, an oxidative tissue that does not carry out fatty acid biosynthesis, contains an isoform of acetyl-CoA carboxylase, ACC2 (Section 20-4B), whose sole function appears to be the synthesis of malonyl-CoA to regulate fatty acid oxidation.

AMP-dependent protein kinase (AMPK), which phosphorylates (inactivates) ACC, may itself be an important regulator of fatty acid metabolism. The enzyme is activated by AMP and inhibited by ATP and thus has been proposed to serve as a fuel gauge for the cell. When ATP levels are high, signaling the fed and rested state, this kinase is inhibited, allowing ACC to become dephosphorylated (activated) so as to stimulate malonyl-CoA production for fatty acid synthesis in adipose tissue and for inhibition of fatty acid oxidation in muscle cells. When activity levels increase, causing ATP levels to decrease with a concomitant increase in AMP levels, AMPK is activated to phosphorylate (inactivate) ACC. The resulting decrease in malonyl-CoA levels causes fatty acid biosynthesis to decrease in adipose tissue while fatty acid oxidation increases in muscle to provide the ATP for continued activity.

Factors such as substrate availability, allosteric interactions, and covalent modification (phosphorylation) control enzyme activity with response times of minutes or less. Such **short-term regulation** is complemented by **long-term**

regulation, which requires hours or days and governs a pathway's regulatory enzyme by altering the amount of enzyme present. This is accomplished through changes in the rates of protein synthesis and/or breakdown.

The long-term regulation of lipid metabolism includes stimulation by insulin and inhibition by starvation of the synthesis of acetyl-CoA carboxylase and fatty

? Trace the arrows that represent pathways that predominate in the fed state or in the fasted state.

CHECKPOINT

- How do hormones link fuel availability to fatty acid synthesis and degradation in humans?
- Explain how malonyl-CoA production can regulate fatty acid metabolism.

acid synthase. The amount of adipose tissue lipoprotein lipase, the enzyme that initiates the entry of lipoprotein-packaged fatty acids into adipose tissue for storage (Section 20-1B), is also increased by insulin and decreased by starvation. Thus, an abundance of glucose, reflected in the level of insulin, promotes fatty acid synthesis and the storage of fatty acids by adipocytes, whereas starvation, when glucose is unavailable, decreases fatty acid synthesis and the uptake of fatty acids by adipocytes.

6 Synthesis of Other Lipids

KEY CONCEPTS

- The triacylglycerol precursors diacylglycerol and phosphatidic acid are used to synthesize glycerophospholipids.
- Sphingolipids are synthesized from palmitoyl-CoA and serine.
- Prostaglandin synthesis from arachidonate can be blocked by drugs.

Fatty acids are the precursors not just of triacylglycerols but also of a variety of other compounds, including membrane lipids and certain signaling molecules. Most membrane lipids are dual-tailed amphipathic molecules composed of either 1,2-diacylglycerol or *N*-acylsphingosine (ceramide) linked to a polar head group that is either a carbohydrate or a phosphate ester (Fig. 20-32). In this section, we describe the biosynthesis of these complex lipids from their simpler components. These lipids are synthesized in membranes, mostly on the cytosolic face of the endoplasmic reticulum, and from there are transported in vesicles to their final cellular destinations (Section 9-4E). Arachidonate groups released from membrane lipids give rise to prostaglandins of various types.

A Glycerophospholipids Are Built from Intermediates of Triacylglycerol Synthesis

Glycerophospholipids have significant asymmetry in their C1- and C2-linked fatty acyl groups: C1 substituents are mostly saturated fatty acids, whereas those at C2 are, by and large, unsaturated fatty acids.

Activated Head Groups or Activated Lipids Are Used to Synthesize Diacylglycerophospholipids. The triacylglycerol precursors 1,2-diacylglycerol and phosphatidic acid are also the precursors of glycerophospholipids (Fig. 20-29). The polar head groups of glycerophospholipids are linked to C3 of the glycerol via a

FIG. 20-32 Glycerolipids and sphingolipids. The structures of the common head groups, X, are presented in Table 9-2. Plant membranes are particularly rich in glyceroglycolipids.

phosphodiester bond. In mammals, the head groups **ethanolamine** and **choline** are activated before being attached to the lipid (Fig. 20-33):

1. ATP phosphorylates the OH group of choline or ethanolamine.
2. The phosphoryl group of the resulting **phosphoethanolamine** or **phosphocholine** then attacks CTP, displacing PP_i , to form the corresponding CDP derivatives, which are activated phosphate esters of the polar head group.
3. The C3-OH group of 1,2-diacylglycerol attacks the phosphoryl group of the activated CDP-ethanolamine or CDP-choline, displacing CMP to yield the corresponding glycerophospholipid.

In liver, phosphatidylethanolamine can also be converted to phosphatidylcholine by the addition of methyl groups.

Phosphatidylserine is synthesized from phosphatidylethanolamine by a head group exchange reaction catalyzed by **phosphatidylethanolamine serine**

FIG. 20-33 Biosynthesis of phosphatidylethanolamine and phosphatidylcholine. In mammals, CDP-ethanolamine and CDP-choline are the precursors of the head groups.

transferase in which serine's OH group attacks the donor's phosphoryl group. The original head group is then eliminated, forming phosphatidylserine:

In the synthesis of **phosphatidylinositol** and **phosphatidylglycerol**, the hydrophobic tail is activated rather than the polar head group. Phosphatidic acid, the precursor of 1,2-diacylglycerol (Fig. 20-29), attacks the α -phosphoryl group of CTP to form the activated **CDP-diacylglycerol** and PP_i (Fig. 20-34). Phosphatidylinositol results from the attack of inositol on CDP-diacylglycerol. Phosphatidylglycerol is formed in two reactions: (1) attack of the C1-OH group of glycerol-3-phosphate on CDP, yielding **phosphatidylglycerol phosphate**; and (2) hydrolysis of the phosphoryl group to form phosphatidylglycerol.

Cardiolipin forms by the condensation of two molecules of phosphatidylglycerol with the elimination of one molecule of glycerol:

Enzymes that synthesize phosphatidic acid have a general preference for saturated fatty acids at C1 and for unsaturated fatty acids at C2. Yet this general preference cannot account, for example, for the observations that ~80% of brain phosphatidylinositol has a stearoyl group (18:0) at C1 and an arachidonoyl group (20:4) at C2, and that ~40% of lung phosphatidylcholine has palmitoyl groups (16:0) at both positions (the latter substance is the major component of the surfactant that prevents the lung from collapsing when air is expelled; its deficiency in premature infants is responsible for respiratory distress syndrome; see Box 9-1). *William Lands showed that such side chain specificity results from "remodeling" reactions in which specific acyl groups of individual glycerophospholipids are exchanged by specific phospholipases and acyltransferases.*

Glycerophospholipids Include the Plasmalogens and Alkylacylglycerophospholipids. Eukaryotic membranes contain significant amounts of two other types of glycerophospholipids: **plasmalogens**, which contain a hydrocarbon chain

FIG. 20-34 Biosynthesis of phosphatidylinositol and phosphatidylglycerol. In mammals, this process involves a CDP-diacylglycerol intermediate.

linked to glycerol C1 via a vinyl ether linkage, and **alkylacylglycerophospholipids**, in which the alkyl substituent at glycerol C1 is attached via an ether linkage.

About 20% of mammalian glycerophospholipids are plasmalogens, but the exact percentage varies both among species and among tissues within a given organism. For example, plasmalogens account for only 0.8% of the phospholipids in human liver but 23% of those in human nervous tissue. The alkylacylglycerophospholipids are much less abundant than the plasmalogens. The biosynthetic pathway for these lipids yields the alkylacylglycerophospholipid, and this ether is then oxidized to a vinyl ether by the action of a desaturase to yield the plasmalogen.

B Sphingolipids Are Built from Palmitoyl-CoA and Serine

Most sphingolipids are **sphingoglycolipids**; that is, their polar head groups consist of carbohydrate units. **Cerebrosides** are ceramide monosaccharides, whereas **gangliosides** are sialic acid-containing ceramide oligosaccharides (Section 9-1D). These lipids are synthesized by attaching carbohydrate units to the C1-OH group of ceramide (*N*-acylsphingosine).

FIG. 20-36 The prostaglandin H₂ synthase reaction. A cyclooxygenase activity (1) catalyzes the additions and rearrangements that generate the cyclopentane ring. The enzyme's peroxidase activity (2) converts the peroxide intermediate to prostaglandin H₂ (PGH₂), which is the precursor of other prostaglandins.

1971 that John Vane discovered its mechanism of action: Aspirin inhibits the synthesis of prostaglandins by acetylating a specific Ser residue of prostaglandin H₂ synthase, which prevents arachidonate from reaching the cyclooxygenase active site. Other **nonsteroidal anti-inflammatory drugs (NSAIDs)** such as **ibuprofen** and **acetaminophen** noncovalently bind to the enzyme to similarly block its active site.

Low doses of aspirin, ~80 mg (baby aspirin) every day, significantly reduce the long-term incidence of heart attacks and strokes. Such low doses selectively inhibit platelet aggregation and thus blood clot formation (Box 11-4) because these enucleated cells, which have a lifetime in the circulation of ~10 days, cannot resynthesize their inactivated enzymes. Vascular endothelial cells are not so drastically affected since, for the most part, they are far from the site where aspirin is absorbed, are exposed to lesser concentrations of aspirin and, in any case, can synthesize additional PGH₂ synthase.

COX-2 Inhibitors Lack the Side Effects of Other NSAIDs. Prostaglandin H₂ synthase has two isoforms, **COX-1** and **COX-2**, that share a high degree (60%) of sequence identity and structural homology. COX-1 is constitutively (without regulation) expressed in most, if not all, mammalian tissues, thereby supporting levels of prostaglandin synthesis necessary to maintain organ and tissue homeostasis. In contrast, COX-2 is expressed only in certain tissues in response to inflammatory stimuli and hence is responsible for the elevated prostaglandin levels that cause inflammation.

Aspirin and ibuprofen are relatively nonspecific and therefore can have adverse side effects (e.g., gastrointestinal ulceration) when used to treat inflammation or fever. A structure-based drug design program (Section 12-4) was therefore instituted to create inhibitors that would target COX-2 but not COX-1. The three-dimensional structures of COX-1 and COX-2 are almost identical. However, their amino acid differences make COX-2's active site channel ~20% larger in volume than that of COX-1. Chemists therefore synthesized inhibitors, collectively known as **coxibs**, that could enter the COX-2 channel but are excluded from that of COX-1. Two of these inhibitors, **rofecoxib (Vioxx)** and **celecoxib (Celebrex)** (at right), became important drugs for the treatment of inflammatory diseases such as arthritis because they lack the major side effects of the nonspecific NSAIDs. However, in 2004, Vioxx was withdrawn from the market because of unanticipated cardiac side effects.

Interestingly, acetaminophen, the most commonly used analgesic/antipyretic (Section 12-4D), binds poorly to both COX-1 and COX-2 and is not (despite its inclusion in this category) an anti-inflammatory agent. Its mechanism of action remained a mystery until Daniel Simmons' discovery of a third COX isozyme, **COX-3**, which is expressed at high levels in the central nervous system and is apparently targeted by drugs that decrease pain and fever.

Rofecoxib (Vioxx)

Celecoxib (Celebrex)

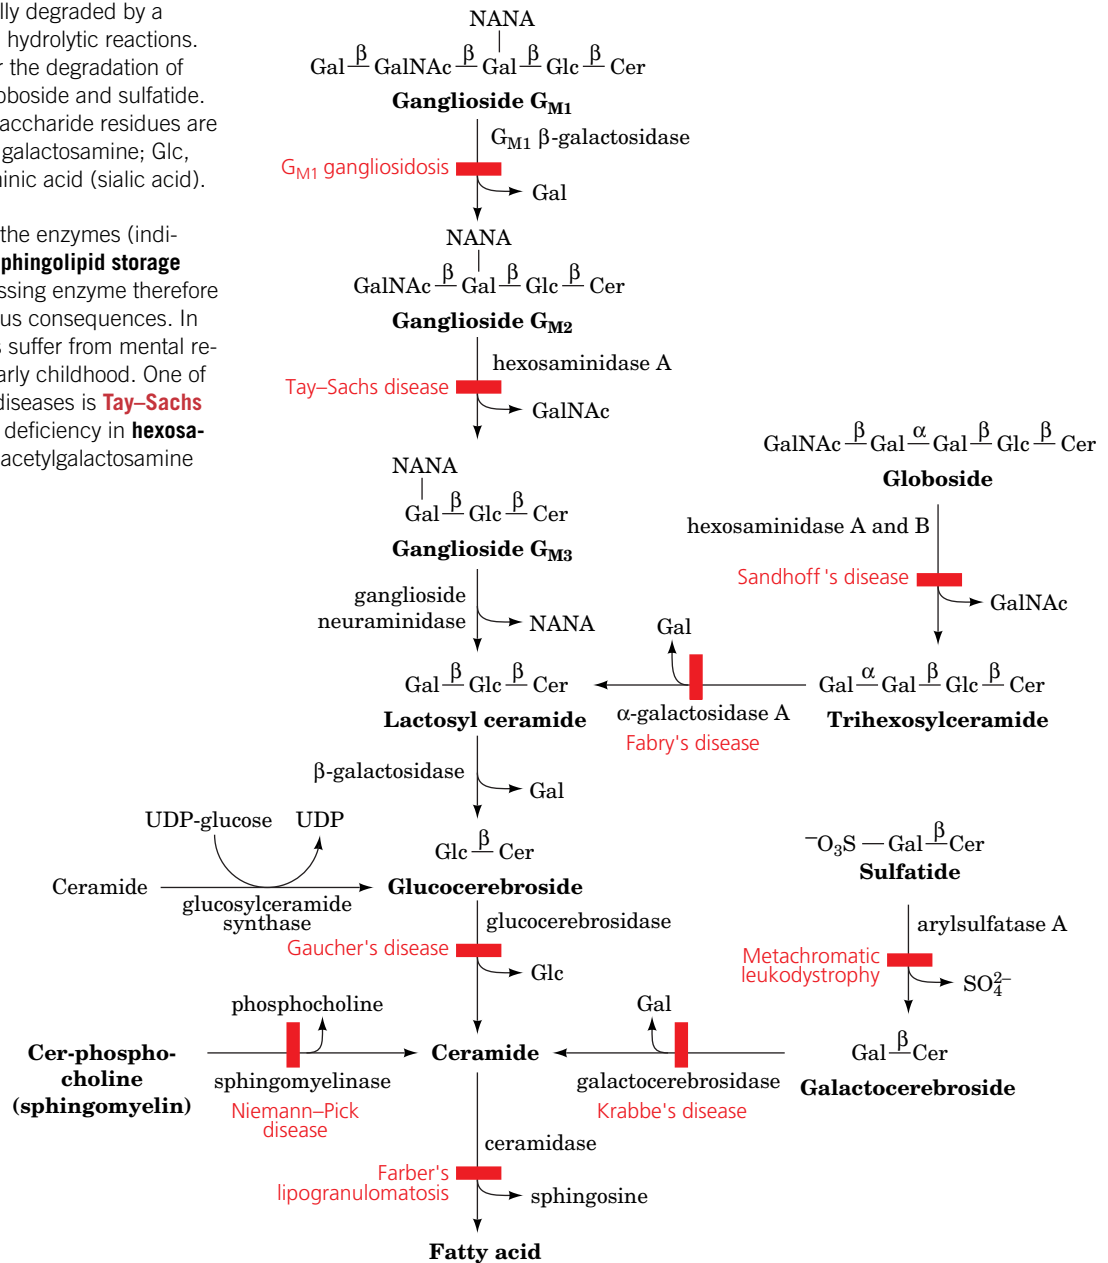

CHECKPOINT

- Where are membrane lipids synthesized?
- Explain how glycerophospholipids are synthesized by activating either the head group or the lipid tail.
- Describe the biosynthesis of ceramide, sphingomyelin, and cerebroside.
- Explain the action of drugs such as aspirin, NSAIDs, and coxibs.

Sphingoglycolipids are lysosomally degraded by a series of enzymatically mediated hydrolytic reactions. At right is shown the pathway for the degradation of ganglioside G_{M1} and a related globoside and sulfatide. The abbreviations for the monosaccharide residues are Gal, galactose; GalNAc, *N*-acetylgalactosamine; Glc, glucose; NANA, *N*-acetylneuraminic acid (sialic acid). Cer represents ceramide.

A hereditary defect in one of the enzymes (indicated by a red bar) results in a **sphingolipid storage disease**. The substrate of the missing enzyme therefore accumulates, often with disastrous consequences. In many cases, affected individuals suffer from mental retardation and die in infancy or early childhood. One of the most common lipid storage diseases is **Tay-Sachs disease**, an autosomal recessive deficiency in **hexosaminidase A**, which hydrolyzes *N*-acetylgalactosamine

7 Cholesterol Metabolism

KEY CONCEPTS

- The liver converts acetyl-CoA to cholesterol by a multistep pathway.
- Cholesterol synthesis is regulated by the activity and amount of HMG-CoA reductase.
- The LDL receptor keeps circulating cholesterol low.

Cholesterol is a vital constituent of cell membranes and the precursor of steroid hormones and bile acids. It is clearly essential to life, yet its deposition in arteries is associated with cardiovascular disease and stroke, two leading causes of death

from ganglioside G_{M2} . The absence of hexosaminidase A activity results in the accumulation of G_{M2} as shell-like inclusions in neuronal cells as shown below.

[ISM Creative/Custom Medical Stock Photo, Inc.]

Although infants born with Tay–Sachs disease at first appear normal, by ~1 year of age, when sufficient G_{M2} has accumulated to interfere

with neuronal function, they become progressively weaker, retarded, and blinded until they die, usually by the age of 3 years. It is possible, however, to screen potential carriers of the disease by a simple serum assay for hexosaminidase A.

There is no known treatment for Tay–Sachs disease. However, the symptoms of **Gaucher's disease** (the most common of which include a greatly enlarged liver and spleen, anemia, and bone abnormalities, but with a life expectancy well into adulthood), which results from the accumulation of **glucocerebroside** due to defective **glucocerebrosidase**, may be alleviated by the intravenous infusion of the recombinant normal enzyme. In some cases, Gaucher's disease may be treated by administering the imino sugar **N-butyldeoxynojirimycin (Miglustat)**,

N-Butyldeoxynojirimycin

which inhibits **glucosylceramide synthase**, an enzyme that synthesizes glucocerebroside. Similar “substrate deprivation” approaches may be effective in treating other lipid storage diseases, particularly when the defective but essential enzyme has some residual activity.

in humans. *In a healthy organism, an intricate balance is maintained between the biosynthesis, utilization, and transport of cholesterol, keeping its harmful deposition to a minimum.* In this section, we study the pathways of cholesterol biosynthesis and transport and how they are controlled.

A Cholesterol Is Synthesized from Acetyl-CoA

Cholesterol biosynthesis follows a lengthy pathway, first outlined by Konrad Bloch, in which acetate (from acetyl-CoA) is converted to **isoprene units** that have the carbon skeleton of **isoprene**:

The isoprene units then condense to form a linear molecule with 30 carbons that cyclizes to form the four-ring structure of cholesterol.

HMG-CoA Is a Key Cholesterol Precursor. Acetyl-CoA is converted to isoprene units by a series of reactions that begins with formation of hydroxymethylglutaryl-CoA (HMG-CoA; this compound is also an intermediate in ketone body synthesis; Fig. 20-21). HMG-CoA synthesis requires thiolase and HMG-CoA synthase. In liver mitochondria, these two enzymes form HMG-CoA for ketone body synthesis. Cytosolic isozymes of the two proteins generate the HMG-CoA that is used in cholesterol biosynthesis. Four additional reactions convert HMG-CoA to the isoprenoid intermediate **isopentenyl pyrophosphate**:

- The CoA thioester group of HMG-CoA is reduced to an alcohol in an NADPH-dependent four-electron reduction catalyzed by **HMG-CoA reductase**, yielding **mevalonate**, a C₆ compound. This is the rate-determining step of cholesterol biosynthesis.

- The new OH group is phosphorylated by **mevalonate-5-phosphotransferase**.

- The phosphate group is converted to a pyrophosphate by **phosphomevalonate kinase**.

- The molecule undergoes an ATP-dependent decarboxylation reaction catalyzed by **pyrophosphomevalonate decarboxylase** to yield isopentenyl pyrophosphate:

Isopentenyl pyrophosphate

Dimethylallyl pyrophosphate

Squalene Is Formed by the Condensation of Six Isoprene Units. Isopentenyl pyrophosphate is converted to **dimethylallyl pyrophosphate** by **isopentenyl pyrophosphate isomerase** (*at left*). Four isopentenyl pyrophosphates and two dimethylallyl pyrophosphates condense to form the C₃₀ cholesterol precursor **squalene** in three reactions catalyzed by two enzymes (**Fig. 20-37**):

- Prenyltransferase** catalyzes the head-to-tail condensation of dimethylallyl pyrophosphate and isopentenyl pyrophosphate to yield the C₁₀ compound **geranyl pyrophosphate**.
- Prenyltransferase** catalyzes a second head-to-tail condensation of geranyl pyrophosphate and isopentenyl pyrophosphate to yield the C₁₅ compound **farnesyl pyrophosphate**. The prenyltransferase catalyzes an S_N1 reaction to form a carbocation intermediate with an ionization–condensation–elimination mechanism:

3. **Squalene synthase** then catalyzes the head-to-head condensation of two farnesyl pyrophosphate molecules to form squalene.

FIG. 20-37 Formation of squalene from isopentenyl pyrophosphate and dimethylallyl pyrophosphate. The pathway involves two head-to-tail condensations catalyzed by prenyltransferase and a head-to-head condensation catalyzed by squalene synthase.

? Determine the number of carbons in each intermediate.

Farnesyl pyrophosphate is also the precursor of other isoprenoid compounds in mammals, including ubiquinone (Section 9-1F) and the isoprenoid tails of some lipid-linked membrane proteins (Section 9-3B).

Squalene Cyclization Eventually Yields Cholesterol. Squalene, a linear hydrocarbon, cyclizes to form the tetracyclic steroid skeleton. First, **squalene epoxidase** catalyzes oxidation of squalene to form **2,3-oxidosqualene**:

Next, **oxidosqualene cyclase** converts this epoxide to the steroid **lanosterol**. The reaction is a chemically complex process involving cyclization of 2,3-oxidosqualene to a **protosterol** cation and rearrangement of the cation to lanosterol by a series of 1,2 hydride and methyl shifts (Fig. 20-38).

Conversion of lanosterol to cholesterol (*at left*) is a 19-step process that involves an oxidation and the loss of three methyl groups. The enzymes required for the process are embedded in the endoplasmic reticulum membrane.

Cholesterol Has Many Uses. In addition to its function as a membrane component, cholesterol is the precursor of steroid hormones such as cortisol, androgens, and estrogens (Section 9-1E). The liver converts cholesterol to bile acids (Fig. 20-1), which act as emulsifying agents in the digestion and absorption of fats (Section 20-1A). An efficient recycling system allows the bile acids to re-enter the bloodstream and return to the liver for reuse several times each day. The bile acids that escape this recycling are further metabolized by intestinal microorganisms and excreted. *This is the only route for cholesterol excretion.*

Cholesterol synthesized by the liver may be esterified by **acyl-CoA:cholesterol acyltransferase (ACAT)** to form cholesteryl esters.

These highly hydrophobic compounds are transported throughout the body in lipoprotein complexes (Section 20-1B).

B HMG-CoA Reductase Controls the Rate of Cholesterol Synthesis

HMG-CoA reductase, which catalyzes the rate-limiting step of cholesterol biosynthesis, is the pathway's main regulatory site. The enzyme is subject to short-term control by competitive inhibition, allosteric effects, and covalent modification involving reversible phosphorylation. Like glycogen phosphorylase, glycogen synthase, and other enzymes, HMG-CoA reductase exists in

FIG. 20-38 The oxidosqualene cyclase reaction. (1) 2,3-Oxidosqualene is cyclized to the protosterol cation in a process that is initiated by the enzyme-mediated protonation of the squalene epoxide oxygen. The opening of the epoxide leaves an electron-deficient center whose migration drives the series of cyclizations that form the protosterol cation. (2) A series of methyl and hydride migrations followed by the elimination of a proton from C9 of the sterol to form a double bond ultimately yields neutral lanosterol.

interconvertible more active and less active forms. When phosphorylated at Ser 871, the enzyme is less active. Phosphorylation is carried out by AMP-dependent protein kinase (AMPK), the same enzyme that inactivates acetyl-CoA carboxylase (Section 20-4B). It appears that this control mechanism conserves energy when ATP levels fall and AMP levels rise, by generally inhibiting biosynthetic pathways.

The primary regulatory mechanism for HMG-CoA reductase activity is long-term feedback control of the amount of enzyme present in the cell. The amount of enzyme can rise as much as 200-fold, due to an increase in enzyme synthesis combined with a decrease in its degradation. In fact, cholesterol itself regulates the expression of the HMG-CoA reductase gene along with more than 20 other genes involved in its biosynthesis and uptake, including the gene encoding the LDL receptor. These genes all contain a specific recognition sequence called a **sterol regulatory element (SRE)**; control of eukaryotic gene expression is discussed in detail in Chapter 28).

The transcription of these genes, as Brown and Goldstein elucidated, requires the binding to their SRE of a portion of **sterol regulatory element binding protein (SREBP)**. However, when cholesterol levels are sufficiently high, SREBP resides in the endoplasmic reticulum (ER) membrane as an inactive 1160-residue precursor that binds to **SREBP cleavage-activating protein (SCAP)**. SCAP is an ~1276-residue intracellular cholesterol sensor that contains two domains: an N-terminal transmembrane domain called the **sterol-sensing domain** that interacts with sterols, and a C-terminal domain containing five copies of a protein-protein interaction motif known as a **WD repeat** that interacts with the C-terminal so-called regulatory domain of SREBP (**Fig. 20-39**).

FIG. 20-39 The cholesterol-mediated proteolytic activation of SREBP. When cholesterol levels in the cell are high, the SREBP-SCAP complex resides in the ER. When cholesterol levels are low, SCAP escorts SREBP via COPII-coated membranous vesicles to the Golgi apparatus, where SREBP undergoes sequential proteolytic cleavage by the membrane-bound proteases S1P and S2P. This releases SREBP's N-terminal domain, which enters the nucleus, where it binds to the SREs of its target genes, thereby inducing their transcription. [After Goldstein, J., Rawson, R.B., and Brown, M., *Arch. Biochem. Biophys.* **397**, 139 (2002).]

When cholesterol in the ER membrane is depleted, SCAP changes conformation and escorts its bound SREBP to the Golgi apparatus via COPII-coated membranous vesicles (Section 9-4E). SREBP is then sequentially cleaved by two Golgi proteases: **site-1 protease (S1P)**, a serine protease that cleaves SREBP only when it is associated with SCAP, and **site-2 protease (S2P)**, a zinc metalloprotease that cleaves SREBP at a peptide bond exposed by the S1P cleavage. This results in the release of the active fragment, a soluble 480-residue protein that travels to the nucleus, where it activates the transcription of genes containing an SRE by binding to the SRE via a DNA-binding motif known as a **basic helix-loop-helix (bHLH)**; (Section 24-4C; Fig. 20-39). The cholesterol level in the cell thereby rises until SCAP no longer induces the translocation of SREBP to the Golgi apparatus, a classic case of feedback inhibition.

Statins Inhibit HMG-CoA Reductase. High levels of circulating cholesterol, a condition known as **hypercholesterolemia**, can be treated with drugs called **statins** that inhibit HMG-CoA reductase (Fig. 20-40). These compounds all contain an HMG-like group that acts as a competitive inhibitor of HMG-CoA binding to the enzyme. The statins bind extremely tightly, with K_I values in the nanomolar range, whereas the substrate, HMG-CoA, has a K_M of $\sim 4 \mu\text{M}$.

The X-ray structures of HMG-CoA reductase in its complexes with six different statins reveal that the bulky hydrophobic groups of the inhibitors play a major role in interfering with enzyme activity. The HMG-CoA reductase active site normally accommodates NADPH as well as the pantothenate portion of CoA. Statin binding does not interfere with NADPH binding. However, the enzyme alters its conformation to accommodate the large hydrophobic groups of the statins. It appears that the inhibitors exploit the inherent flexibility of the enzyme. Furthermore, despite the structural variation among the different statins, they all experience extensive van der Waals contacts with the enzyme. *This high degree of complementarity between the statins and the active site, a result of the enzyme's flexibility, accounts for the extremely low inhibition constants.*

The initial decreased cellular cholesterol supply caused by the presence of statins is met by the induction of the LDL receptor and HMG-CoA reductase (Sections 20-1B and 20-7A; Fig. 20-8) so that at the new steady state, the HMG-CoA level is almost that of the predrug state. However, the increased number of LDL receptors

FIG. 20-40 Competitive inhibitors of HMG-CoA reductase used for the treatment of hypercholesterolemia. The molecular formulas of lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), and atorvastatin (Lipitor; also shown on page 361), which are known as statins, are given. The structures of HMG-CoA and the HMG-CoA reductase product mevalonate are shown for comparison. Note

that lovastatin, pravastatin, and simvastatin are lactones whereas atorvastatin and mevalonate are hydroxy acids. The lactones are hydrolyzed enzymatically *in vivo* to the active hydroxy-acid forms.

? How do these drugs reach their intracellular target?

causes increased removal from the blood of both LDL and IDL (the apoB-100 containing precursor to LDL), decreasing serum LDL-cholesterol levels appreciably.

C Abnormal Cholesterol Transport Leads to Atherosclerosis

As mentioned above, cellular cholesterol concentrations depend not only on the rate of cholesterol synthesis but also on the ability of cells to absorb cholesterol from circulating lipoproteins (Section 20-1B). The role of lipoproteins in cholesterol metabolism has been studied extensively because an elevated cholesterol level in the blood, primarily in the form of LDL, is a strong risk factor for cardiovascular disease.

 **Atherosclerosis Results from Accumulation of Lipid in Vessel Walls.** Approximately half of all deaths in the United States are linked to the vascular disease **atherosclerosis** (Greek: *athera*, mush + *sclerosis*, hardness). Atherosclerosis is a slow progressive disease that begins with the deposition of lipids in the walls of large blood vessels, particularly the coronary arteries. The initial event appears to be the association of lipoproteins with vessel wall proteoglycans (Section 8-3A). The trapped lipids trigger inflammation by inducing the endothelial cells lining the vessels to express adhesion molecules specific for monocytes, a type of white blood cell. Once these cells burrow into the vessel wall, they differentiate into macrophages that take up the accumulated lipids, becoming so engorged that they are known as “foam cells.” Macrophages do not normally take up lipids but do so when the lipids are oxidized, as apparently occurs when LDL particles are trapped for an extended period in blood vessel walls. Factors released by the foam cells, and possibly the oxidized lipids themselves, recruit more white blood cells, perpetuating a state of inflammation.

The damaged vessel wall forms a **plaque** with a core of cholesterol, cholesteryl esters, and remnants of dead macrophages, surrounded by proliferating smooth muscle cells that may undergo calcification, as occurs in bone formation (hence the “hardening” of the arteries). Although a very large plaque can occlude the lumen of the artery (Fig. 20-41), blood flow is usually not completely blocked unless the plaque ruptures. This triggers formation of a blood clot that can prevent circulation to the heart, causing **myocardial infarction** (heart attack). Stoppage of blood flow to the brain causes **stroke**.

The development of atherosclerosis is strongly correlated with the concentration of circulating LDL (often referred to as “bad cholesterol”). Some high-fat diets may contribute to atherosclerosis by boosting LDL levels, but genetic factors and infection also increase the risk of atherosclerosis. Smoking contributes to the disease because cigarette smoke oxidizes LDL, which promotes their uptake by macrophages. Atherosclerosis is less likely to occur in individuals who maintain low total cholesterol levels in their blood and who have high levels of HDL (or “good cholesterol”). These lipoproteins transport excess cholesterol to the liver for disposal as bile acids. Women have more HDL than men and a lower risk of heart disease. Nevertheless, recent epidemiological studies suggest that high levels of HDL are not protective of heart disease. Statins reduce the risk of cardiovascular disease by decreasing blood cholesterol levels.

 **LDL Receptor Deficiency Causes Hypercholesterolemia.** LDL receptors clearly play an important role in the maintenance of plasma LDL levels. Circulating LDL and IDL (which both contain apolipoproteins that specifically bind to the LDL receptor) re-enter the liver through receptor-mediated endocytosis (Fig. 20-8). *Individuals with the inherited disease **familial hypercholesterolemia (FH)** are deficient in functional LDL receptors.* FH homozygotes, who lack the receptors entirely, have such high levels of cholesterol-rich LDL in their plasma that their cholesterol levels are three to five times greater than the average level of ~200 mg/dL. This situation results in the deposition of cholesterol in their skin and tendons as yellow nodules known as **xanthomas**. However, far greater damage is caused by the development of atherosclerosis, which causes

FIG. 20-41 An atherosclerotic plaque in a coronary artery. The vessel wall is dramatically thickened as a result of lipid accumulation and activation of inflammatory processes.

©Eye of Science/Photo Researchers

FIG. 20-42 The role of LDL and HDL in cholesterol metabolism. (a) Cells acquire cholesterol and cholesteryl esters via endocytosis of LDL as mediated by the LDL receptor (purple). Cholesterol efflux to form HDL is assisted by the ABCA1 transporter (orange). (b) In familial

hypercholesterolemia, a lack of functional LDL receptors results in high levels of circulating LDL. (c) In Tangier disease, cells become laden with cholesterol and cholesteryl esters and few HDL are formed because efflux is prevented due to lack of functional ABCA1.

death from heart attacks as early as age 5. FH heterozygotes (about 1 person in 500) have about half the normal number of functional LDL receptors and exhibit plasma LDL levels of about twice the average. They typically develop symptoms of cardiovascular disease after age 30.

The long-term ingestion of a high-fat/high-cholesterol diet has an effect similar to although not as extreme as FH. Cholesterol regulates the synthesis of the LDL receptor by the same mechanism that regulates HMG-CoA reductase synthesis (Section 20-7B). Consequently, high intracellular concentrations of cholesterol suppress LDL receptor synthesis so that more LDL particles remain in the circulation. Excessive dietary cholesterol, delivered to the tissues via chylomicrons, therefore contributes to high plasma LDL levels.

Cholesterol Exits Cells via a Transport Protein. Most cells do not consume cholesterol by converting it to steroid hormones or bile acids, for example, but all cells require cholesterol to maintain membrane fluidity. Cholesterol in excess of the requirement can be esterified by the action of ACAT and stored as cholesteryl esters in intracellular deposits. Cholesterol can also be eliminated from cells by a mechanism illuminated through studies of individuals with **Tangier disease**. In this recessive inherited disorder, almost no HDL are produced, because cells have a defective transport protein, known as **ATP-cassette binding protein A1 (ABCA1)**.

In normal individuals, ABCA1 apparently acts as a flippase (Section 9-4C) to transfer cholesterol, cholesteryl esters, and other lipids from the inner to the outer leaflet of the plasma membrane, from which they can be captured by apolipoprotein A-I to form HDL. Cells lacking ABCA1 are unable to offload cholesterol and accumulate cholesteryl esters in the cytoplasm. Macrophages thus engorged with lipids contribute to the development of atherosclerosis, so that individuals with Tangier disease exhibit symptoms similar to those with FH. The functions of the LDL receptor and ABCA1 in cholesterol homeostasis are presented schematically in **Fig. 20-42**.

CHECKPOINT

- Describe the types of reactions required to produce a molecule of cholesterol.
- How does cholesterol control its own synthesis?
- How do statins reduce cholesterol levels?
- What do familial hypercholesterolemia and Tangier disease reveal about the development of atherosclerosis?

Summary

1 Lipid Digestion, Absorption, and Transport

- Triacylglycerol digestion depends on the emulsifying activity of bile acids and the activation of lipases at the lipid–water interface.
- Lipoproteins, complexes of nonpolar lipids surrounded by a coat of amphipathic lipids and apolipoproteins, transport lipids in the bloodstream. Cells take up cholesterol and other lipids by the receptor-mediated endocytosis of LDL.

2 Fatty Acid Oxidation

- Fatty acid oxidation begins with the activation of the acyl group by formation of a thioester with CoA. The acyl group is transferred to carnitine for transport into the mitochondria, where it is re-esterified to CoA.
- β oxidation occurs in four reactions: (1) formation of an α,β double bond, (2) hydration of the double bond, (3) dehydrogenation to form a β -ketoacyl-CoA, and (4) thiolysis by CoA to produce acetyl-CoA and an acyl-CoA shortened by two carbons. This process is repeated until fatty acids with even numbers of carbon atoms are converted to acetyl-CoA and the fatty acids with odd numbers of carbon atoms are converted to acetyl-CoA and one molecule of propionyl-CoA. The acetyl-CoA is oxidized by the citric acid cycle and oxidative phosphorylation to generate ATP. Propionyl-CoA is converted to the citric acid cycle intermediate succinyl-CoA, in part, by the coenzyme B₁₂-containing enzyme methylmalonyl-CoA mutase.
- The oxidation of unsaturated fatty acids requires an isomerase to convert Δ^3 double bonds to Δ^2 double bonds and a reductase to remove Δ^4 double bonds. The oxidation of odd-chain fatty acids yields propionyl-CoA, which is converted to succinyl-CoA through a cobalamin (B₁₂)-dependent pathway. Very long chain fatty acids are partially oxidized by a three-enzyme system in peroxisomes.

3 Ketone Bodies

- The liver uses acetyl-CoA to synthesize the ketone bodies acetoacetate and β -hydroxybutyrate, which are released into the bloodstream. Tissues that use the ketone bodies for fuel convert them back to acetyl-CoA.

4 Fatty Acid Biosynthesis

- In fatty acid synthesis, mitochondrial acetyl-CoA is shuttled to the cytosol via the tricarboxylate transport system and activated to malonyl-CoA by the action of acetyl-CoA carboxylase.
- A series of seven enzymatic activities, which in mammals are contained in a multifunctional homodimeric enzyme, extend acyl-ACP chains by two carbons at a time. An enzyme-bound acyl group and

malonyl-ACP condense to form a β -ketoacyl intermediate and CO₂. Two reductions and a dehydration yield an acyl-ACP in a series of reactions that resemble the reverse of β oxidation but are catalyzed by separate enzymes in the cytosol. Palmitate (C₁₆), the normal product of fatty acid biosynthesis, is synthesized in seven such reaction cycles and is then cleaved from ACP by a thioesterase.

- Other fatty acids are synthesized from palmitate through the action of elongases and desaturases. Human triacylglycerols synthesized from fatty acyl-CoA and glycerol-3-phosphate or dihydroxyacetone phosphate tend to contain saturated fatty acids at C1 and unsaturated fatty acids at C2.

5 Regulation of Fatty Acid Metabolism

- The opposing pathways of fatty acid degradation and synthesis are hormonally regulated. Glucagon and epinephrine activate hormone-sensitive lipase in adipose tissue, thereby increasing the supply of fatty acids for oxidation in other tissues, and inactivate acetyl-CoA carboxylase. Insulin has the opposite effect. Insulin also regulates the levels of acetyl-CoA carboxylase and fatty acid synthase by controlling their rates of synthesis.

6 Synthesis of Other Lipids

- Mammalian phosphatidylethanolamine and phosphatidylcholine are synthesized from 1,2-diacylglycerol and CDP derivatives of the head groups. Phosphatidylinositol, phosphatidylglycerol, and cardiolipin syntheses begin with CDP-diacylglycerol.
- Sphingoglycolipids are synthesized from ceramide (*N*-acylsphingosine, a derivative of palmitate and serine) by the addition of glycosyl units donated by nucleotide sugars.
- Arachidonate is the precursor of prostaglandins. Certain drugs, including aspirin, block prostaglandin synthesis by inhibiting cyclooxygenase.

7 Cholesterol Metabolism

- Cholesterol is synthesized from acetyl units that pass through HMG-CoA and mevalonate intermediates on the way to being converted to a C₅ isoprene unit. Six isoprene units condense to form the C₃₀ compound squalene, which cyclizes to yield lanosterol, the steroid precursor of cholesterol.
- A cholesterol sensing system in the endoplasmic reticulum regulates the synthesis of HMG-CoA reductase and LDL receptor in the cell. HMG-CoA reductase is competitively inhibited by statin drugs.
- Hypercholesterolemia, associated with certain genetic defects or a high-cholesterol diet, contributes to the development of atherosclerosis.

Problems

EXERCISES

1. The removal of fatty acids from triacylglycerols leaves glycerol. Show how the actions of glycerol kinase and glycerol-3-phosphate dehydrogenase on glycerol produce an intermediate of glycolysis.

2. Identify the products generated by the action of pancreatic lipase on the lipid shown at the top of page 665.

3. (a) What is the charge of bile acids in the small intestine, where the pH is 7–8? (b) According to one hypothesis, bile acids are toxic to

bacteria and so could help limit their growth in the intestine. Propose a mechanism for this bactericidal activity.

4. Bacteria that live in the large intestine metabolize glycocholic acid using amidases and hydroxylases. (a) Draw the reaction product. (b) Compare the solubility of the product and glycocholic acid. (c) Could the change in the bile acid's solubility make it less toxic to bacteria?

5. Two lipoproteins have the following characteristics:

	Diameter (Å)	% Triacylglycerol	% Protein
Lipoprotein A	200	10	20
Lipoprotein B	100	5	55

Which lipoprotein has a higher density?

6. Adipocytes store fat in phospholipid-coated droplets in the cytosol. The protein perilipin is also associated with the surface of the lipid droplet. (a) Describe the likely structure of the perilipin protein. (b) Explain how phosphorylation of perilipin could help expose the lipids in the droplet to digestion by lipases.

7. Explain why individuals with a hereditary deficiency of carnitine palmitoyl transferase II have muscle weakness.

8. Why are the symptoms of carnitine palmitoyl transferase II deficiency more severe during fasting?

9. The first three steps of β oxidation (Fig. 20-12) chemically resemble three successive steps of the citric acid cycle. Which steps are these?

10. The complete combustion of palmitate and glucose yields $9781 \text{ kJ} \cdot \text{mol}^{-1}$ and $2850 \text{ kJ} \cdot \text{mol}^{-1}$ of free energy, respectively. Compare these values to the free energy (as ATP) obtained through catabolism of palmitate and glucose under standard conditions. Which process is more efficient?

11. The structure of *E. coli* ACP includes an extensive hydrophobic pocket. What is its purpose?

12. The surface of *E. coli* ACP has a patch of Glu side chains. What can you conclude about the side chains likely to be located on the surface of the *E. coli* β -hydroxyacyl-ACP dehydrase?

13. Intestinal microbes produce butyrate, which helps regulate the immune system. How many rounds of β oxidation of palmitate are required to produce butyrate?

14. Short-chain fatty acids such as butyrate are absorbed by the mammalian intestine and used as metabolic fuels. How many ATP can be derived from the complete oxidation of butyrate?

15. Why are unsaturated fats preferable to saturated fats for an individual whose caloric intake must be limited?

16. Calculate the ATP yield for the complete oxidation of oleate.

17. Explain why the degradation of odd-chain fatty acids can boost the activity of the citric acid cycle.

18. How many ATP can be produced by the complete oxidation of each propionyl-CoA product of fatty acid oxidation? Compare this to the ATP yield for each acetyl-CoA.

19. Why is it important that liver cells lack 3-ketoacyl-CoA transferase (Fig. 20-21)?

20. An animal is fed palmitate with a ^{14}C -labeled carboxyl group. Under ketogenic conditions, where would the label appear in acetoacetate?

21. On what carbon atoms does the $^{14}\text{CO}_2$ used to synthesize malonyl-CoA from acetyl-CoA appear in palmitate?

22. The compound triclosan

Triclosan

inhibits bacterial enoyl-ACP reductase. Explain why triclosan is useful as a microbicide.

23. Explain why adipocytes need glucose as well as fatty acids in order to synthesize triacylglycerols.

24. The antidiabetes drugs known as thiazolidinediones induce the production of glycerol kinase in adipocytes. Explain why this would decrease the concentration of serum fatty acids, which are often elevated in diabetics.

25. Pharmacological inhibition of acetyl-CoA carboxylase has been proposed as a treatment for obesity. Explain why this enzyme would appear to be a good anti-obesity drug target.

26. Explain why inhibiting the activity of acetyl-CoA carboxylase might not affect a person's body mass.

27. Intestinal bacteria convert choline to trimethylamine, and the liver converts this gas to trimethylamine *N*-oxide (TMAO). TMAO promotes atherosclerosis, possibly by stimulating macrophages to take up LDL. (a) Could this chemistry explain why eating large amounts of eggs (which are rich in phosphatidylcholine) is a risk factor for cardiovascular disease? (b) Some research suggests that ingesting supplemental phosphatidylcholine can slow the aging process. Is this consistent with your answer to Part (a)?

28. An animal is fed palmitate with a ^{14}C -labeled carboxyl group. Under conditions of membrane lipid synthesis, where would the label appear in sphinganine?

29. Which fatty acids were used to build the molecule shown here, which functions as a signaling molecule?

30. Which fatty acids were used to build the molecule shown here, which is synthesized by intestinal cells following a meal?

CHALLENGE QUESTIONS

31. One strategy for converting biomass to conventional hydrocarbon fuels involves the use of naturally occurring bacterial enzymes. In certain cyanobacteria, a fatty acyl-ACP undergoes conversion to a fatty aldehyde. An aldehyde decarbonylase acts on the aldehyde, producing CO and an alkane. Identify the alkanes generated from stearoyl-ACP and palmitoyl-ACP.

32. Biodiesel, a fuel typically derived from plant oils, can be manufactured by treating the oil with a methanol/KOH mixture to produce fatty acid methyl esters. Indicate the structures of the products generated by treating the triacylglycerol on page 665 with methanol/KOH.

33. Digestion of plant materials generates phytanate (derived from chlorophyll molecules; Fig. 19-2).

(a) Explain why phytanate cannot be catabolized by β oxidation.

(b) Instead, phytanate is linked to CoA, then a peroxisomal dioxygenase converts phytanoyl-CoA to 2-hydroxyphytanoyl-CoA. Draw the structure of this intermediate.

(c) 2-Hydroxyphytanoyl-CoA lyase generates an aldehyde (pristanal) and formyl-CoA. Draw the structure of pristanal.

34. Pristanal (see Problem 20-33) can be oxidized to pristanate. Can this compound be further degraded by β oxidation and, if so, what are the reaction products?

35. The tricarboxylate transport system supplies cytosolic acetyl-CoA for palmitate synthesis. What percentage of the NADPH required for palmitate synthesis is thereby provided?

36. Is the fatty acid shown below likely to be synthesized in animals? Explain.

37. Compare the energy cost, in ATP equivalents, of synthesizing stearate from mitochondrial acetyl-CoA to the energy recovered by degrading stearate to acetyl-CoA.

38. Compare the energy cost, in ATP equivalents, of synthesizing stearate from mitochondrial acetyl-CoA to the energy recovered by degrading stearate to CO_2 .

39. Calculate the cost, in ATP equivalents, of converting 12 acetyl-CoA to lignocerate (a C_{24} fatty acid; Table 9-1) when elongation occurs in the mitochondrion.

40. Calculate the cost, in ATP equivalents, of converting 12 acetyl-CoA to lignocerate when elongation occurs in the endoplasmic reticulum.

41. Hypercholesterolemic individuals taking statins are sometimes advised to take supplements of coenzyme Q. Explain.

42. Atorvastatin, which is administered orally, has limited solubility in aqueous solutions. Is it more soluble in the stomach or in the small intestine?

43. A child suffering from severe abdominal pain is admitted to the hospital several hours after eating a meal consisting of hamburgers, fried potatoes, and ice cream. Her blood has the appearance of “creamed tomato soup” and on analysis is found to contain massive quantities of chylomicrons. As the attending physician, what is your diagnosis of the patient’s difficulty (the cause of the abdominal pain is unclear)? What treatment would you prescribe to alleviate the symptoms of this inherited disease?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1. Viewing and Analyzing Fatty Acid Synthase

Exercise 2. Lipid Metabolism and the KEGG Database

Extended Exercises Bioinformatics projects are available on the book companion site (www.wiley.com/college/voet), as well as in WileyPLUS Learning Space.

Project 10 Drug Design and Cholesterol Medications

1. Bile Acid Sequestrants. The relationship between cholesterol and bile acids was exploited in the use of a common laboratory material as a medication.

2. Statins. Follow the history of the development of HMG-CoA reductase inhibitors and explore related structures on the Protein Data Bank web site.

CASE STUDY www.wiley.com/college/voet

Case 23 The Role of Uncoupling Proteins in Obesity

Focus concept: The properties of adipose tissue factors that uncouple oxidative phosphorylation are discussed, and possible links between uncoupling proteins and obesity are examined.

Prerequisites: Chapters 18 and 20

- Electron transport and oxidative phosphorylation
- Mechanisms of uncoupling agents, such as 2,4-dinitrophenol
- Fatty acid oxidation

MORE TO EXPLORE Clinical assays are used to measure the blood levels of triacylglycerols and cholesterol. Why is it necessary to break the total serum cholesterol level into an LDL and an HDL component? What levels of LDL cholesterol and HDL cholesterol are considered normal? What levels are associated with an increased risk of cardiovascular disease? In addition to the statins, what types of drugs affect serum cholesterol levels? How do they work and why are they often prescribed in combination?

CHAPTER 21

Amino Acid Metabolism

Chapter Contents

1 Protein Degradation

- A Lysosomes Degrade Many Proteins
- B Ubiquitin Marks Proteins for Degradation
- C The Proteasome Unfolds and Hydrolyzes Ubiquitinated Polypeptides

2 Amino Acid Deamination

- A Transaminases Use PLP to Transfer Amino Groups
- B Glutamate Can Be Oxidatively Deaminated

3 The Urea Cycle

- A Five Enzymes Carry Out the Urea Cycle
- B The Urea Cycle Is Regulated by Substrate Availability

4 Breakdown of Amino Acids

- A Alanine, Cysteine, Glycine, Serine, and Threonine Are Degraded to Pyruvate
- B Asparagine and Aspartate Are Degraded to Oxaloacetate
- C Arginine, Glutamate, Glutamine, Histidine, and Proline Are Degraded to α -Ketoglutarate
- D Methionine, Threonine, Isoleucine, and Valine Are Degraded to Succinyl-CoA
- E Leucine and Lysine Are Degraded Only to Acetyl-CoA and/or Acetoacetate
- F Tryptophan Is Degraded to Alanine and Acetoacetate
- G Phenylalanine and Tyrosine Are Degraded to Fumarate and Acetoacetate

5 Amino Acid Biosynthesis

- A Nonessential Amino Acids Are Synthesized from Common Metabolites
- B Plants and Microorganisms Synthesize the Essential Amino Acids

6 Other Products of Amino Acid Metabolism

- A Heme Is Synthesized from Glycine and Succinyl-CoA
- B Amino Acids Are Precursors of Physiologically Active Amines
- C Nitric Oxide Is Derived from Arginine

7 Nitrogen Fixation

- A Nitrogenase Reduces N_2 to NH_3
- B Fixed Nitrogen Is Assimilated into Biological Molecules

N. Kedarsha/Science Source Images

Many of the neurotransmitters that relay signals between nerve cells are amino acids or derivatives of amino acids. These small molecules are easily synthesized by the cells, stockpiled until their release, then rapidly degraded or taken up again.

The metabolism of amino acids comprises a wide array of synthetic and degradative reactions by which amino acids are assembled as precursors of polypeptides or other compounds and broken down to recover metabolic energy. The chemical transformations of amino acids are distinct from those of carbohydrates or lipids in that they involve the element nitrogen. We must therefore examine the origin of nitrogen in biological systems as well as its disposal.

The bulk of the cell's amino acids are incorporated into proteins, which are continuously being synthesized and degraded. Aside from this dynamic pool of polymerized amino acids, there is no true storage form of amino acids analogous to glycogen or triacylglycerols. Mammals synthesize certain amino acids and obtain the rest from their diets. *Excess dietary amino acids are not simply excreted but are converted to common metabolites that are precursors of glucose, fatty acids, and ketone bodies and are therefore metabolic fuels.*

In this chapter, we consider the pathways of amino acid metabolism, beginning with the degradation of proteins and the **deamination** (amino group removal) of their component amino acids. We then examine the incorporation of nitrogen into urea for excretion. Next, we examine the pathways by which the carbon skeletons of individual amino acids are broken down and synthesized. We conclude with a brief examination of some other biosynthetic pathways involving amino acids and nitrogen fixation, a process that converts atmospheric N_2 to a biologically useful form.

1 Protein Degradation

KEY CONCEPTS

- Extracellular and intracellular proteins may be digested by lysosomal proteases.
- Other proteins to be degraded are first conjugated to the protein ubiquitin.
- The proteasome, a barrel-shaped complex, unfolds ubiquitinated proteins in an ATP-dependent process and proteolytically degrades them.

The components of living cells are constantly turning over. Proteins have life-times that range from as short as a few minutes to weeks or more. In any case, *cells continuously synthesize proteins from and degrade them to amino acids*. This seemingly wasteful process has three functions: (1) to store nutrients in the form of proteins and to break them down in times of metabolic need, processes that are most significant in muscle tissue; (2) to eliminate abnormal proteins whose accumulation would be harmful to the cell; and (3) to permit the regulation of cellular metabolism by eliminating superfluous enzymes and regulatory proteins. *Controlling a protein's rate of degradation is therefore as important to the cellular and organismal economy as is controlling its rate of synthesis*.

The half-lives of different enzymes in a given tissue vary substantially, as is indicated for rat liver in **Table 21-1**. Remarkably, *the most rapidly degraded enzymes all occupy important metabolic control points, whereas the relatively stable enzymes have nearly constant catalytic activities under all physiological conditions*. The susceptibilities of enzymes to degradation have evidently evolved along with their catalytic and allosteric properties so that cells can efficiently respond to environmental changes and metabolic requirements. The rate of protein degradation in a cell also varies with its nutritional and hormonal state. For example, under conditions of nutritional deprivation, cells increase their rate of protein degradation so as to provide the necessary nutrients for indispensable metabolic processes.

A Lysosomes Degrade Many Proteins

Lysosomes contain ~50 hydrolytic enzymes, including a variety of proteases known as **cathepsins**. The lysosome maintains an internal pH of ~5, and its enzymes have acidic pH optima. This situation presumably protects the cell against accidental lysosomal leakage since lysosomal enzymes are largely inactive at cytosolic pH's.

Lysosomes degrade substances that the cell takes up via endocytosis (Section 20-1B). They also recycle intracellular constituents that are enclosed within vesicles that fuse with lysosomes, a process called **autophagy** (Greek: *autos*, self + *phagein*, to eat). *In well-nourished cells, lysosomal protein degradation is nonselective*. In starving cells, however, such degradation would deplete essential enzymes and regulatory proteins. Lysosomes therefore also have a selective pathway, which is activated only after a prolonged fast, that imports and degrades cytosolic proteins containing the pentapeptide Lys-Phe-Glu-Arg-Gln (KFERQ) or a closely related sequence. Such **KFERQ proteins** are selectively lost from tissues that atrophy in response to fasting (e.g., liver and kidney) but not from tissues that do not do so (e.g., brain and testes). Many normal and pathological processes are associated with increased lysosomal activity—for example, the muscle wastage caused by disuse, denervation, or traumatic injury. The regression of the uterus after childbirth, when the muscular organ reduces its mass from 2 kg to 50 g in nine days, is a striking example of this process. Many chronic infections and inflammatory diseases lead to cell death and the extracellular release of lysosomal enzymes, which break down surrounding tissues.

TABLE 21-1 Half-Lives of Some Rat Liver Enzymes

Enzyme	Half-Life (h)
Short-Lived Enzymes	
Ornithine decarboxylase	0.2
RNA polymerase I	1.3
Tyrosine aminotransferase	2.0
Serine–threonine dehydratase	4.0
PEP carboxylase	5.0
Long-Lived Enzymes	
Aldolase	118
GAPDH	130
Cytochrome <i>b</i>	130
LDH	130
Cytochrome <i>c</i>	150

B Ubiquitin Marks Proteins for Degradation

Protein breakdown in eukaryotic cells also occurs in an ATP-requiring process that is independent of lysosomes. This process involves **ubiquitin** (Fig. 21-1), a 76-residue monomeric protein named for its ubiquity and abundance. It is one of the most highly conserved eukaryotic proteins known (it is identical in such diverse organisms as humans, trout, and *Drosophila*), suggesting that it is uniquely suited for some essential cellular function(s).

Proteins are marked for degradation by covalently linking them to ubiquitin. This process occurs in three steps, elucidated notably by Avram Hershko, Aaron Ciechanover, and Irwin Rose (Fig. 21-2):

1. In an ATP-requiring reaction, ubiquitin's terminal carboxyl group is conjugated, via a thioester bond, to **ubiquitin-activating enzyme (E1)**. Most organisms have only one type of E1.
2. The ubiquitin is then transferred to a specific Cys sulfhydryl group on one of numerous homologous proteins named **ubiquitin-conjugating enzymes (E2s)**; 11 in yeast and >20 in mammals). The various E2s are characterized by an ~150-residue catalytic core containing the active site Cys.
3. **Ubiquitin-protein ligase (E3)** transfers the activated ubiquitin from E2 to a Lys ϵ -amino group of a previously bound protein, thereby forming an **isopeptide bond**. Cells contain many species of E3s, each of which mediates the ubiquitination (alternatively, ubiquitylation) of a specific set of proteins and thereby marks them for degradation. Each E3 is served by one or a few specific E2s. The known E3s are members of two unrelated families, those containing a **HECT** domain (HECT for *homologous to E6AP C-terminus*) and those containing a so-called **RING finger** (RING for *really interesting new gene*), although some E2s react well with members of both families. The human genome contains 28 HECT genes and 616 RING genes, more than its number of protein kinase genes (518), which is indicative of the E3s' specialized and varied functions (see below).

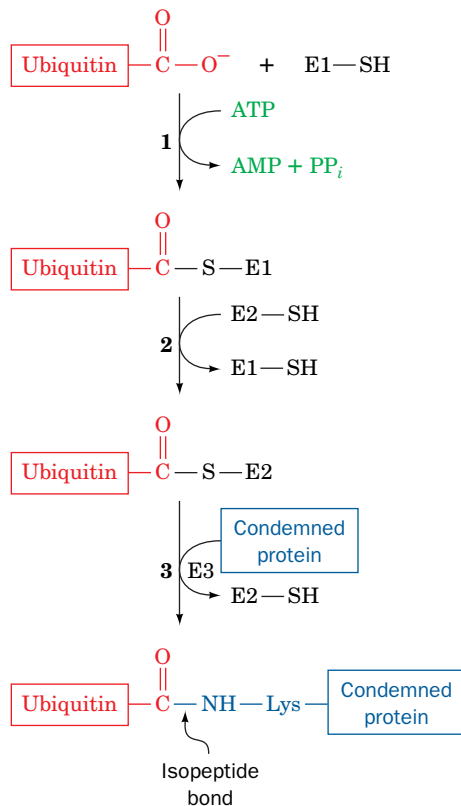

FIG. 21-2 Reactions involved in protein ubiquitination. Ubiquitin's terminal carboxyl group is first joined, via a thioester linkage, to E1 in a reaction driven by ATP hydrolysis. The activated ubiquitin is subsequently transferred to a sulfhydryl group of an E2 and then, in a reaction catalyzed by an E3, to a Lys ϵ -amino group on a condemned protein, thereby marking the protein for proteolytic degradation.

? How many ATP equivalents are consumed in the ubiquitination process?

For a protein to be efficiently degraded, it must be linked to a chain of at least four tandemly linked ubiquitin molecules in which Lys 48 of each ubiquitin forms an isopeptide bond with the C-terminal carboxyl group of the following ubiquitin. These **polyubiquitin** chains may contain 50 or more ubiquitin units. Ubiquitinated proteins are dynamic entities, with ubiquitin molecules being rapidly attached and removed (the latter by **ubiquitin isopeptidases**).

The Ubiquitin System Has Both Housekeeping and Regulatory Functions.

Until the mid-1990s, it appeared that the ubiquitin system functioned mainly in a “housekeeping” capacity to maintain the proper balance among metabolic proteins and to eliminate damaged proteins. Indeed, as Alexander Varshavsky discovered, the half-lives of many cytoplasmic proteins vary with the identities of their N-terminal residues via the so-called **N-end rule**: Proteins with the “destabilizing” N-terminal residues Asp, Arg, Leu, Lys, and Phe have half-lives of only 2 to 3 minutes, whereas those with the “stabilizing” N-terminal residues

Ala, Gly, Met, Ser, Thr, and Val have half-lives of >10 hours in prokaryotes and >20 hours in eukaryotes. The N-end rule applies in both eukaryotes and prokaryotes, which suggests the system that selects proteins for degradation is conserved in eukaryotes and prokaryotes, even though prokaryotes lack ubiquitin.

In eukaryotes, the N-end rule results from the actions of a RING finger E3 named **E3a** whose ubiquitination signals are the destabilizing N-terminal residues. However, it is now clear that the ubiquitin system is far more sophisticated than a simple garbage disposal system. Thus, the many E3s have a variety of ubiquitination signals that often occur on a quite limited range of target proteins, many of which have regulatory functions. For example, it has long been known that proteins with segments rich in Pro (P), Glu (E), Ser (S), and Thr (T), the so-called **PEST proteins**, are rapidly degraded. It is now realized that this is because these PEST elements often contain phosphorylation sites that target their proteins for ubiquitination. The resulting destruction of these regulatory proteins, of course, has important regulatory consequences. Likewise, proteins known as **cyclins** that control the progression of the **cell cycle** (the general sequence of events that occur over the life-times of eukaryotic cells; Section 28-4A) are selectively degraded through their ubiquitination at specific stages of the cell cycle. Interestingly, reversible **monoubiquitination** controls the activities of certain proteins rather than their degradation, in much the same way that phosphorylation and dephosphorylation alter protein activity (Section 12-3B).

C The Proteasome Unfolds and Hydrolyzes Ubiquitinated Polypeptides

Ubiquitinated proteins are proteolytically degraded in an ATP-dependent process mediated by a large (~2500 kD, 26S) multiprotein complex named the **26S proteasome** (Fig. 21-3). The 26S proteasome consists of a hollow cylindrical core, known as the **20S proteasome**, which is covered at one or both ends by a **19S cap**. [Here, the quantities “26S,” “20S,” and “19S” refer to the corresponding particles’ sedimentation coefficients in units of Svedbergs (S); Section 5-2E.]

The yeast 20S proteasome, which is closely similar to other eukaryotic 20S proteasomes, is composed of seven different types of α -like subunits and seven

FIG. 21-3 Electron microscopy-based image of the *Drosophila melanogaster* 26S proteasome. The complex is around $450 \times 190 \text{ \AA}$. The central portion of the twofold symmetric multiprotein complex (yellow), the 20S proteasome, consists of four stacked seven-membered rings of subunits that form a hollow barrel in which the proteolysis of ubiquitin-linked proteins occurs. The 19S caps (blue), which may attach to one or both ends of the 20S proteasome, control the access of condemned proteins to the 20S proteasome (see text).

different types of β -like subunits. The X-ray structure of this enormous (6182-residue, \sim 670-kD) protein complex, determined by Robert Huber, reveals that it consists of four stacked rings of subunits with its outer and inner rings, respectively, consisting of seven different α -type subunits and seven different β -type subunits (Fig. 21-4a). The various α -type subunits have folds that are similar to one another and to the various β -type subunits. Consequently, the 28-subunit complex has exact twofold rotational symmetry relating the two pairs of rings, but only pseudosevenfold rotational symmetry relating the subunits within each ring. The 20S proteasome's hollow core consists of three large chambers (Fig. 21-4b): Two are located at the interfaces between adjoining rings of α and β subunits, with the third, larger chamber centrally located between the two rings of β subunits.

Although the α -type subunits and the β -type subunits are structurally similar, only three of the β -type subunits have proteolytic activity. The X-ray structure together with enzymological studies reveal that the three active sites catalyze peptide bond hydrolysis via a novel mechanism in which the β subunits' N-terminal Thr residues function as catalytic nucleophiles. The active sites are located inside the central chamber of the 20S proteasome, thereby preventing this omnivorous protein-dismantling machine from indiscriminately hydrolyzing the proteins in its vicinity. The polypeptide substrates must enter the central chamber of the barrel through the narrow axially located apertures in the α rings that are lined with hydrophobic residues so that only unfolded proteins can enter the central chamber. Nevertheless, in the X-ray structure of the yeast 20S proteasome (Fig. 21-4b), these apertures are blocked by a plug formed by the interdigitation of the α subunits' N-terminal tails.

The three active β -type subunits have different substrate specificities, cleaving after acidic residues (the $\beta 1$ subunit), basic residues (the $\beta 2$ subunit), and hydrophobic residues (the $\beta 5$ subunit). As a result, the 20S

(a)

FIG. 21-4 X-Ray structure of the yeast 20S proteasome. (a) The arrangement of the 28 subunits represented as spheres. Four rings of seven subunits each are stacked to form a barrel (the ends of the barrel are at the right and left) with the α -type and β -type subunits forming the outer and inner rings, respectively. The complex's twofold (C_2) axis of symmetry is represented by the vertical red line.

(b) Surface view of the proteasome core cut along its cylindrical axis. Three bound protease inhibitor molecules marking the three active β subunits are shown in red as space-filling models. The entry channels at each end of the cylinder are not visible in this model. PDBid 1RYP.

? Compare this structure to that of the GroEL/ES chaperonin (Fig 6-44).

proteasome cleaves its polypeptide substrates into ~8-residue fragments, which then diffuse out of the proteasome. Cytosolic peptidases degrade the peptides to their component amino acids. The ubiquitin molecules attached to the target protein are not degraded, however, but are returned to the cell and reused.

In addition to facilitating normal protein turnover, proteasomes play a role in the immune system. Certain antigen-presenting cells display peptide antigens on their surface to initiate an immune response. Receptors on T lymphocytes (Section 7-3) recognize the peptides, when they are complexed with cell-surface proteins that are members of the **major histocompatibility complex (MHC)**. During a bacterial or viral infection, signals from damaged cells or other immune-system cells stimulate the antigen-presenting cells to increase their synthesis of alternate proteasomal β subunits that have altered substrate specificity. The resulting peptide fragments, which represent normal cellular proteins as well as pathogen-derived proteins, bind optimally to the MHC proteins and hence can better alert T lymphocytes to the presence of the pathogen.

19S Caps Control the Access of Ubiquitinated Proteins to the 20S Proteasome. The 20S proteasome probably does not exist alone *in vivo*; it is most often in complex with two 19S caps that recognize ubiquitinated proteins, unfold them, and feed them into the 20S proteasome in an ATP-dependent manner, while excising their attached ubiquitin. The 19S cap, which consists of ~19 different subunits, has been difficult to characterize due in large part to its low intrinsic stability. Its so-called base complex consists of 10 different subunits, 6 of which are ATPases that form a ring that abuts the α ring of the 20S proteasome (Fig. 21-3). Cecile Pickart demonstrated, via cross-linking experiments, that one of these ATPases, named **S6'**, contacts the polyubiquitin signal that targets a condemned protein to the 26S proteasome. This suggests that the recognition of the polyubiquitin chain as well as substrate protein unfolding are ATP-driven processes. Moreover, the ring of ATPases must open the otherwise closed axial aperture of the 20S proteasome so as to permit the entry of the unfolded substrate protein.

Nine additional subunits form the so-called lid complex, the portion of the 19S cap that, for the most part, is more distant from the 20S proteasome. The functions of the lid subunits are largely unknown, although a truncated 26S proteasome that lacks the lid subunits is unable to degrade polyubiquitinated substrates. Several other subunits may be transiently associated with the 19S cap and/or with the 20S proteasome.

Eubacteria Also Contain Self-Compartmentalized Proteases. Although 20S proteasomes occur in all eukaryotes and archaeobacteria yet examined, they are absent in nearly all eubacteria (which provides further evidence that eukaryotes arose from archaea; Fig. 1-9). Nevertheless, eubacteria have ATP-dependent proteolytic assemblies that share a barrel-shaped architecture with proteasomes and carry out similar functions. For example, in *E. coli*, two proteins known as **Lon** and **Clp** carry out up to 80% of the bacterium's protein degradation. Thus, *all cells appear to contain proteases whose active sites are only available from the inner cavity of a hollow particle to which access is controlled.* These so-called **self-compartmentalized proteases** appear to have arisen early in the history of cellular life, before the advent of eukaryotic membrane-bound organelles such as the lysosome, which similarly carry out degradative processes in a way that protects the cell contents from indiscriminant destruction.

Clp protease consists of two components, the proteolytically active **ClpP** and one of several ATPases, which in *E. coli* are **ClpA** and **ClpX**. The X-ray

CHECKPOINT

- What is the role of the lysosome in degrading extracellular and intracellular proteins?
- Why must protein degradation be somewhat selective?
- Describe the steps of protein ubiquitination. What is the difference between mono- and polyubiquitination?
- Describe the pathway for proteasome-mediated protein degradation, including the roles of ubiquitin and ATP.
- What is the advantage of the proteasomal active sites having different substrate specificities?

structure of ClpP reveals that it oligomerizes to form a hollow barrel $\sim 90 \text{ \AA}$ long and wide that consists of two back-to-back sevenfold symmetric rings of 193-residue subunits and thereby has the same rotational symmetry as does the 20S proteasome (Fig. 21-5). Nevertheless, the ClpP subunit has a novel fold that is entirely different from that of the 20S proteasome's homologous α and β subunits. The ClpP active site, which is only exposed on the inside of the barrel, contains a catalytic triad composed of its Ser 97, His 122, and Asp 171, and hence is a serine protease (Fig. 11-26).

2 Amino Acid Deamination

KEY CONCEPTS

- Transamination interconverts an amino acid and an α -keto acid.
- Oxidative deamination of glutamate releases ammonia for disposal.

Free amino acids originate from the degradation of cellular proteins and from the digestion of dietary proteins. The gastric protease **pepsin**, the pancreatic enzymes trypsin, chymotrypsin, and elastase (discussed in Sections 5-3B and 11-5), and a host of other endo- and exopeptidases degrade polypeptides to oligopeptides and amino acids. These substances are absorbed by the intestinal mucosa and transported via the bloodstream to be absorbed by other tissues.

The further degradation of amino acids takes place intracellularly and includes a step in which the α -amino group is removed. In many cases, the amino group is converted to ammonia, which is then incorporated into urea for excretion (Section 21-3). The remaining carbon skeleton (α -keto acid) of the amino acid can be broken down to other compounds (Section 21-4). This metabolic theme is outlined in Fig. 21-6.

FIG. 21-6 Overview of amino acid catabolism. The amino group is removed and incorporated into urea for disposal. The remaining carbon skeleton (α -keto acid) can be broken down to CO_2 and H_2O or converted to glucose, acetyl-CoA, or ketone bodies.

? Which compounds serve as metabolic fuels?

A Transaminases Use PLP to Transfer Amino Groups

Most amino acids are deaminated by **transamination**, the transfer of their amino group to an α -keto acid to yield the α -keto acid of the original amino acid and a new amino acid. The predominant amino group acceptor is α -ketoglutarate, producing glutamate and the new α -keto acid:

Glutamate's amino group, in turn, can be transferred to oxaloacetate in a second transamination reaction, yielding aspartate and re-forming α -ketoglutarate:

The enzymes that catalyze transamination, called **aminotransferases** or **transaminases**, require the coenzyme **pyridoxal-5'-phosphate (PLP; Fig. 21-7a)**. PLP is a derivative of **pyridoxine (vitamin B₆; Fig. 21-7b)**. The coenzyme is covalently attached to the enzyme via a Schiff base (imine) linkage formed by the condensation of its aldehyde group with the ϵ -amino group of an enzyme Lys residue (**Fig. 21-7c**). The Schiff base, which is conjugated to the

FIG. 21-7 Forms of pyridoxal-5'-phosphate. (a) The coenzyme pyridoxal-5'-phosphate (PLP). (b) Pyridoxine (vitamin B₆). (c) The Schiff base that forms between PLP and an enzyme ϵ -amino group. (d) Pyridoxamine-5'-phosphate (PMP).

? Describe the modifications that transform the vitamin into the functional coenzyme.

pyridinium ring, is the center of the coenzyme's activity. When PLP accepts the amino group from an amino acid as described below, it becomes **pyridoxamine-5'-phosphate (PMP; Fig. 21-7d)**.

Esmond Snell, Alexander Braunstein, and David Metzler demonstrated that the aminotransferase reaction occurs via a Ping Pong mechanism (Section 12-1D) whose two stages consist of three steps each (Fig. 21-8).

Stage I Converts an Amino Acid to an α -Keto Acid.

1. The amino acid's nucleophilic amino group attacks the enzyme-PLP Schiff base carbon atom in a **transamination** reaction to form an amino acid-PLP Schiff base (an aldimine), with concomitant release of the enzyme's Lys amino group. This Lys is then free to act as a general base at the active site.
2. The amino acid-PLP Schiff base tautomerizes to an α -keto acid-PMP Schiff base (a ketimine) by the active site Lys-catalyzed removal of the amino acid α -hydrogen and protonation of PLP atom C4' via a resonance-stabilized carbanion intermediate. This resonance stabilization facilitates the cleavage of the C $_{\alpha}$ -H bond.
3. The α -keto acid-PMP Schiff base is hydrolyzed to PMP and an α -keto acid.

Stage II Converts an α -Keto Acid to an Amino Acid. To complete the aminotransferase's catalytic cycle, the coenzyme must be converted from PMP back to the enzyme-PLP Schiff base. This involves the same three steps as above, but in reverse order:

- 3'. PMP reacts with an α -keto acid to form a Schiff base.
- 2'. The α -keto acid-PMP Schiff base tautomerizes to form an amino acid-PLP Schiff base.
- 1'. The ϵ -amino group of the active site Lys residue attacks the amino acid-PLP Schiff base in a transamination reaction to regenerate the active enzyme-PLP Schiff base and release the newly formed amino acid.

Note that removal of the substrate amino acid's α -proton produces a resonance-stabilized C $_{\alpha}$ carbanion whose electrons are delocalized all the way to the coenzyme's protonated pyridinium nitrogen atom; that is, *PLP functions as an electron sink*. For transamination reactions, this electron-withdrawing capacity facilitates removal of the α proton (*a* bond cleavage, top right of Fig. 21-8) during tautomerization. PLP functions similarly in enzymatic reactions involving *b* and *c* bond cleavage.

Aminotransferases differ in their specificity for amino acid substrates in the first stage of the transamination reaction, thereby producing the correspondingly different α -keto acid products. Most aminotransferases, however, accept only α -ketoglutarate or (to a lesser extent) oxaloacetate as the α -keto acid substrate in the second stage of the reaction, thereby yielding glutamate or aspartate as their only amino acid product. *The amino groups from most amino acids are consequently funneled into the formation of glutamate and aspartate.* The transaminase reaction is freely reversible, so transaminases participate in pathways for amino acid synthesis as well as degradation. Lysine is the only amino acid that is not transaminated.

The presence of transaminases in muscle and liver cells makes them useful markers of tissue damage. Assays of the enzymes' activities in the blood are the basis of the commonly used clinical measurements known as **SGOT (serum glutamate-oxaloacetate transaminase, also known as aspartate transaminase, AST)** and **SGPT (serum glutamate-pyruvate transaminase, or alanine transaminase, ALT)**. The concentrations of these enzymes in the blood increase after a heart attack, when damaged heart muscle leaks its intracellular contents. Liver damage is also monitored by SGOT and SGPT levels.

Steps 1 & 1': Transimination:

Steps 2 & 2': Tautomerization:

Steps 3 & 3': Hydrolysis:

FIG. 21-8 The mechanism of PLP-dependent enzyme-catalyzed transamination. The first stage of the reaction, in which the α -amino group of an amino acid is transferred to PLP yielding an α -keto acid and PMP, consists of three steps: (1) transimination, (2) tautomerization, in which the Lys released during the transimination reaction acts as a general acid–base catalyst, and (3) hydrolysis. The second stage of the reaction, in which the amino group of PMP

is transferred to a different α -keto acid to yield a new α -amino acid and PLP, is essentially the reverse of the first stage: Steps 3', 2', and 1' are, respectively, the reverse of Steps 3, 2, and 1. **WPLS** See the **Animated Figures**.

? Describe the products that would result from cleavage of the amino acid's *b* and *c* bonds indicated at the upper right.

B Glutamate Can Be Oxidatively Deaminated

Transamination, of course, does not result in any net **deamination**. Glutamate, however, can be oxidatively deaminated by **glutamate dehydrogenase (GDH)**, yielding ammonia and regenerating α -ketoglutarate for use in additional transamination reactions.

Glutamate dehydrogenase, a mitochondrial enzyme, is the only known enzyme that can accept either NAD^+ or NADP^+ as its redox coenzyme. Oxidation is thought to occur with transfer of a hydride ion from glutamate's C_α to NAD(P)^+ , thereby forming α -iminoglutarate, which is hydrolyzed to α -ketoglutarate and ammonium ion:

The enzyme is allosterically inhibited by GTP and NADH (signaling abundant metabolic energy) and activated by ADP and NAD^+ (signaling the need to generate ATP). Because the product of the reaction, α -ketoglutarate, is an intermediate of the citric acid cycle, activation of glutamate dehydrogenase can stimulate flux through the citric acid cycle, leading to increased ATP production by oxidative phosphorylation.

The equilibrium position of the glutamate dehydrogenase reaction ($\Delta G'^{\circ} \approx 30 \text{ kJ} \cdot \text{mol}^{-1}$) favors glutamate synthesis, the reverse of the reaction written above. At one time, it was believed that this reaction represented a route for the body to remove free ammonia, which is toxic at high concentrations. Under physiological conditions, the enzyme was thought to function close to equilibrium so changes in ammonia concentration could, in principle, cause a shift in equilibrium toward glutamate synthesis to remove the excess ammonia. However, a form of hyperinsulinism that is characterized by hypoglycemia and **hyperammonemia (HI/HA)**; hyperammonemia is elevated levels of ammonia in the blood) is caused by mutations in GDH resulting in decreased sensitivity to GTP inhibition and therefore increased GDH activity. Since HI/HA patients have increased GDH activity but higher levels of NH_3 than normal, this accepted role of GDH functioning close to equilibrium and preventing ammonia toxicity cannot be correct. Indeed, if GDH functioned close to equilibrium, changes in its activity resulting from allosteric interactions would not result in significant flux changes (recall that enzymes controlling flux must function far from equilibrium).

The ammonia liberated in the GDH reaction as written above is eventually excreted in the form of urea. Thus, *the glutamate dehydrogenase reaction functions to eliminate amino groups from amino acids that undergo transamination reactions with α -ketoglutarate.*

CHECKPOINT

- Describe how α -ketoglutarate and oxaloacetate participate in amino acid catabolism.
- What is the role of PLP in transamination?
- Summarize the reactions that release an amino acid's amino group as ammonia.

3 The Urea Cycle

KEY CONCEPTS

- Five reactions incorporate ammonia and an amino group into urea.
- The rate of the urea cycle changes with the rate of amino acid breakdown.

Living organisms excrete the excess nitrogen arising from the metabolic breakdown of amino acids in one of three ways. Many aquatic animals simply excrete ammonia. Where water is less plentiful, however, processes have evolved that

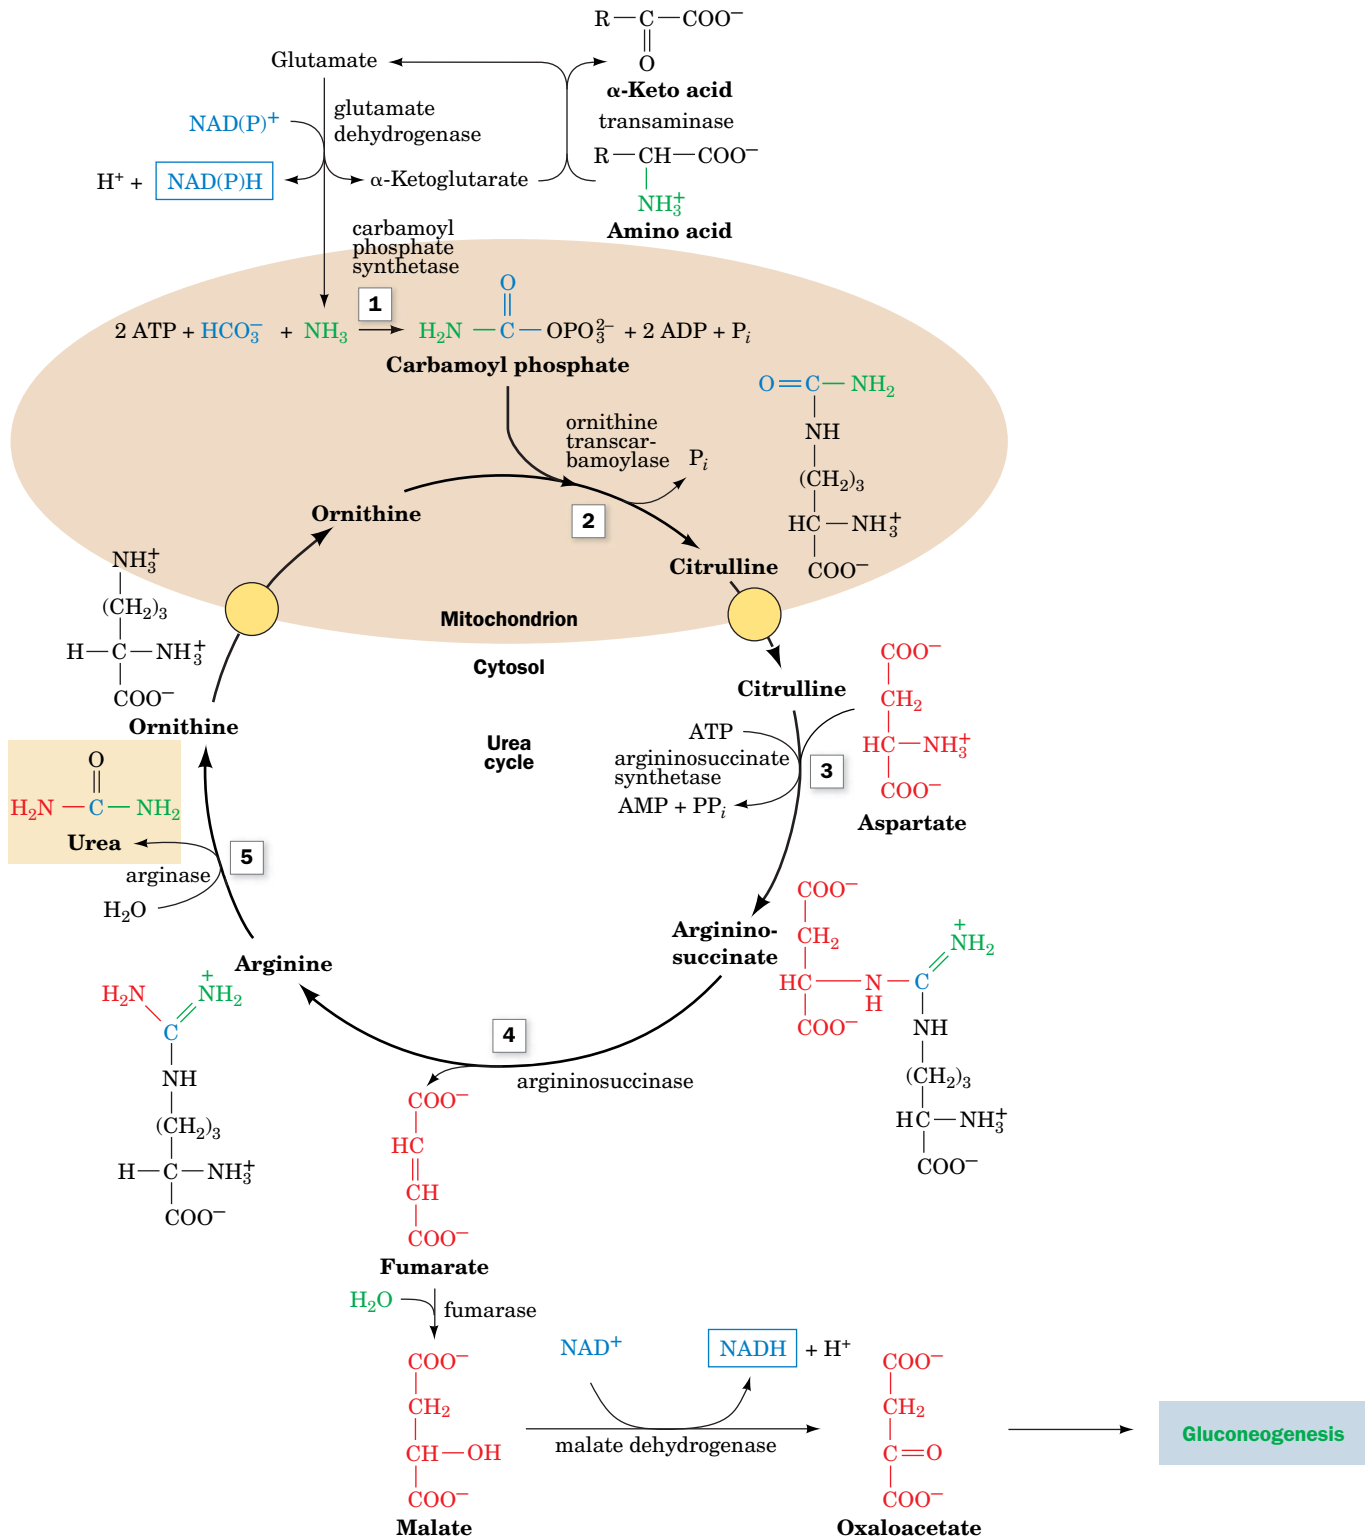

FIG. 21-9 The urea cycle. Five enzymes participate in the urea cycle: (1) carbamoyl phosphate synthetase, (2) ornithine transcarbamoylase, (3) argininosuccinate synthetase, (4) argininosuccinase, and (5) arginase. Enzymes 1 and 2 are mitochondrial and enzymes 3–5 are cytosolic. Ornithine and citrulline must therefore be transported across the mitochondrial membrane by specific transport systems (yellow circles). The urea amino groups arise from the deamination of amino acids. One amino group (green) originates as ammonia that is generated by the glutamate dehydrogenase reaction (top). The

other amino group (red) is obtained from aspartate (right), which is formed via the transamination of oxaloacetate by an amino acid. The fumarate product of Reaction 4 is converted to the gluconeogenic precursor oxaloacetate by the action of cytosolic fumarase and malate dehydrogenase (bottom). **WPLS** See the Animated Figures.

? What factors make the reactions of the cycle irreversible under physiological conditions?

FIG. 21-10 The mechanism of action of CPS I. (1) Phosphorylation activates HCO_3^- to form the intermediate carboxyphosphate. (2) NH_3 attacks carboxyphosphate to form carbamate. (3) ATP phosphorylates carbamate, yielding carbamoyl phosphate.

essentially irreversible reaction that is the rate-limiting step of the urea cycle (Fig. 21-10).

1. ATP activates HCO_3^- to form **carboxyphosphate** and ADP.
2. Ammonia attacks carboxyphosphate, displacing the phosphate to form **carbamate** and P_i .
3. A second ATP phosphorylates carbamate to form carbamoyl phosphate and ADP.

In *E. coli*, a single CPS with the subunit structure $(\alpha\beta)_4$ generates carbamoyl phosphate, using glutamine as its nitrogen donor. The enzyme's small subunit is a **glutaminase** that hydrolyzes glutamine, and its large subunit catalyzes Reactions 1, 2, and 3 of Fig. 21-10. The X-ray structure of *E. coli* CPS, determined by Hazel Holden and Ivan Rayment, reveals the astonishing fact that although the three active sites are widely separated in space, they are connected by a narrow 96-Å-long tunnel that runs nearly the entire length of the protein molecule (Fig. 21-11). The NH_3 produced by the glutaminase active site travels ~ 45 Å in order to react with carboxyphosphate. The resulting carbamate then travels ~ 35 Å to reach the carbamoyl phosphate synthesis site. This phenomenon, in which the intermediate of two reactions is directly transferred from one enzyme active site to another, is called **channeling**.

Channeling increases the rate of a metabolic pathway by preventing the loss of its intermediate products as well as protecting the intermediates from degradation. Channeling is critical for CPS because the intermediates carboxyphosphate and carbamate are extremely reactive, having half-lives of 28 and 70 ms, respectively, at neutral pH. Also, channeling allows the local concentration of NH_3 to reach a higher value than is present in the cellular medium. We will encounter several other examples of channeling in our studies of metabolic enzymes, but the CPS tunnel is the longest known.

2. Carbamoylation of Ornithine Produces Citrulline. **Ornithine transcarbamoylase** transfers the carbamoyl group of carbamoyl phosphate to **ornithine**, yielding **citrulline** (Fig. 21-9, Reaction 2). Note that both of the latter compounds are “nonstandard” α -amino acids that do not occur in proteins. The transcarbamoylase reaction occurs in the mitochondrion, so ornithine, which

FIG. 21-11 X-Ray structure of *E. coli* carbamoyl phosphate synthetase. The protein is represented by its C_α backbone. The small subunit (magenta) contains the glutamine-binding site where NH_3 is produced. The large subunit consists of several domains (green, yellow, blue, and orange) and contains the other two active sites. The 96-Å-long tunnel connecting the three active sites is outlined in red. [Courtesy of Hazel Holden and Ivan Rayment, University of Wisconsin. PDBid 1JDB.]

FIG. 21-12 The mechanism of action of argininosuccinate synthetase. (1) The formation of citrullinyl-AMP activates the ureido oxygen of citrulline. (2) The α -amino group of aspartate displaces AMP.

is produced in the cytosol, must enter the mitochondrion via a specific transport system. Likewise, since the remaining urea cycle reactions occur in the cytosol, citrulline must be exported from the mitochondrion.

3. Argininosuccinate Synthetase Acquires the Second Urea Nitrogen Atom. Urea's second nitrogen atom is introduced by the condensation of citrulline's ureido group with an aspartate amino group by **argininosuccinate synthetase** (Fig. 21-12). ATP activates the ureido oxygen atom as a leaving group through formation of a citrullinyl-AMP intermediate, and AMP is subsequently displaced by the aspartate amino group. The PP_i formed in the reaction is hydrolyzed to 2 P_i, so the reaction consumes two ATP equivalents.

4. Argininosuccinase Produces Fumarate and Arginine. With the formation of argininosuccinate, all of the urea molecule components have been assembled. However, the amino group donated by aspartate is still attached to the aspartate carbon skeleton. This situation is remedied by the **argininosuccinase**-catalyzed elimination of fumarate, leaving arginine (Fig. 21-9, Reaction 4). Arginine is urea's immediate precursor. The fumarate produced in the argininosuccinase reaction is converted to oxaloacetate by the action of fumarase and malate dehydrogenase. These two reactions are the same as those that occur in the citric acid cycle, although they take place in the cytosol rather than in the mitochondrion. The oxaloacetate is then used for gluconeogenesis (Section 16-4).

5. Arginase Releases Urea. The urea cycle's final reaction is the **arginase**-catalyzed hydrolysis of arginine to yield urea and regenerate ornithine (Fig. 21-9, Reaction 5). Ornithine is then returned to the mitochondrion for another round of the cycle.

The urea cycle thus converts two amino groups, one from ammonia and one from aspartate, and a carbon atom from HCO₃⁻ to the relatively nontoxic product, urea, at the cost of four "high-energy" phosphate bonds. The energy spent is more than recovered, however, by the oxidation of the carbon skeletons of the amino acids that have donated their amino groups, via transamination, to glutamate and aspartate. Indeed, half the oxygen that the liver consumes is used to provide this energy.

B The Urea Cycle Is Regulated by Substrate Availability

Carbamoyl phosphate synthetase I, which catalyzes the first committed step of the urea cycle, is allosterically activated by **N-acetylglutamate** (at left). This metabolite is synthesized from glutamate and acetyl-CoA by **N-acetylglutamate**

synthase. When amino acid breakdown rates increase, the concentration of glutamate increases as a result of transamination. The increased glutamate stimulates *N*-acetylglutamate synthesis. The resulting activation of carbamoyl phosphate synthetase increases the rate of urea production. Thus, the excess nitrogen produced by amino acid breakdown is efficiently excreted. Note that the urea cycle, like gluconeogenesis (Section 16-4) and ketogenesis (Section 20-3), is a pathway that occurs in the liver but serves the needs of the body as a whole.

The remaining enzymes of the urea cycle are controlled by the concentrations of their substrates. In individuals with inherited deficiencies in urea cycle enzymes other than arginase, the corresponding substrate builds up, increasing the rate of the deficient reaction so that the rate of urea production is normal (the total lack of a urea cycle enzyme, however, is lethal). The anomalous substrate buildup is not without cost, however. The substrate concentrations become elevated all the way back up the cycle to ammonia, resulting in hyperammonemia. Although the root cause of ammonia toxicity is not completely understood, it is clear that the brain is particularly sensitive to high ammonia concentrations (symptoms of urea cycle enzyme deficiencies include mental retardation and lethargy).

CHECKPOINT

- Summarize the steps of the urea cycle. How do the amino groups of amino acids enter the cycle?
- What are the advantages of channeling?
- How is the rate of amino acid deamination linked to the rate of the urea cycle?

4 Breakdown of Amino Acids

KEY CONCEPTS

- Alanine, cysteine, glycine, serine, and threonine are broken down to pyruvate.
- Asparagine and aspartate are broken down to oxaloacetate.
- α -Ketoglutarate is produced by the degradation of arginine, glutamate, glutamine, histidine, and proline.
- Isoleucine, methionine, threonine, and valine are converted to succinyl-CoA.
- Leucine and lysine degradation yields acetyl-CoA and acetoacetate.
- Tryptophan is degraded to acetoacetate.
- Phenylalanine and tyrosine yield fumarate and acetoacetate.

Amino acids are degraded to compounds that can be metabolized to CO_2 and H_2O or used in gluconeogenesis. Indeed, oxidative breakdown of amino acids typically accounts for 10 to 15% of the metabolic energy generated by animals. In this section we consider how the carbon skeletons of the 20 “standard” amino acids are catabolized. We do not describe in detail all of the many reactions involved. Rather, we consider how the pathways are organized and focus on a few reactions of chemical and/or medical interest.

“Standard” amino acids are degraded to one of seven metabolic intermediates: pyruvate, α -ketoglutarate, succinyl-CoA, fumarate, oxaloacetate, acetyl-CoA, or acetoacetate (Fig. 21-13). The amino acids can therefore be divided into two groups based on their catabolic pathways:

- Glucogenic amino acids**, which are degraded to pyruvate, α -ketoglutarate, succinyl-CoA, fumarate, or oxaloacetate and are therefore glucose precursors (Section 16-4).
- Ketogenic amino acids**, which are broken down to acetyl-CoA or acetoacetate and can thus be converted to fatty acids or ketone bodies (Section 20-3).

FIG. 21-13 Degradation of amino acids to one of seven common metabolic intermediates. Glucogenic and ketogenic degradations are indicated in green and red, respectively.

? Which amino acids are both glucogenic and ketogenic?

Some amino acids are precursors of both carbohydrates and ketone bodies. Since animals lack any metabolic pathways for the net conversion of acetyl-CoA or acetoacetate to gluconeogenic precursors, *no net synthesis of carbohydrates is possible from the purely ketogenic amino acids Lys and Leu.*

In studying the specific pathways of amino acid breakdown, we will organize the amino acids into groups that are degraded to each of the seven metabolites mentioned above.

A Alanine, Cysteine, Glycine, Serine, and Threonine Are Degraded to Pyruvate

Five amino acids—alanine, cysteine, glycine, serine, and threonine—are broken down to yield pyruvate (Fig. 21-14). Alanine is straightforwardly transaminated to pyruvate. Serine is converted to pyruvate through dehydration by **serine–threonine dehydratase**. This PLP-dependent enzyme, like the aminotransferases (Section 21-2A), forms a PLP–amino acid Schiff base, which facilitates the removal of the amino acid's α -hydrogen atom. In the serine–threonine dehydratase reaction, however, the C_α carbanion breaks down with the elimination of the amino acid's C_β OH, rather than with tautomerization (Fig. 21-8, Step 2), so the

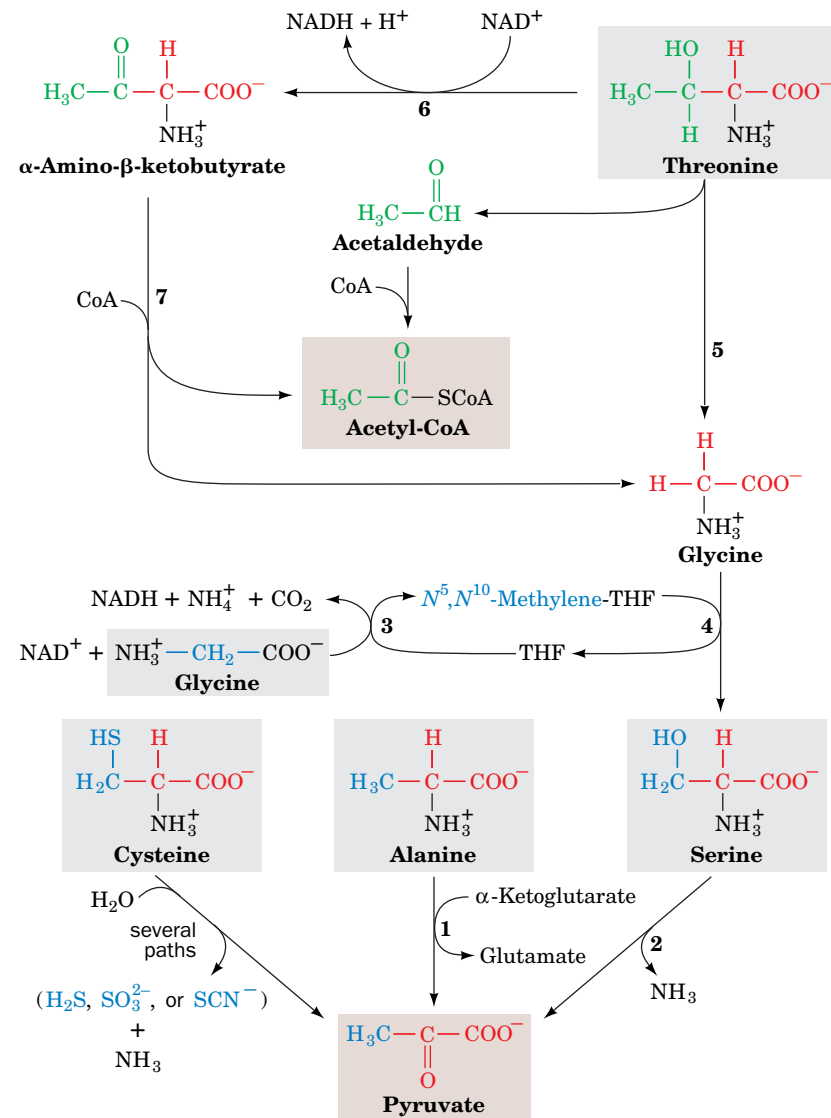

FIG. 21-14 The pathways converting alanine, cysteine, glycine, serine, and threonine to pyruvate. The enzymes involved are (1) alanine aminotransferase, (2) serine–threonine dehydratase, (3) glycine cleavage system, (4 and 5) serine hydroxymethyltransferase, (6) threonine dehydrogenase, and (7) α -amino- β -ketobutyrate lyase.

FIG. 21-15 The serine–threonine dehydratase reaction. This PLP-dependent enzyme catalyzes the elimination of water from serine in six steps: (1) formation of a serine-PLP Schiff base, (2) removal of the α -H atom of serine to form a resonance-stabilized carbanion, (3) β elimination

of OH⁻, (4) hydrolysis of the Schiff base to yield the PLP–enzyme and aminoacrylate, (5) nonenzymatic tautomerization to the imine, and (6) nonenzymatic hydrolysis to form pyruvate and ammonia. Threonine undergoes an analogous series of reactions to yield α -ketobutyrate.

substrate undergoes α,β elimination of H₂O rather than deamination (Fig. 21-15). The product of the dehydration, the enamine **aminoacrylate**, tautomerizes non-enzymatically to the corresponding imine, which spontaneously hydrolyzes to pyruvate and ammonia.

Cysteine can be converted to pyruvate via several routes in which the sulfhydryl group is released as H₂S, SO₃²⁻, or SCN⁻.

Glycine is converted to pyruvate by first being converted to serine by the enzyme **serine hydroxymethyltransferase**, another PLP-containing enzyme (Fig. 21-14, Reaction 4). This enzyme uses *N*⁵,*N*¹⁰-**methylenetetrahydrofolate** (*N*⁵,*N*¹⁰-**methylene-THF**) as a one-carbon donor (the structure and chemistry of THF cofactors are described in Section 21-4D). The methylene group of the THF cofactor is obtained from a second glycine in Reaction 3 of Fig. 21-14, which is catalyzed by the **glycine cleavage system** (called the **glycine decarboxylase multienzyme system** in plants). This enzyme is a multiprotein complex that resembles pyruvate dehydrogenase (Section 17-2). The glycine cleavage system mediates the major route of glycine degradation in mammalian tissues. An inherited deficiency of the glycine cleavage system causes the disease **nonketotic hyperglycinemia**, which is characterized by mental retardation and accumulation of large amounts of glycine in body fluids.

In mammals other than humans, threonine's major route of breakdown is through **threonine dehydrogenase** (Fig. 21-14, Reaction 6), producing **α -amino- β -ketobutyrate**, which is converted to acetyl-CoA and glycine by **α -amino- β -ketobutyrate lyase** (Fig. 21-14, Reaction 7). The glycine can be converted, through serine, to pyruvate as described above. Thus, threonine is both glucogenic and ketogenic.

Serine Hydroxymethyltransferase Catalyzes PLP-Dependent C _{α} –C _{β} Bond Formation and Cleavage. Threonine can also be converted directly to glycine and acetaldehyde (which is subsequently oxidized to acetyl-CoA) via Reaction 5 of Fig. 21-14, which breaks threonine's C _{α} –C _{β} bond. This PLP-dependent reaction is catalyzed by serine hydroxymethyltransferase, the same enzyme that adds a hydroxymethyl group to glycine to produce serine (Fig. 21-14, Reaction 4). In the glycine → serine reaction, the amino acid's C _{α} –H bond is cleaved (as occurs

FIG. 21-16 The π -orbital framework of a PLP–amino acid Schiff base. The bond from X to C_α is in a plane perpendicular to the plane of the PLP π -orbital system (*top*) and is therefore labile. The broken bond's electron pair (*bottom*) is delocalized over the conjugated molecule.

in transamination; Fig. 21-8) and a C_α – C_β bond is formed. In contrast, the degradation of threonine to glycine by serine hydroxymethyltransferase acts in reverse, beginning with C_α – C_β bond cleavage (*at left*).

With the cleavage of any of the bonds to C_α , the PLP group delocalizes the electrons of the resulting carbanion. This feature of PLP action is the key to understanding how the same amino acid–PLP Schiff base can undergo cleavage of different bonds to C_α in different enzymes (bonds *a*, *b*, or *c* in the upper right of Fig. 21-8). The bond that is cleaved is the one that lies in the plane perpendicular to that of the π -orbital system of the PLP (Fig. 21-16). This arrangement allows the PLP π -orbital system to overlap the bonding orbital containing the electron pair being delocalized. Any other geometry would reduce or even eliminate this orbital overlap (the newly formed double bond would be twisted out of planarity) yielding a higher energy arrangement. Different bonds to C_α can be positioned for cleavage by rotation around the C_α –N bond. Evidently, *each enzyme binds its amino acid–PLP Schiff base adduct with the appropriate geometry for bond cleavage*.

B Asparagine and Aspartate Are Degraded to Oxaloacetate

Transamination of aspartate leads directly to oxaloacetate. Asparagine is also converted to oxaloacetate in this manner after its hydrolysis to aspartate by **L-asparaginase**:

Interestingly, L-asparaginase is an effective chemotherapeutic agent in the treatment of cancers that must obtain asparagine from the blood, particularly **acute lymphoblastic leukemia**.

C Arginine, Glutamate, Glutamine, Histidine, and Proline Are Degraded to α -Ketoglutarate

Arginine, glutamine, histidine, and proline are all degraded by conversion to glutamate (Fig. 21-17), which in turn is oxidized to α -ketoglutarate by glutamate dehydrogenase (Section 21-2B). Conversion of glutamine to glutamate involves only one reaction: hydrolysis by **glutaminase**. In the kidney, the action of glutaminase produces ammonia, which combines with a proton to form the ammonium ion (NH_4^+) and is excreted. During metabolic acidosis (Box 2-2), kidney glutaminase helps eliminate excess acid. Although free NH_3 in the blood could serve the same acid-absorbing purpose, ammonia is toxic. It is therefore converted to glutamine by glutamine synthetase in the liver (Section 21-5A). Glutamine therefore acts as an ammonia transport system between the liver, where much of it is synthesized, and the kidneys, where it is hydrolyzed by glutaminase.

FIG. 21-17 The degradation of arginine, glutamate, glutamine, histidine, and proline to α -ketoglutarate. The enzymes catalyzing the reactions are (1) glutamate dehydrogenase, (2) glutaminase, (3) arginase, (4) ornithine- δ -aminotransferase, (5) glutamate-5-semialdehyde dehydrogenase, (6) proline oxidase, (7) spontaneous, (8) histidine

ammonia lyase, (9) urocanate hydratase, (10) imidazolone propionase, and (11) glutamate formiminotransferase.

? Identify the five-carbon "core" in the five amino acids shown here.

Histidines's conversion to glutamate is more complicated: It is nonoxidatively deaminated, then it is hydrated, and its imidazole ring is cleaved to form ***N*-formiminoglutamate**. The formimino group is then transferred to tetrahydrofolate, forming glutamate and ***N*⁵-formiminotetrahydrofolate** (Section 21-4D). Both arginine and proline are converted to glutamate through the intermediate formation of **glutamate-5-semialdehyde**.

D Methionine, Threonine, Isoleucine, and Valine Are Degraded to Succinyl-CoA

Methionine, threonine, isoleucine, and valine have degradative pathways that all yield propionyl-CoA, which is also a product of odd-chain fatty acid degradation. Propionyl-CoA is converted to succinyl-CoA by a series of reactions requiring biotin and coenzyme B₁₂ (Section 20-2E).

Methionine Breakdown Involves Synthesis of *S*-Adenosylmethionine and Cysteine. Methionine degradation (Fig. 21-18) begins with its reaction with ATP to form ***S*-adenosylmethionine (SAM; alternatively AdoMet)**. *This sulfonium ion's highly reactive methyl group makes it an important biological methylating agent.* For instance, SAM is the methyl donor in the synthesis of phosphatidylcholine from phosphatidylethanolamine (Section 20-6A).

Donation of a methyl group from SAM leaves ***S*-adenosylhomocysteine**, which is then hydrolyzed to adenosine and **homocysteine**. The homocysteine can be methylated to re-form methionine via a reaction in which ***N*⁵-methyltetrahydrofolate** (see below) is the methyl donor. Alternatively, the homocysteine can combine with serine to yield **cystathionine**, which subsequently forms cysteine (cysteine biosynthesis) and **α -ketobutyrate**. The α -ketobutyrate continues along the degradative pathway to propionyl-CoA and then succinyl-CoA.

Threonine Is Degraded Mainly to Propionyl-CoA in Humans. The reactions shown in Fig. 21-14 account for only ~20% of threonine breakdown in humans. The remainder, as is indicated in Fig. 21-18, Reaction 11, forms α -ketobutyrate in a reaction catalyzed by serine–threonine dehydratase (Fig. 21-15), and the α -ketobutyrate is converted via propionyl-CoA to succinyl-CoA.

Tetrahydrofolates Are One-Carbon Carriers. Many biosynthetic processes involve the addition of a C₁ unit to a metabolic precursor. In most carboxylation reactions (e.g., pyruvate carboxylase; Fig. 16-18), the enzyme uses a biotin cofactor. In some reactions, *S*-adenosylmethionine (Fig. 21-18) functions as a methylating agent. However, tetrahydrofolate (THF) is more versatile than either of those cofactors because it can transfer C₁ units in several oxidation states.

THF is a 6-methylpterin derivative linked in sequence to a ***p*-aminobenzoic acid** and a Glu residue:

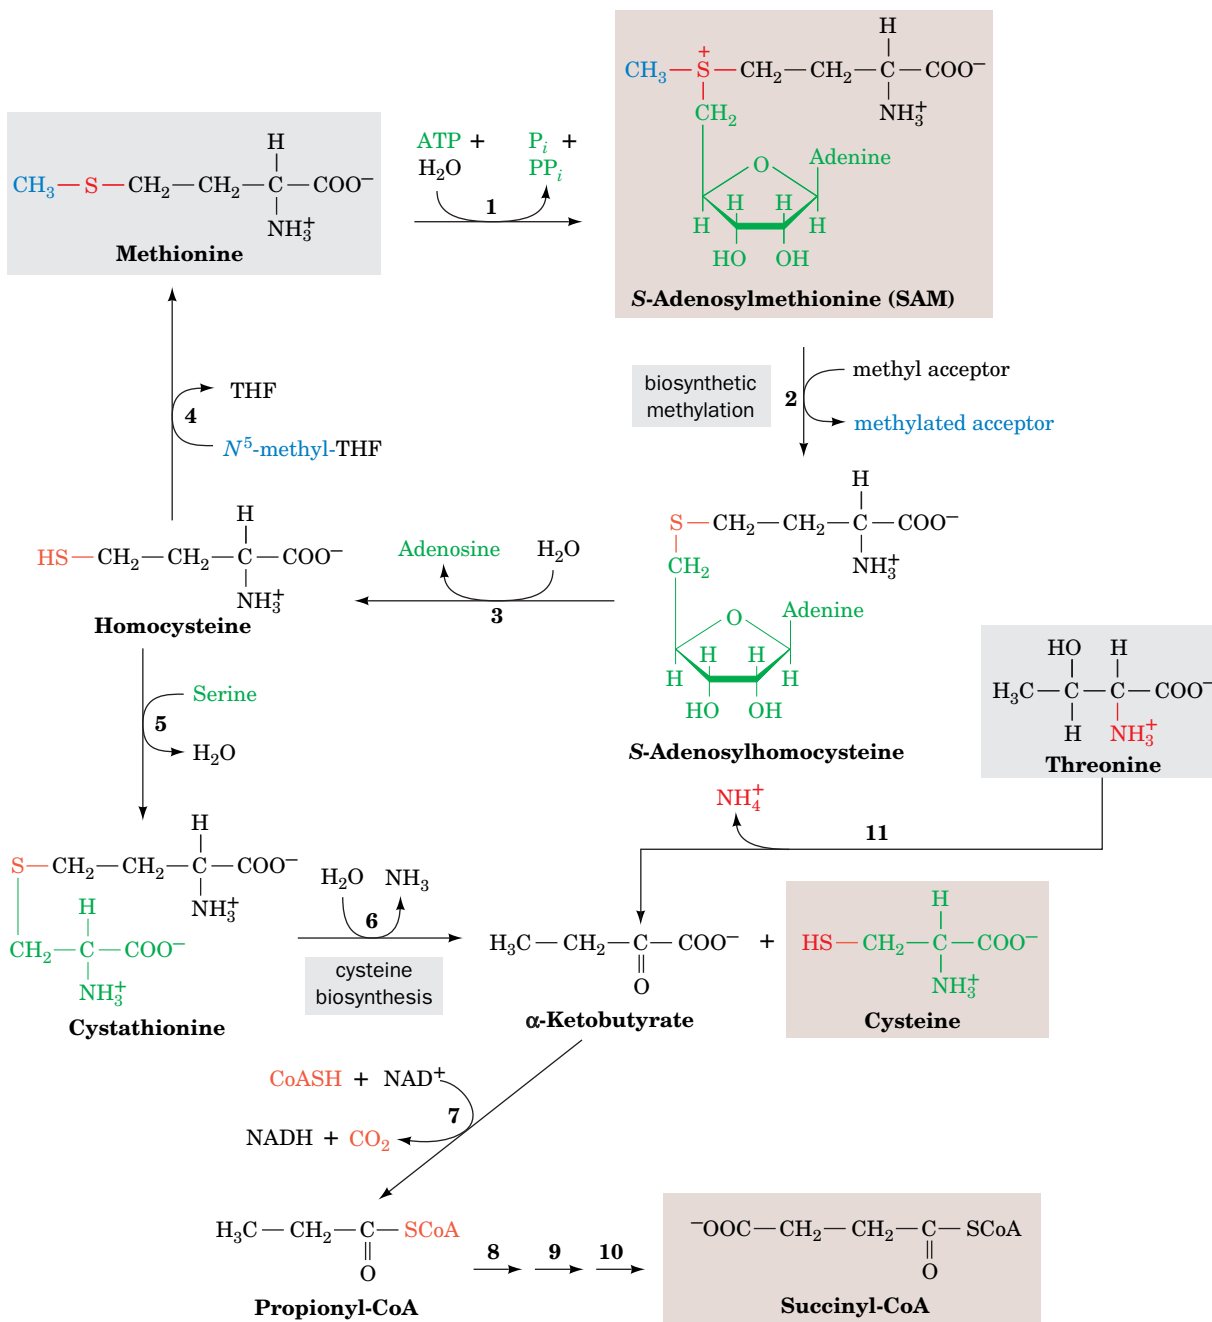

FIG. 21-18 Methionine and threonine degradation. The breakdown of methionine yields cysteine and succinyl-CoA. The enzymes are (1) methionine adenosyltransferase in a reaction that yields the biological methylating agent *S*-adenosylmethionine (SAM), (2) methyltransferase, (3) adenosylhomocysteinase, (4) methionine synthase (a coenzyme B₁₂-dependent enzyme), (5) cystathionine

β-synthase (a PLP-dependent enzyme), (6) cystathionine γ-lyase, (7) α-keto acid dehydrogenase, (8) propionyl-CoA carboxylase, (9) methylmalonyl-CoA racemase, and (10) methylmalonyl-CoA mutase (a coenzyme B₁₂-dependent enzyme). Reactions 8–10 are discussed in Section 20-2E. Threonine is converted to α-ketobutyrate by (11) serine-threonine dehydratase.

Up to five additional Glu residues are linked to the first glutamate via isopeptide bonds to form a polyglutamyl tail. THF is derived from the vitamin **foliac acid** (Latin: *folium*, leaf), a doubly oxidized form of THF that must be enzymatically reduced before it becomes an active coenzyme (Fig. 21-19). Both reductions are catalyzed by **dihydrofolate reductase (DHFR)**. Mammals cannot synthesize folic acid, so it must be provided in the diet or by intestinal microorganisms. Folate is sensitive to light, which suggests that dark skin pigmentation, especially in equatorial regions where sunlight is most intense, is an adaptation for

FIG. 21-19 The two-stage reduction of folate to THF. Both reactions are catalyzed by dihydrofolate reductase.

maintaining the necessary level of the coenzyme, as well as preventing vitamin D intoxication (Section 9-1E).

C₁ units are covalently attached to THF at positions N5, N10, or both N5 and N10. These C₁ units, which may be at the oxidation levels of formate, formaldehyde, or methanol (Table 21-2), are all interconvertible by enzymatic redox reactions (Fig. 21-20).

THF acquires C₁ units in the conversion of serine to glycine by serine hydroxymethyltransferase (the reverse of Reaction 4, Fig. 21-14), in the cleavage of glycine (Fig. 21-14, Reaction 3), and in histidine breakdown (Fig. 21-17, Reaction 11). The C₁ units carried by THF are used in the synthesis of thymine nucleotides (Section 23-3B) and in the synthesis of methionine from homocysteine (Fig. 21-18, Reaction 4). By promoting the latter process, supplemental folate helps prevent diseases associated with abnormally high levels of homocysteine (Box 21-1).

Sulfonamides
(R = H, sulfanilamide)

p-Aminobenzoic acid

Sulfonamides (sulfa drugs) such as **sulfanilamide** are antibiotics that are structural analogs of the *p*-aminobenzoic acid constituent of THF (at left). They competitively inhibit bacterial synthesis of THF at the *p*-aminobenzoic acid incorporation step, thereby blocking THF-requiring reactions. The inability of mammals to synthesize folic acid leaves them unaffected by sulfonamides, which accounts for the medical utility of these widely used antibacterial agents.

Box 21-1 Biochemistry in Health and Disease Homocysteine, a Marker of Disease

The cellular level of homocysteine depends on its rate of synthesis through methylation reactions utilizing SAM (Fig. 21-18, Reactions 2 and 3) and its rate of utilization through remethylation to form methionine (Fig. 21-18, Reaction 4) and reaction with serine to form cystathionine in the cysteine biosynthetic pathway (Fig. 21-18, Reaction 5). An increase in homocysteine levels leads to **hyperhomocysteinemia**, elevated concentrations of homocysteine in the blood, which is associated with cardiovascular disease. The link was first discovered in individuals with **homocysteinuria**, a disorder in which excess homocysteine is excreted in the urine. These individuals develop atherosclerosis as children, possibly because homocysteine causes oxidative damage to the walls of blood vessels even in the absence of elevated LDL levels (Section 20-7C).

Hyperhomocysteinemia is also associated with **neural tube defects**, the cause of a variety of severe birth defects including **spina bifida** (defects in the spinal column that often result in paralysis) and **anencephaly** (the invariably fatal failure of the brain to develop, which is the leading cause of infant death due to congenital anomalies). Hyperhomocysteinemia is readily controlled by ingesting the vitamin precursors of the coenzymes that participate in homocysteine breakdown, namely, B₆ (pyridoxine, the PLP precursor; Fig. 21-7),

B₁₂ (Fig. 20-17), and folate (Section 21-4D). Folate, especially, alleviates hyperhomocysteinemia; its administration to pregnant women dramatically reduces the incidence of neural tube defects in newborns. Because neural tube development is one of the earliest steps of embryogenesis, women of childbearing age are encouraged to consume adequate amounts of folate even before they become pregnant. Despite the foregoing, clinical trials indicate that vitamin therapy in individuals with hyperhomocysteinemia does not reduce their incidence of cardiovascular disease.

Around 10% of the population is homozygous for an Ala → Val mutation in **N⁵,N¹⁰-methylene tetrahydrofolate reductase (MTHFR)**, which catalyzes the conversion of N⁵,N¹⁰-methylene-THF to N⁵-methyl-THF (Fig. 21-20, top center). This reaction generates the N⁵-methyl-THF required to convert homocysteine to methionine (Fig. 21-18, Reaction 4). The mutation does not affect the enzyme's reaction kinetics but instead increases the rate at which its essential flavin cofactor dissociates. Folate derivatives that bind to the enzyme decrease the rate of flavin loss, thus increasing the enzyme's overall activity and decreasing the homocysteine concentration. The prevalence of the MTHFR mutation in the human population suggests that it has (or once had) some selective advantage; however, this is as yet a matter of speculation.

TABLE 21-2 Oxidation Levels of C₁ Groups Carried by THF

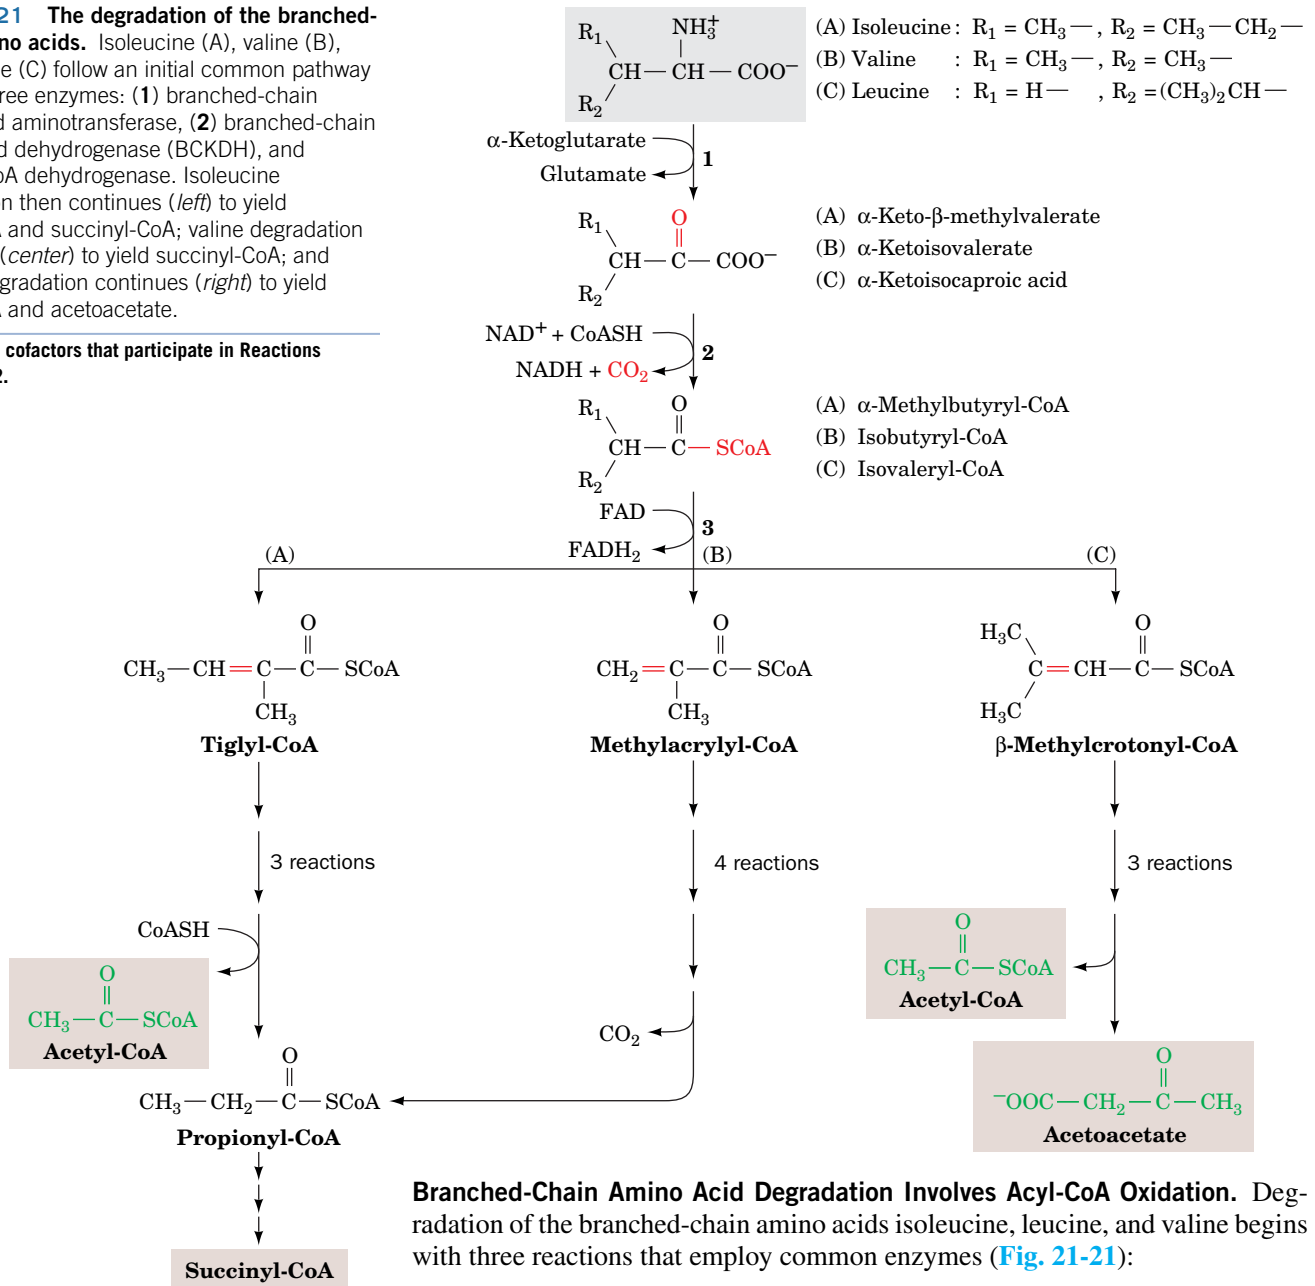

Oxidation Level	Groups Carried	THF Derivative(s)
Methanol	Methyl (—CH ₃)	N ⁵ -Methyl-THF
Formaldehyde	Methylene (—CH ₂ —)	N ⁵ , N ¹⁰ -Methylene-THF
Formate	Formyl (—CH=O)	N ⁵ -Formyl-THF, N ¹⁰ -formyl-THF
	Formimino (—CH=NH)	N ⁵ -Formimino-THF
	Methenyl (—CH=)	N ⁵ , N ¹⁰ -Methenyl-THF

FIG. 21-20 Interconversion of the C₁ units carried by THF.

? Identify the oxidation state of each C₁ group.

FIG. 21-21 The degradation of the branched-chain amino acids. Isoleucine (A), valine (B), and leucine (C) follow an initial common pathway utilizing three enzymes: (1) branched-chain amino acid aminotransferase, (2) branched-chain α -keto acid dehydrogenase (BCKDH), and (3) acyl-CoA dehydrogenase. Isoleucine degradation then continues (*left*) to yield acetyl-CoA and succinyl-CoA; valine degradation continues (*center*) to yield succinyl-CoA; and leucine degradation continues (*right*) to yield acetyl-CoA and acetoacetate.

? List the cofactors that participate in Reactions 1 and 2.

Branched-Chain Amino Acid Degradation Involves Acyl-CoA Oxidation. Degradation of the branched-chain amino acids isoleucine, leucine, and valine begins with three reactions that employ common enzymes (Fig. 21-21):

1. Transamination to the corresponding α -keto acid.
2. Oxidative decarboxylation to the corresponding acyl-CoA.
3. Dehydrogenation by FAD to form a double bond.

The remaining reactions of the isoleucine degradation pathway are analogous to those of fatty acid oxidation (Section 20-2C), thereby yielding acetyl-CoA and propionyl-CoA, which is subsequently converted via three reactions to succinyl-CoA. The degradation of valine, which contains one less carbon than isoleucine, yields CO₂ and propionyl-CoA, which is then converted to succinyl-CoA. The further degradation of leucine, which yields acetoacetate instead of propionyl-CoA, is considered in Section 21-4E.

Branched-chain α -keto acid dehydrogenase (BCKDH), which catalyzes Reaction 2 of Fig. 21-21, is a multienzyme complex that closely resembles the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes (Sections 17-2 and 17-3D). Indeed, all three multienzyme complexes share a common subunit, E3 (dihydrolipoamide dehydrogenase), and employ the coenzymes TPP, lipoamide, and FAD in addition to their terminal oxidizing agent, NAD⁺.

A genetic deficiency in BCKDH causes **maple syrup urine disease**, so named because the consequent buildup of branched-chain α -keto acids imparts the

urine with the characteristic odor of maple syrup. Unless promptly treated by a diet low in branched-chain amino acids, maple syrup urine disease is rapidly fatal.

E Leucine and Lysine Are Degraded Only to Acetyl-CoA and/or Acetoacetate

Leucine degradation begins in the same manner as isoleucine and valine degradation (Fig. 21-21), but the dehydrogenated CoA adduct β -methylcrotonyl-CoA is converted to acetyl-CoA and acetoacetate, a ketone body.

The predominant pathway for lysine degradation in mammalian liver produces acetoacetate and 2 CO₂ via the initial formation of the α -ketoglutarate-lysine adduct **saccharopine** (Fig. 21-22). This pathway is worth examining in

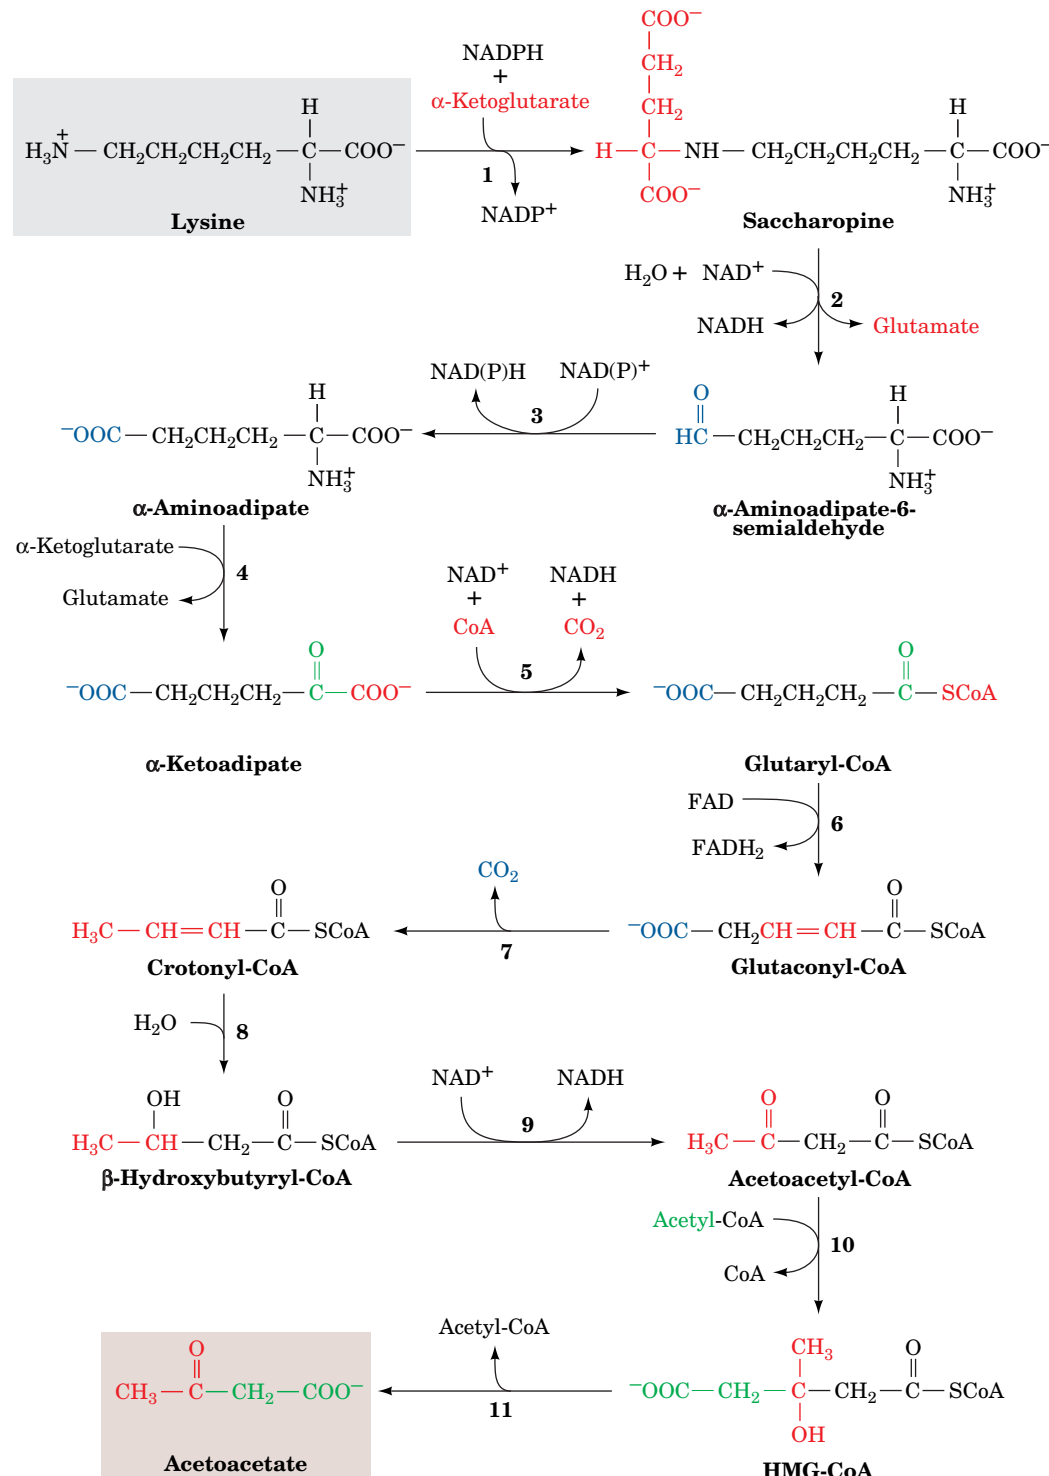

FIG. 21-22 The pathway of lysine degradation in mammalian liver. The enzymes are (1) saccharopine dehydrogenase (NADP⁺, lysine forming), (2) saccharopine dehydrogenase (NAD⁺, glutamate forming), (3) amino adipate semialdehyde dehydrogenase, (4) amino adipate aminotransferase (a PLP-dependent enzyme), (5) α -keto acid dehydrogenase, (6) glutaryl-CoA dehydrogenase, (7) decarboxylase, (8) enoyl-CoA hydratase, (9) β -hydroxyacyl-CoA dehydrogenase, (10) HMG-CoA synthase, and (11) HMG-CoA lyase. Reactions 10 and 11 are discussed in Section 20-3.

? Identify the reactions that resemble those of fatty acid oxidation and ketogenesis.

detail because we have encountered 7 of its 11 reactions in other pathways. Reaction 4 is a PLP-dependent transamination. Reaction 5 is the oxidative decarboxylation of an α -keto acid by a multienzyme complex similar to pyruvate dehydrogenase (Section 17-2). Reactions 6, 8, and 9 are standard reactions of fatty acyl-CoA oxidation: dehydrogenation by FAD, hydration, and dehydrogenation by NAD^+ . Reactions 10 and 11 are standard reactions in ketone body formation. Two moles of CO_2 are produced at Reactions 5 and 7 of the pathway.

The saccharopine pathway is thought to predominate in mammals because a genetic defect in the enzyme that catalyzes Reaction 1 in the sequence results in **hyperlysinemia** and **hyperlysinuria** (elevated levels of lysine in the blood and urine, respectively) along with mental and physical retardation. This is yet another example of how the study of rare inherited disorders has helped to trace metabolic pathways.

F Tryptophan Is Degraded to Alanine and Acetoacetate

The complexity of the major tryptophan degradation pathway (outlined in Fig. 21-23) precludes a detailed discussion of all its reactions. However, one reaction is of particular interest: The fourth reaction is catalyzed by **kynureninase**, whose PLP group facilitates cleavage of the C_β — C_γ bond to release alanine. The kynureninase reaction follows the same initial steps as transamination (Fig. 21-8), but an enzyme nucleophilic group then attacks C_γ of the resonance-stabilized intermediate, resulting in C_β — C_γ bond cleavage. The remainder of the tryptophan skeleton is converted in five reactions to α -ketoacidipate, which is also an intermediate in lysine degradation. α -Ketoacidipate is broken down to 2 CO_2 and acetoacetate in seven reactions, as shown in Fig. 21-22.

FIG. 21-23 The pathway of tryptophan degradation. The enzymatic reactions shown are (1) tryptophan-2,3-dioxygenase, (2) formamidase, (3) kynurenine-3-monooxygenase, and (4) kynureninase (a PLP-dependent enzyme). Five reactions convert 3-hydroxyanthranilate

to α -ketoacidipate, which is converted to acetyl-CoA and acetoacetate in seven reactions as shown in Fig. 21-22, Reactions 5–11.

? What is the metabolic fate of acetoacetate?

G Phenylalanine and Tyrosine Are Degraded to Fumarate and Acetoacetate

Since the first reaction in phenylalanine degradation is its hydroxylation to tyrosine, a single pathway (Fig. 21-24) is responsible for the breakdown of both amino acids. The final products of the six-reaction degradation are fumarate, a citric acid cycle intermediate, and acetoacetate, a ketone body. Defects in the enzymes that catalyze Reactions 1 and 4 cause disease (Box 21-2).

Pterins Are Redox Cofactors. The hydroxylation of phenylalanine by the Fe(III)-containing enzyme **phenylalanine hydroxylase** (Fig. 21-24, Reaction 1) requires the cofactor **biopterin**, a **pterin** derivative. Pterins are compounds that contain the **pteridine** ring (Fig. 21-25). Note the resemblance between the pteridine ring

FIG. 21-25 The pteridine ring nucleus of biopterin and folate. Note the similar structures of pteridine and the isoalloxazine ring of flavin coenzymes.

Archibald Garrod realized in the early 1900s that human genetic diseases result from specific enzyme deficiencies. We have repeatedly seen how this realization has contributed to the elucidation of metabolic pathways. The first such disease Garrod recognized was **alcaptonuria**, which results in the excretion of large quantities of **homogentisic acid** (Section 14-4). This condition results from deficiency of **homogentisate dioxygenase** (Fig. 21-24, Reaction 4). Alcaptonurics suffer no ill effects other than arthritis later in life (although their urine darkens alarmingly on exposure to air because of the rapid oxidation of the homogentisate they excrete).

Individuals suffering from **phenylketonuria (PKU)** are not so fortunate. Severe mental retardation occurs within a few months of birth if the disease is not detected and treated immediately. PKU is caused by the inability to hydroxylate phenylalanine (Fig. 21-24, Reaction 1) and therefore results in increased blood levels of phenylalanine (**hyperphenylalaninemia**). The excess phenylalanine is transaminated to **phenylpyruvate**

Phenylpyruvate

by an otherwise minor pathway. The “spillover” of phenylpyruvate (a phenylketone) into the urine was the first observation connected with

the disease and gave the disease its name. All babies born in the United States are now screened for PKU immediately after birth by testing for elevated levels of phenylalanine in the blood.

Classical PKU results from a deficiency in phenylalanine hydroxylase. When this was established in 1947, it was the first inborn error of metabolism whose basic biochemical defect had been identified. Since all of the tyrosine breakdown enzymes are normal, treatment consists in providing the patient with a low-phenylalanine diet and monitoring the blood level of phenylalanine to ensure that it remains within normal limits for the first 5 to 10 years of life (the adverse effects of hyperphenylalaninemia seem to disappear after that age). **Aspartame (Nutra-Sweet)**, an often-used sweetening ingredient in diet soft drinks and many other dietetic food products, is Asp-Phe-methyl ester (Box 8-2) and is therefore a source of dietary phenylalanine. Consequently, a warning label for phenylketonurics appears on all those products.

Phenylalanine hydroxylase deficiency also accounts for another common symptom of PKU: its victims have lighter hair and skin color than their siblings. This is because elevated phenylalanine levels inhibit tyrosine hydroxylation (Fig. 21-39), the first reaction in the formation of the skin pigment **melanin**.

Other variants of hyperphenylalaninemia have been discovered since the introduction of infant screening techniques. These are caused by deficiencies in the enzymes catalyzing the formation or regeneration of 5,6,7,8-tetrahydrobiopterin, the phenylalanine hydroxylase cofactor (Fig. 21-26).

CHECKPOINT

- Describe the two general metabolic fates of the carbon skeletons of amino acids.
- List the seven metabolites that represent the end products of amino acid catabolism. Which are glucogenic? Which are ketogenic?
- Which three amino acids are substrates or products of serine hydroxymethyltransferase?
- Describe the roles of the cofactors pyridoxal-5'-phosphate, tetrahydrofolate, and tetrahydrobiopterin in the catabolism of amino acids.

and the isoalloxazine ring of the flavin coenzymes; the positions of the nitrogen atoms in pteridine are identical to those of the B and C rings of isoalloxazine. Folate derivatives also contain the pterin ring (Section 21-4D).

Pterins, like flavins, participate in biological oxidations. The active form of biopterin is the fully reduced form, **5,6,7,8-tetrahydrobiopterin**. It is produced from **7,8-dihydrobiopterin** and NADPH, in what may be considered a priming reaction, by dihydrofolate reductase (Fig. 21-26), which also reduces folate to dihydrofolate and then to tetrahydrofolate (Fig. 21-19). In the phenylalanine hydroxylase reaction, 5,6,7,8-tetrahydrobiopterin is hydroxylated to **pterin-4a-carbinolamine** (Fig. 21-26), which is then converted to 7,8-dihydrobiopterin (**quinoid form**) by **pterin-4a-carbinolamine dehydratase**. This quinoid is subsequently reduced by the NAD(P)H-requiring enzyme **dihydropteridine reductase** to regenerate the active cofactor. Although dihydrofolate reductase and dihydropteridine reductase produce the same product, they use different tautomers of the substrate.

5 Amino Acid Biosynthesis

KEY CONCEPTS

- Some amino acids are synthesized in one or a few steps from common metabolites.
- The essential amino acids are derived mostly from other amino acids and glucose metabolites.

*Many amino acids are synthesized by pathways that are present only in plants and microorganisms. Since mammals must obtain these amino acids in their diets, these substances are known as **essential amino acids**. The other amino*

FIG. 21-26 The formation, utilization, and regeneration of 5,6,7,8-tetrahydrobiopterin in the phenylalanine hydroxylase reaction.

acids, which can be synthesized by mammals from common intermediates, are termed **nonessential amino acids**. Their α -keto acid carbon skeletons are converted to amino acids by transamination reactions (Section 21-2A) utilizing the preformed α -amino nitrogen of another amino acid, usually glutamate. Although it was originally presumed that glutamate can be synthesized from ammonia and α -ketoglutarate by GDH acting in reverse, it now appears that the predominant physiological direction of this enzyme is glutamate breakdown (Section 21-2B). Consequently, *preformed α -amino nitrogen should also be considered to be an essential nutrient*. In this context, it is interesting to note that, in addition to the four well-known taste receptors, those for sweet, sour, salty, and bitter tastes, a fifth taste receptor has been characterized, that for the meaty taste of **monosodium glutamate (MSG)**, which is known as **umami** (a Japanese name).

The essential and nonessential amino acids for humans are listed in **Table 21-3**. Arginine is classified as essential, even though it is synthesized by the urea cycle (Section 21-3A), because it is required in greater amounts than can be produced by that route during the normal growth and development of children (but not adults). The essential amino acids occur in animal and vegetable proteins. Different proteins, however, contain different proportions of the essential amino acids. Milk proteins, for example, contain them all in the proportions required for proper human nutrition. Bean protein, on the other hand, contains an abundance of lysine but is deficient in methionine, whereas wheat is deficient in lysine but contains ample methionine. A balanced protein diet, therefore, must

TABLE 21-3 Essential and Nonessential Amino Acids in Humans

Essential	Nonessential
Arginine ^a	Alanine
Histidine	Asparagine
Isoleucine	Aspartate
Leucine	Cysteine
Lysine	Glutamate
Methionine	Glutamine
Phenylalanine	Glycine
Threonine	Proline
Tryptophan	Serine
Valine	Tyrosine

^aAlthough mammals synthesize arginine, they cleave most of it to form urea (Section 21-3A).

contain a variety of different protein sources that complement each other to supply the proper amounts of all the essential amino acids.

In this section we study the pathways involved in the formation of the non-essential amino acids. We also briefly consider such pathways for the essential amino acids as they occur in plants and microorganisms. Keep in mind that *there is considerable variation in these pathways among different species. In contrast, the basic pathways of carbohydrate and lipid metabolism are all but universal.*

A Nonessential Amino Acids Are Synthesized from Common Metabolites

All the nonessential amino acids except tyrosine are synthesized by simple pathways leading from one of four common metabolic intermediates: pyruvate, oxaloacetate, α -ketoglutarate, and 3-phosphoglycerate. Tyrosine, which is really misclassified as being nonessential, is synthesized by the one-step hydroxylation of the essential amino acid phenylalanine (Fig. 21-24). Indeed, the dietary requirement for phenylalanine reflects the need for tyrosine as well. The presence of dietary tyrosine therefore decreases the need for phenylalanine.

Alanine, Asparagine, Aspartate, Glutamate, and Glutamine Are Synthesized from Pyruvate, Oxaloacetate, and α -Ketoglutarate. Pyruvate, oxaloacetate, and α -ketoglutarate are the α -keto acids (the so-called carbon skeletons) that correspond to alanine, aspartate, and glutamate, respectively. Indeed, the synthesis of each of the amino acids is a one-step transamination reaction (Fig. 21-27,

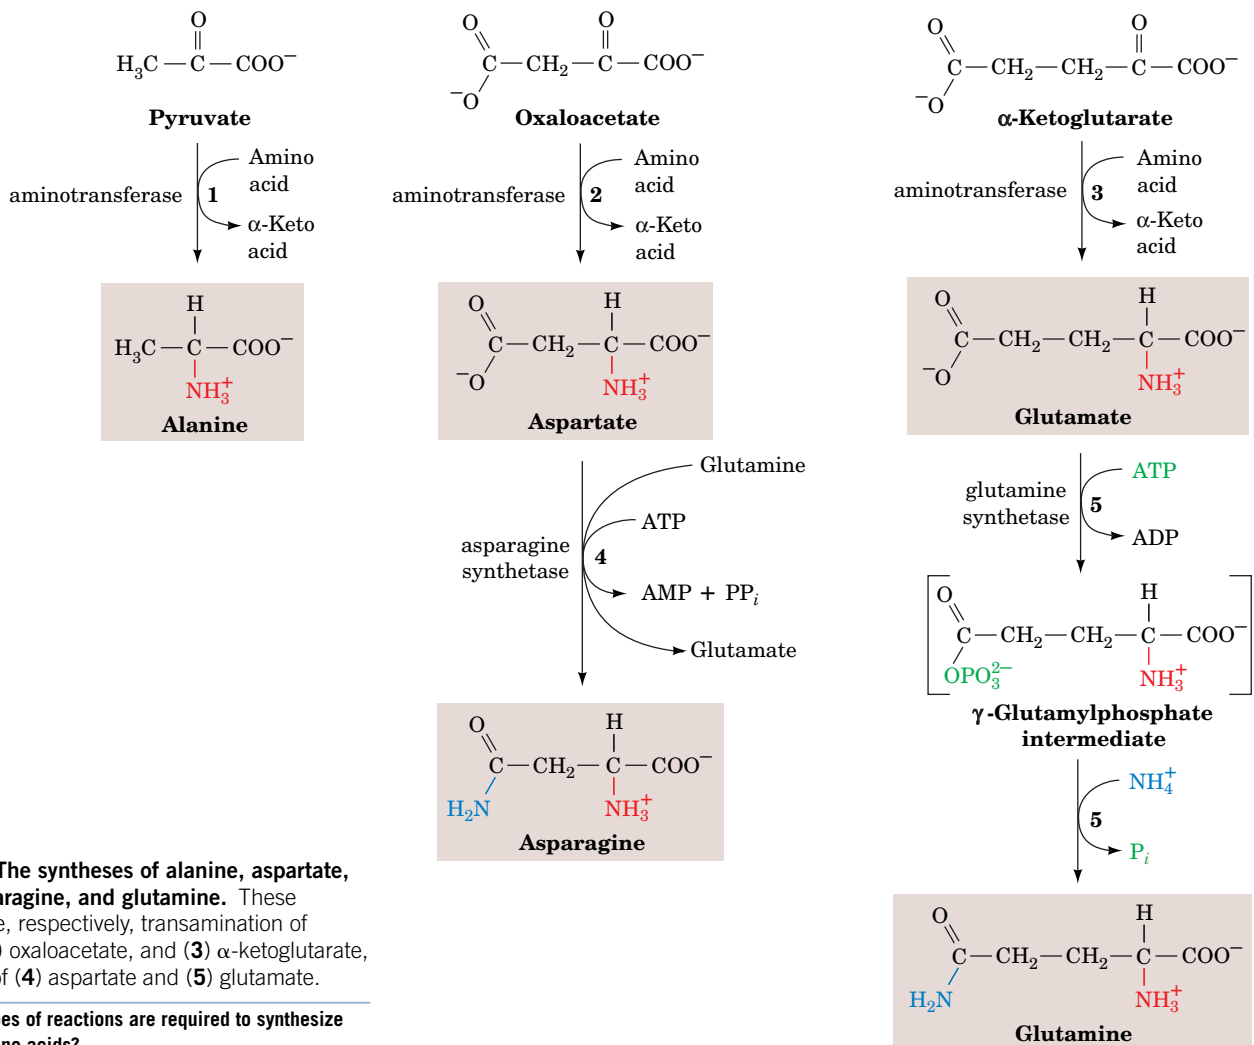

FIG. 21-27 The syntheses of alanine, aspartate, glutamate, asparagine, and glutamine. These reactions involve, respectively, transamination of (1) pyruvate, (2) oxaloacetate, and (3) α -ketoglutarate, and amidation of (4) aspartate and (5) glutamate.

? How many types of reactions are required to synthesize these five amino acids?

Reactions 1–3). The ultimate source of the α -amino group in these transamination reactions is glutamate, which is synthesized in microorganisms, plants, and lower eukaryotes by glutamate synthase (Section 21-7B), an enzyme that is absent in vertebrates.

Asparagine and glutamine are, respectively, synthesized from aspartate and glutamate by ATP-dependent amidation. In the **glutamine synthetase** reaction (Fig. 21-27, Reaction 5), glutamate is first activated by reaction with ATP to form a **γ -glutamylphosphate** intermediate. NH_4^+ then displaces the phosphate group to produce glutamine. Curiously, aspartate amidation by **asparagine synthetase** to form asparagine follows a different route; it uses glutamine as its amino group donor and cleaves ATP to AMP + PP_i (Fig. 21-27, Reaction 4).

Glutamine Synthetase Is a Central Control Point in Nitrogen Metabolism.

Glutamine is the amino group donor in the formation of many biosynthetic products as well as being a storage form of ammonia. The control of glutamine synthetase is therefore vital for regulating nitrogen metabolism. Mammalian glutamine synthetases are activated by α -ketoglutarate, the product of glutamate's oxidative deamination (Section 21-2B). This control presumably helps prevent the accumulation of the ammonia produced by that reaction.

Bacterial glutamine synthetase, as Earl Stadtman showed, has a much more elaborate control system. The enzyme, which consists of 12 identical 468-residue subunits arranged at the corners of a hexagonal prism (Fig. 21-28), is regulated by several allosteric effectors as well as by covalent modification. Several aspects of its control system bear note. *Nine allosteric feedback inhibitors, each with its own binding site, control the activity of bacterial glutamine synthetase in a cumulative manner.* Six of these effectors—histidine, tryptophan, carbamoyl phosphate (as synthesized by carbamoyl phosphate synthetase), glucosamine-6-phosphate, AMP, and CTP—are all end products of pathways leading from glutamine. The other three—alanine, serine, and glycine—reflect the cell's nitrogen level.

FIG. 21-28 X-Ray structure of glutamine synthetase from the bacterium *Salmonella typhimurium*. The enzyme consists of 12 identical subunits, here drawn in ribbon form, arranged with D_6 symmetry (the symmetry of a hexagonal prism). (a) View along the sixfold axis of symmetry showing only the six subunits of the upper ring in different colors, with the lower right subunit colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The subunits of the lower ring are roughly directly below those of the upper ring. A pair of Mn^{2+} ions (*purple spheres*) that occupy the positions of the Mg^{2+} ions

required for enzymatic activity are bound in each active site. The ADP bound to each active site is drawn in stick form with C green, N blue, O red, and P orange. (b) View along one of the protein's twofold axes (rotated 90° about the horizontal axis with respect to Part a) showing only the eight subunits nearest the viewer. The sixfold axis is vertical in this view. [Based on an X-ray structure by David Eisenberg, UCLA. PDBid 1F52.]

? Why is it important for glutamine synthetase to be a multisubunit enzyme?

E. coli glutamine synthetase is covalently modified by **adenylation** (addition of an AMP group) of a specific Tyr residue (Fig. 21-29). The enzyme's susceptibility to cumulative feedback inhibition increases, and its activity therefore decreases, with its degree of adenylation. The level of adenylation is controlled by a complex metabolic cascade that is conceptually similar to that controlling glycogen phosphorylase (Section 16-3B). Both adenylation and deadenylation of glutamine synthetase are catalyzed by **adenyltransferase** in complex with a tetrameric regulatory protein, P_{II} . This complex deadenylates glutamine synthetase when P_{II} is **uridylylated** (also at a Tyr residue) and adenylylates glutamine synthetase when P_{II} lacks UMP residues. The level of P_{II} uridylylation, in turn, depends on the relative levels of two enzymatic activities located on the same protein: a **uridylyltransferase** that uridylylates P_{II} and a

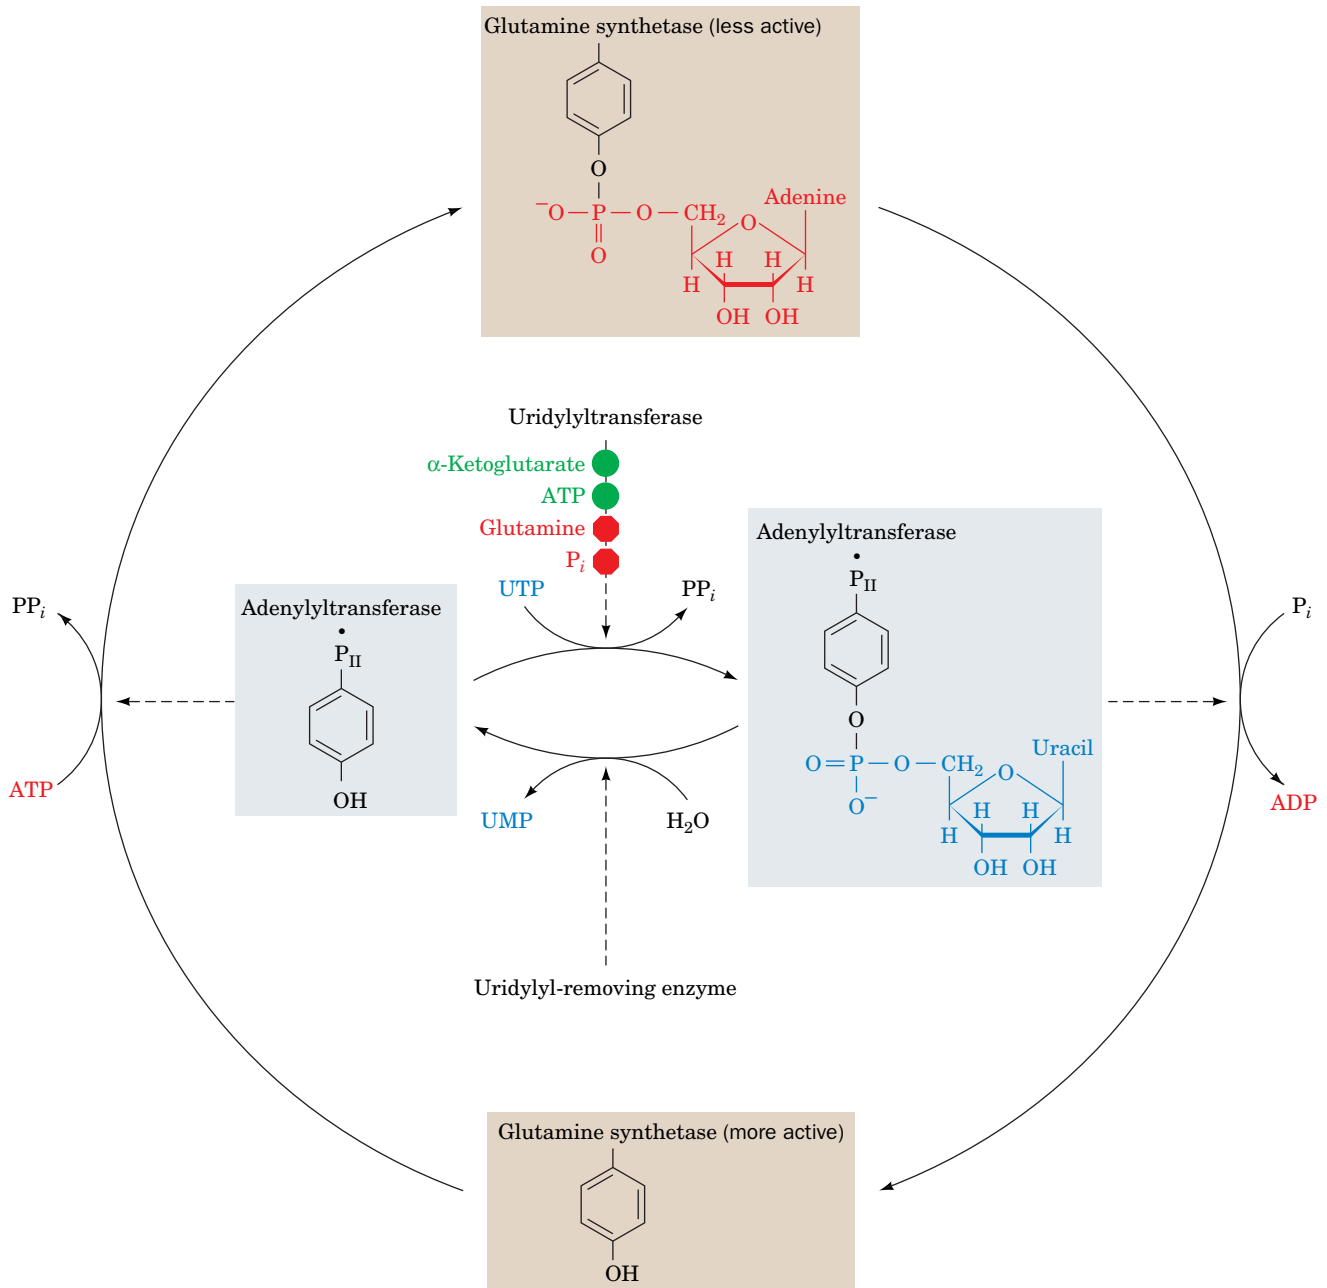

FIG. 21-29 The regulation of bacterial glutamine synthetase. The adenylation/deadenylation of a specific Tyr residue is controlled by the level of uridylylation of a specific adenylyltransferase $\cdot P_{II}$ Tyr residue. This uridylylation level, in turn, is controlled by the relative

activities of uridylyltransferase, which is sensitive to the levels of a variety of nitrogen metabolites, and uridylyl-removing enzyme, whose activity is independent of those metabolite levels.

uridylyl-removing enzyme that hydrolytically excises the attached UMP groups of P_{II} . The uridylyltransferase is activated by α -ketoglutarate and ATP and inhibited by glutamine and P_i , whereas uridylyl-removing enzyme is insensitive to those metabolites. This intricate metabolic cascade therefore renders the activity of *E. coli* glutamine synthetase extremely responsive to the cell's nitrogen requirements.

Glutamate Is the Precursor of Proline, Ornithine, and Arginine. Conversion of glutamate to proline (Fig. 21-30, Reactions 1–4) involves the reduction of the γ -carboxyl group to an aldehyde followed by the formation of an internal Schiff base whose further reduction yields proline. Reduction of the glutamate γ -carboxyl group to an aldehyde is an endergonic process that is facilitated by first phosphorylating the carboxyl group in a reaction catalyzed by **γ -glutamyl kinase**. The unstable product, **glutamate-5-phosphate**, has not been isolated from reaction mixtures but is presumed to be the substrate for the reduction that follows. The resulting **glutamate-5-semialdehyde** (which is also a product of arginine and proline degradation; Fig. 21-17) cyclizes spontaneously to form the

FIG. 21-30 The biosynthesis of the glutamate family of amino acids: arginine, ornithine, and proline. The catalysts for proline biosynthesis are (1) γ -glutamyl kinase, (2) dehydrogenase, (3) nonenzymatic, and (4) pyrroline-5-carboxylate reductase. In mammals, ornithine is produced from glutamate-5-semialdehyde by the action of

ornithine- δ -aminotransferase (5). Ornithine is converted to arginine via the urea cycle (Section 21-3A).

? What are the sources of free energy for these biosynthetic reactions?

FIG. 21-31 The conversion of 3-phosphoglycerate to serine. The pathway enzymes are (1) 3-phosphoglycerate dehydrogenase, (2) a PLP-dependent aminotransferase, and (3) phosphoserine phosphatase.

internal Schiff base Δ^1 -pyrroline-5-carboxylate. The final reduction to proline is catalyzed by **pyrroline-5-carboxylate reductase**. Whether the enzyme requires NADH or NADPH is unclear.

In humans, a three-step pathway leads from glutamate to ornithine via a branch from proline biosynthesis after Step 2 (Fig. 21-30). Glutamate-5-semialdehyde, which is in equilibrium with Δ^1 -pyrroline-5-carboxylate, is directly transaminated to yield ornithine in a reaction catalyzed by **ornithine- δ -amino transferase** (Fig. 21-30, Reaction 5). Ornithine is converted to arginine by the reactions of the urea cycle (Fig. 21-9).

Serine, Cysteine, and Glycine Are Derived from 3-Phosphoglycerate. Serine is formed from the glycolytic intermediate 3-phosphoglycerate in a three-reaction pathway (Fig. 21-31):

1. Conversion of 3-phosphoglycerate's 2-OH group to a ketone, yielding **3-phosphohydroxypyruvate**, serine's phosphorylated keto acid analog.
2. Transamination of 3-phosphohydroxypyruvate to phosphoserine.
3. Hydrolysis of phosphoserine to serine.

Serine participates in glycine synthesis in two ways:

1. Direct conversion of serine to glycine by serine hydroxymethyltransferase in a reaction that also yields N^5, N^{10} -methylene-THF (Fig. 21-14, Reaction 4 in reverse).
2. Condensation of the N^5, N^{10} -methylene-THF with CO_2 and NH_4^+ by glycine synthase (Fig. 21-14, Reaction 3 in reverse).

In animals, cysteine is synthesized from serine and homocysteine, a breakdown product of methionine (Fig. 21-18, Reactions 5 and 6). Homocysteine combines with serine to yield cystathionine, which subsequently forms cysteine and α -ketobutyrate. Since cysteine's sulfhydryl group is derived from the essential amino acid methionine, cysteine can be considered to be an essential amino acid.

B Plants and Microorganisms Synthesize the Essential Amino Acids

Essential amino acids, like nonessential amino acids, are synthesized from familiar metabolic precursors. Their synthetic pathways are present only in microorganisms and plants, however, and usually involve more steps than those of the nonessential amino acids. The enzymes that synthesize essential amino acids were apparently lost early in animal evolution, possibly because of the ready availability of these amino acids in the diet. We will focus on only a few of the many reactions in the biosynthesis of essential amino acids.

Lysine, Methionine, and Threonine Are Synthesized from Aspartate. In bacteria, aspartate is the common precursor of lysine, methionine, and threonine (Fig. 21-32). The biosyntheses of these essential amino acids all begin with the

FIG. 21-32 The biosynthesis of the aspartate family of amino acids: lysine, methionine, and threonine. The pathway enzymes shown are (1) aspartokinase, (2) β-aspartate semialdehyde dehydrogenase, (3) homoserine dehydrogenase, and (4) methionine synthase (a coenzyme B₁₂-dependent enzyme).

aspartokinase-catalyzed phosphorylation of aspartate to yield **aspartyl-β-phosphate**. We have seen that the control of metabolic pathways commonly occurs at the first committed step of the pathway. One might therefore expect lysine, methionine, and threonine biosynthesis to be controlled as a group. Each of these pathways is, in fact, independently controlled. *E. coli* has three isozymes of aspartokinase that respond differently to the three amino acids in terms both of feedback inhibition of enzyme activity and repression of enzyme synthesis. In addition, the pathway direction is controlled by feedback inhibition at the branch points by the amino acid products of the branches.

Methionine synthase (alternatively, **homocysteine methyltransferase**) catalyzes the methylation of homocysteine to form methionine using N⁵-methyl-THF as its methyl group donor (Reaction 4 in both Figs. 21-18 and 21-32). Methionine synthase is the only coenzyme B₁₂-associated enzyme in mammals besides methylmalonyl-CoA mutase (Section 20-2E). However, the coenzyme B₁₂'s Co ion in methionine synthase is axially liganded by a methyl group to form **methylcobalamin** rather than by a 5'-adenosyl group as in

methylmalonyl-CoA mutase (Fig. 20-17). In mammals, the primary function of methionine synthase is not *de novo* methionine synthesis, as Met is an essential amino acid. Instead, it functions in the cyclic synthesis of SAM for use in biological methylations (Fig. 21-18).

Leucine, Isoleucine, and Valine Are Derived from Pyruvate. Valine and isoleucine follow the same biosynthetic pathway utilizing pyruvate as a starting reactant, the only difference being in the first step of the series (Fig. 21-33). In this thiamine pyrophosphate-dependent reaction, which resembles those catalyzed by pyruvate decarboxylase (Fig. 15-20) and transketolase (Fig. 15-32), pyruvate forms an adduct with TPP that is decarboxylated to hydroxyethyl-TPP. This resonance-stabilized carbanion adds either to the keto group of a second pyruvate to form **acetolactate** on the way to valine, or to the keto group of **α -ketobutyrate** to form **α -aceto- α -hydroxybutyrate** on the way to isoleucine. The leucine biosynthetic pathway branches off from the valine pathway. The final step in each of the three pathways, which begin with pyruvate rather than an amino acid, is the

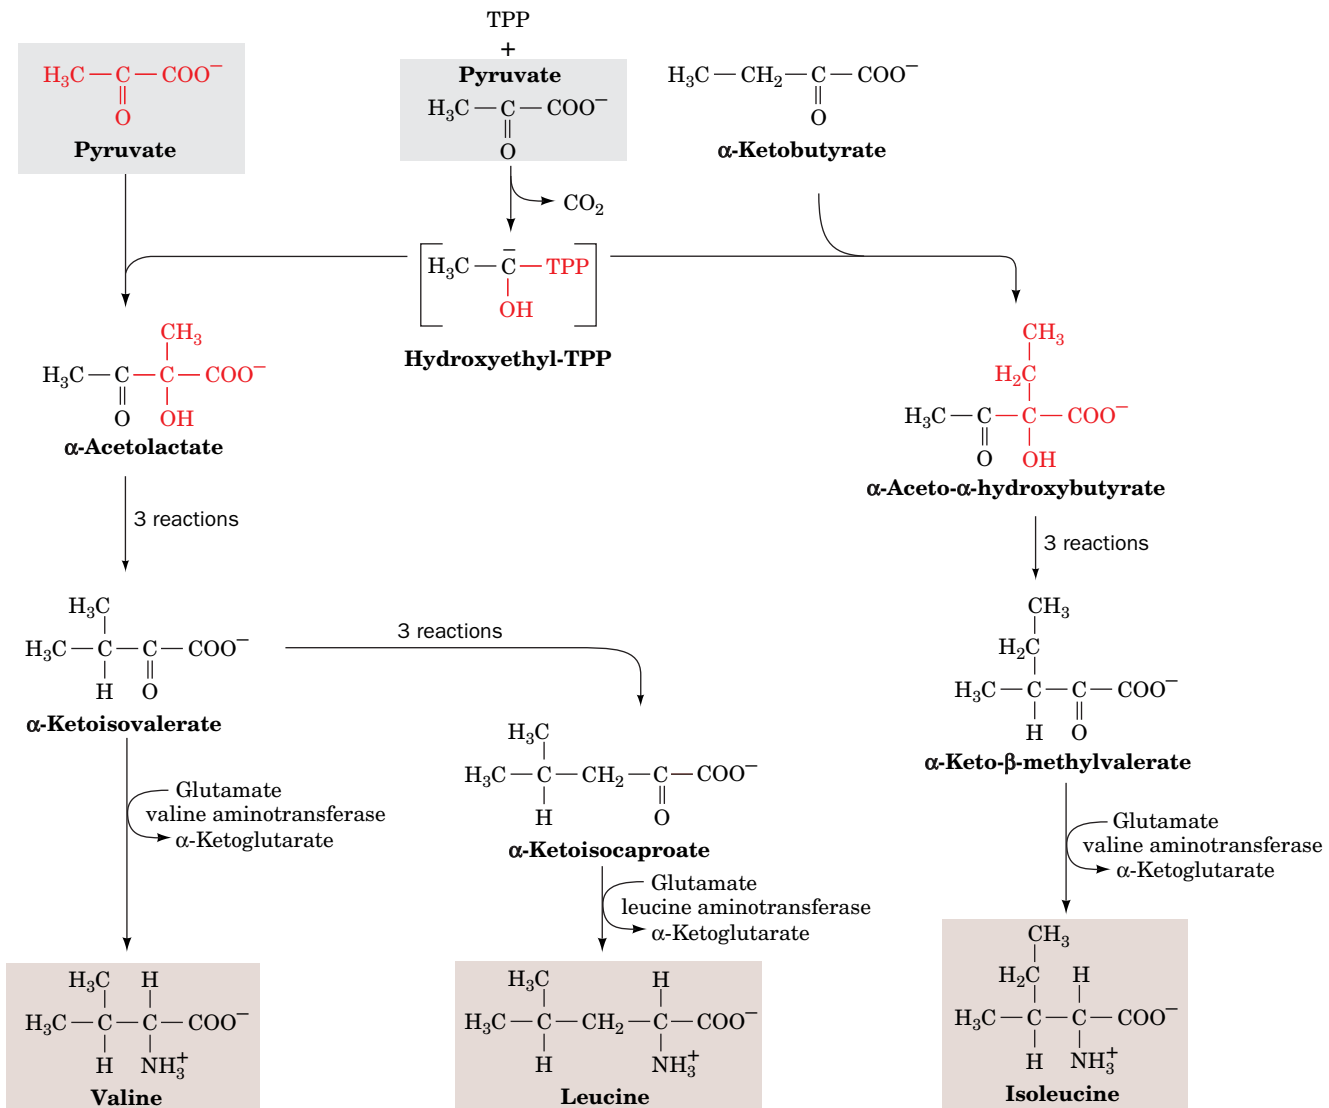

FIG. 21-33 The biosynthesis of the pyruvate family of amino acids: isoleucine, leucine, and valine. The first enzyme, **acetolactate synthase** (a TPP enzyme), catalyzes two reactions, one leading to valine

and leucine, and the other to isoleucine. Note also that **valine aminotransferase** catalyzes the formation of both valine and isoleucine from their respective α -keto acids.

PLP-dependent transfer of an amino group from glutamate to form the amino acid.

The Aromatic Amino Acids Phenylalanine, Tyrosine, and Tryptophan Are Synthesized from Glucose Derivatives. The precursors of the aromatic amino acids are the glycolytic intermediate phosphoenolpyruvate (PEP) and erythrose-4-phosphate (an intermediate in the pentose phosphate pathway; Fig. 15-30). Their condensation forms **2-keto-3-deoxy-D-arabinoheptulosonate-7-phosphate** (Fig. 21-34). This C₇ compound cyclizes and is ultimately converted to **chorismate**, the branch point for tryptophan synthesis. Chorismate is converted to either **anthranilate** and then to tryptophan, or to **prephenate** and on to tyrosine or phenylalanine. Although mammals synthesize tyrosine by the hydroxylation of phenylalanine (Fig. 21-24), many microorganisms synthesize it directly from prephenate. The last step in the synthesis of tyrosine and phenylalanine is the addition of an amino group through transamination. In tryptophan synthesis, the amino group is part of the serine molecule that is added to **indole**.

FIG. 21-34 The biosynthesis of phenylalanine, tryptophan, and tyrosine. The enzymes shown are (1) 2-keto-3-deoxy-D-arabinoheptulosonate-7-phosphate synthase, (2) anthranilate synthase, (3) tryptophan synthase, α subunit, (4) tryptophan synthase, β subunit (a PLP-dependent enzyme), and (5) chorismate mutase.

Indole Is Channeled between Two Active Sites in Tryptophan Synthase. The final two reactions of tryptophan biosynthesis (Reactions 3 and 4 in Fig. 21-34) are both catalyzed by **tryptophan synthase**:

1. The α subunit (268 residues) of the $\alpha_2\beta_2$ bifunctional enzyme cleaves **indole-3-glycerol phosphate**, yielding indole and glyceraldehyde-3-phosphate.
2. The β subunit (396 residues) joins indole with serine in a PLP-dependent reaction to form tryptophan.

Either subunit alone is enzymatically active, but when they are joined in the $\alpha_2\beta_2$ tetramer, the rates of both reactions and their substrate affinities increase by 1 to 2 orders of magnitude. Indole, the intermediate product, does not appear free in solution because it is channeled between the two subunits.

The X-ray structure of tryptophan synthase from *Salmonella typhimurium*, determined by Craig Hyde, Edith Miles, and David Davies, reveals that the protein forms a 150-Å-long, twofold symmetric $\alpha\beta\alpha$ complex in which the active sites of neighboring α and β subunits are separated by ~ 25 Å (Fig. 21-35). The active sites are joined by a solvent-filled tunnel that is wide enough to permit the passage of the intermediate substrate, indole. This structure, the first in which a tunnel connecting two active sites was observed, suggests the following series of events: The indole-3-glycerol phosphate substrate binds to the α subunit through an opening into its active site, its “front door,” and the glyceraldehyde-3-phosphate product leaves via the same route. Similarly, the β subunit active site has a “front door” opening to the solvent through which serine enters and tryptophan leaves. Both active sites also have “back doors” that are connected by the tunnel. The indole intermediate presumably diffuses between the two active sites via the tunnel and hence does not escape to the solvent. Channeling may be particularly important for indole since this nonpolar molecule otherwise can escape the bacterial cell by diffusing through its plasma and outer membranes.

For channeling to increase tryptophan synthase’s catalytic efficiency, (1) its connected active sites must be coupled such that their catalyzed reactions occur in phase, and (2) after substrate has bound to the α subunit, its active site (“front door”) must close off to ensure that the product indole passes through the tunnel (“back door”) to the β subunit rather than escaping into solution. A variety of experimental evidence indicates that this series of events is facilitated through allosteric signals derived from covalent transformations at the β subunit’s active

FIG. 21-35 Ribbon diagram of the bifunctional enzyme tryptophan synthase from *S. typhimurium*. Only one $\alpha\beta$ protomer of the bifunctional $\alpha\beta\alpha$ heterotetramer is shown. The α subunit is blue, the β subunit’s N-terminal domain is orange, its C-terminal domain is red-orange, and all β sheets are tan. The active site of the α subunit is located by its bound competitive inhibitor, **indolepropanol phosphate** (IPP; red ball-and-stick model), whereas that of the β subunit is marked by its PLP coenzyme (yellow ball-and-stick model). The solvent-accessible surface of the ~ 25 -Å-long tunnel connecting the α and β active sites is outlined by yellow dots. Several indole molecules (green ball-and-stick models) have been modeled into the tunnel to show that it is wide enough for indole to pass from one active site to the other.

? What types of side chains are likely to line the tunnel between the active sites?

FIG. 21-36 The biosynthesis of histidine. The enzymes shown are (1) ATP phosphoribosyltransferase and (2) glutamine amidotransferase.

site. These switch the enzyme between an open, low-activity conformation to which substrates bind, and a closed, high-activity conformation from which indole cannot escape.

Histidine Biosynthesis Includes an Intermediate in Nucleotide Biosynthesis. Five of histidine's six C atoms are derived from **5-phosphoribosyl- α -pyrophosphate (PRPP)** (Fig. 21-36), a phospho-sugar intermediate that is also involved in the biosynthesis of purine and pyrimidine nucleotides (Sections 23-1A and 23-2A). The histidine's sixth carbon originates from ATP. The ATP atoms that are not incorporated into histidine are eliminated as **5-aminoimidazole-4-carboxamide ribonucleotide** (Fig. 21-36, Reaction 2), which is also an intermediate in purine biosynthesis (Section 23-1A).

The unusual biosynthesis of histidine from a purine (*N*¹-5'-phosphoribosyl ATP, the product of Reaction 1 in Fig. 21-36) has been cited as evidence supporting the hypothesis that life was originally RNA-based. His residues, as we have seen, are often components of enzyme active sites, where they act as nucleophiles and/or general acid-base catalysts. The discovery that RNA can have catalytic properties therefore suggests that the imidazole moiety of purines plays a similar role in RNA enzymes. This further suggests that the histidine biosynthetic pathway is a "fossil" of the transition to more efficient protein-based life-forms.

CHECKPOINT

- What are the metabolic precursors of the nonessential amino acids?
- Summarize the types of reactions required to synthesize the nonessential amino acids.
- List the compounds that are used to synthesize the essential amino acids in plants and microorganisms.
- Compare the catabolic and anabolic pathways for one or more of the amino acids. In which pathways do oxidation reactions or reduction reactions predominate?

6 Other Products of Amino Acid Metabolism

KEY CONCEPTS

- Heme is synthesized from glycine and succinyl-CoA and is degraded to a variety of colored compounds for excretion.
- The synthesis of bioactive amines begins with amino acid decarboxylation.
- Arginine gives rise to the hormonally active gas nitric oxide.

Certain amino acids, in addition to their major function as protein building blocks, are essential precursors of a variety of important biomolecules, including nucleotides and nucleotide coenzymes, heme, and various hormones and neurotransmitters. In this section, we consider the pathways leading to some of these substances. The biosynthesis of nucleotides is considered in Chapter 23.

A Heme Is Synthesized from Glycine and Succinyl-CoA

Heme, as we have seen, is an Fe-containing prosthetic group that is an essential component of many proteins, notably hemoglobin, myoglobin, and the cytochromes. The initial reactions of heme biosynthesis are common to the formation of other tetrapyrroles including chlorophyll in plants and bacteria (Fig. 19-2) and coenzyme B₁₂ in bacteria (Fig. 20-17).

Elucidation of the heme biosynthetic pathway involved some interesting detective work. David Shemin and David Rittenberg, who were among the first to use isotopic tracers in the elucidation of metabolic pathways, demonstrated, in 1945, that *all of heme's C and N atoms can be derived from acetate and glycine*. Heme biosynthesis takes place partly in the mitochondrion and partly in the cytosol (Fig. 21-37). Mitochondrial acetate is metabolized via the citric acid cycle to succinyl-CoA, which condenses with glycine in a reaction that produces CO₂ and **δ-aminolevulinic acid (ALA)**. ALA is transported to the cytosol, where it combines with a second ALA to yield **porphobilinogen (PBG)**. The reaction is catalyzed by the Zn-requiring enzyme **porphobilinogen synthase**.

 Inhibition of PBG synthase by lead is one of the major manifestations of acute lead poisoning. Indeed, it has been suggested that the accumulation, in the blood, of ALA, which resembles the neurotransmitter **γ-aminobutyric acid** (Section 21-6B), is responsible for the psychosis that often accompanies lead poisoning.

The next phase of heme biosynthesis is the condensation of four PBG molecules to form **uroporphyrinogen III**, the porphyrin nucleus, in a series of reactions catalyzed by **porphobilinogen deaminase** (also called **uroporphyrinogen synthase**) and **uroporphyrinogen III synthase**. The initial product, **hydroxymethylbilane**, is a linear tetrapyrrole that cyclizes.

Hydroxymethylbilane

A = acetyl

P = propionyl

Protoporphyrin IX, to which Fe is added to form heme, is produced from uroporphyrinogen III in a series of reactions catalyzed by (1) **uroporphyrinogen decarboxylase**, which decarboxylates all four acetate side chains (A) to form methyl groups (M); (2) **coproporphyrinogen oxidase**, which oxidatively decarboxylates two of the propionate side chains (P) to vinyl groups (V); and (3) **protoporphyrinogen oxidase**, which oxidizes the methylene groups linking the pyrrole rings to methenyl groups. During the coproporphyrinogen oxidase reaction, the porphyrin is transported back into the mitochondrion. In the final reaction of heme biosynthesis, **ferrochelatase** inserts Fe(II) into protoporphyrin IX.

FIG. 21-37 The pathway of heme biosynthesis. δ -Aminolevulinic acid (ALA) is synthesized in the mitochondrion from succinyl-CoA and glycine by ALA synthase. ALA is transported to the cytosol, where two molecules condense to form PBG, four molecules of which condense to form a porphyrin ring. The next three reactions involve oxidation of the pyrrole ring substituents, yielding protoporphyrin IX, which

is transported back into the mitochondrion during its formation. After oxidation of the methylene groups, ferrochelatase catalyzes the insertion of Fe^{2+} to yield heme. A, P, M, and V, respectively, represent acetyl, propionyl, methyl, and vinyl ($-\text{CH}=\text{CH}_2$) groups. C atoms originating as the carboxyl group of acetate are red.

The Liver and Erythroid Cells Regulate Heme Biosynthesis. The two major sites of heme biosynthesis are erythroid cells, which synthesize ~85% of the body's heme groups, and the liver, which synthesizes most of the remainder. In liver, the level of heme synthesis must be adjusted according to metabolic conditions. For example, the synthesis of the heme-containing cytochromes P450 (Section 12-4D) fluctuates with the need for detoxification. In contrast, heme synthesis in erythroid cells is a one-time event; heme and protein synthesis cease when the cell matures, so that the hemoglobin must last the erythrocyte's lifetime (~120 days).

In liver, the main control target in heme biosynthesis is ALA synthase, the enzyme catalyzing the pathway's first committed step. Heme, or its Fe(III) oxidation product **hemin**, controls this enzyme's activity through feedback inhibition, inhibition of the transport of ALA synthase from its site of synthesis in the cytosol to its reaction site in the mitochondrion (Fig. 21-37), and repression of ALA synthase synthesis.

In erythroid cells, heme exerts quite a different effect on its biosynthesis. Heme induces, rather than represses, protein synthesis in **reticulocytes** (immature erythrocytes). Although the vast majority of the protein synthesized by reticulocytes is globin, heme may also induce these cells to synthesize the enzymes of heme biosynthesis. Moreover, the rate-determining steps of heme biosynthesis in erythroid cells may be the ferrochelatase and porphobilinogen deaminase reactions rather than the ALA synthase reaction. This is consistent with the supposition that when erythroid heme biosynthesis is "switched on," all of its steps function at their maximal rates rather than any one step limiting the flow through the pathway. Heme-stimulated synthesis of globin also ensures that heme and globin are synthesized in the correct ratio for assembly into hemoglobin (Section 28-3C). Genetic defects in heme biosynthesis cause conditions known as **porphyrias** (Box 21-3).

Heme Degradation Products Are Excreted. At the end of their lifetime, red cells are removed from the circulation and their components degraded. Heme catabolism (Fig. 21-38) begins with oxidative cleavage, by heme oxygenase, of the porphyrin between rings A and B to form **biliverdin**, a green linear tetrapyrrole. Biliverdin's central methenyl bridge (between rings C and D) is then reduced to form the red-orange **bilirubin**. The changing colors of a healing bruise are a visible manifestation of heme degradation.

In the reaction forming biliverdin, the methenyl bridge carbon between rings A and B is released as CO, which is a tenacious heme ligand (with 200-fold greater affinity for hemoglobin than O₂; Section 7-1A). Consequently, ~1% of hemoglobin's binding sites are blocked by CO even in the absence of air pollution.

Box 21-3 Biochemistry in Health and Disease **The Porphyrins**

Defects in heme biosynthesis in liver or erythroid cells result in the accumulation of porphyrin and/or its precursors and are therefore known as **porphyrias**. Two such defects are known to affect erythroid cells: uroporphyrinogen III cosynthase deficiency (**congenital erythropoietic porphyria**) and ferrochelatase deficiency (**erythropoietic protoporphyria**). The former results in accumulation of uroporphyrinogen derivatives. Excretion of those compounds colors the urine red; their deposition in the teeth turns them reddish brown; and their accumulation in the skin renders it extremely photosensitive, so that it ulcerates and forms disfiguring scars. Increased hair growth is also observed in afflicted individuals; fine hair may cover much of the face and extremities. These symptoms have prompted speculation that the werewolf legend has a biochemical basis.

The most common porphyria that primarily affects the liver is porphobilinogen deaminase deficiency (**acute intermittent porphyria**). This disease is marked by intermittent attacks of abdominal pain and neurological dysfunction. Excessive amounts of ALA and PBG are excreted in the urine during and after such attacks. The urine may become red resulting from the excretion of excess porphyrins synthesized from PBG in nonhepatic cells, although the skin does not become unusually photosensitive. King George III, who ruled England during the American Revolution, and who has been widely portrayed as being mad, in fact, had attacks characteristic of acute intermittent porphyria; he was reported to have urine the color of port wine, and had several descendants who were diagnosed as having the disease. American history might have been quite different had George III not inherited that metabolic defect.

The highly lipophilic bilirubin is insoluble in aqueous solutions. Like other lipophilic metabolites, such as free fatty acids, it is transported in the blood in complex with serum albumin. Bilirubin derivatives are secreted in the bile and, for the most part, are further degraded by bacterial enzymes in the large intestine. Some of the resulting **urobilinogen** is reabsorbed and transported via the bloodstream to the kidney, where it is converted to the yellow **urobilin** and excreted, thus giving urine its characteristic color. Most urobilinogen, however, is microbially converted to the deeply red-brown **stercobilin**, the major pigment of feces.

When the blood contains excessive amounts of bilirubin, the deposition of this highly insoluble substance colors the skin and the whites of the eyes yellow. This condition, called **jaundice** (French: *jaune*, yellow), signals either an abnormally high rate of red cell destruction, liver dysfunction, or bile duct obstruction. Newborn infants, particularly when premature, often become jaundiced because they lack an enzyme that degrades bilirubin. Jaundiced infants are treated by bathing them with light from a fluorescent lamp; this photochemically converts bilirubin to more soluble isomers that the infant can degrade and excrete.

B Amino Acids Are Precursors of Physiologically Active Amines

Epinephrine (adrenaline), norepinephrine, dopamine, serotonin (5-hydroxytryptamine), γ -aminobutyric acid (GABA), and histamine (*at left*) are hormones and/or neurotransmitters derived from amino acids. Epinephrine, as we have seen, activates muscle adenylate cyclase, thereby stimulating glycogen breakdown (Section 16-3B); deficiency in dopamine production is associated with **Parkinson's disease**, a degenerative condition causing "shaking palsy"; serotonin causes smooth muscle contraction; GABA is one of the brain's major inhibitory neurotransmitters; and histamine is involved in allergic responses (as allergy sufferers who take antihistamines will realize), as well as in the control of acid secretion by the stomach.

The biosynthesis of each of these physiologically active amines involves decarboxylation of the corresponding precursor amino acid. Amino acid decarboxylases are PLP-dependent enzymes that form a PLP-Schiff base with the substrate so as to stabilize (by delocalization) the C _{α} carbanion formed on C _{α} -COO⁻ bond cleavage (Section 21-2A):

Formation of histamine (from histidine) and formation of GABA (from glutamate) are one-step processes; the synthesis of serotonin from tryptophan requires a hydroxylation step as well as decarboxylation. The various **catecholamines**—dopamine, norepinephrine, and epinephrine—are related to **catechol** (*at left*) and are sequentially synthesized from tyrosine (Fig. 21-39):

1. Tyrosine is hydroxylated to **3,4-dihydroxyphenylalanine (L-DOPA)** in a reaction that requires 5,6,7,8-tetrahydrobiopterin (Fig. 21-26).
2. L-DOPA is decarboxylated to dopamine.
3. A second hydroxylation yields norepinephrine.
4. Methylation of norepinephrine's amino group by *S*-adenosylmethionine (Fig. 21-18) produces epinephrine.

The specific catecholamine that a cell produces depends on which enzymes of the pathway are present. In adrenal medulla, for example, epinephrine is the predominant product. In some areas of the brain, norepinephrine is more common. In other areas, the pathway stops at dopamine. In melanocytes, L-DOPA is the

FIG. 21-39 The sequential synthesis of L-DOPA, dopamine, norepinephrine, and epinephrine from tyrosine.

precursor of red and black melanins, which are irregular cross-linked polymers that give hair and skin much of their color.

C Nitric Oxide Is Derived from Arginine

Arginine is the precursor of a substance that was originally called **endothelium-derived relaxing factor (EDRF)** because it was synthesized by vascular endothelial cells and caused the underlying smooth muscle to relax. The signal for vasodilation was not a peptide, as expected, but the stable free radical gas **nitric oxide, NO**. The identification of NO as a vasodilator came in part from studies that identified NO as the decomposition product that mediates the vasodilating effects of compounds such as **nitroglycerin** (*at right*). Nitroglycerin is often administered to individuals suffering from **angina pectoris**, a disease caused by insufficient blood flow to the heart muscle, to rapidly but temporarily relieve their chest pain.

Nitroglycerin

The reaction that converts arginine to NO and citrulline is catalyzed by nitric oxide synthase (NOS):

The reaction proceeds via an enzyme-bound hydroxyarginine intermediate and requires an array of redox coenzymes. NOS is a homodimeric protein of 125-to

CHECKPOINT

- What are the starting materials for heme biosynthesis?
- How does the regulation of heme synthesis differ between the liver and reticulocytes?
- What are the end products of heme metabolism?
- Identify the amino acids that give rise to catecholamines, serotonin, GABA, and histamine.
- What are the substrates and products of the nitric oxide synthase reaction?
- How does NO differ from signaling molecules such as the catecholamines?

160-kD subunits, and each subunit contains one FMN, one FAD, one tetrahydrobiopterin (Fig. 21-26), and one Fe(III)-heme. These cofactors facilitate the five-electron oxidation of arginine to produce NO.

Because NO is a gas, it rapidly diffuses across cell membranes, although its high reactivity (half-life ~ 5 s) prevents it from acting much farther than ~ 1 mm from its site of synthesis. NO is produced by endothelial cells in response to a wide variety of agents and physiological conditions. Neuronal cells also synthesize NO (neuronal NOS is $\sim 55\%$ homologous to endothelial NOS). This endothelium-independent NO synthesis induces the dilation of cerebral and other arteries and is responsible for penile erection (Section 13-4C). The brain contains more NOS than any other tissue in the body, suggesting that NO is essential for the function of the central nervous system. A third type of NOS is found in leukocytes (white blood cells). These cells produce NO as part of their cytotoxic arsenal. NO combines with superoxide (Section 18-4B) to produce **peroxynitrite** (ONOO^-), which combines with a proton and decays to **nitrogen dioxide** (NO_2) and a **hydroxyl radical** ($\cdot\text{OH}$):

The highly reactive $\cdot\text{OH}$ kills invading bacteria. The sustained release of NO has been implicated in **endotoxic shock** (an often fatal immune system overreaction to bacterial infection), in inflammation-related tissue damage, and in the damage to neurons in the vicinity of but not directly killed by a stroke (which often does greater harm than the stroke itself).

7 Nitrogen Fixation

KEY CONCEPTS

- The reduction of N_2 to NH_3 by nitrogenase is an energetically costly process.
- Ammonia is incorporated into amino acids by the action of glutamate synthase.

The most prominent chemical elements in living systems are O, H, C, N, and P. The elements O, H, and P occur widely in metabolically available forms (H_2O , O_2 , and P_i). However, the major forms of C and N, CO_2 and N_2 , are extremely stable (unreactive); for example, the $\text{N}\equiv\text{N}$ triple bond has a bond energy of $945 \text{ kJ} \cdot \text{mol}^{-1}$ (versus $351 \text{ kJ} \cdot \text{mol}^{-1}$ for a C—O single bond). CO_2 , with minor exceptions, is metabolized (fixed) only by photosynthesis (Chapter 19). **Nitrogen fixation** is even less common; N_2 is converted to metabolically useful forms by only a few strains of bacteria, called **diazotrophs**. These organisms include certain marine cyanobacteria and bacteria that colonize the root nodules of legumes (plants belonging to the pea family, including beans, clover, and alfalfa; Fig. 21-40). The remarkable nature of biological nitrogen fixation, which occurs at ambient temperatures and pressures, is indicated by its comparison to the **Haber-Bosch process** for the industrial production of ammonia from N_2 and H_2 : It occurs at $\sim 400^\circ\text{C}$ and ~ 200 atm and requires an iron-based catalyst.

Once N_2 is fixed, the nitrogen is **assimilated** (incorporated) into biological molecules as amino groups that can then be transferred to other molecules. In this section we examine the processes of nitrogen fixation and nitrogen assimilation.

A Nitrogenase Reduces N_2 to NH_3

Diazotrophs produce the enzyme **nitrogenase**, which catalyzes the reduction of N_2 to NH_3 :

FIG. 21-40 Root nodules of a soybean plant. Bacteria of the genus *Rhizobium*, which carry out nitrogen fixation, live symbiotically within the root nodules of such legumes.

In legumes, this nitrogen-fixing system produces more metabolically useful nitrogen than the legume needs; the excess is excreted into the soil, enriching it. It is therefore common agricultural practice to plant a field with alfalfa every few years to build up the supply of usable nitrogen in the soil for later use in growing other crops.

Nitrogenase Contains Novel Redox Centers. Nitrogenase, which catalyzes the reduction of N_2 to NH_3 , is a complex of two proteins:

1. The **Fe-protein**, a homodimer that contains one $[4Fe-4S]$ cluster and two nucleotide-binding sites.
2. The **MoFe-protein**, an $\alpha_2\beta_2$ heterotetramer that contains Fe and Mo.

The X-ray structure of *Azotobacter vinelandii* nitrogenase in complex with the inhibitor $ADP \cdot AlF_4^-$ (which mimics the transition state in ATP hydrolysis), determined by Douglas Rees, reveals that each MoFe-protein protomer associates with an Fe-protein dimer (Fig. 21-41).

Each Fe-protein dimer's single $[4Fe-4S]$ cluster is located in a solvent-exposed cleft between the two subunits and is symmetrically linked to Cys 97 and Cys 132 from both subunits such that an Fe-protein resembles an "iron butterfly" with the $[4Fe-4S]$ cluster at its head. Its nucleotide-binding sites are located at the interface between its two subunits.

The MoFe-protein's α and β subunits assume similar folds and extensively associate to form a pseudotwofold symmetric $\alpha\beta$ dimer, two of which more loosely associate to form the twofold symmetric $\alpha_2\beta_2$ tetramer (Fig. 21-41). Each $\alpha\beta$ dimer has two bound redox centers:

1. The **P-cluster** (Fig. 21-42a,b), which consists of two $[4Fe-3S]$ clusters linked through an additional sulfide ion forming the eighth corner of both of the clusters to make cubane-like structures, and bridged by two thiol

FIG. 21-41 X-Ray structure of the *A. vinelandii* nitrogenase in complex with $ADP \cdot AlF_4^-$. The enzyme, which is viewed along its molecular twofold axis, is an $(\alpha\beta\gamma_2)_2$ heterooctamer in which the β - α - α - β assembly, the MoFe-protein, is flanked by two γ_2 Fe-proteins whose 289-residue subunits are related by local twofold symmetry. The homologous α subunits (cyan and red; 491 residues) and β subunits (light red and light blue; 522 residues) are related by pseudotwofold symmetry. The two γ subunits forming each Fe-protein (pink and green

with their Switch I and Switch II segments red and blue) bind to the MoFe-protein with the twofold axis relating them coincident with the pseudo-twofold axis relating the MoFe-protein's α and β subunits. The $ADP \cdot AlF_4^-$, $[4Fe-4S]$ cluster, FeMo-cofactor, and P-cluster are drawn in space-filling form with C green, N blue, O red, S yellow, Fe orange, Mo pink, and the AlF_4^- ion purple. [Based on an X-ray structure by Douglas Rees, California Institute of Technology. PDBid 1N2C.]

FIG. 21-42 The prosthetic groups of the nitrogenase MoFe-protein. The molecules are drawn in ball-and-stick form with C green, N blue, O red, S yellow, Fe orange, and Mo pink. (a) The reduced *Klebsiella pneumoniae* P-cluster. It consists of two [4Fe–3S] complexes linked by an additional sulfide ion forming the eighth corner of each cubane-like structure, and bridged by two Cys thiol ligands, each coordinating one Fe from each cluster. Four additional Cys thiols coordinate the remaining four Fe atoms. (b) The 2-electron-oxidized *K. pneumoniae* P-cluster. In comparison with the reduced complex in Part a, two of the Fe–S bonds from the centrally located sulfide ion that bridges the two [4Fe–3S] clusters have been replaced by ligands from the Cys 87 α amide N and the Ser 186 β side chain O yielding a [4Fe–3S] cluster (left) and a [4Fe–4S] cluster (right) that remain linked by a direct Fe–S bond and two bridging Cys thiols. (c) The *A. vinelandii* FeMo-cofactor. It consists of a [4Fe–3S] cluster and a [1Mo–3Fe–3S] cluster that are bridged by three sulfide ions. The FeMo-cofactor is linked to the protein by only two ligands at its opposite ends, one from His 442 α to the Mo atom and the other from Cys 275 α to an Fe atom. The Mo atom is additionally doubly liganded by homocitrate. A C⁴⁻ ion (green sphere) is liganded to the FeMo-cluster's six central Fe atoms (dashed black lines). [Parts a and b based on X-ray structures by David Lawson, John Innes Centre, Norwich, U.K. Part c based on an X-ray structure by Douglas Rees, California Institute of Technology. PDBids (a) 1QGU, (b) 1QH1, and (c) 1M1N.]

? Compare these structures to the [Fe–S] clusters on page 598.

ligands, each coordinating one Fe from each cluster. Four additional Cys thiols coordinate the remaining four Fe atoms. The positions of two of the Fe atoms in one of the [4Fe–3S] clusters change on oxidation, rupturing the bonds from these Fe atoms to the linking sulfide ion. These bonds are replaced in the oxidized state by a Ser oxygen ligand to one of the Fe atoms, and by a bond to the amide N of a Cys from the other Fe atom.

2. The FeMo-cofactor (Fig. 21-42c), which consists of a [4Fe–3S] cluster and a [1Mo–3Fe–3S] cluster bridged by three sulfide ions. It is the most complex known biological metallocluster. The FeMo-cofactor's Mo atom is approximately octahedrally coordinated by three cofactor sulfurs, a His imidazole nitrogen, and two oxygens from a bound **homocitrate** ion (at left) (an essential component of the FeMo-cofactor). A central cavity in the FeMo-cofactor contains a carbide (C⁴⁻) ion. This ion is liganded to the FeMo-cofactor's central six Fe atoms such that it completes the approximate tetrahedral coordination environment of each of the Fe atoms. The FeMo cofactor forms the binding site for N₂, although the way it does so and reduces the N₂ to NH₃ remains an enigma.

ATP Hydrolysis Is Coupled to Electron Transfer in Nitrogenase. Nitrogen fixation by nitrogenase requires a source of electrons. These are generated either oxidatively or photosynthetically, depending on the organism. The electrons are transferred to **ferredoxin**, a [4Fe–4S]-containing electron carrier that transfers an electron to the Fe-protein of nitrogenase, beginning the nitrogen fixation process (Fig. 21-43).

The transfer of electrons during the nitrogenase reaction requires ATP-dependent protein conformational changes and the dissociation of the Fe-protein from the MoFe-protein after each electron transfer. During the reaction cycle, two molecules of ATP bind to the reduced Fe-protein dimer. With the nucleotides bound, the Fe-protein has a redox potential of –0.40 V (compared to –0.29 V in the nucleotide-free protein), making its electron capable of N₂ reduction (for the reaction $\text{N}_2 + 6 \text{H}^+ + 6 e^- \rightleftharpoons 2 \text{NH}_3$, $\mathcal{E}^{\circ'} = -0.34 \text{ V}$).

How are events at the ATP-binding site linked to electron transfer? Structural studies show that the binding of ADP · AlF₄⁻ to the Fe-protein induces conformational changes in two regions of the Fe-protein, designated Switch I and Switch II (Fig. 21-41) that are homologous to segments of signal-transducing G proteins in which nucleotide hydrolysis is coupled to protein conformational changes (Section 13-3B).

FIG. 21-43 The flow of electrons in the nitrogenase-catalyzed reduction of N_2 .

At Switch I, these conformational changes affect the interactions between the Fe-protein and the MoFe-protein, whereas at Switch II they affect the environment of the [4Fe-4S] cluster. X-Ray structures of the Fe-protein alone and with bound ADP or ATP indicate that ATP binding triggers a structural change including rotation of the two Fe-protein subunits by about 13° toward each other. This conformational change brings the [4Fe-4S] cluster closer to the P-cluster of the adjacent MoFe-protein (from 18 to 14 Å apart), thereby promoting electron transfer from the Fe-protein to the MoFe-protein. Electron transfer occurs rapidly: First, an electron moves from the MoFe-protein P-cluster to the FeMo cofactor, then an electron from the Fe-protein reduces the P-cluster. ATP hydrolysis does not drive electron transfer, as once thought, but occurs afterward.

Kinetic studies of nitrogenase indicate that the rate-limiting step of N_2 reduction is the dissociation of the Fe-protein from the MoFe-protein. Following electron transfer, the Fe-protein hydrolyzes its two bound ATP to ADP, P_i is released, and, finally, in the slowest step of the catalytic cycle, the proteins separate. Thus, the Fe-protein functions in the same way as a G protein, in which nucleotide hydrolysis triggers a dissociation event (Section 13-3B). Reassociation of the Fe-protein and MoFe-protein occurs as soon as the Fe-protein accepts another electron and exchanges its 2 ADP for 2 ATP.

N_2 Reduction Is Energetically Costly. The actual reduction of N_2 occurs on the MoFe-protein in three discrete steps, each involving an electron pair:

An electron transfer must occur six times per N_2 molecule fixed, so a total of 12 ATP are required to fix one N_2 molecule. However, nitrogenase also reduces H_2O to H_2 , which in turn reacts with **diimine** to re-form N_2 .

This futile cycle is favored when the ATP level is low and/or the reduction of the Fe-protein is sluggish. Even when ATP is plentiful, however, the cycle cannot be suppressed beyond about one H_2 molecule produced per N_2 reduced and hence appears to be a requirement for the nitrogenase reaction. The total cost of N_2 reduction is therefore 8 electrons transferred and 16 ATP hydrolyzed. Under cellular conditions, the cost is closer to 20–30 ATP. Consequently, nitrogen fixation is an energetically expensive process.

Although atmospheric N_2 is the ultimate nitrogen source for all living things, most plants do not support the symbiotic growth of nitrogen-fixing bacteria. They must therefore depend on a source of “prefixed” nitrogen such as nitrate or ammonia. These nutrients come from lightning discharges (the source of $\sim 10\%$ of naturally fixed N_2), decaying organic matter in the soil, or from fertilizer applied to

it (~50% of the nitrogen fixed is now generated by the Haber-Bosch process). One major long-term goal of genetic engineering is to induce agriculturally useful non-leguminous plants to fix their own nitrogen. This would free farmers, particularly those in developing countries, from either purchasing fertilizers, periodically letting their fields lie fallow (giving legumes the opportunity to grow), or following the slash-and-burn techniques that are rapidly destroying the world's tropical forests.

Leghemoglobin Protects Nitrogenase from Oxygen Inactivation. Nitrogenase is rapidly inactivated by O₂, so the enzyme must be protected from this reactive substance. Cyanobacteria provide the necessary protection by carrying out nitrogen fixation in specialized cells called heterocysts, which have Photosystem I but lack the O₂-generating Photosystem II (Section 19-2C). In the root nodules of legumes (Fig. 21-40), however, protection is afforded by the hemoglobin homolog **leghemoglobin**. The globin portion of this ~145-residue monomeric oxygen-binding protein is synthesized by the plant (an evolutionary curiosity, since globins otherwise occur only in animals), whereas the heme is synthesized by the *Rhizobium* (an indication of the close symbiotic relationship between the legume and the *Rhizobium*). Leghemoglobin has a very high O₂ affinity, thus keeping the *p*O₂ low enough to protect the nitrogenase while providing passive O₂ transport for the aerobic bacterium.

B Fixed Nitrogen Is Assimilated into Biological Molecules

After atmospheric N₂ has been converted to a biologically useful form (e.g., ammonia), it must be assimilated into a cell's biomolecules. Once nitrogen has been introduced into an amino acid, the amino group can be transferred to other compounds by transamination. Because most organisms do not fix nitrogen and hence must rely on prefixed nitrogen, nitrogen assimilation reactions are critical for conserving this essential element.

We have already considered the reaction catalyzed by glutamine synthetase (Section 21-5A), which in microorganisms represents a metabolic entry point for fixed nitrogen (in animals, this reaction helps “mop up” excess ammonia). The glutamine synthetase reaction requires the nitrogen-containing compound glutamate as a substrate. So what is the source of the amino group in glutamate? In bacteria and plants, but not animals, the enzyme **glutamate synthase** converts α-ketoglutarate and glutamine to two molecules of glutamate:

This reductive amination reaction requires electrons from NADPH and takes place at three distinct active sites in the α₂β₂ heterotetramer (Fig. 21-44). X-Ray structures of the enzyme reveal that the substrate-binding sites are widely separated. As a result, the ammonia that is transferred from glutamine to α-ketoglutarate must travel through a 31-Å-long tunnel in the protein. This channeling probably helps prevent the loss of NH₃ to the cytosol and maintains this intermediate in its more reactive deprotonated state (in the cytosol, NH₃ would immediately acquire a proton to become NH₄⁺). Furthermore, the tunnel is blocked by the side chains of several residues and opens only when α-ketoglutarate is bound to the enzyme and NADPH is available. This mechanism apparently prevents the wasteful hydrolysis of glutamine.

The net result of the glutamine synthetase and glutamate synthase reactions is

Thus, *the combined action of these two enzymes assimilates fixed nitrogen (NH₄⁺) into an organic compound (α-ketoglutarate) to produce an amino acid (glutamate)*. Once the nitrogen is assimilated as glutamate, it can be used in the synthesis of other amino acids by transamination.

The Nitrogen Cycle Describes the Interconversion of Nitrogen in the Biosphere. The ammonia produced by the nitrogenase reaction and incorporated into amino acids is eventually recycled in the biosphere, as described by the **nitrogen cycle** (Fig. 21-45). Nitrate is produced by certain bacteria that oxidize

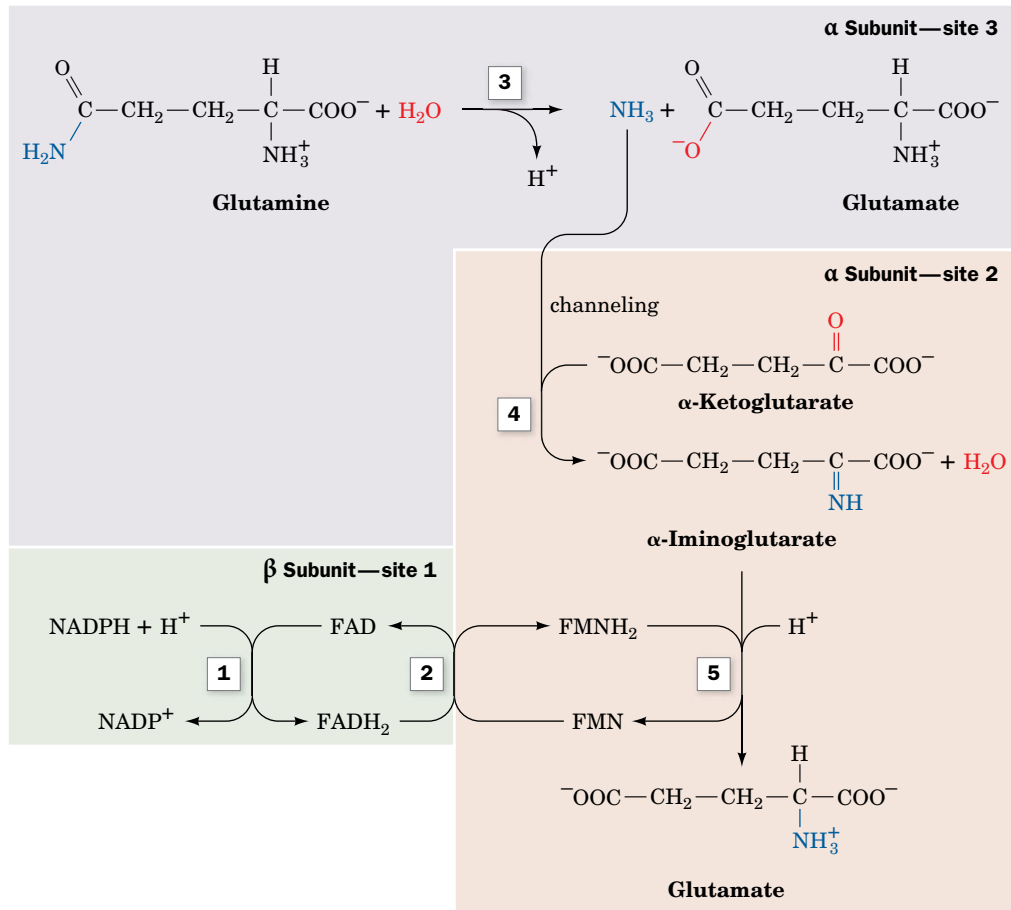

FIG. 21-44 The glutamate synthase reaction. (1) Electrons are transferred from NADPH to FAD at active site 1 on the β subunit to yield FADH₂. (2) Electrons travel from the FADH₂ to FMN at site 2 on an α subunit to yield FMNH₂. (3) Glutamine is hydrolyzed to glutamate

and ammonia at site 3. (4) The ammonia produced in Step 3 moves to site 2 by channeling, where it reacts with α-ketoglutarate. (5) The α-iminoglutarate product is reduced by FMNH₂ to form glutamate.

FIG. 21-45 The nitrogen cycle. Nitrogen fixation by nitrogenase converts N₂ to the biologically useful ammonia. Nitrate can also be converted to ammonia by the sequential actions of nitrate reductase and nitrite reductase. Ammonia is transformed to N₂ by nitrification followed by denitrification. Ammonia may be assimilated into nitrogen-containing biomolecules, which may be decomposed back to ammonia.

CHECKPOINT

- Summarize the mechanistic role of ATP in nitrogen fixation.
- Why is nitrogen fixation so energetically costly?
- Describe the reactions that assimilate NH_3 into amino acids. Which reactions occur in mammals?
- List the enzymes of amino acid metabolism in which channeling occurs.
- How is fixed nitrogen recycled in the biosphere?

NH_3 to NO_2^- and then NO_3^- , a process called **nitrification**. Still other organisms convert nitrate back to N_2 , which is known as **denitrification**. In addition, nitrate is reduced to NH_3 by plants, fungi, and many bacteria, a process called **ammonification** in which **nitrate reductase** catalyzes the two-electron reduction of nitrate to nitrite (NO_2^-):

and then nitrite reductase converts nitrite to ammonia,

The direct anaerobic oxidation of NH_3 back to N_2 without the intermediacy of nitrate, the reverse of nitrogen fixation, occurs in certain bacteria.

Summary

1 Protein Degradation

- Intracellular proteins and extracellular proteins taken up by endocytosis are degraded by lysosomal proteases.
- Proteins tagged by the addition of multiple copies of ubiquitin enter the barrel-shaped proteasome, where they are digested into ~8-residue fragments.

2 Amino Acid Deamination

- The degradation of an amino acid almost always begins with the removal of its amino group in a PLP-facilitated transamination reaction.
- Glutamate undergoes oxidative deamination to α -ketoglutarate.

3 The Urea Cycle

- A nitrogen atom from ammonia (a product of the oxidative deamination of glutamate) and bicarbonate are incorporated into carbamoyl phosphate for entry into the urea cycle.
- A second nitrogen atom introduced from aspartate enters the cycle to produce urea for excretion.
- The rate-limiting step of this process is catalyzed by carbamoyl phosphate synthetase.

4 Breakdown of Amino Acids

- The 20 “standard” amino acids are degraded to compounds that give rise either to glucose or to ketone bodies or fatty acids: pyruvate, α -ketoglutarate, succinyl-CoA, fumarate, oxaloacetate, acetyl-CoA, or acetoacetate.

- The cofactors involved in amino acid degradation include PLP, tetrahydrofolate, and bipterin.

5 Amino Acid Biosynthesis

- The nonessential amino acids are synthesized in all organisms using simple pathways with the starting materials pyruvate, oxaloacetate, α -ketoglutarate, and 3-phosphoglycerate.
- The essential amino acids, which are made only in plants and microorganisms, require more complicated pathways that vary among organisms.

6 Other Products of Amino Acid Metabolism

- Amino acids are the precursors of various biomolecules. Heme synthesis begins with glycine and succinyl-CoA derived from acetyl-CoA, and the porphyrin ring is built in a series of reactions that occur in the mitochondria and the cytosol.
- Heme degradation products include urobilin and stercobilin.
- Various hormones and neurotransmitters are synthesized by the decarboxylation and hydroxylation of histidine, glutamate, tryptophan, and tyrosine.
- The five-electron oxidation of arginine yields the bioactive stable radical nitric oxide.

7 Nitrogen Fixation

- Nitrogen fixation in bacteria, which requires 8 electrons and at least 16 ATP, is catalyzed by nitrogenase, a multisubunit protein with redox centers containing Fe, S, and Mo.
- Fixed nitrogen is incorporated into amino acids via the glutamine synthetase and glutamate synthase reactions.

Problems

EXERCISES

1. Explain why protein degradation by proteasomes requires ATP even though proteolysis is an exergonic process.

2. The compound shown below inhibits an archaeobacterial proteasome, binding to each of its active sites, which (unlike those of eukaryotic proteasomes) are all identical. What can you conclude about the substrate specificity of the archaeobacterial proteasome?

3. Explain why cellular stressors such as high temperatures or oxidative damage would trigger the production of proteasomes.

4. Ritonavir, an inhibitor of HIV protease (Box 12-3), also inhibits the chymotrypsin-like activity of the proteasome. Explain why this dual inhibitory effect could contribute to the neurotoxic side effects of long-term ritonavir use.

5. Explain why it was advantageous for human ancestors to evolve a taste receptor for glutamate.

6. An L-amino acid oxidase in mammalian peroxisomes requires H_2O and O_2 as substrates and catalyzes amino acid deamination, producing H_2O_2 as a product. Write a balanced equation for the reaction.

7. Which of the 20 "standard" amino acids are (a) purely glucogenic, (b) purely ketogenic, and (c) both glucogenic and ketogenic?

8. Alanine, cysteine, glycine, serine, and threonine are amino acids whose breakdown yields pyruvate. Which, if any, of the remaining 15 amino acids also do so?

9. In the degradation pathway for isoleucine (Fig. 21-21), draw the reactions that convert tiglyl-CoA to acetyl-CoA and propionyl-CoA.

10. Draw the amino acid-Schiff base that forms in the breakdown of 3-hydroxykynurenine to yield 3-hydroxyanthranilate in the tryptophan degradation pathway (Fig. 21-23, Reaction 4) and indicate which bond is to be cleaved.

11. Tyrosine and cysteine are listed as nonessential amino acids, but an inadequate diet may cause tyrosine and/or cysteine insufficiency. Explain.

12. Explain why traditional diets from different parts of the world often include combinations of a grain and a legume, such as rice and beans or couscous and lentils.

13. Which three mammalian enzymes can potentially react with and thereby decrease the concentration of free NH_4^+ ?

14. *E. coli* can convert glutamate to ornithine. Describe the two reactions that do so.

15. What are the metabolic consequences of a defective uridylyl-removing enzyme in *E. coli*?

16. Many of the most widely used herbicides inhibit the synthesis of aromatic amino acids. Explain why the compounds are safe to use near animals.

17. Sarcosine dehydrogenase catalyzes *N*-demethylation of the nonstandard amino acid sarcosine. Name the reaction product.

Sarcosine

18. Explain the chemical change that occurs in converting kynurenine (a product of tryptophan degradation) to kynurenate, a reaction in which α -ketoglutarate is transformed to glutamate.

Kynurenate

19. From which amino acid is 2-phenylethanol derived and what chemical changes take place in the conversion?

2-Phenylethanol

20. From what amino acid is the signaling molecule tyramine derived?

Tyramine

21. From which amino acid is the compound **agmatine** derived?

Agmatine

22. The compound shown here is used to treat trypanosome infection. What amino acid does the compound resemble?

23. Describe the reactions that convert epinephrine to the compound shown here.

24. Explain why inhibitors of monoamine oxidase (MAO), the enzyme that catalyzes one of the reactions in epinephrine breakdown (Problem 23), are often used as drugs to treat mood disorders.

25. One of the symptoms of **kwashiorkor**, the dietary protein deficiency disease in children, is the depigmentation of the skin and hair. Explain the biochemical basis of this symptom.

26. From what amino acid is **melatonin** derived? Describe the modifications that have occurred.

Melatonin

27. Some diazotrophs produce a vanadium-containing VFe protein in addition to the MoFe protein. The vanadium-containing nitrogenase converts N_2 to NH_3 and also converts CO to compounds such as ethane and propane. What aspect of the standard nitrogenase reaction is responsible for the production of alkanes?

28. *Nitrosomonas* is a photophobic (light-avoiding) chemoautotrophic bacterium that converts ammonia into nitrite. Explain how the organism can fix CO₂ via the Calvin cycle in the absence of sunlight.

CHALLENGE QUESTIONS

29. Explain why the symptoms of a partial deficiency in a urea cycle enzyme can be attenuated by a low-protein diet.

30. Production of the enzymes that catalyze the reactions of the urea cycle can increase or decrease according to the metabolic needs of the organism. High levels of these enzymes are associated with high-protein diets as well as starvation. Explain this apparent paradox.

31. (a) How many ATP equivalents are consumed by the reactions of the urea cycle? (b) Operation of the urea cycle actually generates more ATP than it consumes. Explain.

32. *Helicobacter pylori*, the bacterium responsible for gastric ulcers, can survive in the stomach (where the pH is as low as 1.5) in part because it synthesizes large amounts of the enzyme urease. (a) Write the reaction for urea hydrolysis by urease. (b) Explain why this reaction could help establish a more hospitable environment for *H. pylori*, which tolerates acid but prefers to grow at near-neutral pH.

33. Unlike the other 19 standard amino acids, lysine does not undergo transamination. What is the fate of its α - and ϵ -amino groups when it is catabolized?

34. Compare the ATP yield for the complete oxidation of glutamate and methionine, both of which contain five carbon atoms, to CO₂.

35. PLP is a cofactor for a number of enzymes involved in amino acid metabolism. Give an example of reaction in which PLP participates in cleavage of the *a*, *b*, and *c* bonds of an amino acid, as diagrammed in Fig. 21-8, top right.

36. Compile a list of all the cofactors involved in adding or removing one-carbon groups in carbohydrate, lipid, and amino acid metabolism. Provide an example of a reaction that uses each cofactor.

37. The nucleotide deoxyuridylylate (dUMP) is converted to deoxythymidylylate (dTMP) by methylation. Could this explain why rapidly dividing cancer cells consume large quantities of glycine?

38. Proliferating cells require NADPH for biosynthetic processes. Much of the NADPH is provided by the pentose phosphate pathway, but 10-formyl tetrahydrofolate is also a source of reducing power. Explain.

39. Mouse embryonic stem cells produce high levels of threonine dehydrogenase, whose activity appears to be essential for maintaining high levels of *S*-adenosylmethionine. Explain the link between threonine metabolism and SAM production.

40. Rice plants that have been engineered to overexpress alanine aminotransferase need about two-thirds less fertilizer than control plants. What does this information reveal about the process of nitrogen assimilation?

41. Heterozygotes for erythropoietic protoporphyria show only 20 to 30% residual ferrochelatase activity rather than the 50% that is normally expected for an autosomal dominant inherited disease. Provide a plausible explanation for this observation.

Mammalian Fuel Metabolism: Integration and Regulation

Chapter Contents

1 Organ Specialization

- A The Brain Requires a Steady Supply of Glucose
- B Muscle Utilizes Glucose, Fatty Acids, and Ketone Bodies
- C Adipose Tissue Stores and Releases Fatty Acids and Hormones
- D Liver Is the Body's Central Metabolic Clearinghouse
- E Kidney Filters Wastes and Maintains Blood pH
- F Blood Transports Metabolites in Interorgan Metabolic Pathways

2 Hormonal Control of Fuel Metabolism

- A Insulin Release Is Triggered by Glucose
- B Glucagon and Catecholamines Counter the Effects of Insulin

3 Metabolic Homeostasis: The Regulation of Energy Metabolism, Appetite, and Body Weight

- A AMP-Dependent Protein Kinase Is the Cell's Fuel Gauge
- B Adipocytes and Other Tissues Help Regulate Fuel Metabolism and Appetite
- C Energy Expenditure Can Be Controlled by Adaptive Thermogenesis

4 Disturbances in Fuel Metabolism

- A Starvation Leads to Metabolic Adjustments
- B Diabetes Mellitus Is Characterized by High Blood Glucose Levels
- C Obesity Is Usually Caused by Excessive Food Intake
- D Cancer Metabolism

Science Photo Library/SuperStock

The fat cells shown here are not simply for storage of surplus triacylglycerols. Instead, they are active players in the body's daily activities of acquiring, stockpiling, and mobilizing metabolic fuels.

In even the simplest prokaryotic cell, metabolic processes must be coordinated so that opposing pathways do not operate simultaneously and so that the organism can respond to changing external conditions such as the availability of nutrients. In addition, the organism's metabolic activities must meet the demands set by genetically programmed growth and reproduction. The challenges of coordinating energy acquisition and expenditure are markedly more complex in multicellular organisms, in which individual cells must cooperate. In animals and plants, this task is simplified by the division of metabolic labor among tissues.

In animals, the interconnectedness of various tissues is ensured by neuronal circuits and by hormones. Such regulatory systems do not simply switch cells on and off but rather elicit an almost infinite array of responses. The exact response of a cell to a given regulatory signal depends on the cell's ability to recognize the signal and on the presence of synergistic or antagonistic signals.

Our examination of mammalian carbohydrate, lipid, and amino acid metabolism (Chapters 15–21) would be incomplete without a discussion of how such processes are coordinated at the molecular level and how their malfunctions produce disease. In this chapter, we summarize the specialized metabolism of different organs and the pathways that link them. We also examine the mechanisms by which extracellular hormones influence intracellular events. We conclude with a discussion of disruptions in mammalian fuel metabolism.

1 Organ Specialization

KEY CONCEPTS

- The major metabolic pathways for glucose, fatty acids, and amino acids center on pyruvate and acetyl-CoA.
- Glucose is the primary fuel for the brain.
- Muscles can generate ATP anaerobically and aerobically.
- Adipose tissue stores triacylglycerols and releases fatty acids as needed.
- The liver makes all types of fuel available to other tissues.
- Some metabolic processes require cooperation among organs.

Many of the metabolic pathways discussed so far have to do with the oxidation of metabolic fuels for the production of ATP. These pathways, which encompass the synthesis and breakdown of glucose, fatty acids, and amino acids, are summarized in **Fig. 22-1**.

1. **Glycolysis.** The metabolic degradation of glucose begins with its conversion to two molecules of pyruvate with the net generation of two molecules of ATP (Section 15-1).
2. **Gluconeogenesis.** Mammals can synthesize glucose from a variety of precursors, such as pyruvate, via a series of reactions that largely reverse the path of glycolysis (Section 16-4).

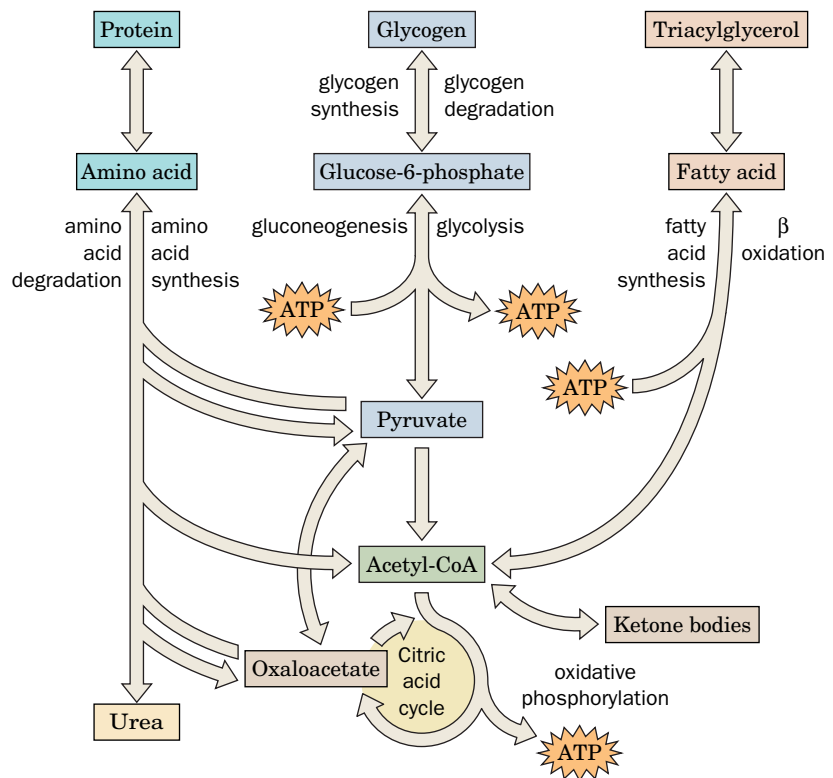

FIG. 22-1 The major pathways of fuel metabolism in mammals. Proteins, glycogen, and triacylglycerols are built up from and broken down to smaller units: amino acids, glucose-6-phosphate, and fatty acids. Oxidation of those fuels yields metabolic energy in the form of ATP. Pyruvate (a product of glucose and amino acid degradation) and acetyl-CoA (a product of glucose, amino acid, and fatty acid degradation) occupy central positions in mammalian fuel metabolism. Compounds that give rise to pyruvate, such as oxaloacetate, can be used for gluconeogenesis; acetyl-CoA can give rise to ketone bodies but not glucose. Not all the pathways shown here occur in all cells or occur simultaneously in a given cell.

? Which pathways are primarily oxidative? Which are primarily reductive?

3. **Glycogen degradation and synthesis.** The opposing processes catalyzed by glycogen phosphorylase and glycogen synthase are reciprocally regulated by hormonally controlled phosphorylation and dephosphorylation (Section 16-3).
4. **Fatty acid synthesis and degradation.** Fatty acids are broken down through β oxidation to form acetyl-CoA (Section 20-2), which, through its conversion to malonyl-CoA, is also the substrate for fatty acid synthesis (Section 20-4).
5. **The citric acid cycle.** The citric acid cycle (Section 17-1) oxidizes acetyl-CoA to CO_2 and H_2O with the concomitant production of reduced coenzymes whose reoxidation drives ATP synthesis. Many glucogenic amino acids can be oxidized via the citric acid cycle following their breakdown to one of its intermediates (Section 21-4), which, in turn, are broken down to pyruvate and then to acetyl-CoA, the cycle's only substrate.
6. **Oxidative phosphorylation.** This mitochondrial pathway couples the oxidation of NADH and FADH_2 produced by glycolysis, β oxidation, and the citric acid cycle to the phosphorylation of ADP (Section 18-3).
7. **Amino acid synthesis and degradation.** Excess amino acids are degraded to metabolic intermediates of glycolysis and the citric acid cycle (Section 21-4). The amino group is disposed of through urea synthesis (Section 21-3). Nonessential amino acids are synthesized via pathways that begin with common metabolites (Section 21-5A).

Two compounds lie at the crossroads of the major metabolic pathways: acetyl-CoA and pyruvate (Fig. 22-1). Acetyl-CoA is the common degradation product of glucose, fatty acids, and ketogenic amino acids. Its acetyl group can be oxidized to CO_2 and H_2O via the citric acid cycle and oxidative phosphorylation or used to synthesize ketone bodies or fatty acids. Pyruvate is the product of glycolysis and the breakdown of glucogenic amino acids. It can be oxidatively decarboxylated to yield acetyl-CoA, thereby committing its atoms either to oxidation or to the biosynthesis of fatty acids. Alternatively, pyruvate can be carboxylated via the pyruvate carboxylase reaction to form oxaloacetate, which can either replenish citric acid cycle intermediates or give rise to glucose or certain amino acids.

Only a few tissues, notably liver, can carry out all the reactions shown in Fig. 22-1, and in a given cell only a small portion of all possible metabolic reactions occur at a significant rate. Nevertheless, about 60% of all metabolic enzymes, representing essential “housekeeping” functions, are expressed at some level in all tissues in the human body. An analysis of tissue-specific proteomes (www.proteinatlas.org) reveals that liver is the most metabolically active tissue, followed by adipose tissue and skeletal muscle.

We will consider the metabolism of five mammalian organs: brain, muscle, adipose tissue, liver, and kidney. Metabolites flow between these organs in well-defined pathways in which flux varies with the nutritional state of the animal (Fig. 22-2). For example, immediately following a meal, glucose, amino acids, and fatty acids are directly available from the intestine. Later, when those fuels have been exhausted, the liver supplies other tissues with glucose and ketone bodies, whereas adipose tissue provides them with fatty acids. All these organs are connected via the bloodstream. In addition, the metabolic activities of numerous microorganisms contribute to mammalian fuel metabolism (Box 22-1).

A The Brain Requires a Steady Supply of Glucose

Brain tissue has a remarkably high respiration rate. Although the human brain constitutes only ~2% of the adult body mass, it is responsible for ~20% of its resting O_2 consumption. Most of the brain's energy production powers the plasma membrane ($\text{Na}^+ - \text{K}^+$)-ATPase (Section 10-3A), which maintains the membrane potential required for nerve impulse transmission.

GATEWAY CONCEPT The Steady State

The metabolism of a single cell—or an entire organism—attains a non-equilibrium steady state in which raw materials are constantly entering and leaving the system. Consequently, metabolic processes never reach equilibrium. Cells can adapt to changing conditions, such as the amount and type of nutrients available or the demands of growth and differentiation, by adjusting flux through various metabolic pathways to achieve a new non-equilibrium steady state.

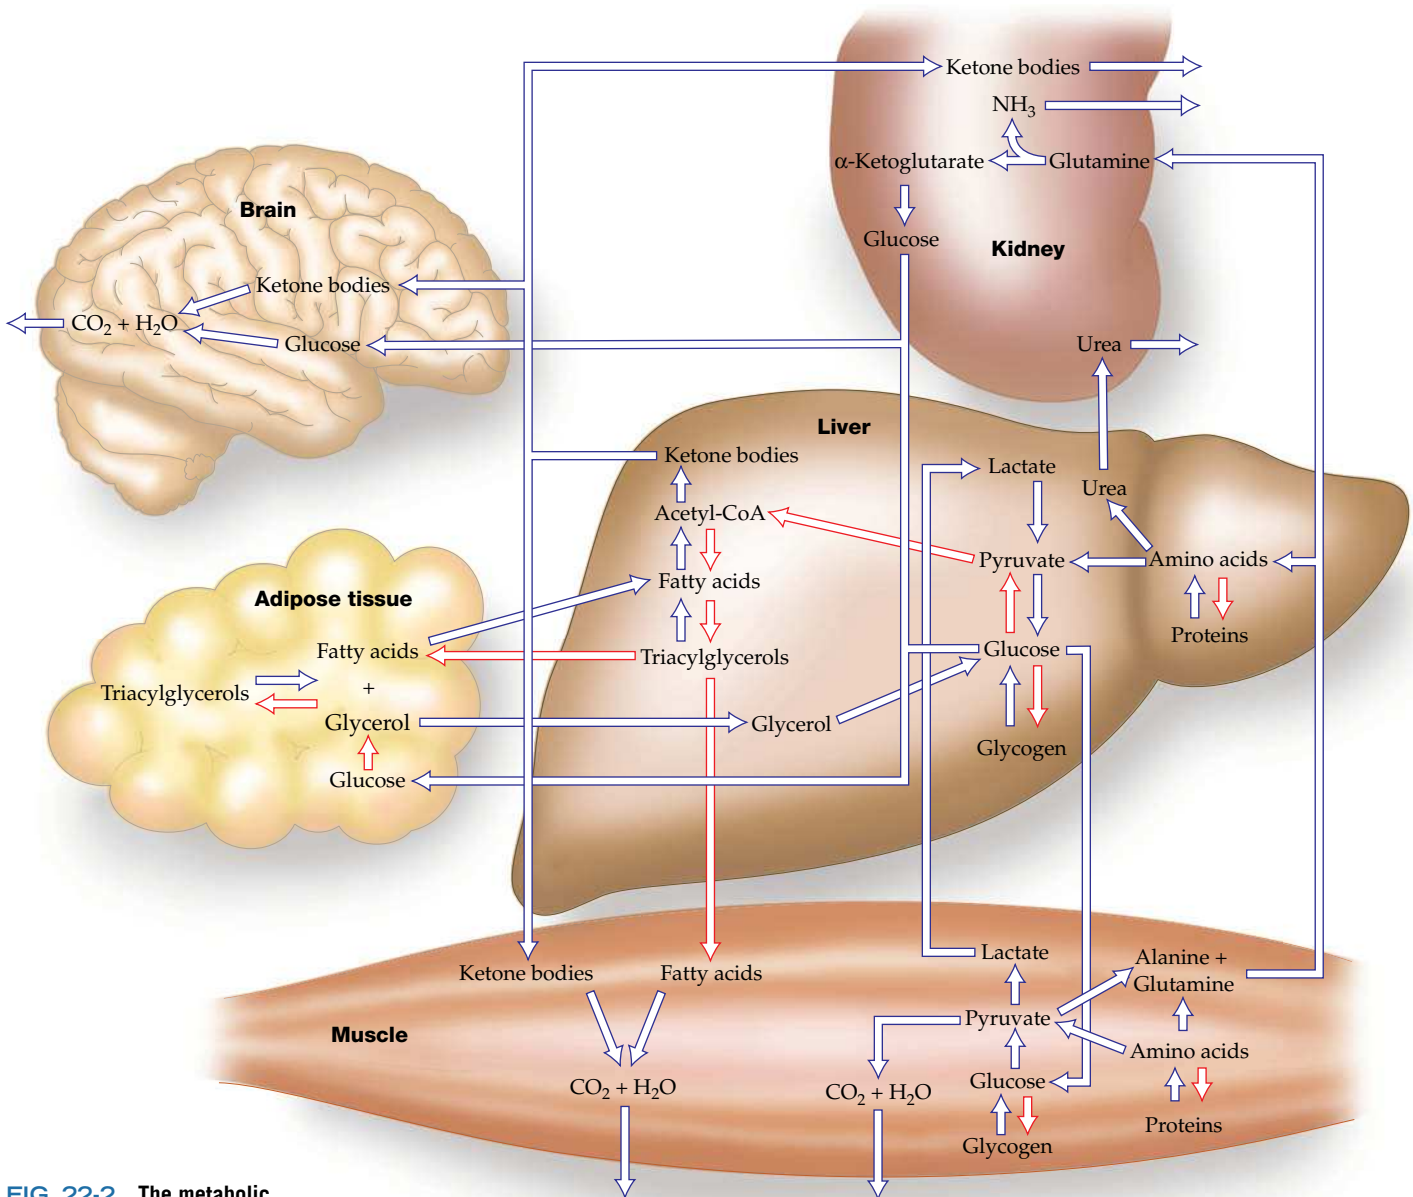

FIG. 22-2 The metabolic interrelationships among brain, adipose tissue, muscle, liver, and kidney. The red arrows indicate pathways that predominate in the well-fed state.

? Name the reaction or pathway that corresponds to each arrow.

Under usual conditions, glucose is the brain's primary fuel (although during an extended fast, the brain gradually switches to ketone bodies; Section 22-4A). Astrocytes and oligodendrocytes, which function as support cells rather than the primary electrical signaling cells (Section 10-2C), anaerobically metabolize glucose at a high rate and provide a portion of the resulting lactate to neurons for further oxidation. Since brain cells store very little glycogen, *they require a steady supply of glucose from the blood*. A blood glucose concentration of less than half the normal value of ~ 5 mM results in brain dysfunction. Levels much below this result in coma, irreversible damage, and, ultimately, death.

B Muscle Utilizes Glucose, Fatty Acids, and Ketone Bodies

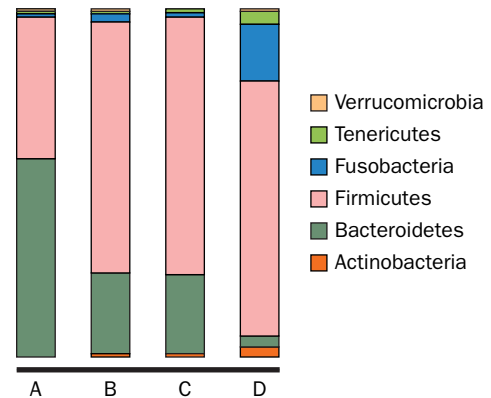

Muscle's major fuels are glucose (from glycogen), fatty acids, and ketone bodies. Rested, well-fed muscle synthesizes a glycogen store comprising 1 to 2% of its mass. Although triacylglycerols are a more efficient form of energy storage (Section 9-1B), the metabolic effort of synthesizing glycogen is cost-effective because glycogen can be mobilized more rapidly than fat and because glucose can be metabolized anaerobically, whereas fatty acids cannot.

The human body contains about ten trillion (10^{13}) cells, and there are probably ten times that number of microorganisms living in the intestine. These organisms, mostly bacteria, form an integrated community called the **microbiome**. At one time, the existence of microbes inside the human host was believed to be a form of commensalism, a relationship in which neither party has much to gain or lose in the partnership. It is now clear, however, that the microbiome plays an active role in providing nutrients (including some vitamins), regulating fuel use and storage, and preventing disease.

DNA sequencing studies have revealed that an individual may host several hundred to a thousand different species. The mixture remains fairly constant throughout the person's lifetime but can vary markedly between individuals, even in the same household. The Human Microbiome Project (<http://www.hmpdacc.org>) aims to better characterize the species that inhabit the human body and assess their contribution to human health and disease. For example, the human gut microbiome has four community types (see figure) that differ in the relative abundance of different groups of microorganisms. An individual's community type is loosely linked to factors such as gender, weight, the amount of protein or fat in the diet, and whether the individual was breastfed. Within each community, the species makeup varies considerably. Collectively, human intestines accommodate an estimated 4000 species, representing ~800,000 genes.

Although there is no "standard" microbiome, the bacteria and fungi in the small intestine carry out a common set of tasks: They ferment undigested carbohydrates, mainly polysaccharides that cannot be broken down by human digestive enzymes, and produce acetate, propionate, and butyrate. These short-chain fatty acids are absorbed by the host and are transformed into triacylglycerols for long-term storage. There is evidence that thin and obese individuals harbor different species of gut bacteria—obese individuals tend to harbor fewer Bacteroidetes and more Firmicutes—and the proportions change when the individual loses weight.

Composition of gut microbiome from four individuals representing different community types [Based on data from Lozupone, C.A., Stombaugh, J.I., Gordon, J.I., Jansson J.K., and Knight, R. *Nature* **489**, 220–230 (2012).]

These results suggest that certain microbial species might play a role in releasing more calories from food—calories that would then be stored as fat. Paradoxically, the use of noncaloric artificial sweeteners (Box 8-2) may actually contribute to obesity rather than weight loss by promoting the growth of more efficient energy-harvesting microbial species.

Intestinal bacteria also produce vitamin K, biotin, and folate, some of which can be taken up and used by the host. The importance of microbial digestion is illustrated by mice grown in a germ-free environment. Without the normal bacterial partners, the mice need to consume about 30% more food than normal animals whose digestive systems have been colonized by microorganisms.

In muscle, glycogen is converted to glucose-6-phosphate (G6P) for entry into glycolysis. Muscle cannot export glucose, however, because it lacks glucose-6-phosphatase. Furthermore, although muscle can synthesize glycogen from glucose, it does not participate in gluconeogenesis because it lacks the required enzymatic machinery. Consequently, *muscle carbohydrate metabolism serves only muscle*.

Muscle Contraction Is Anaerobic under Conditions of High Exertion. Muscle contraction is driven by ATP hydrolysis (Section 7-2) and therefore requires either an aerobic or an anaerobic ATP regeneration system. Respiration (the citric acid cycle and oxidative phosphorylation) is the body's major source of ATP resupply. Skeletal muscle at rest uses ~30% of the O_2 consumed by the human body. A muscle's respiration rate may increase in response to a heavy workload by as much as 25-fold. Yet, its rate of ATP hydrolysis can increase by a much greater amount. The ATP is initially regenerated by the reaction of phosphocreatine with ADP (Section 14-2C):

(phosphocreatine is resynthesized in resting muscle by the reversal of this reaction). Under conditions of maximum exertion, however, such as during a sprint, a muscle has only about a 4-s supply of phosphocreatine. It must then shift to ATP production via glycolysis of G6P, a process whose maximum flux greatly exceeds those of the citric acid cycle and oxidative phosphorylation. Much of the G6P is therefore degraded anaerobically to lactate (Section 15-3A). As we will see in Section 22-1F, export of lactate relieves much of the muscle's respiratory burden. Muscle fatigue, which occurs after ~20 s of maximal exertion, is not caused by exhaustion of the muscle's glycogen supply but by the drop in pH that results from the buildup of lactate. This phenomenon may be an adaptation that prevents muscle cells from

FIG. 22-3 Source of ATP during exercise in humans. The supply of endogenous ATP is extended for a few seconds by phosphocreatine, after which anaerobic glycolysis generates ATP. The shift from anaerobic to aerobic metabolism (oxidative phosphorylation) occurs after about 90 sec, or slightly later in trained athletes. [Adapted from McArdle, W.D., Katch, F.I., and Katch, V.L., *Exercise Physiology*, 2nd ed., Lea & Febiger (1986), p. 348.]

committing suicide by fully depleting their ATP supply. Exercise lasting more than a minute or two is fueled primarily by oxidative phosphorylation, which generates ATP more slowly but much more efficiently than glycolysis alone. The source of ATP during exercise of varying duration is summarized in **Fig. 22-3**.

The Heart Is Largely Aerobic. The heart is a muscular organ that acts continuously rather than intermittently. Therefore, heart muscle relies entirely on aerobic metabolism and is richly endowed with mitochondria; they occupy up to 40% of its cytoplasmic space. The heart can metabolize fatty acids, ketone bodies, glucose, pyruvate, and lactate. Fatty acids are the resting heart's fuel of choice, but during heavy work, the heart greatly increases its consumption of glucose, which is derived mostly from its relatively limited glycogen store.

C Adipose Tissue Stores and Releases Fatty Acids and Hormones

The function of adipose tissue is to store and release fatty acids as needed for fuel as well as to secrete hormones involved in regulating metabolism. Adipose tissue is widely distributed throughout the body but occurs most prominently under the skin, in the abdominal cavity, and in skeletal muscle. The adipose tissue of a normal 70-kg man contains ~15 kg of fat. This amount represents some 590,000 kJ of energy (141,000 dieter's Calories), which is sufficient to maintain life for ~3 months.

Adipose tissue obtains most of its fatty acids for storage from circulating lipoproteins as described in Section 20-1B. Fatty acids are activated by the formation of the corresponding fatty acyl-CoA and then esterified with glycerol-3-phosphate to form the stored triacylglycerols. The glycerol-3-phosphate arises from the reduction of dihydroxyacetone phosphate, which must be glycolytically generated from glucose.

In times of metabolic need, adipocytes hydrolyze triacylglycerols to fatty acids and glycerol through the action of hormone-sensitive lipase (Section 20-5). If glycerol-3-phosphate is abundant, many of the fatty acids so formed are reesterified to triacylglycerols. If glycerol-3-phosphate is in short supply, the fatty acids are released into the bloodstream. Thus, *fatty acid mobilization depends in part on the rate of glucose uptake since glucose is the precursor of glycerol-3-phosphate*. Metabolic need is signaled directly by a decrease in [glucose] as well as by hormonal stimulation.

D Liver Is the Body's Central Metabolic Clearinghouse

The liver maintains the proper levels of circulating fuels for use by the brain, muscles, and other tissues. It is uniquely situated to carry out this task because all the nutrients absorbed by the intestines except fatty acids are released into the portal vein, which drains directly into the liver.

Glucokinase Converts Blood Glucose to Glucose-6-Phosphate. *One of the liver's major functions is to act as a blood glucose "buffer."* It does so by taking up and releasing glucose in response to hormones and to the concentration of glucose itself. After a carbohydrate-containing meal, when the blood glucose concentration reaches ~6 mM, the liver takes up glucose by converting it to G6P. This reaction is catalyzed by **glucokinase**, a liver isozyme of hexokinase (which is therefore also called **hexokinase IV**). The hexokinases in most cells obey Michaelis-Menten kinetics, have a high glucose affinity ($K_M < 0.1$ mM), and are inhibited by their reaction product (G6P). Glucokinase, in contrast, has much lower glucose affinity (reaching half-maximal velocity at ~5 mM) and displays sigmoidal kinetics. Consequently, *glucokinase activity increases rapidly with blood [glucose] over the normal physiological range (Fig. 22-4)*. Glucokinase, moreover, is not inhibited by physiological concentrations of G6P. Therefore, the higher the blood [glucose], the

faster the liver converts glucose to G6P. At low blood [glucose], the liver does not compete with other tissues for the available glucose, whereas at high blood [glucose], when the glucose needs of those tissues are met, the liver can take up the excess glucose at a rate roughly proportional to the blood glucose concentration.

Glucokinase is a monomeric enzyme, so its sigmoidal kinetic behavior is somewhat puzzling (models of allosteric interactions do not explain cooperative behavior in a monomeric protein; Section 7-1D). Glucokinase is subject to metabolic control, however. Emile Van Schaftingen has isolated a **glucokinase regulatory protein** from rat liver, which, in the presence of the glycolytic intermediate fructose-6-phosphate (F6P), is a competitive inhibitor of glucokinase. Since F6P and the glucokinase product G6P are equilibrated in liver cells by phosphoglucose isomerase, glucokinase is, in effect, inhibited by its product. Fructose-1-phosphate (F1P), an intermediate in liver fructose metabolism (Section 15-5A), overcomes this inhibition. Since fructose is normally available only from dietary sources, fructose may be the signal that triggers the uptake of dietary glucose by the liver.

Glucose-6-Phosphate Is at the Crossroads of Carbohydrate Metabolism. G6P has several alternative fates in the liver, depending on the glucose demand (Fig. 22-5):

1. G6P can be converted to glucose, by the action of glucose-6-phosphatase, for transport via the bloodstream to the peripheral organs. This occurs only when the blood [glucose] drops below ~ 5 mM. During exercise or fasting, low concentrations of blood glucose cause the pancreas to secrete glucagon. Glucagon receptors on the liver cell surface respond by activating adenylate cyclase. The resulting increase in intracellular [cAMP] triggers glycogen breakdown (Section 16-3).
2. G6P can be converted to glycogen (Section 16-2) when the body's demand for glucose is low.
3. G6P can be converted to acetyl-CoA via glycolysis and the action of pyruvate dehydrogenase. This glucose-derived acetyl-CoA, if it is not oxidized via the citric acid cycle and oxidative phosphorylation to generate ATP, can be used to synthesize fatty acids (Section 20-4), phospholipids (Section 20-6), and cholesterol (Section 20-7A).
4. G6P can be degraded via the pentose phosphate pathway (Section 15-6) to generate the NADPH required for the biosynthesis of fatty acids and other compounds.

The Liver Can Synthesize or Degrade Triacylglycerols. Fatty acids are also subject to alternative metabolic fates in the liver. When the demand for metabolic fuels is high, fatty acids are degraded to acetyl-CoA and then to ketone bodies for export to the peripheral tissues. The liver itself cannot use ketone bodies as fuel, because liver cells lack 3-ketoacyl-CoA transferase, an enzyme required to convert ketone bodies back to acetyl-CoA (Section 20-3). Fatty acids rather than glucose or ketone bodies are therefore the liver's major acetyl-CoA source under conditions of high metabolic demand. The liver generates its ATP from this acetyl-CoA through the citric acid cycle and oxidative phosphorylation.

When the demand for metabolic fuels is low, fatty acids are incorporated into triacylglycerols that are secreted into the bloodstream as VLDL for uptake by adipose tissue. Fatty acids are also incorporated into phospholipids (Section 20-6). Under these conditions, fatty acids synthesized in the liver are not oxidized to acetyl-CoA because fatty acid synthesis (in the cytosol) is separated from fatty acid oxidation (in the mitochondria) and because malonyl-CoA, an intermediate in fatty acid synthesis, inhibits the transport of fatty acids into the mitochondria.

Amino Acids Are Metabolic Fuels. The liver degrades amino acids to a variety of metabolic intermediates that can be completely oxidized to CO_2 and H_2O or

FIG. 22-4 Relative enzymatic activities of hexokinase and glucokinase over the physiological blood glucose range. Glucokinase has much lower affinity for glucose ($K_M \approx 5$ mM) than does hexokinase ($K_M \approx 0.1$ mM) and exhibits sigmoidal rather than hyperbolic variation with [glucose]. [The glucokinase curve was generated using the Hill equation (Eq. 7-8) with $K = 10$ mM and $n = 1.5$ as obtained from Cardenas, M.L., Rabajille, E., and Niemeyer, H., *Eur. J. Biochem.* **145**, 163–171 (1984).]

? Do the two enzymes have different k_{cat} values?

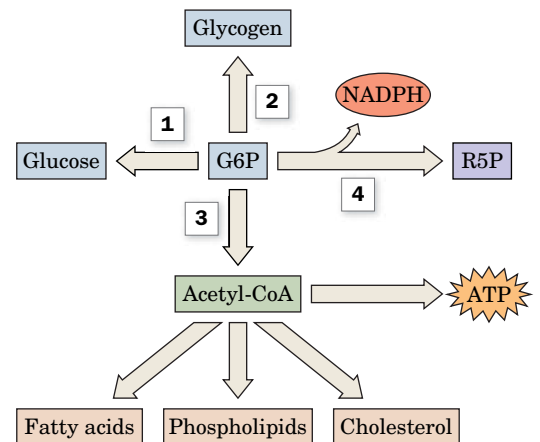

FIG. 22-5 Metabolic fate of glucose-6-phosphate (G6P) in liver. G6P can be converted (1) to glucose for export or (2) to glycogen for storage. Acetyl-CoA derived from G6P degradation (3) is the starting material for lipid biosynthesis. It is also consumed in generating ATP by respiration. Degradation of G6P via the pentose phosphate pathway (4) yields NADPH.

? Which pathways would predominate in rapidly regenerating liver tissue?

converted to glucose or ketone bodies (Section 21-4). Oxidation of amino acids provides a significant fraction of metabolic energy immediately after a meal, when amino acids are present in relatively high concentrations in the blood. During a fast, when other fuels become scarce, glucose is produced from amino acids arising mostly from muscle protein degradation to alanine and glutamine. Thus, *proteins, in addition to their structural and functional roles, are important fuel reserves.*

E Kidney Filters Wastes and Maintains Blood pH

The kidney filters urea and other waste products from the blood while it recovers important metabolites such as glucose. In addition, the kidney maintains the blood's pH by regenerating depleted blood buffers such as bicarbonate (lost by the exhalation of CO_2) and by excreting excess H^+ together with the conjugate bases of excess metabolic acids such as the ketone bodies acetoacetate and β -hydroxybutyrate. Protons are also excreted in the form of NH_4^+ , with the ammonia derived from glutamine or glutamate. The remaining amino acid skeleton, α -ketoglutarate, can be converted to glucose by gluconeogenesis (the kidney is the only tissue besides liver that can carry out glucose synthesis). During starvation, the kidneys generate as much as 50% of the body's glucose supply.

F Blood Transports Metabolites in Interorgan Metabolic Pathways

The ability of the liver to supply other tissues with glucose or ketone bodies, or the ability of adipocytes to make fatty acids available to other tissues, depends, of course, on the circulatory system, which transports metabolic fuels, intermediates, and waste products among tissues. In addition, several important metabolic pathways are composed of reactions occurring in multiple tissues. In this section, we describe two well-known interorgan pathways.

Glucose and Lactate Are Transported in the Cori Cycle. The ATP that powers muscle contraction is generated through oxidative phosphorylation (in mitochondrion-rich slow-twitch muscle fibers; Box 15-3) or by rapid catabolism of glucose to lactate (in fast-twitch muscle fibers). Slow-twitch fibers also produce lactate when ATP demand exceeds oxidative flux. The lactate is transferred via the bloodstream to the liver, where it is reconverted to pyruvate by lactate dehydrogenase and then to glucose by gluconeogenesis. Thus, liver and muscle are linked by the bloodstream in a metabolic cycle known as the **Cori cycle** (Fig. 22-6) in honor of Carl and Gerty Cori (Box 16-1), who first described it.

The ATP-consuming glycolysis/gluconeogenesis cycle would be a futile cycle if it occurred within a single cell. In this case, the two halves of the pathway occur in different organs. Liver ATP powers the synthesis of glucose from lactate produced in muscle. The resynthesized glucose returns to the muscle, where it may be stored as glycogen or catabolized immediately to generate ATP for muscle contraction.

FIG. 22-6 The Cori cycle. Lactate produced by muscle glycolysis is transported by the bloodstream to the liver, where it is converted to glucose by gluconeogenesis. The bloodstream carries the glucose back to the muscle, where it may be stored as glycogen. **WPLS See the Animated Figures.**

? Does the Cori cycle operate while the muscle is at rest?

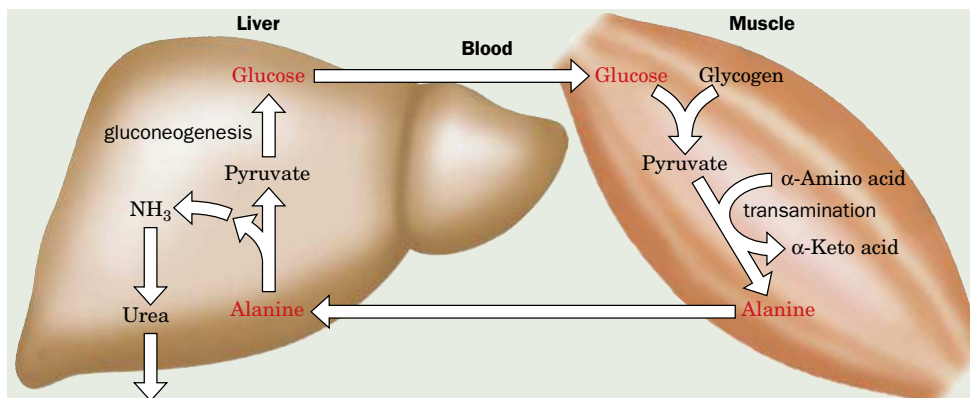

FIG. 22-7 The glucose–alanine cycle. Pyruvate produced by muscle glycolysis is the amino-group acceptor for muscle aminotransferases. The resulting alanine is transported by the bloodstream to the liver, where it is converted back to pyruvate (its amino group is disposed of via urea synthesis). The pyruvate is a substrate for gluconeogenesis, and the bloodstream carries the resulting glucose back to the muscles. **WPLS** See the Animated Figures.

? How does the muscle restore its amino acid pool?

The ATP consumed by the liver during the operation of the Cori cycle is regenerated by oxidative phosphorylation. After vigorous exertion, it may take at least 30 min for the oxygen consumption rate to decrease to its resting level. The elevated O_2 consumption pays off the **oxygen debt** created by the demand for ATP to drive gluconeogenesis.

The Glucose–Alanine Cycle Transfers Alanine to the Liver. In a pathway similar to the Cori cycle, alanine rather than lactate travels from muscle to the liver. In muscle, certain aminotransferases use pyruvate as their α -keto acid substrate rather than α -ketoglutarate or oxaloacetate (Section 21-2A):

The product amino acid, alanine, is released into the bloodstream and transported to the liver, where it undergoes transamination back to pyruvate. This pyruvate is a substrate for gluconeogenesis, and the resulting glucose can be returned to the muscles to be glycolytically degraded. This is the **glucose–alanine cycle** (Fig. 22-7). The amino group carried by alanine ends up in either ammonia or aspartate and can be used for urea biosynthesis (which occurs only in the liver). Thus, *the glucose–alanine cycle is a mechanism for transporting nitrogen from muscle to liver.*

During fasting, the glucose formed in the liver by this route is also used by other tissues, breaking the cycle. Because the pyruvate originates from muscle protein degradation, muscle supplies glucose to other tissues even though it does not carry out gluconeogenesis.

CHECKPOINT

- Summarize the importance of pyruvate and acetyl-CoA for catabolism and anabolism.
- Without looking at Fig. 22-1, draw a diagram of the major metabolic pathways involving proteins, glycogen, and triacylglycerols.
- Summarize the major features of fuel metabolism in the brain, muscle, adipose tissue, liver, and kidney.
- Explain why the high K_M of glucokinase is important for the role of the liver in buffering blood glucose.
- List all the possible fates for a glucose molecule in the liver.
- Describe the conditions under which the Cori cycle and the glucose–alanine cycle operate.
- Without looking at the text, draw diagrams of these two metabolic cycles.

2 Hormonal Control of Fuel Metabolism

KEY CONCEPTS

- Insulin release in response to glucose promotes fuel uptake and storage.
- Glucagon and the catecholamines promote fuel mobilization.

Multicellular organisms coordinate their activities at every level of their organization through complex signaling systems (Chapter 13). Most cells in a multicellular organism cannot take up fuel for growth and metabolism without first receiving a signal to do so. The human endocrine system responds to the needs of an organism by secreting a wide variety of hormones that enable the body to maintain **metabolic homeostasis** (balance between energy inflow and output), respond to external stimuli, and follow various developmental programs.

We have already discussed steroid hormones (Section 9-1E), the peptide hormones insulin and glucagon (Sections 13-1A, 13-4D, and 16-3C), and the

catecholamines epinephrine and norepinephrine (Sections 13-1B, 16-3C, and 21-6B). With the exception of steroids, which can diffuse through cell membranes and interact directly with intracellular components (and which we discuss further in Section 28-3B), these extracellular signals must first bind to a cell-surface receptor. In this section, we review the action of hormones synthesized by the pancreas and adrenal glands, since these play the largest roles in regulating the metabolism of fuels in various mammalian tissues. We will also review the receptors and pathways by which these hormones exert their effects on cells.

A Insulin Release Is Triggered by Glucose

The pancreas responds to increases in the concentration of blood glucose by secreting insulin, which therefore serves as a signal for plentiful metabolic fuel. Pancreatic β cells are most sensitive to glucose at concentrations of 5.5 to 6.0 mM (normal blood glucose concentrations range from 3.6 to 5.8 mM). There is no evidence for a cell-surface glucose “receptor” that might relay a signal to the secretory machinery in the β cell. In fact, glucose enters β cells via passive transport, and its metabolism generates the signal for insulin secretion.

The rate-limiting step of glucose metabolism in β cells is the reaction catalyzed by glucokinase (the same enzyme that occurs in hepatocytes). Consequently, glucokinase is considered the β cell’s glucose “sensor.” Glucokinase’s G6P product is not used to synthesize glycogen, and the activity of the pentose phosphate pathway is minor. Furthermore, lactate dehydrogenase activity is low. As a result, essentially all the G6P produced in β cells is degraded to pyruvate and then converted to acetyl-CoA for oxidation in the mitochondrion. The ATP produced induces an ATP-gated K^+ channel in the plasma membrane to close, and the resulting membrane depolarization (the membrane is normally positive outside) causes a voltage-gated Ca^{2+} channel to open. The consequent Ca^{2+} ion influx into the cell triggers the exocytosis (Section 9-4F) of insulin-containing secretory granules. Thus, the overall level of the β cell’s respiratory activity, which varies with glucose availability, regulates insulin secretion.

FIG. 22-8 GLUT4 activity. Glucose uptake in muscle and fat cells is regulated by the insulin-stimulated exocytosis (the opposite of endocytosis) of specialized membranous vesicles containing GLUT4 (*left*). On insulin withdrawal, the process reverses itself through endocytosis (*right*). **WPLS** See the Animated Figures.

Insulin Promotes Fuel Storage in Muscle and Adipose Tissue.

Insulin signaling is very complex (Fig. 13-31). It acts as the primary regulator of blood glucose concentration by promoting glucose uptake in muscles and adipose tissue and by inhibiting hepatic glucose production. Insulin also stimulates cell growth and differentiation by increasing the synthesis of glycogen, proteins, and triacylglycerols.

Muscle cells and adipocytes express an insulin-sensitive glucose transporter known as **GLUT4**. Insulin stimulates GLUT4 activity. Such an increase can occur through an increase in the intrinsic activity of the transporter molecules, but in the case of GLUT4, the increase is accomplished through the appearance of additional transporter molecules in the plasma membrane (**Fig. 22-8**). In the absence of insulin, GLUT4 is localized in intracellular vesicles and tubular structures known as **GLUT4 storage vesicles**. Insulin promotes the fusion of these vesicles to the plasma membrane in a process that is mediated by SNAREs (Section 9-4F). GLUT4 appears on the cell surface only a few minutes after insulin stimulation. GLUT4 has a relatively low K_M for glucose (2–5 mM), so cells containing this transporter can rapidly take up glucose from the blood. On insulin withdrawal, the glucose transporters are gradually sequestered through endocytosis.

The insulin-dependent GLUT4 transport system allows muscle and adipose tissue to quickly stockpile metabolic fuel immediately after a meal. Tissues such as the brain, which uses glucose almost exclusively as a fuel, constitutively express an insulin-insensitive glucose transporter. Consequently, the central

nervous system does not experience large fluctuations in glucose absorption. Significantly, the liver also lacks GLUT4 and therefore does not respond to increases in insulin levels by increasing its rate of glucose uptake.

Once glucose enters cells, it can be used to synthesize glycogen (in muscle) and triacylglycerols (in adipocytes; the glucose must first be metabolized to acetyl-CoA for fatty acid synthesis). Insulin specifically promotes those metabolic activities. As discussed in Section 16-3, insulin activates glycogen synthase by promoting its dephosphorylation. In adipocytes, insulin activates the pyruvate dehydrogenase complex (by activating the associated phosphatase; Section 17-4A), and it activates acetyl-CoA carboxylase and increases levels of fatty acid synthase (Section 20-5). At the same time, insulin inhibits lipolysis by inhibiting hormone-sensitive lipase.

Insulin Blocks Liver Gluconeogenesis and Glycogenolysis. Although the liver does not respond to insulin by increasing its rate of uptake of glucose, insulin binding to its receptor on hepatocytes has several consequences. The inactivation of phosphorylase kinase decreases the rate of glycogenolysis, and the activation of glycogen synthase promotes glycogen synthesis. Insulin also inhibits transcription of the genes encoding the gluconeogenic enzymes phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase (Section 16-4) and stimulates transcription of the genes for the glycolytic enzymes glucokinase and pyruvate kinase. The expression of lipogenic enzymes such as acetyl-CoA carboxylase and fatty acid synthase also increases. The result of these regulatory changes is that *the liver stores glucose (as glycogen and as triacylglycerols) rather than producing glucose by glycogenolysis or gluconeogenesis*. The major metabolic effects of insulin are summarized in [Table 22-1](#).

B Glucagon and Catecholamines Counter the Effects of Insulin

As we discussed in Section 16-3C, the peptide hormone glucagon activates a series of intracellular events that lead to glycogenolysis in the liver. This control mechanism helps make glucose available to other tissues when the concentration of circulating glucose drops. Muscle cells, which lack a glucagon receptor and cannot respond directly to the hormone, benefit indirectly from the glucose released by the liver. Glucagon also stimulates fatty acid mobilization from adipose tissue by activating hormone-sensitive lipase.

The catecholamines elicit responses similar to glucagon's. Epinephrine and norepinephrine, which are released during times of stress, bind to two different types of receptors (Section 13-1B): the β -adrenergic receptor, which is linked to the adenylate cyclase system (Fig. 13-23), and the α -adrenergic receptor, whose second messenger, inositol-1,4,5-trisphosphate (IP₃; Section 13-4A), causes intracellular Ca²⁺ concentrations to increase.

Liver cells respond to epinephrine directly and indirectly. Epinephrine promotes the release of glucagon from the pancreas, and glucagon binding to its receptor on liver cells stimulates glycogen breakdown. Epinephrine also binds directly to both α - and β -adrenergic receptors on the surfaces of liver cells

TABLE 22-1 Hormonal Effects on Fuel Metabolism

Tissue	Insulin	Glucagon	Epinephrine
Muscle	↑ Glucose uptake ↑ Glycogen synthesis	No effect	↑ Glycogenolysis
Adipose tissue	↑ Glucose uptake ↑ Lipogenesis ↓ Lipolysis	↑ Lipolysis	↑ Lipolysis
Liver	↑ Glycogen synthesis ↑ Lipogenesis ↓ Gluconeogenesis	↓ Glycogen synthesis ↑ Glycogenolysis	↓ Glycogen synthesis ↑ Glycogenolysis ↑ Gluconeogenesis

(Fig. 16-14, right). Binding to the β -adrenergic receptor results in increased intracellular cAMP, which leads to glycogen breakdown and gluconeogenesis. Epinephrine binding to the α -adrenergic receptor stimulates an increase in intracellular $[Ca^{2+}]$, which reinforces the cells' response to cAMP (recall that phosphorylase kinase, which activates glycogen phosphorylase and inactivates glycogen synthase, is fully active only when phosphorylated and in the presence of increased $[Ca^{2+}]$; Section 16-3B). In addition, glycogen synthase is inactivated through phosphorylation catalyzed by several Ca^{2+} -dependent protein kinases.

Epinephrine binding to the β -adrenergic receptor on muscle cells similarly promotes glycogen degradation, thereby mobilizing glucose that can be metabolized by glycolysis to produce ATP. In adipose tissue, epinephrine binding to several α - and β -type adrenergic receptors leads to activation of hormone-sensitive lipase, which results in the mobilization of fatty acids that can be used as fuels by other tissues. In addition, epinephrine stimulates smooth muscle relaxation in the bronchi and blood vessels supplying skeletal muscle, while it

(b) Fasted state/stress

FIG. 22-9 Overview of hormonal control of fuel metabolism.

(a) Immediately after a meal, when glucose and fatty acids are abundant, insulin signals tissues to store fuel as glycogen and triacylglycerols. Insulin also stimulates tissues other than liver to take up glucose via the GLUT4 transporter. (b) When dietary fuels are not

available, glucagon stimulates the liver to release glucose and adipose tissue to release fatty acids. During stress, epinephrine elicits similar responses.

? Identify the major form(s) of stored fuel in each organ.

stimulates constriction of the blood vessels that supply skin and other peripheral organs. Together, these physiological changes prepare the body for sudden action by mobilizing energy reserves and directing them where they are needed. The major responses to glucagon and epinephrine are summarized in Table 22-1, and the metabolic effects of insulin, glucagon, and epinephrine under different conditions are presented schematically in Fig. 22-9.

Several Types of Receptors and Biochemical Signaling Pathways Participate in Metabolic Regulation. As described in Chapter 13, every signaling pathway consists of a receptor, a mechanism for transmitting the ligand-binding event to the cell interior, and a series of intracellular responses that may involve a second messenger and/or chemical changes catalyzed by kinases and phosphatases. There are three major signal transduction pathways: those involving receptor tyrosine kinases associated with the Ras signaling cascade (Section 13-2), those in which adenylate cyclase generates cAMP (3',5'-cyclic AMP) as a second messenger (Section 13-3), and those involving phosphoinositide cleavage by phospholipase C (PLC), with inositol-1,4,5-trisphosphate (IP₃) and 1,2-diacylglycerol (DAG), as well as Ca²⁺, as second messengers (Section 13-4). Both second messenger systems involve G protein-coupled receptors (Section 13-3). The major G protein activating adenylate cyclase is G_s, and the major G protein activating phospholipase C is G_q. Figure 22-10 is a composite of the three signaling systems.

FIG. 22-10 Overview of the major signal transduction pathways.

(a) The binding of a ligand to a receptor tyrosine kinase initiates the Ras signaling cascade of phosphorylations, which leads to changes in gene expression. (b) The binding of a ligand to its corresponding G protein-coupled receptor stimulates (or in some cases inhibits) adenylate cyclase (AC) to synthesize the second messenger cAMP. The cAMP, in turn, activates protein kinase A (PKA) to phosphorylate its target proteins, leading to a cellular response. (c) The binding of a ligand to its corresponding G_q protein-coupled receptor initiates the

phosphoinositide pathway, which activates phospholipase C (PLC) to hydrolyze the membrane lipid PIP₂ to the second messengers IP₃ and DAG. IP₃ causes the release of Ca²⁺ from the endoplasmic reticulum, DAG activates protein kinase C (PKC), and Ca²⁺ activates both PKC and Ca²⁺-calmodulin dependent protein kinase (CaMK). The phosphorylation of target proteins by PKC and CaMK leads to cellular responses.

? Locate the kinases and second messengers involved in each signaling system.

CHECKPOINT

- How does the pancreas sense glucose levels?
- Summarize the role of insulin in regulating fuel metabolism in the liver, muscle, and adipose tissue.
- How do glucagon and epinephrine affect fuel metabolism in liver, muscle, and adipose tissue?
- Describe the three main types of signaling pathways that participate in metabolic regulation.

The hormones described above and in Section 13-1, as well as many other hormones, growth factors, and other signaling molecules, use signal-transduction pathways to set in motion a series of biochemical reactions that produce biological responses such as altered metabolism, cell differentiation, and cell growth and division. The exact nature of the response depends on many factors. Cells respond to a hormone, generally referred to as a ligand, only if they display the appropriate receptor. Specific intracellular responses are modulated by the number, type, and cellular locations of the elements of the signaling systems. Furthermore, a given cell typically contains receptors for many different ligands, so the response to one particular ligand may depend on the level of engagement of the other ligands with the cell's signal-transduction machinery. As a result, *cells can react to discrete signals or combinations of signals with variations in the magnitude and duration of the cellular response.*

3 Metabolic Homeostasis: The Regulation of Energy Metabolism, Appetite, and Body Weight

KEY CONCEPTS

- AMP-dependent protein kinase activates ATP-generating processes and inhibits ATP-consuming processes.
- Fuel use and appetite are regulated by the adipose tissue hormones adiponectin and leptin as well as by hormones produced by the hypothalamus, stomach, and intestine.
- Thermogenesis helps balance energy expenditure with energy intake.

The complex mechanisms that regulate mammalian fuel metabolism permit the body to respond efficiently to changing energy demands and to accommodate changes in the availability of various fuels, maintaining reasonable metabolic homeostasis. This balance depends on the interactions of many factors. In this section we discuss some of the participants in this complex network regulating energy expenditure, appetite, and body weight.

A AMP-Dependent Protein Kinase Is the Cell's Fuel Gauge

All of the metabolic pathways discussed above are affected in one way or another by the need for ATP, as is indicated by the cell's AMP-to-ATP ratio (Section 15-4A). Several enzymes are either activated or inhibited allosterically by AMP, and several others are phosphorylated by **AMP-dependent protein kinase (AMPK)**, a major regulator of metabolic homeostasis. *AMPK activates metabolic breakdown pathways that generate ATP while inhibiting biosynthetic pathways to conserve ATP for more vital processes.* AMPK is an $\alpha\beta\gamma$ heterotrimer found in all eukaryotic organisms from yeast to humans. The α subunit contains a Ser/Thr protein kinase domain, and the γ subunit contains sites for allosteric activation by AMP and inhibition by ATP. Like other protein kinases, AMPK's kinase domain must be phosphorylated for activity. Binding of AMP to the γ subunit causes a conformational change that exposes Thr 172 in the activation loop of the α subunit, promoting its phosphorylation and increasing its activity at least 100-fold. AMP can activate the phosphorylated enzyme up to 5-fold more. The major kinase that phosphorylates AMPK is named **LKB1**. The specific knockout of LKB1 in mouse liver results in the loss of the phosphorylated form of AMPK.

AMPK Activates Glycolysis in Ischemic Cardiac Muscle. AMPK's targets include the heart isozyme of the bifunctional enzyme PFK-2/FBPase-2, which controls the fructose-2,6-bisphosphate (F2,6P) concentration (Section 16-4C). The phosphorylation of this isozyme activates the PFK-2 activity, increasing

[F_{2,6}P], which in turn activates PFK-1 and glycolysis. Consequently, in **ischemic** (blood-starved) heart muscle cells, when there is insufficient oxygen for oxidative phosphorylation to maintain adequate concentrations of ATP, the resulting AMP buildup causes the cells to switch to anaerobic glycolysis for ATP production.

AMPK Inhibits Lipogenesis and Gluconeogenesis in Liver. AMPK-mediated phosphorylation also inhibits acetyl-CoA carboxylase (ACC, which catalyzes the first committed step of fatty acid synthesis; Section 20-4B), hydroxymethylglutaryl-CoA reductase (HMG-CoA reductase, which catalyzes the rate-determining step in cholesterol biosynthesis; Section 20-7B), and glycogen synthase (which catalyzes the rate-limiting reaction in glycogen synthesis; Section 16-2B). Consequently, when the rate of ATP production is inadequate, these biosynthetic pathways are turned off, thereby conserving ATP for the most vital cellular functions.

AMPK Promotes Fatty Acid Oxidation and Glucose Uptake in Skeletal Muscle. The inhibition of ACC results in a decrease in the concentration of malonyl-CoA, the starting material for fatty acid biosynthesis. Malonyl-CoA has an additional role, however. It is an inhibitor of carnitine palmitoyl transferase I (Section 20-5), which is required to transfer cytosolic palmitoyl-CoA into the mitochondria for oxidation. The decrease in malonyl-CoA concentration therefore allows more palmitoyl-CoA to be oxidized. AMPK also increases the expression of GLUT4 in muscle cells, as well as its recruitment to the muscle cell plasma membrane (Section 22-2F), thus facilitating the insulin-independent entry of glucose into the cells.

AMPK Inhibits Lipolysis in Adipocytes. AMPK phosphorylates hormone-sensitive triacylglycerol lipase in adipose tissue (Section 20-5). This phosphorylation inhibits rather than activates the enzyme, in part by preventing the relocation of the enzyme to the lipid droplet, the cellular location of lipolysis. As a result, fewer triacylglycerols are broken down so that fewer fatty acids are exported to the bloodstream. This latter process seems paradoxical (fatty acid oxidation would help relieve an ATP deficit), although it has been speculated that it prevents the cellular buildup of fatty acids to toxic levels. The major effects of AMPK activation on glucose and lipid metabolism in liver, skeletal muscle, heart muscle, and adipose tissue are diagrammed in Fig. 22-11.

FIG. 22-11 Major effects of AMP-activated protein kinase (AMPK) on glucose and lipid metabolism in liver, muscle, and adipose tissue. In skeletal muscle, AMPK stimulates glucose uptake and glucose and fatty acid oxidation while inhibiting glycogen synthesis. In heart muscle, AMPK stimulates glycolysis. In liver, AMPK inhibits lipid biosynthesis and gluconeogenesis while activating fatty acid oxidation. In adipose tissue, AMPK inhibits fatty acid biosynthesis and lipolysis. [After M.C. Towler and D.G. Hardie, *Circulation Res.* **100**, 328 (2007).]

FIG. 22-12 Adiponectin trimers, hexamers, and multimers. These complexes are referred to as low molecular weight (LMW), medium molecular weight (MMW), and high molecular weight (HMW) forms. [After Kadowaki, T. and Yamauchi, T., *Endocrine Rev.* **26**, 439 (2005).]

B Adipocytes and Other Tissues Help Regulate Fuel Metabolism and Appetite

In addition to insulin, glucagon, and epinephrine, a variety of other hormones help regulate fuel acquisition, use, and storage. Some of these, such as **adiponectin**, are secreted exclusively by adipocytes, a cell type whose endocrine activity was not recognized until the early 2000s.

Adiponectin Regulates AMPK Activity. Adiponectin is a 247-residue protein hormone that helps regulate energy homeostasis and glucose and lipid metabolism by controlling AMPK activity. Its monomers consist of an N-terminal collagenlike domain and a C-terminal globular domain. Adiponectin occurs in the bloodstream in several forms: a low molecular weight (LMW) trimer formed by the coiling of its collagenlike domains into a triple helix (Section 6-1C) as well as hexamers (MMW) and multimers (HMW) that form disulfide-cross-linked bouquets (Fig. 22-12). In addition, globular adiponectin, formed by the cleavage of the collagenlike domain to release globular monomers, occurs in lower concentrations.

The binding of adiponectin to **adiponectin receptors**, which occur on the surfaces of both liver and muscle cells, acts to increase the phosphorylation and activity of AMPK. This, as we have seen (Section 22-3A), inhibits gluconeogenesis and stimulates fatty acid oxidation in liver and stimulates glucose uptake and glucose and fatty acid oxidation in muscle. All of these effects act to increase insulin sensitivity, in part because adiponectin and insulin elicit similar responses in tissues such as liver. Decreased adiponectin is associated with insulin resistance (Section 22-4B). Paradoxically, the blood concentration of adiponectin, which is secreted by adipocytes, decreases with increased amounts of adipose tissue. This may be because increased adipose tissue is also associated with increased production of **tumor necrosis factor- α (TNF α)**, a protein growth factor that decreases both the expression and secretion of adiponectin from adipose tissue.

Leptin Is a Satiety Hormone. **Leptin** (Greek: *leptos*, thin) is a 166-residue polypeptide that is normally produced by adipocytes (Fig. 22-13). It was discovered by studying genetically obese mice. Most animals, including humans, tend to have stable weights; that is, if they are given free access to food, they eat just enough to maintain their “set-point” weight. However, a strain of mice that is homozygous for defects in the *obese* gene (known as *ob/ob* mice) are as much as three times the weight of normal (*OB/OB*) mice (Fig. 22-14) and overeat when given access to unlimited quantities of food. The *OB* gene encodes leptin. When leptin is injected into *ob/ob* mice, they eat less and lose weight. Leptin has therefore been considered a “satiety” signal that affects the appetite control system of the brain. Leptin also causes higher energy expenditure.

The simple genetic basis for obesity in *ob/ob* mice does not appear to apply to most obese humans. Leptin levels in humans increase with the percentage of body fat, consistent with the synthesis of leptin by adipocytes. Thus, obesity in humans is apparently the result not of faulty leptin production but of leptin resistance, perhaps due to a decrease in the level of a leptin receptor in the brain or the saturation of the receptor that transports leptin across the blood-brain barrier into the central nervous system.

FIG. 22-13 X-Ray structure of human leptin-E100. This mutant form of leptin (Trp 100 → Glu) has comparable biological activity to the wild-type protein but crystallizes more readily. The protein, which is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), forms a four-helix bundle as do many protein growth factors (e.g., human growth hormone; Fig. 13-3). Residues 25 to 38 are not visible in the X-ray structure. [Based on an X-ray structure by Faming Zhang, Eli Lilly & Co., Indianapolis, Indiana. PDBid 1AX8.]

A small minority of obese individuals are leptin deficient in a manner similar to *ob/ob* mice. For example, two grossly obese children who are members of the same highly consanguineous (descended from the same ancestors) family (they are cousins and both sets of parents are cousins) have been shown to be homozygous for a defective *OB* gene. The children, at the ages of 8 and 2 years old, respectively, weighed 86 and 29 kg and were noted to have remarkably large appetites. Their *OB* genes have a deletion of a single guanine nucleotide in codon 133 that causes all succeeding codons to be misread (a **frameshift mutation**; Section 27-1A), which evidently renders the mutant leptin biologically inactive. In fact, their leptin serum levels were only ~10% of normal. Leptin injections have relieved their symptoms.

A diminished response to leptin leads to high concentrations of **neuropeptide Y (NPY)**,

Neuropeptide Y (NPY)
C-terminal carboxyl is amidated

a 36-residue peptide released by the **hypothalamus**, a part of the brain that controls many physiological functions. NPY stimulates appetite, which in turn leads to fat accumulation. Both leptin and insulin, when bound to their respective receptors in the hypothalamus, inhibit NPY secretion.

Ghrelin and PYY₃₋₃₆ Act as Short-Term Regulators of Appetite. It is not surprising that fuel metabolism, body weight, and appetite are linked. In addition to leptin, insulin, and NPY, other peptide hormones are known to be involved in appetite control. For example, **ghrelin** is an appetite-stimulating peptide secreted by the empty stomach.

Human ghrelin
X = Ser modified with *n*-octanoic acid

Ghrelin appears to boost levels of NPY, and most likely is part of a short-term appetite-control system, since ghrelin levels fluctuate on the order of hours, increasing before meals and decreasing immediately afterward.

The gastrointestinal tract secretes an appetite-suppressing hormone called **PYY₃₋₃₆**:

Human PYY₃₋₃₆

In animals and humans, an infusion of this peptide decreases food intake by inhibiting NPY secretion. In summary, ghrelin stimulates appetite while leptin, insulin, and PYY₃₋₃₆ all suppress it by regulating the secretion of NPY from the hypothalamus.

C Energy Expenditure Can Be Controlled by Adaptive Thermogenesis

The nutritional calories contained in food are utilized by an organism either in the performance of work or in the release of heat. Excess fuel is stored as glycogen or fat for future use. In well-balanced individuals, the storage of excess fuel remains constant over many years. However, when fuel consumed consistently outpaces energy expenditures, obesity results.

The body has several mechanisms for guarding against obesity. One of them, discussed above, is appetite control. Another is **diet-induced thermogenesis**, a

Section 3 Metabolic Homeostasis: The Regulation of Energy Metabolism, Appetite, and Body Weight

FIG. 22-14 Normal (*OB/OB*, left) and obese (*ob/ob*, right) mice.

Courtesy of Richard D. Palmiter, University of Washington

form of adaptive thermogenesis (heat production in response to environmental stress). We have already discussed adaptive thermogenesis in response to cold, which is accomplished by the uncoupling of oxidative phosphorylation in brown adipose tissue (Box 18-4). The mechanism of this thermogenesis involves release of norepinephrine from the brain in response to cold and its binding to β -adrenergic receptors on brown adipose tissue, which is followed by an increase in cAMP that triggers an enzymatic phosphorylation cascade, leading to the activation of hormone-sensitive lipase. The increase in the concentration of free fatty acids provides fuel for oxidation and leads to the opening of a proton channel called uncoupling protein 1 (UCP1; alternatively, thermogenin) in the inner mitochondrial membrane. The opening of UCP1 dissipates the electrochemical gradient generated by electron transport (Section 18-2) and thereby uncouples electron transport from oxidative phosphorylation. The consequent continuation of fuel oxidation without ATP synthesis generates heat.

While it is clear from metabolic measurements that a high energy intake increases thermogenesis, the cause of this increase in adult humans is unclear and is under active investigation. Adult humans have little brown adipose tissue, but in response to stimulation, clusters of mitochondria-rich cells in white adipose tissue also produce UCP1. Some evidence suggests that these so-called beige fat cells play a role in preventing obesity. Intriguingly, exercising muscle releases a 112-residue peptide hormone called **irisin**, which promotes the development of beige adipocytes. This link could explain why exercise helps suppress weight gain both by using food calories to power muscle contraction and by promoting the conversion of excess calories to heat rather than fat. The use of irisin as a weight-loss drug has not yet been tested in humans.

CHECKPOINT

- Why is AMPK called the cell's fuel gauge?
- Summarize AMPK's activity in liver, muscle, and adipose tissue.
- Compare the roles of leptin, ghrelin, insulin, and PYY in controlling appetite.
- How does thermogenesis help prevent obesity?

4 Disturbances in Fuel Metabolism

KEY CONCEPTS

- During starvation, the body makes metabolic changes to maintain blood glucose levels.
- Diabetes may be caused by either insufficient production of insulin (type 1 diabetes) or an insensitivity to its presence (type 2 diabetes).
- Obesity may result from improper regulation of appetite or energy expenditure.
- Cancer cell metabolism is characterized by increased consumption of glucose and glutamine.

The complex systems that regulate fuel metabolism can malfunction, producing acute or chronic diseases of variable severity. Considerable effort has been directed at elucidating the molecular basis of conditions such as diabetes and obesity, both of which are essentially disorders of fuel metabolism. Fuel use also differs in cancerous cells, providing clues to possible anti-cancer therapies. In this section, we examine the metabolic changes that occur in starvation, diabetes, obesity, and cancer.

A Starvation Leads to Metabolic Adjustments

Because humans do not eat continuously, the disposition of dietary fuels and the mobilization of fuel stores shifts dramatically during the few hours between meals. Yet humans can survive fasts of up to a few months by adjusting their fuel metabolism. Such metabolic flexibility certainly evolved before modern humans became accustomed to thrice-daily meals.

Absorbed Fuels Are Allocated Immediately. When a meal is digested, nutrients are broken down to small, usually monomeric, units for absorption by the intestinal mucosa. From there, the products of digestion pass through the circulation to the rest of the body. Dietary proteins, for example, are broken down to amino acids for absorption. The small intestine uses amino acids for fuel, but most

travel to the liver via the portal vein. There, they are used for protein synthesis or, if present in excess, oxidized to produce energy or converted to glycogen for storage. They may also be converted to glucose or triacylglycerols for export, depending on conditions. There is no dedicated storage depot for amino acids; whatever the liver does not metabolize circulates to peripheral tissues to be catabolized or used for protein synthesis.

Dietary polysaccharides, like proteins, are degraded in the intestine, and the absorbed monomeric products (e.g., glucose derived from dietary starch) are delivered to the liver via the portal vein. As much as one-third of the dietary glucose is immediately converted to glycogen in the liver; at least half of the remainder is converted to glycogen in muscle cells, and the rest is oxidized by these and other tissues for immediate energy needs. Excess glucose is converted to triacylglycerol in the liver and exported for storage in adipose tissue. Both glucose uptake and glycogen and fatty acid biosynthesis are stimulated by insulin, whose concentration in the blood increases in response to high blood [glucose].

Dietary fatty acids are packaged as triacylglycerols in chylomicrons (Section 20-1), which circulate first in the lymph and then in the bloodstream and therefore are not delivered directly to the liver as are absorbed amino acids and carbohydrates. Instead, a significant portion of the dietary fatty acids are taken up by adipose tissue. Lipoprotein lipase first hydrolyzes the triacylglycerols, and the released fatty acids are absorbed and reesterified in the adipocytes.

Blood Glucose Remains Nearly Constant. As tissues take up and metabolize glucose, blood [glucose] drops, thereby causing the pancreatic α cells to release glucagon. This hormone stimulates glycogen breakdown and the release of glucose from the liver. It also promotes gluconeogenesis from amino acids and lactate. *The reciprocal effects of insulin and glucagon, which both respond to and regulate blood [glucose], ensure that the concentration of glucose available to extrahepatic tissues remains relatively constant.*

However, the body stores less than a day's supply of carbohydrate (Table 22-2). After an overnight fast, the combination of increased glucagon secretion and decreased insulin secretion promotes the mobilization of fatty acids from adipose tissue (Section 20-5). The diminished insulin also decreases glucose uptake by muscle tissue. Muscles therefore switch from glucose to fatty acid metabolism for energy production. This adaptation spares glucose for use by tissues, such as the brain, that cannot utilize fatty acids.

TABLE 22-2 Fuel Reserves for a Normal 70-kg Man

Fuel	Mass (kg)	Calories ^a
Tissues		
Fat (adipose triacylglycerols)	15	141,000
Protein (mainly muscle)	6	24,000
Glycogen (muscle)	0.150	600
Glycogen (liver)	0.075	300
Circulating fuels		
Glucose (extracellular fluid)	0.020	80
Free fatty acids (plasma)	0.0003	3
Triacylglycerols (plasma)	0.003	30
Total		166,000

^a1 (dieter's) Calorie = 1 kcal = 4.184 kJ.

Source: Cahill, G.E., Jr., *New Engl. J. Med.* **282**, 669 (1970).

FIG. 22-15 Liver glycogen depletion during fasting. The liver glycogen content in seven subjects was measured using ^{13}C NMR over the course of a 64-hour fast. [After Rothman, D.L., Magnusson, I., Katz, L.D., Shulman, R.G., and Shulman, G.I., *Science* **254**, 575 (1991).]

Gluconeogenesis Supplies Glucose during Starvation. After a lengthy fast, the liver's store of glycogen becomes depleted (Fig. 22-15). Under these conditions, the rate of gluconeogenesis increases. Gluconeogenesis supplies ~96% of the glucose produced by the liver after 40 hours of fasting. The kidney also is active in gluconeogenesis under these conditions. In animals, glucose cannot be synthesized from fatty acids. This is because neither pyruvate nor oxaloacetate, the precursors of glucose in gluconeogenesis, can be synthesized in a net manner from acetyl-CoA. During starvation, glucose must therefore be synthesized from the glycerol product of triacylglycerol breakdown and, more importantly, from the amino acids derived from the proteolytic degradation of proteins, the major source of which is muscle. The breakdown of muscle cannot continue indefinitely, however, since loss of muscle mass would eventually prevent an animal from moving about in search of food. The organism must therefore make alternate metabolic arrangements.

Ketone Bodies Become a Major Energy Source during Starvation. After several days of starvation, the liver directs acetyl-CoA, which is derived from fatty acid β oxidation, to the synthesis of ketone bodies (Section 20-3). These fuels are then released into the blood. The brain gradually adapts to using ketone bodies as fuel through the synthesis of the appropriate enzymes: After a 3-day fast, only about one-third of the brain's energy requirements are satisfied by ketone bodies, and after 40 days of starvation, ~70% of its energy needs are so met. The rate of muscle breakdown during prolonged starvation consequently decreases to ~25% of its rate after a several-day fast. *The survival time of a starving individual therefore depends much more on the size of fat reserves than on muscle mass.* Indeed, highly obese individuals can survive a year or more without eating (and have done so in clinically supervised weight-reduction programs).

Caloric Restriction May Increase Longevity. Caloric restriction is a modified form of starvation whereby energy intake is reduced 30–40%, while micronutrient (vitamin and mineral) levels are maintained. Rodents kept on such a diet live up to 50% longer than rodents on normal diets. The lifespans of a large range of organisms from yeast to primates are similarly extended (although a >20-year study of caloric restriction in rhesus monkeys showed no increase in lifespan). Considerable research effort is being expended to determine the biochemical basis of these observations.

B Diabetes Mellitus Is Characterized by High Blood Glucose Levels

In the disease **diabetes mellitus** (often called just **diabetes**), which is the third leading cause of death in the United States after heart disease and cancer, insulin either is not secreted in sufficient amounts or does not efficiently stimulate its target cells. As a consequence, blood glucose levels become so elevated that the

glucose “spills over” into the urine (*mellitus* is Latin for honey-sweet), providing a convenient diagnostic test for the disease. Yet, despite the high blood glucose levels, cells “starve” since insulin-stimulated glucose entry into cells is impaired. Triacylglycerol hydrolysis, fatty acid oxidation, gluconeogenesis, and ketone body formation are accelerated and, in a condition known as **ketosis**, ketone body levels in the blood become abnormally high. Since ketone bodies are acids, their high concentration results in a condition called **acidosis** (which, when present with ketosis, is called **ketoacidosis**) that puts a strain on the buffering capacity of the blood and on the kidney, which controls blood pH by excreting the excess H^+ into the urine. This H^+ excretion is accompanied by NH_4^+ , Na^+ , K^+ , P_i , and H_2O excretion, with the consequent frequent urination causing severe dehydration (excessive thirst is a classic symptom of diabetes) and a decrease in blood volume—ultimately life-threatening situations. The acetone arising from the spontaneous decarboxylation of the ketone body acetoacetate (Section 20-3) is not metabolized but rather is exhaled, giving the breath a solvent-like smell that is often mistaken for ethanol. Consequently, a poorly controlled diabetic who is mentally confused or comatose may be misdiagnosed as being drunk, a potentially fatal error.

There are two major forms of diabetes mellitus:

1. **Insulin-dependent, juvenile-onset, or type 1 diabetes mellitus**, which most often strikes suddenly in childhood.
2. **Non-insulin-dependent, maturity-onset, or type 2 diabetes mellitus**, which usually develops gradually after the age of 40, but is becoming more common in younger adults.

Insulin-Dependent Diabetes Is Caused by a Deficiency of Pancreatic β Cells. In insulin-dependent diabetes mellitus, insulin is absent or nearly so because the pancreas lacks or has defective β cells. This condition usually results from an autoimmune response that selectively destroys pancreatic β cells. Individuals with insulin-dependent diabetes, as Frederick Banting and Charles Best first demonstrated in 1921 (Box 22-2), require daily injections of insulin (for decades extracted from animal pancreases but now recombinant human insulin) to survive and must follow carefully balanced diet and exercise regimens. Their lifespans are, nevertheless, reduced by up to one-third as a result of degenerative complications such as kidney malfunction, nerve impairment, and cardiovascular disease that apparently arise from the imprecise metabolic control provided by periodic insulin injections. The **hyperglycemia** (high blood [glucose]) of diabetes mellitus also leads to blindness through retinal degeneration and the glycosylation of lens proteins, which causes cataracts (Fig. 22-16). However, with the recent development of devices that continually measure the blood glucose level and dispense insulin accordingly, these complications may be largely eliminated.

The usually rapid onset of the symptoms of insulin-dependent diabetes had suggested that the autoimmune attack on the pancreatic β cells is of short duration. Typically, however, the disease develops over several years as the immune system slowly destroys the β cells. Only when $>80\%$ of the cells have been eliminated do the classic symptoms of diabetes suddenly emerge. Consequently, one of the most successful treatments for insulin-dependent diabetes is a β -cell transplant, a procedure that became possible with the development of relatively benign immunosuppressive drugs.

Non-Insulin-Dependent Diabetes May Be Caused by a Deficiency of Insulin Receptors or Insulin Signal Transduction. Non-insulin-dependent diabetes mellitus, which accounts for more than 90% of the diagnosed cases of diabetes and affects as many as 10% of adults worldwide, usually occurs in obese individuals with a genetic predisposition for the condition. These individuals have normal or even greatly elevated insulin levels, but their cells are not responsive to insulin and are therefore said to be **insulin resistant**. As a result, blood glucose concentrations are much higher than normal, particularly after a meal (Fig. 22-17).

Sue Ford/Photo Researchers.

FIG. 22-16 Photo of a diabetic cataract. The accumulation of glucose in the lens leads to swelling and precipitation of lens proteins. The resulting opacification causes blurred vision and ultimately complete loss of sight.

FIG. 22-17 Twenty-four-hour plasma glucose profiles in normal and non-insulin-dependent diabetic subjects. The basal level of glucose and the peaks following meals are higher in the diabetic individuals. [After Bell, G.I., Pillkis, S.J., Weber, I.T., and Polonsky, K.S., *Annu. Rev. Physiol.* **58**, 178 (1996).]

Frederick Banting (1891–1941)
Charles Best (1899–1978)

One of the most celebrated clinical research stories is the discovery and therapeutic use of insulin, the hormone missing in type 1 diabetes. Since the end of the nineteenth century, clinical scientists understood that there was a connection between diabetes and secretions from the pancreas, specifically, from the clumps of cells known as the islets of Langerhans. Several unsuccessful attempts were made to extract the secretions. In 1920, Frederick Banting, reading an account of such work, wondered whether an active extract could be purified if the pancreatic ducts, which collect potentially destructive digestive enzymes, were first ligated (closed off).

Banting, a young surgeon whose medical practice had not yet gotten off the ground, was working as a demonstrator at the University of Western Ontario. He took his idea to John J.R. Macleod, the head of the Department of Physiology at the University of Toronto. A skeptical Macleod gave Banting the use of laboratory space for the summer of 1921, access to experimental dogs, and the help of assistant Charles Best. Banting, despite his medical training and experience with the Canadian Army Medical Service, was not much of an experimentalist. Best, however, had just completed a degree in physiology and biochemistry and had already worked as an assistant to Macleod. Best quickly learned surgical techniques from Banting, as Banting picked up analytical techniques, such as measuring sugar levels in dogs' blood and urine, from Best.

Banting's and Best's experimental protocol required pancreatectomized dogs, but the surgery was difficult, and many dogs died of infection (it was rumored that strays from the streets of Toronto were gathered as replacements). Successfully pancreatectomized dogs, who developed the fatal symptoms of diabetes, were injected with a pancreatic extract that Banting and Best named insulin, after the Latin word *insula* (island). Finally, at the end of July, Banting and Best achieved their desired result, when the insulin injection dramatically reduced the dog's blood sugar level. The experiment was repeated, with similar results, in other dogs.

Although Banting's temporary position was to have been terminated at the end of the summer, his results were promising enough to secure him additional funding, the supervision of a more enthusiastic

Macleod, and the continued assistance of Best, who had originally intended to work with Banting for only 2 months. By fall, Banting's and Best's success at prolonging the lives of diabetic dogs was putting enormous pressure on their ability to produce insulin in large amounts and of consistent purity. Assistance was offered by James Collip, a biochemist on sabbatical leave from the University of Alberta. Collip's insulin preparations, which were made without any clue as to the proteinaceous nature of the hormone, proved good enough for experimental use in humans. At that time, a diagnosis of diabetes was a virtual death sentence, with the only treatment being a severely limited diet that probably extended life for only a few months (many patients died of malnutrition).

In January 1923, Banting injected Collip's extract into Leonard Thompson, a 14-year-old diabetic who was near death. Thompson's blood sugar level immediately returned to normal, and his strength increased. Such a dramatic clinical outcome did not go unnoticed, and within months, Banting opened a clinic to begin treating diabetics desperate for a treatment that restored their hopes for a near-normal life. He enlisted the help of the Connaught Antitoxin Laboratories at the University of Toronto and the Eli Lilly Pharmaceutical Company to produce insulin on a scale suitable for clinical testing. Best, just 23, was put in charge of insulin production for all of Canada. It eventually became clear that Banting's original assumption—that the presence of digestive enzymes compromised the purification of insulin—was mistaken, and insulin could be successfully isolated from an intact pancreas.

Amid some controversy, the 1923 Nobel Prize for Physiology or Medicine was awarded to Banting and Macleod. Banting, annoyed by the omission of Best, split his share of the prize with his assistant. Macleod, who had not offered much support during the initial research, split his share with Collip. Banting subsequently held a variety of administrative posts and pursued research in silicosis, but he never accomplished much. He was killed in a plane crash en route to Britain for a wartime mission in 1941. Best, who replaced Macleod as head of physiology at the age of 29, continued his research into the biological action of insulin. He also supervised efforts to purify the anticoagulant glycosaminoglycan heparin and to produce dried human serum for medical use by the military.

Banting, F.G. and Best, C.H., The internal secretion of the pancreas, *J. Lab. Clin. Med.* **7**, 251–266 (1922).

The hyperglycemia that accompanies insulin resistance induces the pancreatic β cells to increase their production of insulin. Yet the high basal level of insulin secretion diminishes the ability of the β cells to respond to further increases in blood glucose. Consequently, the hyperglycemia and its attendant complications tend to worsen over time.

A small percentage of cases of type 2 diabetes result from mutations in the insulin receptor that affect its insulin-binding ability or tyrosine kinase activity. However, a clear genetic cause has not been identified in the vast majority of cases. It is therefore likely that many factors play a role in the development of the disease. For example, the increased insulin production resulting from overeating may eventually suppress the synthesis of insulin receptors. This hypothesis accounts for the observation that diet alone often decreases the severity of the disease.

Another hypothesis, put forward by Gerald Shulman, is that the elevated concentration of free fatty acids in the blood caused by obesity decreases insulin

signal transduction. This high concentration ultimately results in an activation of a PKC isoform that phosphorylates insulin receptor substrates (IRSs) on Ser and Thr, thereby inhibiting the Tyr phosphorylation that activates them. The failure to activate IRSs decreases the cell's response to insulin (Fig. 13-31).

Other treatments for non-insulin-dependent diabetes are drugs such as **metformin** and the **thiazolidinediones (TZDs)** (at right), which decrease insulin resistance by either suppressing glucose release by the liver (metformin) or promoting insulin-stimulated glucose disposal in muscle (TZDs). The drugs act by increasing cellular levels of AMP, which increases the AMP-to-ATP ratio and promotes AMPK phosphorylation and activity. The increase in AMPK activity decreases gluconeogenesis in liver and increases glucose utilization in muscle (Fig. 22-11). Metformin may also act by inhibiting glucagon signaling in the liver, because the rise in cellular AMP prevents the activation of adenylate cyclase by glucagon.

In addition, the TZDs decrease insulin resistance by binding to and activating a transcription factor known as a **peroxisome proliferator-activated receptor- γ (PPAR- γ)**, primarily in adipose tissue. Among other things, PPAR- γ activation induces the synthesis of adiponectin (Section 22-3B), which leads to an increase in AMPK activity. In adipose tissue, AMPK action leads to a decrease in lipolysis and fatty acid export, decreasing the concentration of free fatty acids in the blood and therefore decreasing insulin resistance (see above). The TZDs are not without side effects, however. For example, **rosiglitazone (Avandia)**

Metformin

A thiazolidinedione (TZD)

Rosiglitazone (Avandia)

appears to increase the risk of heart attack and stroke by as much as 43%. Consequently, it has been banned in Europe, and its use in the United States is limited to patients for whom no other drug is effective.

Adipocytes and some other types of cells secrete a 108-residue polypeptide hormone called **resistin**. The hormone is named for its ability to block the action of insulin on adipocytes. In fact, resistin production is decreased by TZDs, a feature that led to its discovery. Overproduction of resistin has been proposed to contribute to the development of non-insulin-dependent diabetes. However, the effect may be indirect, as resistin functions as a pro-inflammatory signal, and chronic inflammation is often accompanied by insulin resistance.

C Obesity Is Usually Caused by Excessive Food Intake

The human body regulates glycogen and protein levels within relatively narrow limits, but fat reserves, which are much larger, can become enormous. The accumulation of fatty acids as triacylglycerols in adipose tissue is largely a result of excess fat or carbohydrate intake compared to energy expenditure. Fat synthesis from carbohydrates occurs when the carbohydrate intake is high enough that glycogen stores, to which excess carbohydrate is normally directed, approach their maximum capacity.

A chronic imbalance between fat and carbohydrate consumption and utilization increases the mass of adipose tissue through an increase in the number of adipocytes or their size (once formed, adipocytes are not lost, although their size may increase or decrease). The increase in adipose tissue mass increases the pool of fatty acids that can be mobilized to generate metabolic energy. Eventually, a steady state is achieved in which the mass of adipose tissue no longer increases

and fat storage is balanced by fat mobilization. This phenomenon explains in part the high incidence of obesity in affluent societies, where fat- and carbohydrate-rich foods are plentiful and physical activity is not a requirement for survival. Considerable evidence suggests that behavior (e.g., eating habits and levels of physical activity) influences an individual's body composition. Yet, as we have seen (Section 22-3), some cases of obesity are also the result of innate disturbances in an individual's capacity to metabolize fuels.

The hormonal mechanisms that contribute to obesity and its attendant health problems, such as diabetes, may have conferred a selective advantage in premodern times. For example, the ability to gain weight easily would have protected against famine. One theory proposes that as humans evolved, the regulation of fuel metabolism was geared toward overeating large quantities of food when available, thereby obtaining essential nutrients while storing excess nonessential energy as fat for use during famine. In modern cultures in which famines are rare and nutritious food is readily available, human genetic heritage has apparently contributed to an epidemic of obesity: An estimated 30% of U.S. adults are obese and another 35% are overweight.

Severe obesity can sometimes be curbed through gastric bypass surgery or the placement of a gastric band (collectively known as bariatric surgery), which drastically reduces the effective size of the stomach. Although the surgery does not guarantee long-term weight loss, the immediate effects of these procedures include increased insulin sensitivity (i.e., the alleviation of type 2 diabetes) and decreased appetite. These responses likely reflect changes in hormone secretion by the stomach and intestine. In addition, the shortened digestive tract alters patterns of bile acid recycling and allows more oxygen to reach the colon, both of which can affect the makeup of the intestinal microbiome (Box 22-1) and the types or amounts of nutrients absorbed by the body.

 **Obesity Is a Contributing Factor in Metabolic Syndrome.** **Metabolic syndrome** is a disturbance in metabolism characterized by insulin resistance, inflammation, and a predisposition to several disorders, including type 2 diabetes, hypertension, and atherosclerosis. Those disorders are accompanied by an increase in coronary heart disease. Obesity, physical inactivity, and possibly genetic determinants have been implicated in its occurrence, which affects up to 25% of the population in the United States. Metabolic syndrome is particularly prevalent among members of ethnic groups that have adopted modern diets and lifestyles in recent generations.

Individuals with metabolic syndrome tend to have a relatively high proportion of visceral (abdominal) fat. This type of fat exhibits a different hormone profile than subcutaneous fat. For example, visceral fat produces less leptin and adiponectin (hormones that increase insulin sensitivity). Visceral fat also produces more $\text{TNF}\alpha$, which is a powerful mediator of inflammation and a normal part of the body's immune defenses. Chronic inflammation triggered by excess visceral fat may be responsible for some of the symptoms, such as atherosclerosis, that characterize metabolic syndrome. The $\text{TNF}\alpha$ signaling pathway in cells may lead to phosphorylation of IRS-1, a modification that prevents its activation by the insulin receptor kinase. This would explain the insulin resistance of metabolic syndrome. High concentrations of circulating lipids may contribute to fat accumulation in organs such as the liver, which can lead to liver failure. Exercise, calorie/weight reduction, adiponectin, leptin, metformin, and TZDs have all been successfully used to treat metabolic syndrome. All of these increase AMPK activity, making AMPK itself a promising target for drug development.

D Cancer Metabolism

In the mid-1920s, Otto Warburg (Box 15-1) observed that cancer cells have a high rate of glycolysis. At first, this activity was attributed to lack of oxygen in poorly vascularized tumors (glycolysis is an anaerobic pathway), but it is now

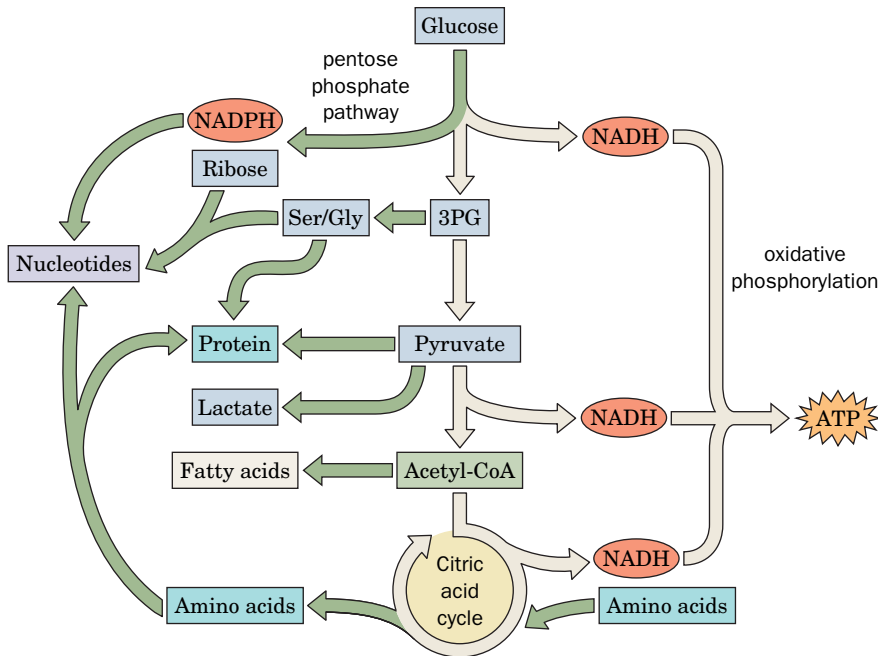

FIG. 22-18 Metabolic changes in cancer. Pathways with increased flux in cancer are highlighted in green.

understood that cancer cells consume large quantities of glucose even when oxygen is plentiful, so this catabolic process is now known as **aerobic glycolysis**. Glucose breakdown does yield some ATP, but it also provides the intermediates for several anabolic pathways. Glucose, along with amino acids such as glutamine, supports the rapid growth and proliferation of cancer cells and some other highly active cells, such as the B and T lymphocytes that respond to infections (Section 7-3). Some features of cancer cell metabolism are summarized in [Fig. 22-18](#).

Glucose Breakdown Provides Intermediates and Reducing Power. Under aerobic conditions, normal cells convert glucose mainly to pyruvate, which provides acetyl groups to feed the citric acid cycle, ultimately leading to the production of ATP by oxidative phosphorylation. In cancer cells, this pathway still occurs, but additional glucose is metabolized to meet the need for biosynthetic precursors and protection against the reactive oxygen species that are a byproduct of oxidative metabolism. In some cancer cells, glycolytic flux is increased in part because the cells overexpress the gene encoding the bifunctional enzyme phosphofructokinase-2/fructose biphosphatase-2. This enzyme generates the allosteric regulator fructose-2,6-bisphosphate that promotes glycolytic flux at the phosphofructokinase-1 step. Increased catabolism of glucose increases the concentrations of glycolytic intermediates. The resulting 3-phosphoglycerate (3PG) can be diverted to generate serine (Section 21-5A), which, when converted to glycine, supplies one-carbon groups for other metabolic processes (Section 21-4D), including thymidine synthesis (Section 23-3B), that support cell growth and division. Glycine itself is a precursor of adenosine and guanosine nucleotides (Section 23-1).

The pyruvate kinase isoform PKM2, which is expressed in many cancer cells, functions as a control point for glucose metabolism. For example, PKM2 activity is stimulated by 5-aminoimidazole-4-(*N*-succinylcarboxamide) ribotide (SAICAR), an intermediate of the purine nucleotide synthesis pathway (Section 23-1A). As SAICAR accumulates, signifying adequate nucleotide synthesis, glucose catabolism is directed toward pyruvate; when nucleotide synthesis consumes SAICAR, glycolytic intermediates are redirected to the pentose phosphate pathway (Section 15-6) and to the synthesis of serine and glycine (Section 21-5A). Serine allosterically activates PKM2, which helps fine-tune the use of glucose carbons for biosynthetic reactions.

Glycolytically generated pyruvate is a precursor of alanine (Section 21-5A), which is, after leucine, the most abundant amino acid in proteins (Table 4-1). Pyruvate can also be processed to acetyl-CoA, which combines with oxaloacetate to form citrate. But rather than continuing through the citric acid cycle in the mitochondrion, the citrate is transported to the cytoplasm, where it is converted by the action of ATP-citrate lyase back to acetyl groups destined for fatty acid synthesis (Section 20-4A). Both citrate and fatty acyl-CoA molecules inhibit the activity of phosphofructokinase-1, thereby directing relatively more glucose through the pentose phosphate pathway. This yields the ribose required for nucleotide synthesis as well as NADPH, whose reducing equivalents are used in lipid synthesis and to generate the reduced glutathione that prevents damage from reactive oxygen species (Box 15-4). Lactate, the primary end product of glycolysis in cancer cells, also inhibits phosphofructokinase-1 activity, further promoting flux through the pentose phosphate pathway.

Lactate may indirectly support the growth of cancer cells by initiating signaling cascades that alter gene expression patterns in the cancer cells themselves or in neighboring cells. For example, the endothelial cells that line blood vessels respond to lactate by multiplying to form new vessels to serve the growing tumor. Other cancer-specific metabolites participate in or interfere with reactions that modify DNA, a mechanism that more or less permanently alters patterns of gene expression in those cells. One of these interfering substances is **2-hydroxyglutarate** (at left), which is generated from isocitrate by a mutant form of isocitrate dehydrogenase that occurs in some cancers.

2-Hydroxyglutarate

Glutamine and Glutamate Metabolism Support Anabolic Processes. Glutamine, the most abundant of the amino acids circulating in the bloodstream, is a key nutrient for cancer cells. Glutamine is a nitrogen source in the synthesis of both purine and pyrimidine nucleotides (Sections 23-1 and 23-2). In addition, glutaminase converts glutamine to glutamate, which then undergoes transamination to produce α -ketoglutarate (Section 21-4C). Although the increased α -ketoglutarate can increase flux through the citric acid cycle to supply oxidative phosphorylation, much of it is used anabolically. For example, malate derived from α -ketoglutarate can be converted by the action of malic enzyme to pyruvate (Section 20-2E); this reaction also generates NADPH that is used in biosynthetic pathways. Oxaloacetate produced from α -ketoglutarate can be transaminated to aspartate, which is a precursor of purine nucleotides (Section 23-1A). Mitochondrial oxaloacetate can also condense with acetyl-CoA to generate citrate, which after transport to the cytoplasm, supplies cytosolic acetyl groups for fatty acid synthesis (Section 20-4A).

The activity of glutamate dehydrogenase, a major control point (Section 21-5A), is allosterically regulated by a variety of metabolites, including ADP (an activator) and GTP (an inhibitor), which helps tie amino acid metabolism to the cell's energy budget. Leucine also stimulates glutamate dehydrogenase activity, which could help balance amino acid use in cancer cells. Palmitoyl-CoA inhibits glutamate dehydrogenase activity, so when fatty acid synthesis rates are high and acyl-CoA groups accumulate, the cataplerotic (metabolite-supplying) function of the citric acid cycle diminishes. When fatty acid oxidation proceeds at a high rate, the glutamate dehydrogenase inhibition is relieved and glutamate can replenish α -ketoglutarate to increase the flux of fat-derived acetyl-CoA through the citric acid cycle.

Increased consumption of glucose and glutamine is characteristic of most cancer cells, but due to the multifactorial nature of cancer, there is no single mechanism that explains all the metabolic changes that occur in the transformation of a normal cell to a cancer cell. In fact, cancer cells are notoriously variable over time and even within the same tumor mass, so each cell may have a unique profile of enzymatic activities and metabolite concentrations. Nevertheless, a better understanding of cancer biology may provide additional targets for the development of anticancer drugs.

CHECKPOINT

- How does the body allocate food-derived fuel molecules?
- Describe the metabolic changes that occur during early and late starvation.
- Distinguish insulin-dependent and non-insulin-dependent diabetes mellitus.
- How does insulin resistance or the lack of insulin contribute to the typical symptoms of diabetes?
- How is obesity related to non-insulin-dependent diabetes mellitus?
- How does aerobic glycolysis differ from anaerobic glycolysis? Why is anaerobic glycolysis not really anaerobic?
- How does the metabolism of glucose and glutamine support the synthesis of nucleotides, lipids, and amino acids?

Summary

1 Organ Specialization

- The pathways for the synthesis and degradation of the major metabolic fuels (glucose, fatty acids, and amino acids) converge on acetyl-CoA and pyruvate. In mammals, flux through the pathways is tissue specific.
- The brain uses glucose as its primary metabolic fuel. Muscle can oxidize a variety of fuels but depends on anaerobic glycolysis for maximum exertion. Adipose tissue stores excess fatty acids as triacylglycerols and mobilizes them as needed.
- The liver maintains the concentrations of circulating fuels. The action of glucokinase allows liver to take up excess glucose, which can then be directed to several metabolic fates. The liver also converts fatty acids to ketone bodies and metabolizes amino acids derived from the diet or from protein breakdown. Both the liver and kidney carry out gluconeogenesis.
- The Cori cycle and the glucose–alanine cycle are multiorgan pathways through which the liver and muscle exchange metabolic intermediates.

2 Hormonal Control of Fuel Metabolism

- Hormones such as insulin, glucagon, and epinephrine transmit regulatory signals to target tissues by binding to receptors that transduce the signal to responses in the interior of the cell. Insulin promotes fuel storage, and glucagon and epinephrine mobilize stored fuels.

3 Metabolic Homeostasis

- AMP-dependent protein kinase (AMPK), the cell's fuel gauge, senses the cell's need for ATP and activates metabolic breakdown pathways while inhibiting biosynthetic pathways.

- Adiponectin, an adipocyte hormone that increases insulin sensitivity, acts by activating AMPK.
- Appetite is controlled in the hypothalamus by the hormones leptin, insulin, ghrelin, and PYY.

4 Disturbances in Fuel Metabolism

- During starvation, when dietary fuels are unavailable, the liver releases glucose first by glycogen breakdown and then by gluconeogenesis from amino acid precursors. Eventually, ketone bodies supplied by fatty acid breakdown meet most of the body's energy needs.
- Diabetes mellitus causes hyperglycemia and other physiological difficulties resulting from destruction of insulin-producing pancreatic β cells or from insulin resistance (from loss of receptors or their insensitivity to insulin).
- Obesity, an imbalance between food intake and energy expenditure, may result from abnormal regulation by peptide hormones produced in different tissues.
- Metabolic syndrome is caused by obesity, physical inactivity, and possibly genetic determinants.
- Increased glucose and glutamine consumption in cancer cells supports biosynthetic processes through pathways such as glycolysis, the pentose phosphate pathway, and the cataplerotic activity of the citric acid cycle.

Problems

EXERCISES

1. Adaptation to high altitude includes increases in GLUT1 and phosphofructokinase in muscle. Explain why this would be advantageous.
2. The heart cannot convert lactate back to glucose, as the liver does, but instead uses it as a fuel. What is the ATP yield from the complete catabolism of one mole of lactate?
3. Toxins that occur in certain mushrooms block β oxidation in humans. Explain why ingesting the mushrooms leads to heart palpitations and severe hypoglycemia (low blood sugar).
4. Growth factor stimulation of cells leads to inhibition of pyruvate kinase. As a result, glycolytic intermediates are redirected to the pentose phosphate pathway. Explain why this would help promote cell growth and division.
5. The passive glucose transporter named GLUT1 (Fig. 10-13) is present in the membranes of many cells, but not in the liver. Instead, liver cells express the GLUT2 transporter, which exhibits different transport kinetics. Given what you know about the role of the liver in buffering blood glucose, compare the K_M values of GLUT1 and GLUT2.
6. Use the results of Problem 5 to explain why a deficiency of GLUT2 produces symptoms resembling those of Type 1 glycogen storage disease (Box 16-2).

7. The small intestine catabolizes amino acids, producing significant amounts of NH_4^+ . Describe the metabolic fate of the NH_4^+ .
8. (a) Identify the two reactions that allow the kidney to produce NH_4^+ . (b) Which gluconeogenic precursor is thereby generated? Describe the pathway by which it can be converted to glucose.
9. The Bacteroides and Firmicutes, the most abundant organisms colonizing the human colon (large intestine), are obligate anaerobes that rely exclusively on fermentation rather than respiration. In response to injury or infection, cells of the immune system generate reactive oxygen species (Section 18-4B) and reactive nitrogen species (Section 21-6C) whose breakdown products, especially nitrate, can serve as electron acceptors for respiration by less-abundant facultative anaerobes such as the Enterobacteriaceae. Explain why the Enterobacteriaceae population flourishes while the Bacteroides and Firmicute populations dwindle during inflammation.
10. Some foods containing live microorganisms, known as probiotics, are advertised for their health benefits. Offer a reason why consuming such foods in most cases has no perceptible effect on the function of an individual's digestive system or his/her health.
11. Explain why insulin is required for adipocytes to synthesize triacylglycerols from fatty acids.

12. Predict the effect of an overdose of insulin on brain function in a normal person.
13. Would you expect insulin to increase or decrease the activity of the enzyme ATP-citrate lyase?
14. Stimulation of a certain G_s protein-coupled receptor activates protein kinase A (PKA). Predict the effect of PKA activation on the following substrates of PKA: (a) acetyl-CoA carboxylase, (b) glycogen synthase, (c) hormone-sensitive lipase, and (d) phosphorylase kinase.
15. Why can adipose tissue be considered to be an endocrine organ?
16. If the circulatory system of an *ob/ob* mouse is surgically joined to that of a normal mouse, what will be the effect on the appetite and weight of the *ob/ob* mouse?
17. In experiments to test the appetite-suppressing effects of PYY₃₋₃₆, why must the hormone be administered intravenously rather than orally?
18. When administered intravenously, the peptide hormone PYY₃₋₃₆ sometimes triggers nausea in humans. Is this consistent with its biological function?
19. In addition to regulating AMPK activity, adiponectin has anti-inflammatory activity, which makes it attractive as a potential drug for treating inflammatory diseases. Explain why researchers are searching for adiponectin receptor agonists rather than testing adiponectin itself as a drug.
20. Explain why mice deficient in UCP1 become obese when raised at 28°C but not at 20°C.
21. Explain why type 1 diabetics require insulin injections, whereas insulin injections are effective in only a portion of type 2 diabetics.
22. Explain why a common diagnostic test for diabetes involves orally administering a glucose solution to an individual and then measuring the concentration of blood glucose two hours later.
23. AMPK activates phosphofruktokinase-2. Explain how this would contribute to the antidiabetic effect of stimulating AMPK activity.
24. Explain why the probability of death as a function of body mass index (a measure of obesity) is a U-shaped curve.
25. High concentrations of 3-phosphoglycerate inhibit 6-phosphogluconate dehydrogenase. How does this regulatory mechanism help control the growth of a cancer cell?
26. What is the advantage for some tumors to stop expressing the genes for glucose-6-phosphatase, phosphoenolpyruvate carboxykinase, and fructose biphosphatase?

CHALLENGE QUESTIONS

27. Why does oxidative metabolism, which generates ATP, cease when a cell's ATP supply is exhausted?
28. Individuals with a deficiency of medium chain acyl-CoA dehydrogenase (MCAD) tend to develop nonketotic hypoglycemia. Explain why this defect makes them unable to undertake (a) ketogenesis and (b) gluconeogenesis.
29. Pancreatic β cells express a receptor for fatty acids. Fatty acid binding to the protein appears to stimulate insulin secretion. Does this phenomenon make metabolic sense?
30. Fatty acids appear to stimulate insulin secretion to a much greater extent when glucose is also present. Why is this significant?
31. Substances derived from food can act as hormones when they enter the circulation. Explain why it is advantageous for leucine to act on the central nervous system to reduce food intake.
32. Explain why it makes metabolic sense for adipocytes to release leptin in response to circulating short-chain fatty acids.
33. Experienced runners know that it is poor practice to ingest large amounts of glucose immediately before running a marathon. What is the metabolic basis for this apparent paradox?
34. After several days of starvation, the capacity of the liver to metabolize acetyl-CoA via the citric acid cycle is greatly diminished. Explain.

35. High concentrations of free fatty acids in the blood are known to cause insulin resistance in muscle, but only after 5 hours. This suggests that a metabolite of the fatty acids may be responsible for this phenomenon. It is also known that an isoform of protein kinase C is activated during the process and that high concentrations of free fatty acids result in intramuscular accumulation of triacylglycerols. With this information, review the mechanism of activation of PKC and the pathway of triacylglycerol biosynthesis and suggest a metabolite that may be responsible for PKC activation.

36. Pancreatic β cells release a peptide hormone, amylin, along with insulin. Amylin acts on the brain to slow gastric emptying and inhibit the release of digestive enzymes from the pancreas. (a) Explain why amylin's effects are synergistic with insulin's. (b) In a hypoglycemic individual, amylin does not slow gastric emptying. Why is this beneficial?

37. Discuss, in terms of AMPK activity and GLUT4, how physical inactivity might lead to insulin resistance.

38. In acute lymphoblastic leukemia, the cancerous white blood cells typically lack the enzyme asparagine synthetase. Why is the administration of asparaginase an effective therapy for this type of cancer?

39. Describe the metabolic effects of liver failure.

40. Among the many eat-all-you-want-and-lose-weight diets that have been popular for a time is one that eliminates all carbohydrates but permits the consumption of all the protein and fat desired. Would such a diet be effective? (*Hint*: Individuals on such a diet often complain that they have bad breath.)

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Insulin Secretion and the KEGG Database

Exercise 2 Insulin Control of Glucose Metabolism and the KEGG Database

CASE STUDIES www.wiley.com/college/voet

Case 25 Glycogen Storage Diseases

Focus concept: Disturbances in glycogen utilization result if an enzyme involved in glycogen synthesis or degradation is missing.

Prerequisites: Chapters 16 and 22

- Glycogen synthesis and degradation pathways
- The link between glycogen metabolism and fat metabolism

Case 28 The Bacterium *Helicobacter pylori* and Peptic Ulcers

Focus concept: The entire genome of *Helicobacter pylori* has been sequenced. This allows biochemists to examine the organism's proteins in detail. In this case, mechanisms employed by *Helicobacter pylori* that permit it to survive in the acidic environment of the stomach are examined.

Prerequisites: Chapters 6 and 15–22

- Protein structure and function
- Basic metabolic pathways up through amino acid metabolism

Case 30 Phenylketonuria

Focus concept: The characteristics of phenylalanine hydroxylase, the enzyme missing in persons afflicted with the genetic disorder phenylketonuria (PKU), are examined.

Prerequisites: Chapters 21 and 22

- Amino acid synthesis and degradation pathways
- Integration of amino acid metabolic pathways with carbohydrate metabolic pathways

MORE TO EXPLORE Anecdotal evidence suggests that sleep and obesity are related: less sleep tends to promote weight gain, and vice versa. What are the hormonal links between the basic drives for food and rest? Is there evidence that increasing the time spent sleeping can lead to weight loss?

CHAPTER 23

Nucleotide Metabolism

Chapter Contents

1 Synthesis of Purine Ribonucleotides

- A Purine Synthesis Yields Inosine Monophosphate
- B IMP Is Converted to Adenine and Guanine Ribonucleotides
- C Purine Nucleotide Biosynthesis Is Regulated at Several Steps
- D Purines Can Be Salvaged

2 Synthesis of Pyrimidine Ribonucleotides

- A UMP Is Synthesized in Six Steps
- B UMP Is Converted to UTP and CTP
- C Pyrimidine Nucleotide Biosynthesis Is Regulated at ATCase or Carbamoyl Phosphate Synthetase II

3 Formation of Deoxyribonucleotides

- A Ribonucleotide Reductase Converts Ribonucleotides to Deoxyribonucleotides
- B dUMP Is Methylated to Form Thymine

4 Nucleotide Degradation

- A Purine Catabolism Yields Uric Acid
- B Some Animals Degrade Uric Acid
- C Pyrimidines Are Broken Down to Malonyl-CoA and Methylmalonyl-CoA

Roger Wilmshurst/Science Source

Certain fungal species, which grow mainly underground, send up fruiting bodies to form a “fairy ring.” The surrounding grass often grows thickly in the same circular pattern, due to the release of a fungal nucleotide derivative that acts as a growth factor for plants.

Nucleotides are phosphate esters of a pentose (ribose or deoxyribose) in which a purine or pyrimidine base is linked to C1' of the sugar (Section 3-1). Nucleoside triphosphates are the monomeric units that act as precursors of nucleic acids; nucleotides also perform a wide range of other biochemical functions. For example, we have seen how the cleavage of “high-energy” compounds such as ATP provides the free energy that makes various reactions thermodynamically favorable. We have also seen that nucleotides are components of some of the central cofactors of metabolism, including FAD, NAD⁺, and coenzyme A. The importance of nucleotides in cellular metabolism is indicated by the observation that nearly all cells can synthesize them both *de novo* (anew) and from the degradation products of nucleic acids. However, unlike carbohydrates, amino acids, and fatty acids, nucleotides do not provide a significant source of metabolic energy.

In this chapter, we consider the nature of the nucleotide biosynthetic pathways. In doing so, we will examine how they are regulated and the consequences of their blockade, both by genetic defects and through the administration of chemotherapeutic agents. We then discuss how nucleotides are degraded. In following the general chemical themes of nucleotide metabolism, we will break our discussion into sections on purines, pyrimidines, and deoxynucleotides (including thymidylate). The structures and nomenclature of the major purines and pyrimidines are given in Table 3-1.

1 Synthesis of Purine Ribonucleotides

KEY CONCEPTS

- IMP is synthesized through the assembly of a purine base on ribose-5-phosphate.
- Kinases convert IMP-derived AMP and GMP to ATP and GTP.
- Purine nucleotide synthesis is regulated by feedback inhibition and feedforward activation.
- Salvage reactions convert purines to their nucleotide forms.

In 1948, John Buchanan obtained the first clues to the *de novo* synthesis of purine nucleotides by feeding a variety of isotopically labeled compounds to pigeons and chemically determining the positions of the labeled atoms in their excreted **uric acid** (a purine; *at right*).

The results of his studies demonstrated that N1 of purines arises from the amino group of aspartate; C2 and C8 originate from formate; N3 and N9 are contributed by the amide group of glutamine; C4, C5, and N7 are derived from glycine (strongly suggesting that this molecule is wholly incorporated into the purine ring); and C6 comes from HCO_3^- .

The actual pathway by which the precursors are incorporated into the purine ring was elucidated in subsequent investigations performed largely by Buchanan and G. Robert Greenberg. The initially synthesized purine derivative is **inosine monophosphate (IMP; at right)**, the nucleotide of the base **hypoxanthine**. IMP is the precursor of both AMP and GMP. Thus, contrary to expectation, *purines are initially formed as ribonucleotides rather than as free bases*. Additional studies have demonstrated that such widely divergent organisms as *E. coli*, yeast, pigeons, and humans have virtually identical pathways for the biosynthesis of purine nucleotides, thereby further demonstrating the biochemical unity of life.

Inosine monophosphate (IMP)

A Purine Synthesis Yields Inosine Monophosphate

IMP is synthesized in a pathway composed of 11 reactions (**Fig. 23-1**):

- 1. Activation of ribose-5-phosphate.** The starting material for purine biosynthesis is α -D-ribose-5-phosphate, a product of the pentose phosphate pathway (Section 15-6). In the first step of purine biosynthesis, **ribose phosphate pyrophosphokinase** activates the ribose by reacting it with ATP to form **5-phosphoribosyl- α -pyrophosphate (PRPP)**. This compound is also a precursor in the biosynthesis of pyrimidine nucleotides (Section 23-2A) and the amino acids histidine and tryptophan (Section 21-5B). As is expected for an enzyme at such an important biosynthetic crossroads, the activity of ribose phosphate pyrophosphokinase is precisely regulated.
- 2. Acquisition of purine atom N9.** In the first reaction unique to purine biosynthesis, **amidophosphoribosyl transferase** catalyzes the displacement of PRPP's pyrophosphate group by glutamine's amide nitrogen. The reaction occurs with inversion of the α configuration at C1 of PRPP, thereby forming **β -5-phosphoribosylamine** and establishing the anomeric form of the future nucleotide. The reaction, which is driven to completion by the subsequent hydrolysis of the released PP_i , is the pathway's flux-controlling step.
- 3. Acquisition of purine atoms C4, C5, and N7.** Glycine's carboxyl group forms an amide with the amino group of phosphoribosylamine, yielding **glycinamide ribotide (GAR)**. This reaction is reversible, despite its concomitant hydrolysis of ATP to ADP + P_i . It is the only step of the purine biosynthetic pathway in which more than one purine ring atom is acquired.

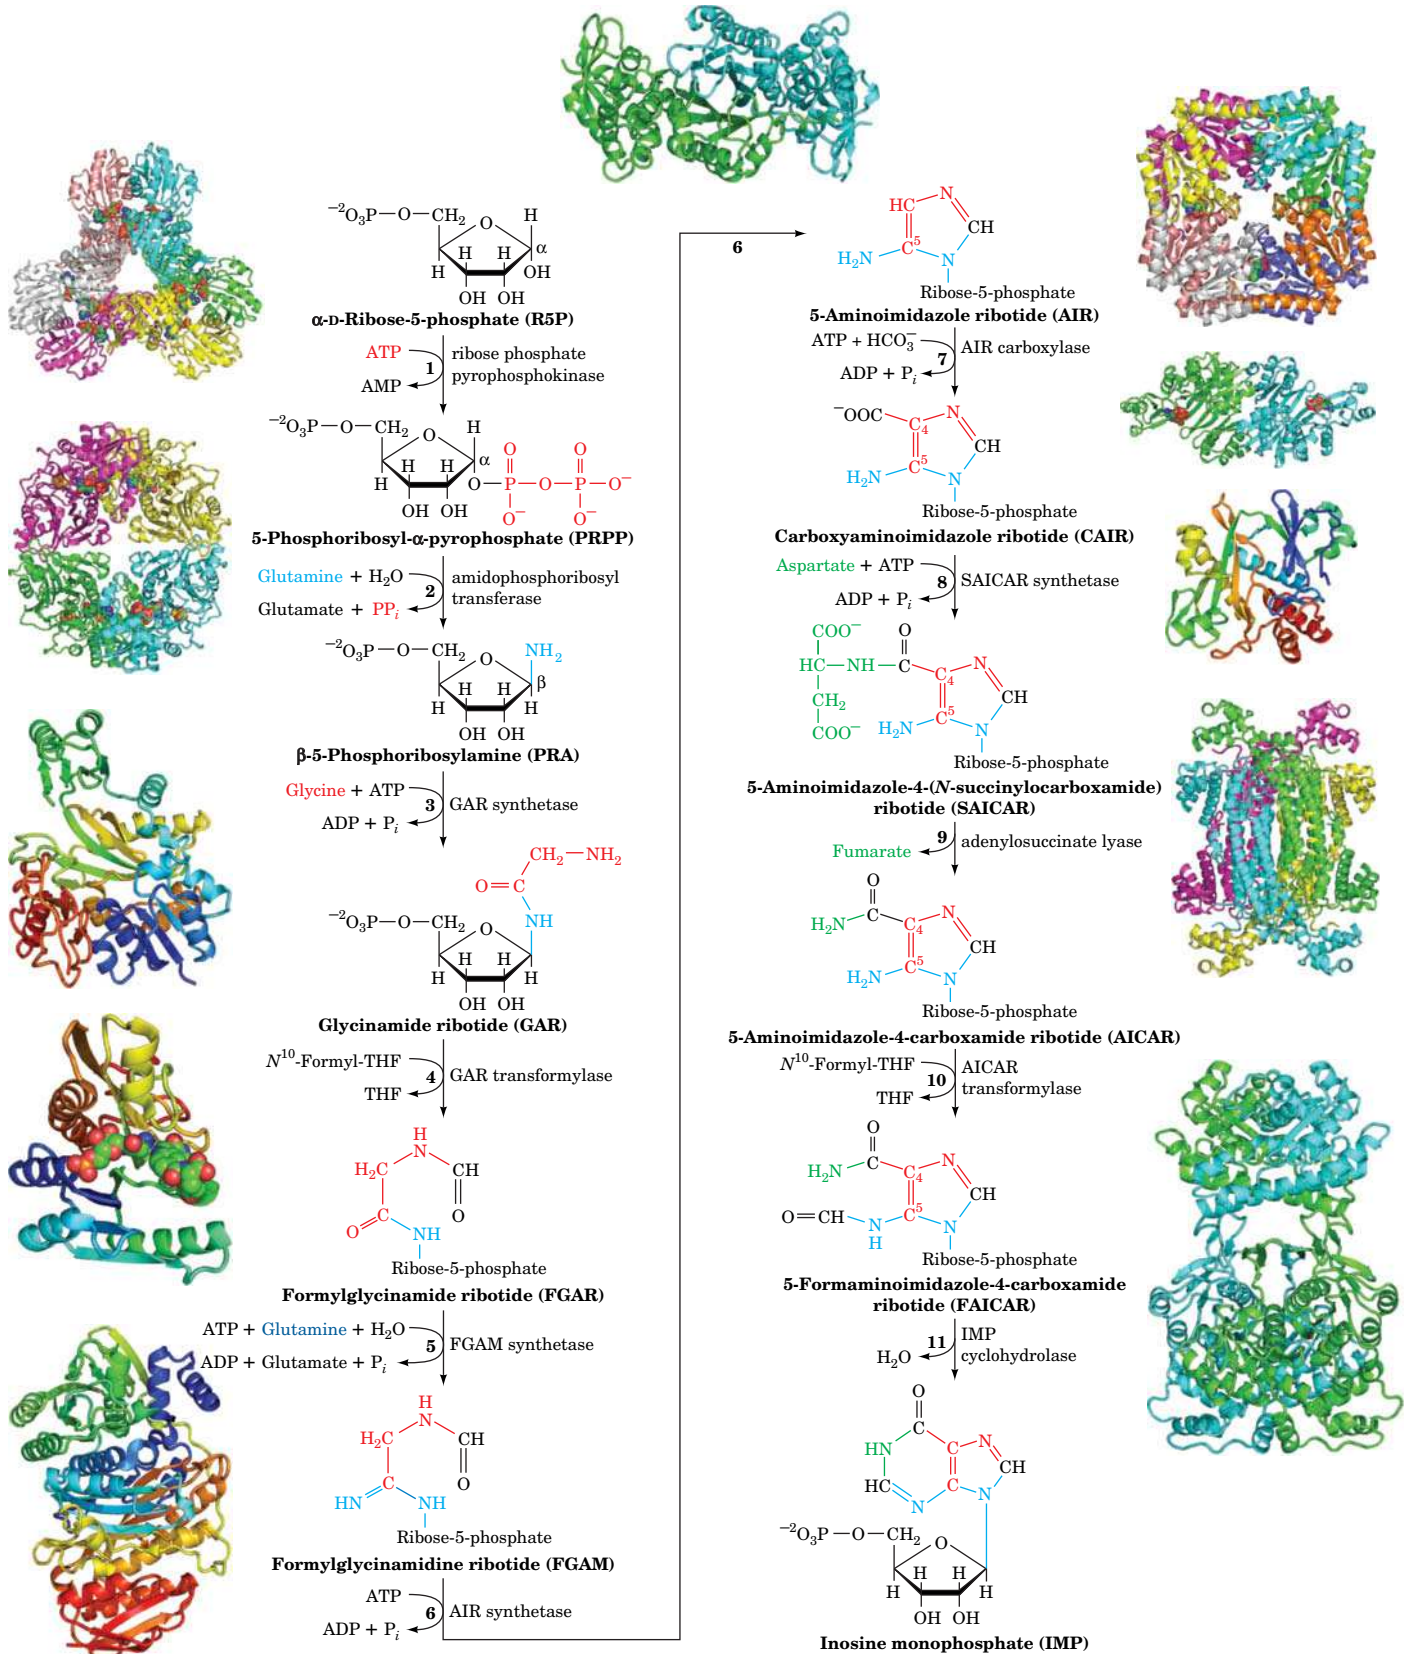

FIG. 23-1 The metabolic pathway for the *de novo* biosynthesis of IMP. Here the purine residue is built up on a ribose ring in 11 enzyme-catalyzed reactions. The X-ray structures for all the enzymes are shown to the outside of the corresponding reaction arrow. The peptide chains of monomeric enzymes are colored in rainbow order from N-terminus (blue) to C-terminus (red). The oligomeric enzymes, all of which consist of identical polypeptide chains, are viewed along a rotation axis with their various chains differently colored. Bound ligands are shown in

space-filling form with C green, N blue, O red, and P orange. [PDBids: enzyme 1, 1DKU; enzyme 2, 1A00; enzyme 3, 1GSO; enzyme 4, 1CDE; enzyme 5, 1VK3; enzyme 6, 1CLI; enzyme 7, 1D7A (PurE) and 1B6S (PurK); enzyme 8, 1A48; enzyme 9, 1C3U; enzymes 10 and 11, 1G8M.] **WPLS** See the Animated Figures.

? Identify the type of reaction that occurs at each step.

4. **Acquisition of purine atom C8.** GAR's free α -amino group is formylated to yield **formylglycinamide ribotide (FGAR)**. The formyl donor in the reaction is N^{10} -formyltetrahydrofolate (N^{10} -formyl-THF), a coenzyme that transfers C_1 units (THF cofactors are described in Section 21-4D). The X-ray structure of the enzyme catalyzing the reaction, **GAR transformylase**, in complex with GAR and the THF analog **5-deazatetrahydrofolate (5dTHF)** was determined by Robert Almassy (Fig. 23-2). Note the proximity of the GAR amino group to N10 of 5dTHF. This supports enzymatic studies suggesting that the GAR transformylase reaction proceeds via the nucleophilic attack of the GAR amine group on the formyl carbon of N^{10} -formyl-THF to yield a tetrahedral intermediate.
5. **Acquisition of purine atom N3.** The amide amino group of a second glutamine is transferred to the growing purine ring to form **formylglycinamide ribotide (FGAM)**. This reaction is driven by the coupled hydrolysis of ATP to ADP + P_i .
6. **Formation of the purine imidazole ring.** The purine imidazole ring is closed in an ATP-requiring intramolecular condensation that yields **5-aminoimidazole ribotide (AIR)**. The aromatization of the imidazole ring is facilitated by the tautomeric shift of the reactant from its imine to its enamine form.
7. **Acquisition of C6.** Purine C6 is introduced as HCO_3^- (CO_2) in a reaction catalyzed by **AIR carboxylase** that yields **carboxyaminoimidazole ribotide (CAIR)**. In yeast, plants, and most prokaryotes (including *E. coli*), AIR carboxylase consists of two proteins called **PurE** and **PurK**. Although PurE alone can catalyze the carboxylation reaction, its K_M for HCO_3^- is ~ 110 mM, so the reaction would require an unphysiologically high HCO_3^- concentration (~ 100 mM) to proceed. PurK decreases the HCO_3^- concentration required for the PurE reaction by >1000 -fold but at the expense of ATP hydrolysis.
8. **Acquisition of N1.** Purine atom N1 is contributed by aspartate in an amide-forming condensation reaction yielding **5-aminoimidazole-4-(*N*-succinylcarboxamide) ribotide (SACAIR)**. This reaction, which is driven by the hydrolysis of ATP, chemically resembles Reaction 3.
9. **Elimination of fumarate.** SACAIR is cleaved with the release of fumarate, yielding **5-aminoimidazole-4-carboxamide ribotide (AICAR)**. Reactions 8 and 9 chemically resemble the reactions in the urea cycle in which citrulline is aminated to form arginine (Section 21-3A). In both pathways, aspartate's amino group is transferred to an acceptor through an ATP-driven coupling reaction followed by the elimination of the aspartate carbon skeleton as fumarate.
10. **Acquisition of C2.** The final purine ring atom is acquired through formylation by N^{10} -formyl-THF, yielding **5-formaminoimidazole-4-carboxamide ribotide (FAICAR)**. This reaction and Reaction 4 of purine biosynthesis are inhibited indirectly by **sulfonamides**, structural analogs of the *p*-aminobenzoic acid constituent of THF (Section 21-4D).
11. **Cyclization to form IMP.** The final reaction in the purine biosynthetic pathway, ring closure to form IMP, occurs through the elimination of water. In contrast to Reaction 6, the cyclization that forms the imidazole ring, this reaction does not require ATP hydrolysis.

FIG. 23-2 X-Ray structure of *E. coli* GAR transformylase in complex with GAR and 5dTHF. The monomeric protein is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). GAR (upper middle) and 5dTHF (lower left) are drawn in stick form with GAR C green, 5dTHF C magenta, N blue, O red, and P orange. Note the close (3.3-Å) approach of the GAR amino group to N10 of 5dTHF. [Based on an X-ray structure by Robert Almassy, Agouron Pharmaceuticals, San Diego, California. PDBid 1CDE.]

In animals, Reactions 10 and 11 are catalyzed by a bifunctional enzyme, as are Reactions 7 and 8. Reactions 3, 4, and 6 also take place on a single protein. *The intermediate products of these multifunctional enzymes are not readily released to the medium but are channeled to the succeeding enzymatic activities of the pathway.* As in the reactions catalyzed by the pyruvate dehydrogenase complex

(Section 17-2), fatty acid synthase (Section 20-4C), bacterial glutamate synthase (Section 21-7), and tryptophan synthase (Section 21-5B), channeling in the nucleotide synthetic pathways increases the overall rate of these multistep processes and protects intermediates from degradation by other cellular enzymes.

B IMP Is Converted to Adenine and Guanine Ribonucleotides

IMP does not accumulate in the cell but is rapidly converted to AMP and GMP. AMP, which differs from IMP only in the replacement of its 6-keto group by an amino group, is synthesized in a two-reaction pathway (Fig. 23-3, left). In the first reaction, aspartate's amino group is linked to IMP in a reaction powered by the hydrolysis of GTP to GDP + P_i to yield **adenylosuccinate**. In the second reaction, **adenylosuccinate lyase** eliminates fumarate from adenylosuccinate to form AMP. The same enzyme catalyzes Reaction 9 of the IMP pathway (Fig. 23-1). Both reactions add a nitrogen with the elimination of fumarate.

GMP is also synthesized from IMP in a two-reaction pathway (Fig. 23-3, right). In the first reaction, IMP is dehydrogenated via the reduction of NAD⁺ to form **xanthosine monophosphate (XMP; the ribonucleotide of the base xanthine)**. XMP is then converted to GMP by the transfer of the glutamine amide nitrogen in a reaction driven by the hydrolysis of ATP to AMP + PP_i (and subsequently to 2 P_i). In B and T lymphocytes, which mediate the immune response, IMP dehydrogenase activity is high in order to supply the guanosine the cells need for proliferation. The fungal compound **mycophenolic acid** (at left) inhibits the enzyme and is used as an immunosuppressant following kidney transplants.

FIG. 23-3 Conversion of IMP to AMP or GMP in separate two-reaction pathways. The X-ray structures of the homo-oligomeric enzymes catalyzing the reactions are shown as is described in the legend for Fig. 23-1. [PDBIds: adenylosuccinate synthetase, 1GIM; adenylosuccinate lyase, 1C3U; IMP dehydrogenase, 1JR1; GMP synthetase, 1GPM.]

adenylosuccinate lyase, 1C3U; IMP dehydrogenase, 1JR1; GMP synthetase, 1GPM.]

? Why does it make sense for GTP to be a cofactor for AMP synthesis and ATP a cofactor for GMP synthesis?

Nucleoside Diphosphates and Triphosphates Are Synthesized by the Phosphorylation of Nucleoside Monophosphates. To participate in nucleic acid synthesis, nucleoside monophosphates must first be converted to the corresponding nucleoside triphosphates. First, nucleoside diphosphates are synthesized from the corresponding nucleoside monophosphates by base-specific **nucleoside monophosphate kinases**. For example, adenylate kinase (Section 14-2C) catalyzes the phosphorylation of AMP to ADP:

Similarly, GDP is produced by **guanylate kinase**:

These nucleoside monophosphate kinases do not discriminate between ribose and deoxyribose in the substrate.

Nucleoside diphosphates are converted to the corresponding triphosphates by **nucleoside diphosphate kinase**; for instance,

Although the reaction is written with ATP as the phosphoryl donor, this enzyme exhibits no preference for the bases of its substrates or for ribose over deoxyribose. Furthermore, the nucleoside diphosphate kinase reaction, as might be expected from the nearly identical structures of its substrates and products, normally operates close to equilibrium ($\Delta G \approx 0$). ADP is, of course, also converted to ATP by a variety of energy-releasing reactions, such as those of glycolysis and oxidative phosphorylation. Indeed, it is those reactions that ultimately drive the foregoing kinase reactions.

C Purine Nucleotide Biosynthesis Is Regulated at Several Steps

The pathways synthesizing IMP, ATP, and GTP are individually regulated in most cells so as to control the total amounts of purine nucleotides available for nucleic acid synthesis, as well as the relative amounts of ATP and GTP. This control network is diagrammed in [Fig. 23-4](#).

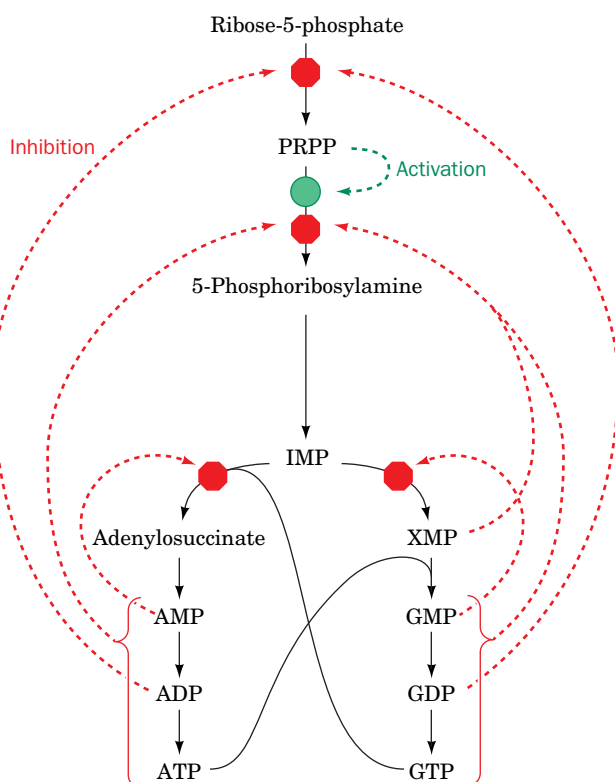

FIG. 23-4 Control of the purine biosynthesis pathway. Red octagons and green circles indicate control points. Feedback inhibition is indicated by dashed red arrows, and feedforward activation is represented by a dashed green arrow. **WPLS** See the Animated Figures.

The IMP pathway is regulated at its first two reactions: those catalyzing the synthesis of PRPP and 5-phosphoribosylamine. Ribose phosphate pyrophosphokinase, the enzyme catalyzing Reaction 1 of the IMP pathway (Fig. 23-1), is inhibited by both ADP and GDP. Amidophosphoribosyl transferase, the enzyme catalyzing the first committed step of the IMP pathway (Reaction 2), is likewise subject to feedback inhibition. In this case, the enzyme binds ATP, ADP, and AMP at one inhibitory site and GTP, GDP, and GMP at another. *The rate of IMP production is therefore independently but synergistically controlled by the levels of adenine nucleotides and guanine nucleotides.* Moreover, amidophosphoribosyl transferase is allosterically stimulated by PRPP (**feedforward activation**).

A second level of regulation occurs immediately below the branch point leading from IMP to AMP and GMP. AMP and GMP are each competitive inhibitors of IMP in their own synthesis, which prevents excessive buildup of the pathway products. In addition, the rates of adenine and guanine nucleotide synthesis are coordinated. Recall that GTP powers the synthesis of AMP from IMP, whereas ATP powers the synthesis of GMP from IMP (Fig. 23-3). This reciprocity balances the production of AMP and GMP (which are required in roughly equal amounts in nucleic acid biosynthesis): *The rate of synthesis of GMP increases with [ATP], whereas that of AMP increases with [GTP].*

D Purines Can Be Salvaged

In most cells, the turnover of nucleic acids, particularly some types of RNA, releases adenine, guanine, and hypoxanthine (Section 23-4A). These free purines are reconverted to their corresponding nucleotides through **salvage pathways**. In contrast to the *de novo* purine nucleotide synthetic pathway, which is virtually identical in all cells, salvage pathways are diverse in character and distribution. In mammals, purines are mostly salvaged by two different enzymes. **Adenine phosphoribosyltransferase (APRT)** mediates AMP formation using PRPP:

Hypoxanthine–guanine phosphoribosyltransferase (HGPRT) catalyzes the analogous reaction for both hypoxanthine and guanine:

 **Lesch–Nyhan Syndrome Results from HGPRT Deficiency.** The symptoms of **Lesch–Nyhan syndrome**, which is caused by a severe HGPRT deficiency, indicate that purine salvage reactions have functions other than conservation of the energy required for *de novo* purine biosynthesis. This sex-linked congenital defect (it affects mostly males) results in excessive uric acid production (uric acid is a purine degradation product; Section 23-4A) and neurological abnormalities such as spasticity, mental retardation, and highly aggressive and destructive behavior, including a bizarre compulsion toward self-mutilation. For example, many children with Lesch–Nyhan syndrome have such an irresistible urge to bite their lips and fingers that they must be restrained. If the restraints are removed, communicative patients will plead that the restraints be replaced, even as they attempt to injure themselves.

The excessive uric acid production in patients with Lesch–Nyhan syndrome is readily explained. The lack of HGPRT activity leads to an accumulation of the PRPP that would normally be used to salvage hypoxanthine and guanine. The excess PRPP activates amidophosphoribosyl transferase (which catalyzes Reaction 2 of the IMP biosynthetic pathway), thereby greatly accelerating the synthesis of purine nucleotides and thus the formation of their degradation product, uric acid. Yet the physiological basis of the associated neurological abnormalities remains obscure. That a defect in a single enzyme can cause such profound but well-defined behavioral changes nevertheless has important neurophysiological implications.

CHECKPOINT

- List the starting materials and cofactors required for IMP biosynthesis.
- Describe the importance of multifunctional enzymes in nucleotide biosynthesis.
- Describe the reactions that convert IMP to ATP and GTP.
- How do guanine and adenine nucleotides inhibit their own synthesis? How do they promote synthesis of each other?
- Describe how free purines are converted back to nucleotides.

2 Synthesis of Pyrimidine Ribonucleotides

KEY CONCEPTS

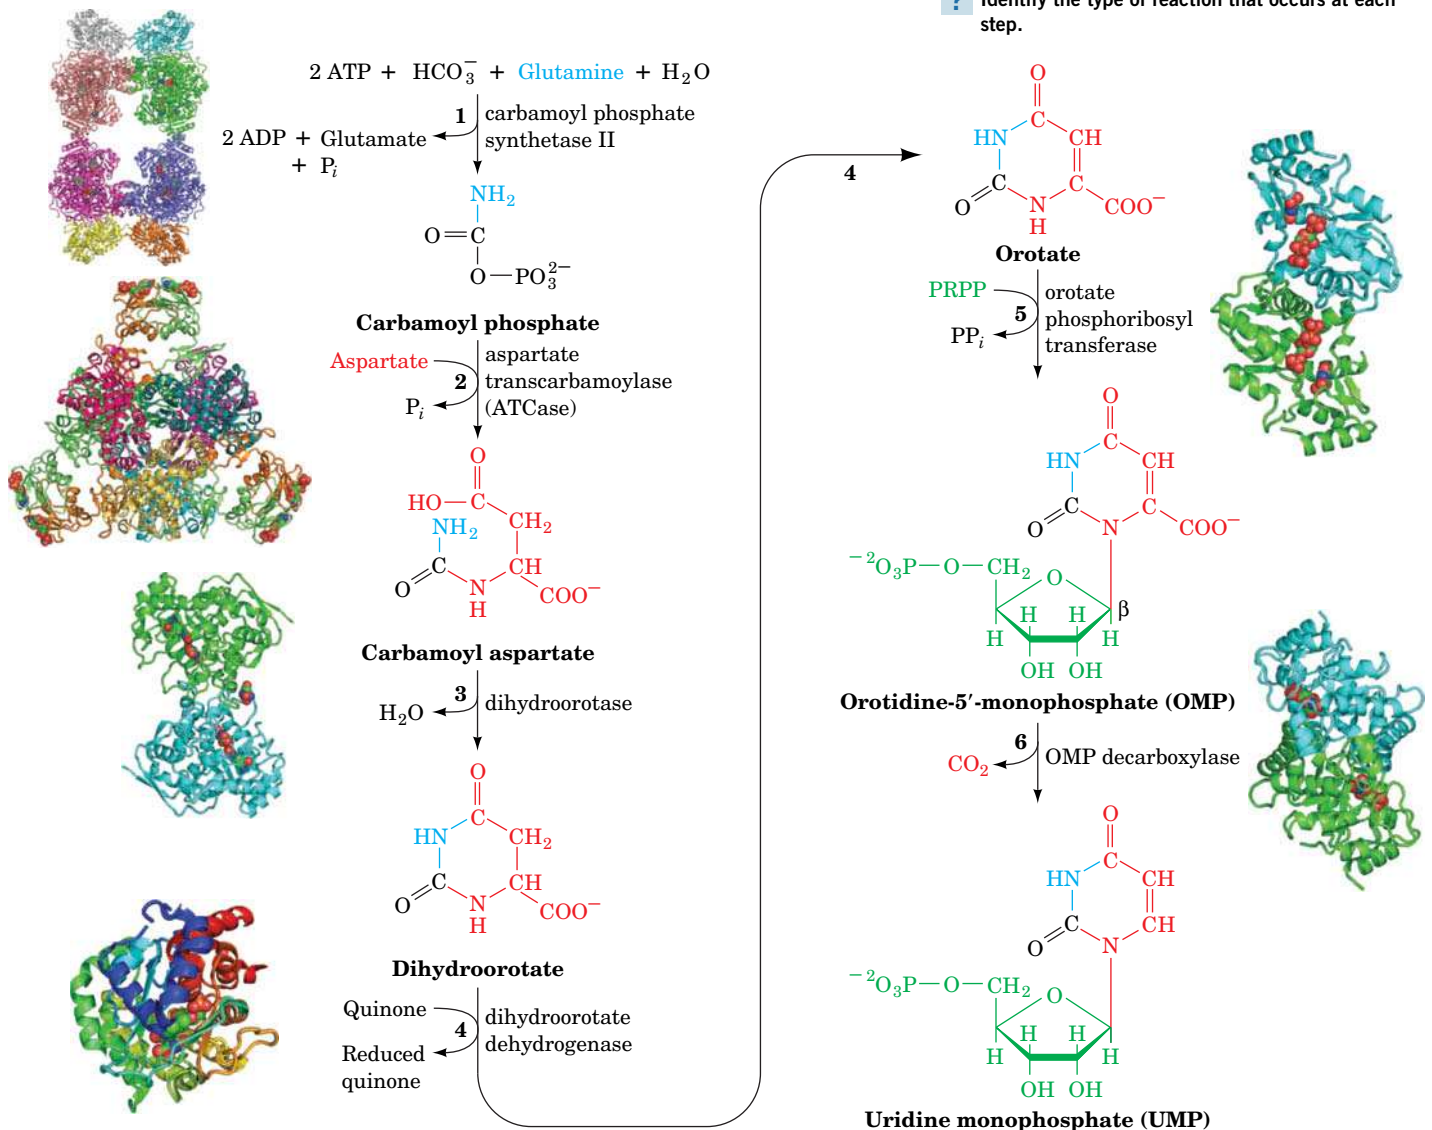

- UMP is synthesized as a pyrimidine base to which ribose-5-phosphate is added.
- CTP and UTP are derived from UMP.
- The early steps of pyrimidine nucleotide synthesis are the pathway's major control points.

The biosynthesis of pyrimidines is simpler than that of purines. Isotopic labeling experiments have shown that atoms N1, C4, C5, and C6 of the pyrimidine ring are all derived from aspartic acid, C2 arises from HCO_3^- , and N3 is contributed by glutamine.

A UMP Is Synthesized in Six Steps

UMP, which is also the precursor of CMP, is synthesized in a six-reaction pathway (Fig. 23-5). In contrast to purine nucleotide synthesis, the pyrimidine ring is coupled to the ribose-5-phosphate moiety *after* the ring has been synthesized.

- 1. Synthesis of carbamoyl phosphate.** The first reaction of pyrimidine biosynthesis is the synthesis of **carbamoyl phosphate** from HCO_3^- and the amide nitrogen of glutamine by the cytosolic enzyme **carbamoyl phosphate synthetase II**. This reaction consumes two molecules of ATP: One provides a phosphate group and the other energizes the reaction. Carbamoyl phosphate is also synthesized in the urea cycle (Section 21-3A). In that reaction, catalyzed by the mitochondrial enzyme carbamoyl phosphate synthetase I, ammonia is the nitrogen source.
- 2. Synthesis of carbamoyl aspartate.** Condensation of carbamoyl phosphate with aspartate to form **carbamoyl aspartate** is catalyzed by **aspartate transcarbamoylase (ATCase)**. This reaction proceeds without ATP hydrolysis because carbamoyl phosphate is already “activated.” The structure and regulation of *E. coli* ATCase are discussed in Section 12-3.
- 3. Ring closure to form dihydroorotate.** The third reaction of the pathway is an intramolecular condensation catalyzed by **dihydroorotase** to yield **dihydroorotate**.
- 4. Oxidation of dihydroorotate.** Dihydroorotate is irreversibly oxidized to **orotate** by **dihydroorotate dehydrogenase**. The eukaryotic enzyme, which contains FMN and nonheme Fe, is located on the outer surface of the inner mitochondrial membrane, where quinones supply its oxidizing power. The other five enzymes of pyrimidine nucleotide biosynthesis are cytosolic in animal cells. Inhibition of dihydroorotate dehydrogenase blocks pyrimidine synthesis in T lymphocytes, thereby attenuating the autoimmune disease rheumatoid arthritis.
- 5. Acquisition of the ribose phosphate moiety.** Orotate reacts with PRPP to yield **orotidine-5'-monophosphate (OMP)** in a reaction catalyzed by **orotate phosphoribosyl transferase**. The reaction, which is driven by the hydrolysis of the eliminated PP_i , fixes the anomeric form of pyrimidine nucleotides in the β configuration. Orotate phosphoribosyl transferase also salvages other pyrimidine bases, such as uracil and cytosine, by converting them to their corresponding nucleotides.
- 6. Decarboxylation to form UMP.** The final reaction of the pathway is the decarboxylation of OMP by **OMP decarboxylase (ODCase)** to form UMP. ODCase enhances the rate (k_{cat}/K_M) by a factor of 2×10^{23} over that of the uncatalyzed reaction, making it the most catalytically proficient enzyme known. Nevertheless, the reaction requires no cofactors to help stabilize its putative carbanion intermediate. Although the mechanism of the ODCase reaction is not fully understood, the removal of OMP's phosphate group, which is quite distant from the C6 carboxyl group, decreases the reaction rate by a factor of 7×10^7 , thus providing a striking example of how binding energy can be applied to catalysis (preferential transition state binding).

Dennis Kunkel/Phototake

FIG. 23-6 *Toxoplasma gondii*. This intracellular parasite (yellow) causes toxoplasmosis.

In bacteria, the six enzymes of UMP biosynthesis occur as independent proteins. In animals, however, as Mary Ellen Jones demonstrated, the first three enzymatic activities of the pathway—carbamoyl phosphate synthetase II, ATCase, and dihydroorotase—occur on a single 210-kD polypeptide chain.

 The pyrimidine biosynthetic pathway is a target for antiparasitic drugs. For example, the parasite *Toxoplasma gondii* (Fig. 23-6), which infects most mammals, causes **toxoplasmosis**, a disease whose complications include blindness, neurological dysfunction, and death in immunocompromised individuals (e.g., those with AIDS). Most parasites have evolved to take advantage of nutrients supplied by their hosts, but *T. gondii* is unable to meet its needs exclusively through nucleotide salvage pathways and retains the ability to synthesize uracil *de novo*. Drugs that target the parasite's carbamoyl phosphate synthetase II (an enzyme whose structure and kinetics distinguish it from its mammalian counterpart) could therefore prevent *T. gondii* growth. Moreover, there is evidence that *T. gondii* strains that have been engineered to lack carbamoyl phosphate synthetase II are avirulent and could be useful as vaccines in humans and livestock.

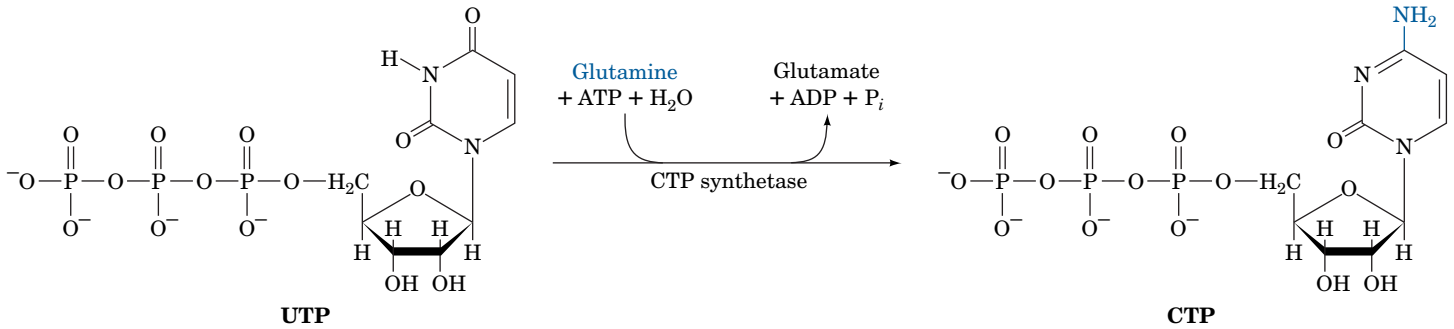

FIG. 23-7 The synthesis of CTP from UTP.

B UMP Is Converted to UTP and CTP

The synthesis of UTP from UMP is analogous to the synthesis of purine nucleoside triphosphates (Section 23-1B). The process occurs by the sequential actions of a nucleoside monophosphate kinase and nucleoside diphosphate kinase:

CTP is formed by the amination of UTP by **CTP synthetase** (Fig. 23-7). In animals, the amino group is donated by glutamine, whereas in bacteria it is supplied directly by ammonia.

C Pyrimidine Nucleotide Biosynthesis Is Regulated at ATCase or Carbamoyl Phosphate Synthetase II

In bacteria, the pyrimidine biosynthetic pathway is primarily regulated at Reaction 2, the ATCase reaction (Fig. 23-8a). In *E. coli*, control is exerted through the

FIG. 23-8 Regulation of pyrimidine biosynthesis. The control networks are shown for (a) *E. coli* and (b) animals. Red octagons and green circles indicate control points. Feedback inhibition is represented by dashed red arrows, and activation is indicated by dashed green arrows. **WPLS** See the Animated Figures.

allosteric stimulation of ATCase by ATP and its inhibition by CTP (Section 12-3). In many bacteria, however, UTP is the major ATCase inhibitor.

In animals, ATCase is not a regulatory enzyme. Rather, pyrimidine biosynthesis is controlled by the activity of carbamoyl phosphate synthetase II, which is inhibited by UDP and UTP and activated by ATP and PRPP (Fig. 23-8b). A second level of control in the mammalian pathway occurs at OMP decarboxylase, for which UMP and to a lesser extent CMP are competitive inhibitors. In all organisms, the rate of OMP production varies with the availability of its precursor, PRPP. Recall that the PRPP level depends on the activity of ribose phosphate pyrophosphokinase (Fig. 23-1, Reaction 1), which is inhibited by ADP and GDP (Section 23-1C).

Orotic Aciduria Results from an Inherited Enzyme Deficiency. Orotic aciduria, an inherited human disease, is characterized by the urinary excretion of large amounts of orotic acid, retarded growth, and severe anemia. It results from a deficiency in the bifunctional enzyme catalyzing Reactions 5 and 6 of pyrimidine nucleotide biosynthesis. Consideration of the biochemistry of this situation led to its effective treatment: the administration of uridine and/or cytidine. The UMP formed through the phosphorylation of the nucleosides, besides replacing that normally synthesized, inhibits carbamoyl phosphate synthetase II so as to attenuate the rate of orotic acid synthesis. No other genetic deficiency in pyrimidine nucleotide biosynthesis is known in humans, presumably because such defects are lethal *in utero*.

.....

CHECKPOINT

- Compare the pathways of purine and pyrimidine nucleotide synthesis with respect to (a) precursors, (b) energy cost, (c) acquisition of the ribose moiety, and (d) number of enzymatic steps.
- How are CTP and UTP derived from UMP?
- How does regulation of pyrimidine synthesis differ in bacteria and animals?

3 Formation of Deoxyribonucleotides

KEY CONCEPTS

- Ribonucleotide reductase uses a free radical mechanism to convert ribonucleotides to deoxyribonucleotides.
- Thymidylate synthase transfers a methyl group to dUMP to form thymine.

DNA differs chemically from RNA in two major respects: (1) Its nucleotides contain 2'-deoxyribose residues rather than ribose residues, and (2) it contains the base thymine (5-methyluracil) rather than uracil. In this section, we consider the biosynthesis of these DNA components.

A Ribonucleotide Reductase Converts Ribonucleotides to Deoxyribonucleotides

Deoxyribonucleotides are synthesized from their corresponding ribonucleotides by the reduction of their C2' position rather than by their de novo synthesis from deoxyribose-containing precursors.

Enzymes that catalyze the formation of deoxyribonucleotides by the reduction of the corresponding ribonucleotides are named **ribonucleotide reductases (RNRs)**. There are three classes of RNRs, which differ in their prosthetic groups, although they all replace the 2'-OH group of ribose with H via a free-radical mechanism involving a thiol radical (see below). Here we discuss the mechanism of Class Ia RNRs, which have an Fe-containing prosthetic group and which occur in all eukaryotes and many aerobic bacteria (Class Ib RNRs have a similar mechanism but have an Mn-containing prosthetic group).

Class Ia RNRs reduce ribonucleoside diphosphates (NDPs) to the corresponding deoxyribonucleoside diphosphates (dNDPs). The active form of *E. coli* ribonucleotide reductase, as Peter Reichard demonstrated, is a heterotetramer that can be decomposed to two catalytically inactive homodimers, α_2 and β_2 (Fig. 23-9). Each 761-residue α subunit has a substrate-binding site that includes three redox-active Cys thiol groups. The α subunits also contain two effector-binding sites that control the enzyme's catalytic activity as well as its substrate specificity (see below).

The X-ray structure of β_2 , determined by Hans Eklund, reveals that the subunits are bundles of eight unusually long helices. Each 375-residue β subunit contains a novel binuclear Fe(III) prosthetic group whose Fe(III) ions are liganded by a variety of groups including a bridging O atom (Fig. 23-9, lower inset). The Fe(III) complex interacts with Tyr 122 to form an unusual tyrosyl free radical [Recall that tyrosyl radicals also participate in the reactions catalyzed by cytochrome *c* oxidase (Section 18-2F) and plant Photosystem II (Section 19-2C)].

The X-ray structure of α_2 in complex with the 20-residue C-terminal segment of the β subunit was also determined by Eklund. The structure of the $\alpha_2\beta_2$ heterotetramer has not been determined. However, Eklund generated the model of the $\alpha_2\beta_2$ heterotetramer shown in Fig. 23-9 by assuming that the α_2 and β_2 homodimers share their twofold axes in forming the heterotetramer and by rotating one homodimer with respect to the other until the C-terminal fragment of the β subunit bound to the α subunit came into coincidence with the corresponding portion of the β subunit. Several spectroscopically determined intersubunit distances are consistent with this model.

FIG. 23-9 Model of *E. coli* ribonucleotide reductase based on the X-ray structures of its α_2 and β_2 subunits. The model is viewed with its twofold axis vertical and is drawn in ribbon form with its α subunits pink and red, and its β subunits light and dark blue. The C-terminal segment of the β subunit that was bound to the α subunit in its X-ray structure is cyan. A portion of the activity site is orange. GDP (green) bound in the catalytic site, TTP (yellow-green) bound in the specificity site, and the Fe_2O core of the diferric cluster (orange) are drawn in space-filling form. The residues forming the radical-transfer pathway are shown in stick form in green. The lower inset depicts the diferric cluster and the upper inset shows the thiol radical. [Courtesy of JoAnne Stubbe, MIT. PDBids 1RIB, 3R1R, and 4R1R.]

A variety of experimental evidence led JoAnne Stubbe to formulate the following catalytic mechanism for *E. coli* ribonucleotide reductase (Fig. 23-10):

1. The free radical on Tyr 122 β is transferred to Cys 439 α (really the transfer of an electron from Cys 439 α to Tyr 122 β) via a mechanism discussed below to form a thiyl radical (Fig. 23-9, upper inset). The thiyl radical abstracts the H atom from C3' of the substrate NDP in the reaction's rate-determining step, thereby transferring the radical to C3'.
2. Base-catalyzed abstraction of a proton from O3' by Glu 441 α , accompanied by the migration of the radical to C2', induces the C2' OH group to abstract a proton from Cys 462 α and leave as H₂O.
3. The resulting radical intermediate is reduced by the enzyme's redox-active sulfhydryl pair (Cys 462 α and Cys 225 α) to yield a disulfide bond and a 2'-deoxynucleotide with the radical on C3'.
4. The radical migrates to Cys 429 α in a reversal of Step 1 to re-form the thiyl radical and yield the enzyme's dNDP product.
5. The dNDP product is released and replaced by a new NDP substrate. The protein thioredoxin in its reduced form (see below) carries out a disulfide exchange reaction with the redox-active disulfide group on the α subunit, yielding oxidized thioredoxin and the enzyme in its initial state, thus completing the catalytic cycle.

The Tyr 122 β radical, which is located ~ 10 Å below the surface of the protein, is remarkably stable: It has a half-life of 4 days at 4°C, in contrast to its half-life of ~ 1 μ s in solution. The Tyr 122 β radical is >35 Å from Cys 439 α , too far for the direct transfer of an electron. Rather, the protein mediates this electron transfer via the side chains of a series of redox-active aromatic residues (Tyr and Trp) bridging the α and β subunits. In each step of this process, an electron transfer is accompanied by a proton transfer, ending in the abstraction of an electron and a proton from Cys 439.

The Inability of Oxidized Ribonucleotide Reductase to Bind Substrate Serves an Essential Protective Function. Comparison of the X-ray structures of reduced α_2 (in which the redox-active Cys 225 and Cys 462 residues are in their SH forms) and oxidized α_2 (in which Cys 225 and Cys 462 are disulfide-linked; Fig. 23-10) reveals that Cys 462 in reduced α_2 has rotated away from its position in oxidized α_2 to become buried in a hydrophobic pocket, whereas Cys 225 moves into the region formerly occupied by Cys 462. The distance between the formerly disulfide-linked S atoms thereby increases from 2.0 Å to 5.7 Å. These movements are accompanied by small shifts of the surrounding polypeptide chain. Cys 225 α in oxidized ribonucleotide reductase prevents the binding of substrate through steric interference of its S atom with the substrate NDP's O2' atom.

The inability of oxidized ribonucleotide reductase to bind substrate has functional significance. In the absence of substrate, the enzyme's free radical is stored in the interior of the β subunit, close to its dinuclear iron center. When substrate is bound, the radical is transferred to the substrate, as described above. If the substrate is unable to properly react after accepting this free radical, as would be the case if the enzyme were in its oxidized state, the highly reactive free radical could potentially destroy both the substrate and the enzyme. Thus, *an important role of the enzyme is to control the release of the radical's powerful oxidizing capability. It does so in part by preventing the binding of NDP while the enzyme is in its oxidized form.*

Thioredoxin Reduces Ribonucleotide Reductase. *The final step in the ribonucleotide reductase catalytic cycle is reduction of the enzyme's newly formed disulfide bond to re-form its redox-active sulfhydryl pair* (Fig. 23-10). One of the enzyme's physiological reducing agents is **thioredoxin**, a ubiquitous monomeric protein with a pair of neighboring Cys residues (and which also participates in

PROCESS DIAGRAM

WPLS See the Animated Process Diagrams.

FIG. 23-11 X-Ray structure of human thioredoxin in its reduced (sulfhydryl) state. The backbone of the 105-residue monomer is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chains of the redox-active Cys residues are shown in space-filling form with C green and S yellow. [Based on an X-ray structure by William Montfort, University of Arizona. PDBid 1ERT.]

regulating the Calvin cycle; Section 19-3C). Thioredoxin reduces oxidized ribonucleotide reductase via disulfide interchange.

The X-ray structure of thioredoxin (**Fig. 23-11**) reveals that its redox-active disulfide group is located on a molecular protrusion, making the protein the only known example of a “male” enzyme.

Oxidized thioredoxin is, in turn, reduced in a reaction mediated by **thioredoxin reductase**, which contains redox-active thiol groups and an FAD prosthetic group. This enzyme, a homolog of glutathione reductase (Box 15-4) and lipoamide dehydrogenase (Section 17-2B), catalyzes a similar reaction, the NADPH-mediated reduction of a substrate disulfide bond. NADPH therefore serves as the terminal reducing agent in the ribonucleotide reductase–catalyzed reduction of NDPs to dNDPs (**Fig. 23-12**).

Ribonucleotide Reductase Is Regulated by a Complex Feedback Network. The synthesis of the four dNTPs in the amounts required for DNA synthesis is accomplished through feedback control. Maintaining the proper intracellular quantities and ratios of dNTPs is essential for normal growth. Indeed, *a deficiency of any dNTP is lethal, whereas an excess is mutagenic because the probability that a given dNTP will be erroneously incorporated into a growing DNA strand increases with its concentration relative to those of the other dNTPs.*

The activities of both *E. coli* and mammalian ribonucleotide reductases are remarkably responsive to the levels of nucleotides in the cell. Thus, the α subunit’s so-called specificity site (Fig. 23-9), which binds ATP, TTP, dGTP, and dATP, functions to balance the pools of the various dNTPs, whereas the activity site controls the rate of NTP reduction by binding ATP, which activates the enzyme, or dATP, which inhibits the enzyme. A variety of physical evidence reveals that the binding of dATP reversibly induces the catalytically active $\alpha_2\beta_2$ *E. coli* enzyme to convert to a catalytically inactive $\alpha_4\beta_4$ form. The X-ray structure of this $\alpha_4\beta_4$ complex, determined by Catherine Drennan, reveals an unexpected ringlike structure (**Fig. 23-13**). The conversion of the $\alpha_2\beta_2$ complex to the $\alpha_4\beta_4$ complex involves a dramatic subunit rearrangement that disrupts the radical-transfer pathway and exposes it to solvent, thereby deactivating the enzyme. For yeast and human ribonucleotide reductases, dATP binding induces the hexamerization of its α subunits.

FIG. 23-12 An electron-transfer pathway for nucleoside diphosphate (NDP) reduction. NADPH provides the reducing equivalents for the process through the intermediacy of thioredoxin reductase, thioredoxin, and ribonucleotide reductase.

? Compare this process to the disulfide interchange reactions shown in Fig. 19-30.

dNTPs Are Produced by Phosphorylation of dNDPs. *The final step in the production of all dNTPs is the phosphorylation of the corresponding dNDPs:*

This reaction is catalyzed by nucleoside diphosphate kinase, the same enzyme that phosphorylates NDPs (Section 23-1B). As before, the reaction is written with ATP as the phosphoryl donor, although any NTP or dNTP can function in this capacity.

B dUMP Is Methylated to Form Thymine

The dTTP substrate for DNA synthesis is derived from dUTP, which is hydrolyzed to dUMP by **dUTP diphosphohydrolase (dUTPase)**:

The dUMP is then methylated to generate dTMP, and the dTMP is phosphorylated to form dTTP. The apparent reason for the energetically wasteful process of dephosphorylating dUTP and rephosphorylating dTMP is that cells must minimize their concentration of dUTP in order to prevent incorporation of uracil into their DNA (the enzyme system that synthesizes DNA from dNTPs does not efficiently discriminate between dUTP and dTTP; Section 25-2A).

Human dUTPase is a homotrimer of 141-residue subunits. Its X-ray structure, determined by John Tainer, reveals the basis for the enzyme's exquisite specificity for dUTP. Each subunit binds dUTP in a snug-fitting cavity that sterically excludes thymine's C5 methyl group via the side chains of conserved residues (Fig. 23-14a). The enzyme differentiates uracil from the similarly shaped cytosine via a set of hydrogen bonds that in part mimic adenine's base pairing interactions (Fig. 23-14b). The 2'-OH group of ribose is likewise sterically excluded by the side chain of a conserved Tyr.

FIG. 23-13 X-Ray structure of the $\alpha_4\beta_4$ complex of *E. coli* ribonucleotide reductase in complex with dATP. The protein is drawn in ribbon form and colored as in Fig. 23-9. The dATP molecules bound to both the activity site and the specificity site of each α subunit, and the Fe atoms bound to each β subunit, are shown in space-filling form with C green, N blue, O red, P orange, and Fe brown. Compare this structure to Fig. 23-9. [Based on an X-ray structure by Catherine Drennan, MIT. PDBid 3UUS.]

(a)

FIG. 23-14 X-Ray structure of human dUTPase. (a) The active site region of dUTPase in complex with dUTP. The protein is represented by its molecular surface colored according to its electrostatic potential (negative, red; positive, blue; and near neutral, white). The dUTP is shown in ball-and-stick form with N blue, O red, and P yellow. Mg^{2+} ions that have been modeled into the structure are represented by green spheres. Note the complementary fit of the uracil ring into its binding pocket, particularly the close contacts that discriminate against a methyl group on C5 of the pyrimidine ring and a 2'-OH group on

(b)

the ribose ring. (b) The binding site of dUMP, showing the hydrogen bonding system responsible for the enzyme's specific binding of a uracil ring. The dUMP and the polypeptide backbone binding it are shown in ball-and-stick form with atoms colored as in Part a; hydrogen bonds are indicated by white dotted lines; and a conserved water molecule is represented by a pink sphere. The side chain of a conserved Tyr is tightly packed against the ribose ring so as to discriminate against the presence of a 2'-OH group.

? Identify the points where dUTP differs from dTTP and from UTP.

Thymidylate Synthase Transfers a Methyl Group to dUMP. Thymidylate (dTMP) is synthesized from dUMP by **thymidylate synthase** with N^5,N^{10} -methylenetetrahydrofolate (N^5,N^{10} -methylene-THF) as the methyl donor:

Note that the transferred methylene group (in which the carbon has the oxidation state of formaldehyde) is reduced to a methyl group (which has the oxidation state of methanol) at the expense of the oxidation of the THF cofactor to **dihydrofolate (DHF)**.

Thymidylate synthase, a highly conserved 65-kD homodimeric protein, follows a mechanistic scheme proposed by Daniel Santi (**Fig. 23-15**):

1. An enzyme nucleophile, identified as the thiolate group of Cys 146, attacks C6 of dUMP to form a covalent adduct.
2. C5 of the resulting enolate ion attacks the CH_2 group of the iminium cation in equilibrium with N^5,N^{10} -methylene-THF to form an enzyme–dUMP–THF ternary covalent complex.
3. An enzyme base abstracts the acidic proton at the C5 position of the enzyme-bound dUMP, forming an exocyclic methylene group and eliminating the THF cofactor. The abstracted proton subsequently exchanges with solvent.
4. The redox change occurs via the migration of the C6-H atom of THF as a hydride ion to the exocyclic methylene group, converting it to a methyl group and yielding DHF. This reduction promotes the displacement of the Cys thiolate group from the intermediate to release product, dTMP, and re-form the active enzyme.

Tetrahydrofolate Is Regenerated in Two Reactions. *The thymidylate synthase reaction is biochemically unique in that it oxidizes THF to DHF; no other enzymatic reaction employing a THF cofactor alters this coenzyme's net oxidation state.* The DHF product of the thymidylate synthase reaction is recycled back to N^5,N^{10} -methylene-THF through two sequential reactions (**Fig. 23-16**):

FIG. 23-15 Catalytic mechanism of thymidylate synthase. The methyl group is supplied by N^5,N^{10} -methylene-THF, which is concomitantly oxidized to dihydrofolate.

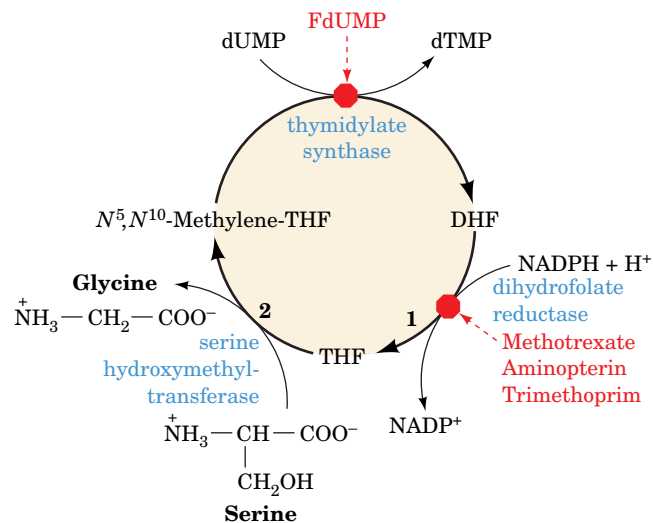

FIG. 23-16 Regeneration of N^5,N^{10} -methylenetetrahydrofolate. The DHF product of the thymidylate synthase reaction is converted back to N^5,N^{10} -methylene-THF by the sequential actions of (1) dihydrofolate reductase and (2) serine hydroxymethyltransferase. The sites of action of some inhibitors are indicated by red octagons. Thymidylate synthase is inhibited by FdUMP, whereas dihydrofolate reductase is inhibited by the antifolates methotrexate, aminopterin, and trimethoprim (Box 23-1).

? Which other step of dTMP synthesis requires NADPH?

FIG. 23-17 X-Ray structure of human dihydrofolate reductase in complex with folic acid. The polypeptide is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The folic acid is drawn in space-filling form with C green, N blue, and O red. [Based on an X-ray structure by Joseph Kraut, University of California at San Diego. PDBid 1DHF.]

CHECKPOINT

- Describe the production of dNTPs from their corresponding NDPs.
- What is the role of thioredoxin and NADPH in the formation of deoxyribonucleotides?
- Describe the roles of dUTPase, thymidylate synthase, and dihydrofolate reductase in the synthesis of dTMP.
- What is the role of NADPH in the formation of thymidylate?

1. DHF is reduced to THF by NADPH as catalyzed by **dihydrofolate reductase (DHFR; Fig. 23-17)**. Although in most organisms DHFR is a monomeric, monofunctional enzyme, in protozoa and some plants DHFR and thymidylate synthase occur on the same polypeptide chain to form a bifunctional enzyme that has been shown to channel DHF from its thymidylate synthase to its DHFR active sites.
2. Serine hydroxymethyltransferase (Section 21-4A) transfers the hydroxymethyl group of serine to THF yielding N^5, N^{10} -methylene-THF and glycine.

Inhibition of thymidylate synthase or DHFR blocks dTMP synthesis and is therefore the basis of certain cancer chemotherapies (Box 23-1).

4 Nucleotide Degradation

KEY CONCEPTS

- Purines are broken down to uric acid.
- Uric acid may be further catabolized for excretion.
- Pyrimidines are converted to CoA derivatives for catabolism.

Most foodstuffs, being of cellular origin, contain nucleic acids. Dietary nucleic acids survive the acidic medium of the stomach; they are degraded to their component nucleotides, mainly in the intestine, by pancreatic nucleases and intestinal phosphodiesterases. The ionic nucleotides, which cannot pass through cell membranes, are then hydrolyzed to nucleosides by a variety of group-specific nucleotidases and nonspecific phosphatases. Nucleosides may be directly absorbed by the intestinal mucosa or further degraded to free bases and ribose or ribose-1-phosphate through the action of **nucleosidases** and **nucleoside phosphorylases**:

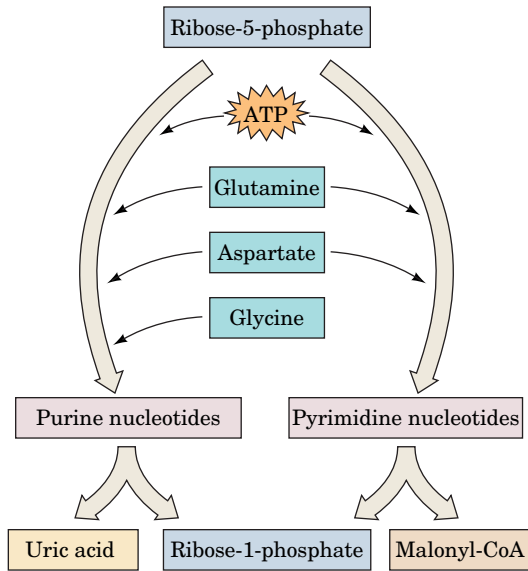

FIG. 23-18 Summary of nucleotide metabolism. Nucleotides are synthesized from amino acids and ribose-5-phosphate by pathways in which the base is built onto the sugar (purine synthesis) or the sugar is added to the base (pyrimidine synthesis). Nucleotide catabolism yields a derivative of the base and releases the sugar as ribose-1-phosphate.

we outline these catabolic pathways and discuss the consequences of several of their inherited defects. A summary of nucleotide metabolism is shown in **Fig. 23-18**.

A Purine Catabolism Yields Uric Acid

The major pathways of purine nucleotide and deoxynucleotide catabolism in animals are diagrammed in **Fig. 23-19**. The pathways in other organisms differ somewhat, but all the pathways lead to uric acid. Of course, the pathway intermediates may be directed to purine nucleotide synthesis via salvage reactions. In addition, ribose-1-phosphate, a product of the reaction catalyzed by **purine nucleoside phosphorylase (PNP)**, is a precursor of PRPP.

Adenosine and deoxyadenosine are not degraded by mammalian PNP. Rather, adenosine nucleosides and nucleotides are deaminated by **adenosine deaminase (ADA)** and **AMP deaminase** to their corresponding inosine derivatives, which can then be further degraded.

FIG. 23-19 The major pathways of purine catabolism in animals. The various purine nucleotides are all degraded to uric acid.

? Compare the activity of PNP to that of glycogen phosphorylase (Section 16-1A).

FIG. 23-20 X-Ray structure of murine adenosine deaminase. The polypeptide is drawn in ribbon form colored according to its secondary structure (helices cyan, β strands magenta, and loops pink) and viewed approximately down the axis of the enzyme's α/β barrel from the N-terminal ends of its β strands. The transition state analog **6-hydroxy-1,6-dihydropurine ribonucleoside (HDPR)** is shown in stick form with C green, N blue, and O red. The enzyme-bound Zn^{2+} ion, which is coordinated by HDPR's 6-hydroxyl group, is represented by a silver sphere. [Based on an X-ray structure by Florante Quioco, Baylor College of Medicine. PDBid 1ADA.]

ADA is an eight-stranded α/β barrel (Fig. 23-20) with its active site in a pocket at the C-terminal end of the β barrel, as in nearly all known α/β barrel enzymes. A catalytically essential zinc ion is bound in the deepest part of the active site pocket. Mutations that affect the active site of ADA selectively kill lymphocytes, causing **severe combined immunodeficiency disease (SCID)**. Without special protective measures, the disease is invariably fatal in infancy because of overwhelming infection.

Biochemical considerations provide a plausible explanation of SCID's etiology (causes). In the absence of active ADA, deoxyadenosine is phosphorylated to yield levels of dATP that are 50-fold greater than normal. This high concentration of dATP inhibits ribonucleotide reductase (Section 23-3A), thereby preventing the synthesis of the other dNTPs, choking off DNA synthesis and thus cell proliferation. The tissue-specific effect of ADA deficiency on the immune system can be explained by the observation that lymphoid tissue is particularly active in deoxyadenosine phosphorylation. ADA deficiency was one of the first genetic diseases to be successfully treated by gene therapy (Section 3-5D).

The Purine Nucleotide Cycle Generates Fumarate. The deamination of AMP to IMP, when combined with the synthesis of AMP from IMP (Fig. 23-3, left), has the net effect of deaminating aspartate to yield fumarate (Fig. 23-21). John Lowenstein demonstrated that this **purine nucleotide cycle** has an important metabolic role in skeletal muscle. An increase in muscle activity requires an increase in the activity of the citric acid cycle. This process usually occurs through the generation of additional citric acid cycle intermediates (Section 17-5B). Muscles, however, lack most of the enzymes that catalyze these anaplerotic (filling up) reactions in other tissues. Instead, muscle replenishes its citric acid cycle intermediates with fumarate generated in the purine nucleotide cycle.

The importance of the purine nucleotide cycle in muscle metabolism is indicated by the observation that the activities of the three enzymes involved are all severalfold higher in muscle than in other tissues. In fact, individuals with an inherited deficiency in muscle AMP deaminase (**myoadenylate deaminase deficiency**) are easily fatigued and usually suffer from cramps after exercise.

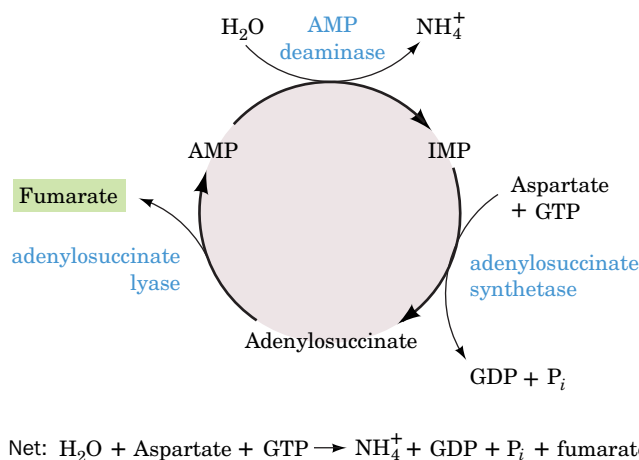

FIG. 23-21 The purine nucleotide cycle. This pathway functions in muscle to prime the citric acid cycle by generating fumarate.

? Describe the metabolic fates of the cycle products.

Xanthine Oxidase Is a Mini-Electron-Transport System. Xanthine oxidase converts hypoxanthine (the base of IMP) to xanthine, and xanthine to uric acid (Fig. 23-19, *bottom*). The reaction product is an enol (which has a pK of 5.4; hence the name *uric acid*). The enol tautomerizes to the more stable keto form:

In mammals, xanthine oxidase occurs mainly in the liver, the small intestinal mucosa, and in milk. Each subunit of this dimer of identical 1322-residue subunits contains an entire “zoo” of electron-transfer agents: an FAD, two different [2Fe–2S] clusters, and a **molybdopterin complex** (Fig. 23-22).

FIG. 23-22 X-Ray structure of bovine milk xanthine oxidase. The homodimeric protein is viewed with its twofold axis vertical. One semi-transparent subunit is light cyan and the other is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The FAD and the molybdopterin complex are drawn in stick form with C green, N blue, O red, P orange, and S yellow. The [2Fe–2S] clusters and the Mo atom are shown in space-filling form with S yellow, Fe red-brown, and Mo purple. [Based on an X-ray structure by Emil Pai, University of Toronto, Canada. PDBid 3UNC.]

The Mo atom, which reacts directly with the substrate, cycles between its Mo(VI) and Mo(IV) oxidation states. The terminal electron acceptor is O_2 , which is converted to H_2O_2 , a potentially harmful oxidizing agent (Section 18-4B) that is subsequently decomposed to H_2O and O_2 by catalase.

B Some Animals Degrade Uric Acid

In humans and other primates, the final product of purine degradation is uric acid, which is excreted in the urine. The same is true in birds, terrestrial reptiles, and many insects, but those organisms, which do not excrete urea, also catabolize their excess amino acid nitrogen to uric acid via purine biosynthesis. This complicated system of nitrogen excretion has a straightforward function: *It conserves water*. Uric acid is only sparingly soluble in water, so its excretion as a paste of uric acid crystals is accompanied by very little water. In contrast, the excretion of an equivalent amount of the much more water-soluble urea osmotically sequesters a significant amount of water.

In all other organisms, uric acid is further processed before excretion (Fig. 23-23). Mammals other than primates oxidize it to their excretory product, **allantoin**, in a reaction catalyzed by the Cu-containing enzyme **urate oxidase**. A further degradation product, **allantoic acid**, is excreted by teleost (bony) fish. Cartilaginous fish and amphibia further degrade allantoic acid to urea prior to excretion. Finally, marine invertebrates decompose urea to NH_4^+ .

 **Gout Is Caused by an Excess of Uric Acid.** **Gout** is a disease characterized by elevated levels of uric acid in body fluids. Its most common manifestation is excruciatingly painful arthritic joint inflammation of sudden onset, most often of the big toe (Fig. 23-24), caused by deposition of nearly insoluble crystals of sodium urate. Sodium urate and/or uric acid may also precipitate in the kidneys and ureters as stones, resulting in renal damage and urinary tract obstruction.

Gout, which affects ~3 per 1000 persons, predominantly males, has been traditionally, although inaccurately, associated with overindulgent eating and drinking. The probable origin of this association is that in previous centuries, when wine was often contaminated with lead during its manufacture and storage, heavy drinking resulted in chronic lead poisoning that, among other things, decreases the kidney's ability to excrete uric acid.

The most prevalent cause of gout is impaired uric acid excretion (although usually for reasons other than lead poisoning). Gout may also result from a number of metabolic insufficiencies, most of which are not well characterized. One well-understood cause is HGPRT deficiency (Lesch-Nyhan syndrome in severe cases), which leads to excessive uric acid production through PRPP accumulation (Section 23-1D).

FIG. 23-24 *The Gout*, a cartoon by James Gillray (1799).

FIG. 23-23 **Degradation of uric acid to ammonia.** The process is arrested at different stages in the indicated species, and the resulting nitrogen-containing product is excreted.

Gertrude Elion (1918–1999) Gertrude Elion's choice of career was made at age 15 when she graduated from high school in New York City. As she watched her grandfather suffer and die from stomach cancer, she decided to dedicate herself to finding a cure for cancer. When she enrolled at Hunter College the next fall, she began to study chemistry. Despite her academic accomplishments, she was unable to obtain a scholarship for graduate school and spent the next two years as a teacher and lab assistant. She eventually obtained a master of science degree in 1941.

After finding that working in an industrial chemistry laboratory bored her, Elion obtained a position with George Hitchings at the pharmaceutical company Burroughs Wellcome. There, she found an intellectually stimulating environment where she was able to expand her understanding of chemistry as well as pharmacology, immunology, and other fields. Although she ultimately received numerous honorary degrees, Elion never formally earned a doctoral degree; after several years of attending classes at night, she was forced to choose between her work with Hitchings, which she loved, and full-time study. Fortunately for science and medicine, Elion kept her job and significantly advanced the development of drugs for cancer, gout, organ transplants, and infectious diseases.

Hitchings asked Elion to investigate purine metabolism, with the idea that disrupting a cell's supply of nucleotides could interfere with its ability to synthesize DNA. Ideally, compounds that blocked DNA synthesis would disable rapidly growing cancer cells, bacteria, and viruses, without affecting normal cells. Without knowing the structures of the relevant enzymes, or even of DNA, Elion and her colleagues used a simple bacterial growth assay to investigate the ability of various purine derivatives to act as "antimetabolites."

Elion's first clinical success was **6-mercaptopurine**, which was used to treat leukemia in children. Many patients showed a dramatic recovery, but to Elion's dismay they often relapsed and later died. Their initial improvement, however, confirmed Elion's belief that interfering with nucleotide metabolism was a sound therapeutic strategy.

6-Mercaptopurine

A related compound, **azathioprine**, is converted to 6-mercaptopurine intracellularly. It turned out to be effective not as an anticancer drug but as an inhibitor of the immune response. This drug helped solve the problem of rejection in organ transplants and was used for the first successful human kidney transplant in 1961.

Azathioprine

Studies aimed at improving the effectiveness of purine derivatives by preventing their degradation by xanthine oxidase led to the discovery of allopurinol (Section 23-4B), which is still used to treat gout and some parasitic diseases. Elion also helped develop the antibacterial agent trimethoprim (Box 23-1) and the widely used antiviral drug **acyclovir** (Zovir).

Acyclovir

After Hitchings' retirement, Elion became head of the Department of Experimental Therapy in 1967. Although she formally retired in 1983, Elion's line of research continued to bear fruit with the development of azidothymidine (AZT; Box 12-3), a nucleoside analog that was the sole drug that was effective for treating AIDS until 1991 and is still in use.

Elion, together with Hitchings and James Black [who discovered cimetidine (Tagamet), the first drug to inhibit stomach acid secretion, and propranolol (Inderol), which is widely used in the treatment of high blood pressure], was awarded the Nobel Prize for Physiology or Medicine in 1988, a rare accomplishment for a scientist in the pharmaceutical industry. It was her research, which was based on an understanding of nucleotide metabolism, rather than her ability to simply synthesize novel compounds, that merited recognition.

Allopurinol

Hypoxanthine

Alloxanthine

Gout can be treated by administering the xanthine oxidase inhibitor **allopurinol** (at left), a hypoxanthine analog with interchanged N7 and C8 positions. Xanthine oxidase hydroxylates allopurinol, as it does hypoxanthine, yielding **alloxanthine** (at left), which remains tightly bound to the reduced form of the enzyme, thereby inactivating it. Allopurinol consequently alleviates the symptoms of gout by decreasing the rate of uric acid production while increasing the levels of the more soluble hypoxanthine and xanthine. Although allopurinol controls the gouty symptoms of Lesch–Nyhan syndrome, it has no effect on its neurological symptoms. Allopurinol, along with several other notable purine derivatives, was developed by the chemist Gertrude Elion (Box 23-2).

FIG. 23-25 The major pathways of pyrimidine catabolism in animals. The amino acid products of these reactions are taken up in other metabolic processes. UMP and dTMP are degraded by the same enzymes; the pathway for dTMP degradation is given in parentheses.

? Which of these reactions are similar to reactions in purine catabolism?

C Pyrimidines Are Broken Down to Malonyl-CoA and Methylmalonyl-CoA

Animal cells degrade pyrimidine nucleotides to their component bases (Fig. 23-25, top). The reactions, like those of purine nucleotides, occur through dephosphorylation, deamination, and glycosidic bond cleavages. The resulting uracil and thymine are then broken down in the liver through reduction (Fig. 23-25, middle) rather than by oxidation as occurs in purine catabolism. The end products of pyrimidine catabolism, **β -alanine** and **β -aminoisobutyrate**, are amino acids and are metabolized as such. They are converted, through transamination and activation reactions, to malonyl-CoA and methylmalonyl-CoA (Fig. 23-25, bottom left). Malonyl-CoA is a precursor of fatty acid synthesis (Fig. 20-26), and methylmalonyl-CoA is converted to the citric acid cycle intermediate succinyl-CoA (Fig. 20-16). Thus, *to a limited extent, catabolism of pyrimidine nucleotides contributes to the energy metabolism of the cell.*

CHECKPOINT

- What compounds are produced by the degradation of purines and pyrimidines?
- Describe the reactions catalyzed by nucleoside phosphorylase, adenosine deaminase, and xanthine oxidase.
- What is the function of the purine nucleotide cycle?
- What are the physiological implications of excreting waste nitrogen in the form of urate, urea, or ammonia?
- Describe how purine catabolism is related to SCID, muscle function, and gout.

Summary

1 Synthesis of Purine Ribonucleotides

- The purine nucleotide IMP is synthesized in 11 steps from ribose-5-phosphate, aspartate, fumarate, glutamine, glycine, and HCO_3^- . Purine nucleotide synthesis is regulated at its first and second steps.
- IMP is the precursor of AMP and GMP, which are phosphorylated to produce the corresponding di- and triphosphates.

2 Synthesis of Pyrimidine Ribonucleotides

- The pyrimidine nucleotide UMP is synthesized from 5-phosphoribosyl pyrophosphate, aspartate, glutamine, and HCO_3^- in six reactions. UMP is converted to UTP and CTP by phosphorylation and amination.
- Pyrimidine nucleotide synthesis is regulated in bacteria at the ATCase step and in animals at the step catalyzed by carbamoyl phosphate synthetase II.

3 Formation of Deoxyribonucleotides

- Deoxyribonucleoside diphosphates (dNDPs) are synthesized from the corresponding NDPs in a free radical-mediated oxidation reaction catalyzed by ribonucleotide reductase, which contains a binuclear Fe(III) prosthetic group, a tyrosyl radical, and three redox-active sulfhydryl

groups. Enzyme activity is regenerated through disulfide interchange with thioredoxin.

- Ribonucleotide reductase is regulated by allosteric effectors, which ensure that deoxynucleotides are synthesized in the amounts and ratios required for DNA synthesis.
- dTMP is synthesized from dUMP by thymidylate synthase. The dihydrofolate produced in the reaction is converted back to tetrahydrofolate by dihydrofolate reductase (DHFR).

4 Nucleotide Degradation

- Purine nucleotides are degraded by nucleosidases and purine nucleoside phosphorylase (PNP). Adenine nucleotides are deaminated by adenosine deaminase and AMP deaminase. The synthesis and degradation of AMP in the purine nucleotide cycle yield the citric acid cycle intermediate fumarate in muscles. Xanthine oxidase catalyzes the oxidation of hypoxanthine to xanthine and of xanthine to uric acid.
- In primates, birds, reptiles, and insects, the final product of purine degradation is uric acid, which is excreted. Other organisms degrade urate further.
- Pyrimidines are broken down to intermediates of fatty acid metabolism.

Problems

EXERCISES

1. Which reaction of the $\text{IMP} \rightarrow \text{AMP}$ pathway resembles a reaction of the urea cycle?
2. From which purine is caffeine derived?

Caffeine

3. How does 2-azahypoxanthine, a fungal product that stimulates plant growth, differ from guanine?

2-Azahypoxanthine

4. When starved, bacteria produce the intracellular signaling molecule ppGpp (guanosine-3',5'-bisdiphosphate). Draw its structure.

5. List all the enzymes of nucleotide biosynthesis that use glutamine as an amino group donor.

6. Certain glutamine analogs irreversibly inactivate enzymes that bind glutamine. Identify the nucleotide biosynthetic intermediates that accumulate in the presence of those compounds.

7. Calculate the cost, in ATP equivalents, of synthesizing *de novo* (a) IMP, (b) AMP, and (c) CTP. Assume all substrates (e.g., ribose-5-phosphate and glutamine) and cofactors are available.

8. The compound shown here is being tested as an anticancer agent. (a) Explain why it inhibits CTP production. (b) Explain why it also inhibits phospholipid synthesis.

9. Explain why hydroxyurea, which destroys tyrosyl radicals, is useful as an antitumor agent.

Hydroxyurea

10. Why is dATP toxic to mammalian cells?

11. The purine and pyrimidine rings are built from the amino acids aspartate, glutamine, and glycine. Why is serine required for the synthesis of deoxyribonucleotides?

12. Why do individuals who are undergoing chemotherapy with FdUMP or methotrexate often temporarily go bald?

13. Explain why methotrexate inhibits the synthesis of histidine and methionine.

14. Some microorganisms lack DHFR activity, but their thymidylate synthase has an FAD cofactor. What is the function of the FAD?

15. Is trimethoprim a mechanism-based inhibitor of bacterial dihydrofolate reductase?

16. *p*-Aminosalicylate is used to treat infections with *Mycobacterium tuberculosis*. Explain how this compound blocks the production of thymidylate.

***p*-Aminosalicylate**

17. Is allopurinol a mechanism-based inhibitor of xanthine oxidase?

18. Describe how the fumarate produced by the purine nucleotide cycle could be catabolized to CO₂.

19. Individuals with a complete deficiency of dihydropyrimidine dehydrogenase exhibit a variety of symptoms. What compounds are likely to be present at high levels in the urine of these patients?

20. Individuals with a partial deficiency of dihydropyrimidine dehydrogenase experience severe toxic effects when given high doses of the anticancer drug 5-fluorouracil. Explain.

21. In animals, one pathway for NAD⁺ synthesis begins with nicotinamide. Draw the structures generated by the reactions shown.

Nicotinamide

22. A nucleotide derivative that may have intracellular signaling activity is synthesized from NAD⁺ by the removal of the nicotinamide group and addition of an acetyl group at the 2' position of the ribose attached to ADP. Draw its structure.

23. In the synthesis of FAD, riboflavin is phosphorylated by a kinase to form FMN (Fig. 18-10). The FMN then reacts with ATP. How many "high-energy" bonds are broken in this process?

24. Calculate the ATP yield of converting the carbons of thymine to CO₂.

CHALLENGE QUESTIONS

25. Why does it make metabolic sense for UTP to inhibit carbamoyl phosphate synthetase II, whereas ATP activates the enzyme?

26. Why does it make metabolic sense for ADP and GDP to inhibit ribose phosphate pyrophosphokinase?

27. Mouse embryonic stem cells divide extremely rapidly, about once every 5 hours. These cells require large amounts of threonine in their medium. Explain how threonine catabolism (Fig. 21-14) helps meet the cells' energy needs and their high rate of DNA synthesis.

28. Normal cells die in a nutrient medium containing thymidine and methotrexate, whereas mutant cells defective in thymidylate synthase survive and grow. Explain.

29. Why is it important that muscle cells have low levels of glutamate dehydrogenase?

30. Why does von Gierke's glycogen storage disease (Box 16-2) cause symptoms of gout?

31. Why is gout more prevalent in populations that eat relatively large amounts of meat?

32. Gout resulting from the *de novo* overproduction of purines can be distinguished from gout caused by impaired excretion of uric acid by feeding a patient ¹⁵N-labeled glycine and determining the distribution of ¹⁵N in his or her excreted uric acid. What isotopic distributions are expected for each type of defect?

33. Rats are given cytidine that is ¹⁴C-labeled at both its base and ribose components. Their DNA is then extracted and degraded with nucleases. Describe the labeling pattern of the recovered deoxycytidylate residues if deoxycytidylate production in the cell followed a pathway in which (a) intact CDP is reduced to dCDP, and (b) CDP is broken down to cytosine and ribose before reduction.

34. **6-Mercaptopurine** (Box 23-2), after its conversion to the corresponding nucleotide through salvage reactions, is a potent competitive inhibitor of IMP in the pathways for AMP and GMP biosynthesis. It is therefore a clinically useful anticancer agent. The chemotherapeutic effectiveness of 6-mercaptopurine is enhanced when it is administered with allopurinol. Explain the mechanism of this enhancement.

BIOINFORMATICS

Exercise 1 Viewing and Analyzing Thymidylate Synthase

Exercise 2 Nucleotide Metabolism and the KEGG Database

MORE TO EXPLORE One long-standing shortcoming of the RNA world hypothesis (Section 3-2C) is the lack of a plausible explanation for the origin of ribonucleotides. Although a molecule such as UMP has a modular structure (base + ribose + phosphate), why is it unlikely that these components spontaneously assembled to form the first nucleotides? Why is it more likely that such compounds arose from the combination of two molecules that were half-base, half-ribose?

Nucleic Acid Structure

Chapter Contents

1 The DNA Helix

- A DNA Can Adopt Different Conformations
- B DNA Has Limited Flexibility
- C DNA Can Be Supercoiled
- D Topoisomerases Alter DNA Supercoiling

2 Forces Stabilizing Nucleic Acid Structures

- A Nucleic Acids Are Stabilized by Base Pairing, Stacking, and Ionic Interactions
- B DNA Can Undergo Denaturation and Renaturation
- C RNA Structures Are Highly Variable

3 Fractionation of Nucleic Acids

- A Nucleic Acids Can Be Purified by Chromatography
- B Electrophoresis Separates Nucleic Acids by Size

4 DNA-Protein Interactions

- A Restriction Endonucleases Distort DNA on Binding
- B Prokaryotic Repressors Often Include a DNA-Binding Helix
- C Eukaryotic Transcription Factors May Include Zinc Fingers or Leucine Zippers

5 Eukaryotic Chromosome Structure

- A DNA Coils around Histones to Form Nucleosomes
- B Chromatin Forms Higher-Order Structures

From Kleinschmidt, A.K., Lang, D., Jacherts, D., and Zahn, R.K., *Biochimica et Biophysica Acta*, **61**, 861 (1962). Reproduced with permission from Elsevier.

DNA molecules, such as that spilling out of the osmotically lysed bacteriophage T2 shown here, are enormous. A cell must be able to efficiently package and safely store its DNA. However, despite DNA's highly condensed structure, a cell must be able to read and interpret the meaning of the encoded genetic information.

In every organism, the ultimate source of biological information is nucleic acid. The shapes and activities of individual cells are, to a large extent, determined by genetic instructions contained in DNA (or RNA, in some viruses). According to the central dogma of molecular biology (Section 3-3B), sequences of nucleotide bases in DNA encode the amino acid sequences of proteins. Many of the cell's proteins are enzymes that carry out the metabolic processes we have discussed in Chapters 15–23. Other proteins have a structural or regulatory role or participate in maintaining and transmitting genetic information.

Two kinds of nucleic acids, DNA and RNA, store information and make it available to the cell. The structures of these molecules are consistent with the following:

1. Genetic information must be stored in a form that is manageable in size and stable over a long period.

2. Genetic information must be decoded—often many times—in order to be used. **Transcription** is the process by which nucleotide sequences in DNA are copied onto RNA so that they can direct protein synthesis, a process known as **translation**.
3. Information contained in DNA or RNA must be accessible to proteins and other nucleic acids. These agents must recognize nucleic acids (in many cases, in a sequence-specific fashion) and bind to them in a way that alters their function.
4. The progeny of an organism must be equipped with the same set of instructions as in the parent. Thus, DNA is **replicated** (an exact copy made) so that each daughter cell receives the same information.

As we will see, many cellular components are required to execute all the functions of nucleic acids. Yet nucleic acids are hardly inert “read-only” entities. RNA in particular, owing to its single-stranded nature, is a dynamic molecule that provides structural scaffolding as well as catalytic proficiency in a number of processes that decode genetic information. In this chapter, we focus on the structural properties of nucleic acids, including their interactions with proteins that allow them to carry out their duties. In subsequent chapters, we will examine the processes of replication (Chapter 25), transcription (Chapter 26), and translation (Chapter 27).

1 The DNA Helix

KEY CONCEPTS

- A DNA helix can have the A, B, or Z conformation.
- The conformational freedom of the glycosidic bond, the ribose ring, and the sugar–phosphate backbone is limited.
- Supercoiled DNA can be described in terms of linking number, twist, and writhing number.
- Topoisomerases cut one (type I) or both (type II) strands of DNA to add or remove supercoils.

We begin our discussion of nucleic acid structure by examining the various forms of DNA, with an eye toward understanding how the molecule safeguards genetic information while leaving it accessible for replication and transcription.

A DNA Can Adopt Different Conformations

DNA is a two-stranded polymer of deoxynucleotides linked by phosphodiester bonds (Figs. 3-3 and 3-6). The biologically most common form of DNA is known as **B-DNA**, which has the structural features first noted by James Watson and Francis Crick, together with Rosalind Franklin and others (Section 3-2B and Box 24-1):

1. The two antiparallel polynucleotide strands wind in a right-handed manner around a common axis to produce an $\sim 20\text{-\AA}$ -diameter double helix.
2. The planes of the nucleotide bases, which form hydrogen-bonded pairs, are nearly perpendicular to the helix axis. In B-DNA, the bases occupy the core of the helix while the sugar–phosphate backbones wind around the outside, forming the major and minor grooves. Only the edges of the base pairs are exposed to solvent.

Rosalind Franklin (1920–1958) James Watson and Francis Crick were the first to publish an accurate model of the structure of DNA. This seminal discovery was not only based on their own insights but, like all scientific discoveries, was also built on the work of others. One of the major contributors to this process was Rosalind Franklin, who was probably never fully aware of her role in this discovery and did not share the 1962

Nobel Prize in Physiology or Medicine awarded to Watson, Crick, and Maurice Wilkins.

Franklin was born in England in an intellectually oriented and well-to-do family. She excelled in mathematics, and although career opportunities for women with her talents were few, she obtained a doctorate in physical chemistry at the University of Cambridge in 1945. From 1947 to 1950 she worked in a French government laboratory, where she became an authority in applying X-ray diffraction techniques to imperfectly crystalline substances such as coal; her numerous publications on the structures of coal and other forms of carbon changed the way that these substances were viewed.

In 1951, she returned to England at the invitation of John Randall, the head of the Medical Research Council's (MRC's) Biophysics Research Unit at King's College London, to investigate the structure of DNA. Randall had indicated to Franklin that she would be given an independent position, whereas Wilkins, who had been working on DNA at King's for some time, was given the impression that Franklin would be working under his direction. That misunderstanding, together with their sharply contrasting personalities (Franklin was quick, assertive, and confrontational, whereas Wilkins was deliberate, shy, and indirect), led to a falling out between the two such that they were barely on speaking terms. Hence, they worked independently. Some popular accounts of Franklin's life and work have implied that the atmosphere at King's College was inhospitable to women, but Franklin's correspondence, as well as firsthand accounts, indicate that the atmosphere was in fact congenial. Still, she was unhappy at King's, apparently for personal reasons, and in the spring of 1953, departed for Birkbeck College in London. There, until her untimely death from ovarian cancer in 1958, she carried out groundbreaking investigations on the structures of viruses.

Early in her tenure at King's, Franklin discovered, through the analysis of X-ray fiber diffraction patterns, that DNA (which she obtained from Wilkins, who had gotten it from Rudolf Signer in Switzerland) exists in two distinct conformations, which she called the A and B forms. Prior to this discovery, the X-ray diffraction patterns of DNA that had been obtained were confusing because they were of mixtures of the A and B forms. Through careful control of the humidity, Franklin obtained an X-ray fiber diffraction photograph of B-DNA of unprecedented clarity (Fig. 3-5) that strikingly indicated the DNA's helical character. Analysis of the photograph (using the theory of how helical molecules diffract X-rays that Crick, an X-ray crystallographer by training, had previously participated in formulating) permitted Franklin to determine that B-DNA is double helical, it has a diameter of 20 Å, and each turn of the helix is 34 Å long and contains 10 base pairs, each separated by 3.4 Å. Further analysis suggested that the hydrophilic sugar–phosphate chains were on the outside of the helix

and the relatively hydrophobic bases were on the inside. However, although Franklin was aware of Chargaff's rules (Section 3-2A) and Jerry Donohue's work concerning the tautomeric forms of the bases (Section 3-2B), she did not deduce the existence of base pairs in double-stranded DNA.

In January 1953, Wilkins showed Franklin's X-ray photograph of B-DNA to Watson, when he visited King's College. Moreover, in February 1953, Max Perutz (Box 7-2), Crick's thesis advisor at Cambridge University, showed Watson and Crick his copy of the 1952 Report of the MRC, which summarized the work of all of its principal investigators, including that of Franklin. Within a week (and after 13 months of inactivity on the project), Watson and Crick began building a model of DNA with a backbone structure compatible with Franklin's data [in earlier modeling attempts, they had placed the bases on the outside of the helix (as did a model published by Linus Pauling; Box 6-1) because they assumed that the bases could transmit genetic information only if they were externally accessible]. On several occasions Crick acknowledged that Franklin's findings were crucial to this enterprise.

Watson and Crick published their model of B-DNA in *Nature* in April 1953. The paper was followed, back-to-back, by papers by Wilkins and by Franklin on their structural studies of DNA.

Franklin's manuscript had been written in March 1953, before she knew about Watson and Crick's work. The only change that Franklin made to her manuscript when she became aware of Watson and Crick's model was the addition of a single sentence, "Thus our general ideas are not inconsistent with the model proposed by Watson and Crick in the preceding communication." She was apparently unaware that the Watson–Crick model was, to a significant extent, based on her work. Since Watson and Crick did not acknowledge Franklin in their 1953 *Nature* paper, her paper was widely taken as data that supported the Watson–Crick model rather than being an important element in its formulation. Only after her death did Watson and Crick indicate the crucial role of Franklin's contributions.

Interestingly, Watson, Crick, and Franklin developed a close friendship. Starting in 1954, they maintained a correspondence and commented on each other's work. In the summer of 1954, Watson offered to drive Franklin across the United States from Woods Hole, Massachusetts, to her destination at Caltech, where he was also going. In the spring of 1956, she toured Spain with Crick and his wife Odile and, later, stayed with them at their house in Cambridge when she was recovering from her treatments for ovarian cancer.

If Watson and Crick had not formulated their model of B-DNA, would Franklin, who had a distaste for speculative modeling, have eventually done so? We, of course, will never know. And, had she lived, would Franklin have received the Nobel prize together with Watson, Crick, and Wilkins? (The prize cannot be awarded posthumously.) Those who argue that she was an indispensable participant in the discovery process would say yes. However, the Nobel committee typically awards those who initiate the research (i.e., Wilkins), and the prize cannot be shared by more than three individuals.

Franklin, R.E. and Gosling, R.G., Molecular configuration in sodium thymonucleate, *Nature* **171**, 740–741 (1953).

FIG. 24-1 The Watson-Crick base pairs. The line joining the C1' atoms is the same length in both A · T and G · C base pairs and makes equal angles with the glycosidic bonds to the bases. This gives DNA a series of pseudo-twofold symmetry axes that pass through the center of each base pair (red line) and are perpendicular to the helix axis. [After Arnott, S., Dover, S.D., and Wonacott, A.J., *Acta Cryst.* **B25**, 2196 (1969).]

? Explain why the consistent size of base pairs would simplify the task of storing large amounts of DNA in a cell's nucleus.

- Each base pair has approximately the same width (Fig. 24-1), which accounts for the near-perfect symmetry of the DNA molecule, regardless of base composition. A · T and G · C base pairs are interchangeable: *They can replace each other in the double helix without altering the positions of the sugar-phosphate backbones' C1' atoms.* Likewise, the partners of a Watson-Crick base pair can be switched (i.e., by changing a G · C to a C · G or an A · T to a T · A). In contrast, any other combination of bases would significantly distort the double helix.
- The canonical (ideal) B-DNA helix has 10 base pairs (bp) per turn (a helical twist of 36° per bp) and, since the aromatic bases have van der Waals thicknesses of 3.4 \AA and are partially stacked on each other, the helix has a pitch (rise per turn) of 34 \AA .

Double-helical DNA can assume several distinct structures depending on the solvent composition and base sequence. The major structural variants of DNA are **A-DNA** and **Z-DNA**. The geometries of the molecules are summarized in **Table 24-1** and **Fig. 24-2**.

A-DNA's Base Pairs Are Inclined to the Helix Axis. Under dehydrating conditions, B-DNA undergoes a reversible conformational change to A-DNA, which forms a wider and flatter right-handed helix than does B-DNA. A-DNA

TABLE 24-1 Structural Features of Ideal A-, B-, and Z-DNA

	A	B	Z
Helical sense	Right handed	Right handed	Left handed
Diameter	~26 Å	~20 Å	~18 Å
Base pairs per helical turn	11.6	10	12 (6 dimers)
Helical twist per base pair	31°	36°	9° for pyrimidine–purine steps; 51° for purine–pyrimidine steps
Helix pitch (rise per turn)	34 Å	34 Å	44 Å
Helix rise per base pair	2.9 Å	3.4 Å	7.4 Å per dimer
Base tilt normal to the helix axis	20°	6°	7°
Major groove	Narrow and deep	Wide and deep	Flat
Minor groove	Wide and shallow	Narrow and deep	Narrow and deep
Sugar pucker	C3'-endo	C2'-endo	C2'-endo for pyrimidines; C3'-endo for purines
Glycosidic bond conformation	Anti	Anti	Anti for pyrimidines; syn for purines

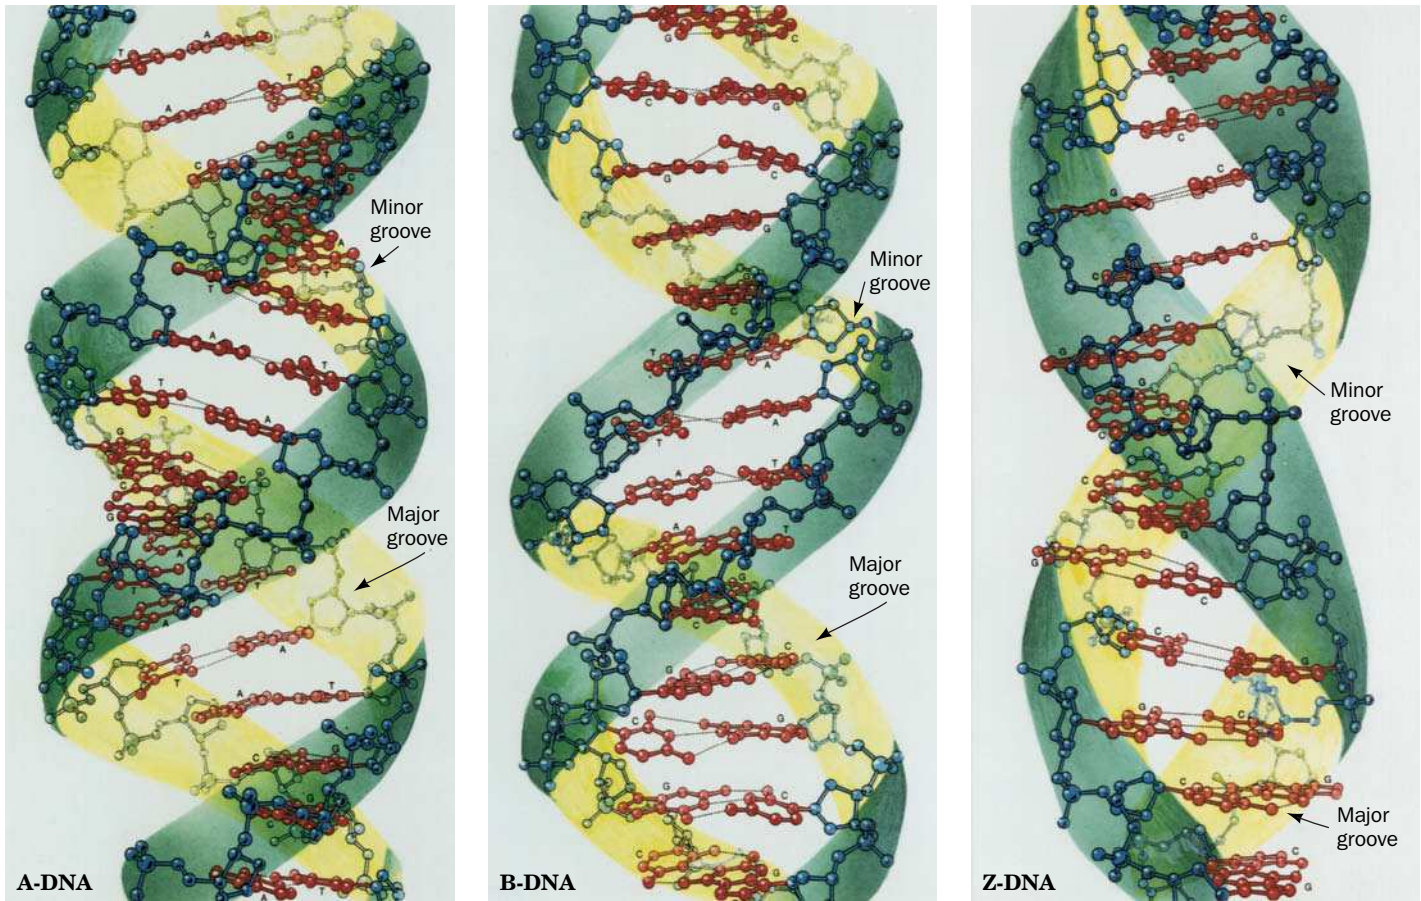

Source: Mainly Arnott, S., in Neidle, S. (Ed.), *Oxford Handbook of Nucleic Structure*, p. 35, Oxford University Press (1999).

has 11.6 bp per turn and a pitch of 34 Å, which gives it an axial hole (Fig. 24-2c, left). A-DNA's most striking feature, however, is that the planes of its base pairs are tilted 20° with respect to the helix axis. Since the axis does not pass through its base pairs, A-DNA has a deep major groove and a very shallow minor groove; it can be described as a flat ribbon wound around a 6-Å-diameter cylindrical hole. A short segment of A-DNA occurs in the active site of DNA polymerase during the replication of DNA (Section 25-2A).

Z-DNA Forms a Left-Handed Helix. Occasionally, a seemingly familiar system exhibits quite unexpected properties. Over 25 years after the discovery of the Watson–Crick DNA structure, the crystal structure determination of d(CGCGCG) by Andrew Wang and Alexander Rich revealed, quite surprisingly, that this self-complementary sequence formed a left-handed double helix. This helix, which was dubbed Z-DNA, has 12 Watson–Crick base pairs per turn, a pitch of 44 Å, a deep minor groove, and no discernible major groove. Z-DNA therefore resembles a left-handed drill bit in appearance (Fig. 24-2, right).

Fiber diffraction and NMR studies have shown that complementary polynucleotides with alternating purines and pyrimidines, such as poly d(GC) · poly d(GC) or poly d(AC) · poly d(GT), assume the Z conformation at high salt concentrations. The salt stabilizes Z-DNA relative to B-DNA by reducing the electrostatic repulsions between closest approaching phosphate groups on opposite strands (which are 8 Å apart in Z-DNA and 12 Å apart in B-DNA).

Does Z-DNA have a biological function? The discovery of Z-DNA-binding proteins strongly suggests that Z-DNA does exist *in vivo*. Rich has determined the X-ray structure of a Z-DNA-binding domain named **Zα** in complex with DNA. One Zα domain binds to each strand of Z-DNA via hydrogen bonds and ionic interactions between polar and basic side chains and the sugar-phosphate backbone of the DNA; none of the DNA's bases participate in these associations (Fig. 24-3). The protein's DNA-binding surface is complementary in shape to the Z-DNA and is positively charged, as is expected for a protein that interacts with closely spaced anionic phosphate groups. Sequences capable of forming Z-DNA frequently occur near the start of genes, and the reversible conversion of B-DNA to Z-DNA at these sites may play a role in the control of transcription.

(a)

FIG. 24-2 Structures of A-, B-, and Z-DNA. (a) View perpendicular to the helix axis. The sugar–phosphate backbones, which wind about the periphery of each molecule, are outlined by a green ribbon and the bases, which occupy its core, are red. Note that the two sugar–phosphate chains in each helix run in opposite directions so as to form right-handed double helices in A- and B-DNAs and a left-handed double helix in Z-DNA. (b) Space-filling models colored according to atom type with C white, N blue, O red, and P orange. H atoms have been omitted for clarity. (c) View along the helix axis. The ribose ring O atoms are red and the nucleotide pair nearest the viewer is white. Note that the helix axis passes far “above” the major groove of A-DNA, through the base pairs of B-DNA, and through the edge of the minor groove of Z-DNA. Consequently, A-DNA has a hollow core whereas B- and Z-DNAs have

solid cores. Also note that the deoxyribose residues in A- and B-DNAs have the same conformation in each helix, but those in Z-DNA have two different conformations so that alternate ribose residues lie at different radii. [Based on structures by Olga Kennard, Dov Rabinovitch, Zippora Shakked, and Mysore Viswamitra, Cambridge University, U.K., Nucleic Acid Database ID ADH010 (A-DNA); Richard Dickerson and Horace Drew, Caltech, PDBid 1BNA (B-DNA); and Andrew Wang and Alexander Rich, MIT, PDBid 2DCG (Z-DNA). Model coordinates for Part b generated by Helen Berman, Rutgers University.]

? Would a protein that binds to a segment of B-DNA be able to bind to A-DNA or Z-DNA?

RNA Can Form an A Helix. Double-stranded RNA is the genetic material of certain viruses, but it is synthesized only as a single strand. Nevertheless, single-stranded RNA can fold back on itself so that complementary sequences base-pair to form double-stranded stems with single-stranded loops (Fig. 3-9). Moreover, short segments of double-stranded RNA have been implicated in the control of gene expression (Section 28-3C). Double-stranded RNA is unable to assume a B-DNA-like conformation because of steric clashes involving its 2'-OH groups. Rather, it usually assumes a conformation resembling A-DNA (Fig. 24-2) that ideally has 11.0 bp per helical turn, a pitch of 30.9 Å, and base pairs that, on average, are inclined to the helix axis by 16.7°.

FIG. 24-2 Continued

FIG. 24-3 X-Ray structure of Z α in complex with Z-DNA. The DNA sequence d(CGCGCG) is shown in stick form with its backbone red and its base pairs pink. The Z α domains are drawn with α helices blue and β sheets light green. Note that each Z α domain contacts only one strand of Z-DNA and that none of the bases of the Z-DNA interact directly with the protein. PBDId 1QBJ.

FIG. 24-4 X-Ray structure of a 10-bp RNA–DNA hybrid helix. The complex consists of the RNA UUCGGGCGCC that is base paired to its DNA complement. The structure is shown in stick form with RNA C atoms cyan, DNA C atoms green, N blue, O red except for RNA O2' atoms, which are magenta, and P gold. [Based on an X-ray structure by Nancy Horton and Barry Finzel, Pharmacia & Upjohn, Inc., Kalamazoo, Michigan. PDBid 1FIX.]

Hybrid double helices, which consist of one strand each of RNA and DNA, also have an A-DNA-like conformation (Fig. 24-4), although hybrid helices also have B-DNA-like qualities in that their overall conformation is intermediate to those of A-DNA and B-DNA. Short stretches of RNA–DNA hybrid helices occur during the initiation of DNA replication by small segments of RNA (Section 25-1) and during the transcription of RNA on DNA templates (Section 26-1C).

B DNA Has Limited Flexibility

The structurally distinct A, B, and Z forms of DNA are not thought to freely interconvert *in vivo*. Rather, the transition from one form to another requires unusual physical conditions (e.g., dehydration) or the influence of DNA-binding proteins. In addition, real DNA molecules deviate from the ideal structures described in the preceding section. X-Ray structures of B-DNA segments reveal that *individual residues significantly depart from the average conformation in a sequence-dependent manner*. For example, the helical twist per base pair may range from 26° to 43°. Each base pair can also deviate from its ideal conformation by rolling or twisting like the blade of a propeller. Such conformational variation appears to be important for the sequence-specific recognition of DNA by the proteins that process genetic information.

B-DNA molecules, which are 20 Å thick and many times as long, are not perfectly rigid rods. In fact, it is imperative that the molecules be somewhat flexible so that they can be packaged in cells. DNA helices can adopt different degrees of curvature ranging from gentle arcs to sharp bends. The more severe distortions from linearity generally occur in response to the binding of specific proteins.

Bond Rotation Is Hindered. The conformation of a nucleotide unit, as Fig. 24-5 indicates, is specified by the six torsion angles of the sugar–phosphate backbone and the torsion angle describing the orientation of the base around the glycosidic bond (the bond joining C1' to the base). It would seem that these seven degrees of freedom per nucleotide would render polynucleotides highly flexible. Yet these torsion angles are subject to a variety of internal constraints that greatly restrict their rotational freedom.

The rotation of a base around its glycosidic bond (angle χ) is greatly hindered. Purine residues have two sterically permissible orientations known as the

FIG. 24-5 The seven torsion angles that determine the conformation of a nucleotide unit.

? Identify bonds in the structure in Fig. 24-4 that correspond to the seven torsion angles.

FIG. 24-6 The sterically allowed orientations of purine and pyrimidine bases with respect to their attached ribose units. In B-DNA, the nucleotide residues all have the anti conformation.

syn (Greek: with) and **anti** (Greek: against) conformations (Fig. 24-6). Only the anti conformation of pyrimidines is stable, because, in the syn conformation, the sugar residue sterically interferes with the pyrimidine's C2 substituent. In most double-helical nucleic acids, all bases are in the anti conformation. The exception is Z-DNA (Section 24-1A), in which the alternating pyrimidine and purine residues are anti and syn, respectively (this is one reason why the repeating unit of Z-DNA is a dinucleotide).

The flexibility of the ribose ring itself is also limited. The vertex angles of a regular pentagon are 108° , a value quite close to the tetrahedral angle (109.5°), so one might expect the ribofuranose ring to be nearly flat. However, the ring substituents are eclipsed when the ring is planar. To relieve this crowding, which occurs even between hydrogen atoms, the ring puckers; that is, it becomes slightly nonplanar. In the great majority of known nucleoside and nucleotide X-ray structures, four of the ring atoms are coplanar to within a few hundredths of an angstrom and the remaining atom is out of the plane by several tenths of an angstrom. The out-of-plane atom is almost always C2' or C3' (Fig. 24-7). The two most common ribose conformations are known as **C3'-endo** and **C2'-endo**; "endo" (Greek: *endon*, within) indicates that the displaced atom is on the same side of the ring as C5', whereas "exo" (Greek: *exo*, out of) indicates displacement toward the opposite side of the ring from C5'.

The ribose pucker is conformationally important in nucleic acids because it governs the relative orientations of the phosphate substituents to each ribose residue. In fact, B-DNA has the C2'-endo conformation, whereas A-DNA is

FIG. 24-7 Nucleotide sugar conformations. (a) The C3'-endo conformation (C3' is displaced to the same side of the ring as C5'), which occurs in A-DNA. (b) The C2'-endo conformation, which occurs

in B-DNA. The distances between adjacent P atoms in the sugar-phosphate backbone are indicated. [After Saenger, W., *Principles of Nucleic Acid Structure*, p. 237, Springer-Verlag (1983).]

C3'-endo. In Z-DNA, the purine nucleotides are all *C3'-endo* and the pyrimidine nucleotides are *C2'-endo*.

The Sugar–Phosphate Backbone Is Conformationally Constrained. Finally, if the torsion angles of the sugar–phosphate chain (angles α to ζ in Fig. 24-5) were completely free to rotate, there could probably be no stable nucleic acid structure. However, these angles are actually quite restricted. This is because of noncovalent interactions between the ribose ring and the phosphate groups and, in polynucleotides, steric interference between residues. The overall result is that *the sugar–phosphate chains of the double helix are stiff, although the sugar–phosphate conformational angles are reasonably strain-free.*

C DNA Can Be Supercoiled

The chromosomes of many viruses and bacteria are circular molecules of duplex DNA. In electron micrographs (e.g., Fig. 24-8), some of the molecules have a peculiar twisted appearance, a phenomenon known as **supercoiling** or **superhelicity**. Supercoiled DNA molecules are more compact than “relaxed” molecules with the same number of nucleotides. This has important consequences for packaging DNA in cells (Section 24-5) and for the unwinding events that occur as part of DNA replication and RNA transcription.

Superhelix Topology Can Be Simply Described. Consider a double-helical DNA molecule in which each of its polynucleotide strands forms a covalently closed circle, thus forming a circular duplex molecule (because duplex DNA’s two strands are antiparallel, each strand must close on itself). A geometric property of such an assembly is that *its number of coils cannot be altered without first cleaving at least one of its strands*. You can easily demonstrate this with a buckled belt in which each edge of the belt represents a strand of DNA. The number of times the belt is twisted before it is buckled cannot be changed without first unbuckling the belt (cutting a polynucleotide strand).

The phenomenon is mathematically expressed as

$$L = T + W \quad [24-1]$$

in which:

1. **L** , the **linking number**, is the number of times that one DNA strand winds around the other. This integer quantity is most easily counted when the duplex axis of the DNA is made to lie flat on a plane. The linking number cannot be changed by twisting or distorting the molecule, as long as both its polynucleotide strands remain covalently intact.

FIG. 24-8 Electron micrographs of circular duplex DNAs. Their conformations vary from no supercoiling (*left*) to tightly supercoiled (*right*).

- T , the twist**, is the number of complete revolutions that one polynucleotide strand makes around the duplex axis. By convention, T is positive for right-handed duplex turns so that, for B-DNA, the twist is normally the number of base pairs divided by 10.5 (the observed number of base pairs per turn of the B-DNA double helix in aqueous solution).
- W , the writhing number**, is the number of turns that the duplex axis makes around the superhelix axis. *It is a measure of the DNA's superhelicity.* The difference between writhing and twisting is illustrated in **Fig. 24-9**. When a circular DNA is constrained to lie in a plane, $W = 0$.

The two DNA conformations diagrammed on the right of **Fig. 24-10** are topologically equivalent; that is, they have the same linking number, L , but differ in their twists and writhing numbers (topology is the study of the geometric properties of objects that are unaltered by deformation but not by cutting). Note that the two strands, of a circular duplex DNA, although not covalently linked, cannot be separated without breaking a covalent bond; that is, they are **topologically linked**.

Since L is a constant in an intact duplex DNA circle (it is topologically invariant), for every new double-helical twist, ΔT , there must be an equal and opposite superhelical twist; that is, $\Delta W = -\Delta T$ (T and W , which need not be integers, are not topologically invariant). For example, a closed circular DNA without supercoils (**Fig. 24-10, upper right**) can be converted to a negatively supercoiled conformation (**Fig. 24-10, lower right**) by winding the duplex helix the same number of positive (right-handed) turns.

Supercoiled DNA Is Relaxed by Nicking One Strand. Supercoiled DNA may be converted to **relaxed circles** (as appears in the leftmost panel of **Fig. 24-8**) by treatment with **pancreatic DNase I**, an **endonuclease** (an enzyme that cleaves phosphodiester bonds within a polynucleotide strand), which cleaves only one strand of a duplex DNA. *One single-strand nick is sufficient to relax a supercoiled DNA.* This is because the sugar-phosphate chain opposite the nick is free to swivel about its backbone bonds (**Fig. 24-5**) so as to change the molecule's linking number and thereby alter its superhelicity. Supercoiling builds up elastic strain in a DNA circle (it resists any deviation from its preferred twist of 1 turn/10.5 bp), much as it does in a rubber band. This is why the relaxed state of a DNA circle is not supercoiled.

Naturally Occurring DNA Circles Are Underwound. The linking numbers of natural DNA circles are less than those of their corresponding relaxed circles; that is, they are underwound. However, because DNA tends to adopt an overall

FIG. 24-9 The difference between writhing and twist as demonstrated by a coiled spring or telephone cord. In its relaxed state (*left*), the spring or cord is in a helical form that has a large writhing number and a small twist. As the coil is pulled out (*center*) until it is nearly straight (*right*), its writhing number becomes small and its twist becomes large.

FIG. 24-10 Two ways of introducing one supercoil into a DNA that has 10 duplex turns. The two closed circular forms shown (*right*) are topologically equivalent; that is, they are interconvertible without breaking any covalent bonds. The linking number L , twist T , and writhing number W are indicated for each form. Strictly speaking, the linking number is defined only for a covalently closed circle.

FIG. 24-11 Progressive unwinding of a negatively supercoiled DNA molecule. (a) As the double helix in a negatively supercoiled circle ($W < 0$) is unwound without breaking covalent bonds (T decreases), W increases until it reaches 0. Further unwinding of the double helix then causes the DNA to supercoil in the opposite direction, yielding a positively coiled superhelix ($W > 0$). (b) Gel electrophoresis patterns of the 5243-bp covalently closed circular DNA from **simian virus 40 (SV40)**. Lane 1 contains the negatively supercoiled native DNA (*lower band*; the DNA was applied to the top of the gel). In lanes 2 and 3, the DNA was treated for 5 and 30 minutes, respectively, with a type I topoisomerase, an enzyme that relaxes negative supercoils one at a time (see below), thereby progressively reducing the DNA's degree of supercoiling [incrementally increasing the DNA's linking number (L) and hence increasing its writhing number (W) because its twist (T) remains essentially unchanged]. The **topoisomers** (molecules that differ only in their topologies) in consecutively higher bands of a given lane therefore differ by $\Delta L = +1$. [Part b from Keller, W., *Proc. Natl. Acad. Sci.* **72**, 2550 (1975).]

conformation that maintains its preferred twist of 1 turn/10.5 bp, the molecule is negatively supercoiled ($W < 0$; Fig. 24-11a, left). If the duplex is unwound (if T decreases), then W increases (L must remain constant). At first, this reduces the superhelicity of an underwound circle. However, with continued unwinding, the value of W passes through zero (a relaxed circle; Fig. 24-11a, center) and then becomes positive, yielding a positively coiled superhelix (Fig. 24-11a, right). Since, as can be seen in Figs. 24-8 and 24-11a, the compactness of a circular duplex DNA increases with its degree of supercoiling (its absolute value of W), its electrophoretic mobility also does so (Fig. 24-11b). Note that supercoiling also occurs in linear segments of duplex DNA whose ends are, in effect, joined in a circle or held in fixed orientations through their associations with proteins.

D Topoisomerases Alter DNA Supercoiling

DNA functions normally only if it is in the proper topological state. In such basic biological processes as replication and transcription, complementary polynucleotide strands must separate. The negative supercoiling of naturally occurring DNAs in both prokaryotes and eukaryotes promotes such separations since it tends to unwind the duplex helix (an increase in W must be accompanied by a decrease in T). *If DNA lacks the proper superhelical tension, the above vital processes cannot occur.* Indeed, the need to replicate and transcribe DNA presents what appears to be an insurmountable problem: The separation of DNA's two strands, it would seem, necessitates that they unwind from one another by enormous numbers of turns (~12 million in an average human chromosome). How is this possible within the narrow confines of a bacterial cell or a eukaryotic nucleus and how can it happen at all with circular DNAs? The discovery, in 1971 by James Wang, of a remarkable enzyme now known as a **topoisomerase** eliminated this conundrum. Topoisomerases, which control the level of supercoiling in DNA, are so named because they alter DNA's topological state (linking number) but not its covalent structure.

Prokaryotes and eukaryotes both express two classes of topoisomerases:

1. **Type I topoisomerases** act by creating transient single-strand breaks in DNA. Type I enzymes are further classified as **type IA** and **type IB topoisomerases**, which differ in sequence and reaction mechanism.
2. **Type II topoisomerases** act by making transient double-strand breaks in DNA.

Type IA Topoisomerases Relax Negatively Supercoiled DNA. *Type I topoisomerases catalyze the relaxation of supercoiled DNA by changing the linking number in increments of one.* Type IA enzymes, which are present in all cells, relax only negatively supercoiled DNA. A clue to the mechanism of type IA topoisomerases was provided by the observation that they reversibly **catenate** (interlink) single-stranded circles (Fig. 24-12a). Apparently the enzyme operates by cutting a single strand, passing a single-strand loop through the resulting gap, and then resealing the break (Fig. 24-12b). For negatively supercoiled DNA, this increases the linking number and makes the writhing number more positive (fewer negative supercoils). The process can be repeated until all of the supercoils have been removed ($W = 0$). This **strand passage** mechanism is supported by the observation that the denaturation of type IA topoisomerase that has been incubated with single-stranded circular DNA yields a linear DNA that has its 5'-terminal phosphoryl group linked to the enzyme via a phospho-Tyr diester linkage:

Formation of the covalent enzyme–DNA intermediate conserves the free energy of the cleaved phosphodiester bond so that no free energy input is needed to later reseal the nick in the DNA.

E. coli **topoisomerase III**, a type IA enzyme, is a 659-residue monomer (type I topoisomerases are denoted by odd Roman numerals; e.g., topoisomerase I, III, etc.). The X-ray structure of its catalytically inactive Y328F mutant in complex with the single-stranded octanucleotide d(CGCAACTT) was determined by Alfonso Mondragón. The enzyme folds into four domains that enclose an ~20 by 28 Å hole which is large enough to contain duplex DNA and which is lined with numerous Arg and Lys residues (Fig. 24-13). The octanucleotide binds in a groove that is also lined with Arg and Lys side chains with its sugar–phosphate backbone in contact with the protein and with most of its bases exposed for possible base pairing. This single-stranded

FIG. 24-13 X-Ray structure of the Y328F mutant of *E. coli* topoisomerase III in complex with the single-stranded octanucleotide d(CGCAACTT). The protein's four domains are drawn in different colors and the two views shown are related by a 90° rotation about a vertical axis. The DNA is drawn in space-filling form with C white, N blue, O red, and P yellow. This type IA topoisomerase's active site is marked by the side chain of Phe 328, which is shown in space-filling form in light green. [Based on an X-ray structure by Alfonso Mondragón, Northwestern University. PDBid 117D.]

? Explain why the substitution of Tyr 328 by Phe inactivates the enzyme.

FIG. 24-12 Type IA topoisomerase action. By cutting a single-stranded DNA, passing a loop of a second strand through the break, and then resealing the break, a type IA topoisomerase can (a) catenate two single-stranded circles or (b) unwind duplex DNA by one turn.

? Count the number of full helical turns in the DNA at point 1 and point 3.

DNA assumes a B-DNA-like conformation even though its complementary strand would be sterically excluded from the groove. The DNA strand is oriented with its 3' end near the active site where, if the mutant Phe 328 were the wild-type Tyr, its side chain would be properly positioned to nucleophilically attack the phosphate group bridging the DNA's C-6 and T-7 nucleotides to form a 5'-phospho-Tyr linkage with T-7 and release C-6 with a free 3'-OH. This structure suggests the mechanism for the type IA topoisomerase-catalyzed strand passage reaction that is diagrammed in Fig. 24-14.

Type IB Topoisomerases Relax Supercoiled DNA via Controlled Rotation. Type IB topoisomerases, which occur only in eukaryotes, can relax both negative and positive supercoils. In doing so, they transiently cleave one strand of a duplex DNA through the nucleophilic attack of an active site Tyr on a DNA P atom to yield a 3'-linked phospho-Tyr intermediate and a free 5'-OH group on the succeeding nucleotide (in contrast to the 5'-linked phospho-Tyr and free 3'-OH group formed by type IA topoisomerases). The X-ray structure of the catalytically inactive Y723F mutant of human **topoisomerase I**, a type IB topoisomerase, in complex with a 22-bp duplex DNA was determined by Wim Hol. The core domain of the bilobal protein is wrapped around the DNA in a tight embrace (Fig. 24-15). If the mutant Phe 723 were the wild-type Tyr, its OH group would be ideally positioned to nucleophilically attack the P on the scissile P—O5' bond so as to form a covalent linkage with the 3' end of the cleaved strand. The protein interacts to a much greater extent with the five base pairs of the DNA's "upstream" segment (which would contain the cleaved strand's newly formed 5' end) than it does with the base pairs of the DNA's "downstream" segment (to which Tyr 723 would be covalently linked), and in both cases it does so in a largely sequence-independent manner.

Topoisomerase I does not appear sterically capable of unwinding supercoiled DNA via the strand passage mechanism that type IA topoisomerases follow

PROCESS DIAGRAM

FIG. 24-14 Proposed mechanism for type IA topoisomerases. The enzyme is shown in blue with the yellow patch representing the binding groove for single-stranded (ss) DNA. The two DNA strands, which are drawn in red and green, could represent the two strands of a covalently closed circular duplex or two ss circles. If the two strands form a negatively supercoiled duplex DNA, the reaction results in its linking

number, L , increasing by 1; if they are separate ss circles, they become catenated or decatenated. For negatively supercoiled duplex DNA, this process can be repeated until all of its supercoils have been removed ($W = 0$). [After a drawing by Alfonso Mondragón, Northwestern University.]

WPLS See the Animated Process Diagrams.

FIG. 24-15 X-Ray structure of the Y723F mutant of human topoisomerase I in complex with a 22-bp duplex DNA. This type IB topoisomerase consists of several domains and subdomains that are drawn here in different colors. Tyr 723 is on the C-terminal domain (*green*). The DNA's uncleaved strand is cyan, and the upstream and downstream portions of the scissile strand are magenta and pink, respectively. [Courtesy of Wim Hol, University of Washington. PDBid 1A36.]

(Fig. 24-14). Rather, it is likely that topoisomerase I relaxes DNA supercoils by permitting the cleaved duplex DNA's loosely held downstream segment to rotate relative to the tightly held upstream segment. This rotation can only occur about the sugar–phosphate bonds in the uncleaved strand (α , β , γ , ϵ , and ζ in Fig. 24-5) that are opposite the cleavage site because the cleavage frees those bonds to rotate. In support of this mechanism, the protein region surrounding the downstream segment contains 16 conserved, positively charged residues that form a ring about the duplex DNA, which apparently holds the DNA but not in any specific orientation. Nevertheless, the downstream segment is unlikely to rotate freely because the cavity containing it is shaped so as to interact with the downstream segment during some portions of its rotation. Hence, type IB topoisomerases are said to mediate a **controlled rotation** mechanism in relaxing supercoiled DNA. The unwinding is driven by the superhelical tension in the DNA and hence requires no other energy input. Eventually, the DNA is religated by a reversal of the cleavage reaction and the now less supercoiled DNA is released.

Type II Topoisomerases Function Via an ATP-Dependent Strand Passage Mechanism. Type II topoisomerases are multimeric enzymes that require ATP hydrolysis to complete a reaction cycle in which two DNA strands are cleaved, duplex DNA is passed through the break, and the break is resealed. Type II topoisomerases therefore change the linking number in increments of two rather than one, as do type I topoisomerases (if the DNA in Fig. 24-11*b* had been treated with a type II topoisomerase, then only every second band in the electrophoretogram would be present). Both prokaryotic and eukaryotic type II enzymes relax negative and positive supercoils. However, only the prokaryotic enzyme (also known as **DNA gyrase** or just **gyrase**) can introduce negative supercoils [in contrast, the negative supercoils in eukaryotic chromosomes result primarily from its packaging in nucleosomes (Section 24-5B)]. Gyrases are A_2B_2 heterotetramers in which the B subunits bind and hydrolyze ATP and the A subunits mediate the double-strand cleavage, strand passage, and reunion reactions. The eukaryotic type II topoisomerases are homologous to gyrases but with their A and B subunits fused so that they are homodimers.

FIG. 24-16 X-Ray structures of yeast topoisomerase II. (a) Structure of a homodimer of the N-terminal ATPase domain (residues 7–406 of the 1428-residue subunits, which correspond to the B subunits of gyrases) in complex with AMPPNP as viewed with its twofold axis vertical. The protein is displayed in ribbon form with one subunit gray and the other colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The bound AMPPNP molecules are shown in space-filling form with C green, N blue, O red, and P orange. (b) Structure of a homodimer of the DNA breakage/reunion domain (residues 419–1177, which correspond to the A subunits of gyrases) in complex with a doubly nicked 34-bp DNA. The structure is viewed with its twofold axis vertical. The DNA, which describes a 150° arc, is drawn in stick form with C green, N blue, O red, and P orange embedded in its semitransparent molecular surface (*orange*). The protein is displayed in ribbon form with one subunit gray and the other colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chains of the two active site Tyr residues (Y782) are shown in space-filling form with C magenta and O red. The polypeptides in Parts *a* and *b*, which in the intact protein are joined by a 12-residue linker (represented by the dotted lines), presumably share the same twofold axis as drawn, although their relative orientation about the axis is unknown. [Based on X-ray structures by James Berger, University of California at Berkeley. PDBids 1PVG and 2RGR.]

Type II topoisomerases superficially resemble the type I enzymes in that they have a pair of catalytic Tyr residues, which form transient covalent intermediates with the 5' ends of duplex DNA. They thereby mediate the cleavage of the two DNA strands at staggered sites to produce 4-nucleotide “sticky ends.”

The X-ray structure of the homodimeric ATPase fragment of yeast **topoisomerase II** (type II topoisomerases are denoted by even Roman numerals; e.g., topoisomerase II, IV, etc.) in complex with the nonhydrolyzable ATP analog AMPPNP (Section 13-2A), determined by James Berger, consists of two domains (**Fig. 24-16a**). The N-terminal domain binds AMPPNP and the C-terminal domains form the walls of a large hole through the dimer, which in the X-ray structure of the structurally similar *E. coli* gyrase is 20 Å across, the same width as the B-DNA double helix.

PROCESS DIAGRAM

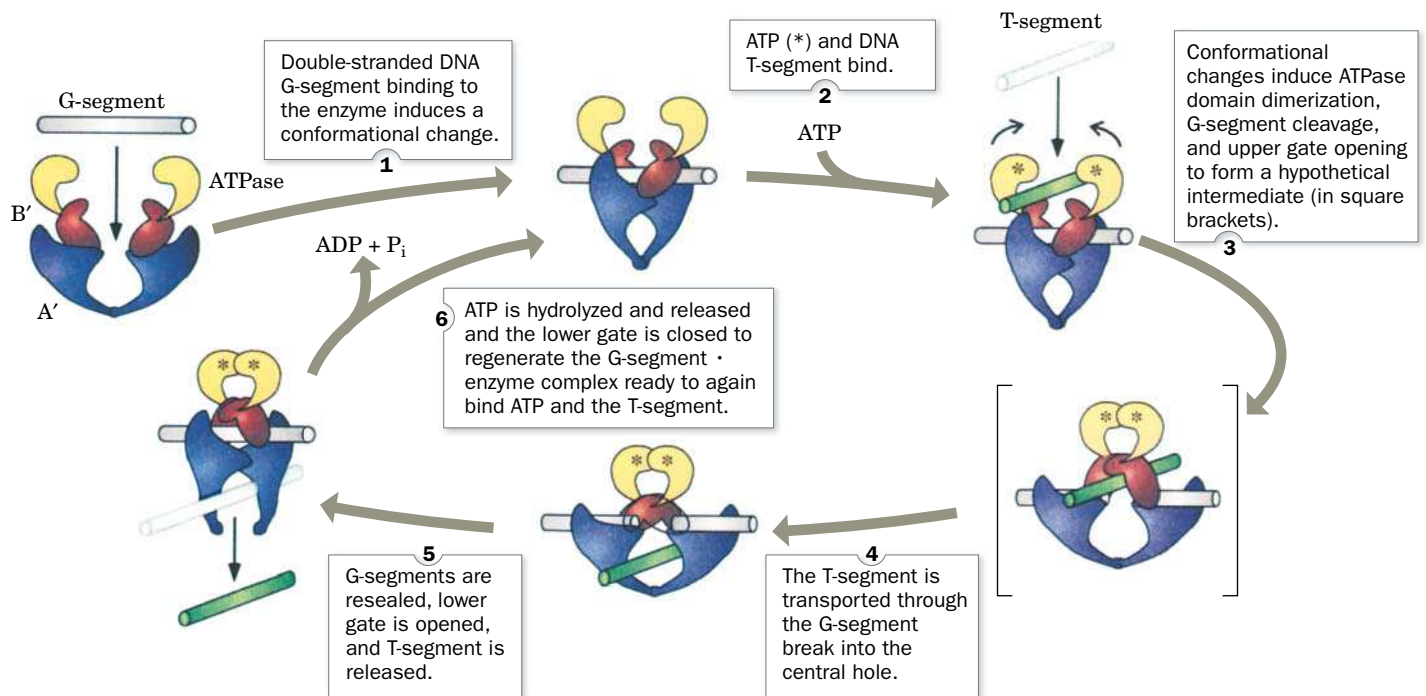

FIG. 24-17 Model for the enzymatic mechanism of type II topoisomerases. The protein's ATPase domain and the upper and lower portions of the breakage/reunion domain are colored yellow, red, and

purple, respectively, and the DNA's G- and T-segments (G for gate; T for transported) are colored gray and green. [Courtesy of James Wang, Harvard University.] **WPLS** See the Animated Process Diagrams.

Berger also determined the X-ray structure of the yeast topoisomerase II breakage/reunion domain in complex with a 15-bp DNA that has a self-complementary 4-nucleotide overhang on the 5' end of one of its strands. The DNA thereby forms a twofold symmetric 34-bp duplex with nicks on opposite strands separated by 4 bp (Fig. 24-16b). These are precisely the sites at which the enzyme would cleave an intact DNA by linking its newly formed 5'-ending strands to the active site Tyr residues. The protein binds the DNA in a positively charged groove that spans the width of the dimer and, in doing so, bends it through an arc of 150° (as we will see, DNA-binding proteins often deform their bound DNA, although such an extreme deformation is unusual). Interestingly, the DNA between the two cleavage sites is essentially in the A form. There are almost no direct contacts between the protein and the DNA bases, as is expected for a protein with little sequence specificity. Note also that the C-terminal portions of the protein come together to enclose a large centrally located empty space.

Consideration of the foregoing two structures and those of the corresponding portions of *E. coli* gyrase suggests a model for the mechanism of type II topoisomerases (Fig. 24-17). The DNA to be cleaved first binds to the enzyme and is clamped in place. In the presence of ATP, the bound DNA is cleaved and a second duplex DNA is passed through the opening into the central hole of the protein. The cleaved DNA is then resealed and the transported DNA exits the complex at a point opposite its point of entry. ATP hydrolysis to ADP + P_i prepares the enzyme for an additional catalytic cycle. The importance of topoisomerases in maintaining DNA in its proper topological state is indicated by the fact that many antibiotics and chemotherapeutic agents are inhibitors of topoisomerases (Box 24-2).

CHECKPOINT

- Describe the structural differences between A-, B-, and Z-DNA, including handedness, diameter, and presence of grooves.
- How do the structures of RNA and DNA differ?
- Explain why most nucleotides adopt the anti conformation.
- In what nucleic acid conformation(s) does the ribose pucker with C2' *endo*? C3' *endo*?
- Summarize the relationship between linking number, twist, and writhing number.
- Why is it necessary for naturally occurring DNA molecules to be negatively supercoiled?
- How do type IA, type IB, and type II topoisomerases alter DNA topology? Which processes require the input of free energy?

Type II topoisomerases are inhibited by a variety of compounds. For example, **ciprofloxacin** and **novobiocin** (*below*) specifically inhibit DNA gyrase but not eukaryotic topoisomerase II and are therefore antibiotics. In fact, ciprofloxacin is the most efficacious oral antibiotic presently in clinical use. In contrast, novobiocin's adverse side effects and the rapid generation of bacterial resistance to its presence have resulted in the discontinuation of its use in the treatment of human infections. A number of substances, including **doxorubicin** and **etoposide** (*below*), inhibit eukaryotic type II topoisomerases and are therefore widely used in cancer chemotherapy.

Different type II topoisomerase inhibitors act in one of two ways. Many of these agents, including novobiocin, inhibit their target enzyme's ATPase activity. They therefore kill cells by blocking topoisomerase activity, which results in the arrest of DNA replication and RNA transcription since the cell can no longer control the level of supercoiling in its DNA. However, other substances, including ciprofloxacin, doxorubicin, and etoposide, enhance the rate at which their target type II topoisomerases cleave double-stranded DNA and/or reduce the rate at which the breaks are resealed. Consequently, these substances

induce higher than normal levels of transient protein-bridged breaks in the DNA of treated cells. The protein bridges are easily ruptured by the passage of the replication and transcription machinery, thereby rendering the breaks permanent. Although all cells have extensive enzymatic machinery for repairing damaged DNA (Section 25-5), a sufficiently high level of DNA damage can overwhelm the repair mechanisms and trigger cell death. Consequently, since rapidly replicating cells such as cancer cells have elevated levels of type II topoisomerases, they are far more likely to incur lethal DNA damage through the inhibition of their type II topoisomerases than are slow-growing or quiescent cells.

Camptothecin (*below*) and its derivatives, the only known inhibitors of type IB topoisomerases, act by prolonging the lifetime of the covalent enzyme–DNA intermediate. These substances bind to the complex between the ends of the severed DNA strand, positioning the 5'-OH groups more than 4.5 Å away from the phosphate groups that must be reattached in the religation reaction. Because the nicked DNA cannot be replicated, camptothecin prevents the proliferation of rapidly growing cells such as cancer cells and hence is a potent anticancer agent.

2 Forces Stabilizing Nucleic Acid Structures

KEY CONCEPTS

- A double-stranded nucleic acid structure is stabilized by hydrogen bonding between base pairs, by stacking interactions, and by ionic interactions.
- DNA can be denatured by heating and renatured through annealing.
- RNA assumes more varied shapes than DNA and, in some cases, has catalytic activity.

DNA does not exhibit the structural complexity of proteins because it has only a limited repertoire of secondary structures and no comparable tertiary or quaternary structures. This is perhaps to be expected since the 20 amino acid residues of

proteins have a far greater range of chemical and physical properties than do the four DNA bases. Nevertheless, many RNAs have well-defined tertiary structures. In this section, we examine the forces that determine the structures of nucleic acids.

A Nucleic Acids Are Stabilized by Base Pairing, Stacking, and Ionic Interactions

Base pairing is apparently a “glue” that holds together double-stranded nucleic acids, although other intramolecular forces help shape nucleic acid structures. Only **Watson–Crick base pairs** normally occur in DNA structures, but other hydrogen-bonded base pairs are known, particularly in RNA (**Fig. 24-18**). For example, in some A · T base pairs, adenine N7 is the hydrogen bond acceptor (**Hoogsteen** geometry; Fig. 24-18a) rather than N1 (Watson–Crick geometry; Fig. 24-1).

Observations of DNA structures indicate that *Watson–Crick geometry is the most stable mode of base pairing in the double helix, even though non-Watson–Crick base pairs are theoretically possible*. Initially, it was believed that the geometrical constraints of the double helix precluded other types of base pairing. Recall that because A · T, T · A, G · C, and C · G base pairs are geometrically similar, they can be interchanged without altering the conformation of the sugar–phosphate chains. However, experimental measurements show that a major reason that other base pairs do not appear in the double helix is that *Watson–Crick base pairs have an intrinsic stability that non-Watson–Crick base pairs lack; that is, the bases in a Watson–Crick pair have a higher mutual affinity than those in a non-Watson–Crick pair*. Nevertheless, as we will see, the double-helical segments of many RNAs contain unusual base pairs, such as G · U, that help stabilize their tertiary structures.

Hydrogen Bonds Only Weakly Stabilize Nucleic Acid Structures. It is clear that hydrogen bonding is required for the specificity of base pairing in DNA. Yet, as is also true for proteins (Section 6-4A), *hydrogen bonding contributes little to the stability of nucleic acid structures*. This is because, on denaturation, the hydrogen bonds between the base pairs of a native nucleic acid are replaced by energetically similar hydrogen bonds between the bases and water. Other types of forces must therefore play an important role in stabilizing nucleic acid structures.

Stacking Interactions Result from Hydrophobic Forces. Purines and pyrimidines tend to form extended stacks of planar parallel molecules. This has been

FIG. 24-18 Some non-Watson–Crick base pairs. (a) Hoogsteen pairing between adenine and thymine residues. (b) An A · A base pair. (c) A U · C base pair. (R represents ribose-5-phosphate).

? Compare these base pairs to those shown in Fig. 24-1.

FIG. 24-19 The stacking of adenine rings in the X-ray structure of 9-methyladenine. The partial overlap of the rings such that their atoms are not in direct opposition is typical of the association between bases in crystal structures and in double-helical nucleic acids. [After Stewart, R.F. and Jensen, L.H., *J. Chem. Phys.* **40**, 2071 (1964).]

observed in the structures of nucleic acids (Fig. 24-2c) and in the structures of crystallized nucleic acid bases (e.g., Fig. 24-19). These **stacking interactions** are a form of van der Waals interaction (Section 2-1A). Interactions between stacked G and C bases are greater than those between stacked A and T bases (Table 24-2), which largely accounts for the greater thermal stability of DNAs with a high G + C content. Note also that differing sets of base pairs in a stack have different stacking energies. These differences arise, in part, from the competition between stacking and hydrogen bonding interactions for their optimum geometries. Thus, *the stacking energy of a double helix is sequence-dependent.*

One might assume that hydrophobic effects in nucleic acids are qualitatively similar to those that stabilize protein structures. This is not the case. Recall that folded proteins are stabilized primarily by the increase in entropy of the solvent water molecules (the hydrophobic effect; Section 6-4A); in other words, protein folding is enthalpically opposed and entropically driven. In contrast, thermodynamic measurements reveal that the base stacking in nucleic acids is enthalpically driven and entropically opposed, although the theoretical basis for this observation is not well understood. The difference between hydrophobic effects in proteins and in nucleic acids may reflect the fact that nucleic acid bases are much more polar than most protein side chains (e.g., adenine versus the side chain of Phe or Leu). Whatever their origin, hydrophobic effects are of central importance in determining nucleic acid structures, as is clear from the denaturing effect of adding nonpolar solvents to aqueous solutions of DNA.

Cations Shield the Negative Charges of Nucleic Acids. Any theory of the stability of nucleic acid structures must take into account the electrostatic interactions of their charged phosphate groups. For example, DNA is stabilized by Na^+ ions because the ions electrostatically shield the anionic phosphate groups from each other. Other monovalent cations such as Li^+ and K^+ have similar nonspecific interactions with phosphate groups. Divalent cations, such as Mg^{2+} , Mn^{2+} , and Co^{2+} , in contrast, specifically bind to phosphate groups, so *they are far more effective shielding agents for nucleic acids than are monovalent cations.* For example, an Mg^{2+} ion has an influence on the DNA double helix comparable to that of 100 to 1000 Na^+ ions. Indeed, enzymes that mediate reactions with nucleic acids or nucleotides almost always require an Mg^{2+} ion cofactor for activity. Mg^{2+} ions also play an essential role in stabilizing the complex structures assumed by many RNAs.

B DNA Can Undergo Denaturation and Renaturation

When a solution of duplex DNA is heated above a characteristic temperature, its native structure collapses and its two complementary strands separate and assume random conformations (Fig. 24-20). The denaturation process is accompanied by a qualitative change in the DNA's physical properties. For example,

FIG. 24-20 A schematic representation of DNA denaturation.

the characteristic high viscosity of native DNA solutions, which arises from the resistance to deformation of its rigid and rodlike duplex molecules, drastically decreases when the DNA decomposes to the conformationally flexible single chains. Likewise, DNA's ultraviolet absorbance, which is almost entirely due to its aromatic bases, increases by ~40% on denaturation (Fig. 24-21) as a consequence of the disruption of the electronic interactions among neighboring bases. The increase in absorbance is known as the **hyperchromic effect**.

Monitoring the changes in absorbance at a single wavelength (usually 260 nm) as the temperature increases reveals that the increase in absorbance occurs over a narrow temperature range (Fig. 24-22). This indicates that *the denaturation of DNA is a cooperative phenomenon in which the collapse of one part of the structure destabilizes the remainder*. In analogy with the melting of a solid, Fig. 24-22 is referred to as a **melting curve**, and the temperature at its midpoint is defined as its **melting temperature, T_m** .

FIG. 24-21 The UV absorbance spectra of native and heat-denatured *E. coli* DNA.

Note that denaturation does not change the general shape of the absorbance curve but only increases its intensity. [After Voet, D., Gratzer, W.B., Cox, R.A., and Doty, P., *Biopolymers* **1**, 205 (1963).] **WPLS** See the Animated Figures.

FIG. 24-22 An example of a DNA melting curve. The relative absorbance is the ratio of the absorbance (customarily measured at 260 nm) at the indicated temperature to that at 25°C. The melting temperature, T_m , is the temperature at which half of the maximum absorbance increase is attained. **WPLS** See the Animated Figures.

? Sketch melting curves for A · T-rich and G · C-rich DNA.

FIG. 24-23 Partially renatured DNA. This schematic representation shows the imperfectly base-paired structures assumed by DNA that has been heat-denatured and then rapidly cooled. Note that both intramolecular and intermolecular aggregation can occur.

? Would the same structures form if this sample of DNA were reheated and then cooled again?

The stability of the DNA double helix, and hence its T_m , depends on several factors, including the nature of the solvent, the identities and concentrations of the ions in solution, and the pH. T_m also increases linearly with the mole fraction of G · C base pairs, due to their greater stacking energy and not, as one might naively assume, because G · C base pairs contain one more hydrogen bond than A · T base pairs.

DNA Can Be Renatured by Cooling. If a solution of denatured DNA is rapidly cooled below its T_m , the resulting DNA will be only partially base-paired (Fig. 24-23), because the complementary strands will not have had sufficient time to find each other before the randomly base-paired structure becomes effectively “frozen in.” If, however, the temperature is maintained $\sim 25^\circ\text{C}$ below the T_m , enough thermal energy is available for short base-paired regions to rearrange by melting and re-forming. Under such **annealing** conditions, as Julius Marmur discovered in 1960, denatured DNA eventually completely renatures. Likewise, complementary strands of RNA and DNA, in a process known as **hybridization**, form RNA–DNA hybrid double helices (e.g., Fig. 24-4) that are only slightly less stable than the corresponding DNA double helices.

C RNA Structures Are Highly Variable

The structure of RNA is stabilized by the same forces that stabilize DNA, and its conformational flexibility is limited by many of the same features that limit DNA conformation. In fact, RNA may be even more rigid than DNA owing to the presence of a greater number of water molecules that form hydrogen bonds to the 2'-OH groups of RNA. Even so, RNA comes in a greater variety of shapes and sizes than DNA and, in some cases, has catalytic activity.

RNAs May Contain Double-Stranded Segments. Bacterial ribosomes, which are two-thirds RNA and one-third protein, contain three highly conserved RNA molecules (Section 27-3). The smallest of these is the 120-nucleotide **5S RNA** [so named because it sediments in the ultracentrifuge at the rate of 5 Svedbergs (S); Section 5-2E]. 5S RNA has a secondary structure consisting of several base-paired regions connected by loops of various kinds (Fig. 24-24a). These structural elements can be discerned in the X-ray structure of this RNA molecule, in which the base-paired segments form mostly A-type helices

FIG. 24-24 Secondary and tertiary structure of 5S RNA from *Haloarcula marismortui*. (a) Secondary structure diagram. This single-stranded RNA molecule contains four double-stranded base-paired helices, as well as hairpin loops, internal loops, and bulges. The dashes indicate Watson-Crick base pairing, and circles indicate other modes of base pairing. (b) The X-ray structure in stick form colored according to its secondary structure as in Part a. [Based on an X-ray structure by Peter Moore and Thomas Steitz, Yale University. PDBid 1JJ2.]

(Fig. 24-24b). Approximately two-thirds of the bases in 5S rRNA participate in base-pairing interactions; the remaining nucleotides, which are located in loops and at the 3' and 5' ends, are free to interact with ribosomal proteins or with unpaired nucleotides in the ribosome's other rRNA molecules.

Large RNA molecules presumably fold in stages, as do multidomain proteins (Section 6-5). RNA folding is almost certainly a cooperative process, with the rapid formation of short duplex regions preceding the collapse of the structure into its mature conformation. The complete folding process may take several minutes, it may involve relatively stable intermediates, and it may require the assistance of proteins.

RNA Molecules Are Stabilized by Stacking Interactions. The three-dimensional structure of the yeast transfer RNA that forms a covalent complex with Phe (tRNA^{Phe}) was elucidated in 1974 by Alexander Rich in collaboration with Sung-Hou Kim and, in a different crystal form, by Aaron Klug. The molecule is compact and L-shaped, with each leg of the L ~60 Å long (Fig. 24-25). The structural complexity of yeast tRNA^{Phe} is reminiscent of that of a protein. Although only 42 of its 76 bases occur in double-helical stems, 71 of them participate in stacking associations.

tRNA structures are characterized by the presence of covalently modified bases and unusual base pairs, including hydrogen-bonding associations involving three bases. These tertiary interactions contribute to the compact structure of the tRNAs (tRNA structure is discussed in greater detail in Section 27-2A).

Some RNAs Are Catalysts. Although the discovery of catalytic RNA, by Thomas Cech in 1982, was initially greeted with skepticism, subsequent studies have demonstrated that the catalytic potential of RNA is virtually unlimited. *At least nine naturally occurring types of catalytic RNAs have been described, and many more ribozymes have been developed in the laboratory.* Most naturally

FIG. 24-25 Structure of yeast tRNA^{Phe}. The 76-nucleotide RNA is shown in stick form with C green, N blue, O red, and P orange and with successive P atoms linked by orange rods. Nearly all the bases are stacked, thereby stabilizing the compact structure of the tRNA. [Based on an X-ray structure by Alexander Rich and Sung-Hou Kim, MIT. PDBid 6TNA.]

The observations that nucleic acids but not proteins can direct their own synthesis, that cells contain batteries of protein-based enzymes for manipulating DNA (Chapter 25) but few for processing RNA, and that many coenzymes in biosynthetic processes and energy-harvesting pathways are ribonucleotides (e.g., ATP, NAD⁺, FAD, and coenzyme A) led to the hypothesis that RNAs were the original biological catalysts in precellular times—the so-called **RNA world**. Indeed, RNA remains the carrier of genetic information in viruses with single- or double-stranded RNA genomes. The fact that RNA-based functions are distributed across all three domains of life provides additional evidence that the role of RNA in modern cells reflects its establishment very early in evolution.

Assuming that an RNA world did once exist, we must ask two questions: Why did protein catalysts take the place of most ribozymes, and why did DNA become the dominant molecule of heredity? The first question is readily answered by observing that the 20 amino acid residues of proteins contain functional groups—hydroxyl, sulfhydryl, amide, and carboxylate groups—that are lacking in RNA, whose four nucleotide residues are more uniform and less reactive. Thus, proteins probably replaced RNA as cellular workhorses by virtue of their greater chemical virtuosity. Nevertheless, RNA continues to play the dominant role in the synthesis of proteins: Ribosomes are predominantly RNA, which is now known to catalyze peptide bond formation (Section 27-4B).

As for DNA, it is more stable than RNA because RNA is highly susceptible to base-catalyzed hydrolysis by the reaction mechanism at the right. The base-induced deprotonation of the 2'-OH group facilitates its nucleophilic attack on the adjacent phosphorus atom, thereby cleaving the RNA backbone. The resulting 2',3'-cyclic phosphate group subsequently hydrolyzes to produce a 2'- or 3'-nucleotide product (the RNase A-catalyzed hydrolysis of RNA follows a nearly identical reaction sequence but generates only 3'-nucleotides; Section 11-3A). DNA is not susceptible to such degradation because it lacks a 2'-OH group. This greater chemical stability of DNA makes it more suitable than RNA for the long-term storage of genetic information.

occurring RNA catalysts participate in aspects of RNA metabolism such as mRNA splicing (Section 26-3B) and hydrolytic RNA processing (Section 26-3C). The formation of peptide bonds during protein synthesis is catalyzed by ribosomal RNA (Section 27-4). *In vitro*, RNA molecules can catalyze some of the reactions required for their own production, such as the synthesis of glycosidic bonds and nucleotide polymerization. This functional versatility has led to the hypothesis that RNA once carried out many of the basic activities of early life, before DNA or proteins had evolved. This scenario has been dubbed the RNA world (Box 24-3).

One of the best-characterized ribozymes is the **hammerhead ribozyme**, a minimally ~40-nt molecule that participates in the replication of certain virus-like RNAs that infect plants and also occurs in schistosomes (species of parasitic flatworms). The hammerhead ribozyme catalyzes the site-specific cleavage of one of its own phosphodiester bonds. The secondary structures of the 63-nt hammerhead ribozyme from *Schistosoma mansoni*, which cleaves itself between its C-17 and C-1.1 nucleotides, has three duplex stems and a catalytic core of two nonhelical segments (Fig. 24-26a). The X-ray structure of this hammerhead

FIG. 24-26 Structure of a hammerhead ribozyme. (a) The sequence and schematic structural representation of the ribozyme oriented and colored to match the X-ray structure drawn in Part *b*. Base pairs are represented by colored lines, and dotted lines represent tertiary interactions. Nucleotides are labeled according to the universal numbering system for hammerhead ribozymes. (b) X-Ray structure of the ribozyme drawn in paddle form with C atoms the same color as in Part *a* except that those of G-12 are light green and those of C-1.1 are light blue, N blue, O red, and P orange. Adjacent P atoms in the same strand are connected by thin orange rods. The P atom of the scissile phosphate group (bridging C-17 and C-1.1) and the nucleophile (O2' of C-17) are represented by small spheres. (c) The ribozyme's active site residues are drawn in stick form with C green, O red, N blue, and P orange. Hydrogen bonds are represented by dashed black lines. The proposed reaction mechanism is indicated by the curved arrows with the dotted black line marking the in-line trajectory taken by atom O2' of C-17 in nucleophilically attacking the P atom of the scissile phosphate group. [Part *a* courtesy of and Parts *b* and *c* based on an X-ray structure by William Scott, University of California at Santa Cruz. PDBid 2GOZ.]

ribozyme (Fig. 24-26*b*), determined by William Scott, reveals that it forms three A-type helices. The nucleotides in the helical stems mainly form normal Watson–Crick base pairs, whereas the various loops and bulges interact through a variety of hydrogen bonding and base stacking interactions.

The bases in the highly conserved catalytic core of the hammerhead ribozyme participate in an extensive hydrogen bonded network (Fig. 24-26*c*). This helps position C-17 such that its O2' atom is properly oriented for nucleophilic attack on the P atom linking atom O3' of C-17 to atom O5' of C-1.1, so as to yield a cyclic 2',3'-phosphodiester on C-17 together with a free 5'-OH on C-1.1. The 2'-OH of the invariant G-8 and N1 of the invariant G-12, when deprotonated, appear to be properly positioned to act as acid and base catalysts in the reaction. Interestingly, no metal ions are present in the ribozyme's active site region.

CHECKPOINT

- Describe the forces that stabilize nucleic acid structure. Which is most important?
- Explain the molecular events of nucleic acid denaturation and renaturation.
- What properties allow RNA molecules to act as catalysts?

The hammerhead ribozyme is not a true catalyst, since it is its own substrate and hence cannot return to its original state. However, other ribozymes catalyze multiple turnovers without themselves undergoing alteration. Ribozymes are comparable to protein enzymes in their rate enhancement ($\sim 10^7$ -fold for the hammerhead ribozyme), in their ability to use cofactors such as metal ions or imidazole groups, and in their regulation by small allosteric effectors. Although RNA molecules lack the repertoire of functional groups possessed by protein catalysts, RNA molecules can assume conformations that specifically bind substrates, orient them for reaction, and stabilize the transition state—all hallmarks of enzyme catalysts.

3 Fractionation of Nucleic Acids

KEY CONCEPT

- Nucleic acids can be fractionated on the basis of size, composition, and sequence by chromatography and electrophoresis.

In Section 5-2 we considered the most common procedures for isolating and characterizing proteins. Most of these methods, often with some modifications, are also used to fractionate nucleic acids according to size, composition, and sequence. There are also many techniques that apply only to nucleic acids. In this section, we outline some of the most useful nucleic acid fractionation procedures.

Nucleic acids in cells are invariably associated with proteins. Once cells have been broken open, their nucleic acids are usually deproteinized. This can be accomplished by shaking the protein–nucleic acid mixture with a phenol solution so that the protein precipitates and can be removed by centrifugation. Alternatively, the protein can be dissociated from the nucleic acids by detergents, guanidinium chloride, or high salt concentration, or it can be enzymatically degraded by proteases. In all cases, the nucleic acids, a mixture of RNA and DNA, can then be isolated by precipitation with ethanol. The RNA can be recovered from such precipitates by treating them with pancreatic DNase to eliminate the DNA. Conversely, the DNA can be freed of RNA by treatment with RNase.

In all these and subsequent manipulations, the nucleic acids must be protected from degradation by nucleases that occur both in the experimental material and on human hands. Nucleases can be inhibited by chelating agents such as EDTA, which sequester the divalent metal ions they require for activity. Laboratory glassware should also be autoclaved to heat-denature the nucleases. Nevertheless, nucleic acids are generally easier to handle than proteins because most lack a complex tertiary structure and are therefore relatively tolerant of extreme conditions.

GATEWAY CONCEPT Molecular Behavior

The exact conformations of individual DNA molecules vary in a population of otherwise identical molecules. For this reason, measuring the melting temperature or characterizing a DNA sample by chromatography or electrophoresis depends on the average chemical and physical properties of the molecules in the population.

A Nucleic Acids Can Be Purified by Chromatography

Many of the chromatographic techniques that are used to separate proteins (Section 5-2C) also apply to nucleic acids. Affinity chromatography is used to isolate specific nucleic acids. For example, most eukaryotic messenger RNAs (mRNAs) have a poly(A) sequence at their 3' ends (Section 26-3A). They can be isolated on agarose or cellulose to which poly(U) is covalently attached. The poly(A) sequences specifically bind to the complementary poly(U) in high salt and at low temperature and can later be released by altering those conditions.

B Electrophoresis Separates Nucleic Acids by Size

Nucleic acids of a given type can be separated by polyacrylamide gel electrophoresis (Section 3-4B) because their electrophoretic mobilities in such gels vary inversely with their molecular masses. However, DNAs of more than a few thousand base pairs cannot penetrate even a weakly cross-linked polyacrylamide gel and so must be separated in agarose gels. Yet conventional gel electrophoresis is limited to DNAs of <100,000 bp, because larger DNA molecules tend to worm their way through the agarose at a rate independent of their size. Charles Cantor and Cassandra Smith overcame this limitation by developing **pulsed-field gel electrophoresis (PFGE)**, which can resolve DNAs of up to 10 million bp (6.6 million kD). In the simplest type of PFGE apparatus, the polarity of the electrodes is periodically reversed, with the duration of each pulse varying from 0.1 to 1000 s, depending on the sizes of the DNAs being separated. With each change in polarity, the migrating DNA must reorient to the new electrical field before it can resume movement. A DNA molecule may actually migrate backward for part of the time. Because small molecules reorient more quickly than large molecules, different-sized DNA molecules gradually separate (Fig. 24-27).

Intercalation Agents Stain Duplex DNA. The various DNA bands in a gel can be stained by planar aromatic cations such as **ethidium ion, acridine orange, or proflavin**:

Ethidium

Proflavin

Acridine orange

The dyes bind to double-stranded DNA by **intercalation** (slipping in between the stacked bases; Fig. 24-28), where they exhibit a fluorescence under UV light that

FIG. 24-28 X-Ray structure of a complex of ethidium with 5-iodo-UpA. Ethidium (*red*) intercalates between the base pairs of the double-helically paired dinucleotide and thereby provides a model of the binding of ethidium to duplex DNA. [After Tsai, C.-C., Jain, S.C., and Sobell, H.M., *Proc. Natl. Acad. Sci.* **72**, 629 (1975).]

FIG. 24-27 Pulsed-field gel electrophoresis (PFGE) of a set of yeast chromosomes.

The yeast chromosomes, which were run as identical samples in the 13 inner lanes, have sizes 260, 290, 370, 460, 580/600, 700, 780, 820, and 850 kb. The two outer lanes, which provide molecular mass standards, contained twenty successively larger multimers of a ~43.5-kb bacteriophage λ DNA (bottom to top) to an observed limit of ~850 kb.

[Electrophoretogram by Margit Burmeister, University of Michigan in Wilson, K. and Walker, J., *Principles and Techniques of Biochemistry and Molecular Biology* (6th ed.), p. 477, Cambridge University Press (2005).]

FIG. 24-29 Agarose gel electrophoretogram of double-helical DNA. After electrophoresis, the gel was soaked in a solution of ethidium bromide, washed, and photographed under UV light. The fluorescence of the ethidium cation is strongly enhanced by binding to DNA, so each fluorescent band marks a different sized DNA fragment.

Klaus Guldbrandsen/Photo Researchers.

is far more intense than that of the free dye (Fig. 24-29). As little as 50 ng of DNA can be detected in a gel by staining it with ethidium bromide. Single-stranded DNA and RNA also stimulate the fluorescence of ethidium but to a lesser extent than does duplex DNA.

Fig. 24-28 reveals that intercalating dyes partially unwind DNA, that is, they decrease its twist, T . Consequently, titrating duplex circular DNA with an intercalating dye such as ethidium progressively increases the DNA's writhe, W (recall that $\Delta W = -\Delta T$ in intact DNA), as is diagrammed, left-to-right, in Fig. 28-11a.

Southern Blotting Identifies DNAs with Specific Sequences. DNA with a specific base sequence can be identified through a procedure developed by Edwin Southern known as **Southern blotting** (Fig. 24-30). This procedure takes advantage of the ability of nitrocellulose to tenaciously bind single-stranded but not duplex DNA. Following gel electrophoresis of double-stranded DNA, the gel is soaked in 0.5 M NaOH to convert the DNA to its single-stranded form. The gel is then overlaid by a sheet of nitrocellulose paper. Molecules in the gel are forced through the nitrocellulose by drawing out the liquid with a stack of absorbent towels compressed against the far side of the nitrocellulose, or by using an electrophoretic process

PROCESS DIAGRAM

FIG. 24-30 The detection of DNAs containing specific base sequences by Southern blotting. **WPLS** See the Animated Process Diagrams.

? What would happen if the hybridization temperature were very low or very high?

(electroblotting). The single-stranded DNA binds to the nitrocellulose at the same position it had in the gel. After drying at 80°C, which permanently fixes the DNA in place, the nitrocellulose sheet is moistened with a minimal quantity of solution containing a single-stranded DNA or RNA probe that is complementary in sequence to the DNA of interest. The probe is typically tagged with a fluorescent group or a radioactive isotope such as ^{32}P . The moistened nitrocellulose is held at a suitable renaturation temperature for several hours to permit the probe to hybridize to its target sequence(s), washed to remove the unbound probe, dried, and then analyzed. If the probe is radioactive, an autoradiogram is made by placing the nitrocellulose for a time over a sheet of X-ray film. The positions of the molecules that are complementary to the radioactive probe are indicated by a blackening of the developed film (alternatively, a position-sensitive radiation detector can be used). If the probe is fluorescent, an imaging instrument is used to produce a digital photograph.

Specific RNA sequences can be detected through a variation of the Southern blot, punningly named a **Northern blot**, in which the RNA is immobilized on nitrocellulose paper and probed with a complementary RNA or DNA probe. A specific protein can be analogously detected in an **immunoblot** or **Western blot** through the use of antibodies directed against the protein in a procedure similar to that used in an ELISA (Fig. 5-3).

CHECKPOINT

- How is DNA separated from protein? From RNA?
- Which fractionation procedures separate nucleic acids according to their binding affinity? According to their size?
- Describe the methods for visualizing DNA molecules after separation.

4 DNA–Protein Interactions

KEY CONCEPTS

- Restriction endonucleases make base-specific contacts with palindromic DNA.
- Prokaryotic repressors interact with DNA by inserting a helix or a β strand into the major groove.
- Many eukaryotic DNA-binding proteins contain zinc fingers or leucine zipper structural motifs.

The accessibility of genetic information depends on the ability of proteins to recognize and interact with DNA in a manner that allows the encoded information to be copied as DNA (in replication) or as RNA (in transcription). Even the most basic steps of these processes require many proteins that interact with each other and with the nucleic acids. In addition, cells regulate the expression of most genes, which requires yet other proteins that act as repressors or activators of transcription.

Many proteins bind DNA nonspecifically, that is, without regard to the sequence of nucleotides. For example, histones (which are involved in packaging DNA; Section 24-5A) and certain DNA replication proteins (which must potentially interact with all the sequences of an organism's genome) bind to DNA primarily through interactions between protein functional groups and the sugar–phosphate backbone of DNA. Proteins that recognize specific DNA sequences presumably also bind nonspecifically but loosely to DNA so that they can scan the polynucleotide chain for their target sequences to which they then bind specifically and tightly. Most DNA–protein complexes have dissociation constants ranging from 10^{-9} to 10^{-12} M; these values represent binding that is 10^3 to 10^7 times stronger than nonspecific binding. Sequence-specific DNA–protein interactions must be extremely precise so that the proteins can exert their effects at sites selected from among—in the human genome—billions of base pairs. How do such proteins interact with their target sites on DNA?

Sequence-specific DNA-binding proteins generally do not disrupt the base pairs of the duplex DNA to which they bind. They do, however, *discriminate among the four base pairs (A · T, T · A, G · C, and C · G) according to the functional groups of the base pairs that project into DNA's major and minor grooves.* As can be seen in Fig. 24-2, these groups are more exposed in the major groove of B-DNA than in its narrower minor groove. Moreover, the major groove contains more sequence-specific functional groups than does the minor groove (Fig. 24-1). However, as revealed in a systematic survey of 129 protein–DNA complexes,

FIG. 24-31 X-Ray structure of EcoRI endonuclease in complex with DNA. The segment of duplex DNA has the self-complementary sequence TCGCGAATTCGCG (12 bp with an overhanging T at both 5' ends; the enzyme's 6-bp target sequence is underlined) and is drawn as a space-filling model with its sugar–phosphate chains yellow, its target sequence bases cyan, and its other bases white. The protein is drawn in ribbon form with its two identical subunits red and blue.

The complex is shown (a) with its DNA helix axis vertical and (b) in end view (rotated relative to Part a by 90° about a horizontal axis). The complex's twofold axis is horizontal and the DNA's major groove faces right (toward the protein) in both views. This was the first known X-ray structure of a protein–DNA complex. [Based on an X-ray structure by John Rosenberg, University of Pittsburgh. PDBid 1ERI.]

only about one-third of the interactions between the binding protein and the DNA involve hydrogen bonds, either directly or via intervening water molecules. Approximately two-thirds of all interactions are van der Waals contacts. Ionic interactions with backbone phosphate groups also occur. The complementarity of the binding partners in many cases is augmented by an “induced fit” phenomenon in which the protein and the nucleic acid change their conformations for greater stability. In some cases, these changes allow the binding proteins to interact with other proteins or alter the accessibility of the DNA to other molecules. Below, we examine some examples of specific DNA–protein binding. We will encounter many more examples of nucleic acid–protein interactions in subsequent chapters.

A Restriction Endonucleases Distort DNA on Binding

Type II restriction endonucleases rid bacterial cells of foreign DNA by cleaving the DNA at specific sites that have not yet been methylated by the host's modification methylase (Section 3-4A). Restriction enzymes recognize palindromic DNA sequences of ~4 to 8 base pairs with such remarkable specificity that a single base change can reduce their activity by a millionfold. This degree of specificity is necessary to prevent accidental cleavage of other sites in a DNA sequence.

The X-ray structure of EcoRI endonuclease in complex with a segment of B-DNA containing the enzyme's recognition sequence was determined by John Rosenberg. The DNA binds in the symmetric cleft between the two identical 276-residue subunits of the dimeric enzyme (Fig. 24-31), thereby accounting for the DNA's palindromic recognition sequence. Protein binding causes the dihedral angle between the recognition sequence's central two base pairs to open up by ~50° toward the minor groove. These base pairs thereby become unstacked, but the DNA remains nearly straight due to compensating bends at the adjacent base pairs. Nevertheless, this unwinds the DNA by 28° and widens the major

FIG. 24-32 X-Ray structure of EcoRV endonuclease in complex with DNA. The 10-bp segment of DNA has the self-complementary sequence GGGATATCCC (the enzyme's 6-bp target sequence is underlined). The DNA and protein are colored as in Fig. 24-31. (a) The complex as viewed along its twofold axis, facing the DNA's major groove. The two symmetry-related protein loops that overlie the

major groove (composed of residues 182–186) are the only parts of the enzyme that make base-specific contacts with the DNA. (b) The complex as viewed from the right in Part a (the DNA's major groove faces left). Note how the protein kinks the DNA toward its major groove. [Based on an X-ray structure by Fritz Winkler, Hoffman-LaRoche Ltd., Basel, Switzerland. PDBid 4RVE.]

groove by 3.5 Å at the recognition site. The N-terminal ends of a pair of parallel helices from each protein subunit are inserted into the widened major groove, where they participate in a hydrogen-bonded network with the bases of the recognition sequence. The phosphodiester cleavage points are located two bases from the center of the palindrome (Table 3-2).

Certain other restriction endonucleases, including EcoRV (Fig. 24-32), also induce kinks in the DNA, in some cases by opening up the minor groove and compressing the major groove. However, *complementary hydrogen bonding between the nucleotide bases and protein side chain and backbone groups, rather than the DNA distortion per se, is the primary prerequisite for the formation of a sequence-specific endonuclease–DNA complex.* For example, in the BamHI–DNA complex, every potential hydrogen bond donor and acceptor in the major groove of the recognition site takes part in direct or water-mediated hydrogen bonds with the protein. No other DNA sequence could support this degree of complementarity with BamHI.

B Prokaryotic Repressors Often Include a DNA-Binding Helix

In prokaryotes, the expression of many genes is governed at least in part by **repressors**, proteins that bind at or near the gene so as to prevent its transcription (Section 28-2). These repressors often contain ~20-residue polypeptide segments that form a **helix–turn–helix (HTH) motif** containing two α helices that cross at an angle of ~120°. HTH motifs, which are apparently evolutionarily related, occur as components of domains that otherwise have widely varying structures, although all of them bind DNA. Note that HTH motifs are structurally stable only when they are components of larger proteins from which they protrude, permitting them to interact with DNA.

Like restriction endonuclease recognition sites, the sequences to which repressors bind (called **operators**) exhibit palindromic symmetry or nearly so.

(a)

(b)

FIG. 24-33 X-Ray structure of a portion of the 434 phage repressor in complex with its target DNA. One strand of the 20-bp DNA has the sequence d(TATACAAGAAAGTTTGTACT). (a) The complex as viewed with the homodimeric protein's twofold axis horizontal. The protein is drawn in ribbon form with one of its subunits blue and the other pink and with their helix–turn–helix (HTH) motifs in darker shades. The DNA is drawn in stick form with C white, N blue, O red, and P orange, and with successive P atoms in the same chain connected by orange rods. (b) A schematic drawing indicating how the helix–turn–helix motif, which encompasses helices $\alpha 2$ and $\alpha 3$, interacts with the DNA. Residues are identified by single-letter codes. Short bars emanating from the polypeptide chain represent peptide NH groups, dashed lines represent hydrogen bonds, and numbered circles represent DNA phosphates. The small circle is a water molecule. [Part a based on an X-ray structure by and Part b courtesy of Aneel Aggarwal, John Anderson, and Stephen Harrison, Harvard University. PDBId 2OR1.]

Typically, the repressors are dimeric, although their interactions with DNA may not be perfectly symmetrical. Binding involves interactions between the amino acid side chains extending from the second helix of the HTH motif (the “recognition” helix) and the bases and sugar–phosphate chains of the DNA. The X-ray structure of a dimeric repressor from **bacteriophage 434** bound to its 20-bp recognition sequence was determined by Stephen Harrison. The **434 repressor** associates with the DNA in a twofold symmetric manner with a recognition helix from each subunit bound in successive turns of the DNA's major groove (Fig. 24-33). The repressor closely conforms to the DNA surface and interacts with its paired bases and sugar–phosphate chains through elaborate networks of hydrogen bonds, salt bridges, and van der Waals contacts. In the repressor–DNA complex, the DNA bends around the protein in an arc of radius ~ 65 Å, which compresses the minor groove by ~ 2.5 Å near its center (between the two protein monomers) and widens it by ~ 2.5 Å toward its ends.

The *E. coli trp* Repressor Binds DNA Indirectly. The *E. coli trp* repressor regulates the transcription of genes required for tryptophan biosynthesis (Section 28-2C). Paul Sigler determined the X-ray structure of the protein in complex with a DNA containing an 18-bp palindrome (of single-strand sequence TGTACTAGTTTAACTAGTAC, where the *trp* repressor's target sequence is underlined) that closely resembles the *trp* operator. The homodimeric repressor protein also has HTH motifs whose recognition helices bind, as expected, in successive major grooves of the DNA, each in contact with half of the operator sequence (ACTAGT; Fig. 24-34). There are numerous hydrogen-bonding contacts between the *trp* repressor and the DNA's nonesterified phosphate oxygens. Astoundingly, however, there are no direct hydrogen bonds or nonpolar contacts that can explain the repressor's specificity for its operator. Rather, all but one of the side chain–base hydrogen-bonding interactions are mediated by bridging water molecules. In addition, the operator contains several base pairs that are not in contact with the repressor but whose mutation nevertheless greatly decreases repressor binding affinity. This suggests that *the operator assumes a sequence-specific conformation that makes favorable contacts with the repressor*. Other DNA sequences could conceivably assume the same conformation but at too high an energy cost to form a stable complex with the repressor. This phenomenon, in which a protein senses the base sequence of DNA through the DNA's backbone conformation and/or flexibility, is referred to as **indirect readout**. This finding puts to rest the notion that proteins recognize nucleic acid sequences exclusively via particular sets of pairings between amino acid side chains and nucleotide bases analogous to Watson–Crick base pairing.

The *met* Repressor Binds DNA via a Two-Stranded β Sheet. Simon Phillips first determined the X-ray structure of the *E. coli met* repressor in the absence of DNA (the *met* repressor regulates the transcription of genes involved in methionine biosynthesis). The homodimeric protein lacks an HTH motif, but model-building

FIG. 24-34 X-Ray structure of an *E. coli trp* repressor-operator complex. The complex is viewed with its molecular twofold axis horizontal. The protein's two identical subunits are drawn in ribbon form colored pink and blue with their HTH motifs more deeply colored. The 18-bp self-complementary DNA is shown in stick form with C white, N blue, O red, P orange, and with successive P atoms in the same chain connected by orange rods. The *trp* repressor binds its operator only when L-tryptophan, drawn in space-filling form with C green, is simultaneously bound. Note that the protein's recognition helices bind, as expected, in successive major grooves of the DNA but extend approximately perpendicular to the DNA helix axis, whereas those of 434 phage repressor are nearly parallel to the major grooves of its bound DNA (Fig. 24-33). [Based on an X-ray structure by Paul Sigler, Yale University. PDBid 1TRO.]

studies suggested that the repressor might bind to its palindromic target DNA via a symmetry-related pair of protruding α helices, reminiscent of the way the recognition helices of HTH motifs interact with DNA. However, the subsequently determined X-ray structure of the *met* repressor-operator complex showed that the protein actually binds its target DNA sequence through a pair of symmetrically related β strands (located on the opposite side of the protein from the protruding α helices) that form a two-stranded antiparallel β sheet that inserts into the DNA's major groove (Fig. 24-35). The β strands make sequence-specific contacts with the DNA via hydrogen bonding and, probably, indirect readout. This result indicates that the conclusions of even what appear to be straightforward model-building studies should be viewed with skepticism. In the case of the *met* repressor-operator complex, the model-building study favored the incorrect model because it could not take into account the small conformational adjustments that both the protein and the DNA make on binding one another.

FIG. 24-35 X-Ray structure of the *E. coli met* repressor-SAM-operator complex. The complex is viewed along its twofold axis of symmetry. The self-complementary 18-bp DNA is drawn in stick form, and S-adenosylmethionine (SAM), which must be bound to the repressor for it to also bind DNA, is shown in space-filling form. DNA C atoms are white, SAM C green, N blue, O red, P orange, and S yellow. Note that the DNA has four bound repressor subunits: Pairs of subunits (*light cyan* and *lavender*) form symmetric dimers in which each subunit donates one strand of the two-stranded β sheet that is inserted in the DNA's major groove (*upper left and lower right*). Two such dimers pair across the complex's twofold axis via their antiparallel N-terminal helices, which contact each other over the DNA's minor groove. [Based on an X-ray structure by Simon Phillips, University of Leeds, U.K. PDBid 1CMA.]

C Eukaryotic Transcription Factors May Include Zinc Fingers or Leucine Zippers

In eukaryotes, genes are selectively expressed in different cell types; this requires more complicated regulatory machinery than in prokaryotes. Prokaryotic repressors of known structure either contain an HTH motif or resemble the *met* repressor. However, eukaryotic DNA-binding proteins employ a much wider variety of structural motifs to bind DNA. A number of proteins known as **transcription factors** (Section 26-2C) promote the transcription of genes by binding to specific DNA sequences at or near those genes. In this section, we describe a variety of the DNA-binding motifs in eukaryotic transcription factors.

Zinc Fingers Form Compact DNA-Binding Structures. The first of the predominantly eukaryotic DNA-binding motifs, the **zinc finger**, was discovered by Klug in **transcription factor IIIA (TFIIIA)** from *Xenopus laevis* (an African clawed toad). The 344-residue TFIIIA contains nine similar, tandemly repeated, ~30-residue modules, each of which contains two invariant Cys residues and two invariant His residues. Each of these units binds a Zn^{2+} ion, which is tetrahedrally liganded by the Cys and His residues (a **Cys₂-His₂ zinc finger**; Fig. 6-37). In some zinc fingers, the two Zn^{2+} -liganding His residues are replaced by two additional Cys residues, whereas others have six Cys residues liganding two Zn^{2+} ions. Indeed, structural diversity is a hallmark of zinc finger proteins. In all cases, however, the Zn^{2+} ions appear to knit together relatively small globular domains, thereby eliminating the need for much larger hydrophobic protein cores (Section 6-4A).

The Cys₂-His₂ zinc finger contains a two-stranded antiparallel β sheet and one α helix. Three of these motifs are incorporated into a 72-residue segment of the mouse protein **Zif268**, whose X-ray structure in complex with a target DNA was elucidated by Carl Pabo (Fig. 24-36). The three zinc fingers are arranged as separate domains in a C-shaped structure that fits snugly into the DNA's major groove. Each zinc finger interacts in a conformationally identical manner with successive 3-bp segments of the DNA, predominantly through hydrogen bonds between the zinc finger's α helix and one strand of the DNA. Each zinc finger specifically hydrogen-bonds to two bases in the major groove. Interestingly, five

FIG. 24-36 X-Ray structure of the three-zinc finger segment of Zif268 in complex with DNA. The 10-bp DNA has a single nucleotide overhang at each end. The DNA is drawn in paddle form with C magenta, N blue, O red, and P orange and with successive P atoms connected by orange rods. The protein is drawn in cartoon form with finger 1 lavender, finger 2 colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), and finger 3 dark yellow. The Zn^{2+} ions are represented by cyan spheres, and their liganding His and Cys side chains are drawn in stick form with C green, N blue, and S yellow. Note how the N-terminal end of each zinc finger's helix extends into the DNA's major groove to contact three base pairs. [Based on an X-ray structure by Carl Pabo, MIT. PDBid 1ZAA.]

FIG. 24-37 X-Ray structure of the GAL4 DNA-binding domain in complex with DNA. (a) A ribbon diagram of the protein's zinc finger domain (residues 8–40) colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The six Cys side chains are shown in stick form with C green and S yellow, and the two Zn^{2+} ions are represented by cyan spheres. (b) The complex of the dimeric protein with the 19-bp DNA. The DNA is drawn in paddle form with C green, N blue, O red, and P orange and with successive P atoms connected by orange rods. The

protein is shown in ribbon form with one subunit pink and the other lavender. The views are along the complex's twofold axis (left) and turned 90° with the twofold axis horizontal (right). Note how the C-terminal end of each subunit's N-terminal helix extends into the DNA's major groove. [Based on an X-ray structure by Ronen Marmorstein and Stephen Harrison, Harvard University. PDBid 1D66.]

? Compare the structure in Part a with Fig. 6-37.

of the six associations involve Arg–guanine pairs. In addition to these sequence-specific interactions, each zinc finger hydrogen-bonds with the DNA's phosphate groups via conserved Arg and His residues.

The $\text{Cys}_2\text{-His}_2$ zinc finger broadly resembles the prokaryotic HTH motif as well as most other DNA-binding motifs we will encounter (including other types of zinc fingers). All these DNA-binding motifs provide a platform for inserting an α helix into the major groove of B-DNA. However, the $\text{Cys}_2\text{-His}_2$ zinc fingers, unlike other DNA-binding motifs, occur as modules that each contact successive DNA segments (some transcription factors contain over 60 zinc fingers). *Such a modular system can recognize extended asymmetric base sequences.*

A binuclear **Cys_6 zinc finger** mediates the DNA binding of the yeast protein **GAL4**, a transcriptional activator of several genes that encode galactose-metabolizing enzymes. Residues 1 to 65 of this 881-residue protein include six Cys residues that collectively bind two Zn^{2+} ions (Fig. 24-37a). Each Zn^{2+} ion is tetrahedrally coordinated by four Cys residues, with two of the residues ligating both metal ions. GAL4 binds to its 17-bp target DNA as a symmetric dimer (Fig. 24-37b), although in the absence of DNA it is a monomer. Each subunit includes a compact zinc finger (residues 8–40) that binds DNA, an extended linker (residues 41–49), and an α helix (residues 50–64) that assists in GAL4 dimerization. The N-terminal helix of the zinc finger inserts into the DNA's major groove, making sequence-specific contacts with a highly conserved CCG sequence at each end of the recognition sequence. The bound DNA retains its B conformation.

The dimerization helices of GAL4 (center of Fig. 24-37b) are positioned over the minor groove of the DNA. The linkers connecting those helices to the zinc fingers wrap around the DNA, largely following its minor groove. The two symmetrically related DNA-binding zinc fingers thereby approach

the major groove from opposite sides of the DNA, ~ 1.5 helical turns apart, rather than from the same side of the DNA, ~ 1 turn apart, as do HTH motifs. The resulting relatively open structure could permit other proteins to bind simultaneously to the DNA.

Some Transcription Factors Include Leucine Zippers. Segments of certain eukaryotic transcription factors, such as the yeast protein **GCN4**, contain a Leu at every seventh position. We have already seen that α helices with the seven-residue pseudorepeating sequence $(a-b-c-d-e-f-g)_n$, in which the a and d residues are hydrophobic, have a hydrophobic strip along one side that allows them to dimerize as a coiled coil (e.g., α -keratin; Section 6-1C). Steven McKnight suggested that DNA-binding proteins containing such **heptad repeats** also form coiled coils in which the Leu side chains might interdigitate, much like the teeth of a zipper (Fig. 24-38). In fact, these **leucine zippers** mediate the dimerization of certain DNA-binding proteins but are not themselves DNA-binding motifs.

The X-ray structure of the 33-residue polypeptide corresponding to the leucine zipper of GCN4 was determined by Peter Kim and Thomas Alber. The first 30 residues, which contain ~ 3.6 heptad repeats (Fig. 24-38a), coil into an ~ 8 -turn α helix that dimerizes as McKnight predicted to form $\sim 1/4$ turn of a parallel left-handed coiled coil (Fig. 24-38b). The dimer can be envisioned as a twisted ladder whose sides consist of the helix backbones and whose rungs are formed by the interacting hydrophobic side chains. The conserved Leu residues in the heptad position d , which corresponds to every second rung, are not interdigitated as McKnight originally suggested, but instead make side-to-side contacts. The alternate rungs are likewise formed by the a residues of the heptad repeat (which are mostly Val). These contacts form an extensive hydrophobic interface between the two helices.

In many leucine zipper-containing proteins, a DNA-binding region that is rich in basic residues is immediately N-terminal to the leucine zipper, and hence these proteins are known as **basic region leucine zipper (bZIP) proteins**. For example, in GCN4, the C-terminal 56 residues form an extended α helix. The last 25 residues of two such helices associate as a leucine zipper. The N-terminal portions of the helices smoothly diverge to bind in the major grooves on opposite sides of the DNA, thereby clamping the DNA in a sort of scissors grip

FIG. 24-38 The GCN4 leucine zipper motif. (a) A helical wheel representation of the motif's two helices as viewed from their N-termini. The sequences of residues at each position are indicated by the adjacent column of one-letter codes. Residues that form ion pairs in the crystal structure are connected by dashed lines. Note that all residues at positions d and d' are Leu (L), those at positions a and a' are mostly Val (V), and those at other positions are mostly polar. [After

O'Shea, E.K., Klemm, J.D., Kim, P.S., and Alber, T., *Science* **254**, 540 (1991).] (b) The X-ray structure, in side view, in which the helices are shown in ribbon form. Side chains are shown in stick form with the contacting Leu residues at positions d and d' yellow and side chains at positions a and a' with C green, N blue, and O red. [Based on an X-ray structure by Peter Kim, MIT, and Tom Alber, University of Utah School of Medicine. PDBid 2ZTA.]

FIG. 24-39 X-Ray structure of the GCN4 bZIP region in complex with its target DNA viewed with its twofold axis vertical. The DNA consists of a 19-bp segment with a single nucleotide overhang at each end and contains the protein's palindromic (except for the central base pair) 7-bp target sequence. The DNA is drawn in paddle form with C magenta, N blue, O red, and P orange and with successive P atoms connected by orange rods. The two identical GCN4 subunits, shown in ribbon form, each contain a continuous 52-residue α helix. At their C-terminal ends (*yellow*), the two subunits associate in a parallel coiled coil (a leucine zipper), and at their basic regions (*green*), they smoothly diverge to each engage the DNA in its major groove at the target sequence. [Based on an X-ray structure by Stephen Harrison, Harvard University. PDBid 1YSA.]

FIG. 24-40 X-Ray structure of Max binding to DNA viewed with its twofold axis vertical. Residues 22–113 of the 160-residue transcription factor Max form a complex with a 22-bp DNA containing the protein's palindromic 6-bp target sequence. The DNA is drawn in paddle form with C magenta, N blue, O red, and P orange and with successive P atoms connected by orange rods. The homodimeric protein is shown in ribbon form. Its N-terminal basic region (*green*) forms an α helix that engages its target sequence in the DNA's major groove and then merges smoothly with the H1 helix (*yellow*) of the basic helix–loop–helix (bHLH) motif. Following the loop (*red*), the protein's two H2 helices (*purple*) of the bHLH motif form a short parallel four-helix bundle with the two H1 helices. Each H2 helix then merges smoothly with the leucine zipper (Z) motif (*cyan*) to form a parallel coiled coil. The protein's C-terminal ends are pink [Based on an X-ray structure by Edward Ziff and Stephen Burley. The Rockefeller University. PDBid 1AN2.]

(Fig. 24-39). The basic region residues that are conserved in bZIP proteins make numerous contacts with both the bases and the phosphate oxygens of their DNA target sequence without distorting its conformation.

Many eukaryotic transcription factors contain a conserved DNA-binding basic region that is immediately followed by two amphipathic helices connected by a loop to form a so-called **basic helix–loop–helix (bHLH) motif**. The basic region, together with the N-terminal portion of the first (H1) helix of the bHLH motif, binds in the major groove of its target DNA. The C-terminal (H2) helix of the bHLH motif mediates the dimerization of the protein via the formation of a coiled coil. In many proteins, the bHLH motif is continuous with a leucine zipper (Z) that presumably augments the dimerization. Thus, as is shown in Fig. 24-40 for the protein **Max**, the dimeric **bHLH/Z** protein grips the DNA in a manner reminiscent of a pair of forceps. Each basic region contacts specific bases of the DNA as well as phosphate groups. Side chains of both the loop and the N-terminal end of the H2 helix also contact DNA phosphate groups.

CHECKPOINT

- Describe the types of interactions between nucleic acids and proteins.
- Why do restriction endonucleases make both site-specific and nonspecific contacts with DNA?
- How does the DNA binding of a zinc finger-containing transcription factor differ from that of a prokaryotic repressor?
- Explain why dimeric or multidomain proteins can bind to DNA with very high specificity.

5 Eukaryotic Chromosome Structure

KEY CONCEPTS

- Eukaryotic DNA is negatively supercoiled around a core of histone proteins to form a nucleosome.
- Nucleosomes are folded into higher-order chromatin structures.

Andrew Syred/Photo Researchers, Inc.

FIG. 24-41 Scanning electron micrograph of a metaphase chromosome. It consists of two sister (identical) **chromatids** joined at their **centromere** (the constricted region near the center of a chromosome through which it also attaches to the mitotic spindle). Chromosomes constitute a cell's largest molecular entities.

? How many DNA molecules does this chromosome contain?

Although each base pair of B-DNA contributes only $\sim 3.4 \text{ \AA}$ to its **contour length** (the end-to-end length of a stretched-out native molecule), DNA molecules are generally enormous (as shown on page 831). Indeed, the 23 chromosomes of the 3 billion-bp human genome have a total contour length of almost 1 m. One of the enduring questions of molecular biology is how such vast quantities of genetic information can be scanned and decoded in a reasonable time while stored in a small portion of the cell's volume.

The elongated shape of duplex DNA (its diameter is only 20 \AA) and its relative stiffness make it susceptible to mechanical damage when outside the protective environment of the cell. For example, a *Drosophila* chromosome, if expanded by a factor of 500,000, would have the shape and some of the mechanical properties of a 6-km-long strand of uncooked spaghetti. In fact, the **shear degradation** of DNA by stirring, shaking, or pipetting a DNA solution is a standard laboratory method for preparing DNA fragments.

Prokaryotic genomes typically comprise a single circular DNA molecule containing several million bp. However, eukaryotes condense and package their far larger genomes in several **chromosomes**. Each chromosome is a complex of linear duplex DNA and protein, a material known as **chromatin**, and is a dynamic entity whose appearance varies dramatically with the stage of the **cell cycle** (the general sequence of events that occur in the lifetime of a eukaryotic cell; Section 28-4A). For example, chromosomes assume their most condensed forms only during metaphase (**Fig. 24-41**), the stage of the cell cycle when the chromosomes align on the mitotic spindle. During the remainder of the cell cycle, when the DNA is transcribed and replicated, the chromosomes of most cells are highly dispersed. Yet the DNA of the chromosomes is still compacted relative to its free B-helix form. The DNAs in human chromosomes have contour lengths between 1.5 and 8.4 cm but in their most condensed state are only 1.3 to $10 \text{ }\mu\text{m}$ long. In this section, we examine how DNA is packaged in cells to achieve that degree of condensation.

A DNA Coils around Histones to Form Nucleosomes

Chromatin is about one-half protein by mass, and $\sim 90\%$ of this protein consists of **histones**. To understand how DNA is packaged, we must first examine the histone proteins. The five major classes of histones, **H1**, **H2A**, **H2B**, **H3**, and **H4**, all have a large proportion of positively charged residues (Arg and Lys; **Table 24-3**). These proteins can therefore bind DNA's negatively charged phosphate groups through electrostatic interactions.

Histones Are Highly Conserved. The amino acid sequences of histones H2A, H2B, H3, and H4 are remarkably conserved. For example, histones H4 from cows and peas, species that diverged 1.2 billion years ago, differ by only two conservative residue changes, which makes this protein among the most evolutionarily conserved proteins known (Section 5-4A). *Such evolutionary stability implies that the histones have critical functions to which their structures are so well tuned that they are all but intolerant to change.* The fifth histone, H1, is more variable than the other histones; we will see below that it also has a somewhat different role.

Histones are subject to numerous types of posttranslational modifications including methylation, acetylation, phosphorylation, glycosylation, and ubiquitination of specific Arg, Glu, His, Lys, Ser, Thr, and Tyr residues. Despite the histones' great evolutionary stability, their degree of modification varies enormously with the species, the tissue, and the stage of the cell cycle. As we will see in Section 28-3A, histone modifications have been linked to specific biological functions. These modifications probably create new protein binding sites on the histones themselves or on

TABLE 24-3 Calf Thymus Histones

Histone	Number of Residues	Mass (kD)	% Arg	% Lys
H1	215	23.0	1	29
H2A	129	14.0	9	11
H2B	125	13.8	6	16
H3	135	15.3	13	10
H4	102	11.3	14	11

the DNA with which they associate. In addition, many, if not all, eukaryotes have numerous genetically distinct subtypes of the canonical (standard) histones. These variant histones are associated with such essential functions as transcriptional initiation and termination, DNA repair, and recombination, and in the formation of specialized chromosomal segments known as **telomeres** (the chromosomal ends; Section 25-3C) and **centromeres** [the chromosomal regions through which paired chromatids are joined (Fig. 24-41) and which attach to the mitotic spindle].

The Nucleosome Core Particle Contains a Histone Octamer and 146 bp of DNA. The first level of chromatin organization was pointed out by Roger Kornberg in 1974 from several lines of evidence:

1. Chromatin contains roughly equal numbers of histones H2A, H2B, H3, and H4, and no more than half that number of histone H1.
2. Electron micrographs of chromatin preparations at low ionic strength reveal ~ 10 -nm-diameter particles connected by thin strands of apparently naked DNA, rather like beads on a string (Fig. 24-42).
3. Brief digestion of chromatin by **micrococcal nuclease** (which hydrolyzes double-stranded DNA) cleaves the DNA only between the above particles; apparently the particles protect the DNA closely associated with them from nuclease digestion. Gel electrophoresis indicates that each particle contains ~ 200 bp of DNA.

Kornberg proposed that the chromatin particles, which are called **nucleosomes**, consist of the octamer $(H2A)_2(H2B)_2(H3)_2(H4)_2$ in association with ~ 200 bp of DNA. The fifth histone, H1, was postulated to be associated in some other manner with the nucleosome (see below).

Micrococcal nuclease initially degrades chromatin to single nucleosomes in complex with histone H1. Further digestion trims away additional DNA, releasing histone H1. This leaves the so-called **nucleosome core particle**, which consists of a 146-bp segment of DNA associated with the histone octamer. A segment of **linker DNA**, the DNA that is removed by the nuclease, joins neighboring nucleosomes. Its average length varies between 10 and 50 bp among organisms and tissues.

The X-ray structure of the nucleosome core particle, independently determined by Timothy Richmond and Gerard Bunick, reveals a nearly twofold symmetric complex in which B-DNA is wrapped around the outside of the histone octamer in 1.65 turns of a left-handed superhelix (Fig. 24-43). Despite

FIG. 24-42 Electron micrograph of *D. melanogaster* chromatin showing strings of closely spaced nucleosomes.

FIG. 24-43 X-Ray structure of the chicken nucleosome core particle. (a) The entire core particle as viewed along its superhelical axis (*left*) and rotated 90° about the vertical axis (*right*). The proteins of the histone octamer are drawn in ribbon form with H3 blue, H4 green, H2A yellow, and H2B red. The 146-bp DNA is drawn in paddle form with one strand cyan and the other strand orange. In both views, the pseudo-twofold axis is vertical and passes through the DNA center at the top. (b) The half of the nucleosome core particle that is closest to the viewer in Part a, *left*. The numbers 0 through 7 arranged about the

inside of the DNA superhelix mark the positions of sequential double-helical turns. The four histones that are drawn in their entirety are primarily associated with this DNA segment, whereas only fragments of the H3 from the other half of the particle are shown. The two 4-helix bundles shown are labeled H3' H3 and H4 H2B. [Based on an X-ray structure by Gerard Bunick, University of Tennessee and Oak Ridge National Laboratory, Oak Ridge, Tennessee. PDBid 1EQZ.]

? Do the histones interact with specific DNA sequences?

FIG. 24-44 X-Ray structure of half of a histone octamer within the nucleosome core

particle. The portions of H2A, H2B, H3, and H4 that form the histone folds are yellow, red, blue, and green, respectively, with their N- and C-terminal tails colored in lighter shades. [Based on an X-ray structure by Gerard Bunick, University of Tennessee and Oak Ridge National Laboratory, Oak Ridge, Tennessee. PDBid 1EQZ.]

having only weak sequence similarity, all four types of histones share a similar ~ 70 -residue fold in which a long central helix is flanked on each side by a loop and a shorter helix (Fig. 24-44). Pairs of histones interdigitate in a sort of “molecular handshake” to form the crescent-shaped heterodimers H2A–H2B and H3–H4, each of which binds 2.5 turns of duplex DNA that curves around it in a 140° bend. The H3–H4 pairs interact, via a bundle of four helices from the two H3 histones, to form an $(\text{H3–H4})_2$ tetramer with which each H2A–H2B pair interacts, via a similar four-helix bundle between H2B and H4, to form the histone octamer (Fig. 24-43b).

The histones bind exclusively to the inner face of the DNA, primarily via its sugar–phosphate backbones, through hydrogen bonds, salt bridges, and helix dipoles (their positive N-terminal ends), all interacting with phosphate oxygens, as well as through hydrophobic interactions with the deoxyribose rings. There are few contacts between the histones and the bases, in accord with the nucleosome’s lack of sequence specificity. However, an Arg side chain is inserted into the DNA’s minor groove at each of the 14 positions at which it faces the histone octamer. The DNA superhelix has a radius of 42 Å and a pitch (rise per turn) of 26 Å. The DNA does not follow a uniform superhelical path but, rather, is bent fairly sharply at several locations due to outward bulges of the histone core. Moreover, the DNA double helix exhibits considerable conformational variation along its length such that its twist, for example, varies from 7.5 to 15.2 bp/turn with an average value of 10.4 bp/turn (versus 10.5 bp/turn for DNA in solution). Approximately 75% of the DNA surface is accessible to solvent and hence appears to be available for interactions with DNA-binding proteins.

Since the linking number of intact DNA is invariant, the negative supercoils produced by the left-handed wrapping of the DNA in forming nucleosomes must be accompanied by an equal number of positive supercoils in the adjacent linker DNA. The positive supercoils are subsequently removed by type II topoisomerase, the most abundant chromosomal protein after the histones. This is the origin of the negative supercoiling in eukaryotic DNA.

Linker Histones Bring Nucleosomes Together. In the micrococcal nuclease digestion of chromatin fibers, the ~ 200 -bp DNA is first degraded to 166 bp. Then there is a pause before histone H1 is released and the DNA is further shortened to 146 bp. Since the 146-bp DNA of the core particle makes 1.65 superhelical turns, the 166-bp intermediate should make nearly two full superhelical turns, which would bring its two ends close together. Klug has proposed that histone H1 binds to nucleosomal DNA at this point, where the DNA segments enter and leave the core particle (Fig. 24-45a). Chromatin fibers containing H1 have closely spaced nucleosomes (Fig. 24-45b), consistent with DNA entering and exiting the nucleosome on the same side. In H1-depleted chromatin (e.g., Fig. 24-42), the nucleosomes are more dispersed, suggesting that linker histones play a role in condensing chromatin fibers and regulating the access of other proteins to the DNA.

B Chromatin Forms Higher-Order Structures

Winding the DNA helix around a nucleosome reduces its contour length sevenfold (the 560-Å length of 166 bp is compacted to an ~ 80 -Å-high supercoil). Under physiological conditions, chromatin condenses further by folding in a zigzag fashion to form a helical fiber with a diameter of ~ 30 nm.

FIG. 24-45 Binding of histone H1 to the nucleosome. (a) Model of histone H1 binding to the DNA of the 166-bp nucleosome. The two complete superhelical turns of the DNA (blue) enable H1 (orange cylinder) to bind to the DNA's two ends and its middle. The histone octamer is represented by the yellow central spheroid. (b) Electron micrograph of H1-containing chromatin.

? Compare Part b with Fig. 24-42.

Guohong Li determined the cryo-EM-based structure (Section 6-2A) of a 12-nucleosome segment of a **30-nm chromatin fiber** that was reconstituted *in vitro* from recombinant histones (including histone H1) that lacked posttranslational modifications and DNA consisting of 12 tandem repeats of 187 bp that have high affinity for histone octamers. (Fig. 24-46a). The nucleosomes, which form tetranucleosome units, follow a zigzag path such that all odd-numbered nucleosomes form a stack as do all even-numbered nucleosomes (Fig. 24-46b). This ~300-Å-diameter structure, in which the two stacks wind around each other in two left-handed helices, has ~28 nucleosomes per turn spanning a distance of ~500 Å along the fiber axis. The ~18,000-Å-long DNA in this assembly is thereby compacted by ~36-fold.

FIG. 24-46 Cryo-EM structure of a 12-nucleosome segment of the 30-nm chromatin fiber in which the DNA consists of 12 tandem repeats of 187 bp. (a) A surface diagram of the 11-Å-resolution structure in which each tetranucleosome unit is differently colored. The upper view is along the assembly's double helical axis and the lower view is related to it by a 90° rotation about the horizontal axis. In the lower view, successive nucleosomes along the DNA are numbered N1, N2, etc. (b) A schematic model of the cryo-EM structure in which the histone

octamers are colored and numbered as in Part a and the DNA is represented by a green filament. (c) A model of the 30-nm chromatin fiber constructed by stacking multiple copies of the 12-nucleosome unit in Part a on top of one another. The color of the DNA component of the nucleosomes alternates as it does in Part a, the histone octamers in one helix are green, and those in the other helix are red. [Courtesy of Guohong Li, Chinese Academy of Sciences, Beijing, China.]

The nucleosomes in the 12-nucleosome assembly are equally spaced along its DNA so that the linker DNA segments joining successive nucleosomes all consist of 41 bp. These segments appear to be straight in the cryo-EM structure (Figs. 24-46*a* and *b*). However, in naturally occurring chromatin, the nucleosomes are irregularly spaced along the DNA so that the linker DNA segments are of variable lengths. Consequently, naturally occurring 30-nm chromatin fibers are expected to have irregular structures compared to that depicted in Fig. 24-46*c*. This irregularity is compounded by variable histone modifications and different histone variants.

The 30-nm fiber is stabilized by interactions involving H2A–H2B dimers and histone H4. As the X-ray structure of the nucleosome shows (Fig. 24-43*a*), H4's positively charged N-terminal tail can bind to an intensely negatively charged region on an exposed face of the H2A–H2B dimer in a neighboring nucleosome. Acetylation of H4's N-terminal tail reduces its positive charge and would therefore weaken this interaction. The highly basic tails of H2B and H3 also extend out from the nucleosome core (Fig. 24-43*a*). Since histone tails contain numerous acetylation sites, higher-order chromatin structure is likely to be controlled, at least in part, by the acetylation of certain histone residues but not others.

Loops of DNA Are Attached to a Scaffold. Histone-depleted metaphase chromosomes exhibit a central fibrous protein “scaffold” surrounded by an extensive halo of DNA (Fig. 24-47*a*). The strands of DNA that can be followed form loops that enter and exit the scaffold at nearly the same point (Fig. 24-47*b*). Most of the loops are 15 to 30 μm long (which corresponds to 45–90 kb), so when condensed as 30-nm filaments, they would be $\sim 0.6 \mu\text{m}$ long. Electron micrographs of metaphase chromosomes in cross section, such as Fig. 24-48, strongly suggest that the loops of chromatin are radially arranged and would each contribute 0.3 μm to the diameter of the chromosome (a fiber must double back on itself to form a loop). These loops, along with the 0.4- μm width of the scaffold, would account for the

FIG. 24-47 Electron micrographs of a histone-depleted metaphase human chromosome. (a) The fibrous central protein matrix (scaffold)

anchors the surrounding DNA. (b) Higher magnification reveals that the DNA is attached to the scaffold in loops.

FIG. 24-48 Cross section of a metaphase human chromosome. Note the mass of chromatin fibers radially projecting from the central scaffold.

1.0- μm diameter of the metaphase chromosome. Each loop, in effect, forms a closed circle by the attachment of its base to the scaffold and thereby maintains its negative supercoiling.

A typical human chromosome, which contains ~ 140 million bp and is about 6 μm long, would therefore have ~ 2000 radial loops. Nonhistone proteins, which constitute $\sim 10\%$ of the chromosomal proteins, participate in organizing the DNA in these higher-order structures (Fig. 24-49) and managing the interconversion of highly condensed metaphase chromosomes with the more dispersed DNA present during the rest of the cell cycle.

FIG. 24-49 Model diagramming the various levels of metaphase chromatin organization. B-DNA winds around histone octamers to form nucleosomes; these fold into a 30-nm fiber. Loops of chromatin are attached to a protein scaffold to form the metaphase chromosome.

FIG. 24-50 The chromosomal organization in a human interphase nucleus as determined by FISH. A computer-generated section through the nucleus in which each chromosomal species is identified by its number and is assigned a different false color. A stack of such images locates each of the cell's 46 chromosomes in three dimensions. Note that homologous chromosomes (e.g., the two copies of chromosome 7) occupy different although usually similarly placed territories in the nucleus. [Courtesy of Thomas Cremer and Andreas Bolzer, University of Munich, Germany.]

In prokaryotes, DNA is also packaged through its association with highly basic proteins that functionally resemble histones. Nucleosome-like particles condense to form large loops that are attached to a protein scaffold, yielding a relatively compact chromosome.

Interphase Chromosomes Occupy Discrete Nuclear Territories. During **interphase**, the portion of the cell cycle between cell divisions, the chromosomes form diffuse structures that collectively fill the cell nucleus (Fig. 1-8). How are these chromosomes distributed? This question was answered using a method known as **fluorescence *in situ* hybridization (FISH; *in situ*, Latin: on site)** in which the chromosomes in an interphase nucleus are “painted” with a mixture of RNA or DNA probes complementary to specific sequences that are scattered throughout the chromosomes and in which the probes are labeled by a chromosome-specific combination of **fluorophores** (fluorescent groups). The chromosomal sites to which the probes hybridize are then located in three dimensions by a sophisticated form of fluorescence microscopy that acquires a series of images at different levels in the nucleus and spectrally differentiates the various combinations of fluorophores. The resulting images reveal that each chromosome occupies a specific space or **territory** in the nucleus that does not greatly overlap the territories of other chromosomes (Fig. 24-50). The territory occupied by a particular chromosome does not greatly vary during the lifetime of a cell, but changes after cell division.

Images such as Fig. 24-50 might naively suggest that the nucleus is tightly packed with chromatin. However, a rough calculation indicates that chromatin as 10-nm fibers occupies only ~17% of the nuclear volume. Moreover, electron micrographs of interphase nuclei reveal that their chromatin is dispersed mainly as 10- and 30-nm fibers, and FISH experiments have shown that RNA transcripts are distributed throughout chromosomal territories. Evidently, there is sufficient space within chromosomal territories to allow free access of the transcriptional machinery and presumably the replicational machinery to its target DNA.

CHECKPOINT

- Explain why histones from different species are so similar.
- What is the role of histones in compacting DNA?
- How do histones differ from the DNA-binding proteins described in the preceding section?
- Describe the levels of DNA packaging in eukaryotic cells, from B-DNA to a metaphase chromosome.

Summary

1 The DNA Helix

- The most common form of DNA is B-DNA, which is a right-handed double helix containing A · T and G · C base pairs of similar geometry. The A-DNA helix, which also occurs in double-stranded RNA, is wider and flatter than the B-DNA helix. The left-handed Z-DNA helix may occur in sequences of alternating purines and pyrimidines.
- The flexibility of nucleotides in nucleic acids is constrained by the allowed rotation angles around the glycosidic bond, the puckering of the ribose ring, and the torsion angles of the sugar–phosphate backbone.
- The linking number (L) of a covalently closed circular DNA is topologically invariant. Consequently, any change in the twist (T) of a circular duplex must be balanced by an equal and opposite change in its writhing number (W), which indicates its degree of supercoiling.
- Naturally occurring DNA is negatively supercoiled (underwound). Topoisomerases relax supercoils by cleaving one or both strands of the DNA, passing the DNA through the break (type IA and II topoisomerases) or allowing controlled rotation of the uncleaved strand (type IB topoisomerase), and resealing the broken strand(s).

2 Forces Stabilizing Nucleic Acid Structures

- The structures of nucleic acids are stabilized by Watson–Crick base pairing, by hydrophobic interactions between stacked base pairs, and by divalent cations that shield adjacent phosphate groups.
- Nucleic acids can be denatured by increasing the temperature above their T_m and renatured by lowering the temperature to $\sim 25^\circ\text{C}$ below their T_m .

- RNA molecules assume a variety of structures consisting of double-stranded stems and single-stranded loops. Some RNAs have catalytic activity.

3 Fractionation of Nucleic Acids

- Nucleic acids are fractionated by methods similar to those used to fractionate proteins, including solubilization, affinity chromatography, and electrophoresis.

4 DNA–Protein Interactions

- Sequence-specific DNA-binding proteins interact primarily with bases in the major groove and with phosphate groups through direct and indirect hydrogen bonds, van der Waals interactions, and ionic interactions. The conformations of both the protein and the DNA may change on binding.
- Common structural motifs in DNA-binding proteins include the helix–turn–helix (HTH) motif in prokaryotic repressors, and zinc fingers, leucine zippers, and basic helix–loop–helix (bHLH) motifs in eukaryotic transcription factors.

5 Eukaryotic Chromosome Structure

- The DNA of eukaryotic chromatin winds around histone octamers to form nucleosome core particles that further condense in the presence of linker histones. Additional condensation is accomplished by folding chromatin into 30-nm-diameter filaments, which are then attached in loops to a fibrous protein scaffold to form a condensed (metaphase) chromosome. During interphase, chromosomes are loosely distributed in territories.

Problems

EXERCISES

1. Unusual bases and non-Watson–Crick base pairs frequently appear in tRNA molecules. Which base is most likely to pair with hypoxanthine (Section 23-1)? Draw this base pair.
2. Draw the structure of a G · U base pair.
3. Amino acid residues in proteins are each specified by three contiguous bases. What is the contour length of a segment of B-DNA that encodes a 50-kD protein?
4. Calculate the contour length for the gene in in Problem 3 if it assumed an A-DNA conformation.

5. Virus-infected cells produce the intracellular messenger cGAMP, a cyclic dinucleotide in which the GMP 2'-OH group is linked to the 5'-phosphate of AMP. Draw its structure.

6. Use the information in Table 11-1 to estimate the half-life, in years, of a phosphodiester bond in DNA.

7. The ends of eukaryotic chromosomes terminate in a G-rich single-stranded overhang that can fold up on itself to form a four-stranded structure. In this structure, four guanine residues assume a hydrogen-bonded planar arrangement with an overall geometry that can be represented as shown below. Draw the complete structure of this “G quartet,” including the hydrogen bonds between the purine bases.

8. Show schematically how a single strand of four repeating TTAGGG sequences can fold to generate a structure with three stacked G quartets linked by TTA loops.
9. Which of the DNAs shown in Figure 24-8 would move fastest during agarose gel electrophoresis?
10. You have discovered an enzyme secreted by a particularly virulent bacterium that cleaves the C2'—C3' bond in the deoxyribose residues of duplex DNA. What is the effect of this enzyme on supercoiled DNA?
11. How is the melting curve of duplex DNA affected by decreasing the ionic strength of the solution?
12. How is the melting curve of duplex DNA affected by adding a small amount of ethanol?
13. Compare the melting temperature of a 1-kb segment of DNA containing 20% A residues to that of a 1-kb segment containing 30% A residues under the same conditions.
14. The melting curve for the polyribonucleotide poly(A) is shown below. (a) Explain why absorbance increases with increasing temperature. (b) Why does the shape of the curve differ from the one shown in Fig. 24-22?

15. For the RNA sequence AUUGGCAUCCGAUAA, draw the secondary structure that maximizes its base pairing.
16. In addition to the standard base-paired helical structures (e.g., Fig. 24-2), DNA can form X-shaped hairpin structures called **cruciforms** in which most bases are involved in Watson–Crick pairs. Such structures tend to occur at sequences with inverted repeats. Draw the cruciform structure formed by the DNA sequence TCAAGTCCACG-GTGGACTTGC.
17. *E. coli* ribosomes contain three RNA molecules named for their sedimentation behavior: 5S, 16S, and 23S. Draw a diagram showing the approximate positions of the three RNA species following electrophoresis.

18. Mouse genomic DNA is treated with a restriction endonuclease and electrophoresed in an agarose gel. A radioactive probe made from the human gene *rxr-1* is used to perform a Southern blot. The experiment was repeated three times. Explain the results of these repeated experiments:

Experiment 1. The autoradiogram shows a large smudge at a position corresponding to the top of the lane in which the mouse DNA was electrophoresed.

Experiment 2. The autoradiogram shows a smudge over the entire lane containing the mouse DNA.

Experiment 3. The autoradiogram shows three bands of varying intensity.

19. What is the probability that the palindromic symmetry of the *trp* repressor target DNA sequence (Section 24-4B) is merely accidental?

20. The *E. coli* genome contains approximately 4639 kb. (a) How many copies of the 6-bp recognition sequence for the *trp* repressor would be expected to occur in the *E. coli* chromosome? (b) Explain why it is advantageous for the *trp* repressor to be a dimer that recognizes two adjacent 6-bp sequences.

21. Protamines are small proteins that take the place of histones during spermatogenesis in vertebrates. What amino acids are likely to be abundant in protamines?

22. The enzyme ornithine decarboxylase generates a product that has been proposed to play a role in stabilizing compacted DNA. Draw the structure of the ornithine decarboxylase reaction product and explain how it interacts with DNA.

23. Infection with the influenza virus interferes with the normal expression of genes in the host cell. The viral protein M1 binds to histones electrostatically. (a) Would increasing the salt concentration promote or weaken M1–histone binding? (b) Would decreasing the pH promote or weaken M1–histone binding?

24. The NS1 protein in the H3N2 strain of the influenza virus has a C-terminal sequence of –KMARTARSKV (using one-letter amino acid abbreviations). The N-terminus of histone H3 has the sequence ART-KQTARKS–. (a) Identify the four-residue segment that is almost identical in the two proteins. (b) NS1 does not appear to compete with histone H3 for DNA binding (since the N-terminus of H3 does not directly contact the DNA). How else might NS1's similarity to H3 interfere with host gene expression?

25. For a linear B-DNA molecule of 50,000 kb, calculate (a) the contour length and (b) the length of the DNA as packaged in nucleosomes with linker histones present.

26. Calculate the length of the 50,000-bp DNA in a 30-nm fiber.

27. Most protein-coding genes are present in just one copy per genome. Explain why eukaryotic genomes typically contain dozens of copies of histone genes.

28. Eukaryotic DNA is typically covalently modified by methylation of certain nucleotide bases. How would the addition of methyl groups affect the packaging of DNA in nucleosomes?

CHALLENGE QUESTIONS

29. A standard A · T base pair is shown in Fig. 24-1. Under certain conditions, an adenine residue in B-DNA can transiently adopt the syn conformation. Draw the resulting A · T base pair. (*Hint:* It has two hydrogen bonds.) Is the helix diameter larger or smaller in this alternate arrangement?

30. A standard G · C base pair is shown in Fig. 24-1. Under certain conditions, the guanine residue can transiently adopt the syn conformation. Draw the resulting G · C base pair, which has two hydrogen bonds.

31. Compounds known as peptide nucleic acids (PNAs) have been developed as nucleic acid-binding probes. A PNA molecule has a polypeptide-like backbone with purine and pyrimidine bases attached as side chains. Draw the PNA backbone resulting from amide bond formation between two molecules of *N*-(2-aminoethyl)glycine.

32. The asterisk in the structure shown in Problem 31 indicates the site where the base is attached via a two-carbon linker. Compare the overall backbone length for a PNA and a DNA molecule and explain why the two molecules can form base-paired duplexes.

33. Why are the most commonly observed conformations of the ribose ring those in which either atom C2' or atom C3' is out of the plane of the other four ring atoms? (*Hint:* In puckering a planar ring such that one atom is out of the plane of the other four, the substituents about the bond opposite the out-of-plane atom remain eclipsed. This is best observed with a ball-and-stick model.)

34. At Na^+ concentrations >5 M, the T_m of DNA decreases with increasing $[\text{Na}^+]$. Explain this behavior. (*Hint:* Consider the solvation requirements of Na^+ .)

35. When the helix axis of a closed circular duplex DNA of 2310 bp is constrained to lie in a plane, the DNA has a twist (T) of 207. When released, the DNA takes up its normal twist of 10.5 bp per turn. Indicate the values of the linking number (L), writhing number (W), and twist for both the constrained and unconstrained conformational states of this DNA circle. What is the superhelix density, $\sigma = W/T$, of both the constrained and unconstrained DNA circles?

36. A closed circular duplex DNA has a 100-bp segment of alternating C and G residues. On transfer to a high salt solution, the segment undergoes a transition from the B conformation to the Z conformation. What is the change in its linking number, writhing number, and twist?

37. Polyoma virus DNA can be separated by sedimentation in an ultracentrifuge (Section 5-2E) at neutral pH into three components that have sedimentation coefficients of 20, 16, and 14.5S and that are known as Types I, II, and III DNAs, respectively. These DNAs all have identical base sequences and molecular masses. In 0.15 M NaCl, both Types II and III DNA have melting curves of normal cooperativity and a T_m of 88°C. Type I DNA, however, exhibits a very broad melting curve and a T_m of 107°C. At pH 13, Types I and III DNAs have sedimenta-

tion coefficients of 53 and 16S, respectively, and Type II separates into two components with sedimentation coefficients of 16 and 18S. How do Types I, II, and III DNAs differ from one another? Explain their different physical properties.

38. A bacterial chromosome consists of a protein–DNA complex in which its single DNA molecule appears to be supercoiled. However, in contrast to the case with naked circular duplex DNA, the light single-strand nicking of chromosomal DNA does not abolish this supercoiling. What does this indicate about the structure of the bacterial chromosome, that is, how do its proteins constrain its DNA?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Conformations of DNA

Exercise 2 Melting Temperature and the GC Content of Duplex DNA

Exercise 3 Viewing and Analyzing DNA-Binding Proteins

CASE STUDY www.wiley.com/college/voet

Case 31 Hyperactive DNase I Variants: A Treatment for Cystic Fibrosis

Focus concept: Understanding the mechanism of action of an enzyme can lead to the construction of hyperactive variant enzymes with a greater catalytic efficiency than the wild-type enzyme.

Prerequisites: Chapters 12 and 24

- Enzyme kinetics and inhibition
- DNA structure
- The hyperchromic effect
- The properties of supercoiled DNA

MORE TO EXPLORE How many histone variants occur in human cells? How do they differ from each other? How does the histone variant CENP-A relate to chromosomal structure? Which histone variant is associated with X-chromosome inactivation?

CHAPTER 25

DNA Replication, Repair, and Recombination

Chapter Contents

1 Overview of DNA Replication

2 Prokaryotic DNA Replication

- A DNA Polymerases Add the Correctly Paired Nucleotide
- B Replication Initiation Requires Helicase and Primase
- C The Leading and Lagging Strands Are Synthesized Simultaneously
- D Replication Terminates at Specific Sites
- E DNA Is Replicated with High Fidelity

3 Eukaryotic DNA Replication

- A Eukaryotes Use Several DNA Polymerases
- B Eukaryotic DNA Is Replicated from Multiple Origins
- C Telomerase Extends Chromosome Ends

4 DNA Damage

- A Environmental and Chemical Agents Generate Mutations
- B Many Mutagens Are Carcinogens

5 DNA Repair

- A Some Damage Can Be Directly Reversed
- B Base Excision Repair Requires a Glycosylase
- C Nucleotide Excision Repair Removes a Segment of a DNA Strand
- D Mismatch Repair Corrects Replication Errors
- E Some DNA Repair Mechanisms Introduce Errors

6 Recombination

- A Homologous Recombination Involves Several Protein Complexes
- B DNA Can Be Repaired by Recombination
- C CRISPR–Cas9, a System for Editing and Regulating Genomes
- D Transposition Rearranges Segments of DNA

Dr. Gopal Murthi/Science Source

In these human nuclei, fluorescent spots mark the locations of DNA polymerase, many copies of which are required to replicate the enormous chromosomes quickly and efficiently.

Watson and Crick's seminal paper describing the DNA double helix ended with the statement: "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material." As they predicted, when DNA replicates, each polynucleotide strand acts as a template for the formation of a complementary strand through base pairing interactions. The two strands of the parent molecule must therefore separate so that a complementary daughter strand can be enzymatically synthesized on the surface of each parental strand. This results in two molecules of duplex DNA, each consisting of one polynucleotide strand from the parental molecule and a newly synthesized complementary strand (Fig. 3-11). Such a mode of replication is termed **semiconservative** (in **conservative replication**, the parental DNA would remain intact and both strands of the daughter duplex would be newly synthesized).

The semiconservative nature of DNA replication was elegantly demonstrated in 1958 by Matthew Meselson and Franklin Stahl. The density of DNA was increased by labeling it with ^{15}N , a heavy isotope of nitrogen (^{14}N is the naturally abundant isotope). This was accomplished by growing *E. coli* in a medium that contained $^{15}\text{NH}_4\text{Cl}$ as its only nitrogen source. The labeled bacteria were then abruptly transferred to a ^{14}N -containing medium and the density of their DNA was monitored over several generations by density gradient ultracentrifugation (Section 5-2E).

Meselson and Stahl found that after one generation (one doubling of the cell population), all the DNA had a density exactly halfway between the densities of fully ^{15}N -labeled DNA and unlabeled DNA. This DNA must therefore contain equal amounts of ^{14}N and ^{15}N as is expected after one generation of

FIG. 25-1 The Meselson and Stahl experiment. Parental (^{15}N -labeled or “heavy”) DNA is replicated semiconservatively so that in the first generation, DNA molecules contain one parental (*blue*) strand and one newly synthesized (*red*) strand. In succeeding generations, the proportion of ^{14}N -labeled (“light”) strands increases, but hybrid molecules containing one heavy and one light strand persist. **WPLS** See the Animated Figures.

? Draw a diagram of the DNA molecules that would be produced by conservative replication.

semiconservative replication (**Fig. 25-1**). Conservative DNA replication, in contrast, would preserve the fully ^{15}N -labeled parental strand and generate an equal amount of unlabeled DNA. After two generations, half of the DNA molecules were unlabeled and the remainder were ^{14}N - ^{15}N hybrids. In succeeding generations, the amount of unlabeled DNA increased relative to the amount of hybrid DNA although the hybrid never totally disappeared. This is in accord with semiconservative replication but at odds with conservative replication, in which hybrid DNA never forms.

The details of DNA replication, including the unwinding of the parental strands and the assembly of complementary strands from nucleoside triphosphates, have emerged gradually since 1958. DNA replication is far more complex than the overall chemistry of the process might suggest, in large part because replication must be extremely accurate to preserve the integrity of the genome from generation to generation. In this chapter, we examine the protein assemblies that mediate DNA replication in prokaryotes and eukaryotes. We also discuss the mechanisms for ensuring fidelity during replication and for correcting polymerization errors and other types of DNA damage.

1 Overview of DNA Replication

KEY CONCEPTS

- DNA polymerase requires a template and primers to synthesize DNA.
- Double-stranded DNA is replicated semidiscontinuously.

GATEWAY CONCEPT The Central Dogma

DNA replication can be considered as part of the central dogma of molecular biology. Biological information in the form of a DNA sequence is copied—with great accuracy—when one DNA molecule is replicated to produce two identical DNA molecules. When the cell divides, each daughter cell will receive one of the copies.

DNA is replicated by enzymes known as **DNA-directed DNA polymerases** or simply **DNA polymerases**. These enzymes use single-stranded DNA (ssDNA) as templates on which to catalyze the synthesis of the complementary strand from the appropriate deoxynucleoside triphosphates (**Fig. 25-2**). The reaction occurs through the nucleophilic attack of the growing DNA chain’s 3’-OH group on the α -phosphoryl of an incoming nucleoside triphosphate. This otherwise

FIG. 25-2 Action of DNA polymerases.

These enzymes assemble incoming deoxynucleoside triphosphates on single-stranded DNA templates. The OH group at the 3’ end of a growing polynucleotide strand is a nucleophile that attacks the α -phosphate group of an incoming dNTP that base-pairs with the template DNA strand, and hence the growing strand is elongated in its 5’ \rightarrow 3’ direction. Although formation of the new phosphodiester bond is reversible (one P–O bond replaces another), the subsequent exergonic hydrolysis of the PP_i product by inorganic pyrophosphatase makes the overall reaction irreversible.

FIG. 25-3 An autoradiogram and its interpretive drawing of a replicating *E. coli* chromosome. The bacterium had been grown in a medium containing [^3H]thymidine, thereby labeling the subsequently synthesized DNA so that it appears as a line of dark grains in the photographic emulsion (*red lines in the drawing*). The size of the **replication eye** indicates that this circular chromosome is about one-eighth duplicated. The arrows indicate the direction of movement of the replication forks. [Courtesy of John Cairns, Cold Spring Harbor Laboratory.]

? Make an interpretive drawing of the chromosome when it is seven-eighths replicated.

reversible reaction is driven by the subsequent hydrolysis of the eliminated PP_i . The incoming nucleotides are selected by their ability to form Watson–Crick base pairs with the template DNA so that the newly synthesized DNA strand forms a double helix with the template strand. Nearly all known DNA polymerases can add a nucleotide only to the free 3'-OH group of a base-paired polynucleotide so that *DNA chains are extended only in the 5' → 3' direction*.

DNA Replication Occurs at Replication Forks. John Cairns observed DNA replication through the autoradiography of chromosomes from *E. coli* grown in a medium containing [^3H]thymidine. These circular chromosomes contain replication “eyes” or “bubbles” (Fig. 25-3), called **θ structures** (after their resemblance to the Greek letter theta), that form when the two parental strands of DNA separate to allow the synthesis of their complementary daughter strands. DNA replication involving θ structures is known as **θ replication**.

The branch points in a replication eye, at which DNA synthesis occurs, are called **replication forks**. Autoradiographic studies have demonstrated that θ replication is almost always **bidirectional**. In other words, *DNA synthesis proceeds in both directions from the point where replication is initiated, so that the replication forks move apart*.

Replication Is Semidiscontinuous. The low-resolution images provided by autoradiograms such as Fig. 25-3 suggest that duplex DNA's two antiparallel strands are simultaneously replicated at an advancing replication fork. Yet since DNA polymerases extend DNA strands only in the 5' → 3' direction, how can they copy the parental strand that extends in the 5' → 3' direction past the replication fork? This question was answered in 1968 by Reiji Okazaki through the following experiment. If a growing *E. coli* culture is **pulse labeled** for 30 s with [^3H]thymidine before the DNA is isolated, much of the radioactive and hence newly synthesized DNA consists of 1000- to 2000-nucleotide (**nt**) fragments (in eukaryotes, these so-called **Okazaki fragments** are 100–200 nt long). When the cells are transferred to an unlabeled medium after the [^3H]thymidine pulse, the size of the labeled fragments increases over time. *The Okazaki fragments must therefore become covalently incorporated into larger DNA molecules*.

Okazaki interpreted his experimental results in terms of the **semidiscontinuous replication** model (Fig. 25-4). The two parent strands are replicated in different ways. The newly synthesized DNA strand that extends 5' → 3' in the direction of replication fork movement, the **leading strand**, is continuously synthesized in its 5' → 3' direction as the replication fork advances. The other new strand, the **lagging strand**, is also synthesized in its 5' → 3' direction. However, it can only be made discontinuously, as Okazaki fragments, as single-stranded

FIG. 25-4 Semidiscontinuous DNA replication. Both daughter strands (*leading strand red, lagging strand blue*) are synthesized in their 5' → 3' direction. The leading strand is synthesized continuously, whereas the lagging strand is synthesized discontinuously. The lagging strand segments are known as Okazaki fragments.

? Identify the newest and oldest Okazaki fragments.

FIG. 25-5 Priming of DNA synthesis by short RNA segments. Each Okazaki fragment consists of an RNA primer (green) that has been extended by DNA polymerase. The RNA primer is later removed.

CHECKPOINT

- What did Meselson and Stahl's experiment reveal about DNA replication?
- Explain why DNA polymerase requires a template and a primer.
- Why must DNA be replicated semidiscontinuously?

parental DNA becomes newly exposed at the replication fork. The Okazaki fragments are later covalently joined together by the enzyme **DNA ligase**.

DNA Synthesis Extends RNA Primers. Given that DNA polymerases require a free 3'-OH group to extend a DNA chain, how is DNA synthesis initiated? Careful analysis of Okazaki fragments revealed that their 5' ends consist of RNA segments of 1 to 60 nt (the length is species dependent) that are complementary to the template DNA chain (**Fig. 25-5**). In *E. coli*, these **RNA primers** are synthesized by the enzyme **primase**, which, like all RNA polymerases, initiates RNA synthesis by linking together two ribonucleotides. Multiple primers are required for lagging strand synthesis, but only one primer is required to initiate synthesis of the leading strand. Mature DNA, however, does not contain RNA. *The RNA primers are eventually replaced with DNA.*

2 Prokaryotic DNA Replication

KEY CONCEPTS

- DNA polymerases include 3' → 5' exonuclease activity and, in the case of Pol I, 5' → 3' exonuclease activity.
- DNA replication requires additional proteins to separate DNA strands, unwind the helix, bind to single-stranded DNA, and synthesize RNA primers.
- A sliding clamp is loaded onto the template DNA to enhance the processivity of DNA polymerase.
- Complete replication of DNA requires DNA ligase, a termination factor, and topoisomerases.
- Balanced nucleotide levels, the polymerase mechanism, its proofreading mechanism, and the activities of DNA repair enzymes contribute to the accuracy of DNA replication.

DNA replication involves a great variety of enzymes in addition to those mentioned above. Many of the required enzymes were first isolated from prokaryotes and are therefore better understood than their eukaryotic counterparts. Accordingly, we begin with a detailed consideration of prokaryotic DNA replication. Replication in eukaryotes is discussed in Section 25-3.

Arthur Kornberg (1918–2007) Like a number of his contemporaries during the Great Depression, Arthur Kornberg entered medical school because of the lack of jobs in teaching or industry. He subsequently served in the U.S. Coast Guard as a ship's doctor but quickly realized that he was better suited to the laboratory than the sea. When he began his work at the

National Institutes of Health in 1942, the classic studies of nutrition and vitamins were giving way to the new science of enzymology.

After purifying aconitase from rat hearts, Kornberg stated that he found enzymes intoxicating. He likened purifying an enzyme to ascending an uncharted mountain, with the reward being the view from the top and the satisfaction of being the first one there.

Kornberg spent 6 months at the Cori laboratory (Box 16-1) and in 1948 began working on enzymes involved in the synthesis of nucleotide cofactors. He found that the enzyme nucleotide pyrophosphorylase catalyzed a reaction in which a nucleotide was incorporated into a coenzyme:

Next, Kornberg began to search for an enzyme that could assemble many nucleotides to make a nucleic acid chain. Some people have mistakenly assumed that Kornberg was inspired to look for DNA polymerase by the publication of the Watson–Crick model of DNA in 1953. In fact, Kornberg was following his instincts as an enzymologist, and his curiosity stemmed from his familiarity with other enzymes, including glycogen phosphorylase, which was capable of synthesizing the polymer glycogen *in vitro*. Kornberg had also experimented with enzymes involved in the synthesis of phospholipids, which—like DNA—contain phosphodiester bonds (he abandoned this line of investigation because he didn't like working with “greasy” molecules).

To purify a DNA-synthesizing enzyme, Kornberg started with extracts of fast-growing *E. coli* cells, which had replaced slower growing yeast cells as a laboratory subject. He added radioactive thymidine to the extracts and measured the production of radioactive DNA. Disappointingly, the incorporation of thymidine was extremely low, but thymidine phosphate (TMP) worked better, and thymidine

triphosphate (TTP) better still. Kornberg also discovered that the amount of newly synthesized DNA increased when a small amount of DNA was included in the reaction mixture. This was not entirely unexpected, as Kornberg already knew that a small amount of glycogen could serve as a primer for additional glycogen synthesis. At first, however, Kornberg believed that the DNA added to his reaction mixture acted as substrates for nucleases that were present in cell extracts and thereby protected the newly synthesized radioactive DNA from degradation. Later, he realized that the added DNA functioned as a template for the synthesis of a new strand and, through its partial degradation, also supplied the other, nonradioactive nucleotides required for polymerization. The idea of a template was, at the time, foreign to most enzymologists and other biochemists, but biologists seemed more receptive to the role of a template in DNA synthesis. For his discovery and characterization of DNA polymerase (later known as DNA polymerase I or Pol I), Kornberg was awarded the 1959 Nobel Prize in Physiology or Medicine.

Even with purified Pol I in hand, Kornberg was faced with the need to prove that the reaction product was biologically active. He therefore used Pol I to synthesize the 5386-bp DNA of bacteriophage ϕ X174 on viral DNA templates and then used DNA ligase to close up the synthetic DNA molecule to yield a circular DNA that was infectious. To Kornberg's chagrin, the popular press misunderstood this work, hailing it as the creation of life in a test tube.

Kornberg later confessed that he was amazed by the virtuosity of the DNA polymerase he had isolated from *E. coli*: The enzyme could synthesize a chain of thousands of nucleotides with an accuracy that exceeded chemical predictions. However, during the 1970s, genetic studies and other evidence clearly indicated that other proteins were responsible for DNA replication in *E. coli*, and DNA polymerases II and III were soon discovered and characterized. For the next two decades, Kornberg led the effort to determine the mechanism of DNA replication. Indeed, many of the leading researchers in the field were trained in his laboratory.

Kornberg, A., *For Love of Enzymes: The Odyssey of a Biochemist*, Harvard University Press (1989). [A scientific autobiography.]

A DNA Polymerases Add the Correctly Paired Nucleotides

In 1957, Arthur Kornberg discovered an *E. coli* enzyme that catalyzes the synthesis of DNA, based on its ability to incorporate the radioactive label from [^{14}C] thymidine triphosphate into DNA (Box 25-1). This enzyme, which is now known as **DNA polymerase I** or **Pol I**, consists of a single 928-residue polypeptide. Pol I is said to be a **processive enzyme** because *it catalyzes a series of successive nucleotide polymerization steps, typically 20 or more, without releasing the single-stranded template*.

Pol I Has Exonuclease Activity. In addition to its polymerase activity, Pol I has two independent hydrolytic activities that occupy separate active sites: a $3' \rightarrow 5'$ exonuclease and a $5' \rightarrow 3'$ exonuclease. *The $3' \rightarrow 5'$ exonuclease activity allows Pol I to edit its mistakes.* If Pol I erroneously incorporates a mispaired nucleotide at the end of a growing DNA chain, the polymerase activity is inhibited and the $3' \rightarrow 5'$ exonuclease hydrolytically excises the offending nucleotide

FIG. 25-6 The 3' → 5' exonuclease function of DNA polymerase I. This enzymatic activity excises mispaired nucleotides from the 3' end of the growing DNA strand (blue).

(Fig. 25-6). The polymerase activity then resumes DNA replication. This **proof-reading** mechanism explains the high fidelity of DNA replication by Pol I (one error every 10^6 – 10^8 nucleotide additions). Note that the exonuclease reaction, a hydrolysis, is not the reverse of the polymerase reaction, a pyrophosphorolysis, and therefore yields dNMP, not dNTP.

The Pol I 5' → 3' exonuclease binds to duplex DNA at single-strand nicks (breaks). It cleaves the nicked DNA strand in a base-paired region beyond the nick to excise the DNA as either mononucleotides or oligonucleotides of up to 10 residues (Fig. 25-7).

FIG. 25-7 The 5' → 3' exonuclease function of DNA polymerase I. This enzymatic activity excises up to 10 nucleotides from the 5' end of a single-strand nick. The nucleotide immediately past the nick (X) may or may not be paired.

Although Pol I was the first of the *E. coli* DNA polymerases to be discovered, it is not *E. coli*'s primary replicase. Rather, its most important (and only essential) function is in lagging strand synthesis, in which it removes the RNA primers and replaces them with DNA. This process involves the 5' → 3' exonuclease and polymerase activities of Pol I working in concert to excise the ribonucleotides on the 5' end of the single-strand nick between the new and old (previously synthesized) Okazaki fragments and to replace them with deoxynucleotides that are appended to the 3' end of the new Okazaki fragment (Fig. 25-8). The nick is thereby translated

(moved) toward the DNA strand's 3' end, a process known as **nick translation**. When the RNA has been entirely excised, the nick is sealed by the action of DNA ligase (Section 25-2C), thereby linking the new and old Okazaki fragments.

FIG. 25-8 The replacement of RNA primers by DNA in lagging strand synthesis. (1) The RNA primer at the 5' end of a previously synthesized Okazaki fragment (*Fragment 1*) is excised through the action of Pol I's 5' → 3' exonuclease function and replaced through its polymerase function, which adds deoxynucleotides to the 3' end of the newly synthesized Okazaki fragment (*Fragment 2*). This, in effect, translates the nick originally at the 5' end of the RNA to the position that was occupied by its 3' end (nick translation). (2) The nick is sealed by the action of DNA ligase.

Biochemists use nick translation to prepare radioactive DNA. Double-stranded DNA (**dsDNA**) is nicked in only a few places by treating it with small amounts of pancreatic **DNase I**. Radioactively labeled dNTPs are then added and Pol I translates the nicks, thereby replacing unlabeled deoxynucleotides with labeled deoxynucleotides.

Pol I also functions in the repair of damaged DNA. As we discuss in Section 25-5, damaged DNA is detected by a variety of DNA repair systems, many of which endonucleolytically cleave the damaged DNA on the 5' side of the lesion. Pol I's 5' → 3' exonuclease activity then excises the damaged DNA while its polymerase activity fills in the resulting single-strand gap in the same way it replaces the RNA primers of Okazaki fragments. Thus, Pol I has indispensable roles in *E. coli* DNA replication and repair although it is not, as was first supposed, responsible for the bulk of DNA synthesis.

The Klenow Fragment Is a Model DNA Polymerase. *E. coli* DNA polymerase I, a protein whose three enzymatic activities occupy three separate active sites, can be proteolytically cleaved to a large or “**Klenow**” fragment (residues 324–928), which contains both the polymerase and the 3' → 5' exonuclease activities, and a small fragment (residues 1–323), which contains the 5' → 3' exonuclease activity. The X-ray structure of the Klenow fragment, determined by Thomas Steitz, reveals that it consists of two domains (**Fig. 25-9**). The smaller domain (residues 324–517; the lower portion of the structure shown in Fig. 25-9) contains the 3' → 5' exonuclease site. The larger domain (residues 521–928) contains the polymerase active site at the bottom of a prominent cleft, a surprisingly large distance (~25 Å) from the 3' → 5' exonuclease site. The cleft, which is lined with positively charged residues, has the appropriate size and shape (~22 Å × ~30 Å) to bind a B-DNA molecule in a manner resembling a right hand grasping a rod (note the thumb, fingers, and palm structures in Fig. 25-9). The active sites of nearly all DNA and RNA polymerases of known structure are located at the bottoms of similarly shaped clefts.

Steitz cocrystallized the Klenow fragment with a short DNA “template” strand and a complementary “primer” strand. The protein contacts only the

FIG. 25-9 X-Ray structure of *E. coli* DNA polymerase I Klenow fragment in complex with a double-helical DNA. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) and embedded in its semitransparent molecular surface. The DNA is shown in stick form with the C atoms of its 10-nt template strand cyan, the C atoms of its 13-nt primer strand magenta, N blue, O red, and P orange, and with successive P atoms in each polynucleotide strand connected by orange rods. A Zn²⁺ ion (*purple*) marks the 3' → 5' exonuclease active site. Note that the 3' end of the primer strand occupies the enzyme's 3' → 5' exonuclease site and hence this structure is a so-called editing complex. [Based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1KLN.]

phosphate backbone of the duplex DNA, consistent with Pol I's lack of sequence specificity in binding DNA. The separation of the polymerase and 3' → 5' exonuclease active sites suggests that the bound DNA undergoes a large conformational shift in shuttling between the sites.

DNA Polymerase Senses Watson–Crick Base Pairs via Sequence-Independent Interactions. The C-terminal domain of the thermostable *Thermus aquaticus* (*Taq*) DNA polymerase I (**Klentaq1**) is 50% identical in sequence and closely similar in structure to the large domain of Klenow fragment (Klentaq1 lacks a functional 3' → 5' exonuclease site). Gabriel Waksman crystallized Klentaq1 in complex with a double-stranded DNA molecule with a GGAAA overhang at its 5' end (representing a template with a complementary DNA primer). The crystals were then incubated with 2',3'-dideoxy-CTP (ddCTP, which lacks a 3'-OH group). The X-ray structure of the crystals (**Fig. 25-10a**) reveals that a ddC residue is covalently linked to the 3' end of the primer, where it forms a Watson–Crick pair with the G residue at the 3' end of the overhang. Moreover, a separate ddCTP molecule (to which the primer's new 3'-terminal ddC residue is incapable of forming a covalent bond) occupies the enzyme's active site, where it forms a Watson–Crick pair with the template's next G. Clearly, Klentaq1 retains its catalytic activity in the crystals.

A DNA polymerase must distinguish correctly paired bases from mismatches and yet do so via sequence-independent interactions with the incoming dNTP. The Klentaq1 structure reveals that this occurs in an active site pocket whose shape is complementary to Watson–Crick base pairs. In addition, although the bound dsDNA is mainly in the B conformation, the 3 base pairs nearest the active site assume the A conformation, as has also been observed in the X-ray structures

FIG. 25-10 X-Ray structure of Klentaq1 in complex with DNA in the closed and open conformations. (a) The closed conformation (with ddCTP). (b) The open conformation (ddCTP depleted). The protein, which is viewed as in Fig. 25-9, is represented in worm form with its N-terminal, palm, fingers, and thumb domains colored yellow, magenta, green, and blue, respectively. The DNA is shown in stick form, whereas the primer strand's 3'-terminal ddC residue is drawn in space-filling

form as is the ddCTP in Part a that is base-paired with a template G residue in the enzyme's active site pocket. The atoms are colored according to type with template strand C cyan, primer strand C green, ddCTP C yellow, N blue, O red, and P orange. [Based on X-ray structures by Gabriel Waksman, Washington University School of Medicine. PDBids 3KTQ and 2KTQ.]

of several other DNA polymerases in their complexes with DNA. The resulting wider and shallower minor groove (Section 24-1A) permits protein side chains to form hydrogen bonds with the otherwise inaccessible N3 atoms of the purine bases and O2 atoms of the pyrimidine bases. The positions of these hydrogen bond acceptors are sequence-independent, as can be seen from an inspection of Fig. 24-1 (in contrast, the positions of the hydrogen bonding acceptors in the major groove vary with the sequence). However, with a non-Watson–Crick pairing—that is, with a mismatched dNTP in the active site—these hydrogen bonds would be greatly distorted if not completely disrupted. The polymerase also makes extensive sequence-independent hydrogen bonding and van der Waals interactions with the DNA's sugar–phosphate backbone and excludes ribo-NTPs through steric interference with their 2'-OH groups.

After the Klenotaq1 · DNA · ddCTP crystals described above were depleted of ddCTP by soaking them in a ddCTP-free solution, the enzyme's fingers domain assumed a so-called open conformation (Fig. 25-10b), which differs significantly from the closed conformation shown in Fig. 25-10a. Evidently, the fingers' helices in the open conformation move toward the active site when ddCTP binds, thereby burying the nucleotide in the catalytically active closed complex. These observations are consistent with kinetic measurements indicating that the binding of the correct dNTP to Pol I induces a rate-limiting conformational change that yields a tight ternary complex. It therefore appears that the enzyme rapidly samples the available dNTPs in its open conformation, but only when it binds the correct dNTP in a Watson–Crick pairing with the template base does it form the catalytically competent closed conformation. In the rare instances that a polymerase binds a non-Watson–Crick base pair in its closed form, the resulting distortions render the polymerase catalytically incompetent. *This is a type of proofreading, in which the enzyme checks for the presence of a Watson–Crick base pair in two independent ways, thereby greatly increasing the accuracy of the polymerase reaction.*

After formation of the phosphodiester bond, a second conformational change releases the PP_i product. The DNA is then translocated by one nucleotide toward the 5' end of the primer strand so as to position it for the next reaction cycle.

The DNA Polymerase Catalytic Mechanism Involves Two Metal Ions. The X-ray structures of a variety of DNA polymerases suggest that they share a common catalytic mechanism for nucleotidyl transfer. Their active sites all contain two metal ions, usually Mg²⁺, that are liganded by two invariant Asp side chains in the palm domain (Fig. 25-11). Metal ion B is liganded by all three phosphate groups of the bound dNTP, whereas metal ion A bridges the α-phosphate group of this dNTP and the primer's 3'-OH group. Metal ion A activates the primer's 3'-OH group for a nucleophilic attack on the α-phosphate group, whereas metal ion B functions to orient its bound triphosphate group and to electrostatically shield its negative charges as well as the additional negative charge on the transition state leading to the release of the PP_i ion. The 3' → 5' exonuclease employs a similar two metal ion mechanism, in which one Mg²⁺ ion nucleophilically activates a water molecule to cleave the phosphodiester bond to the 3' nucleotide, and the other Mg²⁺ ion properly orients the dNMP leaving group and stabilizes its developing negative charge.

DNA Polymerase III Is *E. coli*'s DNA Replicase. The discovery of normally growing *E. coli* mutants that have very little (but not entirely absent) Pol I activity stimulated the search for additional DNA polymerizing activities. This effort was

FIG. 25-11 Role of metal ions in nucleotidyl transfer. A and B represent enzyme-bound metal ions, usually Mg²⁺, in the DNA polymerase active site. Atoms are colored according to type (C gray, N blue, O red, and P yellow), and metal ion coordination is represented by green dotted lines. Metal ion A activates the primer's 3'-OH group for nucleophilic attack (arrow) on the α-phosphate group of the incoming nucleotide (here, ddCTP). Metal ion B orients and electrostatically stabilizes the negatively charged triphosphate group.

? Explain whether the cellular concentrations of Pol I and Pol III are consistent with their roles in DNA replication.

rewarded, in the 1970s, by the discovery of two more enzymes, designated, in the order they were discovered, **DNA polymerase II (Pol II)** and **DNA polymerase III (Pol III)**. The properties of these enzymes are compared with those of Pol I in **Table 25-1**. Pol II and Pol III had not previously been detected because their combined activities in the assays used are normally <5% that of Pol I. Pol II participates in DNA repair; mutant cells lacking Pol II can therefore grow normally. The absence of Pol III, however, is lethal, demonstrating that it is *E. coli*'s DNA replicase. [Later studies revealed that *E. coli* has two additional DNA polymerases, Pol IV and Pol V, that also participate in DNA repair (Section 25-4E)].

The catalytic core of Pol III consists of three subunits: α , which contains the complex's DNA polymerase activity (**Fig. 25-12**); ϵ , its 3' → 5' exonuclease; and θ , whose function is unknown. However, at least seven other subunits (τ , γ , δ , δ' , χ , Ψ , and β) combine with them to form a labile multisubunit enzyme known as the **Pol III holoenzyme**. The catalytic properties of the Pol III core resemble those of Pol I except that Pol III lacks 5' → 3' exonuclease activity on dsDNA. Thus, *Pol III can synthesize a DNA strand complementary to a single-stranded template and can edit the polymerization reaction to increase replication fidelity, but it cannot catalyze nick translation.*

FIG. 25-12 X-Ray structure of the *Thermus aquaticus* Pol III α subunit in complex with a primer–template DNA. The protein is drawn in ribbon form with its thumb, palm, fingers, and PHP domains yellow, magenta, orange, and light blue, respectively. The DNA is drawn in space-filling form with C green, N blue, O red, and P orange. The fragmented appearance of the protein is largely attributable to its low (4.6 Å) resolution. Note the handlike shape of the protein but its entirely different fold from that of Klenow fragment and KlenTaq1 (Figs. 25-9 and 25-10), with which it has no significant sequence similarity. [Based on an X-ray structure by Thomas Steitz, Yale University. PDBid 3EOD.]

B Replication Initiation Requires Helicase and Primase

The *E. coli* chromosome is a supercoiled DNA molecule of 4.6×10^6 bp. Since DNA polymerase requires a single-stranded template, other proteins participate in DNA replication by locating the replication initiation site, unwinding the DNA, and preventing the single strands from reannealing.

Replication of *E. coli* dsDNA is initiated at a 245-bp region known as *oriC* (*ori* for origin), elements of which are highly conserved among gram-negative bacteria. The dsDNA strands are separated by the binding of multiple copies of a 467-residue protein named **DnaA** (the product of the *dnaA* gene) that bind to a ~45-bp AT-rich segment of *oriC* DNA as a helical filament [DnaA is a member of the **AAA+ family** (AAA+ for ATPases associated with cellular activities); a functionally diverse protein family]. This melting requires the free energy of ATP hydrolysis and is probably also facilitated by both the AT-rich nature of the DNA segment and the negative supercoiling (underwinding) of the circular DNA chromosome [the latter being generated by DNA gyrase, a type II topoisomerase (Section 24-1D), whose activity is required for prokaryotic DNA replication].

Helicases Unwind DNA. DnaA bound to *oriC* recruits two hexameric complexes of **DnaB**, one to each end of the melted region. DnaB is a **helicase** that further separates the DNA strands. Helicases are a diverse group of enzymes that unwind DNA during replication, transcription, and a variety of other processes. DnaB is one of 12 helicases expressed by *E. coli*. Helicases function by translocating along one strand of a double-helical nucleic acid like a moving wedge so as to mechanically unwind the helix in their path, a process that is driven by the free energy of NTP hydrolysis. Some helicases translocate in the 5' → 3' direction and others do so in the 3' → 5' direction; some are hexamers and some are dimers.

DnaB forms a hexamer (DnaB₆) of identical 471-residue subunits that separates the two strands of the parental DNA during its replication by translocating along the lagging strand template in the 5' → 3' direction. This process is driven by the hydrolysis of NTPs with little preference for the identity of the base.

The X-ray structure of *Bacillus stearothermophilus* DnaB₆ in complex with dT₁₄ and GDP · AlF₄⁻ (a mimic of the transition state of NTP hydrolysis), determined by Steitz, is shown in **Fig. 25-13**. The DnaB₆ forms a two-layered trimer

of dimers shaped like a single turn of a right-handed spiral staircase (alternatively, a lockwasher) in which the N-terminal domains (NTDs) of the DnaB subunits are arranged about a pseudo 3-fold axis in the form of a 3-step staircase and the C-terminal domains (CTDs) form a 6-step staircase. The dT_{14} occupies the central channel of the $DnaB_6$ hexamer (which is too narrow to admit double-stranded DNA), where it assumes the conformation of a single strand of A-DNA oriented with its 5' end toward the top of the complex in Fig. 25-13b. Each DnaB subunit engages the ssDNA via a loop that interacts with two consecutive nucleotides through hydrogen bonds with their phosphate oxygens. $GDP \cdot AlF_4^-$ binds at each interface between two CTDs and, because the highest and lowest CTDs in the complex are not in contact, only five $GDP \cdot AlF_4^-$ complexes are bound to the $DnaB_6$ hexamer.

The $DnaB_6$ structure suggests the mechanism through which it translocates along the lagging strand of a dsDNA to separate its two strands (Fig. 25-14). In this so-called **hand-over-hand mechanism**, NTP hydrolysis and release induces the top subunit in the spiral staircase to dissociate from its adjacent subunit and from its bound two nucleotides. The top subunit then binds to a position 12 nucleotides in the 5' → 3' direction along the lagging strand, where it becomes the bottom subunit of the $DnaB_6$ assembly and rebinds an NTP, thus separating the leading and lagging strands of the dsDNA by two nucleotides. This cycle is then repeated, thereby separating the two strands by pulling the DnaB hexamer along the lagging strand, in two-nucleotide steps, in the hand-over-hand manner reminiscent of a person climbing a rope.

Note that in separating the lagging strand from the leading strand, the $DnaB_6$ helicase pushes the twist in the dsDNA ahead of it. The resulting buildup of torsional stress would resist and eventually stop the translocation of the helicase. Thus the action of topoisomerases (primarily gyrase in *E. coli*) in relieving torsional stress is indispensable for separating the leading and lagging strands (~440,000 twists must be removed in replicating the 4.6-million-bp *E. coli* chromosome).

How is the DnaB hexamer loaded onto the ssDNA at the newly opened replication eye? This is the job of **DnaC**, an AAA+ protein that is a monomer in solution. However, as EM studies have shown, DnaC · ATP assembles on the CTDs of $DnaB_6$ to form a lockwasher-shaped hexamer. This cracks open the

FIG. 25-14 The hand-over-hand mechanism for the 5' → 3' translocation of the DnaB hexamer along the lagging strand of replicating dsDNA. The six DnaB subunits, which are labeled A through F, are colored and viewed as in Fig. 25-13b. The lagging strand, along which $DnaB_6$ translocates, is yellow and the leading

strand is orange. Red nucleotides represent those that interact with $DnaB_6$ in its initial position and green nucleotides are those to which the hexamer binds after ATP turnover. The thick black arrows indicate the direction of $DnaB_6$ translocation along the lagging strand. [Courtesy of Thomas Steitz, Yale University.]

FIG. 25-15 X-Ray structure of SSB in complex with dC(pC)₃₄. The homotetramer, which has D_2 symmetry, is viewed along one of its twofold axes with its other twofold axes horizontal and vertical. Each of its subunits (which include the N-terminal 134 residues of the 177-residue polypeptide) are differently colored. Its two bound ssDNA molecules are drawn in space-filling form colored according to atom type with the upper strand C cyan, lower strand C green, N blue, O red, and P orange. (The lower strand is partially disordered and hence appears to consist of two fragments). [Based on an X-ray structure by Timothy Lohman and Gabriel Waksman, Washington University School of Medicine. PDBid 1EYG.]

DnaB hexamer, which, with the assistance of DnaA, slips around the ssDNA. Then, in a process driven by ATP hydrolysis, the DnaC dissociates from the DnaB₆, which then closes around the ssDNA.

Single-Strand Binding Protein Prevents DNA from Reannealing. The separated DNA strands behind an advancing helicase do not reanneal to form dsDNA because they become coated with **single-strand binding protein (SSB)**. The SSB coat also prevents ssDNA from forming secondary structures such as stem-loops that would impede its replication and protects it from nucleases. Evidently, DNA polymerase displaces SSB from the template strand as replication proceeds.

E. coli SSB is a homotetramer of 177-residue subunits that can bind to DNA in several different ways. In the major binding mode (Fig. 25-15), each U-shaped strand of ssDNA is draped across two of SSB's four subunits. This would permit an unlimited series of SSB tetramers to interact end-to-end along the length of a ssDNA. The DNA-binding cleft of SSB, which is contained in its N-terminal 115 residues, is positively charged so that the protein can interact electrostatically with DNA phosphate groups. The cleft is too narrow to accommodate dsDNA.

The Primosome Synthesizes RNA Primers. All DNA synthesis, both of leading and lagging strands, requires the prior synthesis of an RNA primer. Primer synthesis in *E. coli* is mediated by an ~600-kD protein assembly known as a **primosome**, which includes the DnaB helicase and an RNA-synthesizing primase, also called **DnaG**, as well as five other types of subunits. *E. coli* DnaG is a monomeric protein whose catalytic domain does not resemble any of the other DNA and RNA polymerases of known structure. Nevertheless, it catalyzes the same polymerization reaction (Fig. 25-2 using NTPs rather than dNTPs) to produce an RNA segment of ~11 nucleotides.

The primosome is propelled in the 5' → 3' direction along the DNA template for the lagging strand (i.e., toward the replication fork) in part by DnaB-catalyzed ATP hydrolysis. This motion, which displaces the SSB in its path, is opposite in direction to that of template reading during DNA chain synthesis. Consequently, the primosome reverses its migration momentarily to allow primase to synthesize an RNA primer in the 5' → 3' direction (Fig. 25-5).

The primosome is required to initiate each Okazaki fragment. The single RNA segment that primes the synthesis of the leading strand can be synthesized, at least *in vitro*, by either primase or RNA polymerase (the enzyme that synthesizes RNA transcripts from a DNA template; Section 26-1), but its rate of synthesis is greatly enhanced when both enzymes are present.

C The Leading and Lagging Strands Are Synthesized Simultaneously

In *E. coli*, the Pol III holoenzyme catalyzes the synthesis of both the leading and lagging strands. This occurs in a single multiprotein particle, the **replisome**, which contains two Pol III enzymes. In some other prokaryotes and in eukaryotes, two different polymerases synthesize the leading and lagging strands, but

like Pol III, they are part of a multiprotein replisome. *In order for the replisome to move as a single unit in the 5' → 3' direction along the leading strand, the lagging strand template must loop around (Fig. 25-16).* This **trombone model**, which was first proposed by Bruce Alberts, is so called because the extension of the lagging strand loop from the replisome resembles the motion of a trombone slide.

After completing the synthesis of an Okazaki fragment, the lagging strand holoenzyme relocates to a new primer near the replication fork and resumes synthesis. *The result of this process is a continuous leading strand and a series of RNA-primed Okazaki fragments separated by single-strand nicks.* The RNA primers are replaced with DNA through Pol I-catalyzed nick translation, and the nicks in the lagging strand are then sealed through the action of DNA ligase (see below). An alternative means for primer excision is through the action of **RNase H** (H for *hybrid*), which specifically degrades the RNA in RNA–DNA hybrid

FIG. 25-16 The trombone model for the replication of DNA.

(a) The replisome, which contains two DNA polymerase III holoenzymes, synthesizes both the leading and the lagging strands. The lagging strand template must loop around to permit the holoenzyme to extend the primed lagging strand. (b) The holoenzyme releases the lagging strand template when it encounters the previously synthesized Okazaki fragment. This may signal the primosome to initiate synthesis

of a lagging strand RNA primer. (c) The holoenzyme rebinds the lagging strand template and extends the RNA primer to form a new Okazaki fragment. Note that in this model, leading strand synthesis is always ahead of lagging strand synthesis.

? Add arrows to indicate the direction of movement of each polymerase and the primosome.

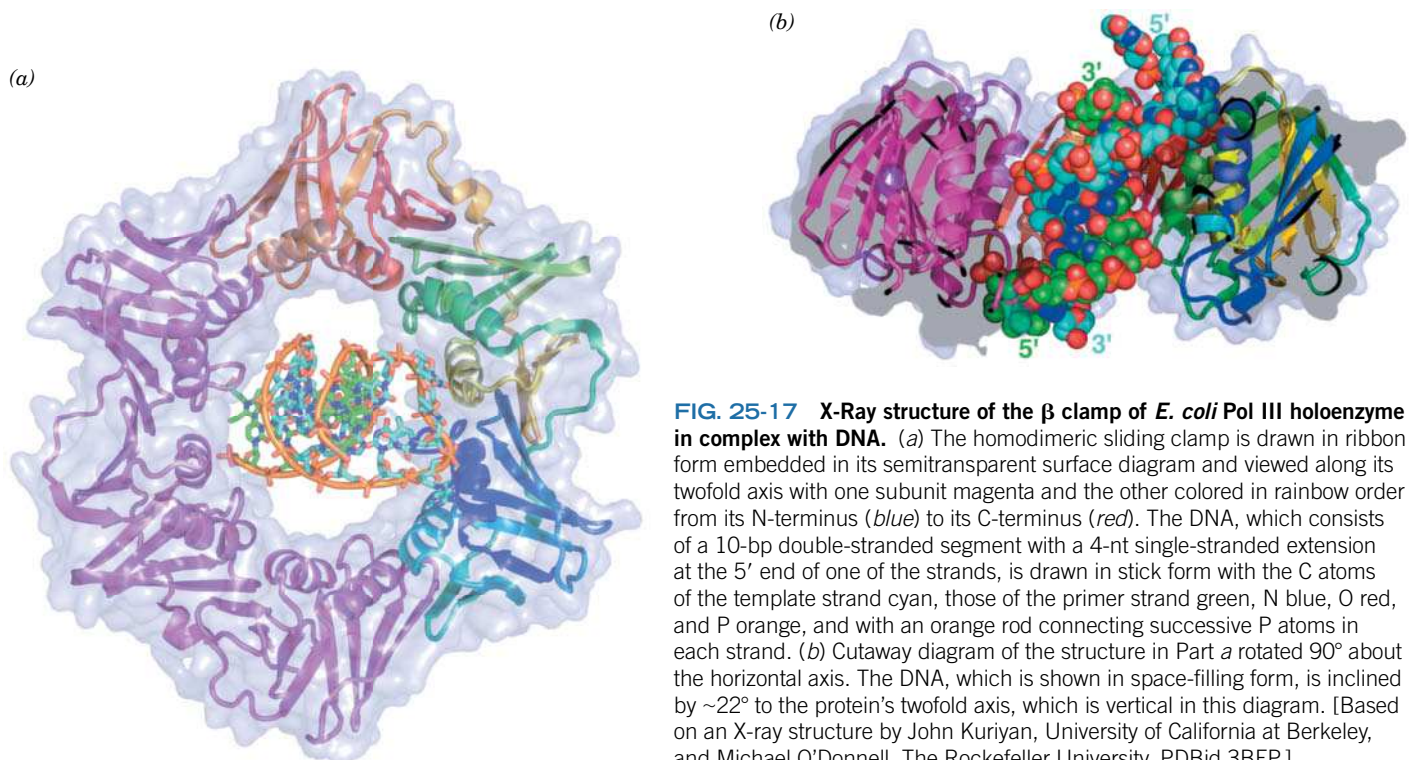

helices. Since RNase H can only hydrolyze the phosphodiester bond between ribonucleotides, Pol I is still required to remove the primer's 3'-ribonucleotide.

A Sliding Clamp Promotes Pol III Processivity. The Pol III core enzyme dissociates from the template DNA after replicating only ~ 12 residues; that is, it has a processivity of ~ 12 residues. However, the Pol III holoenzyme has a processivity of >5000 residues, due to the presence of its **β subunit**. A β subunit bound to a cut circular DNA slides to the break and falls off. This suggests that the β subunit *forms a ring around the DNA that functions as a sliding clamp (alternatively, β clamp) that can move along it, thereby keeping the Pol III holoenzyme from diffusing away*. The β clamp also greatly increases the rate of nucleotide polymerization.

The X-ray structure of the β clamp in complex with DNA, determined by John Kuriyan and Michael O'Donnell, reveals that the protein is a dimer of C-shaped monomers that form an ~ 80 -Å-diameter donut-shaped structure (Fig. 25-17). Each β subunit contains three domains of similar structure (although with $<20\%$ sequence identity) so that the dimeric ring is a pseudosymmetrical six-pointed star. The interior surface of the ring is positively charged, whereas its outer surface is negatively charged.

The central ~ 35 -Å-diameter hole of the β clamp is larger than the 20- and 26-Å diameters of B- and A-DNAs (the hybrid helices containing RNA primers and DNA have an A-DNA-like conformation; Section 24-1A). The X-ray structure of the β clamp–DNA complex indicates that the protein's α helices span the major and minor grooves of the DNA rather than entering into them as do, for example, the recognition helices of helix–turn–helix motifs (Section 24-4B). It appears that the β subunit is designed to minimize its associations with double-stranded DNA. This presumably permits the protein to freely slide along the DNA helix.

E. coli replicates its DNA at the astounding rate of ~ 1000 nt/s. Thus, in lagging strand synthesis, the DNA polymerase holoenzyme must be reloaded onto the template strand every second or so (Okazaki fragments are ~ 1000 nt long). Consequently, a new β clamp, which promotes Pol III's processivity, must be

FIG. 25-18 Architecture of the *E. coli* replisome. See the text for details. Compare this to Fig. 25-16, in which only the τ_2 component of the clamp loader is drawn. [Courtesy of Charles Richardson, Harvard Medical School.]

installed around the lagging strand template about once every second. The **γ complex** of the Pol III holoenzyme (subunit composition $\gamma\tau_2\delta\delta'\chi\psi$) is also known as the **clamp loader** because it opens the dimeric β clamp to load it onto the DNA template in an ATP-dependent manner. The γ complex bridges the replisome's two Pol III cores ($\alpha\epsilon\theta$) via the C-terminal segments (τ_c) of its two τ subunits (Fig. 25-18), which also bind the DnaB helicase. This apparently allows the helicase to match the pace of the two polymerases.

Once the β clamp has been loaded onto the DNA, the Pol III core binds to the β clamp more tightly than does the γ complex, thereby displacing it and permitting processive DNA replication to occur. When the polymerase encounters the previously synthesized Okazaki fragment, that is, when the gap between the two successively synthesized Okazaki fragments has been reduced to a nick, the Pol III core releases the DNA and loses its affinity for the β clamp. However, the components of the replisome do not go far; the γ subunit and the Pol III core are held in the vicinity of the lagging strand template through their linkage to the Pol III core engaged in leading strand synthesis (which remains tethered to the DNA by its associated β clamp; Fig. 25-18). Consequently, the γ complex can quickly load a new β clamp around the lagging strand template DNA at the next primer so that Pol III can begin synthesizing a new Okazaki fragment.

The β clamp, which remains around the completed Okazaki fragment, recruits Pol I and DNA ligase to replace the RNA primer on the previously synthesized Okazaki fragment with DNA and seal the remaining nick. However, the sliding clamp must eventually be recycled. It was initially assumed that this was the job of the clamp loader. However, it is now clear that the release of the sliding clamp from its associated DNA is carried out by free δ subunit (the “wrench” in the clamp loader that cracks apart the β subunits forming the sliding clamp), which is synthesized in around tenfold excess over that required to populate the cell's few clamp loaders. Nevertheless, a free δ subunit cannot load a β clamp onto DNA.

All five of *E. coli*'s DNA polymerases, as well as DNA ligase and the clamp loader, bind to the same region of the β clamp. Consequently, only when the β clamp is no longer associated with any of these proteins can it be recycled by the δ subunit.

Recent studies suggest that the clamp loader complex contains three τ subunits rather than the two depicted in Figs. 25-16 and 25-18, and that the replisome therefore has three rather than two Pol III core- β clamp complexes. Presumably, two of these complexes alternate in synthesizing the lagging strand, and one of them initiates the synthesis of an Okazaki fragment before the other one has completed the synthesis of the preceding Okazaki fragment. Since the release of the Pol III core from the β clamp and its rebinding to a new one is a slower process than DNA synthesis, this would better allow lagging strand synthesis to keep up with leading strand synthesis.

DNA Ligase Is Activated by NAD⁺ or ATP. The free energy for the DNA ligase reaction is obtained, in a species-dependent manner, through the coupled hydrolysis of either NAD⁺ to **nicotinamide mononucleotide (NMN⁺)** + AMP, or ATP to PP_i + AMP. *E. coli* DNA ligase, a 671-residue monomer that uses NAD⁺, catalyzes a three-step reaction (Fig. 25-19):

1. The adenylyl group of NAD⁺ is transferred to the ϵ -amino group of an enzyme Lys residue to form an unusual phosphoamide adduct.
2. The adenylyl group of this activated enzyme is transferred to the 5'-phosphoryl terminus of the nick to form an adenylylated DNA. Here, AMP is linked to the 5'-nucleotide via a pyrophosphate rather than the usual phosphodiester bond.
3. DNA ligase catalyzes the formation of a phosphodiester bond by attack of the 3'-OH on the 5'-phosphoryl group, thereby sealing the nick and releasing AMP.

DNA ligase does not catalyze nick closure with RNA, which ensures that RNA primers are completely removed before nicks are sealed.

ATP-requiring DNA ligases, such as those of eukaryotes, release PP_i in the first step of the reaction rather than NMN⁺. The DNA ligase from the bacteriophage T4 is notable because it can link together two duplex DNAs that lack complementary single-stranded ends (**blunt end ligation**) in a reaction that is a boon to genetic engineering (Section 3-5).

D Replication Terminates at Specific Sites

The *E. coli* replication terminus is a large (350-kb) region flanked by ten nearly identical nonpalindromic ~23-bp terminator sites, *TerH*, *TerI*, *TerE*, *TerD*, and *TerA* on one side and *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* on the other (Fig. 25-20);

FIG. 25-20 Map of the *E. coli* chromosome showing the positions of the *Ter* sites. The *TerC*, *TerB*, *TerF*, *TerG*, and *TerJ* sites, in combination with Tus protein, allow a counterclockwise-moving replisome to pass but not a clockwise-moving replisome. The opposite is true of the *TerA*, *TerD*, *TerE*, *TerI*, and *TerH* sites. Consequently, two replication forks that initiate bidirectional DNA replication at *oriC* will meet between the oppositely facing *Ter* sites.

FIG. 25-19 The reactions catalyzed by *E. coli* DNA ligase. In eukaryotic and T4 ligases, NAD⁺ is replaced by ATP so that PP_i rather than NMN⁺ is eliminated in the first reaction step. Here A, R, and N represent the adenine, ribose, and nicotinamide residues, respectively.

? Compare the free energy requirements of the reactions catalyzed by DNA polymerase and DNA ligase.

note that *oriC* is directly opposite the termination region on the *E. coli* chromosome). A replication fork, traveling counterclockwise as drawn in Fig. 25-20, passes through *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* but stops on encountering either *TerA*, *TerD*, *TerE*, *TerI*, or *TerH* (*TerD*, *TerE*, *TerI*, and *TerH* are presumably backup sites for *TerA*). Similarly, a clockwise-traveling replication fork passes *TerH*, *TerI*, *TerE*, *TerD*, and *TerA* but halts at *TerC* or, failing that, *TerB*, *TerF*, *TerG*, or *TerJ*. Thus, these termination sites are polar; they act as one-way valves that allow replication forks to enter the terminus region but not to leave it. *This arrangement guarantees that the two replication forks generated by bidirectional initiation at oriC will meet in the replication terminus even if one of them arrives there well ahead of its counterpart.*

The arrest of replication fork motion at *Ter* sites requires the action of **Tus protein** (for terminator utilization substance), a 309-residue monomer that is the product of the *tus* gene. Tus protein specifically binds to a *Ter* site, where it prevents strand displacement by DnaB helicase, thereby arresting replication fork advancement.

The X-ray structure of Tus in complex with a 15-bp *Ter* fragment (Fig. 25-21) reveals that the protein forms a deep positively charged cleft in which the DNA binds. A 5-bp segment of the DNA near the side of Tus that permits the passage of the replication fork is deformed and underwound relative to canonical (ideal) DNA: Its major groove is deeper, and its minor groove is significantly expanded. Protein side chains at the bottom of the cleft penetrate the DNA's widened major groove to make sequence-specific contacts such that the protein cannot release the bound DNA without a large conformational change. Nevertheless, the mechanism through which Tus prevents replication fork advancement from one side of a *Ter* site but not the other is unclear.

Curiously, the Tus–*Ter* system is not essential for termination. If the *Ter* sites are deleted, replication simply stops when the opposing replication forks collide. Nevertheless, this termination system is highly conserved in gram-negative bacteria, strongly suggesting that it confers a growth advantage. A plausible explanation for this hypothesis involves the relationship between the transcription and replication of DNA. An *E. coli*'s genes are distributed all around its circular chromosome and are transcribed during all stages of its life cycle. Consequently,

FIG. 25-21 X-Ray structure of *E. coli* Tus in complex with a 15-bp *Ter*-containing DNA. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The DNA is shown in stick form with C gray, N blue, O red, and P orange and with successive P atoms in the same strand joined by orange rods. [Based on an X-ray structure by Kosuke Morikawa, Protein Engineering Research Institute, Osaka, Japan. PDBid 1ECR.]

replication forks and RNA polymerase frequently collide. If they are moving in the same direction they do not impede one another. However, if they are moving in opposite directions, that is, if they collide head-on, this causes the replication fork to pause and could abort the transcription process (see Box 26-1). Most bacterial genes are oriented such that transcription and replication occur in the same direction, provided that the replication forks do not proceed more than halfway around the circular chromosome. Thus, the Tus–Ter system probably functions to increase the rate of DNA replication and transcription, and thereby confers a growth advantage on the bacterium.

As two oppositely moving replication forks collide at the termination site, the newly synthesized strands become covalently linked to yield two covalently closed double-stranded chromosomes. The parental DNA strands remain wound about each other by several turns (presumably because DNA gyrase cannot gain access to the DNA when the colliding replication forks closely approach each other) and consequently the product dsDNA strands must be wound about each other by the same number of turns (Fig. 25-22). The resulting catenated circular dsDNAs must be separated so that each can be passed to a different daughter cell. This is the job of the type II topoisomerase named **topoisomerase IV** (Section 24-1D).

E DNA Is Replicated with High Fidelity

Since a single polypeptide as small as the Pol I Klenow fragment can replicate DNA by itself, why does *E. coli* maintain a battery of more than 20 intricately coordinated proteins to replicate its chromosome? The answer apparently is *to ensure the nearly perfect fidelity of DNA replication required to accurately transmit genetic information*.

The rates of reversion of mutant *E. coli* or T4 phages to the wild type indicates that only one mispairing occurs per 10^8 to 10^{10} base pairs replicated. This corresponds to ~ 1 error per 1000 bacteria per generation. Such high replication accuracy arises from four sources:

1. Cells maintain balanced levels of dNTPs through the mechanisms discussed in Sections 23-1C and 23-2C. This is important because a dNTP present at aberrantly high levels is more likely to be misincorporated and, conversely, one present at low levels is more likely to be replaced by one of the dNTPs present at higher levels.
2. The polymerase reaction itself has extraordinary fidelity because it occurs in two stages. First, the incoming dNTP base-pairs with the template while the enzyme is in an open, catalytically inactive conformation. Polymerization occurs only after the polymerase has closed around the newly formed base pair, which properly positions the catalytic residues (induced fit; Fig. 25-10). *The protein conformational change constitutes a double-check for correct Watson–Crick base pairing between the dNTP and the template.*
3. The $3' \rightarrow 5'$ exonuclease functions of Pol I and Pol III detect and eliminate the occasional errors made by their polymerase functions.
4. A remarkable set of enzyme systems in all cells repairs residual errors in the newly synthesized DNA as well as any damage that may occur after its synthesis through chemical and/or physical insults. We discuss the DNA repair systems in Section 25-5.

In addition, the inability of a DNA polymerase to initiate chain elongation without a primer increases DNA replication fidelity. The first few nucleotides of a chain are those most likely to be mispaired because of the cooperative nature of base-pairing interactions (Section 24-2). The use of RNA primers eliminates this source of error since the RNA is eventually replaced by DNA under conditions that permit more accurate base pairing.

FIG. 25-22 The formation and separation of catenated dsDNAs at the replication termination site. The parental strands are red and black and the daughter strands are green and blue. For clarity, the double-helical character of the newly formed dsDNA molecules is not shown.

CHECKPOINT

- Summarize the functions of the following proteins in *E. coli* DNA replication: DNA polymerase I, DNA polymerase III, DnaA, helicase, SSB, primase, the sliding clamp, clamp loader, DNA ligase, Tus, and topoisomerases.
- Why is it important for DNA polymerase I to have three active sites?
- What is the role of the metal ions in the polymerase active site?
- How many sliding clamps and clamp-loading events are required for synthesis of the leading and lagging strands?
- What feature of the clamp allows it to slide along the DNA?
- Explain why Tus is the only replication protein that is sequence-specific.
- Describe the four factors that contribute to the high fidelity of DNA replication.

3 Eukaryotic DNA Replication

KEY CONCEPTS

- Eukaryotic DNA replication requires DNA polymerases with different degrees of accuracy and processivity.
- Prereplication complexes assemble at multiple origins distributed throughout the eukaryotic genome.
- Telomerase uses an RNA template to extend the 3' ends of eukaryotic chromosomes.

Eukaryotic and prokaryotic DNA replication mechanisms are remarkably similar, although the eukaryotic system is vastly more complex in terms of the amount of DNA to be replicated and the number of proteins required (estimated at >27 in yeast and mammals). Several different modes of DNA replication occur in eukaryotic cells, which contain nuclear DNA as well as mitochondrial and, in plants, chloroplast DNA. In this section, we consider some of the proteins of eukaryotic DNA replication as well as the challenge of replicating the ends of linear chromosomes.

A Eukaryotes Use Several DNA Polymerases

Animal cells contain at least 13 distinct DNA polymerases, which were named with Greek letters according to their order of discovery. A newer classification scheme uses sequence homology to group eukaryotic as well as prokaryotic polymerases into six families: A, B, C, D, X, and Y. In this section, we describe the three main enzymes involved in replicating eukaryotic nuclear DNA: **polymerases α , δ , and ϵ** (Table 25-2), which are all B-family polymerases (*E. coli* Pol I and Pol III are respectively members of the A and C families).

DNA polymerase α (**pol α**), like all DNA polymerases, replicates DNA by extending a primer in the 5' \rightarrow 3' direction under the direction of a ssDNA template. This enzyme has no exonuclease activity and therefore cannot proofread its polymerization product. Pol α is only moderately processive (polymerizing \sim 100 nucleotides at a time) and associates tightly with a primase, indicating that it is involved in initiating DNA replication. The pol α /primase complex synthesizes a 7- to 10-nt RNA primer and extends it by an additional 15 or so deoxynucleotides. Its lack of proofreading activity is not problematic, since the first few residues of newly synthesized DNA are typically removed and replaced along with the RNA primer.

DNA polymerase δ (**pol δ**) does not associate with a primase and contains a 3' \rightarrow 5' exonuclease active site. In addition, the processivity of pol δ is essentially unlimited (it can replicate the entire length of a template DNA), but only when it is in complex with a sliding-clamp protein named **proliferating cell nuclear antigen (PCNA)**. The X-ray structure of PCNA (Fig. 25-23), also determined by Kuriyan, reveals that it forms a trimeric ring with almost identical structure (and presumably function) as the *E. coli* β_2 sliding clamp (Fig. 25-17). Intriguingly, PCNA and the β clamp exhibit no significant sequence identity, even when their structurally similar portions are aligned.

TABLE 25-2 Properties of Some Eukaryotic DNA Polymerases

	α	δ	ϵ
3' \rightarrow 5' Exonuclease	no	yes	yes
Associates with primase	yes	no	no
Processivity	moderate	high	high
Requires PCNA	no	yes	no

FIG. 25-23 X-Ray structure of PCNA. The three subunits, which form a threefold symmetric ring, are drawn in ribbon form embedded in their semitransparent surface diagram. One of the subunits is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), another is pink, and the third is light green. A space-filling model of B-DNA viewed along its helix axis has been drawn in the center of the PCNA ring. [Based on an X-ray structure by John Kuriyan, University of California at Berkeley. PDBid 1AXC.]

? Compare this structure to that of the β clamp of the *E. coli* Pol III holoenzyme (Fig. 25-17).

Pol δ in complex with PCNA is required for lagging strand DNA synthesis. During replication, **RFC (replication factor C)**, a clamp loader that is the eukaryotic counterpart of the *E. coli* γ complex) loads PCNA onto the template strand near the primer. This displaces pol α , which in a process called **template switching** allows pol δ to bind to the lagging strand template strand and subsequently processively extend the new DNA strand.

Pol ϵ , a heterotetrameric nuclear enzyme, is the most enigmatic participant in DNA replication. Pol ϵ is highly processive in the absence of PCNA and has a $3' \rightarrow 5'$ exonuclease activity that degrades single-stranded DNA to 6- or 7-residue oligonucleotides rather than to mononucleotides, as does that of pol δ . Although pol ϵ is necessary for the viability of yeast, its essential function can be carried out by only the noncatalytic C-terminal half of its 256-kD catalytic subunit, which is unique among B-family DNA polymerases. This suggests that the C-terminal half of the pol ϵ catalytic subunit is required for the assembly of the replication complex. Nevertheless, Thomas Kunkel has shown that pol ϵ is probably the leading strand replicase, although it may also contribute to lagging strand synthesis. Moreover, pol δ may also participate in leading strand synthesis.

DNA polymerase γ (pol γ), an A-family enzyme, occurs exclusively in the mitochondrion, where it presumably replicates the mitochondrial genome. Chloroplasts contain a similar enzyme. An additional member of the polymerase family of proteins is the viral enzyme **reverse transcriptase**, an RNA-directed DNA polymerase (Box 25-2).

Additional Enzymes Participate in Eukaryotic DNA Replication. As in prokaryotic DNA replication, a helicase is required to pry apart the two template strands. In eukaryotes, this function is carried out by the heterohexameric complex known as **MCM** that tracks along the leading strand template in the $3' \rightarrow 5'$ direction. Single-stranded DNA becomes coated with the trimeric **replication protein A (RPA)**, the eukaryotic equivalent of the bacterial SSB. The eukaryotic replisome also includes additional proteins that have no prokaryotic counterparts and whose functions are poorly understood.

Eukaryotes lack a nick-translating polymerase like *E. coli* Pol I. Instead, the RNA primers of Okazaki fragments are removed through the actions of two enzymes: **RNase H1** removes most of the RNA, leaving only a $5'$ -ribonucleotide adjacent to the DNA, which is then removed through the action of **flap**

Reverse transcriptase (RT) is an essential enzyme of **retroviruses**, which are RNA-containing eukaryotic viruses such as **human immunodeficiency virus (HIV)**, the causative agent of AIDS; Box 12-3). RT, which was independently discovered in 1970 by Howard Temin and David Baltimore, synthesizes DNA in the 5' → 3' direction from an RNA template. Although the activity of the enzyme was initially considered antithetical to the central dogma of molecular biology (Section 3-3B), there is no thermodynamic prohibition to the RT reaction (in fact, under certain conditions, Pol I can copy RNA templates). RT catalyzes the first step in the conversion of the virus' single-stranded RNA genome to a double-stranded DNA.

After the virus enters a cell, its RT uses the viral RNA as a template to synthesize a complementary DNA strand, yielding an RNA–DNA hybrid helix. The DNA synthesis is primed by a host cell tRNA whose 3' end unfolds to base-pair with a complementary segment of viral RNA. The viral RNA strand is then nucleolytically degraded by an RNase H. Finally, the DNA strand acts as a template for the synthesis of its complementary DNA, yielding dsDNA that is then integrated into a host cell chromosome.

RT has been a particularly useful tool in genetic engineering because it can transcribe mRNAs to complementary strands of DNA (**cDNA**; see diagram). mRNA-derived cDNAs can be used, for example, to express eukaryotic structural genes in *E. coli* (Section 3-5D). Since *E. coli* lacks the machinery to splice out introns (Section 26-3B), the use of genomic DNA to express a eukaryotic structural gene in *E. coli* would require the prior excision of its introns—a technically difficult feat.

HIV-1 reverse transcriptase is a dimeric protein whose subunits are synthesized as identical 66-kD polypeptides, known as **p66** (*opposite, top*), that each contain a polymerase domain and an RNase H domain. However, the RNase H domain of one of the two subunits is proteolytically excised, thereby yielding a 51-kD polypeptide named **p51** (*opposite, bottom*). Thus, RT is a dimer of p66 and p51.

The X-ray structure of HIV-1 RT shows that the two subunits have different structures, although each has a fingers, palm, and thumb domain as well as a “connection” domain. The RNase H domain of

endonuclease-1 (FEN1). Yet, as we have seen, pol α extends the RNA primer by ~15 nt of DNA before it is displaced by pol δ . Since pol α lacks proofreading ability, this primer extension is more likely to contain errors than the DNA synthesized by pol δ . However, FEN1, which is recruited by PCNA, provides what is, in effect, pol α 's proofreading function: It is also an endonuclease that excises mismatch-containing oligonucleotides up to 15 nt long from the 5' end of an annealed DNA strand. Moreover, FEN1 can make several such excisions in succession to remove more distant mismatches. The excised segment is later replaced by pol δ as it synthesizes the succeeding Okazaki fragment (Fig. 25-24).

B Eukaryotic DNA Is Replicated from Multiple Origins

Replication fork movement in eukaryotes is ~10 times slower than in prokaryotes. Since a eukaryotic chromosome typically contains 60 times more DNA than

FIG. 25-24 Removal of RNA primers in eukaryotes. (1) RNase H1 excises all but the 5'-ribonucleotide of the RNA primer. (2) FEN1, a 5' → 3' endonuclease, then removes the remaining ribonucleotide along with a segment of adjoining DNA if it contains mismatches. (3) The excised nucleotides are replaced as DNA polymerase δ completes the synthesis of the next Okazaki fragment (on the left in this diagram). The nick is eventually sealed by DNA ligase.

? How does this process compare to the removal of RNA primers in *E. coli*?

p66

p51

the p66 subunit follows the connection domain. The p66 and p51 subunits are not related by twofold molecular symmetry (a rare but not unprecedented phenomenon) but instead associate in a sort of head-to-tail arrangement. Consequently, RT has only one polymerase active site.

Reverse transcriptase lacks a proofreading exonuclease function and hence is highly error-prone. Indeed, it is HIV's capacity to rapidly evolve, even within a single host, that presents a major obstacle to the development of an anti-HIV vaccine. This high rate of mutation is also the main contributor to the ability of HIV to rapidly develop resistance to drugs that inhibit virally encoded enzymes, including RT.

[Based on an X-ray structure by Edward Arnold, Rutgers University. PDBid 3JYT.]

does a prokaryotic chromosome, its bidirectional replication from a single origin, as in prokaryotes, would require ~ 1 month. Electron micrographs such as [Fig. 25-25](#), however, show that *eukaryotic chromosomes contain multiple origins*, one every 3 to 300 kb, depending on both the species and the tissue, so replication usually requires just a few hours to complete.

In yeast, the initiation of DNA replication occurs at **autonomously replicating sequences (ARS)**, which are conserved 11-bp sequences adjacent to easily unwound DNA. In mammalian genomes, replication origins do not exhibit sequence conservation, yet these sites all support the binding of a six-subunit **origin recognition complex (ORC)**. Additional ATP-hydrolyzing proteins help assemble the MCM helicase. The resulting **prereplication complex (pre-RC)** is not competent to initiate replication until it has been activated by other factors

From Kreigstein, H.J., and Hogness, D.S. *Proc. Natl. Acad. Sci.* **7**, 136 (1974)

FIG. 25-25 Electron micrograph of a fragment of replicating *Drosophila* DNA. The arrows indicate the multiple replication eyes.

? Identify the replication forks of one of the replication eyes.

that control progress through the cell cycle (Section 28-4A). Presumably, the separate control of pre-RC assembly and activation allows cells to select replication origins before MCM unwinds the template DNA and replication commences. Once DNA synthesis is under way, no new pre-RC complexes can form, thereby ensuring that the DNA is replicated once and only once per cell cycle.

Initiation sites are uniformly distributed across the genome in early embryogenesis, when cell division is rapid. However, after cells have differentiated, the distribution of replication origins changes, possibly reflecting patterns of gene expression and/or alterations in DNA packaging in different cell types.

Cytological observations indicate that the various chromosomal regions are not all replicated simultaneously. Rather, clusters of 20 to 80 adjacent **replicons** (replicating units; DNA segments that are each served by a replication origin) are activated simultaneously. New sets of replicons are activated until the entire chromosome has been replicated. DNA replication proceeds in each direction from the origin of replication until each replication fork collides with a fork from the adjacent replicon. Eukaryotes appear to lack termination sequences analogous to the *Ter* sites in *E. coli*.

In eukaryotes, the products of DNA replication—two identical DNA molecules—remain associated at a region known as the centromere. When cell division commences and chromatin becomes highly condensed, the two sister chromatids, which each contain one of the DNA molecules, become visible as an X-shaped structure (e.g., Fig. 24-41). Each daughter cell ultimately receives one sister chromatid from each replicated chromosome.

Nucleosomes Reassemble behind the Replication Forks. Unlike prokaryotic DNA, eukaryotic DNA is packaged in nucleosomes (Section 24-5A). Some alteration of this structure is probably necessary for initiation, but once replication is under way, nucleosomes do not seem to impede the progress of DNA polymerases. Experiments with labeled histones indicate that nucleosomes just ahead of the replication fork disassemble and the freed histones, either individually or as dimers or tetramers, immediately reassociate with the emerging daughter duplexes. The parental histones randomly associate with the leading and lagging duplexes. DNA replication (which occurs in the nucleus) is coordinated with histone protein synthesis in the cytosol so that new histones are available in the required amounts.

C Telomerase Extends Chromosome Ends

The ends of linear chromosomes present a problem for the replication machinery. Specifically, *DNA polymerase cannot synthesize the extreme 5' end of the lagging strand* (Fig. 25-26). Even if an RNA primer were paired with the 3' end of the DNA template, it could not be replaced with DNA (recall that DNA polymerase operates only in the 5' → 3' direction; it can only extend an existing primer, and the primer must be bound to its complementary strand). Consequently, *in the absence of a mechanism for completing the lagging strand, linear chromosomes would be shortened at both ends by at least the length of an RNA primer with each round of replication.*

Telomeres Are Built from an RNA Template. The ends of eukaryotic chromosomes, the **telomeres** (Greek: *telos*, end), have an unusual structure. Telomeric DNA consists of 1000 or more tandem repeats of a short G-rich sequence (TTGGGG in the protozoan *Tetrahymena* and TTAGGG in humans) on the 3'-ending strand of each chromosome end.

Elizabeth Blackburn, Carol Greider, and Jack Szostak have shown that telomeric DNA is synthesized and maintained by an enzyme named **telomerase**, which is a **ribonucleoprotein** (a complex of protein and RNA). The RNA component (451 nt in humans) includes a segment that is complementary to the repeating telomeric sequence and acts as a template for a reaction in which

FIG. 25-26 Replication of a linear chromosome. Leading strand synthesis can proceed to the end of the chromosome (*top*). However, DNA polymerase cannot synthesize the extreme 5' end of the lagging strand because it can only extend an RNA primer that is paired with the 3' end of a template strand (*bottom*). Removal of the primer and degradation of the remaining single-stranded extension would cause the chromosome to shorten with each round of replication.

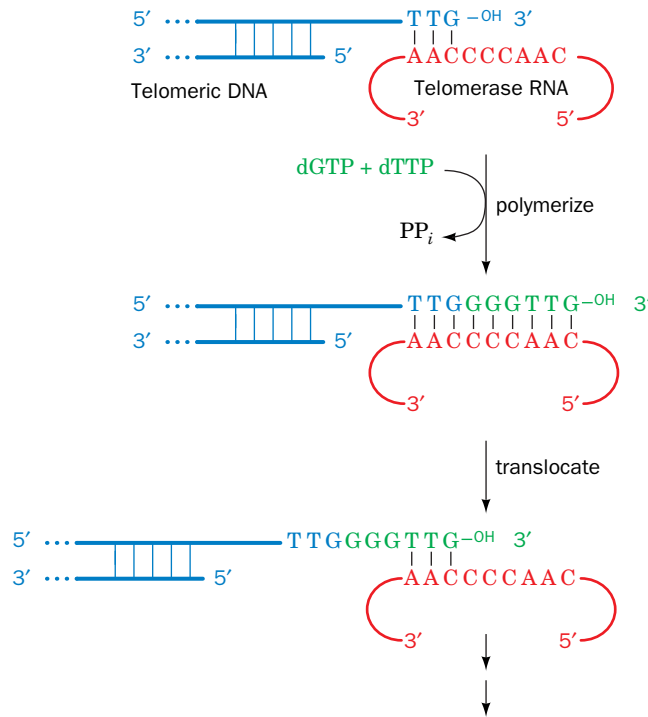

FIG. 25-27 Mechanism for the synthesis of telomeric DNA by *Tetrahymena* telomerase. The telomere’s 5’-ending strand is later extended by normal lagging strand synthesis. [After Greider, C.W. and Blackburn, E.H., *Nature* **337**, 336 (1989).]

? What processes are represented by the two arrows at the bottom of the diagram?

nucleotides are added to the 3’ end of the DNA (Fig. 25-27, top). Telomerase repeatedly translocates to the new 3’ end of the DNA strand, thereby adding multiple telomeric sequences to the DNA (Fig. 25-27, bottom). The DNA strand complementary to the telomeric G-rich strand is apparently synthesized by the normal cellular machinery for lagging strand synthesis, leaving a 100- to 300-nt single-stranded overhang on the G-rich strand.

Telomerase, a multienzyme complex, functions similarly to reverse transcriptase (Box 25-2); in fact, its highly conserved catalytic subunit, called **TERT**, is homologous to reverse transcriptase. In addition to the fingers, palm, and thumb domains typical of other polymerases, TERT includes an N-terminal telomere repeat binding domain (TRBD). The X-ray structure of TERT from the flour beetle *Tribolium castaneum* in complex with a nucleic acid hairpin containing its RNA template and its telomeric DNA (Fig. 25-28a), was determined by Emmanuel Skordalakes. The protein had been cocrystallized with a 21-nt RNA–DNA hybrid hairpin with a 5’-triribonucleotide overhang (Fig. 25-28b). However, the X-ray structure revealed that the enzyme had appended the 3’-trideoxynucleotide d(CAG), which is

FIG. 25-28 X-Ray structure of TERT in complex with a nucleic acid hairpin containing its RNA template and its telomeric DNA. (a) The protein, from the flour beetle *Tribolium castaneum*, is shown in ribbon form with its four domains in different colors. The nucleic acid is drawn in paddle form with its ten 5’-terminal ribonucleotides cyan and its fourteen 3’-terminal deoxynucleotides green. [Based on an X-ray structure by Emmanuel Skordalakes, The Wistar Institute, Philadelphia, Pennsylvania. PDBid 3KYL.] (b) The sequence and secondary structure of the 24-bp RNA–DNA hybrid hairpin cocrystallized with TERT, colored as in Part a. The RNA templating segment and the telomeric DNA are boxed and the Watson-Crick base pairs are represented by the vertical black lines. A hairpin consisting of only the 5’-terminal 21 nucleotides of the 24-mer was cocrystallized with TERT but the enzyme added the trideoxynucleotide 5’-CAG-3’ to the 3’ end of the hairpin.

FIG. 25-29 Structure of the telomeric oligonucleotide d(GGGGTTTGGGG). (a) The base-pairing interactions in the G-quartet. (b) Schematic diagram of the NMR structure in which the strand directions are indicated by arrows. The nucleotides are numbered 1 to 12 in one strand and 1* to 12* in the symmetry-related strand. Guanine residues G1 to G4 are represented by blue rectangles, G9 to G12 are cyan, G1* to G4* are red, and G9* to G12* are pink. CHECKPOINT

- Describe how pol α , pol δ , PCNA, RNase H1, FEN1, and DNA ligase participate in eukaryotic DNA synthesis.
- In what ways does replication differ between eukaryotes and prokaryotes?
- What is the function of the prereplication complex?
- What happens to nucleosomes during and after replication?
- Describe the structure, function, and synthesis of telomeres.
- What does telomerase do and why is this enzyme unlike other DNA polymerases?

complementary to the 5' overhang, thereby demonstrating that TERT was catalytically active.

The absence of telomerase, which allows the gradual truncation of chromosomes with each round of DNA replication, contributes to the normal senescence of cells. Conversely, enhanced telomerase activity permits the uncontrolled replication and cell growth that occur in cancer (Box 25-3).

Telomeres Form G-Quartets. Guanine-rich polynucleotides are notoriously difficult to work with. This is because of their propensity to aggregate via Hoogsteen-type base pairing (Section 24-2A) to form cyclic tetramers known as **G-quartets** (Fig. 25-29a). Indeed, the G-rich overhanging strands of telomeres fold back on themselves to form a hairpin, two of which associate in an antiparallel fashion to form stable complexes of stacked G-quartets (Fig. 25-29b). Such structures presumably serve as binding sites for capping proteins, which may help regulate telomere length and prevent activation of DNA repair mechanisms that recognize the ends of broken DNA molecules.

4 DNA Damage

KEY CONCEPTS

- DNA is susceptible to damage from a variety of sources.
- Mutagenicity, which is related to carcinogenicity, can be tested in living cells.

The fidelity of DNA replication carried out by DNA polymerases and their attendant proofreading functions is essential for the accurate transmission of genetic information during cell division. Yet errors in polymerization occasionally occur and, if not corrected, may alter the nucleotide sequences of genes. DNA can also be chemically altered by agents that are naturally present in the cell or in the cell's external environment.

Without the action of telomerase, a chromosome would be shortened at both ends by at least the length of an RNA primer with every cycle of DNA replication and cell division. It was therefore initially assumed that, in the absence of active telomerase, essential genes located near the ends of chromosomes would eventually be lost, thereby killing the descendants of the originally affected cells. However, it is now evident that telomeres serve another vital chromosomal function that must be compromised before this can happen. Free DNA ends trigger DNA damage repair systems that normally function to rejoin the ends of broken chromosomes (Section 25-5E). Consequently, exposed telomeric DNA would result in the end-to-end fusion of chromosomes, a process that leads to chromosomal instability and eventual cell death (fused chromosomes often break in mitosis; their two centromeres cause them to be pulled in opposite directions). However, in a process known as **capping**, telomeric DNA is specifically bound by proteins that hide the DNA ends. There is mounting evidence that capping is a dynamic process in which the probability of a telomere spontaneously uncapping increases as telomere length decreases.

The somatic cells of multicellular organisms lack telomerase activity. This explains why such cells in culture can undergo only a limited number of doublings (20–60) before they reach **senescence** (a stage in which they cease dividing) and eventually die. Indeed, otherwise immortal *Tetrahymena* cultures with mutationally impaired telomerases exhibit characteristics reminiscent of senescent mammalian cells

before dying off. Apparently, *the loss of telomerase function in somatic cells is a basis for aging in multicellular organisms.*

Despite the foregoing, there is only a weak correlation between the proliferative capacity of a cultured cell and the age of its donor. There is, however, a strong correlation between the initial telomere length in a cell and its proliferative capacity. Cells that initially have relatively short telomeres undergo significantly fewer doublings than cells with longer telomeres. Moreover, fibroblasts from individuals with **progeria** (a rare disease characterized by rapid and premature aging resulting in childhood death) have short telomeres, an observation that is consistent with their known reduced proliferative capacity in culture. In contrast, sperm (which are essentially immortal) have telomeres that do not vary in length with donor age, which indicates that telomerase is active during germ-cell growth. Likewise, those few cells in culture that become immortal (capable of unlimited proliferation) exhibit an active telomerase and a telomere of stable length, as do the cells of unicellular eukaryotes (which are also immortal).

What selective advantage might multicellular organisms gain by eliminating the telomerase activity in their somatic cells? An intriguing possibility is that cellular senescence is a mechanism that protects multicellular organisms from cancer. Indeed, ~90% of cancer cells, which are immortal and grow uncontrollably, contain active telomerase. For example, the enzyme is active in ovarian cancer cells but not in normal ovarian tissue. This hypothesis makes telomerase inhibitors an attractive target for antitumor drug development.

In many cases, damaged DNA can be repaired, as discussed in Section 25-5. Severe lesions, however, may be irreversible, leading to the loss of genetic information and, often, cell death. Even when damaged DNA can be mended, the restoration may be imperfect, producing a **mutation**, a heritable alteration of genetic information. In multicellular organisms, genetic changes are usually notable only when they occur in germline cells so that the change is passed on to all the cells of the organism's offspring. Damage to the DNA of a somatic cell, in contrast, rarely has an effect beyond that cell unless the mutation contributes to a malignant transformation (cancer).

A Environmental and Chemical Agents Generate Mutations

Environmental agents such as ultraviolet light, ionizing radiation, and certain chemical agents can physically damage DNA. For example, UV radiation (200–300 nm) promotes the formation of a cyclobutyl ring between adjacent thymine residues on the same DNA strand to form an intrastrand **thymine dimer** (Fig. 25-30). Similar cytosine and thymine–cytosine dimers also form but less frequently. Such **pyrimidine dimers** locally distort DNA's base-paired structure, interfering with transcription and replication. Ionizing radiation also damages DNA either through its direct action on the DNA molecule or indirectly by inducing the formation of free radicals, particularly the hydroxyl radical (HO•), in the surrounding aqueous medium. This can lead to strand breakage.

The DNA damage produced by **chemical mutagens**, substances that induce mutations, falls into two major classes:

1. **Point mutations**, in which one base pair replaces another. These are subclassified as:
 - (a) **Transitions**, in which one purine (or pyrimidine) is replaced by another.
 - (b) **Transversions**, in which a purine is replaced by a pyrimidine or vice versa.

FIG. 25-30 The cyclobutylthymine dimer. The dimer forms on UV irradiation of two adjacent thymine residues on a DNA strand. The ~1.6-Å-long covalent bonds joining the thymine rings (red) are much shorter than the normal 3.4-Å spacing between stacked rings in B-DNA, thereby locally distorting the DNA.

FIG. 25-31 Oxidative deamination by nitrous acid. (a) Cytosine is converted to uracil, which base-pairs with adenine. (b) Adenine is converted to hypoxanthine, a guanine derivative (it lacks guanine's 2-amino group) that base-pairs with cytosine.

? Describe the makeup of the DNA following replication of the deaminated DNA.

2. **Insertion/deletion mutations**, in which one or more nucleotide pairs are inserted in or deleted from DNA. These are collectively known as **indels**.

Point Mutations Result from Altered Bases. One cause of point mutations is treatment of DNA with nitrous acid (HNO_2), which oxidatively deaminates aromatic primary amines. Cytosine is thereby converted to uracil and adenine to the guaninelike hypoxanthine (which forms two of guanine's three hydrogen bonds with cytosine; Fig. 25-31). Hence, treatment of DNA with nitrous acid results in both $\text{A} \cdot \text{T} \rightarrow \text{G} \cdot \text{C}$ and $\text{G} \cdot \text{C} \rightarrow \text{A} \cdot \text{T}$ transitions. Despite its potential mutagenic activity, nitrite (the conjugate base of nitrous acid) is used as a preservative in prepared meats such as frankfurters because it also prevents the growth of *Clostridium botulinum*, the organism that causes botulism. Base deamination reactions also occur spontaneously in the absence of nitrous acid.

Cellular metabolism itself exposes DNA to the damaging effects of reactive oxygen species (e.g., the superoxide ion O_2^- , the hydroxyl radical, and H_2O_2) that are normal by-products of oxidative metabolism (Section 18-4B). More than 100 different oxidative modifications to DNA have been catalogued. For example, guanine can be oxidized to **8-oxoguanine (oxoG)** (at left). When the modified DNA strand is replicated, the oxoG can base-pair with either C or A, causing a $\text{G} \cdot \text{C} \rightarrow \text{T} \cdot \text{A}$ transversion.

Alkylating agents such as dimethyl sulfate, **nitrogen mustard**, **ethylnitrosourea**, and ***N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG)**

8-Oxoguanine (oxoG) residue

***O*⁶-Methylguanine residue**

can also generate transversions. For example, the exposure of DNA to MNNG yields, among other products, ***O*⁶-methylguanine** residues (at left), which can base-

pair with either C or T. The metabolic methylating agent *S*-adenosylmethionine (Section 21-4D) occasionally nonenzymatically methylates a base to form derivatives such as 3-methyladenine and 7-methylguanine residues. However, base methylations also have normal physiological functions (Box 25-4).

The alkylation of the N7 position of a purine nucleotide increases the susceptibility of its glycosidic bond to hydrolysis, leading to loss of the base. The resulting gap in the sequence is filled in by an error-prone enzymatic repair system. Transversions arise when the missing purine is replaced by a pyrimidine. Even in the absence of alkylating agents, the glycosidic bonds of an estimated 20,000 of the 6.0 billion purine nucleotides in each diploid human cell spontaneously hydrolyze every day.

Insertion/Deletion Mutations Are Generated by Intercalating Agents. Insertion/deletion mutations (indels) may arise from the treatment of DNA with intercalating agents such as acridine orange or proflavin (Section 24-3B). The distance between two consecutive base pairs is roughly doubled by the intercalation of such a molecule between them. The replication of the distorted DNA occasionally results in the insertion or deletion of one or more nucleotides in the newly synthesized polynucleotide. (Insertions and deletions of large segments generally arise from aberrant crossover events; Section 25-6A.)

All Mutations Are Random. The bulk of the scientific data regarding mutagenesis is that mutations, whether the result of polymerase errors, spontaneous modification, or chemical damage to DNA, occur at random. This paradigm was challenged by John Cairns, who demonstrated that bacteria unable to digest lactose preferentially acquired the mutations they needed to use lactose when it was the only nutrient available. This observation, which suggests that bacteria can “direct” mutations that benefit them, more likely reflects a nonspecific adaptive response in which the overall rate of mutation—useful as well as nonuseful—increases when the cells are under metabolic stress. *The hypermutable state appears to reflect the activation of error-prone DNA repair and recombination systems that are relatively inactive in normally growing cells.*

B Many Mutagens Are Carcinogens

Not all alterations to DNA have phenotypic consequences. For example, mutations in noncoding segments of DNA are often invisible. Similarly, the redundancy of the genetic code (more than one trinucleotide may specify a particular amino acid; Section 27-1C) can mask point mutations. Even when a protein’s amino acid sequence is altered, its function may be preserved if the substitution is conservative (Section 5-4A) or occurs on a surface loop. Nevertheless, even a single point mutation, if appropriately located, can irreversibly alter cellular metabolism, for example, by causing cancer. As many as 80% of human cancers may be caused by **carcinogens** that damage DNA or interfere with its replication or repair. Consequently, many mutagens are also carcinogens.

There are presently more than 80,000 man-made chemicals of commercial importance, and ~1000 new ones are introduced every year. The standard animal tests for carcinogenesis, exposing rats or mice to high levels of the suspected carcinogen and checking for cancer, are expensive and require ~3 years to complete. Thus, relatively few substances have been tested in that manner. Likewise, epidemiological studies in humans are costly, time-consuming, and often inconclusive.

Bruce Ames devised a rapid and effective bacterial assay for carcinogenicity that is based on the high correlation between carcinogenesis and mutagenesis. He constructed special strains of the bacterium *Salmonella typhimurium* that are *his*⁻ (cannot synthesize histidine and therefore cannot grow in its absence). Mutagenesis in these strains is indicated by their reversion to the *his*⁺ phenotype. In the **Ames test**, ~10⁹ test bacteria are spread on a culture plate that lacks histidine. A

Not all DNA modifications are detrimental. For example, the A and C residues of DNA may be methylated, in a species-specific pattern, to form ***N*⁶-methyladenine (m⁶A)**, ***N*⁴-methylcytosine (m⁴C)**, and **5-methylcytosine (m⁵C)** residues:

***N*⁶-Methyladenine (m⁶A) residue**

5-Methylcytosine (m⁵C) residue

***N*⁴-Methylcytosine (m⁴C) residue**

The methyl groups project into B-DNA's major groove, where they can interact with DNA-binding proteins. In most cells, only a few percent of the susceptible bases are methylated, although this figure rises to >30% of the C residues in some plants.

Bacterial DNAs are methylated at their own particular restriction sites by modification methylases, thereby preventing the corresponding restriction endonuclease from cleaving the DNA (Section 3-4A). Other **methyltransferases** also modify DNA bases in a sequence-specific manner. For example, in *E. coli*, the **Dam methyltransferase** methylates the A residue in all GATC sequences and the **Dcm methyltransferase**

methylates both C residues in CC₄GG at their C5 positions. Note that both of these sequences are palindromic.

In addition to its role in restriction–modification systems, DNA methylation in prokaryotes functions most conspicuously as a marker of parental DNA in the repair of mismatched base pairs. Any replicational mispairing that has eluded the editing functions of Pol I and Pol III may still be corrected by a process known as mismatch repair (Section 25-5D). However, if this system is to correct errors rather than perpetuate them, it must distinguish the parental DNA, which has the correct base, from the daughter strand, which has the incorrect although normal base. The observation that *E. coli* cells with a deficient Dam methyltransferase have higher mutation rates than wild-type bacteria suggests how this distinction is made. A newly replicated daughter strand is undermethylated compared to the parental strand because DNA methylation lags behind DNA synthesis.

5-Methylcytosine is the only methylated base in most eukaryotic DNAs, including those of vertebrates. This modification occurs largely in the CG dinucleotide of various palindromic sequences. CG is present in the vertebrate genome at only about one-fifth its randomly expected frequency. The upstream regions of many genes, however, have normal CG frequencies and are therefore known as **CpG islands**.

There is clear evidence that *DNA methylation switches off eukaryotic gene expression, particularly when it occurs in the promoter regions upstream of a gene's transcribed sequence* (Section 28-3A). For example, globin genes are less methylated in erythroid cells than they are in nonerythroid cells and, in fact, the specific methylation of the control region in a recombinant globin gene inhibits its transcription. Moreover, the methylation pattern of a parental DNA strand directs the methylation of its daughter strand (a methylated CG sequence directs a methyltransferase to methylate its complementary CG sequence), so that the “inheritance” of a methylation pattern in a cell line permits all the cells to have the same differentiated phenotype. Variations in methylation are responsible for **genomic imprinting** in mammals, the phenomenon in which certain maternal and paternal genes are differentially expressed in the offspring (Section 28-3A).

mutagen placed in the culture medium causes some of the *his*[−] bacteria to become *his*⁺ so that they grow into visible colonies after 2 days at 37°C (Fig. 25-32). The mutagenicity of a substance is scored as the number of such colonies minus the few spontaneously revertant colonies that occur in the absence of the mutagen. Dose–response curves, which are generated by testing a given compound at a number of concentrations, are almost always linear, indicating that *there is no threshold concentration for mutagenesis*.

About 80% of the compounds determined to be carcinogens in whole-animal experiments are also mutagenic by the Ames test. Because many noncarcinogens

FIG. 25-32 The Ames test for mutagenesis. A filter paper disk containing a mutagen, in this case the alkylating agent ethyl methanesulfonate, is centered on a culture plate containing *his*[−] strains of *Salmonella typhimurium* in a medium that lacks histidine. A dense halo of revertant bacterial colonies appears around the disk from which the mutagen diffused. The larger colonies distributed around the culture plate are spontaneous revertants. The bacteria near the disk have been killed by the toxic mutagen's high concentration.

? Describe the appearance of a culture plate in which the disk contains a substance that is not mutagenic.

are converted to carcinogens in the liver or in other tissues via a variety of detoxification reactions (e.g., those catalyzed by the cytochromes P450; Section 12-4D), a small amount of rat liver homogenate is therefore included in the Ames test medium in order to approximate the effects of mammalian metabolism. Alternatively, carcinogenicity testing may be carried out using mammalian cell cultures rather than bacteria.

Several compounds to which humans had been extensively exposed that were found to be mutagenic by the Ames test were later found to be carcinogenic in animal tests. These include **tris(2,3-dibromopropyl)phosphate**, which was used as a flame retardant in children's sleepwear in the mid-1970s and can be absorbed through the skin; and **furylfuramide**, which was used in Japan in the 1960s and 1970s as an antibacterial additive in many prepared foods (and which had passed two animal tests before it was found to be mutagenic).

CHECKPOINT

- Make a list of the environmental and chemical agents that can alter DNA.
- Describe the different kinds of mutations.
- Why is it practical to test carcinogens by a mutagenesis assay?
- Must a carcinogen also be a mutagen?

5 DNA Repair

KEY CONCEPTS

- Some DNA damage can be repaired by the action of a single enzyme.
- Damaged bases can be removed and replaced by base excision repair.
- In nucleotide excision repair, a segment of one damaged DNA strand is removed and replaced.
- Replication errors can be corrected by mismatch repair.
- Some repair mechanisms are error-prone.

A typical mammalian cell incurs DNA damage at the rate of more than 100,000 molecular lesions per day. These lesions, which arise from both environmental and metabolic insults, must be repaired to maintain genomic integrity. The biological importance of DNA repair is indicated by the great variety of repair mechanisms in even simple organisms such as *E. coli*. These systems include enzymes that simply reverse the chemical modification of nucleotide bases as well as more complicated multienzyme systems that depend on the inherent redundancy of the information in duplex DNA to restore the damaged molecule.

A Some Damage Can Be Directly Reversed

Several enzymes recognize and reverse certain types of DNA damage. For example, pyrimidine dimers (Fig. 25-30) may be restored to their monomeric forms by **photoreactivation** catalyzed by light-absorbing enzymes known as **DNA photolyases**. These 55- to 65-kD monomeric enzymes are found in many prokaryotes and eukaryotes but not in placental mammals such as humans. Photolyases contain two prosthetic groups: a light-absorbing cofactor and FADH⁻. In the *E. coli* enzyme, the cofactor *N*⁵,*N*¹⁰-methenyltetrahydrofolate (MTHF; Section 21-4D) absorbs UV-visible light (300–500 nm) and transfers the excitation energy to the FADH⁻, which then transfers an electron to the pyrimidine dimer, thereby splitting it. The resulting pyrimidine anion reduces the FADH⁻ to regenerate the enzyme.

The X-ray structure of the 474-residue DNA photolyase from the cyanobacterium *Anacystis nidulans* in complex with a 9-bp dsDNA containing a synthetic thymine dimer whose bridging phosphate group was replaced by a —O—CH₂—O— group (which does not affect the enzyme's ability to split the dimer) reveals how the enzyme splits the thymine dimer. The DNA binds to a highly positively charged surface on the protein with its thymine dimer flipped out of the double

FIG. 25-33 X-Ray structure of *A. nidulans* DNA photolyase in complex with dsDNA containing a synthetic thymine dimer. The protein is drawn in worm form embedded in its semitransparent surface diagram. The DNA, in which the phosphate group bridging the nucleotides of the thymine dimer is replaced by an $-O-CH_2-O-$ group, is drawn mainly in stick form but with the bases of the thymine dimer in space-filling form, all colored according atom type (C green, N blue, O red, and P orange) and with successive P atoms in each polynucleotide chain connected by orange rods. The FAD and N^5, N^{10} -methylene tetrahydrofolate (MTHF) are drawn in stick form with their flavin and flavinlike rings in space-filling form and with FAD C magenta and MTHF C yellow. [Based on an X-ray structure by Thomas Carell, Ludwig Maximilians University, Munich, Germany, and Lars-Oliver Essen, Philipps University, Marburg, Germany. PDBid 1TEZ.]

helix and bound in a deep cavity (Fig. 25-33). This flip-out is probably facilitated by the relatively weak base-pairing interactions of the thymine dimer and the distortions it imposes on the double helix. In the following discussions we will see that this so-called **base flipping** (really nucleotide flipping, since entire nucleotides flip out of the double helix) is by no means an unusual process for enzymes that perform chemistry on the bases of dsDNA. The DNA outside of the thymine dimer assumes the B conformation but at the thymine dimer is bent by 50° away from the protein, thereby unstacking the adenine bases complementary to the dimerized thymine bases. The “hole” in the DNA helix left by the flipped out thymine dimer is partially occupied by an irregular protein ridge.

In the X-ray structure, the thymine dimer’s C5—C5 and C6—C6 bonds are broken. Yet, in the crystal, the enzyme-bound thymine dimer is stable in the dark for at least a year. Apparently, the X-rays used to generate the diffraction data mimic the effects of the light that normally ruptures these bonds. Moreover, the FAD’s isoalloxazine ring exhibits a 9° “butterfly” bend about its N5—N10 axis (the isoalloxazine ring’s atomic numbering scheme is given in Fig. 14-14), which indicates that it is in the fully reduced $FADH^-$ form. The isoalloxazine ring and adenine ring of the $FADH^-$, which has a folded conformation, are in van der Waals contact with one or the other bases of the thymine dimer, and the isoalloxazine ring is ~ 10 Å distant from the flavin-like ring of the MTHF. This permits the observed efficient energy transfer in the photolyase reaction (which has a quantum yield of ~ 0.9).

Another type of direct DNA repair is the reversal of base methylation by **alkyltransferases**. For example, O^6 -methylguanine and O^6 -ethylguanine lesions of DNA (Section 25-4A) are repaired by **O^6 -alkylguanine-DNA alkyltransferase**, which directly transfers the offending methyl or ethyl group to one of its own Cys residues. This reaction inactivates the protein, which therefore cannot be strictly classified as an enzyme. Apparently, the high cost of sacrificing the alkyltransferase is justified by the highly mutagenic nature of the modified guanine residue.

B Base Excision Repair Requires a Glycosylase

Damaged bases that cannot be directly repaired may be removed and replaced in a process, discovered by Tomas Lindahl, known as **base excision repair (BER)**. This pathway, as its name implies, begins with removal of the damaged base. Cells contain a variety of **DNA glycosylases** that each cleave the glycosidic bond of a corresponding type of altered nucleotide, leaving a deoxyribose residue with no attached base (Fig. 25-34). Such **apurinic** or **apyrimidinic sites (AP or abasic sites)** also result from the occasional spontaneous hydrolysis of glycosidic bonds. The deoxyribose residue is then cleaved on one side by an **AP endonuclease**, the deoxyribose and several adjacent residues are removed by the action of a cellular exonuclease (possibly associated with a DNA polymerase), and the gap is filled in and sealed by a DNA polymerase and DNA ligase.

FIG. 25-34 Action of DNA glycosylases. These enzymes hydrolyze the glycosidic bond of their corresponding altered base (red) to yield an AP site.

? List the steps that occur to fully repair this DNA.

Box 25-5 Perspectives in Biochemistry Why Doesn't DNA Contain Uracil?

Three of the deoxynucleotide bases in DNA (adenine, guanine, and cytosine) also occur as ribonucleotide bases in RNA. The fourth deoxynucleotide base, thymine, is synthesized—at considerable metabolic effort (Section 23-3B)—from uracil, which occurs in RNA. Since uracil and thymine have identical base-pairing properties, why do cells bother to synthesize thymine at all?

This enigma was solved by the discovery of cytosine's penchant for conversion to uracil by deamination, either spontaneously or by reaction with nitrites (Section 25-4A). If U were a normal DNA base, the deamination of C would be highly mutagenic because there would be

no indication of whether the resulting mismatched G · U base pair had initially been G · C or A · U. Since T is DNA's normal base, however, any U in DNA is almost certainly a deaminated C and can be removed by uracil–DNA glycosylase.

Uracil–DNA glycosylase also has an important function in DNA replication. dUTP, an intermediate in dTTP synthesis, is present in all cells in small amounts. DNA polymerases do not discriminate well between dUTP and dTTP, both of which can base-pair with template A's. Consequently, newly synthesized DNA contains an occasional U. These U's are rapidly replaced by T through base excision repair.

The enzymes of BER, which correct the most frequent type of DNA damage, include a glycosylase that recognizes 8-oxoguanine and the enzyme **uracil–DNA glycosylase (UDG)**, which excises uracil residues. The latter arise from cytosine deamination as well as the occasional misincorporation of uracil instead of thymine into DNA (Box 25-5).

The X-ray structure of human UDG in complex with a 10-bp DNA containing a U · G mismatch (which forms a doubly hydrogen-bonded base pair whose shape differs from that of Watson–Crick base pairs; Section 24-1A), determined by John Tainer, reveals that the enzyme has bound the DNA with the U · G base pair's uridine nucleotide flipped out of the double helix (**Fig. 25-35**). Moreover, the enzyme has hydrolyzed the uridine's glycosidic bond, yielding the free uracil base and an AP site on the DNA, although both products remain bound to the enzyme. The cavity in the DNA's base stack that would otherwise be occupied by the flipped-out uracil is filled by the side chain of Arg 272, which intercalates into the DNA from its minor groove side.

How does UDG detect a base-paired uracil in the center of DNA and how does it discriminate so acutely between uracil and other bases, particularly the closely similar thymine? The X-ray structure indicates that the phosphate groups flanking the flipped-out base are 4 Å closer together than they are in B-DNA (8 Å versus 12 Å), which causes the DNA to kink by $\sim 45^\circ$ in the direction parallel to the view in Fig. 25-35. Tainer has postulated that UDG rapidly scans a DNA molecule for uracil by periodically binding to it so as to compress and thereby slightly bend the DNA backbone. The DNA bends more readily at a uracil-containing site (a U · G base pair is smaller than C · G and hence leaves a space in the base stack, whereas a U · A base pair is even weaker than T · A), permitting the enzyme to flip out the uracil by inserting Arg 272 into the minor groove. The exquisite specificity of UDG's binding pocket for uracil prevents the binding and hydrolysis of any other base that the enzyme might have induced to

FIG. 25-35 X-Ray structure of a complex of human uracil–DNA glycosylase with a 10-bp DNA containing a U · G base pair. The protein (the C-terminal 223 residues of the 304-residue monomer) is represented by its ribbon diagram embedded in its transparent molecular surface. The DNA, viewed looking into its major groove, is drawn in stick form colored according to atom type (C green, N blue, O red, and P orange). The U · G base pair's uridine nucleotide has flipped out of the double helix (to the right of the DNA) and has been hydrolyzed to yield an AP site (stick form with C cyan) and uracil (space-filling form with C cyan), which remains bound in the enzyme's binding pocket. The side chain of Arg 272 (space-filling form with C yellow) has intercalated into the DNA base stack to fill the space vacated by the flipped-out uracil base. [Based on an X-ray structure by John Tainer, The Scripps Research Institute, La Jolla, California. PDBid 4SKN.]

flip. Thus the overall shapes of adenine and guanine exclude them from this pocket, whereas thymine's 5-methyl group is sterically blocked by the rigidly held side chain of Tyr 147. Cytosine, which has approximately the same shape as uracil, is excluded through a set of hydrogen bonds emanating from the protein that mimic those made by adenine in a Watson–Crick A · U base pair (dUTPase discriminates similarly between uracil and other bases; Fig. 23-14).

AP sites in mammalian DNA are highly cytotoxic because they irreversibly trap mammalian topoisomerase I in its covalent complex with DNA (Section 24-1D). Moreover, since the ribose at the AP site lacks a glycosidic bond, it can readily convert to its linear form (Section 8-1B), whose reactive aldehyde group can cross-link to other cell components. This rationalizes why AP sites remain tightly bound to UDG in solution. UDG activity is enhanced by AP endonuclease, the next enzyme in the base excision repair pathway, but the two enzymes do not interact in the absence of DNA. This suggests that UDG remains bound to an AP site it generated until it is displaced by the more tightly binding AP endonuclease, thereby protecting the cell from the AP site's cytotoxic effects. It seems likely that other damage-specific DNA glycosylases function similarly.

C Nucleotide Excision Repair Removes a Segment of a DNA Strand

All cells have a more elaborate pathway, **nucleotide excision repair (NER)**, to correct pyrimidine dimers and other DNA lesions in which the bases are displaced from their normal position or have bulky substituents. The NER system, which was elucidated by Aziz Sancar, appears to respond to helix distortions rather than by the recognition of any particular group. In humans, NER is the major defense against two important carcinogens, sunlight and tobacco smoke.

In *E. coli*, NER is carried out in an ATP-dependent process through the actions of the **UvrA**, **UvrB**, and **UvrC** proteins (the products of the *uvrA*, *uvrB*, and *uvrC* genes). This system, which is often referred to as the **UvrABC endonuclease** (although there is no complex that contains all three subunits), cleaves the damaged DNA strand at the seventh and at the third or fourth phosphodiester bonds from the lesion's 5' and 3' sides, respectively (Fig. 25-36). The excised 11- or 12-nt oligonucleotide is then displaced by the binding of **UvrD** (also called **helicase II**) and is replaced through the actions of Pol I and DNA ligase.

FIG. 25-36 The mechanism of nucleotide excision repair (NER) of pyrimidine dimers.

Xeroderma Pigmentosum and Cockayne Syndrome Are Caused by Genetically Defective NER. In eukaryotes, NER requires at least 16 proteins and removes oligonucleotides of ~30 residues. The proteins are conserved from yeast to humans but none of them exhibit any sequence similarity to the prokaryotic proteins, suggesting that the two NER systems arose by convergent evolution. Many of the enzymes involved in the human pathway have been identified through mutations that are manifested as two genetic diseases. The inherited disease **xeroderma pigmentosum (XP)**; Greek: *xeros*, dry + *derma*, skin) is mainly characterized by the inability of skin cells to repair UV-induced DNA lesions. Individuals suffering from this autosomal recessive condition are extremely sensitive to sunlight. During infancy they develop marked skin changes such as dryness, excessive freckling, and keratoses (a type of skin tumor; the skin of these children is described as resembling that of farmers with many years of sun exposure), together with eye damage, such as opacification and ulceration of the cornea. Moreover, they develop often fatal skin cancers at an ~2000-fold greater rate than normal and internal cancers at a 10- to 20-fold increased rate. Curiously, many individuals with XP also have a bewildering variety of seemingly unrelated symptoms, including progressive neurological degeneration and developmental deficits, mostly due to the inability to repair oxidative damage to the DNA in neurons.

Cockayne syndrome (CS), a rare inherited disease that is also associated with defective NER, arises from defects in three of the same genes that are defective in XP as well as in two additional genes. Individuals with CS are hypersensitive to UV radiation and exhibit stunted growth, neurological dysfunction due to neuron demyelination, and the appearance of premature aging but, intriguingly, have a normal incidence of skin cancer. The proteins that are defective in CS normally recognize an RNA polymerase whose progress has been halted by a damaged or distorted DNA template. In order for transcription to resume, the stalled RNA polymerase must be removed so that the DNA damage can be repaired by the NER system. In CS, the DNA cannot be repaired, which causes the cell to undergo **apoptosis** (programmed cell death; Section 28-4C). The death of transcriptionally active cells may account for the developmental symptoms of Cockayne syndrome.

D Mismatch Repair Corrects Replication Errors

Any replicational mispairing that has eluded the editing functions of the DNA polymerases may still be corrected by a process known as **mismatch repair (MMR)**. The MMR system, discovered by Paul Modrich, can also correct insertions or deletions of up to four nucleotides (which arise from the slippage of one strand relative to the other in the active site of DNA polymerase). The importance of mismatch repair is indicated by the fact that defects in the human mismatch repair system result in a high incidence of cancer, most notably **hereditary nonpolyposis colorectal cancer syndrome**, which affects several organs and may be the most common inherited predisposition to cancer.

Mismatch repair in *E. coli* is carried out by three proteins (Fig. 25-37). A homodimer of **MutS** binds to a mismatched base pair, or to unpaired bases, and then binds a homodimer of **MutL**. Then, in an ATP-dependent process, the resulting MutS₂MutL₂ complex translocates along the DNA in both directions, thereby causing the duplex DNA to form a mismatch-containing loop that is closed by the MutS₂MutL₂ complex. If an MMR system is to correct errors in replication rather than perpetuate them, it must distinguish the parental DNA, which has the correct base, from the daughter strand, which has an incorrect

FIG. 25-37 The mechanism of mismatch repair in *E. coli*. (1) MutS binds. (2) MutL binds. (3) The mismatch-containing DNA loops out. (4) MutH endonuclease binds. (5) The unmethylated DNA strand containing the mismatched base is excised.

? Describe the next step of the repair process.

although normal base. The mismatch repair system in *E. coli* can distinguish the two DNA strands because newly replicated DNA remains hemimethylated until methyltransferases such as Dam methyltransferase have had sufficient time to methylate the daughter strand (Box 25-4). On encountering a hemimethylated GATC palindrome, the MutS₂MutL₂ complex recruits **MutH** and activates this endonuclease to make a nick on the 5' side of the unmethylated GATC sequence. This site may be located on either side of the mismatch and over 1000 bp distant from it. The UvrD helicase, which also participates in NER, separates the parental and daughter strands. An exonuclease completely removes the defective daughter segment, which is then replaced by the action of DNA polymerase III holoenzyme.

Eukaryotic cells contain several homologs of MutS and MutL but not of MutH and must therefore use some other cue than methylation status to differentiate the daughter and parental strands. One possibility is that a newly synthesized daughter strand is identified by its as yet unsealed nicks between Okazaki fragments. DNA resynthesis is probably mediated by pol δ .

E Some DNA Repair Mechanisms Introduce Errors

Individuals with a variant form of XP exhibit increased rates of skin cancer even though their NER proteins are normal. The defect in this disorder has been pinpointed to an enzyme known as **DNA polymerase η (pol η)**. When functioning normally, pol η can bypass DNA lesions such as UV-induced thymine dimers, incorporating two adenine bases in the new strand. Although it is useful as a **translesion polymerase**, pol η is relatively inaccurate and has no proofreading exonuclease activity: It inserts an incorrect base on average every 30 nucleotides.

Error-prone polymerases provide a fail-safe mechanism for replicating stretches of DNA that cannot be navigated by the standard replication machinery. In fact, such alternative DNA polymerases typically outnumber the polymerases devoted to normal replication. For example, humans have at least ten such translesion polymerases that act on different types of lesions and with different degrees of accuracy. However, the errors generated by translesion polymerases may still be corrected by the mismatch repair system. Translesion polymerases are usually replaced within a few bp by normal replicative DNA polymerases, thus limiting the size of the mismatched segment. The low fidelity of translesion polymerases arises, in part, because their active sites are more open than those of replicative polymerases, and, in part, because they lack 3'-exonucleolytic proofreading functions.

End-Joining Repairs Double-Strand Breaks. Both the base excision repair and nucleotide excision repair pathways act when a lesion affects only one strand of DNA. However, DNA is susceptible to double-strand breaks (**DSBs**) generated by ionizing radiation or the free radical by-products of oxidative metabolism, as well as when the replication fork encounters a nick. In fact, around 5 to 10% of dividing cells in culture exhibit at least one chromosome break at any given time. Unrepaired DSBs can be lethal to cells or cause chromosomal aberrations that may lead to cancer. Hence the efficient repair of DSBs is essential for cell viability and genomic integrity.

Cells have two general mechanisms to repair DSBs: **recombination repair** and **nonhomologous end-joining (NHEJ)**. Here we discuss NHEJ, a process which, as its name implies, directly rejoins DSBs. The recombination repair of DSBs is discussed in Section 25-6B.

In NHEJ, the ends of the broken DNA must be aligned, frayed ends trimmed off or filled in, and the strands ligated. The core of the end-joining machinery in eukaryotes includes the protein **Ku** (a heterodimer of homologous 70- and 83-kD subunits, **Ku70** and **Ku80**), which appears to be the cell's broken-DNA sensor. The X-ray structure of Ku in complex with a 14-bp DNA, determined by Jonathan Goldberg, reveals that the protein cradles the dsDNA segment along its

FIG. 25-38 X-Ray structure of human Ku protein in complex with a 14-bp DNA. The subunits of Ku70 (red helices and yellow β strands) and Ku80 (blue helices and green β strands) are viewed along the pseudotwofold axis relating them. The DNA is drawn in space-filling form with its sugar–phosphate backbone dark gray and its base pairs light gray. Note that the DNA is surrounded by a ring of protein. [Courtesy of John Tainer, The Scripps Research Institute, La Jolla, California. Based on an X-ray structure by Jonathan Goldberg, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1JEY.]

entire length and encircles its central ~ 3 bp segment (Fig. 25-38). Ku makes no specific contacts with the DNA's bases and few with its backbone but instead fits snugly into the major and minor grooves. Ku–DNA complexes dimerize to align both halves of a double-strand break while leaving the strand ends accessible to nucleases, polymerases, and ligases. Nucleotide trimming, of course, generates mutations, but an unrepaired double-strand break would be even more detrimental to the cell.

The genome in a somatic cell of a 70-year-old human typically contains ~ 2000 “scars” caused by NHEJ. The reason that such mutations are usually not unacceptably deleterious is that only a small fraction of the mammalian genome is expressed (Section 28-1A), and that for somatic diploid cells the mutations are not heritable and are counterbalanced by the undamaged information in the homologous chromosome.

The *E. coli* SOS Response Is Mutagenic. In *E. coli*, agents that damage DNA induce a complex system of cellular changes known as the **SOS response**. Cells undergoing the SOS response cease dividing and increase their capacity to repair damaged DNA. **LexA**, a repressor, and **RecA**, a DNA-binding protein, regulate the activity of this system. [RecA, a homolog of DnaB (Section 25-2B), is also a key player in homologous recombination, discussed in the following section, which offers a means for repairing damaged DNA after it has been replicated.] During normal growth, LexA represses SOS gene expression. However, when DNA is damaged (and cannot fully replicate), the resulting single strands bind to RecA to form a complex that activates LexA to cleave and thereby inactivate itself. The SOS genes, which include *recA* and *lexA* as well as the NER genes *uvrA* and *uvrB* (Section 25-5C), are thereby expressed. On the repair of the DNA, the DNA \cdot RecA complex is no longer present, so the newly synthesized LexA again represses the expression of the SOS genes.

Among the 43 genes controlled by the SOS system are **DNA polymerases IV and V**. Because these translesion polymerases can synthesize DNA even when there is no information as to which bases were originally present, *the SOS repair system is error-prone and consequently mutagenic*. It is therefore a process of last resort that is initiated only ~ 50 min after SOS induction if the DNA has not already been repaired by other means. Hence, the SOS repair system is a testimonial to the proposition that, at least for single-celled organisms, survival with a chance of loss of function (and the possible gain of a new one) is advantageous, in the Darwinian sense, over death, although only a small fraction of cells survive this process. It has therefore been suggested that, under conditions of environmental stress, the SOS system functions to increase the rate of mutation so as to increase the rate at which the *E. coli* adapt to the new conditions.

CHECKPOINT

- What are the functions of DNA photolyases and alkyltransferases?
- Describe the enzymatic activities required for base excision repair, nucleotide excision repair, and mismatch repair.
- What are the symptoms of defective nucleotide excision repair and mismatch repair?
- Describe why cells require error-prone repair systems such as pol η , nonhomologous end-joining, and the SOS response.

6 Recombination

KEY CONCEPTS

- In homologous recombination, DNA strands cross over to exchange places.
- Recombination can repair damaged replication forks and double-strand breaks.
- Transposons move themselves and sometimes additional genes to new chromosomal locations.

Over the years, genetic studies have shown that genes are not immutable. In higher organisms, pairs of genes may exchange by crossing-over when homologous chromosomes are aligned (Fig. 25-39). Bacteria, which do not contain duplicate chromosomes, also have an elaborate mechanism for recombining genetic information. In addition, foreign DNA can be installed in a host's chromosome through recombination. In this section, we examine the molecular events of recombination and discuss the biochemistry of **transposons**, which are mobile genetic elements.

A Homologous Recombination Involves Several Protein Complexes

Homologous recombination (also called **general recombination**) occurs between DNA segments with extensive homology; **site-specific recombination** occurs between two short, specific DNA sequences. The prototypical model for homologous recombination (Fig. 25-40) was proposed by Robin Holliday in

FIG. 25-39 Crossing-over. (a) An electron micrograph and (b) its interpretive drawing of two homologous pairs of chromatids during meiosis in the grasshopper *Chorthippus parallelus*. Nonsister chromatids (different colors) may recombine at any of the points where they cross over.

FIG. 25-40 The Holliday model of general recombination between homologous DNA duplexes. WPLS See the Animated Figures.

FIG. 25-41 X-Ray structure of a Holliday junction. (a) The secondary structure of the four-stranded Holliday junction formed by the palindromic sequence d(CCGGTACCGG) in which the four strands, A, B, C, and D, are individually colored, their nucleotides are numbered 1 to 10 from their 5' to 3' termini, and Watson-Crick base-pairing interactions are represented by black dashes. The twofold axis relating the two helices is represented by the black lenticular symbol. (b) The three-dimensional structure of the Holliday junction, as viewed along its

twofold axis, in which the oligonucleotides are represented in stick form with their backbones traced by ribbons, all colored as in Part a. With the exception of the backbones of strands B and D at the crossovers, the two arms of this structure each form an undistorted B-DNA helix, including the stacking of the base pairs flanking the crossovers. Note that Fig. 25-40g is a schematic representation of this structure as viewed from the side in this drawing. PDBid 1DCW.

1964. The corresponding strands of two aligned homologous DNA duplexes are nicked, and the nicked strands cross over to pair with the nearly complementary strands on the homologous duplex, thereby forming a segment of **heterologous DNA**, after which the nicks are sealed (Fig. 25-40a–e). The crossover point is a four-stranded structure known as a **Holliday junction**. A Holliday junction has, in fact, been observed in the X-ray structure of the self-complementary d(CCGGTACCGG), determined by Shing Ho (Fig. 25-41). The crossover point can move in either direction, often thousands of nucleotides, in a process known as **branch migration** (Fig. 25-40e, f).

The Holliday junction can be “resolved” into two duplex DNAs in two equally probable ways (Fig. 25-40g–l):

1. Cleavage of the strands that did not cross over exchanges the ends of the original duplexes to form, after nick sealing, the traditional recombinant DNA molecule (right branch of Fig. 25-40j–l).
2. Cleavage of the strands that crossed over exchanges a pair of homologous single-stranded segments (left branch of Fig. 25-40j–l).

RecA Promotes Recombination in *E. coli*. The observation that *recA*[−] *E. coli* have a 10⁴-fold lower recombination rate than the wild-type indicates that *RecA protein* has an important function in recombination. Indeed, RecA greatly increases the rate at which complementary strands renature *in vitro*. This versatile protein (recall it also stimulates the autoproteolysis of LexA to trigger the SOS response; Section 25-5E) polymerizes cooperatively without regard to base sequence on ssDNA or on dsDNA that has a single-stranded gap. The resulting filaments, which may contain up to several thousand RecA monomers, specifically bind the homologous dsDNA, and, in an ATP-dependent reaction, catalyze strand exchange.

EM studies by Edward Egelman revealed that RecA filaments bound to ssDNA or dsDNA form a right-handed helix with ~6.2 RecA monomers per turn and a pitch (rise per turn) of 95 Å. The DNA in these filaments binds to the protein with 3 nt (or bp) per RecA monomer and hence is underwound with ~18.5 nt (or bp) per turn (versus 10 bp per turn for canonical B-DNA).

The formation of RecA–DNA filaments is highly cooperative; it requires five or six RecA protomers to form a stable assembly. Consequently attempts to crystallize RecA–DNA filaments over many years were unsuccessful. Nikola Pavletich ingeniously solved this conundrum by linking five *E. coli* RecA genes (each corresponding to residues 1–335 of this 353-residue protein) in tandem via 14-residue linkers and mutating the first and last RecA to prevent them from forming longer filaments. This fusion protein, which has DNA-dependent ATPase and strand-exchange activities comparable to that of monomeric RecA, formed crystals containing both ssDNA and dsDNA.

The X-ray structure of the RecA₅–(ADP–AlF₄[−])₅–(dT)₁₅–(dA)₁₂ complex (Fig. 25-42; ADP–AlF₄[−] is a nonhydrolyzable ATP analog) exhibits a straight filament axis with overall helical parameters that are closely similar to those derived from EM studies. Each RecA unit consists of a largely helical 30-residue N-terminal segment, a 240-residue α/β ATPase core, and a 64-residue C-terminal globular domain. The linkers connecting adjacent RecA units are disordered. Each RecA unit makes extensive contacts with its nearest neighbors so as to form a filament with a deep helical groove that exposes the DNA bound in its interior (Fig. 25-42a is viewed looking into this groove).

The two DNA strands, which lie close to the filament axis, form a complete set of Watson–Crick base pairs (Fig. 25-42b). However, rather than being smoothly stretched out, as had been expected, the dsDNA assumes an irregular conformation in which each 3-bp segment that is bound to a RecA unit closely resembles B-DNA with the steps between successive base pairs in this triplet having an axial rise of ~3.4 Å and a helical twist of ~30° (versus 3.4 Å and 36° for canonical B-DNA; Table 24-1). In contrast, the step between successive base pair triplets has an axial rise of 8.4 Å and a helical twist of −4°, thereby forming

FIG. 25-42 X-Ray structure of the RecA₅–(ADP–AlF₄[−])₅–(dT)₁₅–(dA)₁₂ complex viewed with its filament axis vertical. (a) The RecA units RecA¹ (the N-terminal unit) through RecA⁴ are colored green, cyan, magenta, and gray, respectively, with the C-terminal unit, RecA⁵, colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The DNA and ADP–AlF₄[−] are drawn in space-filling form with DNA C gray, ADP C green, N blue, O red, P orange, F light blue, and Al

purple. (b) The DNA in the complex, viewed and colored as in Part a, but with C atoms of the (dT)₁₅ green. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 3CMX.]

? How does RecA differ from helicase in unwinding DNA?

PROCESS DIAGRAM

FIG. 25-43 A model for RecA-mediated pairing. (1) A ssDNA binds to RecA to form an initiation complex. (2) dsDNA binds to the initiation complex so as to transiently form a three-stranded helix. (3) RecA

rotates the bases of the aligned homologous strands to effect strand exchange in an ATP-driven process. [After West, S.C., *Annu. Rev. Biochem.* **61**, 618 (1992).] **WPLS** See the Animated Process Diagrams.

a 5-Å-high gap between successive triplets that is partially filled by the side chain of the conserved Ile 199. The sugar-phosphate backbone of the (dT)₁₅ (the DNA strand furthest from the viewer in Fig. 25-42) makes extensive contacts with RecA. In contrast, the other strand [the (dA)₁₂] makes few contacts with the protein; it is held in place almost entirely by base pairing with the first strand. The ADP-AlF₄⁻ is sandwiched between adjacent α/β ATPase cores, where it is completely buried.

The X-ray structure of the ssDNA-containing RecA₆-(ADP-AlF₄⁻)₆-(dT)₁₈ complex closely resembles that of the foregoing dsDNA-containing complex but with the absence of the DNA strand closest to the viewer in Fig. 25-42. Thus, each RecA unit binds a (dT)₃ segment that is held in a B-DNA-like conformation with successive (dT)₃ segments separated by a 7.8-Å axial rise.

How does RecA mediate DNA strand exchange between ssDNA and dsDNA? On encountering a duplex DNA with a strand that is complementary to its bound ssDNA, RecA partially unwinds the duplex and exchanges the ssDNA with the corresponding strand on the dsDNA, a process that involves a three-stranded DNA intermediate (Fig. 25-43). ATP binding to RecA is required for strand exchange, but ATP hydrolysis does not occur until the dissociation step. The strand-exchange process tolerates only a limited degree of mispairing and therefore occurs only between homologous DNA segments. As the RecA filament rotates about its axis, the duplex DNA is spooled in (Fig. 25-44). Presumably, by keeping most of its bound ssDNA in the B conformation, RecA prevents the formation of non-Watson-Crick base pairings. Two such strand-exchange

FIG. 25-44 Model for RecA-mediated strand exchange. Homologous DNA molecules are paired in advance of strand exchange in a three-stranded helix. The ATP-driven rotation of the RecA filament (purple)

around its helix axis causes duplex DNA to be “spooled in” to the filament, left to right as drawn. [After West, S.C., *Annu. Rev. Biochem.* **61**, 617 (1992).]

processes must occur simultaneously in a Holliday junction. In eukaryotes, the protein **Rad51**, which is homologous to *E. coli* RecA, apparently functions in a similar ATP-dependent manner to mediate DNA recombination.

RecBCD Initiates Recombination by Making a Single Strand Available. In *E. coli*, the single-strand segments to which RecA binds are made by the **RecBCD** protein, the 330-kD heterotrimeric product of the SOS genes *recB*, *recC*, and *recD*, which has both helicase and nuclease activities (Fig. 25-45). The process begins with RecBCD binding to the end of a dsDNA and then unwinding it via its ATP-driven helicase function. As it does so, it nucleolytically degrades the unwound single strands behind it, with the 3'-ending strand being cleaved more often and hence broken down to smaller fragments than the 5'-ending strand. However, on encountering the sequence GCTGGTGG from its 3' end (the so-called **Chi sequence**, which occurs about every 5 kb in the *E. coli* genome), it stops cleaving the 3'-ending strand and increases the rate at which it cleaves the 5'-ending strand, thereby yielding the 3'-ending single-strand segment to which RecA binds. This explains the observation that regions containing Chi sequences have elevated rates of recombination. RecB also functions to recruit RecA and nucleate its binding to the 3'-ending strand.

Dale Wigley determined the X-ray structure of *E. coli* RecBCD in complex with a 51-nt DNA that could form a hairpin loop containing an up to 21-bp dsDNA stem (Fig. 25-46). The structure shows that RecB (1180 residues) and RecC (1122 residues) are intimately intertwined, with RecB's C-terminal nuclease domain connected to the rest of the subunit by an extended 21-residue polypeptide tether. A 15-bp segment of dsDNA enters the protein through a tunnel between RecB and RecC. There it encounters a loop from RecC that appears to wedge the two strands apart, with the 6-nt 3'-ending single strand of the DNA binding to RecB and the 10-nt 5'-ending single strand binding to RecD (608 residues; the 5-nt loop connecting the two strands of the dsDNA at the top of Fig. 25-46 is disordered).

The structure explains the different rates of cleavage of the two DNA strands. The 3'-ending strand emerges from a tunnel through RecC in the vicinity of the RecB nuclease domain, which is positioned to processively cleave it. The 5'-ending strand competes with the 3'-ending strand for the nuclease site, but since the 5'-ending strand is less favorably located, it is cleaved less frequently. However, after RecC has bound a Chi sequence, the 3'-ending strand is no longer available for cleavage, which permits the nuclease to cleave the 5'-ending strand more frequently.

FIG. 25-45 The generation of a 3'-ending single-strand DNA segment by RecBCD to initiate recombination. (1) RecBCD binds to a free end of a dsDNA and, in an ATP-driven process, advances along the helix, unwinding the DNA and degrading the resulting single strands behind it, with the 3'-ending strand cleaved more often than the 5'-ending strand. (2) When RecBCD encounters a properly oriented Chi sequence, it binds it and thus stops cleaving the 3'-ending strand but increases the frequency at which it cleaves the 5'-ending strand. This generates the potentially invasive 3'-ending strand segment to which RecA binds.

FIG. 25-46 X-Ray structure of *E. coli* RecBCD in complex with a 51-nt DNA capable of forming a 21-bp hairpin loop. The protein is drawn in semitransparent ribbon form with RecB yellow, RecC cyan, and RecD magenta. Note how the RecB nuclease domain is linked to the rest of the subunit by an extended polypeptide tether. The DNA is shown in space-filling form with C gray, N blue, O red, and P orange. A loop from RecC, which is drawn in space-filling form in green, is situated so as to wedge apart the two strands of the incoming dsDNA with the 3'-ending strand binding to the 3' → 5' helicase of RecB and the 5'-ending strand passing through RecC to bind to the 5' → 3' helicase of RecD. [Based on an X-ray structure by Dale Wigley, The London Research Institute, Herts, U.K. PDBid 3K70.]

RecBCD can commence unwinding DNA only at a free duplex end. Such ends are not normally present in *E. coli*, which has a circular genome, but become available during recombinational processes.

RuvABC Mediates Branch Migration and the Resolution of the Holliday Junction. Branch migration requires the proteins **RuvA** and **RuvB**. The X-ray structure of *Mycobacterium leprae* (the cause of leprosy) RuvA in complex with a Holliday junction, determined by Kosuke Morikawa, indicates that RuvA forms a homotetramer with the appearance of a four-petaled flower (C_4 symmetry) and is relatively flat ($80 \times 80 \times 45 \text{ \AA}$) with one face concave and the other convex (Fig. 25-47). The concave face (facing the viewer in Fig. 25-47), which is highly positively charged and is studded with numerous conserved residues, has four symmetry-related grooves that bind the Holliday junction's four arms. Four negatively charged projections or "pins" are centrally located. The repulsive forces between the pins and the Holliday junction's anionic phosphate groups probably facilitate the separation of the ssDNA segments and guide them from one double helix to another. However, this is not the entire story. The X-ray structure of a RuvA–Holliday junction complex crystallized under different conditions than that in Fig. 25-47 resembles the complex in Fig. 25-47 but with a second RuvA tetramer in face-to-face contact with the first. Here the Holliday junction is contained in two intersecting tunnels running through the resulting D_4 -symmetric RuvA octamer.

In the presence of dsDNA, RuvB, an AAA+ family ATPase, oligomerizes to form a pseudohexameric ring with a 30-Å-diameter hole through which a dsDNA can be threaded, much like a hexameric helicase (Section 25-2B). A model for the RuvA · RuvB · Holliday junction complex, based on X-ray structures and electron micrographs, is shown in Fig. 25-48. In the complex, two RuvB hexamers encircle the DNA on opposite sides of a RuvA octamer. This

FIG. 25-47 X-Ray structure of a RuvA–Holliday junction complex. The protein tetramer, which is viewed along its fourfold axis, is represented by its molecular surface with its subunits alternately colored pink and light blue. The DNA is drawn in space-filling form colored according to atom type with C atoms in different chains in different colors, N blue, O red, and P orange. [Based on an X-ray structure by Kosuke Morikawa, Biomolecular Engineering Research Institute, Osaka, Japan. PDBid 1C7Y.]

FIG. 25-48 Model of the RuvAB–Holliday junction complex. The model is based on X-ray structures and on electron micrographs such as that in the inset. The proteins are represented by their surface diagrams with the RuvA tetramer green and the two oppositely oriented RuvB hexamers white. The DNA of the Holliday junction is drawn in space-filling form with its homologous blue and magenta strands complementary to its red and gray strands. A second RuvA tetramer, which overlies the RuvA tetramer shown and thus sandwiches the DNA

in two perpendicular tunnels, has been removed to show the path of the DNA. The complex is postulated to drive branch migration via the ATP-driven movement of loops projecting from the center of the RuvB hexamers along the DNA. This pumps the horizontal dsDNAs through the RuvB hexamers to the center of the Holliday junction, where the strands separate and then base-pair with their homologs to form new dsDNAs, which are pumped out vertically.

arrangement suggests a mechanism for branch migration in which RuvB's DNA-contacting loops unidirectionally “walk” along the horizontal dsDNA's grooves in an ATP-dependent process. This pulls the dsDNAs through the center of each RuvB hexamer toward the RuvA octamer. The DNA strands of the Holliday junction are thereby pushed through the center of RuvA, where they rejoin to form the vertical dsDNAs and exit the complex. (An alternative model, in which the two RuvB hexamers counterrotate so as to screw the dsDNA into the RuvA octamer, seems unlikely due to the large contact area between RuvA and RuvB.) The direction of branch migration depends on which pair of opposing arms of the Holliday junction the RuvB hexamers are loaded onto.

The final stage of homologous recombination is the resolution of the Holliday junction into its two homologous dsDNAs. This process is carried out by **RuvC**, a homodimeric nuclease. One of the RuvA tetramers must dissociate from the octameric RuvA complex to expose the Holliday junction DNA. RuvC presumably sits down on the open face of the resulting RuvA–Holliday junction complex (the side visible in Fig. 25-47) to cleave oppositely located strands at the Holliday junction (Figs. 25-40*i, j*). The resulting single-strand nicks are then sealed by DNA ligase (Figs. 25-40*k, l*).

B DNA Can Be Repaired by Recombination

In haploid organisms such as bacteria, homologous recombination between chromosomal DNA and exogenously supplied DNA as occurs, for example, in transformation (Section 3-3A), is such a rare event that the vast majority of such cells never participate in this process. Similarly, in multicellular organisms, the only time that gene shuffling through homologous recombination occurs is during meiosis (Fig. 25-39), which takes place only in germline cells. Why then do nearly all cells have elaborate systems for mediating homologous recombination? This is because damaged replication forks occur at least once per bacterial cell generation and perhaps ten times per eukaryotic cell cycle. The underlying DNA lesions can be corrected via homologous recombination in a process named **recombination repair** [error-prone repair (Section 25-5E), which is highly mutagenic, is a process of last resort]. Indeed, the rates of synthesis of RuvA and RuvB are greatly enhanced by the SOS response. Thus, as Michael Cox pointed out, *the primary function of homologous recombination is to repair damaged replication forks.*

Recombination repair in *E. coli* occurs as follows (Fig. 25-49):

1. When a replication fork encounters an unrepaired single-strand nick or gap, the fork collapses (the replication machinery dissociates).
2. The repair process begins via the RecBCD + RecA-mediated invasion of the newly synthesized and undamaged 3'-ending strand into the homologous dsDNA starting at its broken end.
3. Branch migration, as mediated by RuvAB, then yields a Holliday junction, which exchanges the replication fork's 3'-ending strands.
4. RuvC then resolves the Holliday junction yielding a reconstituted replication fork ready for replication restart.

PROCESS DIAGRAM

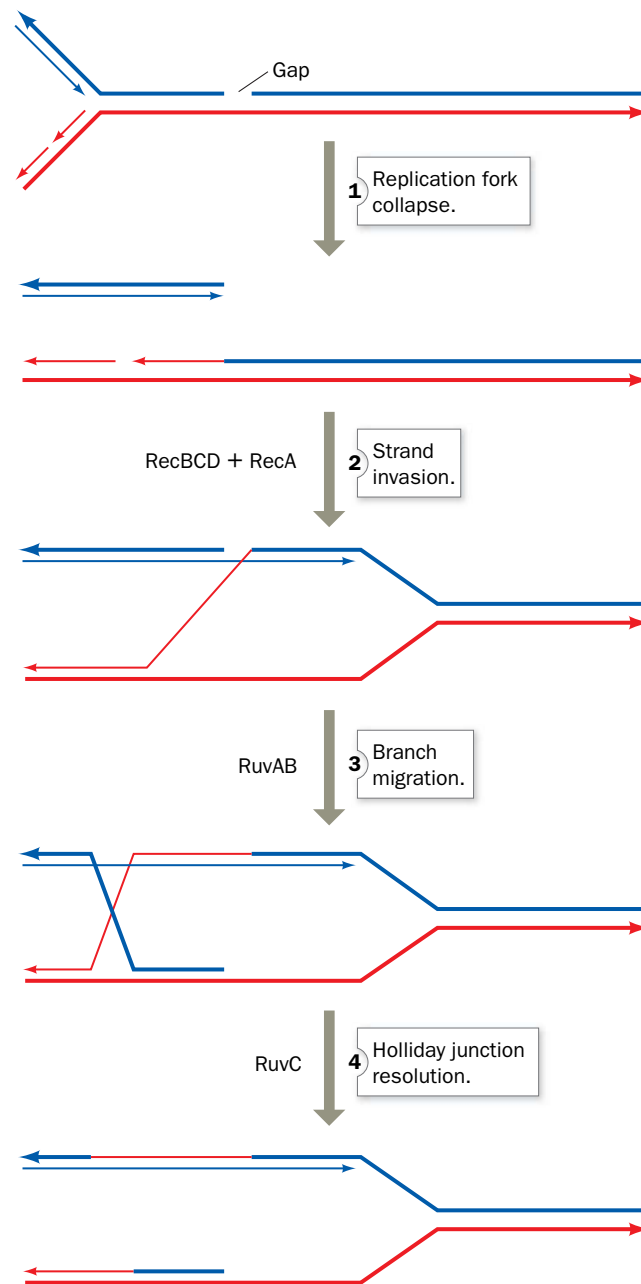

FIG. 25-49 The recombination repair of a replication fork that has encountered a single-strand nick. Thick lines indicate parental DNA, thin lines indicate newly synthesized DNA, and the arrows point in

the 5' → 3' direction. [After Cox, M.M., *Annu. Rev. Genet.* **35**, 53 (2001).] **WPLS** See the Animated Process Diagrams.

Thus, the 5'-ending strand of the nick has, in effect, become the 5' end of an Okazaki fragment.

The final step in the recombination repair process is the restart of DNA replication. This process is, of necessity, distinct from the replication initiation that occurs at *oriC* (Section 25-2B). **Origin-independent replication restart** is mediated by a specialized seven-subunit primosome, which has therefore been named the **restart primosome**.

Recombination Repair Reconstitutes Double-Strand Breaks. We have seen that double-strand breaks (DSBs) in DNA can be rejoined, often mutagenically, by nonhomologous end-joining (NHEJ; Section 25-5E). DSBs may also be nonmutagenically repaired through a recombination repair process known as **homology-directed repair (HDR; also called homologous end-joining)**, which occurs via two Holliday junctions (Fig. 25-50):

1. The DSB's double-stranded ends are resected to produce single-stranded ends. One of the 3'-ending strands invades the corresponding sequence of a homologous chromosome to form a Holliday junction, a process mediated by Rad51 (the eukaryotic RecA homolog). The other 3'-ending strand pairs with the displaced strand segment on the homologous chromosome to form a second Holliday junction.
2. DNA polymerase fills in the gaps, and ligase seals the joints.
3. Both Holliday junctions are resolved to yield two intact double-stranded DNAs.

Thus, the sequences that may have been lost in the formation of the DSB are copied from the homologous chromosome. Of course, a limitation of homologous

PROCESS DIAGRAM

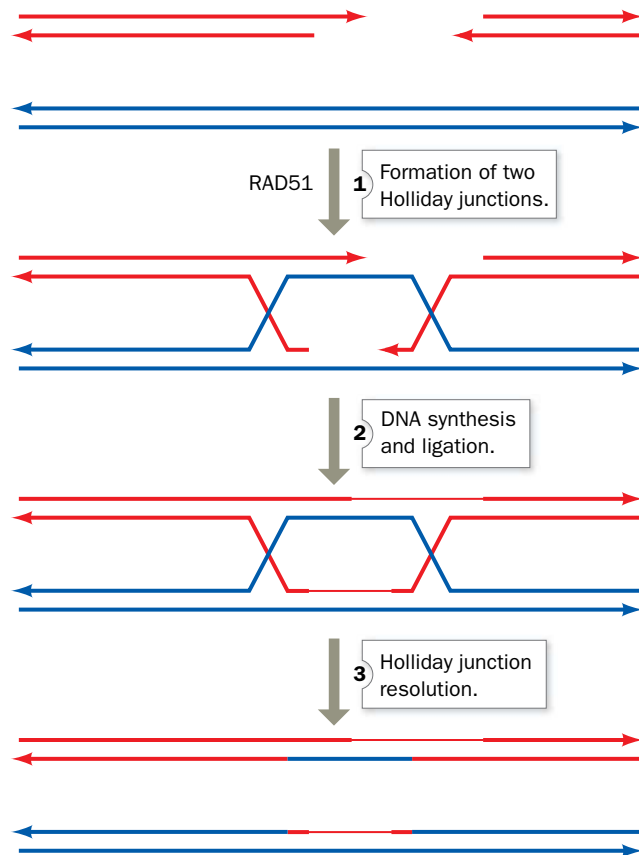

FIG. 25-50 The repair of a double-strand break in DNA by **homology-directed repair**. Thick lines indicate parental DNA, thin lines indicate newly synthesized DNA, and the arrows point in the 5' → 3'

direction. [After Haber, J.E., *Trends Genet.* **16**, 259 (2000).]

WPLS See the Animated Process Diagrams.

end-joining, particularly in haploid cells, is that a homologous chromosomal segment may not be available.

The importance of recombination repair in humans is demonstrated by the observation that defects in the proteins **BRCA1** (1863 residues) and **BRCA2** (3418 residues), both of which interact with Rad51, are associated with a greatly increased incidence of breast, ovarian, prostate, and pancreatic cancers. Indeed, individuals with mutant *BRCA1* or *BRCA2* genes have up to an 80% lifetime risk of developing cancer.

C CRISPR–Cas9, a System for Editing and Regulating Genomes

Prokaryotes are under almost constant attack by bacteriophages. How do they defend themselves against such existential threats? One way, as we have seen, is through restriction–modification systems (Section 3-4A). A more recently discovered defense system, possessed by many eubacteria and nearly all archaea, is characterized by **CRISPRs** (for clustered regularly interspersed short palindromic repeats), which are arrays of DNA consisting of a several hundred repeating, often partially palindromic sequences, typically 20 to 50 bp long, interspersed by unique sequences of similar lengths known as **protospacers** (Fig. 25-51a). The protospacers contain sequences that are identical to segments of bacteriophage DNA. In fact, the protospacers form a sort of historical record of the

FIG. 25-51 The CRISPR–Cas9 system. The black triangles indicate cleavage sites on the target DNA. See the text for details.

foreign DNAs that the prokaryote's ancestors encountered (and survived): A short segment of the latest viral sequence that the prokaryote encountered is integrated into the prokaryotic DNA at the 5' end of the CRISPR **locus** (site) as a protospacer.

The CRISPR locus is transcribed to form a single RNA that is then processed to yield ~30-nt transcripts of the protospacers known as **crRNAs** (Fig. 25-51b). The crRNAs are bound by certain **Cas** (CRISPR-associated) proteins, which they guide to hydrolytically cleave complementary segments of invading double-stranded DNAs, thereby inactivating them (Fig. 24-51c). The **CRISPR-Cas** system, like the mammalian immune system (Section 7-3), "learns" from its encounters with foreign DNAs. The efficacy of the CRISPR-Cas system is indicated by the fact that bacteriophages continually mutate to evade being targeted by existing crRNAs.

The Cas proteins function to acquire new protospacers, to excise the crRNAs from the transcript of a CRISPR array, and to catalyze the destruction of invading DNAs. There are three major types of CRISPR-Cas systems among the various prokaryotes. Here we only discuss how the type II system cleaves its target DNA.

The type II system requires only a single multifunctional protein, **Cas9**, for the crRNA-guided recognition and cleavage of its target DNA. Cas9 has two DNA nuclease activities, an HNH-like domain that cleaves the target DNA on the strand that is complementary to the crRNA, the so-called target strand, and a RuvC-like domain (Section 25-6A) that cleaves the DNA on the opposite strand, the non-target strand. Together, the two nuclease activities generate a blunt double-strand break (DSB) in the target DNA (Fig. 25-51c).

The CRISPR-Cas9 system requires an additional component, **tracrRNA** (for *transactivating CRISPR RNA*) that is also encoded by the prokaryote's DNA (Fig. 25-51b). A tracrRNA binds to Cas9 and forms a short base-paired interaction with a crRNA, which serves to identify the crRNA to Cas9 (tracrRNA also identifies the crRNA segments in the transcript of a CRISPR array). The crRNA-tracrRNA complex then directs Cas9 to cleave the target DNA if its target strand has a short **PAM** (for *protospacer-adjacent motif*) sequence on the 3' side of its cleavage site (Fig. 25-51c). The requirement for the PAM presumably prevents Cas9 from destroying the protospacer from which its bound crRNA was transcribed. The PAM required by Cas9 from *Streptococcus pyogenes* (spCas9) has the sequence 5'-NGG-3' (where N is any nucleotide), which occurs in DNA every 8 bp on average (the PAM varies in length and sequence with the prokaryote that produces the corresponding Cas9). The CRISPR-Cas9 system cleaves DNA 3 to 4 nucleotides from the 5' end of the PAM.

The crRNA, tracrRNA, and Target DNA Form a Four-Way Junction When Bound to spCas9. The X-ray structure of the 1372-residue spCas9 in complex with an 83-nt **sgRNA** [for *single-guide RNA*, which is a crRNA whose 3' end is covalently linked to the 5' end of tracrRNA; also called **gRNA** (for *guide RNA*)] and a partially duplexed target DNA, was determined by Martin Jinek (Fig. 25-52). The DNA consists of a 28-bp target strand, whose 20-nt 3' end is base paired with the sgRNA, and a 12-bp non-target strand that contains the 5'-NGG-3' PAM. The spCas9's HNH nuclease domain, which would otherwise cleave the target strand, had been mutationally inactivated, whereas the non-target strand is captured as its RuvC nuclease-cleaved product. The spCas9 recognizes the PAM's GG dinucleotide through major groove interactions with two Arg side chains. Comparison of this X-ray structure with that of spCas9 alone reveals that in the absence of bound RNA, spCas9 undergoes an extensive conformational change to a catalytically inactive form, which prevents it from indiscriminately cleaving DNA. It has been postulated that the energetics of this conformational change (which is not ATP-dependent) drives the separation of the target and non-target DNA strands that permits the crRNA to base pair with the target strand.

FIG. 25-52 X-Ray structure of spCas9 in complex with an sgRNA and its partially duplex target DNA. (a) Schematic diagram of the base pairing within and between the sgRNA and the target DNA. The sgRNA is orange, the target DNA strand is blue, and the non-target DNA strand is black except for its PAM trinucleotide, which is yellow. Empty ovals represent nucleotides not observed in the X-ray structure. (b) Structure

of the sgRNA–target DNA four-way junction. The nucleic acids are drawn in paddle form colored as in Part a. (c) The spCas9–sgRNA–DNA complex viewed as in Part b. The protein is drawn in ribbon form colored according to the accompanying key. The nucleic acids are shown in cartoon form colored as in Part a. [Courtesy of Martin Jinek, University of Zurich, Switzerland. PDBid 4UN3.]

The sgRNA–Cas9 System Has Been Adapted for Use in Editing Genomes.

Although the editing of bacterial genomes has become routine (Section 3-5), the editing of eukaryotic genomes had remained difficult and time-consuming. However, in 2012, Jennifer Doudna and Emmanuelle Charpentier demonstrated that by tailoring sgRNAs to target specific gene sequences they caused Cas9 to edit these genes *in vivo*. How is this done?

The sgRNA–Cas9 system can be inserted into a eukaryote in several ways: (1) by transforming a cultured eukaryotic cell with (inducing it to take up) a plasmid encoding an sgRNA and Cas9; (2) by microinjecting the sgRNA and Cas9 into a fertilized ovum to generate a transgenic animal (Section 3-5D); or

(3) using viral vectors to introduce the sgRNA and Cas9 into an animal or a plant.

Upon entering a eukaryotic cell, the sgRNA–Cas9 system cleaves a gene at its targeted site. Cells, as we have seen, repair DSBs in either of two ways:

1. By nonhomologous end-joining (NHEJ, Section 25-5E), which generates variable length insertions and deletions and is therefore likely to inactivate the targeted gene, most often by changing its reading frame (Sections 27-1A) and/or introducing a premature Stop codon (Section 27-1C). To maximize the probability of this occurring, the selected position of the DSB should be near the N-terminus of the coding region of the gene being disrupted.
2. By homology-directed repair (HDR; Section 25-6B). If the cell is also exogenously supplied with a DNA segment containing a mutant version of the gene segment being edited, the mutation, which can be an insertion, deletion, or modification, will be copied into the cell's chromosome. Note that this repair template should not contain the sgRNA's target sequence followed by a PAM or it will be cleaved by Cas9.

Many other ways of modifying genes using the sgRNA–Cas9 system have been developed. For example, two sgRNAs specific for different target sites on a gene can be used in concert with Cas9 to delete/replace the DNA segment between these sites (Fig. 25-53a). If both the HNH and RuvC activities of Cas9 are mutationally inactivated and the resulting dCas9 (d for *dead*) is tethered to a protein module that activates or represses gene transcription (Section 28-3B), then using an appropriate sgRNA to direct the dCas9 to bind at or near a gene will enhance or inhibit the transcription of that gene (Fig. 25-53b). In fact, the

FIG. 25-53 Examples of gene modification techniques using the CRISPR–Cas9 system.

(a) Using two sgRNAs specific for relatively close chromosomal sites will excise the DNA segment between the two cleavage sites. (b) Covalently linking dCas9 to an activation (or repressor) module and using an sgRNA targeted to a site at or near a gene will enhance (or inhibit) the transcription of the gene.

binding of sgRNA–dCas9 alone to a gene can interfere with its transcription. Fusing dCas9 to a fluorescent marker such as green fluorescent protein (GFP; Box 4-3) yields a customizable DNA label that can be located in the chromosomes of live cells by fluorescence microscopy.

The introduction of CRISPR–Cas9-based technology in 2012 revolutionized the field of genomic engineering within a period of less than two years. Genetic alterations that previously took many months to accomplish, if at all, can now be made in days or weeks with high efficiency. This technology has been used to genetically manipulate a wide variety of eukaryotes ranging from yeast to fruit flies to mice to monkeys and several species of plants. Efforts are underway to adapt the CRISPR–Cas9 system to the gene therapy (Section 3-5D) of diseases caused by point mutations, such as sickle cell anemia (Section 7-1E) and cystic fibrosis (Box 3-1). Methods for safely delivering the sgRNA–Cas9 system into adult animals are under intense investigation. However, our ignorance of the risks of germline modification in humans has motivated a group of molecular biologists who have been central in the development of the CRISPR–Cas9 technology to propose a moratorium on any effort to modify the human germline until the safety, ethical, and legal aspects of doing so have been thoroughly assessed.

D Transposition Rearranges Segments of DNA

In the early 1950s, Barbara McClintock reported that the variegated pigmentation pattern of maize (Indian corn) kernels results from the action of genetic elements that can move within the maize genome. This proposal was resoundingly ignored because it was contrary to the then-held orthodoxy that chromosomes consist of genes linked in fixed order. Another 20 years were to pass before evidence of mobile genetic elements was found in another organism, *E. coli*.

Transposons Move Genes between Unrelated Sites. It is now known that **transposable elements**, or **transposons**, are common in both prokaryotes and eukaryotes, where they influence the variation of phenotypic expression over the short term and evolutionary development over the long term. Each transposon codes for the enzymes that insert it into the recipient DNA. This process differs from homologous recombination in that it requires no homology between donor and recipient DNA and occurs at a rate of only one event in every 10^4 to 10^7 cell divisions.

Prokaryotic transposons with three levels of complexity have been characterized:

1. The simplest transposons are named **insertion sequences** or **IS elements**.

They are normal constituents of bacterial chromosomes and **plasmids** (autonomously replicating circular DNA molecules that usually consist of several thousand base pairs; Section 3-5A). For example, a common *E. coli* strain has eight copies of **IS1** and five copies of **IS2**. IS elements generally consist of <2000 bp containing a so-called **transposase** gene and, in some cases, a regulatory gene, flanked by short inverted (having opposite orientation) terminal repeats. On each side of an inserted IS element is a directly (having the same orientation) repeated segment of host DNA (**Fig. 25-54**). This suggests that *an IS element is inserted in the host*

FIG. 25-54 Structure of IS elements. These and other transposons have inverted terminal repeats (*numerals*) and are flanked by direct repeats of host DNA sequences (*letters*).

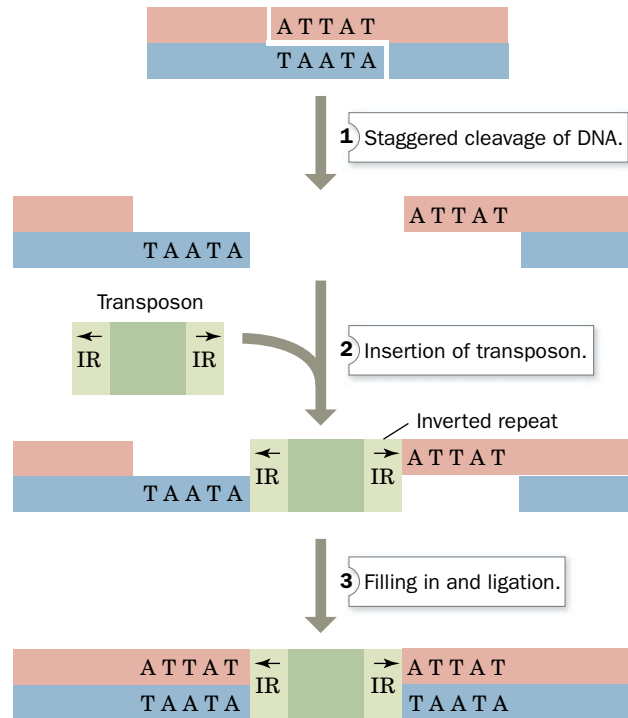

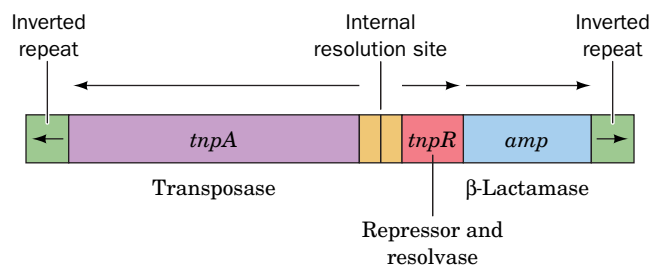

FIG. 25-55 A model for transposon insertion. A staggered cut that is later filled in generates direct repeats of the target sequence. IR stands for inverted repeat. **WPLS** See the Animated Process Diagrams.

DNA at a staggered cut that is later filled in (Fig. 25-55). The length of the target sequence (most commonly 5–9 bp), but not its sequence, is characteristic of the IS element.

2. More complex transposons carry genes not involved in the transposition process, such as antibiotic-resistance genes. For example, **Tn3** consists of 4957 bp and has inverted terminal repeats of 38 bp each.

The central region of Tn3 codes for three proteins: (1) a 1015-residue transposase named **TnpA**; (2) a 185-residue protein known as **TnpR**, which represses the expression of both *tnpA* and *tnpR* and mediates the site-specific recombination reaction necessary for transposition (see below); and (3) a **β-lactamase** (encoded by *amp*) that inactivates the antibiotic ampicillin (Box 8-3). The site-specific recombination occurs in an AT-rich region, the **internal resolution site**, between *tnpA* and *tnpR* (see below).

FIG. 25-56 A composite transposon. This element consists of two identical or nearly identical IS-like modules (green) flanking a central

region carrying various genes. The IS-like modules may have either (a) direct or (b) inverted relative orientations.

3. The so-called **composite transposons** (Fig. 25-56) consist of a gene-containing central region flanked by two identical or nearly identical IS-like modules that have either the same or an inverted relative orientation. Composite transposons apparently arose by the association of two originally independent IS elements. Experiments demonstrate that *composite transposons can transpose any sequence of DNA in their central region.*

The Mechanisms of Certain Transposons Require Replication. The transposons known as **replicative transposons** do not simply jump from point to point within a genome. Instead, *their mechanism of transposition involves the replication of the transposon.* A model for the movement of such a transposon between two plasmids consists of the following steps (Fig. 25-57):

1. A pair of staggered single-strand cuts (such as in Fig. 25-55) is made at the target sequence of the recipient plasmid. Similarly, single-strand cuts are made on opposite strands on either side of the transposon.
2. Each of the transposon's free ends is ligated to a protruding single strand at the insertion site. This forms a replication fork at each end of the transposon.
3. The transposon is replicated, thereby yielding a **cointegrate** (the fusion of the two plasmids). Such cointegrates have been isolated.
4. Through a site-specific crossover between the internal resolution sites of the two transposons, the cointegrate is resolved into two separate plasmids, each of which contains the transposon. This recombination process is catalyzed by a transposon-coded **resolvase** (TnpR in Tn3) rather than by RecA.

Transposition Is Responsible for Much Genetic Rearrangement. In addition to mediating their own insertion into DNA, *transposons promote inversions, deletions, and rearrangements of the host DNA.* Inversions can occur when the host DNA contains two copies of a transposon in inverted orientation. The recombination of the transposons inverts the region between them (Fig. 25-58a). If, instead, the two transposons have the same orientation, recombination deletes the segment between them (Fig. 25-58b). The deletion of a chromosomal segment in this manner, followed by its integration into the chromosome at a different site by a separate recombination event, results in chromosomal rearrangement.

Transposons can be considered nature's genetic engineering "tools." For example, the rapid evolution, since antibiotics came into common use, of plasmids that confer resistance to several antibiotics (Section 3-5A) has resulted from the accumulation of the corresponding antibiotic-resistance transposons in these plasmids. Transposon-mediated rearrangements may also have been responsible for forming new proteins by linking two formerly independent gene segments.

FIG. 25-57 A model for transposition involving the intermediacy of a cointegrate. More lightly shaded bars represent newly

synthesized DNA. [After Shapiro, J.A., *Proc. Natl. Acad. Sci.* **76**, 1934 (1979).] **WPLS** See the Animated Process Diagrams.

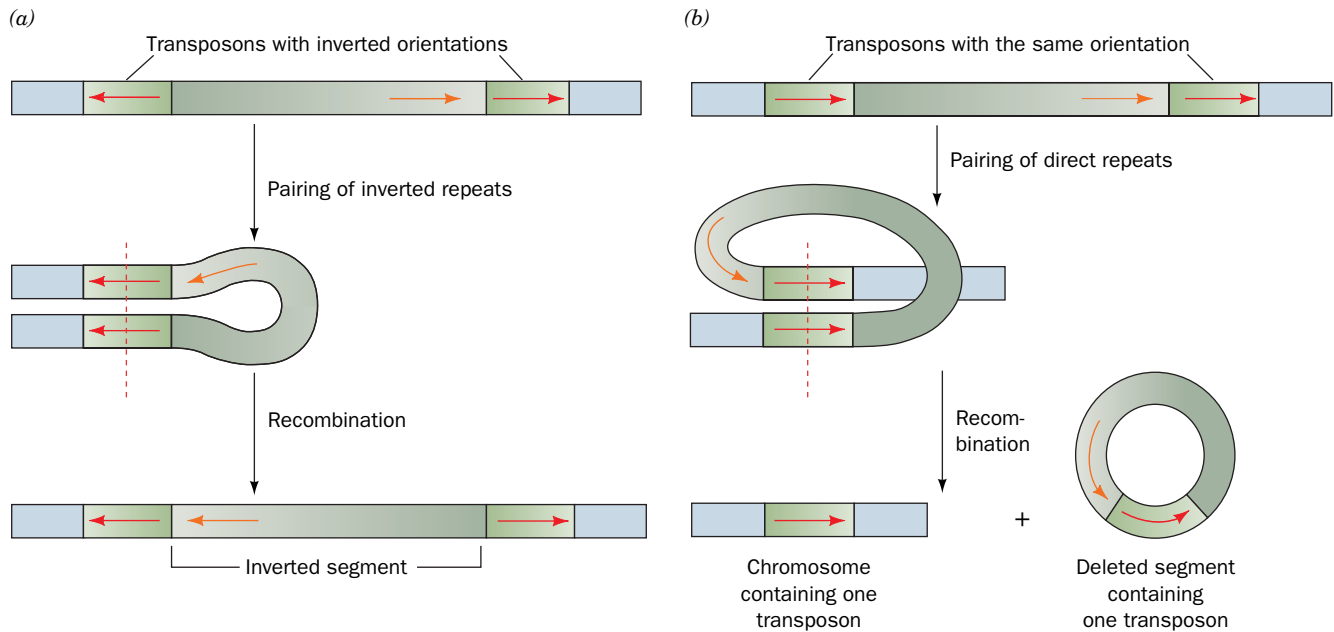

FIG. 25-58 Chromosomal rearrangement via recombination. (a) The inversion of a DNA segment between two identical transposons with

inverted orientations. (b) The deletion of a DNA segment between two identical transposons with the same orientation.

Moreover, transposons can apparently mediate the transfer of genetic information between unrelated species.

Most Eukaryotic Transposons Resemble Retroviruses. Transposons occur in such distantly related eukaryotes as yeast, maize, fruit flies, and humans. In fact, ~3% of the human genome consists of DNA-based transposons although, in most cases, their sequences have mutated so as to render them inactive; that is, these transposons are evolutionary fossils.

Most eukaryotic transposons exhibit little similarity to those of prokaryotes. Mostly, their base sequences resemble those of **retroviruses** (Box 25-2), which suggests that these transposons are degenerate retroviruses. The transposition of these so-called **retrotransposons** occurs via a pathway that resembles the replication of retroviral DNA: (1) their transcription to RNA, (2) the reverse transcriptase-mediated copying of the RNA to cDNA, and (3) the largely random insertion of the DNA into the host organism's genome as mediated by enzymes known as **integrases** (which resemble DNA transposases in structure and mechanism). Other retrotransposons replicate via a different mechanism. *Collectively, retrotransposons account for nearly two-thirds of the human genome.*

CHECKPOINT

- Describe the processes of strand invasion, branch migration, and resolution during homologous recombination.
- How does the DNA conformation change during recombination?
- What is the role of recombination in repairing damaged DNA?
- Can recombination occur in haploid as well as diploid cells?
- How is the CRISPR–Cas9 system used to generate specific mutations?
- Explain why all transposons include inverted repeats.
- How do transposons mediate genetic rearrangements?
- What fraction of the human genome consists of transposons and retrotransposons?

Summary

1 Overview of DNA Replication

- DNA is replicated semiconservatively through the action of DNA polymerases that use the separated parental strands as templates for the synthesis of complementary daughter strands.
- Replication is semidiscontinuous: The leading strand is synthesized continuously while the lagging strand is synthesized as RNA-primed Okazaki fragments that are later joined.

2 Prokaryotic DNA Replication

- *E. coli* DNA polymerase I (Pol I), which has 3' → 5' and 5' → 3' exonuclease activities in addition to its 5' → 3' polymerase activity, excises

RNA primers and replaces them with DNA. Pol III is the primary polymerase in *E. coli*.

- To initiate replication, parental strands are first melted apart at a specific site named *oriC* and further unwound by a helicase. Single-strand binding protein (SSB) prevents the resulting single strands from reannealing. A primase-containing primosome synthesizes an RNA primer.
- Because DNA polymerases operate only in the 5' → 3' direction, the lagging strand template must loop back to the replisome, which contains two polymerases. A sliding clamp increases Pol III's processivity. DNA ligase seals the nicks between Okazaki fragments. Replication proceeds until the two replication forks meet between oppositely facing *Ter* sequences.

• The high fidelity of DNA replication is achieved by the regulation of dNTP levels, by the low error rate of the polymerase reaction, by the requirement for RNA primers, by 3' → 5' proofreading, and by DNA repair mechanisms.

3 Eukaryotic DNA Replication

• Eukaryotes contain a number of DNA polymerases. Pol α extends primers, the highly processive pol δ is the lagging strand polymerase, and pol ϵ appears to be the leading strand polymerase. Eukaryotic replication has multiple origins and proceeds through nucleosomes.

• In order to replicate the 5' end of the lagging strand, eukaryotic chromosomes end with repeated telomeric sequences appended by the ribonucleoprotein telomerase. The 3' extension at the end of each chromosome serves as a template for primer synthesis. Somatic cells lack telomerase activity, which may prevent them from transforming to cancer cells.

4 DNA Damage

• Mutations in nucleotide sequences arise spontaneously from replication errors and from alterations triggered by agents such as UV light, radiation, and chemical mutagens. Many compounds that are mutagenic in the Ames test are also carcinogenic.

5 DNA Repair

• Some forms of DNA damage (e.g., alkylated bases and pyrimidine dimers) may be reversed in a single step. In base excision repair, glycosylases remove damaged bases. In nucleotide excision repair, an oligonucleotide containing the lesion is removed and replaced. Repair pathways that use error-prone polymerases, nonhomologous end-joining, and the *E. coli* SOS response are mutagenic.

6 Recombination

• Homologous recombination, in which strands of homologous DNA segments are exchanged, involves a crossover structure (Holliday junction). Recombination requires proteins to unwind DNA, mediate strand exchange, drive branch migration, and resolve the Holliday junction. Damaged DNA can be repaired through homology-directed repair.

• The CRISPR–Cas system enables many prokaryotes to defend themselves from previously encountered bacteriophages. CRISPR–Cas9 technology has permitted the facile editing and regulation of genomes.

• Transposons are genetic elements that move within a genome, often by mechanisms involving their replication. Transposons mediate rearrangement of the host DNA. Most eukaryotic transposons are retrotransposons.

Problems

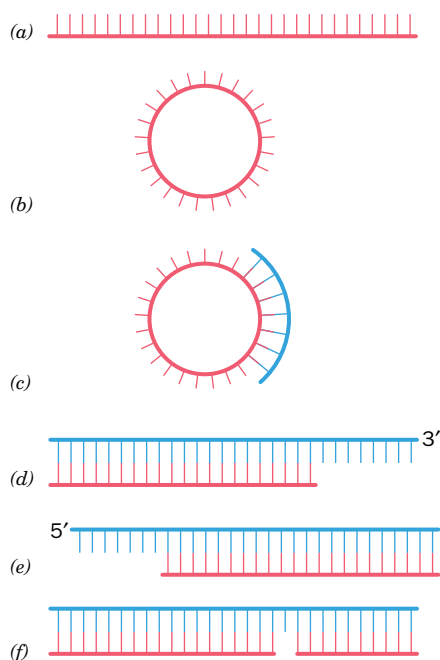

EXERCISES

1. Approximately how many Okazaki fragments are synthesized in the replication of the *E. coli* chromosome?
2. Approximately how many Okazaki fragments are synthesized in the replication of the human genome?
3. You have discovered a drug that inhibits the activity of inorganic pyrophosphatase. What effect would this drug have on DNA synthesis?

4. Why are there no Pol I mutants that completely lack 5' → 3' exonuclease activity?

5. The three DNA base pairs that fit within the active site of DNA polymerase have a conformation similar to that of A-DNA rather than the usual B-DNA. Why is it important for DNA polymerase to accommodate an A-type helix?

6. A reaction mixture contains DNA polymerase, the four dNTPs, and one of the DNA molecules whose structure is represented below. Which reaction mixtures generate PP_i?

7. *E. coli oriC* is rich in A · T base pairs. Why is this advantageous?
8. Explain why DNA gyrase is required for efficient unwinding of DNA by helicase at the replication fork.
9. In some experimental systems, a newly synthesized RNA primer is transferred from primase to the clamp or clamp loader rather than directly to DNA polymerase. Explain why this would maximize the efficiency of DNA replication.
10. Why is the observed mutation rate of *E. coli* 10⁻⁸ to 10⁻¹⁰ per base pair replicated, even though the error rates of Pol I and Pol III are 10⁻⁶ to 10⁻⁷ per base pair replicated?
11. Why can't a linear duplex DNA, such as that of bacteriophage T7, be fully replicated by just *E. coli*-encoded proteins?
12. How does a eukaryotic cell distinguish the end of a broken chromosome from the end of an intact linear chromosome?
13. Telomerase adds six deoxynucleotides to the end of a DNA strand using a built-in RNA template. Explain why the templating region of the RNA includes one and a half repeats of the telomeric sequence (~9 nucleotides).
14. Give the name of the enzyme that catalyzes each of the following reactions:
- Makes a DNA strand from a DNA template
 - Makes a DNA strand from an RNA template
 - Makes an RNA strand from a DNA template

15. The base analog **5-bromouracil (5BU)**,

5-Bromouracil (5BU) residue

which sterically resembles thymine, more readily undergoes tautomerization from its keto form to its enol form than does thymine. 5BU can be incorporated into newly synthesized DNA when it pairs with adenine on the template strand. However, the enol form of 5BU pairs with guanine rather than adenine. (a) Draw the 5BU · G base pair. (b) What type of mutation results?

16. **Hydroxylamine** (NH₂OH) converts cytosine to the compound shown below.

With which base does this modified cytosine pair? Does this generate a transition or a transversion mutation?

17. Oxidative deamination of adenine produces hypoxanthine (the base of inosine), which can base pair with cytosine. (a) If no repair takes place, describe the makeup of the DNA in the two daughter cells following cell division. (b) Describe the makeup of the DNA in the four daughter cells following a second round of cell division.

18. A certain mutant DNA polymerase is error-prone, tending to incorporate C opposite a template A. When such a DNA polymerase replicates a segment of DNA containing an A · T base pair, what will be the DNA composition in the daughter cells after (a) one and (b) two rounds of cell division? Assume that DNA repair does not occur.

19. In eukaryotic cells, a specific triphosphatase cleaves deoxy-8-oxo-guanosine triphosphate (oxo-dGTP) to oxo-dGMP + PP_i. What is the advantage of this reaction?

20. Under cellular conditions, dATP can be oxidized to its 2-hydroxy form, which is a substrate for an enzyme that converts 2-OH-dATP to 2-OH-dAMP + PP_i. Explain why compounds that inhibit the activity of this enzyme would be effective anticancer agents.

21. Yeast and some other organisms produce proteins that closely resemble O⁶-alkylguanine-DNA alkyltransferase but lack a Cys at the active site. (a) Explain why these proteins cannot remove an alkyl group attached to guanine. (b) These proteins do protect cells against DNA alkylation damage. In which type of repair process are these proteins most likely to participate?

22. Explain why mutations are more likely to occur on the lagging strand than on the leading strand in eukaryotes.

23. Certain sites in the *E. coli* chromosome are known as **hot spots** because they have unusually high rates of point mutations. Many of these sites contain a 5-methylcytosine residue. Explain the existence of such hot spots.

24. Since mammalian DNA contains roughly 25% thymine residues, why do mammalian cells need a thymine-DNA glycosylase?

25. What type of repair system would cells most likely use to repair DNA with a deaminated adenine?

26. Explain why base excision repair, nucleotide excision repair, and mismatch repair—which all require nucleases to excise damaged DNA—require DNA ligase.

27. Ribonucleotides are erroneously incorporated into newly synthesized DNA as a result of incomplete primer removal or misincorporation by DNA polymerase. What types of enzymes would be required to remove and replace a single ribonucleotide in a DNA strand?

28. Explain why interstrand DNA cross-links are much more mutagenic than intrastrand cross-links.

29. Broken DNA can be repaired by DNA ligase (single-strand breaks) or nonhomologous end-joining (double-strand breaks). Explain why the cell's set of repair enzymes also includes tyrosyl-DNA phosphodiesterases.

30. A DNA template strand containing a thymine dimer can be replicated by DNA polymerase η. Does pol η fix the damaged DNA?

31. *E. coli* DNA polymerase V has the ability to bypass thymine dimers. However, Pol V tends to incorporate G rather than A opposite the damaged T bases. Would you expect Pol V to be more or less processive than Pol III? Explain.

32. Predict whether loss of the following *E. coli* genes would be lethal or not: (a) *dnaB* (which encodes DnaB), (b) *polA* (which encodes Pol I), (c) *ssb*, (d) *recA*.

33. During bacterial conjugation, two cells of the same or similar species make close contact and transfer genetic information. In the donor cell, an endonuclease nicks the DNA so that a single strand can enter the recipient cell. Explain why the stable incorporation of the transferred DNA requires RecBCD activity in the recipient cell.

34. Two approaches for correcting single-gene defects are gene therapy such as is discussed in Section 3-5D and the CRISPR–Cas9 system. Explain why the CRISPR–Cas9 approach can potentially provide more complete restoration of normal tissue function than gene therapy.

CHALLENGE QUESTIONS

35. Explain why a DNA polymerase that could synthesize DNA in the 3' → 5' direction would have a selective disadvantage even if it had 5' → 3' proofreading activity.

36. The 3' → 5' exonuclease activity of Pol I excises only unpaired 3'-terminal nucleotides from DNA, whereas this enzyme's pyrophosphorolysis activity removes only properly paired 3'-terminal nucleotides. Discuss the mechanistic significance of this phenomenon in terms of the polymerase reaction.

37. To put the *E. coli* replication system on a human scale, let us imagine that the 20-Å-diameter B-DNA was expanded to 1 m in diameter. If everything were proportionally expanded, then each DNA polymerase III holoenzyme would be about the size of a medium-sized truck. In such an expanded system: (a) How fast would each replisome be moving? (b) How far would each replisome travel during a complete replication cycle? (c) What would be the length of an Okazaki fragment? (d) What would be the average distance a replisome would travel between each error it made? Provide your answers in km/hr and km.

38. A high rate of base-substitution mutations can result from a polymerase's tendency to incorporate a mispaired nucleotide or from its poor ability to incorporate the correct nucleotide. Use the following information about the catalytic efficiency (k_{cat}/K_M) of two error-prone polymerases to compare their ability to generate substitution mutations.

Polymerase	Template nucleotide	Incoming nucleotide	k_{cat}/K_M ($\mu\text{M} \cdot \text{min}^{-1} \times 10^3$)
polymerase η	T	A	420
	T	G	22
HIV reverse transcriptase	T	A	800
	T	G	0.07

39. Why is it necessary to use only the Klenow fragment, rather than intact *E. coli* Pol I, in DNA sequencing reactions (Sections 3-4C and D)?

40. In *E. coli*, all newly synthesized DNA appears to be fragmented (an observation that could be interpreted to mean that the leading strand as well as the lagging strand is synthesized discontinuously). However, in

E. coli mutants that are defective in uracil–DNA glycosylase, only about half the newly synthesized DNA is fragmented. Explain.

41. According to the text, approximately 20,000 of 6.0 billion glycosidic bonds in the DNA of a diploid human cell spontaneously hydrolyze each day. What is the half-life in years of such a bond? (*Hint*: See Section 12-1A.)

42. The *E. coli* genome contains 1009 Chi sequences. Do these sequences occur at random, and, if not, how much more or less frequently than random do they occur?

43. *Deinococcus radiodurans*, which the *Guinness Book of World Records* has dubbed the world's toughest bacterium, can tolerate doses of ionizing radiation ~3000-fold greater than those that are lethal to humans (it was first discovered growing in a can of ground meat that had been “sterilized” by radiation). It appears to have several strategies to repair radiation damage to its DNA (which large doses of ionizing radiation fragment to many pieces) including a particularly large number of genes encoding proteins involved in DNA repair and 4 to 10 copies per cell of its genome, which consists of two circular chromosomes and two circular plasmids. Yet, these strategies, alone, do not account for *D. radiodurans*' enormously high radiation resistance. However, in an additional strategy, it organizes its multiple identical dsDNA circles into stacks in which, it is thought, the identical genes in the neighboring circles are aligned side by side. How would this latter strategy help *D. radiodurans* efficiently repair its fragmented DNA?

44. A composite transposon integrated in a circular plasmid occasionally transposes the DNA comprising the original plasmid rather than the transposon's central region. Explain how this is possible.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 DNA Replication and the KEGG Database

Exercise 2 Viewing and Analyzing Uracil–DNA Glycosylase in DNA Repair

MORE TO EXPLORE Following DNA replication in eukaryotes, the two DNA molecules (sister chromatids) remain associated through the binding of a protein complex called cohesin. Describe cohesin's structure and explain how it binds to DNA and how it eventually releases the DNA. What role does cohesin play in recombination?

CASE STUDY www.wiley.com/college/voet

Case 32 Glucose-6-Phosphate Dehydrogenase Activity and Cell Growth

Focus concept: The activity of the pentose phosphate pathway enzyme glucose-6-phosphate dehydrogenase has been found to be important in the regulation of cell growth.

Prerequisites: Chapters 5, 13, 15, and 25

- Pentose phosphate pathway reactions
- SDS-PAGE analysis
- DNA replication
- Signal transduction pathways involving tyrosine phosphorylation

CHAPTER 26

Transcription and RNA Processing

Chapter Contents

1 Prokaryotic RNA Transcription

- A RNA Polymerase Resembles Other Polymerases
- B Transcription Is Initiated at a Promoter
- C The RNA Chain Grows from the 5' to 3' End
- D Transcription Terminates at Specific Sites

2 Transcription in Eukaryotes

- A Eukaryotes Have Several RNA Polymerases
- B Each Polymerase Recognizes a Different Type of Promoter
- C Transcription Factors Are Required to Initiate Transcription

3 Posttranscriptional Processing

- A Messenger RNAs Undergo 5' Capping and Addition of a 3' Tail
- B Splicing Removes Introns from Eukaryotic Genes
- C Ribosomal RNA Precursors May Be Cleaved, Modified, and Spliced
- D Transfer RNAs Are Processed by Nucleotide Removal, Addition, and Modification

Based on an NMR structure by Frédéric Allain and Franz Narberhaus, ETH Zürich, Switzerland. PDBid 2G10

Certain bacteria alter gene expression by using an RNA thermometer, a base-paired messenger RNA segment whose conformation is disrupted when the temperature rises. RNA melting exposes a ribosome-binding site, allowing production of the encoded protein, which is often a heat shock protein that helps the bacteria survive at the higher temperature.

DNA is confined almost exclusively to the nucleus of eukaryotic cells, as shown by microscopists in the 1930s. By the 1950s, the site of protein synthesis was identified by showing that radioactively labeled amino acids that had been incorporated into proteins were associated with cytosolic RNA–protein complexes called ribosomes. Thus, *protein synthesis is not immediately directed by DNA because, at least in eukaryotes, DNA and ribosomes are never in contact.* The intermediary between DNA and the protein-biosynthesis machinery, as outlined in Francis Crick's central dogma of molecular biology (Section 3-3B), is RNA.

Cells contain three major types of RNA: **ribosomal RNA (rRNA)**, which constitutes two-thirds of the ribosomal mass; **transfer RNA (tRNA)**, a set of small, compact molecules that deliver amino acids to the ribosomes for assembly into proteins; and **messenger RNA (mRNA)**, whose nucleotide sequences direct protein synthesis. In addition, a host of other **noncoding RNA** species play various roles in the regulation of gene expression and the processing of newly transcribed RNA molecules (Table 26-1). All types of RNA can be shown to hybridize with complementary sequences on DNA from the same organism. Thus, *all cellular RNAs are transcribed from DNA templates.*

GATEWAY CONCEPT: The Central Dogma

RNA synthesis represents one step of the central dogma of molecular biology, in which the information encoded in DNA is rewritten (transcribed) in the form of RNA. The RNA may undergo extensive modification before it is used, and it is relatively quickly degraded, but the information in DNA remains intact.

TABLE 26-1 Some Noncoding RNAs

Type	Size (nt)	Function
Ribosomal RNA (rRNA)	120–4718	Translation (ribosome structure and catalytic activity)
Transfer RNA (tRNA)	54–100	Delivery of amino acids to ribosomes during translation
Small interfering RNA (siRNA)	20–25	Sequence-specific inactivation of mRNA
Micro RNA (miRNA)	20–25	Sequence-specific inactivation of mRNA
Large intergenic noncoding RNA (lincRNA)	Up to 17,200	Transcriptional control
Small nuclear RNA (snRNA)	60–300	RNA splicing
Small nucleolar RNA (snoRNA)	70–100	Sequence-specific methylation of rRNA

The transcription of DNA to RNA is carried out by **RNA polymerases (RNAPs)** that operate as multisubunit complexes, as do the DNA polymerases that catalyze DNA replication. In this chapter, we examine the catalytic properties of RNAPs and discuss how these proteins—unlike DNA polymerases—are targeted to specific genes. We will also see how newly synthesized RNA is processed to become fully functional.

1 Prokaryotic RNA Transcription

KEY CONCEPTS

- RNA polymerase resembles DNA polymerase in structure and mechanism.
- Bacterial transcription begins with the RNAP holoenzyme binding to a promoter to melt apart the DNA.
- As the polymerase processively extends an RNA chain, another polymerase can initiate transcription.
- Transcription termination in prokaryotes depends on intrinsic terminator sequences or Rho factor.

RNAP, the enzyme responsible for the DNA-directed synthesis of RNA, was discovered independently in 1960 by Samuel Weiss and Jerard Hurwitz. The enzyme couples together the ribonucleoside triphosphates (NTPs) ATP, CTP, GTP, and UTP on DNA templates in a reaction that is driven by the release and subsequent hydrolysis of PP_i :

An RNAP can join two NTPs *de novo* (Latin: from the beginning) so that, unlike DNA polymerases, it does not require a primer.

All cells contain RNAP. In bacteria, one enzyme synthesizes all of the cell's RNA except the short RNA primers employed in DNA replication (Section 25-2B). Eukaryotic cells contain four or five RNAPs that each synthesize a different class of RNA. We will first consider the bacterial enzyme because it is smaller and simpler than the eukaryotic enzymes.

A RNA Polymerase Resembles Other Polymerases

The *E. coli* RNAP **holoenzyme** is an ~449-kD protein with subunit composition $\alpha_2\beta\beta'\omega\sigma$ (Table 26-2). Once RNA synthesis has been initiated, however, the σ subunit (also called the **σ factor**) dissociates from the **core enzyme**, $\alpha_2\beta\beta'\omega$, which carries out the actual polymerization process. RNAP is large enough to be clearly visible in electron micrographs (Fig. 26-1).

TABLE 26-2 Components of *E. coli* RNA Polymerase Holoenzyme

Subunit	Number of Residues
α	329
β	1342
β'	1407
ω	91
σ^{70}	613

FIG. 26-1 An electron micrograph of *E. coli* RNA polymerase holoenzyme. This soluble enzyme, one of the largest known, is attached to various promoter sites on bacteriophage T7 DNA.

From Williams, R.C. Proc. Natl. Acad. Sci. 74, 2313 (1977)

FIG. 26-2 X-Ray structure of the Tth core RNAP in complex with a 23-nt template DNA, a 14-nt nontemplate DNA, and a 16-nt RNA. The protein is drawn in ribbon form with its two α subunits yellow and green, its β subunit cyan, its β' subunit pink, and its ω subunit gray. Its bound Mg^{2+} and Zn^{2+} ions are represented by red and orange spheres, respectively. The DNA and RNA are shown in ladder form with template DNA green, nontemplate DNA purple, and RNA red. Residues 208 to 390 of the β' subunit, which extend from the tip of its pincer, are disordered and hence not visible. [Based on an X-ray structure by Dmitry Vassylyev, University of Alabama at Birmingham. PDBid 5051.]

The X-ray structure of the related RNAP core enzymes from *Thermus aquaticus* (Taq) and *Thermus thermophilus* (Tth) were independently determined by Seth Darst and Dmitry Vassylyev. The structure of the Tth core enzyme (which closely resembles that of the Taq enzyme) in complex with DNA and RNA has the overall shape of a crab claw whose two pincers are formed by the β and β' subunits (Fig. 26-2). In this so-called **open complex**, the ~ 27 -Å-high space between the pincers, the main channel, is occupied by the dsDNA. The template DNA continues to the active site at the end of the main channel where it base-pairs with the incoming NTP (not present in the structure) at the so-called $i + 1$ site near a bound Mg^{2+} ion. The 3' end of the newly synthesized RNA forms a 9-bp hybrid helix with the 5' end of the template DNA strand and then exits the protein through a channel between the β and β' subunits, the RNA exit channel, in which it adopts a conformation similar to that of a single strand within an RNA double helix. However, the paths taken by the template and nontemplate DNA strands to rejoin at the end of the so-called **transcription bubble** are unclear.

In the X-ray structure of the Tth holoenzyme in complex with dsDNA containing a promoter (a sequence that specifies the transcription initiation site; Section 26-1B), determined by Richard Ebright, the σ subunit extends across the core enzyme, which causes its pincers to come together so as to narrow the channel between them by ~ 10 Å, thereby forming the so-called **closed complex** (Fig. 26-3). In this structure, the σ subunit has opened the transcription bubble by specifically binding the nontemplate strand's -10 promoter element. The outer surface of the holoenzyme is almost uniformly negatively charged, whereas those surfaces that interact with nucleic acids, particularly the inner walls of the main channel, are positively charged.

Only One Strand of DNA Is Copied. RNA synthesis is normally initiated only at specific sites on the DNA template. In contrast to replication, which requires

FIG. 26-3 X-Ray structure of the Tth RNAP holoenzyme in complex with a 19-nt template DNA and 27-nt nontemplate DNA with a -10 promoter element at its 5' end. The core enzyme, which is colored as in Fig. 26-2, is represented by its semitransparent surface diagram and viewed approximately from the bottom of Fig. 26-2. The σ subunit is drawn in cartoon form with its α helices as cylinders and colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The DNA is represented in ladder form with its template strand green and its nontemplate strand purple except for its -10 promoter element (Section 26-1B), which is red. Both DNA strands, with the exception of the -10 element, are buried between the β and β' subunits. [Based on an X-ray structure by Richard Ebright, Rutgers University. PDBid 4G7H.]

FIG. 26-4 Sense and antisense DNA strands. The template strand of duplex DNA is known as its antisense or noncoding strand. Its complementary sense or coding strand has the same nucleotide sequence and orientation as the transcribed RNA.

? If the sequence of the sense strand in the transcription bubble reads CTGATCTAGA, what is the sequence of the corresponding antisense strand and RNA?

that both strands of the chromosome be entirely copied, the regulated expression of genetic information involves the copying of much smaller, single-strand portions of the genome. The DNA strand that serves as a template during transcription is known as the **antisense** or **noncoding strand** because its sequence is complementary to that of the RNA. The other DNA strand, the nontemplate strand, which has the same sequence as the transcribed RNA (except for the replacement of U with T), is known as the **sense** or **coding strand** (Fig. 26-4). The two strands of DNA in an organism's chromosome can therefore contain different sets of genes.

Keep in mind that “gene” is a relatively loose term that refers to sequences that encode polypeptides, as well as those that correspond to the sequences of rRNA, tRNA, and other RNA species. Furthermore, a gene typically includes sequences that participate in initiating and terminating transcription (and translation) that are not actually transcribed (or translated). The expression of many genes also depends on regulatory sequences that do not directly flank the coding regions but may be located a considerable distance away.

Most protein-coding genes (called **structural genes**) in eukaryotes are transcribed individually. In prokaryotic genomes, however, genes are frequently arranged in tandem along a single DNA strand so that they can be transcribed together. These genetic units, called **operons**, typically contain genes with related functions. For example, the three different rRNA genes of *E. coli* occur in single operons (Section 26-3C). The *E. coli* **lac operon**, whose expression is described in detail in Section 28-2A, contains three genes encoding proteins involved in lactose metabolism as well as sequences that control their transcription (Fig. 26-5). Other operons contain genes encoding proteins required for biosynthetic pathways, for example, the **trp operon**, whose six **gene products** (proteins are often referred to as gene products) catalyze tryptophan synthesis. An operon is transcribed as a single unit, giving rise to a **polycistronic mRNA** that directs the more-or-less simultaneous synthesis of each of the encoded polypeptides (the term **cistron** is a somewhat archaic synonym for gene). In contrast, eukaryotic structural genes, which are not part of operons, give rise to **monocistronic mRNAs**.

FIG. 26-5 The *E. coli* lac operon. This DNA includes genes encoding the proteins mediating lactose metabolism and the genetic sites that control their expression. The Z, Y, and A genes, respectively, specify the proteins **β -galactosidase** (Box 8-1), **galactoside permease** (Section 10-3D), and **thiogalactoside transacetylase**. The closely linked regulatory gene, *I*, which is not part of the *lac* operon, encodes a repressor that inhibits transcription of the *lac* operon.

B Transcription Is Initiated at a Promoter

How does RNAP recognize the correct DNA strand and initiate RNA synthesis at the beginning of a gene (or operon)? *RNAP binds to its initiation sites through base sequences known as promoters that are recognized by the corresponding σ factor.* The existence of promoters was first revealed through mutations that enhanced or diminished the transcription rates of certain genes. Promoters consist of ~40-bp sequences that are located on the 5' side of the transcription start site. By convention, the sequence of this DNA is represented by its sense (nontemplate) strand so that it will have the same sequence and directionality as the transcribed RNA. A base pair in a promoter region is assigned a negative or positive number that indicates its position, upstream or downstream in the direction of RNAP travel, from the first nucleotide that is transcribed to RNA; this start site is +1 and there is no 0. Because RNA is synthesized in the 5' → 3' direction (see below), the promoter is said to lie upstream of the RNA's starting nucleotide.

The holoenzyme forms tight complexes with promoters. This tight binding can be demonstrated by showing that the holoenzyme protects the bound DNA segments from digestion *in vitro* by the endonuclease DNase I. Sequence determinations of the protected regions from numerous *E. coli* genes have identified the “consensus” sequence of *E. coli* promoters (Fig. 26-6). Their most conserved sequence is a hexamer centered at about the -10 position (alternatively called the **Pribnow box** after David Pribnow, who described it in 1975). It has a consensus sequence of TATAAT in which the leading TA and the final T are highly conserved. Upstream sequences around position -35 also have a region of sequence similarity, TTGACA. The initiating (+1) nucleotide, which is nearly always A or G, is centered in a poorly conserved CAT or CGT sequence. Most promoter sequences vary considerably from the consensus sequence (Fig. 26-6). Nevertheless, a mutation in one of the partially conserved regions can greatly increase or decrease a promoter's initiation efficiency. This is because *the rates at which E. coli genes are transcribed vary directly with the rates at which their promoters form stable initiation complexes with the RNAP holoenzyme.*

FIG. 26-6 The sense (coding) strand sequences of selected *E. coli* promoters. A 6-bp region centered around the -10 position (red shading) and a 6-bp sequence around the -35 region (blue shading) are both conserved. The transcription initiation sites (+1), which in most promoters occur at a single purine nucleotide, are shaded in green. The bottom row shows the consensus sequence of 298 *E. coli* promoters with the number below each base indicating its percentage occurrence.

[After Rosenberg, M. and Court, D., *Annu. Rev. Genet.* **13**, 321-323 (1979). Consensus sequence from Lissner, D. and Margalit, H., *Nucleic Acids Res.* **21**, 1512 (1993).]

? Approximately how many helical turns separate the two blocks of conserved sequence?

Initiation Requires the Formation of a Transcription Bubble. The promoter regions in contact with the RNAP holoenzyme have been identified by a procedure named **footprinting**. In this procedure, DNA is incubated with a protein to which it binds and is then treated with an alkylation agent such as dimethyl sulfate (DMS). This results in alkylation of the DNA's bases followed by backbone cleavage at the alkylated positions. However, those portions of the DNA that bind proteins are protected from alkylation and hence cleavage. The resulting pattern of protection is called the protein's footprint. The footprint of RNAP holoenzyme indicates that it contacts the promoter primarily at its -10 and -35 regions. In some genes, additional upstream sequences may also influence RNAP binding to DNA.

DMS methylates G residues at N7 and A residues at N3 in both double- and single-stranded DNA. DMS also methylates N1 of A and N3 of C, but only if the latter positions are not involved in base-pairing interactions. The pattern of DMS methylation therefore reveals whether the DNA is single or double stranded. Footprinting studies indicate that holoenzyme binding "melts" (separates) ~ 11 bp of DNA (from -9 to $+2$). The resulting **transcription bubble** (e.g., Fig. 26-4) resembles the region of unwound DNA at the replication origin (Section 25-2B).

In the X-ray structure of the Tth holoenzyme (Fig. 26-3), the σ subunit makes extensive, base-specific contacts with the -10 element (TATAAT) of the promoter on the sense (nontemplate) strand in a way that opens the transcription bubble. This demonstrates both that the -10 element recognized by the σ subunit is on the sense strand and that the holoenzyme must melt open the transcription bubble for the -10 element to be recognized.

The core enzyme, which does not specifically bind promoters, tightly binds duplex DNA (the complex's dissociation constant is $K \approx 5 \times 10^{-12}$ M, and its half-life is ~ 60 min). *The holoenzyme, in contrast, binds to nonpromoter DNA comparatively loosely* ($K \approx 10^{-7}$ M and a half-life of > 1 s). Evidently, the σ subunit allows the holoenzyme to move rapidly along a DNA strand in search of the σ subunit's corresponding promoter to which it tightly binds ($K = 10^{-14}$ M). Once transcription has been initiated and the σ subunit jettisoned, the tight binding of the core enzyme to DNA apparently stabilizes the ternary enzyme-DNA-RNA complex.

Gene Expression Is Controlled by Different σ Factors. Because different σ factors recognize different promoters, *a cell's complement of σ factors determines which genes are transcribed*. Development and differentiation, which involve the temporally ordered expression of sets of genes, can be orchestrated through a "cascade" of σ factors. For example, infection of *Bacillus subtilis* by **bacteriophage SP01** requires the expression of different sets of phage genes at different times. The first set, known as the **early genes**, are transcribed using the bacterial σ factor. One of the early phage gene products is a σ subunit known as σ^{gp28} (gp for gene product), which displaces the host σ factor and thereby permits the RNAP to recognize only the phage **middle gene** promoters. The phage middle genes, in turn, specify $\sigma^{gp33/34}$, which promotes transcription of only phage **late genes**.

Many bacteria, including *E. coli* and *Bacillus subtilis*, likewise have several different σ factors. These are not necessarily used in a sequential manner. Thus, σ factors in *E. coli* that differ from its primary σ factor (which is named σ^{70} because its molecular mass is 70 kD) control the transcription of coordinately expressed groups of special-purpose genes whose promoters are quite different from those recognized by σ^{70} . For example, *E. coli* σ^{32} recognizes the promoters in the heat shock genes that are activated at high temperatures.

C The RNA Chain Grows from the 5' to 3' End

RNA synthesis is catalyzed via a two-metal mechanism, much like that employed by DNA polymerases (Fig. 25-11). Because RNA synthesis, like DNA synthesis,

FIG. 26-7 5' → 3' RNA chain growth. Nucleotides are added to the 3' end of the growing RNA chain via attack of the 3'-OH group on the incoming nucleoside triphosphate. A radioactive label at the γ position of an NTP (indicated by an asterisk) is retained in the initial nucleotide

of the RNA (the 5' end) but is lost as PP_i during the polymerization of subsequent nucleotides.

? What is the driving force for this reaction?

proceeds in the 5' → 3' direction (Fig. 26-7), the growing RNA molecule has a 5'-triphosphate group. Mature RNA molecules, as we will see, may also be chemically modified at one or both ends.

A portion of the double-stranded DNA template remains opened up at the point of RNA synthesis (Fig. 26-4). This allows the antisense strand to direct the synthesis of its complementary RNA strand. The RNA chain transiently forms a short length of RNA–DNA hybrid duplex. The unpaired “bubble” of DNA in the open initiation complex apparently travels along the DNA with the RNAP (Fig. 26-8).

As DNA's helical turns are pushed ahead of the advancing transcription bubble, they become more tightly wound (more positively supercoiled) while the DNA behind the bubble becomes equivalently unwound (more negatively supercoiled). This scenario is supported by the observation that the transcription of plasmids in *E. coli* induces their positive supercoiling in gyrase mutants (which cannot relax positive supercoils; Section 24-1D) and their negative supercoiling in topoisomerase I mutants (which cannot relax negative supercoils). Inappropriate superhelicity in the DNA being transcribed halts transcription. Quite possibly, the torsional tension in the DNA generated by negative superhelicity behind the transcription bubble is required to help drive the transcriptional process, whereas too much such tension prevents the opening and maintenance of the transcription bubble.

Strain that builds up in the DNA template is apparently responsible for a curious property of RNAP: It frequently releases its newly synthesized RNA after only ~9 to 11 nt have been polymerized, a process known as **abortive initiation**. When RNAP begins transcribing, it keeps its grip on the promoter (which is on the DNA's nontemplate strand). Consequently, conformational tension builds up as the template strand is pulled through the RNAP's active site, a

FIG. 26-8 DNA supercoiling during transcription. In the region being transcribed, the DNA double helix is unwound by about a turn to permit the DNA's antisense strand to form a short segment of DNA–RNA hybrid double helix. As the RNA polymerase advances along the DNA template (here to the right), the DNA unwinds ahead of the RNA's growing 3' end and rewinds behind it, thereby stripping the newly synthesized RNA from the template strand. Because the ends of the

DNA as well as the RNA polymerase are apparently prevented from rotating by attachments within the cell (*black bars*), the DNA becomes overwound (positively supercoiled) ahead of the advancing transcription bubble and underwound (negatively supercoiled) behind it (consider the consequences of placing your finger between the twisted DNA strands in this model and pushing toward the right). [After Futcher, B., *Trends Genet.* **4**, 272 (1988).]

Box 26-1 Perspectives in Biochemistry

Collisions between DNA Polymerase and RNA Polymerase

In rapidly proliferating bacterial cells, DNA synthesis is likely to occur even as genes are being transcribed. The DNA replication machinery moves along the circular chromosome at a rate many times faster than the movement of the transcription machinery. Collisions between DNA polymerase and RNA polymerase seem unavoidable. What happens when the two enzyme complexes collide? Using *in vitro* model systems, Bruce Alberts has shown that when both enzymes are moving in the same direction, the replication fork passes the RNA polymerase without displacing it, leaving it fully competent to resume RNA chain elongation.

When the replication fork collides head-on with a transcription complex, however, the replisome pauses briefly before moving past the RNA polymerase. Surprisingly, this causes the RNA polymerase

to switch its template strand. The growing RNA chain dissociates from the original template DNA strand and hybridizes with the newly synthesized daughter DNA strand of the same sequence before RNA elongation resumes.

Head-on collisions are disadvantageous because (1) replication slows when DNA polymerase pauses, and (2) dissociation of the RNA polymerase during the jump from one template strand to the other could abort the transcription process. Indeed, in many bacterial and phage genomes, the most heavily transcribed genes are oriented so that replication and transcription complexes move in the same direction. It remains to be seen whether a similar arrangement holds in eukaryotic genomes, which contain multiple replication origins and genes that are much larger than are prokaryotic genes.

process called **scrunching** because the resulting increased size of the transcription bubble in the downstream direction must somehow be accommodated within the RNAP. In successful initiation, the strain eventually provides enough energy to strip the promoter from the RNAP, which then continues its progress along the template. In abortive initiation, the RNAP fails to escape the promoter and instead relieves the conformational tension by releasing the newly synthesized RNA fragment, thereby letting the transcription bubble relax to its normal size. The RNAP then reinitiates transcription from the +1 position.

RNA Polymerase Is Processive. Once the open complex has been formed, transcription proceeds without dissociation of the enzyme from the template. Processivity is accomplished without an obvious clamplike structure (e.g., the β clamp of *E. coli* DNA polymerase III; Fig. 25-16), although the RNAP itself apparently functions as a sliding clamp by binding tightly but flexibly to the DNA–RNA complex. In experiments in which the RNAP was immobilized and a magnetic bead was attached to the DNA, up to 180 rotations (representing nearly 1900 base pairs at 10.5 bp per turn) were observed before the polymerase slipped. Such processivity is essential, since genes are often thousands (in eukaryotes, sometimes millions) of nucleotides in length.

The tight association between RNAP and DNA and their multiple attachment sites may explain why a transcription complex does not completely dissociate from a DNA template even when transcription is interrupted by the DNA replication machinery proceeding along the same strand of DNA (see Box 26-1).

Transcription Is Rapid. In *E. coli*, the *in vivo* rate of transcription is 20 to 50 nt/s at 37°C (but still many times slower than the DNA replication rate of ~1000 nt/s; Section 25-2C). The error frequency in RNA synthesis is one wrong base incorporated for every $\sim 10^4$ transcribed. This frequency, which is 10^4 to 10^6 times higher than that for DNA synthesis, is tolerable because most genes are repeatedly transcribed, because the genetic code contains numerous synonyms (Section 27-1C), and because amino acid substitutions in proteins are often functionally innocuous.

Once an RNAP molecule has initiated transcription and moved away from the promoter, another RNAP can follow suit. The synthesis of RNAs that are needed in large quantities, rRNAs, for example, is initiated as often as is sterically possible, about once per second. This gives rise to an arrowhead appearance of the transcribed DNA (Fig. 26-9). mRNAs encoding proteins are generally synthesized at less frequent intervals, and there is enormous variation in the amounts of different polypeptides produced. For example, an *E. coli* cell may contain 10,000 copies of a ribosomal protein, whereas a regulatory protein may be present in only a few copies per cell. Many enzymes, particularly those involved in

FIG. 26-9 An electron micrograph of three contiguous ribosomal genes undergoing transcription. The “arrowhead” structures result from the increasing lengths of the nascent RNA chains as the RNA

polymerases synthesizing them move from the initiation site on the DNA to the termination site. [Courtesy of Ulrich Scheer, University of Würzburg, Germany.]

? Identify the 5' and 3' ends of the RNA transcripts.

basic cellular “housekeeping” functions, are synthesized at a more or less constant rate; they are called **constitutive enzymes**. Other enzymes, termed **inducible enzymes**, are synthesized at rates that vary with the cell’s circumstances. To a large extent, the regulation of gene expression relies on mechanisms that govern the rate of transcription, as we will see in Section 28-2. The products of transcription also vary in their stabilities. Ribosomal RNA turns over much more slowly than mRNA, which is rapidly synthesized and rapidly degraded (sometimes so fast that the 5' end of an mRNA is degraded before its 3' end has been synthesized).

D Transcription Terminates at Specific Sites

Electron micrographs such as Fig. 26-9 suggest that DNA contains specific sites at which transcription is terminated. The transcription termination sequences of about half of *E. coli* genes share two common features (Fig. 26-10):

1. A series of 4 to 10 consecutive A · T base pairs, with the A’s on the template strand. The transcribed RNA is terminated in or just past this sequence.
2. A G + C–rich region with a palindromic sequence that immediately precedes the series of A · T’s.

The RNA transcript of this region, called an **intrinsic terminator**, can therefore form a self-complementary “hairpin” structure that is terminated by several U residues.

The structural stability of an RNA transcript at its terminator’s G + C–rich hairpin and the weak base pairing of its oligo(U) tail to template DNA appear to be important factors in ensuring proper chain termination. The formation of the G + C–rich hairpin causes RNAP to pause for several seconds at the termination site. This probably induces a conformational change in the RNAP that permits the nontemplate DNA strand to displace the weakly bound oligo(U) tail from the template strand, thereby spontaneously terminating transcription.

Despite the foregoing, experiments by Michael Chamberlin indicate that the RNA-terminator hairpin and U-rich 3' tail do not function independently of their upstream and downstream flanking regions. Indeed, terminators that lack a U-rich segment can be highly efficient when joined to the appropriate sequence

FIG. 26-10 An *E. coli* intrinsic terminator. Its transcription yields an RNA (red) with a self-complementary G + C–rich segment that forms a base-paired hairpin immediately followed by a sequence of 4 to 10 consecutive U’s that base-pair with the template A’s (black) in the transcription bubble. The oval symbol represents the binding site for an incoming NTP. [After a drawing by Joo-Soep Park and Jeffrey Roberts, Cornell University.]

immediately downstream from the termination site. Termination efficiency also varies with the concentrations of nucleoside triphosphates, with the level of supercoiling in the DNA template, with changes in the salt concentration, and with the sequence of the terminator. These results suggest that *termination is a complex multistep process*.

Termination Often Requires Rho Factor. Approximately half the termination sites in *E. coli* lack any obvious similarities to the intrinsic terminator described above and are unable to form strong hairpins. Instead, *they require the action of a protein known as Rho factor to terminate transcription*. Rho factor, a hexamer of identical 419-residue subunits, enhances the termination efficiency of spontaneously terminating transcripts and induces termination of nonspontaneously terminating transcripts.

Several key observations have led to a model of Rho-dependent termination:

1. Rho is a helicase that unwinds RNA–DNA and RNA–RNA double helices by translocating along a single strand of RNA in its 5' → 3' direction. This process is powered by the hydrolysis of NTPs to NDPs + P_i with little preference for the identity of the base.
2. Genetic manipulations indicate that Rho-dependent termination requires the presence of a specific recognition sequence on the newly transcribed RNA upstream of the termination site. The recognition sequence must be on the nascent RNA rather than the DNA as is demonstrated by Rho's inability to terminate transcription in the presence of pancreatic RNase A. The essential features of this termination site have not been fully elucidated; the construction of synthetic termination sites indicates that it consists of 80 to 100 nucleotides that lack a stable secondary structure and contain multiple regions, known as **rut sites** (for Rho *utilization*), that are rich in C and poor in G.

These observations suggest that Rho factor attaches to the RNA at its recognition sequence and then migrates along the RNA in the 5' → 3' direction until it encounters an RNAP paused at the termination site (without the pause, Rho might not be able to overtake the RNAP). There, as Jeffrey Roberts has shown, Rho pushes the RNAP forward in a way that partially rewinds its dsDNA helix at the transcription bubble while unwinding the RNA–DNA hybrid helix, thus releasing the RNA. This process appears to be facilitated by a Rho-induced conformational change in the RNAP thought to be similar to that induced by the G + C-rich hairpin in intrinsic terminators. Rho-terminated transcripts have 3' ends that typically vary over a range of ~50 nt. This suggests that Rho gradually pries the RNA away from its template DNA rather than liberating the RNA at a specific point.

Each Rho subunit consists of two domains: Its N-terminal domain binds single-stranded polynucleotides and its C-terminal domain, which is homologous to the α and β subunits of the F₁-ATPase (Section 18-3B), binds an NTP. The X-ray structure of Rho in complex with AMPPNP and an 8-nt RNA (Fig. 26-11a), determined by James Berger, reveals that Rho forms a hexameric lock washer-shaped helix that is 120 Å in diameter with an ~30-Å-diameter central hole and whose first and sixth subunits are separated by a 12-Å gap and a rise of 45 Å along the helix axis. The RNA binds along the interior of the protein helix to the so-called primary RNA binding sites on the N-terminal domains and to the so-called secondary RNA binding sites on the C-terminal domains. This structure represents an open state that is poised to bind mRNA that has entered its central cavity through the notch.

In the X-ray structure of Rho in complex with rU₁₂ and the ATP mimic ADP · BeF₃⁻ (Fig. 26-11b), the protein's six subunits have formed a closed ring in which each subunit has a different conformation. Protein loops that extend from the walls of the central channel to interact with the RNA are helically arranged like the steps of a right-handed spiral staircase such that they track the RNA's

(a)

FIG. 26-11 X-Ray structures of Rho factor. (a) Rho in complex with $r(\text{UC})_4$ (only one UC unit of which is visible) and AMPPNP. Each of the protein's six subunits is drawn in tube-and-arrow form in different colors with the upper right subunit colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The UC units and the AMPPNP are shown in space-filling form with UC C green, AMPPNP C gray, N blue, O red, and P orange. The hexamer has a lock washer-like shape with the blue subunit $\sim 45 \text{ \AA}$ closer to the viewer than the pink subunit. (b) Rho in complex with $r\text{U}_{12}$ (only 6 nt of which are visible) and $\text{ADP} \cdot \text{BeF}_3^-$.

(b)

BeF_3^- . The protein is drawn and colored as in Part a. The RNA, whose 5' end is closest to the viewer, and $\text{ADP} \cdot \text{BeF}_3^-$ are shown in stick and space-filling form, respectively, with RNA C green, ADP C gray, N blue, O red, P orange, Be light green, and F light blue. Note that each of the Rho subunits has a different conformation. [Based on X-ray structures by James Berger, University of California at Berkeley. PDBid 1PVO and 3ICE.]

? Compare the structure in Part b to that of the $\text{F}_1\text{-ATPase}$ shown in Fig. 18-22b and DnaB in Fig. 25-13.

CHECKPOINT

- Compare DNA and RNA polymerases with respect to structure, substrates, products, mechanism, error rate, and template specificity.
- Why is it hard to precisely define "gene"?
- What is the significance of the different DNA-binding properties of prokaryotic RNA polymerase core enzyme and holoenzyme?
- Why is it important for the transcription bubble to remain a constant size?
- Explain why a single gene can quickly give rise to many copies of its gene products (RNA or protein).
- Describe how transcription is terminated with and without Rho factor.

sugar-phosphate backbone, much as the central loops of DnaB (also a hexagonal helicase) track its centrally bound ssDNA (Fig. 25-14). The different conformations of Rho's six subunits indicate that they sequentially undergo a series of six NTP-driven conformational changes in which they bind successive intermediates in the hydrolysis of NTP, much like that observed in the structure of $\text{F}_1\text{-ATPase}$ (Section 18-3B). These conformational changes are allosterically coupled so that they progress around the hexamer in a wavelike manner, with the uppermost loop in the staircase, as viewed in Fig. 26-11b, jumping, in the $5' \rightarrow 3'$ direction, to the bottom of the staircase. Since each of these loops maintains its grip on the same nucleotide until it makes this jump, it appears that the hexamer pulls itself down, as viewed in Fig. 26-11b, by one nucleotide along the RNA for every NTP it hydrolyzes. Note that Rho's translocation mechanism differs from that employed by the lockwasher-shaped DnaB, in which entire subunits rather than only its DNA-contacting loops translocate along its bound ssDNA by two nucleotides for each NTP hydrolyzed (Section 25-2B).

2 Transcription in Eukaryotes

KEY CONCEPTS

- Eukaryotes use three RNA polymerases to carry out DNA-directed RNA synthesis.
- The three RNA polymerases recognize different and sometimes highly variable promoter sequences.
- A set of general transcription factors are required to initiate transcription in eukaryotes.

Although the fundamental principles of transcription are similar in prokaryotes and eukaryotes, *eukaryotic transcription is distinguished by having multiple RNAPs and by much more complicated control sequences.* Moreover, the eukaryotic

transcription machinery, as we will see, is far more complex than that of prokaryotes, requiring well over 100 polypeptides that form assemblies with molecular masses of several million daltons to recognize the control sequences and initiate transcription.

A Eukaryotes Have Several RNA Polymerases

Eukaryotic nuclei contain three distinct types of RNA polymerase that differ in the RNAs they synthesize:

1. **RNA polymerase I (RNAP I)**, which is located in the **nucleoli** (dark-staining nuclear bodies where ribosomes are assembled; Fig. 1-8), synthesizes the precursors of most rRNAs.
2. **RNA polymerase II (RNAP II)**, which occurs in the nucleoplasm, synthesizes the mRNA precursors.
3. **RNA polymerase III (RNAP III)**, which also occurs in the nucleoplasm, synthesizes the precursors of 5S rRNA, the tRNAs, and a variety of other small nuclear and cytosolic RNAs.

In addition to these nuclear enzymes, eukaryotic cells contain separate mitochondrial and (in plants) chloroplast RNAPs. The essential function of RNAPs in all cells makes them attractive targets for antibiotics and other drugs (Box 26-2).

Eukaryotic RNAPs, which have molecular masses of as much as 600 kD, have considerably greater subunit complexity than the prokaryotic enzymes. Each eukaryotic RNAP contains two nonidentical “large” (>120 kD) subunits, which are homologs of the prokaryotic β and β' subunits, and an array of up to 12 different “small” (<50 kD) subunits, two of which are homologs of the prokaryotic α subunit and one of which is a homolog of the ω subunit. Five of the small subunits, including the ω homolog, are identical in all three eukaryotic enzymes, and the α homologs are identical in RNAPs I and III. Moreover, the sequences of these subunits are highly conserved (~50% identical) across species from yeast to humans. In fact, in all ten cases tested, a human RNAP II subunit could replace its counterpart in yeast without loss of cell viability.

In a crystallographic tour de force, Roger Kornberg determined the X-ray structure of yeast RNAP II (Fig. 26-12). This enzyme, as expected, resembles

FIG. 26-12 X-Ray structure of yeast RNA polymerase II. (a) The enzyme is oriented similarly to the Tth RNAP in Fig. 26-2, and subunits that are homologous to those in Tth RNA polymerase are given the same colors as in Fig. 26-2. The position of an active site Mg^{2+} ion is marked by a red sphere, and eight Zn^{2+} ions are represented by orange

spheres. Two nonessential polymerase subunits and the C-terminus of the β' homolog are not visible in this structure. (b) View of the enzyme from the right of Part a, showing the DNA-binding cleft. The circle has the approximate diameter of B-DNA. [Based on an X-ray structure by Roger Kornberg, Stanford University. PDBid 1I50.]

rods connecting successive P atoms). The actinomycin's phenoxazone ring system intercalates between the DNA's base pairs, thereby unwinding the DNA helix by 23° and separating the neighboring base pairs by 7.0 \AA . Actinomycin's chemically identical cyclic **depsipeptides** (depsipeptides have both peptide bonds and ester linkages) extend in opposite directions from the intercalation site along the minor groove of the DNA. Other intercalation agents, including ethidium and proflavin (Section 24-3B), also inhibit nucleic acid synthesis, presumably by similar mechanisms.

The poisonous mushroom *Amanita phalloides* (death cap), which is responsible for the majority of fatal mushroom poisonings in Europe, contains several types of toxic substances, including a series of unusual bicyclic octapeptides known as **amatoxins**. **α -Amanitin**,

which is representative of the amatoxins, forms a tight 1:1 complex with RNAP II ($K = 10^{-8} \text{ M}$) and a looser one with RNAP III ($K = 10^{-6} \text{ M}$) so as to specifically block their elongation steps. The X-ray structure of RNAP II in complex with α -amanitin reveals that α -amanitin binds in the funnel beneath the protein's bridge helix (Fig. 26-13b) such that it interacts almost exclusively with the residues of the bridge helix and the adjacent part of Rpb1. The α -amanitin binding site is too far away from the enzyme active site to directly interfere with NTP entry or RNA synthesis, consistent with the observation that α -amanitin does not influence the affinity of RNAP II for NTPs. Most probably, α -amanitin binding impedes the conformational change of the bridge helix postulated to motivate the RNAP translocation step (Section 26-2A), which further supports this mechanism. RNAP I as well as mitochondrial, chloroplast, and prokaryotic RNA polymerases are insensitive to α -amanitin.

Despite the amatoxins' high toxicity (5–6 mg, contained in $\sim 40 \text{ g}$ of fresh mushrooms, is sufficient to kill a human adult), they act slowly. Death, usually from liver dysfunction, occurs no earlier than several days after mushroom ingestion (and after recovery from the effects of other mushroom toxins). This, in part, reflects the slow turnover rate of eukaryotic mRNAs and proteins.

[Structure of actinomycin D–DNA complex based on an NMR structure by Andrew Wang, University of Illinois. PDBid 1DSC.]

hydroxyl-rich protein segment are subject to reversible phosphorylation by **CTD kinases** and **CTD phosphatases**. RNAP II initiates transcription only when the CTD is unphosphorylated but commences elongation only after the CTD has been phosphorylated, which suggests that this process triggers the conversion of RNAP II's initiation complex to its elongation complex. Charge–charge repulsions between nearby phosphate groups probably cause a highly phosphorylated CTD to project as far as 500 \AA from the globular portion of the polymerase. As we will see, the phosphorylated CTD provides the binding sites for numerous protein factors that are essential for transcription.

The RNA Polymerase Structure Explains Its Function. To produce a snapshot of RNAP II in action, Kornberg incubated the enzyme with a dsDNA molecule bearing a $3'$ single-stranded tail (the template strand) together with all the NTP substrates except UTP. As a consequence, the polymerase synthesized a short

(14-nt) RNA strand before pausing at the first template A residue (when the crystals of this complex were soaked in UTP, transcription resumed, demonstrating that the complex was active). The X-ray structure and a cutaway diagram of this paused RNAP II are shown in **Fig. 26-13**.

In the RNAP–DNA–RNA complex, a massive (~50-kD) portion of the **Rpb2** subunit (the β homolog; cyan in Fig. 26-12), named the “clamp,” has swung downward over the DNA to trap it in the cleft, in large part accounting for the enzyme’s essentially infinite processivity.

The DNA unwinds by three nucleotides before entering the active site (which is contained on Rpb1). Past this point, however, a portion of Rpb2 dubbed the “wall” directs the template strand out of the cleft in an $\sim 90^\circ$ turn. As a consequence, the template base at the active ($i + 1$) site points toward the floor of the active site where it can be read out by the polymerase. This base is paired with the ribonucleotide at the 3' end of the RNA, which is positioned above a 12-Å-diameter pore at the end of a funnel (also called the secondary channel) to the protein exterior through which NTPs presumably gain access to the otherwise sealed-off active site.

The hybrid helix adopts a nonstandard conformation intermediate between those of A- and B-DNAs, which is underwound relative to that in the X-ray structure of an RNA–DNA hybrid helix alone (Fig. 24-4). Nearly all contacts that the protein makes with the RNA and DNA are to their sugar–phosphate backbones; none are with the edges of their bases. The specificity of the enzyme for a ribonucleotide rather than a deoxyribonucleotide appears due to the enzyme’s recognition of both the incoming ribose sugar and the RNA–DNA hybrid helix. After about one turn of hybrid helix, a loop extending from the clamp known as the

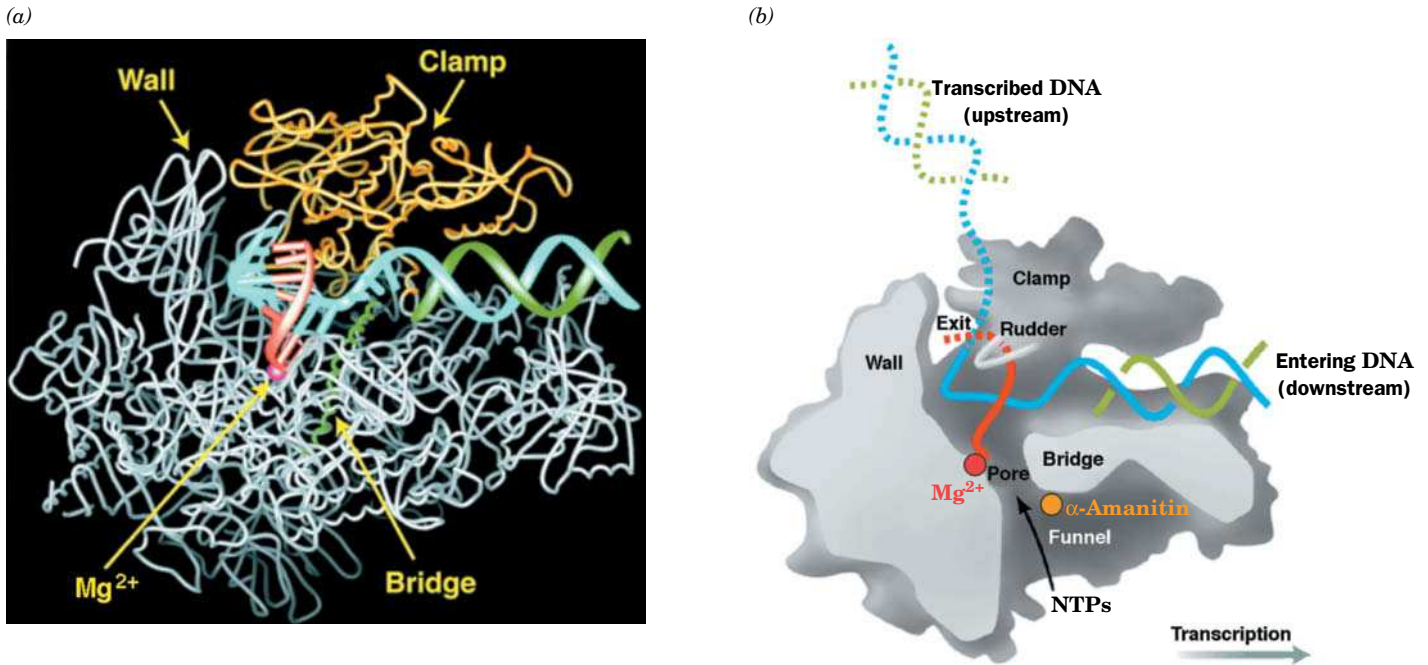

FIG. 26-13 The RNA polymerase II elongation complex. (a) X-Ray structure of the complex as viewed from the bottom of Fig. 26-12a (portions of Rpb2 that form the near side of the cleft have been removed to expose the bound RNA–DNA complex). The protein is represented by its backbone in which the clamp, which is closed over the downstream DNA duplex, is yellow, the bridge helix is green, and the remaining portions of the protein are gray. The template DNA strand (cyan), the nontemplate DNA strand (green), and the newly synthesized RNA (red) are drawn with their well-ordered portions in ladder form and their less ordered portions in backbone form. An active

site Mg^{2+} ion is represented by a red sphere. (b) Cutaway diagram of the transcribing complex in Part a in which the cut surfaces of the protein are light gray, its remaining surfaces are darker gray, and several of its functionally important structural features are labeled. The DNA, RNA, and active site Mg^{2+} ion are colored as in Part a with portions of the DNA and RNA that are not visible in the X-ray structure represented by dashed lines. α -Amanitin (orange ball) is discussed in Box 26-2. [Modified from diagrams by Roger Kornberg, Stanford University. PDBid 116H.]

“rudder” separates the RNA and template DNA strands, thereby permitting the DNA double helix to re-form as it exits the enzyme (although the unpaired 5' tail of the nontemplate strand and the 3' tail of the template strand are disordered in the X-ray structure).

How does RNAP translocate its bound DNA–RNA assembly at the end of each catalytic cycle? A highly conserved helical segment of Rpb1 called the “bridge” (because it bridges the two pincers forming the enzyme’s cleft) non-specifically contacts the template DNA base at the $i + 1$ position. The bridge is straight in the X-ray structures of RNAP II (Figs. 26-12a and 26-13a) but bent in the X-ray structure of the bacterial RNAPs (Fig. 26-2). If the bridge helix, in fact, alternates between its straight and bent conformations, it would move by 3 to 4 Å. Kornberg has therefore speculated that translocation occurs through the bending of the bridge helix so as to push the paired nucleotides at position $i + 1$ to position $i - 1$. The recovery of the bridge helix to its straight conformation would then yield an empty site at position $i + 1$ for entry of the next NTP, thereby preparing the enzyme for a new round of nucleotide addition. The reversal of this process is presumably prevented by the binding of the next substrate NTP, and hence this mechanism is that of a **Brownian ratchet** [in which otherwise random thermal (Brownian) back-and-forth fluctuations are converted (rectified) to coherent forward motion by inhibiting the backward motion].

RNAP II selects its substrate ribonucleotide through a two-stage process. The incoming NTP first binds to the so-called E (for entry) site (Fig. 26-14), which exhibits no selectivity for the identity of its base. The NTP then pivots to enter the A (for addition) site, which accepts only an NTP that forms a Watson–Crick base pair with the template base in the $i + 1$ position. This process is mediated by the RNAP’s so-called trigger loop, which swings in beneath the correctly base-paired NTP in the A site to form an extensive hydrogen-bonded network involving both the NTP and other portions of the RNAP, interactions that acutely discriminate against dNTPs.

RNAPs Can Correct Their Mistakes. RNAPs cannot read through a damaged template strand and consequently stall at the damage site. Moreover, if a deoxy-nucleotide or a mismatched ribonucleotide is mistakenly incorporated into RNA,

FIG. 26-14 The A and E sites and the trigger loop in RNA polymerase II. A cutaway view of the transcribing complex viewed as in Fig. 26-13. The template DNA is cyan, the nontemplate DNA green, newly transcribed RNA red, GTP in the A site orange, and ATP in the E site

blue. The trigger loop is magenta, the bridge helix is green, and the two Mg^{2+} ions at the active site are represented by magenta spheres. The RNAP II surface is gray. PDBid 2E2H.

the DNA–RNA hybrid helix becomes distorted, which also causes the RNAP to stall. How, then, do RNAPs avoid accumulating at damaged or mispaired sites, which, if it occurred on an essential gene, would be lethal?

RNAPs do not monotonically move forward along the template DNA. Instead, they frequently backtrack such that the RNA's penultimate nucleotide, which was in the $i - 1$ position, has re-entered the $i + 1$ position and the 3'-nucleotide, now in the $i + 2$ position, enters the secondary channel, where it binds in the so-called P (for *proofreading*) site. If the forward movement of the RNA is impeded by damage to the template or by mispairing, further backtracking becomes favored so that several more ribonucleotides enter the secondary channel. The backtracking of only one or a few nucleotides is reversible. Otherwise, transcription is arrested until the RNA is hydrolytically cleaved at the active site. In *E. coli*, this requires the assistance of the homologous proteins **GreA** and/or **GreB**, whereas with RNAP II, this function is carried out by the unrelated protein **TFIIS**. These proteins induce the RNAP active site to hydrolyze the phosphodiester bond between the ribonucleotides in the $i + 1$ and $i - 1$ positions (a reaction that is not the reverse of the polymerase reaction since this would be pyrophosphorolysis). In this way, RNAP can correct its mistakes and resume RNA synthesis. RNAP I and RNAP III also efficiently correct their mistakes.

B Each Polymerase Recognizes a Different Type of Promoter

In eukaryotes, RNAP does not include a removable σ factor. Instead, a number of accessory proteins identify promoters and recruit RNAP to the transcription start site (as described more fully in Section 26-2C). As expected, eukaryotic promoters are more complex and diverse than prokaryotic promoters. In addition, the three eukaryotic RNAPs recognize different types of promoters.

Mammalian RNA Polymerase I Has a Bipartite Promoter. Both prokaryotic and eukaryotic genomes contain multiple copies of their rRNA genes to meet the enormous demand for these rRNAs (which comprise, e.g., ~60% of a eukaryotic cell's RNA content). Since the numerous rRNA genes in a given eukaryotic cell have essentially identical sequences, its RNAP I recognizes only one promoter. Yet, in contrast to RNAP II and III promoters, RNAP I promoters are species specific; that is, an RNAP I recognizes only its own promoter and those of closely related species.

RNAP I promoters were identified by determining how the transcription rate of an rRNA gene is affected by a series of increasingly longer deletions approaching its transcription start site from either its upstream or its downstream side. Such studies have indicated, for example, that mammalian RNAP I requires a so-called **core promoter element**, which spans positions -31 to $+6$ and hence overlaps the transcribed region. However, efficient transcription also requires an **upstream promoter element**, which is located between residues -187 and -107 . These elements, which are G + C-rich and ~85% identical, are bound by specific transcription factors which then recruit RNAP I to the transcription start site.

RNA Polymerase II Promoters Are Complex and Diverse. The promoters recognized by RNAP II are considerably longer and more diverse than those of prokaryotic genes. The structural genes expressed in all tissues (the housekeeping genes, which are thought to be constitutively transcribed) have GC-rich stretches of DNA located upstream from their transcription start sites. *These CpG islands (Box 25-4) function analogously to prokaryotic promoters.* On the other hand, structural genes that are selectively expressed in one or a few cell types often lack these GC-rich sequences. Instead, *they contain a core promoter of 40 to 50 nt*

that includes the transcription start site. Within the core promoter for a given gene are one or more conserved elements that act—for the most part in a cooperative fashion—to direct transcription initiation.

Among the best-known core promoter elements is the **TATA box**, an AT-rich sequence located 25 to 31 bp upstream from the transcription start site. The TATA box (consensus sequence $TATA_{T}^{A}A_{T}^{A}$) resembles the -10 region of a prokaryotic promoter (TATAAT), although it differs in its location relative to the transcription start site (-27 versus -10). Around two-thirds of protein-encoding genes lack a TATA box, but approximately half have a conserved 7-nt **Inr (initiator) element** that includes the initiating ($+1$) nucleotide. The consensus sequences and relative positions of several core promoter elements are shown in **Fig. 26-15**. Most of these elements have been identified from their conservation in many genes from different eukaryotic species, and their participation in RNAP II-directed transcription has been verified experimentally by mutating their sequences and/or positions and by introducing them into genes whose original core promoter elements had been deleted. None of the core promoter elements occurs in all promoters, although some general patterns are apparent; for example, core promoters that lack a TATA box use **MTE** or **DPE**, and vice versa. All of the core promoter elements, either singly or as sets, interact with their corresponding protein factors that in turn recruit RNAP II to the initiation site (Section 26-2C).

The gene region extending between about -50 and -110 also contains promoter elements. For instance, many eukaryotic structural genes have a conserved consensus sequence of CCAAT (the **CCAAT box**) located between about -70 and -90 whose alteration greatly reduces the gene's transcription rate. Evidently, *the sequences upstream of the core promoter constitute additional DNA-binding sites for proteins involved in transcription initiation.*

Enhancers Are Transcriptional Activators That Can Have Variable Positions and Orientations. *Perhaps the most surprising aspect of eukaryotic transcriptional control elements is that some of them need not have fixed positions and orientations relative to their corresponding transcribed sequences.* For example, the genome of **simian virus 40 (SV40)**, in which such elements were first discovered, contains two repeated sequences of 72 bp each that are located upstream from the promoter for early gene expression. Transcription is unaffected if one of the repeats is deleted but is nearly eliminated when both are absent. The analysis of a series of SV40 mutants containing only one of the repeats demonstrated that its ability to stimulate transcription from its corresponding promoter is all but independent of its position and orientation. Indeed, transcription is unimpaired when this segment is several thousand base pairs upstream or downstream from the transcription start site. Gene segments with such properties are named **enhancers** to indicate that they differ from promoters, which are site-specific and strand-specific regarding transcription initiation.

FIG. 26-15 Some core promoter sequences for RNA polymerase II. The consensus sequence of each element is given (some positions can accommodate two or more nucleotides; N represents any nucleotide). The approximate positions of the various motifs are given relative to the transcription initiation ($+1$) site. Note that a specific core promoter may contain all, some, or none of these motifs. The **BRE (TFIIIB recognition**

element) is an upstream extension of the TATA box. The **DPE (downstream core promoter element)** and the **MTE (motif ten element)** must be accompanied by an Inr.

? Compare these sequences to the *E. coli* promoter in Fig. 26-6.

Enhancers occur in cellular genes as well as eukaryotic viruses and are required for the full activities of their cognate promoters. Rather than interacting with RNAP II directly, *enhancers are recognized by specific transcription factors that stimulate RNAP II to bind to the corresponding but distant promoter*. This requires that the DNA between the enhancer and promoter loop around so that the transcription factor can simultaneously contact the enhancer and RNAP II at the promoter. Most cellular enhancers are associated with genes that are selectively expressed in specific tissues. It therefore seems, as we discuss in Section 28-3B, that *enhancers mediate much of the selective gene expression in eukaryotes*.

RNA Polymerase III Promoters Can Be Located Downstream from Their Transcription Start Sites. *The promoters of some genes transcribed by RNAP III are located entirely within the genes' transcribed regions.* In a gene for the 5S RNA of *Xenopus borealis*, deletions of base sequences that start from outside one or the other end of the transcribed portion of the gene prevent transcription only if they extend into the segment between nucleotides +40 and +80. This portion of the gene is effective as a promoter because it contains the binding site for a transcription factor that stimulates upstream binding of RNAP III. Further studies have shown, however, that the promoters of other RNAP III-transcribed genes lie entirely upstream of their start sites. These upstream sites also bind transcription factors that recruit RNAP III.

C Transcription Factors Are Required to Initiate Transcription

Differentiated eukaryotic cells possess a remarkable capacity for the selective expression of specific genes. The synthesis rates of a particular protein in two cells of the same organism may differ by as much as a factor of 10^9 . Thus, for example, reticulocytes (immature red blood cells) synthesize large amounts of hemoglobin but no detectable insulin, whereas the pancreatic β cells produce large quantities of insulin but no hemoglobin. In contrast, prokaryotic systems generally exhibit no more than a thousandfold range in their transcription rates so that at least a few copies of all the proteins they encode are present in any cell. Nevertheless, *the basic mechanism for initiating transcription of structural genes is the same in eukaryotes and prokaryotes: Protein factors bind selectively to the promoter regions of DNA.* With class II promoters (those transcribed by RNAP II), a complex of at least six **general transcription factors (GTFs; Table 26-3)** operates as a formal equivalent of a prokaryotic σ factor. The structures of several eukaryotic transcription factors are described in Section 24-4C.

TABLE 26-3 Properties and Functions of the Eukaryotic General Transcription Factors

Factor	Number of Unique Subunits in Yeast	Mass in Yeast (kD)	Number of Unique Subunits in Humans	Mass in Humans (kD)	Functions
TFIIA	2	46	3	69	Stabilizes TBP and TAF binding
TFIIB	1	38	1	35	Stabilizes TBP binding; recruits RNAP II; influences start site selection
TFIID TBP	1	27	1	38	Recognizes TATA box; recruits TFIIA and TFIIB; has positive and negative regulatory functions
TAFs	14	824	14	1084	
TFIIE	2	184	2	165	An $\alpha_2\beta_2$ heterotetramer; recruits TFIIF and stimulates its helicase activity; enhances promoter melting
TFIIF	3	156	2	87	Facilitates promoter targeting; stimulates elongation
TFIIH	11	525	10	490	Contains Ssl2, an ATP-dependent helicase that functions in promoter melting and clearance, and a CTD kinase

The six GTFs, which are highly conserved from yeast to humans, are required for the synthesis of all mRNAs, even those with strong promoters. The GTFs allow a low (basal) level of transcription that can be augmented by the participation of other gene-specific factors. We will examine the actions of some of those other proteins in Section 28-3. The GTFs, whose names begin with TF (for *transcription factor*) followed by the Roman numeral II to indicate that they are involved in transcription by RNAP II, combine with RNAP II and promoter DNA in an ordered sequence to form a **preinitiation complex (PIC)**.

PIC Formation Often Begins with TATA-Binding Protein Binding to the TATA Box. As indicated in Section 26-2B, the promoters of many eukaryotic structural genes contain a TATA box at around position -27 . The GTFs are targeted to this and other sequences that make up the core promoter. The first transcription factor to bind to TATA box-containing promoters is the **TATA-binding protein (TBP)**, which as its name indicates, binds to the TATA box and thereby helps identify the transcription start site. TBP is subsequently joined on the promoter by additional subunits to form, in humans, the ~ 1122 -kD, 15-subunit complex **TFIID**.

The highly conserved C-terminal domain of TBP contains two $\sim 40\%$ identical direct repeats of 66 residues separated by a highly basic segment. Its X-ray structure, which was independently determined by Roger Kornberg and Stephen Burley, reveals a saddle-shaped protein that consists of two structurally similar domains arranged with pseudo-twofold symmetry (**Fig. 26-16a**). TBP's structure suggests that it could fit snugly astride an undistorted B-DNA helix. However, the X-ray structures of TBP–DNA complexes, independently determined by Burley and Paul Sigler, reveal a quite different interaction. The DNA indeed binds to the concave surface of TBP but with its duplex axis nearly perpendicular rather than parallel to the saddle's cylindrical axis (**Fig. 26-16b**). The bound DNA is kinked by $\sim 45^\circ$ between the first two base pairs of the 7-bp TATA box and between its last base pair and the succeeding base pair, thereby assuming a crank-like shape. The TBP, which undergoes little conformational change on binding

FIG. 26-16 X-Ray structures of TATA-binding protein (TBP). (a) A ribbon diagram of yeast TBP in the absence of DNA, in which α helices are red, β strands are yellow, and the remainder of the polypeptide backbone is cyan. The protein's pseudo-twofold axis of symmetry is vertical. [Based on an X-ray structure by Roger Kornberg, Stanford University. PDBid 1TBP.] (b) The structure of human TBP in complex with a 16-bp TATA box-containing duplex DNA. The DNA, which is largely in the B form, is drawn in stick form and colored according to atom type with sense strand C green, antisense strand C cyan, N blue, O red, and P orange. It enters its binding site with the 5' end of the sense strand on the right and exits on the left with its helix axis nearly perpendicular to the page. The protein is drawn in worm form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The side chains of Phe residues 193, 210, 284, and 301, which induce sharp kinks in the DNA, are drawn in stick form (*magenta*). Between the kinks, which are located at each end of the TATA box, the DNA is partially unwound with the central eight strands of the protein's ten-stranded β sheet inserted into the DNA's greatly widened minor groove. The TBP does not contact the DNA's major groove. [Based on an X-ray structure by Stephen Burley, Structural Genomix, Inc., San Diego, California. PDBid 1CDW.]

DNA, does so via hydrogen bonding and van der Waals interactions. The kinked and partially unwound DNA is stabilized by a wedge of two Phe side chains on each side of the saddle structure that pry apart the two base pairs flanking each kink from their minor groove sides. The bent conformation of DNA creates a stage for the assembly of other proteins to form the PIC.

The remaining components of TFIID are known as **TBP-associated factors (TAFs)**. Portions of 9 of the 14 TAFs, which are highly conserved from yeast to humans, are homologous to nonlinker histones (Section 24-5A). Indeed, X-ray and other studies suggest that four of the TAFs associate to form a nucleosome-like heterooctamer. Nevertheless, it is unlikely that the DNA wraps around the TAFs as it does in a nucleosome (Section 24-5A) because many of the histone residues that make critical contacts with the DNA in the nucleosome have not been conserved in the histone-like TAFs.

TFIIA, TFIIB, and TAFs Interact with TBP and RNAP II. The other GTFs required for basal transcription assemble as is diagrammed in Fig. 26-17. The PIC requires,

PROCESS DIAGRAM

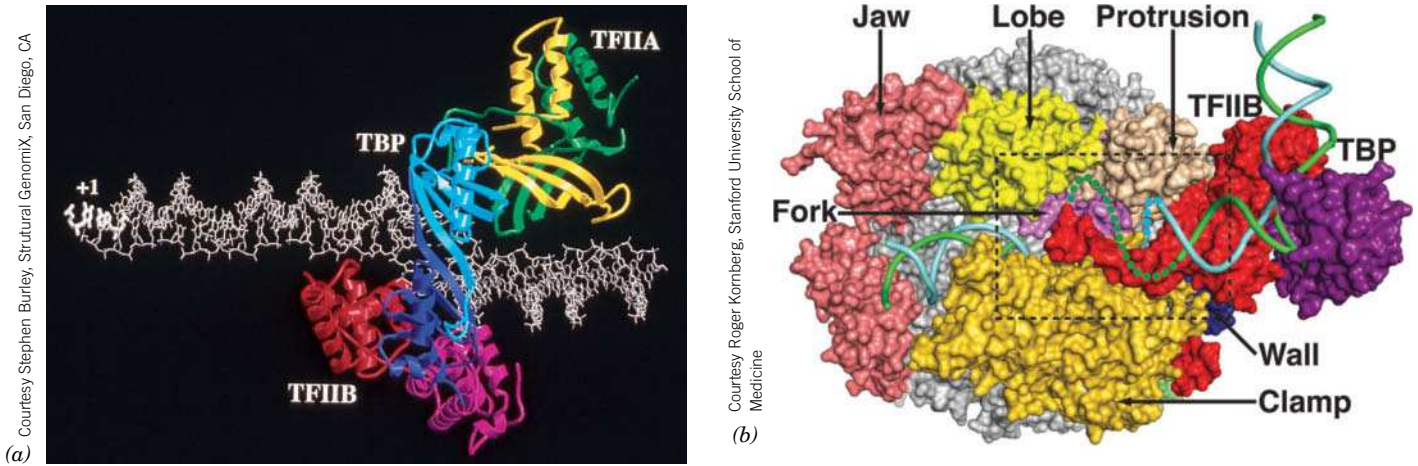

FIG. 26-18 Structural models for the interactions of TFIIIB.

(a) Model of the TFIIA-TBP-TFIIIC-promoter complex based on the independently determined X-ray crystal structures of the TFIIA-TBP-promoter and TFIIIC-TBP-promoter complexes. The DNA (*white sticks*) has been extended in both directions beyond the TATA box. The pseudosymmetrical TBP (*cyan and purple*), viewed from above, induces two sharp kinks in the DNA, giving it a cranklike shape. Both TFIIA (*yellow and green*) and TFIIIC (*magenta and red*) interact with TBP, but each interacts with independent sites on the DNA. The transcription start site (+1) is at the left. Based on PDBids 1YTF and 1VOL. (b) Model of the TFIIIB-TBP-RNAP II-promoter open complex

based on the X-ray structures of the TFIIIB_N-RNAP II and TFIIIB_C-TBP-promoter complexes. The view of the RNAP II is approximately from the top of Fig. 26-13 after it has been rotated 90° about the horizontal axis. The proteins are represented by their solvent-accessible surfaces with TFIIIB red, TBP purple, and the various portions of RNAP II in other colors. The DNA is drawn in cartoon form with its template and nontemplate strands cyan and green and with the dotted segments representing its transcription bubble. Its upstream end is at the upper right. Note how the leftmost portion of TFIIIB, its B finger, extends into the active center of RNAP II to contact the DNA. Based on PDBids 3K7A, 1R5u, and 1VOL.

at a minimum, TBP, **TFIIIB**, **TFIIE**, **TFIIF**, and **TFIIH**. TFIIIB consists of two domains, an N-terminal domain (**TFIIIB_N**), which interacts with RNAP II, and a C-terminal domain (**TFIIIB_C**), which binds DNA and interacts with TBP. The X-ray structures of TFIIA-TBP-DNA and TFIIIC-TBP-DNA complexes have permitted the generation of a plausible model for the TFIIA-TFIIIC-TBP-DNA complex (**Fig. 26-18a**). The three proteins bind to the DNA just upstream from the transcription start site, leaving ample room for additional proteins and RNAP II to bind. Since the pseudosymmetric TBP has been shown to bind to the TATA box in either orientation, it appears that base-specific interactions between TFIIIB and the promoter function to position TFIIIB to properly orient the TBP on the promoter.

In the final steps of PIC formation (**Fig. 26-17**), TFIIF recruits RNAP II to the promoter in a manner reminiscent of the way that σ factor interacts with bacterial RNAP. In fact, the second largest of TFIIF's three subunits is homologous to σ^{70} , the predominant *E. coli* σ factor, and, moreover, can specifically interact with bacterial RNAPs (although it does not participate in promoter recognition). Finally, TFIIE and TFIIH join the assembly. Once this complex has been assembled, **Ssl2**, the ATP-dependent helicase subunit of TFIIH, induces the formation of the open complex so that RNA synthesis can commence (see below). Note that the human PIC, exclusive of the ~14-subunit RNAP II, contains 33 subunits (**Table 26-3**), which makes the PIC larger than a ribosome (**Section 28-3A**). Many of the proteins in the PIC are targets of transcriptional regulators.

The X-ray structure of the TFIIIB_N-RNAP II complex, determined by Kornberg, reveals that TFIIIB_N contacts the “dock” domain of RNAP II near its RNA exit channel and that TFIIIB_N inserts its “finger” domain into the active center of RNAP II. A model of the TFIIIB-TBP-RNAP II-DNA complex based on this X-ray structure together with that of the TFIIIC-TBP-DNA complex is shown in **Fig. 26-18b**.

The cryo-EM structure of the yeast PIC in its closed state (**Fig. 26-19**), also determined by Kornberg, reveals that the PIC consists of two well-separated lobes, one containing the GTFs and the other containing RNAP II. Unexpectedly, the promoter DNA is associated only with the GTFs; it does not contact the

defective for TATA box binding can still support *in vitro* transcriptional initiation by both RNAP I and RNAP III. Clearly, TBP, the only known universal transcription factor, is an unusually versatile protein.

Elongation Requires Different Transcription Factors. After RNAP II initiates RNA synthesis and successfully produces a short transcript, the transcription machinery undergoes a transition to the elongation mode. The switch appears to involve displacement of the finger domain of TFIIB, which would otherwise clash with the growing RNA chain in the active site, as well as phosphorylation of the C-terminal domain (CTD) of RNAP II's Rpb1 subunit. Phosphorylated RNAP II releases some of the transcription-initiating factors and advances beyond the promoter region. In fact, when RNAP II moves away from (“clears”) the promoter, it leaves behind some GTFs, including TFIID. These proteins can reinitiate transcription by recruiting another RNAP II to the promoter. Consequently, *the first RNAP to transcribe a gene may act as a “pioneer” polymerase that helps pave the way for additional rounds of transcription.*

During elongation, a six-protein complex called **Elongator** binds to the phosphorylated CTD of Rpb1, taking the place of the jettisoned transcription factors. Although Elongator is not essential for transcription by RNAP II *in vitro*, its presence accelerates transcription. Interestingly, TFIIF and TFIIH remain associated with the polymerase during elongation. Well over a dozen other proteins are known to associate with an elongating RNAP II. Some of the proteins are involved in processing the nascent RNA, modifying the packaging of the DNA template, and terminating transcription.

Eukaryotes Lack Precise Transcription Termination Sites. The sequences signaling transcriptional termination in eukaryotes have not been identified. This is largely because the termination process is imprecise; that is, the primary transcripts of a given structural gene have heterogeneous 3' sequences. *However, a precise termination site is not required because the transcript undergoes processing that includes endonucleolytic cleavage at a specific site* (see below). The endonuclease may act even while the polymerase is still transcribing, so RNA cleavage itself may signal the polymerase to stop.

CHECKPOINT

- What are the functions of the three eukaryotic RNA polymerases?
- Explain the functions of RNAP II's CTD, clamp, wall, funnel, rudder, bridge, and trigger.
- What are the advantages of having multiple types of promoters and enhancers?
- Summarize the role of TBP in transcription initiation in eukaryotes.
- Explain why both the sequence and structure of DNA help recruit RNA polymerase.
- Describe the assembly of the RNAP II preinitiation complex.
- Why is TBP considered to be a universal transcription factor?

3 Posttranscriptional Processing

KEY CONCEPTS

- Eukaryotic mRNAs are modified by a 5' cap and a 3' poly(A) tail.
- Eukaryotic genes include introns that must be spliced out by the action of snRNPs in the spliceosome.
- A single gene can generate several protein products through alternative mRNA splicing.
- Prokaryotic and eukaryotic rRNA and tRNA precursors are variously processed by endonucleolytic cleavage, covalent modification, splicing, and nucleotide addition.

The immediate products of transcription, the **primary transcripts**, are not necessarily functional. In order to acquire biological activity, many of them must be specifically altered: (1) by the exo- and endonucleolytic removal of polynucleotide segments; (2) by appending nucleotide sequences to their 3' and 5' ends; and/or (3) by the modification of specific nucleotide residues. The three major classes of RNA—mRNA, rRNA, and tRNA—are altered in different ways in prokaryotes and in eukaryotes. In this section, we outline these **posttranscriptional modification** processes.

A Messenger RNAs Undergo 5' Capping and Addition of a 3' Tail

In prokaryotes, most primary mRNA transcripts are translated without further modification. Indeed, protein synthesis usually begins before transcription is complete (Section 27-4). In eukaryotes, however, mRNAs are synthesized in the cell nucleus, whereas translation occurs in the cytosol. Eukaryotic mRNA transcripts can therefore undergo extensive posttranscriptional processing while still in the nucleus.

Eukaryotic mRNAs Have 5' Caps. Eukaryotic mRNAs have a **cap** structure consisting of a **7-methylguanosine (m^7G)** residue joined to the transcript's initial ($5'$) nucleotide via an unusual $5'-5'$ triphosphate bridge (Fig. 26-20). The cap, which is added to the growing transcript when it is ~ 30 nt long, identifies the eukaryotic translation start site (Section 27-4A). Capping involves several enzymatic reactions: (1) the removal of the leading phosphate group from the mRNA's $5'$ terminal triphosphate group by an **RNA triphosphatase**; (2) the guanylylation of the mRNA by **capping enzyme** (also called **guanylyltransferase**), which requires GTP and yields the $5'-5'$ triphosphate bridge and PP_i ; and (3) the methylation of guanine by **guanine-7-methyltransferase**, in which the methyl group is supplied by *S*-adenosylmethionine (SAM). In addition, the cap may be O^2' -methylated at the first and second nucleotides of the transcript by a SAM-requiring **2'-*O*-methyltransferase**. Capping enzyme binds to RNAP II's phosphorylated CTD (Section 26-2A), which ensures that only mRNAs are capped. The $5'$ cap is then bound by **cap-binding complex (CBC)**, which also associates with the phosphorylated CTD. Capping, which marks the completion of RNAP II's switch from transcription initiation to elongation, renders mRNAs resistant to $5'$ -exonucleolytic degradation.

FIG. 26-20 Structure of the 5' cap of eukaryotic mRNAs. A cap may be O^2' -methylated at the transcript's leading nucleoside (the predominant cap in multicellular organisms), at its first two nucleosides, or at neither of those positions (the predominant cap in unicellular eukaryotes). If the first nucleoside is adenosine (it is usually a purine), it may also be N^6 -methylated.

? Describe the actions of the enzymes required to make each of the modifications shown.

Eukaryotic mRNAs Have Poly(A) Tails. Eukaryotic RNA transcripts have heterogeneous $3'$ sequences because the transcription termination process is imprecise. Mature eukaryotic mRNAs, however, have well-defined $3'$ ends terminating in **poly(A) tails** of ~ 250 nt (~ 80 nt in yeast). The poly(A) tails are enzymatically appended to the primary transcripts in two reactions:

1. A transcript is cleaved 10 to 20 nt downstream from a highly conserved AAUAAA sequence and less than 50 nt before a less-conserved U-rich or G + U-rich sequence. The precision of this cleavage reaction has apparently eliminated the need for accurate transcription termination. Nevertheless, the identity of the endonuclease that cleaves the RNA is uncertain although **cleavage factors I and II (CFI and CFII)** are required for this process.
2. The poly(A) tail is subsequently generated from ATP through the stepwise action of **poly(A) polymerase (PAP)**, a template-independent RNA polymerase that elongates an mRNA primer with a free $3'$ -OH group. PAP is activated by **cleavage and polyadenylation specificity factor (CPSF)** when the latter protein recognizes the AAUAAA sequence. Once the poly(A) tail has grown to ~ 10 residues, the AAUAAA sequence is no longer required for further chain elongation. This suggests that CPSF becomes disengaged from its recognition site in a manner reminiscent of the way σ factor is released from the transcription initiation site once the elongation of prokaryotic RNA is under-way.

CPSF binds to the phosphorylated RNAP II CTD; deleting the CTD inhibits polyadenylation. Evidently, the CTD couples polyadenylation to transcription, that is, polyadenylation occurs cotranscriptionally.

PAP is part of a 500- to 1000-kD complex that also contains the proteins required for mRNA cleavage. Consequently, the cleaved transcript is polyadenylated before it can dissociate and be digested by cellular nucleases (see below). The maximum length of the poly(A) tail may be determined by the stoichiometric binding of multiple copies of **poly(A) binding protein II (PAB II)**.

In vitro studies indicate that a poly(A) tail is not required for mRNA translation. Rather, the observation that an mRNA's poly(A) tail shortens as it ages in the cytosol suggests that poly(A) tails have a protective role. In fact, the only mature mRNAs that lack poly(A) tails, those encoding histones (which are required in large quantities only during the relatively short period during the cell cycle when DNA is being replicated), have cytosolic lifetimes of <30 min versus hours or days for most other mRNAs. The poly(A) tails are specifically complexed in the cytosol by **poly(A)-binding protein (PABP)**; not related to PAB II), which organizes poly(A)-bearing mRNA's into ribonucleoprotein particles. PABP is thought to protect mRNA from degradation as is suggested, for example, by the observation that the addition of PABP to a cell-free system containing mRNA and mRNA-degrading nucleases greatly reduces the rate at which the mRNAs are degraded and the rate at which their poly(A) tails are shortened. However, as we will see (Section 28-3C), the degradation of mRNAs is regulated by multiple signals, not just the lengths of their poly(A) tails.

The cleavage of a transcript past its AAUAAA sequence does not, in itself, terminate transcription. However, in yeast, the protein **Rtt103**, which binds to the phosphorylated CTD of RNAP II, recognizes the AAUAAA sequence and recruits the 5' → 3' exonuclease known as **Rat1 (Xrn2 in humans)**. Then, in what is termed the **torpedo model**, the highly processive Rat1/Xrn2 loads onto the newly liberated and uncapped 5' end of the still nascent RNA and rapidly degrades it until it intercepts the RNAP and induces it to terminate RNA synthesis. It has been hypothesized that this occurs in much the same way as Rho factor terminates bacterial transcription (Section 26-1D). This frees the RNAP to initiate a new round of transcription.

B Splicing Removes Introns from Eukaryotic Genes

The most striking difference between eukaryotic and prokaryotic structural genes is that *the coding sequences of most eukaryotic genes are interspersed with unexpressed regions*. The primary transcripts, also called **pre-mRNAs** or **heterogeneous nuclear RNAs (hnRNAs)**, are variable in length and are much larger (~2000 to >20,000 nt) than expected from the known sizes of eukaryotic proteins. Rapid labeling experiments demonstrated that little of the hnRNA is ever transported to the cytosol; most of it is quickly degraded in the nucleus. Yet the hnRNA's 5' caps and 3' tails eventually appear in cytosolic mRNAs. The straightforward explanation of these observations, that pre-mRNAs are processed by the excision of internal sequences, seemed so bizarre that it came as a great surprise in 1977 when Phillip Sharp and Richard Roberts independently demonstrated that this is actually the case (Box 26-3). Thus, *pre-mRNAs are processed by the excision of nonexpressed intervening sequences (introns), following which the flanking expressed sequences (exons) are spliced (joined) together*.

A pre-mRNA typically contains eight introns whose aggregate length averages 4 to 10 times that of its exons. This situation is graphically illustrated in **Fig. 26-21**,

FIG. 26-21 The chicken ovalbumin gene and its mRNA. The electron micrograph and its interpretive drawing show the hybridization of the antisense (template) strand of the chicken ovalbumin gene and its corresponding mRNA. The complementary segments of the DNA

(blue line in drawing) and mRNA (green dashed line) have annealed to reveal the exon positions (L, 1–7). The looped-out segments (I–VII), which have no complementary sequences in the mRNA, are the introns.

**Richard J. Roberts (1943–)****Phillip A. Sharp (1944–)**

For several decades following the discovery that DNA is the genetic material in all organisms, it was believed that genes were continuous sequences of nucleic acid. A messenger RNA molecule was thought to be a faithful copy of the gene, aligning exactly with the DNA sequence. In fact, this is largely true for simple genetic systems such as bacteria and bacteriophages, which were widely used in early studies of molecular biology. However, Richard Roberts and Phillip Sharp, working independently, showed in 1977 that genes could be discontinuous. We now understand that the mRNA segments corresponding to these “split genes” must be spliced together in order for the gene to be properly expressed.

Richard Roberts began his scientific career as an organic chemist. While working on his thesis, he read a book by John Kendrew (who had determined the X-ray structure of myoglobin;

Section 7-1A) and became hooked on the new field of molecular biology. His first project in the world of nucleic acids was to determine the sequence of nucleotides in a tRNA molecule. He was able to take advantage of new sequencing techniques devised by Frederick Sanger (who subsequently developed the dideoxy sequencing method; Section 3-4C). Roberts next turned his attention to restriction endonucleases. He recognized that the enzymes could be invaluable tools for cutting large DNA molecules down to size, including the adenovirus-2 genome that he began to characterize.

During roughly the same period, Phillip Sharp completed a thesis describing his use of statistical and physical theories to describe the DNA polymer. By his own admission, he was not a skilled experimenter. His outlook changed, however, when he joined a molecular biology laboratory that made extensive use of electron microscopy to examine DNA–RNA heteroduplexes. When Sharp subsequently turned to the study of eukaryotic gene expression, the only practical experimental systems were animal viruses with DNA genomes, such as adenovirus-2.

Because that virus, which is a cause of the common cold, infects mammalian cells, its genes were thought to resemble those of its host.

Thus, in the mid-1970s, both Roberts (at the Cold Spring Harbor Laboratory on Long Island, New York) and Sharp (at the Massachusetts Institute of Technology) came to be mapping the adenovirus genome. They located viral genes by obtaining expressed mRNA molecules and hybridizing them to segments of the viral DNA. Sharp observed that the nuclei of virus-infected cells accumulated viral mRNAs that were not transported to the cytoplasm, and he speculated that the nuclear mRNAs were processed in order to generate the cytoplasmic mRNAs. Meanwhile, Roberts observed that “late” (mature) mRNAs began with an oligonucleotide that was not encoded in the DNA next to the main body of the mRNA.

Both scientists prepared samples in which the mRNA was allowed to hybridize with the DNA, and then visualized the hybrid by electron microscopy. The results were as exciting as they were unexpected: A single mRNA molecule hybridized with as many as four well-separated segments of the DNA molecule, so that the unpaired DNA sequences between the hybrid segments looped out (as in Fig. 26-21). The inescapable conclusion was that viral genetic information was organized discontinuously, a notion that contradicted commonly held views about the nature of genes. Nevertheless, other researchers were eager to see whether split genes occurred in other viruses and animal cells. Within a year, similar results were confirmed for a handful of other genes. Subsequent research showed that most animal genes are discontinuous. The sequences that are ultimately expressed were termed exons, and the intervening sequences that did not appear in the mature mRNA were named introns. For their discoveries of split genes, Roberts and Sharp shared the 1993 Nobel Prize in Physiology or Medicine.

The existence of split genes solved some biochemical puzzles but, as is always the case with important discoveries, introduced new ones: How are introns cut out and the remaining exons joined together? Are the same exons spliced together in all cells? Could evolution occur more rapidly through exon shuffling? Answers to these questions are still being refined.

Chow, L.T., Gelinias, R.E., Broker, T.R., and Roberts, R.J., An amazing sequence arrangement at the 5' ends of adenovirus 2 messenger RNA, *Cell* **12**, 1–8 (1977).
Berget, S.M., Moore, C., and Sharp, P.A., Spliced segments at the 5' terminus of adenovirus 2 late mRNA, *Proc. Natl. Acad. Sci.* **74**, 3171–3175 (1977).

which is an electron micrograph of chicken **ovalbumin** mRNA hybridized to the antisense (template) strand of the ovalbumin gene (ovalbumin is the major protein component of egg white). In humans, the number of introns in a gene varies from none to 364 (in the ~2400-kb gene encoding the 35,213-residue muscle protein **titin**, the largest known gene and single-chain protein; Section 7-2A) with an average number of ~8. Intron lengths range from ~65 to ~800,000 nt (in the gene encoding the muscle protein **dystrophin**; Section 7-2A) with an average length of ~1800 nt. Exons, in contrast, have lengths that average 123 nt and range up to 17,106 nt (in the gene encoding titin). The introns from corresponding genes in two vertebrate species rarely vary in number and position, but often differ extensively in length and sequence so as to bear little resemblance to one another.

The production of a translation-competent eukaryotic mRNA begins with the transcription of the entire gene, including its introns (Fig. 26-22). Capping occurs soon after initiation, and splicing commences during the elongation phase of transcription. The mature mRNA emerges only after splicing is complete and the RNA has been polyadenylated. The mRNA is then transported to the cytosol, where the ribosomes are located, for translation into protein.

FIG. 26-22 The sequence of steps in the production of mature eukaryotic mRNA. This example shows the chicken ovalbumin gene. Following transcription, the primary transcript is capped and polyadenylated. The introns are excised and the exons spliced together to form the mature mRNA. Note that capping and splicing may occur cotranscriptionally, so that introns nearer the capped 5' end may be excised before transcription of the 3' end is complete.

Exons Are Spliced in a Two-Stage Reaction. Sequence comparisons of exon–intron junctions from a diverse group of eukaryotes indicate that they have a high degree of homology (Fig. 26-23), with most of them having an invariant GU at the intron’s 5’ boundary and an invariant AG at its 3’ boundary. Although these highly conserved sequences are necessary to define splice junctions, they provide insufficient information to reliably do so. We shall see below that numerous other signals participate in splice site definition.

The splicing reaction occurs via two transesterification reactions (Fig. 26-24):

1. A 2',5'-phosphodiester bond forms between an intron adenosine residue and the intron’s 5'-terminal phosphate group. The 5' exon is thereby released and the intron assumes a novel **lariat structure** (so called because of its shape). The adenosine at the lariat branch point, which forms three phosphodiester bonds, is typically located in a conserved sequence 20 to 50 residues upstream of the 3' splice site. Mutations that change this branch point A residue abolish splicing at that site.
2. The 5' exon’s free 3'-OH group displaces the 3' end of the intron, forming a phosphodiester bond with the 5'-terminal phosphate of the 3' exon and yielding the spliced product. The intron is thereby eliminated in its lariat form with a free 3'-OH group. Mutations that alter the conserved AG at the 3' splice junction block this second step, although they do not interfere with lariat formation. The lariat is eventually debranched (linearized) and, *in vivo*, is rapidly degraded.

FIG. 26-23 The consensus sequences at the exon–intron junctions of eukaryotic pre-mRNAs. The subscripts indicate the percentage of pre-mRNAs in which the specified base(s) occurs. Note that the 3' splice site is preceded by a tract of 11 predominantly pyrimidine nucleotides. [Based on data from Padgett, R.A., Grabowski, P.J., Konarska, M.M., Seiler, S.S., and Sharp, P.A., *Annu. Rev. Biochem.* **55**, 1123 (1986).]

FIG. 26-24 The splicing reaction. Two transesterification reactions splice together the exons of eukaryotic pre-mRNAs. The exons and introns are drawn in blue and orange, and R and Y represent purine and pyrimidine residues. (1) The 2'-OH group of a specific intron A residue nucleophilically attacks the 5'-phosphate at the 5' intron boundary to displace the 3' end of the 5' exon, thereby yielding a 2',5'-phosphodiester bond and forming a lariat structure. (2) The liberated 3'-OH group attacks the 5'-phosphate of the 5'-terminal residue of the 3' exon, forming a 3',5'-phosphodiester bond, thereby displacing the intron in lariat form and splicing the two exons together.

? How many bonds are broken and how many are formed during splicing?

Note that the splicing process proceeds without free energy input; its transesterification reactions preserve the free energy of each cleaved phosphodiester bond through the concomitant formation of a new one. The sequences required for splicing are the short consensus sequences at the 3' and 5' splice sites and at the branch site. Nevertheless, these sequences are poorly conserved, and even highly sophisticated computer programs are only ~50% successful in predicting actual splice sites over apparently equally good candidates that are not.

A simplistic interpretation of Fig. 26-24 suggests that any 5' splice site could be joined with any following 3' splice site, thereby eliminating all the intervening exons together with the introns joining them. However, such **exon skipping** does not normally take place (but see below). Rather, all of a pre-mRNA's introns are individually excised in what appears to be a largely fixed order that more or less proceeds in the 5' → 3' direction. This occurs, at least in part, because splicing occurs cotranscriptionally. Thus, as a newly synthesized exon emerges from an RNAP II, it is bound by splicing factors (see below) that are also bound to the RNAP II's highly phosphorylated CTD. This tethers the exon and its associated splicing machinery to the CTD so as to ensure that splicing occurs when the next exon emerges from the RNAP II.

Splicing Is Mediated by snRNPs in the Spliceosome. How are splice junctions recognized and how are the two exons to be joined brought together in the splicing process? Part of the answer to these questions was established by Joan Steitz going on the assumption that one nucleic acid is best recognized by another. The eukaryotic nucleus contains numerous copies of highly conserved 60- to 300-nt RNAs called **small nuclear RNAs (snRNAs)**, which form protein complexes termed **small nuclear ribonucleoproteins (snRNPs)**; pronounced "snurps"). Steitz noted that the 5' end of one of these snRNAs, **U1-snRNA** (which is so named because of its high uridine content), is partially complementary to the consensus sequence of 5' splice junctions. Apparently, *U1-snRNP* recognizes the 5' splice junction. Other snRNPs that participate in splicing are **U2-snRNP**, **U4-U6-snRNP** (in which the **U4-** and **U6-snRNAs** associate via base pairing), and **U5-snRNP**.

Splicing takes place in an ~60S particle dubbed the **spliceosome** that brings together a pre-mRNA, the snRNPs, and a variety of pre-mRNA binding proteins. The spliceosome, which in humans consists of 5 RNAs and >300 polypeptides, is arguably the cell's most complicated machine. It is a highly dynamic entity, with its various components associating and dissociating during specific stages of the splicing process. This includes several ATP-driven rearrangements of base-paired stems among the snRNAs, as the spliceosome carries out the two transesterification reactions. The U6-snRNA coordinates a catalytically essential metal ion that enhances the nucleophilicity of the attacking OH group and stabilizes the leaving group. The existence of self-splicing introns (see below) and the results of experiments with protein-free snRNAs strongly suggest that the RNA components of the spliceosome, rather than the proteins, catalyze splicing.

All four snRNPs involved in mRNA splicing contain the same so-called **snRNP core protein**, which consists of seven **Sm proteins**, named **B, D1, D2, D3, E, F, and G proteins**. These proteins collectively bind to a conserved AAUUUGUGG sequence known as the **Sm RNA motif**, which occurs in U1-, U2-, U4-, and U5-snRNAs. The X-ray structures of the D3–B and D1–D₂ heterodimers reveal that these four proteins share a common fold, which consists of an N-terminal helix followed by a five-stranded antiparallel sheet that is strongly bent so as to form a hydrophobic core (**Fig. 26-25**). Model building based on the X-ray structures together with biochemical and mutagenic evidence suggest that the seven Sm proteins form a heptameric ring in which the fourth β strand of one Sm protein interacts with the fifth β strand of an adjacent Sm protein through main-chain hydrogen bonding. The funnel-shaped central hole of the Sm ring, which is lined with positive charges, is large enough to accommodate snRNA. An Sm-like protein from the hyperthermophilic archaeobacterium *Pyrobaculum aerophilum* forms a homoheptameric ring, suggesting that the seven eukaryotic Sm proteins arose through a series of duplications of an archaeal Sm-like protein gene.

Mammalian U1-snRNP consists of U1-snRNA and ten proteins, namely, the seven Sm proteins that are common to all U-snRNPs as well as three that are specific to U1-snRNP: **U1-70K, U1-A, and U1-C**. The predicted secondary structure of the 165-nt U1-snRNA (**Fig. 26-26a**) contains five double-helical stems, four of which come together at a four-way junction. U1-70K and U1-A bind directly to RNA stem-loops (SL) 1 and 2, respectively, whereas U1-C is bound by other proteins.

Kiyoshi Nagai determined the X-ray structure of human U1 snRNP at 5.5 Å resolution (**Fig. 26-26b,c**). At this low resolution the major and minor grooves of the double-stranded RNA stems are visible. Moreover, the helices and sheets of the proteins are apparent, which allows the placement of protein folds of known structure. SL2 of the U1-snRNA had been altered and shortened to promote crystallization, which eliminated the binding site for U1-A. However, U1 snRNP in which U1-A is depleted is active in a splicing assay. The Sm proteins form the predicted heteroheptameric ring, which is ~70 Å in diameter. The Sm RNA motif and SL4 are threaded through the ring's funnel-shaped central hole such that the Sm RNA motif interacts with the Sm proteins. U1-C associates with the Sm ring via an interaction between its zinc finger domain and the D3 subunit.

Fortuitously, the 5' ends of two neighboring U1-snRNAs in the crystal form a double-helical segment, which serves as a model for how the 5' end of U1-snRNA base-pairs with the 5' splice site of the pre-mRNA in the spliceosome. The zinc finger domain of U1-C interacts with this double helix (left side of Fig. 26-26c) and presumably stabilizes it. This is consistent with the observation that mutants of U1-C in this region cannot initiate spliceosome formation.

Gene Splicing Offers Evolutionary Advantages. Analysis of the large body of known DNA sequences reveals that introns are rare in prokaryotic structural

FIG. 26-25 X-Ray structure of an Sm dimer. The D3 protein is gold and the B protein is blue. The $\beta 5$ strand of D3 associates with the $\beta 4$ strand of B to form a continuous antiparallel β sheet. Note that their corresponding loops extend in similar directions. PDBid 1D3B.

(c)

genes, uncommon in lower eukaryotes such as yeast (which has a total of 239 introns in its ~6600 genes and, with two exceptions, only one intron per polypeptide), and abundant in higher eukaryotes (the only known vertebrate structural genes lacking introns are those encoding histones and the antiviral proteins known as **interferons**). Pre-mRNA introns, as we have seen, can be quite long and many genes contain large numbers of them. Consequently, unexpressed sequences constitute ~80% of a typical vertebrate structural gene and >99% of a few of them.

The argument that introns are only molecular parasites (**junk DNA**) seems untenable since it would then be difficult to rationalize why the evolution of complex splicing machinery offered any selective advantage over the elimination of the split genes. What then is the function of gene splicing? Although, since its

discovery, the significance of gene splicing has been debated, often vehemently, two important roles for it have emerged:

1. Gene splicing is an agent for rapid protein evolution. Many eukaryotic proteins consist of modules that also occur in other proteins (Section 5-4B). For example, SH2 and SH3 domains occur in many of the proteins involved in signal transduction (Section 13-2B). *It therefore appears that the genes encoding these modular proteins arose by the stepwise collection of exons that were assembled by (aberrant) recombination between their neighboring introns.*
2. Through **alternative splicing**, which we discuss below, gene splicing permits a single gene to encode several (sometimes many) proteins that may have significantly different functions.

Alternative mRNA Splicing Yields Multiple Proteins from a Single Gene. *The expression of numerous cellular genes is modulated by the selection of alternative splice sites.* Thus, genes containing multiple exons may give rise to transcripts containing mutually exclusive exons. In effect, certain exons in one type of cell may be introns in another. For example, a single rat gene encodes seven tissue-specific variants of the muscle protein **α -tropomyosin** (Section 7-2A) through the selection of alternative splice sites (Fig. 26-27).

Alternative splicing occurs in all multicellular organisms and is especially prevalent in vertebrates. In fact, microarray-based comparisons of the cDNAs obtained from various tissues indicate that >95% of human structural genes are subject to at least one alternative splicing event. This helps explain the discrepancy between the ~21,000 genes identified in the human genome (Section 3-4E) and earlier estimates that it contains over 100,000 structural genes. The variations in spliced mRNA sequences can take several different forms: Exons can be retained or skipped; introns may be excised or retained; and the positions of 5'

FIG. 26-27 Alternative splicing in the rat α -tropomyosin gene. Seven alternative splicing pathways give rise to cell-specific α -tropomyosin variants. The thin kinked lines indicate the positions occupied by the introns before they are spliced out to form the mature mRNAs. Tissue-specific exons are indicated together with the amino acid (aa) residues they encode: “constitutive” exons (those expressed in all tissues) are green; those expressed only in smooth muscle (SM)

are brown; those expressed only in striated muscle (STR) are purple; and those variably expressed are yellow. Note that the smooth and striated muscle exons encoding amino acid residues 39 to 80 are mutually exclusive and, likewise, there are alternative 3' untranslated (UT) exons. [After Breitbart, R.E., Andreadis, A., and Nadal-Ginard, B., *Annu. Rev. Biochem.* **56**, 481 (1987).]

and 3' splice sites can be shifted to make exons longer or shorter. Alterations in the transcriptional start site and/or the polyadenylation site can further contribute to the diversity of the mRNAs that are transcribed from a single gene.

A particularly striking example of alternative splicing occurs in the *Drosophila* protein **DSCAM** (*Down syndrome cell-adhesion molecule*), which functions in neuronal development. The protein is encoded by 24 exons of which there are 12 mutually exclusive variants of exon 4, 48 of exon 6, 33 of exon 9, and 2 of exon 17 (which are therefore known as **cassette exons**) for a total of 38,016 possible variants of the protein (compared to ~14,000 identified genes in the *Drosophila* genome). Although it is unknown whether all possible DSCAM variants are produced, experimental evidence suggests that the *Dscam* gene expresses many thousands of them. [Dscam is a membrane-anchored cell-surface protein of the immunoglobulin superfamily. The specific isoform expressed in a given neuron binds to itself but rarely to other isoforms. This permits the neuron to distinguish its own processes (axons and dendrites) from those of other neurons and thereby plays an essential role in neural patterning. However, the precise identity of a given isoform appears to be unimportant.] Clearly, *the number of genes in an organism's genome does not by itself provide an adequate assessment of its protein diversity*. Indeed, it has been estimated that, on average, each human structural gene encodes three different proteins.

The types of changes that alternative splicing confers on expressed proteins span the entire spectrum of protein properties and functions. Entire functional domains or even single amino acid residues may be inserted into or deleted from a protein, and the insertion of a **Stop codon** may truncate the expressed polypeptide [a codon is a 3-nt sequence that specifies an amino acid in a polypeptide; a Stop codon is a 3-nt sequence that instructs the ribosome to terminate polypeptide synthesis (Section 27-1C)]. Splice variations may, for example, control whether a protein is soluble or membrane bound, whether it is phosphorylated by a specific kinase, the subcellular location to which it is targeted, whether an enzyme binds a particular allosteric effector, or the affinity with which a receptor binds a ligand. Changes in an mRNA, particularly in its noncoding regions, may also influence the rate at which it is transcribed and its susceptibility to degradation. Since the selection of alternative splice sites is both tissue- and developmental stage-specific, splice site choice must be tightly regulated in both space and time.

How are alternative splice sites selected? One example of this process occurs in the *transformer* (*tra*) gene during sex determination in *Drosophila*. Exon 2 of *tra* pre-mRNA contains two alternative 3' splice sites, with the proximal (close; to exon 1) site used in males and the distal (far) site used in females (Fig. 26-28). The region between the two sites contains a Stop codon with the sequence UAG. In males, the splicing factor **U2-snRNP auxiliary factor (U2AF)** binds to the proximal 3' splice site to yield an mRNA containing the premature Stop codon, which thereby directs the synthesis of a truncated and hence nonfunctional **TRA** protein. However, in females, the proximal 3' splice site is bound by the female-specific **SXL** protein, the product of the *sex-lethal* (*sxl*) gene (which is expressed only in females), so as to block the binding of U2AF, which then binds to the distal 3' splice site, thereby inducing the expression of functional TRA protein.

FIG. 26-28 Alternative splice site selection in the *Drosophila tra* gene. Exons of the pre-mRNA are represented by colored rectangles, and introns are shown as gray bands with those to be excised flanked by kinked lines. UAG is a Stop codon. In females,

the protein SXL directs the spliceosome to the second of two possible splice sites, to generate mRNA for a full-length TRA protein. [After a drawing by Maniatis, T. and Tasic, B., *Nature* **418**, 236 (2002).]

In females, the TRA protein directs the splicing of mRNA from another sex-determination gene, leading to production of a repressor of male-specific genes.

Similar mechanisms for repressing or activating a splice site occur in vertebrates. Some of the proteins involved in splice site selection—both constitutive and alternative—include **SR proteins** and several members of the **heterogeneous nuclear ribonucleoprotein (hnRNP)** family. SR proteins each have one or more **RNA recognition motifs (RRMs)**, which bind RNA sequences, near their N-terminus and a distinctive C-terminal **RS domain**, which contains numerous Ser-Arg (SR) repeats and which participates in protein–protein interactions (U2AF and TRA both contain an SR domain, but neither has an RRM and so are not considered to be SR proteins). SR proteins, when appropriately phosphorylated on their RS domains, specifically bind to corresponding small (5–10 nt) **exonic splicing enhancers (ESEs)** via their RRMs and thereby recruit the splicing machinery to the flanking 5' and 3' splice sites. The hnRNPs, which are highly abundant RNA-binding proteins, lack RS domains and hence cannot recruit the splicing machinery. Instead, they bind to their corresponding **exonic** and **intronic splicing silencers (ESSs and ISSs)** to block the binding of the splicing machinery at the flanking splice sites. Such interactions help the splicing machinery distinguish true exons (which are relatively short) from the more numerous sequences within introns (which are relatively long) that happen to exhibit the consensus splice-site sequences. Indeed, extensive analysis of the sequences of numerous alternative splice sites has revealed the existence of a “splicing code” that uses combinations of over 200 RNA features that are present in both introns and exons and which are recognized by the foregoing regulators. Tissue-specific expression of hnRNPs and SR proteins, together with the latter’s reversible phosphorylation, undoubtedly contribute to the complex regulation of mRNA splicing.

Around 15% of human genetic diseases are caused by point mutations that result in pre-mRNA splicing defects. Some of these mutations delete functional splice sites, thereby activating nearby preexisting **cryptic splice sites**. Others generate new splice sites that are used instead of the normal ones. In addition, tumor progression is correlated with changes in levels of proteins implicated in alternative splice site selection. Even a seemingly harmless mutation to a protein coding sequence [the genetic code has many synonyms (Table 27-1) and many amino acid changes are functionally innocuous] may alter an ESE or ESS and consequently have deleterious effects. Thus, protein coding sequences are subject to the dual evolutionary pressures of conserving protein function and the elements that regulate their splicing.

mRNA May Be Edited. Additional posttranscriptional modifications of eukaryotic mRNAs include the methylation of certain A residues. In a few cases, mRNAs undergo **RNA editing**, which involves base changes, deletions, or insertions. In the most extreme examples of this phenomenon, which occur in the trypanosomes and related protozoa, several hundred U residues may be added and removed to produce a translatable mRNA. Not surprisingly, the mRNA editing machinery includes RNAs known as **guide RNAs (gRNAs)** that base-pair with the immature mRNA to direct its alteration.

In a few mRNAs, specific bases are chemically altered—for example, by enzyme-catalyzed deamination of C to produce U and/or deamination of A to produce inosine (which is read as G by the ribosome), a process called **substitutional editing**. For example, humans express two forms of **apolipoprotein B (apoB)**: **apoB-48**, which is made only in the small intestine and functions in chylomicrons to transport triacylglycerols from the intestine to the liver and peripheral tissues; and **apoB-100**, which is made only in the liver and functions with VLDL, IDL, and LDL to transport cholesterol from the liver to the peripheral tissues (Table 20-1). ApoB-100 is an enormous 4536-residue protein, whereas apoB-48 consists of apoB-100’s N-terminal 2152 residues and therefore lacks the C-terminal domain of apoB-100 that mediates LDL receptor binding. Although apoB-48 and apoB-100 are expressed from the same gene, the mRNAs

encoding the two proteins differ by a single C → U change: The codon for Gln 2153 (CAA) in apoB-100 mRNA is, in apoB-48 mRNA, a UAA Stop codon. The enzyme that catalyzes this conversion is site-specific **cytidine deaminase**.

Substitutional editing may contribute to protein diversity. For example, *Drosophila cacophony* pre-mRNA, which encodes a voltage-gated Ca²⁺ channel subunit, contains 10 different substitutional editing sites and hence has the potential of generating 2¹⁰ = 1024 different isoforms in the absence of alternative splicing. Substitutional editing can also generate alternative splice sites. For example, the enzyme **ADAR2** (ADAR for *adenosine deaminase acting on RNA*) edits its own pre-mRNA by converting an intronic AA dinucleotide to AI, which mimics the AG normally found at 3' splice sites (Fig. 26-24). The consequent new splice site adds 47 nucleotides near the 5' end of the ADAR2 mRNA so as to generate a new translational initiation site. The resulting ADAR2 isozyme is catalytically active but is produced in smaller amounts than that from unedited transcripts, perhaps due to a less efficient translational initiation site. Thus, ADAR2 appears to regulate its own rate of expression.

Mature Eukaryotic mRNAs Are Actively Transported from the Nucleus to the Cytoplasm. The translation of prokaryotic mRNAs is often initiated before their synthesis is complete. This cannot occur in eukaryotes because the transcription and posttranscriptional processing of eukaryotic mRNAs occur in the nucleus but their translation takes place in the cytosol. Consequently, mature mRNAs must be transported from the nucleus to the cytoplasm. This is a highly selective process because mature mRNAs comprise only a small fraction of the RNAs present in the nucleus, the remainder being pre-mRNAs, excised introns (which are usually much larger than the exons from which they were liberated), rRNAs, tRNAs, snRNAs, and a variety of RNAs that participate in the processing of rRNAs and tRNAs (Section 26-3C). Indeed, only ~5% of the RNA that is synthesized ever leaves the nucleus.

How are mature mRNAs recognized and transported? As we have seen, throughout their residency in the nucleus, pre-mRNAs are continually associated with numerous proteins, including those that participate in synthesizing their m⁷G caps and poly(A) tails, and in splicing out their introns. In addition, the **exon junction complex (EJC)**, which consists of four core proteins and several transiently associating proteins, is deposited onto mRNA during the splicing process at a site that is 20 to 24 nt upstream of the splice junction without regard to its sequence. The population of proteins bound to an mRNA changes as the mRNA is processed but some of the proteins, including SR proteins, hnRNPs, and EJCs, remain associated with mature mRNAs in the nucleus. However, it appears that it is its entire collection of bound proteins rather than any individual protein that serves to identify an mRNA to the nuclear export machinery. Excised introns, in contrast, are bound by proteins that block their export.

The eukaryotic nucleus (Fig. 1-8) is a double membrane-enveloped organelle that in animals is penetrated by an average of ~3000 pores. These are formed by **nuclear pore complexes (NPCs)**, which are massive (~120,000 kD), eight-fold symmetric assemblies of ~30 different proteins known as **nucleoporins**. NPCs, which have inner diameters of ~90 Å (although this may be expandable to as much as 260 Å), allow the free diffusion of molecules of up to ~40 kD, but most macromolecules, including mRNAs in their complexes with proteins, require an active transport process to pass through an NPC. Some of the proteins associated with mature mRNAs bear nuclear export signals that are recognized by an ATP-driven RNA helicase that in yeast is named **Dbp5**. Dbp5 also binds to the NPC, which permits it to pull the mRNA out into the cytosol while simultaneously stripping away many of its bound proteins. The remaining proteins are removed the first time their bound mRNA passes through a ribosome. The proteins are later recycled by returning them to the nucleus through the NPCs.

The mRNAs are eventually degraded to their component nucleotides. This is a highly regulated process that selectively degrades mRNAs at rates that vary with their identities, the cell type, and its developmental stage. Consequently, the

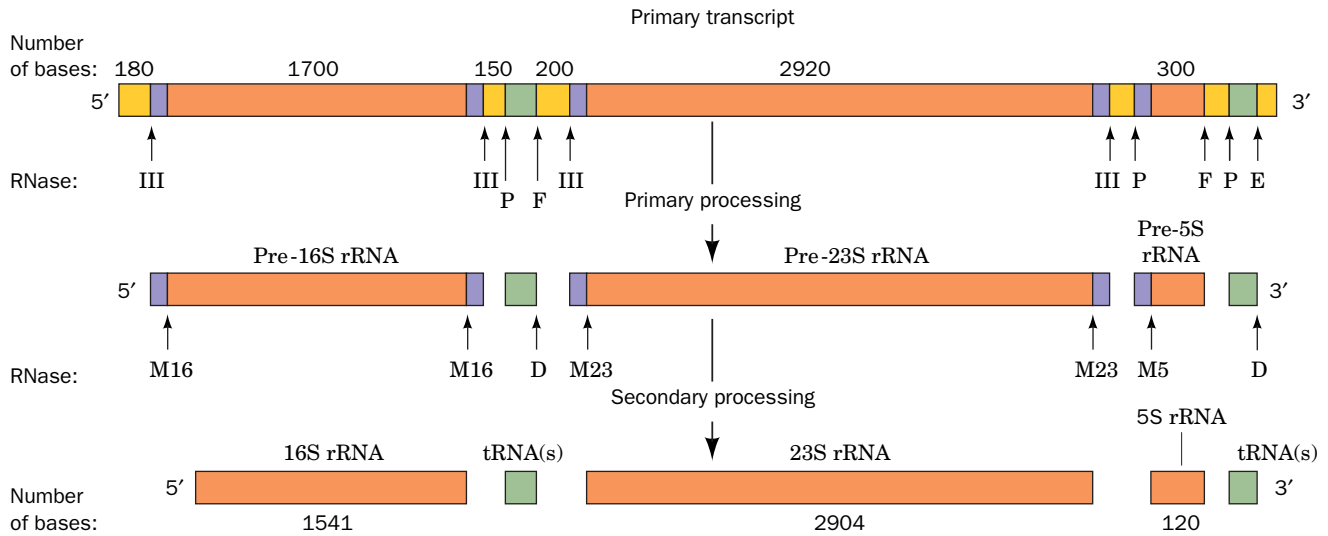

FIG. 26-29 The posttranscriptional processing of *E. coli* rRNA. The transcriptional map is shown approximately to scale. The labeled arrows indicate the positions of the various nucleolytic cuts and the nucleases that generate them. [After Apiron, D., Ghora, B.K., Plantz, G., Misra, T.K., and Gegenheimer, P., in Söll, D., Abelson, J.N., and Schimmel, P.R. (Eds.), *Transfer RNA: Biological Aspects*, p. 148, Cold Spring Harbor Laboratory (1980).]

rate of degradation of a specific mRNA is as important for regulating its level as is its rate of synthesis. The mechanisms of mRNA degradation are discussed in Section 28-3C.

C Ribosomal RNA Precursors May Be Cleaved, Modified, and Spliced

E. coli has three types of rRNAs, the **5S**, **16S**, and **23S rRNAs**. These are specified by seven operons, each of which contains one nearly identical copy of each of the three rRNA genes, although their introns differ in sequence. The polycistronic primary transcripts of these operons are >5500 nt long and contain, in addition to the rRNAs, transcripts for as many as four tRNAs (Fig. 26-29). The steps in processing the primary transcripts to mature rRNAs were elucidated with the aid of mutants defective in one or more of the processing enzymes.

The initial processing, which yields products known as **pre-rRNAs**, commences while the primary transcript is still being synthesized. It consists of specific endonucleolytic cleavages by **RNase III**, **RNase P**, **RNase E**, and **RNase F** at the sites indicated in Fig. 26-29. The cleavage sites are probably recognized on the basis of their secondary structures.

The 5' and 3' ends of the pre-rRNAs are trimmed away in secondary processing steps through the action of **RNases D**, **M16**, **M23**, and **M5** to produce the mature rRNAs. These final cleavages occur only after the pre-rRNAs become associated with ribosomal proteins. During ribosomal assembly, specific rRNA residues are methylated, which may help protect them from inappropriate nuclease digestion.

snoRNAs Direct the Methylation of Eukaryotic rRNAs. The eukaryotic genome typically has several hundred tandemly repeated copies of rRNA genes. These genes are transcribed and processed in the **nucleolus** (Fig. 1-8), a small dark-staining body in the nucleus that is not membrane enveloped. The primary eukaryotic rRNA transcript is an ~7500-nt **45S RNA** that contains the **18S**, **5.8S**, and **28S rRNAs** separated by spacer sequences:

In the first stage of its processing, 45S RNA is specifically methylated at numerous sites (106 in humans) that occur mostly in its rRNA sequences. About 80% of these modifications yield O^2 -methylribose residues, and the remainder yield methylated bases such as N^6,N^6 -dimethyladenine and 2-methylguanine. The subsequent cleavage and trimming of the 45S RNA superficially resemble those of prokaryotic rRNAs. In fact, enzymes exhibiting RNase III- and RNase P-like activities occur in eukaryotes. Eukaryotic ribosomes contain four different rRNAs (Section 27-3). The fourth type, 5S eukaryotic rRNA, is separately processed in a manner resembling that of tRNA (Section 26-3D).

The methylation sites in yeast and vertebrate rRNAs generally occur in invariant sequences, although the methylation sites do not appear to have a consensus structure that might be recognized by a single methyltransferase. How then are the methylation sites targeted? Pre-rRNAs interact with members of a large family of **small nucleolar RNAs (snoRNAs)**. Mammals have ~200 snoRNAs, most of which are encoded by the introns of structural genes (and hence not all excised introns are discarded). The snoRNAs, whose lengths vary from 70 to 100 nt, contain segments of 10 to 21 nt that are precisely complementary to segments of the mature rRNAs that contain O^2 -methylation sites. The snoRNAs appear to direct a protein complex containing a methyltransferase to the methylation site. Presumably, without the snoRNAs, the cell would need to synthesize a different methyltransferase to recognize each methylation sequence. Complexes of small RNAs and proteins also catalyze the conversion of certain rRNA uridine residues to pseudouridine (ψ):

Some Eukaryotic rRNAs Are Self-Splicing. A few eukaryotic rRNA genes contain introns. In fact, it was Thomas Cech's study of how these introns are spliced out that led to the astonishing discovery, in 1982, that *RNA can act as an enzyme* (a ribozyme; Section 24-2C). Cech showed that when the isolated pre-rRNA of the ciliated protozoan *Tetrahymena thermophila* is incubated with guanosine or a free guanine nucleotide (GMP, GDP, or GTP), but in the absence of protein, its single 413-nt intron excises itself and splices together its flanking exons; that is, *the pre-rRNA is self-splicing*. The three-step reaction sequence of this process (Fig. 26-30) resembles that of mRNA splicing:

FIG. 26-30 The sequence of reactions in the self-splicing of *Tetrahymena* pre-rRNA. (1) The 3'-OH group of a guanine nucleoside or the 5'-nucleotide attacks the intron's 5'-terminal phosphate to form a phosphodiester bond, displacing the 5' exon. (2) The newly generated 3'-OH group of the 5' exon attacks the 5'-terminal phosphate of the 3' exon, thereby splicing the two exons and displacing the intron. (3) The 3'-OH group of the intron attacks the phosphate of the nucleotide that is 15 residues from the 5' end so as to cyclize the intron and displace its 5'-terminal fragment. Throughout this process, the RNA maintains a folded, internally hydrogen-bonded conformation that permits the precise excision of the intron.

? How many phosphodiester bonds are broken and formed in this process?

1. The 3'-OH group of the guanosine attacks the intron's 5' end, displacing the 3'-OH group of the 5' exon and thereby forming a new phosphodiester linkage with the 5' end of the intron.
2. The 3'-terminal OH group of the newly liberated 5' exon attacks the 5'-phosphate of the 3' exon to form a new phosphodiester bond, thereby splicing together the two exons and displacing the intron.
3. The 3'-terminal OH group of the intron attacks a phosphate of the nucleotide 15 residues from the intron's end, displacing the 5' terminal fragment and yielding the 3' terminal fragment in cyclic form.

The self-splicing process consists of a series of transesterifications and therefore does not require free energy input.

Self-splicing RNAs that react as shown in Fig. 26-30 are known as **group I introns** and occur in the nuclei, mitochondria, and chloroplasts of diverse eukaryotes (but not vertebrates), and in some bacteria. **Group II introns**, which occur in the mitochondria and chloroplasts of fungi and plants, employ an internal A residue (instead of an external G) to form a lariat intermediate. The chemical similarities of the pre-mRNA and group II intron splicing reactions therefore suggest that *spliceosomes are ribozymal systems whose RNA components have evolved from primordial self-splicing RNAs and that their protein components serve mainly to fine-tune ribozymal structure and function*. This, of course, is consistent with the hypothesis that RNAs were the original biological catalysts in precellular times (the RNA world; Box 24-3).

The *Tetrahymena* Group I Ribozyme Has a Complex Tertiary Structure. Group I introns are the most abundant self-splicing introns with >2000 such sequences known. The sequence of the 413-nt *Tetrahymena* group I intron, together with phylogenetic comparisons, indicates that it contains nine double-helical segments that are designated P1 through P9 (Fig. 26-31a; P for base paired segment). Such analysis further indicates that the conserved catalytic core of group I introns consists of sets of coaxially stacked helices interspersed with internal loops that are organized into two domains, the P4-P5-P6 domain (also called P4-P6) and the P3-P7-P8-P9 domain (also called P3-P9).

Cech designed a 247-nt RNA (Fig. 26-31a) that encompasses both the P4-P6 and P3-P9 domains of the *Tetrahymena* group I intron (it lacks the P1-P2 domain and the attached exons), with the addition of a 3' G (ω G), which functions as an internal guanosine nucleophile. This RNA is catalytically active; it binds the P1-P2 domain via tertiary interactions and, with the assistance of ω G, cleaves P1 in a manner similar to the intact intron.

The X-ray structure of this RNA (Fig. 26-31b,c) reveals that it is largely composed of three coaxially stacked sets of A-RNA-like helices with P4-P6 consisting of two pseudocontinuous and straight parallel helices connected by a sharp bend and P3-P9 consisting of a curved helix that wraps around one side of P4-P6 through extensive interdomain interactions that form the ribozyme's active site. Of particular note are its so-called A-rich bulge, a 7-nt sequence about half-way along the short arm of the U-shaped P4-P6, and the 6-nt sequence at the tip of the short arm of the U, whose central GAAA assumes a characteristic conformation known as a **tetraloop**. In both of these substructures, the bases are splayed outward so as to stack on each other and to associate in the minor groove of specific segments of the long arm of the U via hydrogen bonding interactions involving ribose residues as well as bases. In many such interactions, the close packing of phosphate groups is mediated by hydrated Mg^{2+} ions. Throughout this structure, the defining characteristic of RNA, its 2'-OH group, is both a donor and an acceptor of hydrogen bonds to phosphates, bases, and other 2'-OH groups. Interestingly, although this overall fold is highly conserved among group I introns, their sequences are poorly conserved with the exception of a few crucial active site residues.

(a)

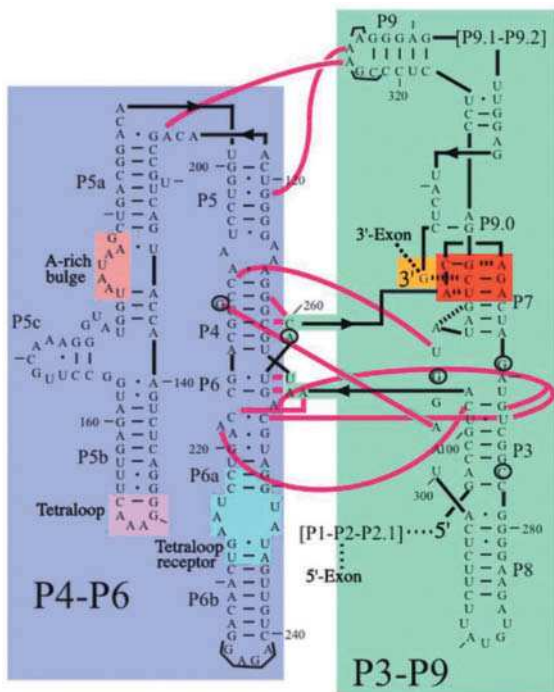

FIG. 26-31 The group I intron from *Tetrahymena thermophila*. (a) The secondary structure of the 414-nt ribozyme. Its P4-P6 and P3-P9 domains are shaded in blue and green, respectively, with the catalytically active 3' ω G residue shaded in yellow, the base triples of the P7 domain shaded in red, and the A-rich bulge, the tetraloop, and the tetraloop receptor on the P4-P6 domain shaded in orange, pink, and cyan, respectively. Watson-Crick and non-Watson-Crick base pairing interactions are represented by short horizontal lines and small filled circles, whereas interdomain interactions are indicated by magenta lines. Every tenth residue is marked by an outwardly pointing dash. The positions of five residues that have been mutated to stabilize the ribozyme structure are circled and those of the seven mutations that facilitated crystallization are bracketed (this mutant form retains its catalytic activity). (b) The X-ray structure of the ribozyme, drawn in cartoon form with its bases shown as paddles, and colored as in Part a. The inferred positions of Mg^{2+} ions are represented by orange spheres. (c) As in Part b but rotated 140° about the vertical axis to better show the A-rich bulge and the interaction between the tetraloop and the tetraloop receptor. [Part a modified from a drawing by and Parts b and c based on an X-ray structure by Thomas Cech, University of Colorado. PDBid 1X8W.]

(b)

(c)

Divalent metal ions, usually Mg^{2+} , are often required for both the structural stability and the catalytic activity of ribozymes. In particular, an Mg^{2+} ion is in contact with the 2'-OH group of ω G as well as being liganded by the phosphate groups of three surrounding nucleotides. This both orients the ribose group of ω G and nucleophilically activates its 3'-OH group. A second Mg^{2+} ion, which accompanies the phosphate group of the RNA substrate, also participates in the catalytic reaction. Note that two Mg^{2+} ions similarly participate in the phosphoryl-transfer reactions catalyzed by protein enzymes such as DNA polymerase (Section 25-2A).

D Transfer RNAs Are Processed by Nucleotide Removal, Addition, and Modification

A tRNA molecule, as we discussed in Section 24-2C, consists of around 76 nucleotides, many of which are chemically modified, that assume a cloverleaf-shaped secondary structure with four base-paired stems (Fig. 26-32). The *E. coli* chromosome contains ~60 tRNA genes. Some of them are components of rRNA operons; the others are distributed, often in clusters, throughout the chromosome. The primary tRNA transcripts, which contain as many as five identical tRNA species, have extra nucleotides at the 3' and 5' ends of each tRNA sequence. The excision and trimming of these tRNA sequences resemble *E. coli* rRNA processing (Fig. 26-29) in that the two processes employ some of the same nucleases.

E. coli **RNase P**, which processes rRNA and generates the 5' ends of tRNAs, is a particularly interesting enzyme because it is a ribozyme with a catalytically essential RNA and, in bacteria, one highly conserved protein subunit. At first, the RNA was assumed to recognize the substrate through base pairing and thereby guide the protein subunit, which was presumed to be the nuclease, to the cleavage site on the substrate pre-tRNA. However, Sidney Altman showed that *the RNA component of RNase P is, in fact, the enzyme's catalytic subunit by demonstrating that free RNase P RNA catalyzes the cleavage of substrate RNA at high salt concentrations*. The RNase P protein, which is basic, increases the reaction rate by two to three orders of magnitude by stabilizing the P RNA structure, binding the 5' "leader" sequence of the pre-tRNA, and assisting in product release. RNase P activity also occurs in eukaryotes, although the enzyme includes 9 or 10 protein subunits whose functions are poorly understood. RNase P, unlike the self-splicing introns, is a true enzyme capable of multiple turnovers. Indeed, RNase P mediates one of the two ribozymal activities that occur in all cellular life, the other being ribosomally catalyzed peptide bond formation (Section 27-4B).

The RNase P holoenzyme from *Thermotoga maritima* contains a 117-residue (14-kD) protein and a 338-residue (110-kD) RNA whose secondary structure includes numerous base-paired stems. The X-ray structure of this RNase P in complex with tRNA^{Phe} [Fig. 26-33; tRNA^{Phe} conveys Phe to the ribosome (Section 27-4)], a ribozyme-product complex, was determined by Alfonso Mondragón. It reveals that RNase P has an overall compact structure typical of protein enzymes and binds the tRNA^{Phe} through shape complementarity, base stacking,

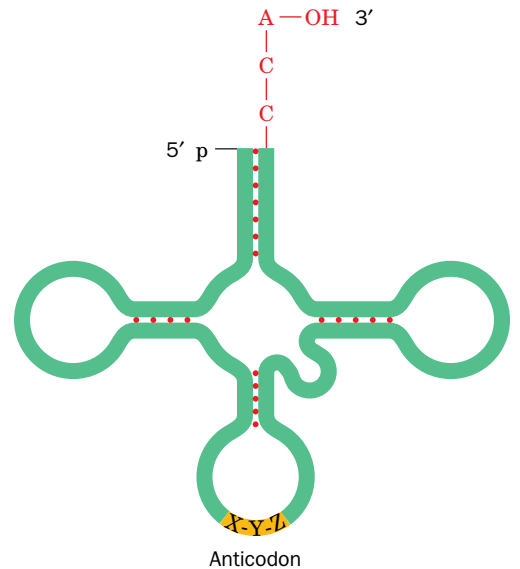

FIG. 26-32 Schematic diagram of the tRNA cloverleaf secondary structure. Each red dot indicates a base pair in the hydrogen-bonded stems. The positions of the **anticodon** (the 3-nt sequence that binds to mRNA during translation) and the 3'-terminal —CCA are indicated.

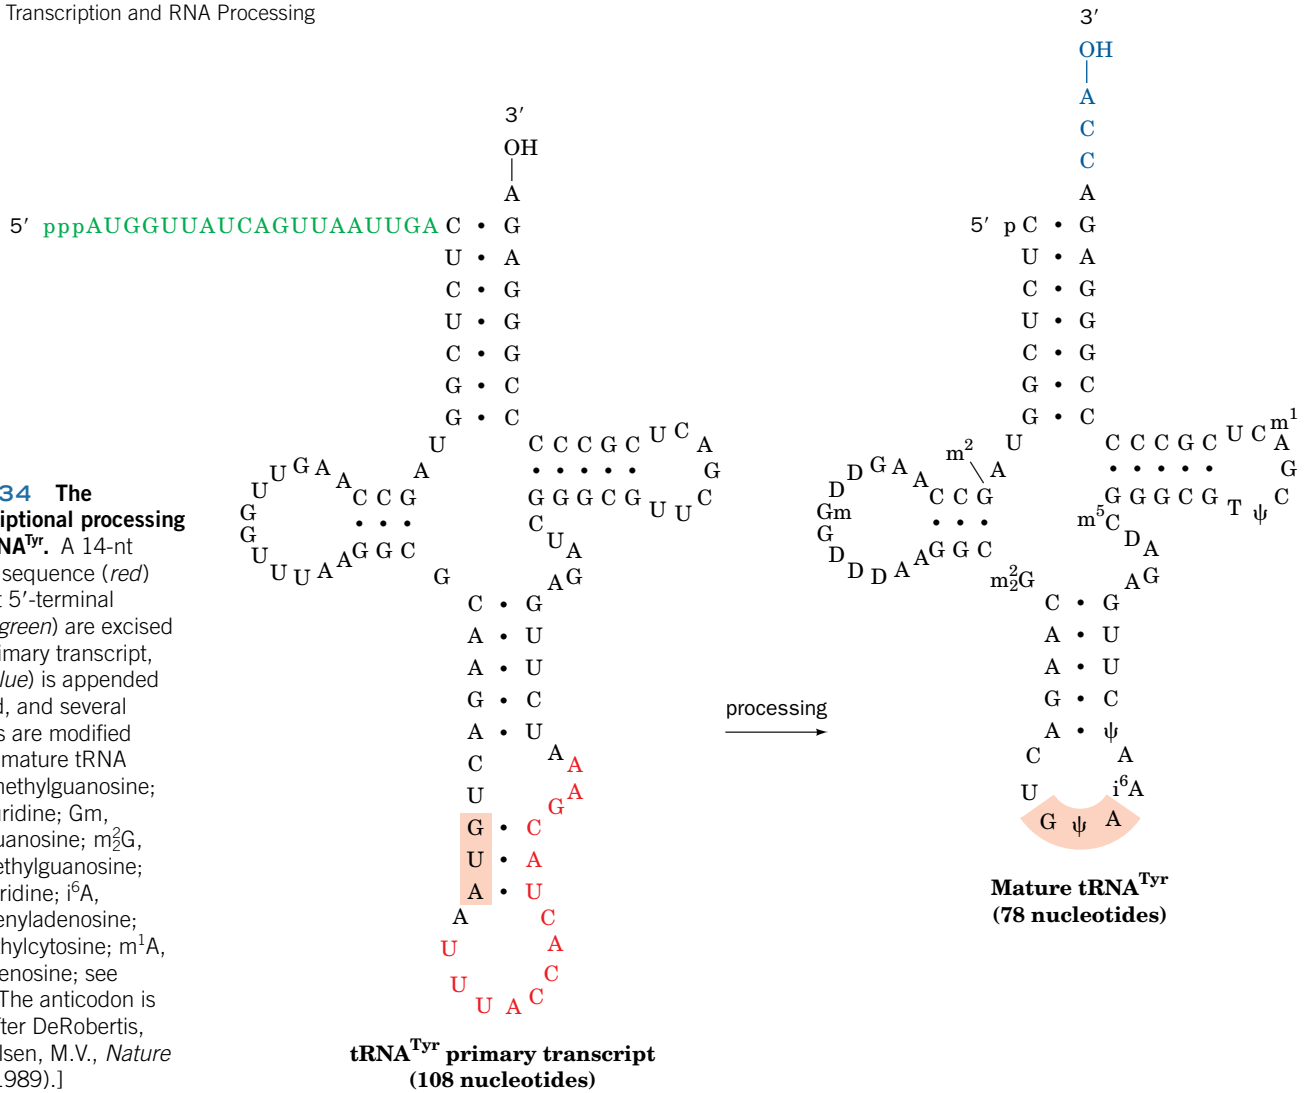

FIG. 26-33 X-Ray structure of *T. maritima* RNase P in complex with tRNA^{Phe}. The RNAs are drawn in ladder form with the tRNA^{Phe} pink and the P RNA colored in rainbow order from its 5' end (*blue*) to its 3' end (*red*). The protein component of RNase P, which is positioned to bind a substrate pre-tRNA's 5' extension, is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The tRNA^{Phe} lacks the 5' extension present in pre-tRNAs and hence this is a ribozyme-product complex. Gray segments of the RNAs represent additional sequences that were required to crystallize the complex. [Based on an X-ray structure by Alfonso Mondragón, Northwestern University. PDBid 3Q1R.]

FIG. 26-34 The posttranscriptional processing of yeast tRNA^{Tyr}. A 14-nt intervening sequence (red) and a 19-nt 5'-terminal sequence (green) are excised from the primary transcript, a —CCA (blue) is appended to its 3' end, and several of the bases are modified to form the mature tRNA (m²G, N²-methylguanosine; D, dihydrouridine; Gm, 2'-methylguanosine; m²G, N²,N²-dimethylguanosine; ψ, pseudouridine; i⁶A, N⁶-isopentenyladenosine; m⁵C, 5-methylcytosine; m¹A, 1-methyladenosine; see Fig. 27-4). The anticodon is shaded. [After DeRobertis, E.M. and Olsen, M.V., *Nature* **278**, 142 (1989).]

CHECKPOINT

- Summarize the posttranscriptional modifications of eukaryotic mRNA.
- Why is splicing described as transesterification?
- What is the advantage of starting RNA processing before transcription is complete?
- Discuss the advantages, in terms of protein structure and evolution, that result from alternative mRNA splicing.
- What does the existence of self-splicing RNAs reveal about the evolution of spliceosomes?
- Explain why self-splicing introns are not true enzymes.
- Describe the modifications that occur during processing of prokaryotic and eukaryotic rRNAs and tRNAs.

base pairing, and specific RNA–RNA contacts. The enzyme's active site includes a universally conserved U residue and two metal ions, probably Mg²⁺, that are postulated to participate directly in catalysis. A portion of the RNA is present in all known RNase P's and hence is known as the universal minimum consensus structure. This structure was presumably present in the primordial RNase P.

Many Eukaryotic Pre-tRNAs Have Introns. Eukaryotic genomes each contain from several hundred to several thousand tRNA genes. Many eukaryotic primary tRNA transcripts, for example, that of yeast tRNA^{Tyr} (Fig. 26-34), contain a small intron as well as extra nucleotides at their 5' and 3' ends. The intron is excised by the action of an ATP-dependent **splicing endonuclease**, not a spliceosome, that recognizes the pre-tRNA's splice sites. The exons are then joined by an **RNA ligase**.

The three nucleotides, CCA, at the 3' termini of all tRNAs, the sites at which amino acids are attached (Section 27-2B), are lacking in the primary tRNA transcripts of eukaryotes. This trinucleotide is appended by the enzyme **CCA-adding polymerase**, which sequentially adds two C's and an A to tRNA using CTP and ATP as substrates. This enzyme also occurs in prokaryotes, although, at least in *E. coli*, all tRNA genes encode a —CCA terminus. The *E. coli* CCA-adding polymerase is therefore likely to function in the repair of degraded tRNAs.

Summary

1 Prokaryotic RNA Transcription

- RNA polymerase synthesizes a polynucleotide chain from ribonucleoside triphosphates using a single strand (the antisense or noncoding strand) of DNA as a template.
- The σ factor of *E. coli* RNA polymerase holoenzyme recognizes and binds to a promoter sequence to position the enzyme to initiate transcription.
- RNA synthesis requires the formation of an open complex. The transcription bubble travels along the DNA as the RNA chain is elongated by the processive activity of RNA polymerase.
- In *E. coli*, RNA synthesis is terminated in response to specific secondary structural elements in the transcript and may require the action of Rho factor.

2 Transcription in Eukaryotes

- Eukaryotes contain three nuclear RNA polymerases that synthesize its different types of RNAs.
- Eukaryotic promoters are diverse: They vary in position relative to the transcription start site and may consist of multiple sequences. Enhancers

form the binding sites for regulatory proteins that function as activators of transcription.

- Basal transcription of eukaryotic genes requires six general transcription factors, including TBP, that form a preinitiation complex (PIC) with RNA polymerase at the promoter. Some of these proteins remain with the polymerase when its C-terminal domain (CTD) is phosphorylated and shifts to elongation.

3 Posttranscriptional Processing

- The primary transcripts of most eukaryotic structural genes are posttranscriptionally modified by the addition of a 5' cap and a 3' poly(A) tail. Pre-mRNAs that contain introns undergo splicing, in which the introns are excised and the flanking exons are joined together via two transesterification reactions mediated by an snRNA-containing spliceosome.
- The processing of pre-rRNAs includes nucleolytic cleavage and snoRNA-assisted methylation. Some eukaryotic rRNA transcripts undergo splicing catalyzed by the intron itself.
- tRNA transcripts may be processed by the addition, removal, and modification of nucleotides.

Problems

EXERCISES

1. The antibiotic **cordycepin** inhibits bacterial RNA synthesis.

Cordycepin

- (a) Of which nucleoside is cordycepin a derivative?
- (b) Explain cordycepin's mechanism of action.

2. The bacterial enzyme polynucleotide phosphorylase (PNPase) is a 3' \rightarrow 5' exoribonuclease that degrades mRNA.

(a) The enzyme catalyzes a phosphorolysis reaction, as does glycogen phosphorylase (Section 16-1), rather than hydrolysis. Write an equation for the mRNA phosphorolysis reaction.

(b) *In vitro*, PNPase also catalyzes the reverse of the phosphorolysis reaction. What does this reaction accomplish and how does it differ from the reaction carried out by RNA polymerase?

(c) PNPase includes a binding site for long ribonucleotides, which may promote the enzyme's processivity. Why would this be an advantage for the primary activity of PNPase *in vivo*?

3. Design a six-residue nucleic acid probe that would hybridize with the greatest number of *E. coli* gene promoters.
4. Why does promoter efficiency tend to decrease with the number of G \cdot C base pairs in the -10 region of a prokaryotic gene?

5. Many bacterial genes with related functions are arranged in operons, sets of contiguous genes that are under the control of a single promoter and are transcribed together. (a) What is the advantage of this arrangement? (b) How might eukaryotic cells, which do not contain operons, ensure the simultaneous transcription of different genes?
6. A eukaryotic ribosome contains four different rRNA molecules and ~82 different proteins. Why does a cell contain many more copies of the rRNA genes than the ribosomal protein genes?
7. Replication of many RNA viruses depends on RNA polymerase. The antiviral drug ribavirin does not inhibit the polymerase but instead increases its error rate. Explain how this affects the virus.
8. Collisions between DNA polymerase and a slower-moving RNA polymerase using the same template strand may be responsible for the observation that leading strand synthesis in bacteria is discontinuous *in vivo*. Draw a diagram to show how DNA synthesis that has been halted after the DNA polymerase–RNA polymerase collision can resume using the RNA transcript as a primer.
9. Predict the effect of the antibiotic bicyclomycin, an antibiotic that inhibits Rho, on gene expression in *E. coli*.
10. Certain *E. coli* bacteriophages encode a protein called Q, which binds to RNAP shortly after transcription initiation but before σ^{70} is released. Q increases the rate of transcription and renders RNAP resistant to Rho-dependent termination. (a) Explain how Q could enhance expression of bacteriophage genes. (b) Explain why the effect of Q depends on its ability to interact with specific DNA sequences, not just RNAP.
11. Design an oligonucleotide-based affinity chromatography system for purifying mature mRNAs from eukaryotic cell lysates.
12. A eukaryotic cell carrying out transcription and RNA processing is incubated with ^{32}P -labeled ATP. Where will the radioactive isotope appear in mature mRNA if the ATP is labeled at the (a) α position, (b) β position, and (c) γ position?
13. Compare DNA polymerase, RNA polymerase, poly(A) polymerase, and CCA-adding polymerase with respect to requirement for a primer, template, and substrates.
14. Explain why the active site of poly(A) polymerase is much narrower than that of DNA and RNA polymerases.
15. Explain why the O^2 -methylation of ribose residues protects rRNA from RNases.
16. The 5' end of some bacterial regulatory RNAs are linked to the 3'-OH group of the adenosine residue of NAD^+ . Propose a biological function for the modification and explain how the activity of the modified RNA might reflect the cell's overall metabolic activity.
17. Would you expect spliceosome-catalyzed intron removal to be reversible in a highly purified *in vitro* system and *in vivo*? Explain.
18. Introns in eukaryotic protein-coding genes may be quite large, but almost none are smaller than about 65 bp. What is the reason for this minimum intron size?
19. In what ways do histone gene transcripts differ from transcripts of other vertebrate protein-coding genes?
20. N^6 methylation of adenosine residues is one of the most common mRNA modifications. (a) Draw the structure of the modified base.

(b) Would you expect the modification to alter the RNA's ability to form stem-loop structures?

21. Infection with certain viruses inhibits snRNA processing in eukaryotic cells. Explain why this favors the expression of viral genes in the host cell.
22. Draw a diagram, including exons and introns, of a gene that encodes both membrane-bound and soluble forms of a protein. Explain how one gene can code for two different forms of a protein.

CHALLENGE QUESTIONS

23. Indicate the -10 region, the -35 region, and the initiating nucleotide on the sense strand of the *E. coli* tRNA^{Tyr} promoter.
5'-CAACGTAACACTTTACAGCGGGCGCGTCATTGTGATGATGCGCCCGCTTCCCGATA-3'
3'-GTTGCATTGTGAAATGTCGCGCGCAGTAAACTATACTACGGGGGCGAAGGGCTAT-5'
24. Diagram the likely secondary structure of an RNA with the sequence
5'-UGCUGCCAUCUCUUUCCUCUCUAUUGCGAGGAUUUGGACUGGCAGCG-3'
25. Explain why inserting 5 bp of DNA at the -50 position of a eukaryotic gene decreases the rate of RNA polymerase II transcription initiation to a greater extent than inserting 10 bp at the same site.
26. The RNA polymerase from bacteriophage T7 differs structurally from prokaryotic and eukaryotic RNAPs and is extremely specific for its own promoter. Why do these properties make T7 RNAP useful in experiments with recombinant DNA?
27. TFIIB appears to interact with proteins that bind to sequences at the 3' end of genes. Explain how this interaction could enhance transcription of a gene.
28. Human cells contain a protein that binds to the 5' triphosphate groups of RNA. Explain why this protein would be part of the defense against viral infection.
29. If an enhancer is placed on one plasmid and its corresponding promoter is placed on a second plasmid that is catenated (linked) with the first, initiation is almost as efficient as when the enhancer and promoter are on the same plasmid. However, initiation does not occur when the two plasmids are unlinked. Explain.
30. Why aren't primary rRNA transcripts present in wild-type *E. coli*?

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1 Viewing and Analyzing RNA Polymerase

Exercise 2 RNA Polymerase, Transcription, and the KEGG Database

MORE TO EXPLORE A so-called gene trap vector is engineered to include a reporter gene flanked by a splice acceptor sequence and a polyadenylation signal. How is this vector used to reveal patterns of gene expression in mammalian cells? Why does the gene trapping method depend on the size of a gene's introns? How is the trapped gene identified?

CHAPTER 27

Protein Synthesis

Chapter Contents

1 The Genetic Code

- A Codons Are Triplets That Are Read Sequentially
- B The Genetic Code Was Systematically Deciphered
- C The Genetic Code Is Degenerate and Nonrandom

2 Transfer RNA and Its Aminoacylation

- A All tRNAs Have Similar Structures
- B Aminoacyl-tRNA Synthetases Attach Amino Acids to tRNAs
- C Most tRNAs Recognize More than One Codon

3 Ribosomes

- A The Prokaryotic Ribosome Consists of Two Subunits
- B The Eukaryotic Ribosome Contains a Buried Prokaryotic Ribosome

4 Translation

- A Chain Initiation Requires an Initiator tRNA and Initiation Factors
- B The Ribosome Decodes the mRNA, Catalyzes Peptide Bond Formation, Then Moves to the Next Codon
- C Release Factors Terminate Translation

5 Posttranslational Processing

- A Ribosome-Associated Chaperones Help Proteins Fold
- B Newly Synthesized Proteins May Be Covalently Modified

Dichroa febrifuga has a long history of medicinal use in Asia. A drug derived from this plant acts against the malaria parasite, *Plasmodium falciparum*, by inhibiting the enzyme that attaches proline to its tRNA. The resulting accumulation of uncharged tRNAs slows the growth of the parasitic cells.

How is the genetic information encoded in DNA decoded? In the preceding chapter, we saw how the base sequence of DNA is transcribed into that of RNA. In this chapter, we consider the remainder of the decoding process by examining how the base sequences of RNAs are translated into the amino acid sequences of proteins. This second part of the central dogma of molecular biology (DNA → RNA → protein) shares a number of features with both DNA replication and transcription, the other major events of nucleic acid metabolism. First, all three processes are carried out by large, complicated protein-containing macromolecular machines whose proper functioning depends on a variety of specific and nonspecific protein–nucleic acid interactions. Accessory factors are also required for the initiation, elongation, and termination phases of these processes. Furthermore, translation, like replication and transcription, must be executed with accuracy. Although translation involves base pairing between complementary nucleotides, it is amino acids, rather than nucleotides, that are ultimately joined to generate a polymeric product. This process, like replication and transcription, is endergonic and must be driven by the cleavage of “high-energy” phosphoanhydride bonds.

An understanding of translation requires not only a knowledge of the macromolecules that participate in polypeptide synthesis, but also an appreciation for the mechanisms that produce a chain of linked amino acids in the exact order specified by mRNA. Accordingly, we begin this chapter by examining the **genetic code**, the correspondence between nucleic acid sequences and polypeptide sequences. We then consider in turn the structures and properties of tRNAs and ribosomes. Next, we examine how the translation machinery operates as a coordinated whole. Finally, we take a brief look at some posttranslational steps of protein synthesis.

GATEWAY CONCEPT The Central Dogma

During the final step of the central dogma of molecular biology, a ribosome uses the information encoded in a messenger RNA molecule to synthesize a polypeptide chain. In this way, a sequence of nucleotides (the first language) is translated to a sequence of amino acids (the second language).

1 The Genetic Code

KEY CONCEPTS

- The genetic code is based on sets of three-nucleotide codons that are read sequentially.
- Each codon represents one amino acid or a Stop signal.
- The genetic code is degenerate, nonrandom, and nearly universal.

One of the most fascinating puzzles in molecular biology is how a sequence of nucleotides composed of only four types of residues can specify the sequence of up to 20 types of amino acids in a polypeptide chain. Clearly, a one-to-one correspondence between nucleotides and amino acids is not possible. A *group of several bases, termed a **codon**, is necessary to specify a single amino acid.* A triplet code—that is, one with 3 bases per codon—is more than sufficient to specify all the amino acids since there are $4^3 = 64$ different triplets of bases. A doublet code with 2 bases per codon ($4^2 = 16$ possible doublets) would be inadequate. The triplet code allows many amino acids to be specified by more than one codon. Such a code, in a term borrowed from mathematics, is said to be **degenerate**.

How does the polypeptide-synthesizing apparatus group DNA's continuous sequences of bases into codons? For example, the code might be overlapping; that is, in the sequence

ABCDEFGHIJ...

ABC might code for one amino acid, BCD for a second, CDE for a third, etc. Alternatively, the code might be nonoverlapping, so that ABC specifies one amino acid, DEF a second, GHI a third, etc. In fact, *the genetic code is a nonoverlapping, degenerate, triplet code.* A number of elegant experiments, some of which are outlined below, revealed the workings of the genetic code.

A Codons Are Triplets That Are Read Sequentially

In genetic experiments on bacteriophage T4, Francis Crick and Sydney Brenner found that a mutation that resulted in the deletion of a nucleotide could abolish the function of a specific gene. However, a second mutation, in which a nucleotide was inserted at a different but nearby position, could restore gene function. The two mutations are said to be **suppressors** of one another; that is, they cancel each other's mutant properties. On the basis of these experiments, Crick and Brenner concluded that *the genetic code is read in a sequential manner starting from a fixed point in the gene.* The insertion or deletion of a nucleotide shifts the **reading frame** (grouping) in which succeeding nucleotides are read as codons. Insertions or deletions of nucleotides are therefore known as **frameshift mutations**.

In further experiments, Crick and Brenner found that whereas two closely spaced deletions or two closely spaced insertions could not suppress each other (restore gene function), three closely spaced deletions or insertions could do so. These observations clearly established that *the genetic code is a triplet code.*

The foregoing principles are illustrated by the following analogy. Consider a sentence (gene) in which the words (codons) each consist of three letters (bases):

THE BIG RED FOX ATE THE EGG

Here, the spaces separating the words have no physical significance; they are present only to indicate the reading frame. The deletion of the fourth letter, which shifts the reading frame, changes the sentence to

THE IGR EDF OXA TET HEE GG

so that all words past the point of deletion are unintelligible (specify the wrong amino acids). An insertion of any letter, however, say an X in the ninth position,

THE IGR EDX FOX ATE THE EGG

restores the original reading frame. Consequently, only the words between the two changes (mutations) are altered. As in this example, such a sentence might still be intelligible (the gene could still specify a functional protein), particularly if the changes are close together. Two deletions or two insertions, no matter how close together, would not suppress each other but just shift the reading frame. However, three insertions, say X, Y, and Z in the fifth, eighth, and twelfth positions, respectively, would change the sentence to

THE BXI GYR EDZ FOX ATE THE EGG

which, after the third insertion, restores the original reading frame. The same would be true of three deletions. As before, if all three changes were close together, the sentence might still retain its meaning. Like this textual analogy, *the genetic code has no internal punctuation to indicate the reading frame; instead, the nucleotide sequence is read sequentially, triplet by triplet.*

Since any nucleotide sequence may have three reading frames, it is possible, at least in principle, for a polynucleotide to encode two or even three different polypeptides. In fact, some single-stranded DNA bacteriophages (which presumably must make maximal use of their small complement of DNA) contain completely overlapping genes that have different reading frames. A similar form of coding economy is exhibited by bacteria, in which the ribosomal initiation sequence of one gene in a polycistronic mRNA often overlaps the end of the preceding gene.

B The Genetic Code Was Systematically Deciphered

In order to understand how the genetic code dictionary was elucidated, we must first review how proteins are synthesized. An mRNA does not directly recognize amino acids. Rather, *it specifically binds molecules of tRNA that each carry a corresponding amino acid* (Fig. 27-1). Each tRNA contains a trinucleotide sequence, its **anticodon**, that is complementary to an mRNA codon specifying the tRNA's amino acid. During translation, amino acids carried by tRNAs are joined together according to the order in which the tRNA anticodons bind to the mRNA codons at the ribosome (Fig. 3-13).

FIG. 27-1 Transfer RNA in its “cloverleaf” form. Its covalently linked amino acid residue is at the top, and its anticodon (X-Y-Z, a trinucleotide segment that base-pairs with the complementary mRNA codon during translation) is at the bottom.

? Explain why an anticodon sequence is written 3' → 5' rather than 5' → 3'.

The genetic code could, in principle, be determined by simply comparing the base sequence of an mRNA with the amino acid sequence of the polypeptide it specifies. In the 1960s, however, techniques for isolating and sequencing mRNAs had not yet been developed. Moreover, techniques for synthesizing RNAs were quite rudimentary. They utilized **polynucleotide phosphorylase**, an enzyme from *Azotobacter vinelandii* that links together nucleotides without the use of a template.

Thus, the NDPs are linked together at random so the base composition of the product RNA reflects that of the reactant NDP mixture. (The discovery of polynucleotide phosphorylase in 1951 by Severo Ochoa generated intense interest because it was presumed to be the enzyme that transcribes DNA to RNA—that is, an RNA polymerase.) The elucidation of the genetic code therefore proved to be a difficult task, even with the development of cell-free translation systems.

E. coli cells that have been gently broken open and centrifuged to remove cell walls and membranes yield an extract containing DNA, mRNA, ribosomes, enzymes, and other cell constituents necessary for protein synthesis. When fortified with ATP, GTP, and amino acids, this system synthesizes small amounts of protein. A cell-free translation system, of course, produces proteins specified by the cell's DNA. Adding DNase halts protein synthesis after a few minutes because the system can no longer synthesize mRNA, and the mRNA originally present is rapidly degraded. At this point, purified mRNA or synthetic mRNA can be added to the system and the resulting polypeptide products can be subsequently recovered.

In 1961, Marshall Nirenberg and Heinrich Matthaei added the synthetic polyribonucleotide poly(U) to a cell-free translation system containing isotopically labeled amino acids and recovered a labeled poly(Phe) polypeptide. They concluded that *UUU must be the codon that specifies Phe*. Similar experiments with poly(A) and poly(C) yielded poly(Lys) and poly(Pro), respectively, thereby identifying AAA as a codon for Lys and CCC as a codon for Pro [poly(G) could not be used because it is insoluble in aqueous solution].

In another series of experiments, different trinucleotides were tested for their ability to promote tRNA binding to ribosomes. The ribosomes, with their bound tRNAs, are retained by a nitrocellulose filter, but free tRNAs are not. The bound tRNA can be identified by the radioactive amino acid attached to it. This simple binding assay revealed that, for instance, UUU stimulates the ribosomal binding of only Phe tRNA. Likewise, UUG, UGU, and GUU stimulate the binding of Leu, Cys, and Val tRNAs, respectively. Hence UUG, UGU, and GUU must be codons that specify Leu, Cys, and Val, respectively. In this way, the amino acids specified by some 50 codons were identified. For the remaining codons, the binding assay was either negative (no tRNA bound) or ambiguous.

The genetic code dictionary was completed and previous results confirmed through H. Gobind Khorana's chemical synthesis of polynucleotides with specified repeating sequences (at the time, an extremely laborious process). In a cell-free translation system, UCUCUCUC ..., for example, is read

so it specifies a polypeptide chain of two alternating amino acid residues. This particular mRNA stimulated the production of

since UCU codes for Ser and CUC codes for Leu.

Alternating sequences of three nucleotides, such as poly(UAC), specify three different homopolypeptides because ribosomes may initiate polypeptide synthesis on these synthetic mRNAs in any of the three possible reading frames (Fig. 27-2). Analyses of the polypeptides specified by various alternating sequences of two and three nucleotides confirmed the identify of many codons and filled out missing portions of the genetic code.

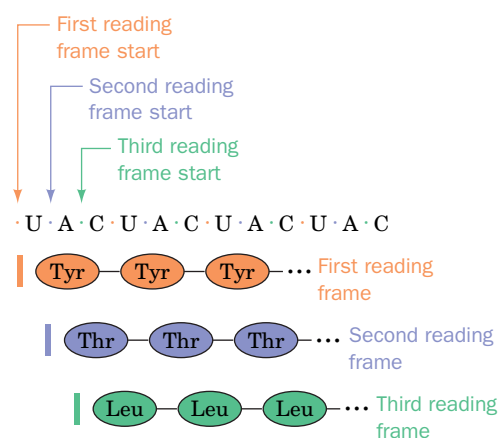

FIG. 27-2 The three potential reading frames of an mRNA. Each reading frame would yield a different polypeptide.

As we shall see in Section 27-4A, the initiation of polypeptide synthesis *in vivo* is a complex process that requires specific mRNA sequences. The foregoing experiments worked only because the cell-free translation systems that were used serendipitously had unphysiologically high concentrations of Mg^{2+} .

C The Genetic Code Is Degenerate and Nonrandom

The genetic code, presented in Table 27-1, has several remarkable features:

1. *The code is highly degenerate.* Three amino acids—Arg, Leu, and Ser—are each specified by six different codons, and most of the rest are specified by either four, three, or two codons. Only Met and Trp, two of the least common amino acids in proteins (Table 4-1), are represented by a single codon. Codons that specify the same amino acid are termed **synonyms**.
2. *The arrangement of the code table is nonrandom.* Most synonyms occupy the same box in Table 27-1; that is, they differ only in their third nucleotide. XYU and XYC always specify the same amino acid; XYA and XYG do so in all but two cases. Moreover, changes in the first codon position tend to specify similar (if not the same) amino acids, whereas codons with second position pyrimidines encode mostly hydrophobic amino acids (gold in Table 27-1), and those with second position purines encode mostly polar amino acids (blue, red, and purple in Table 27-1). These observations suggest a nonrandom origin of the genetic code and indicate that the code evolved so as to minimize the deleterious effects of mutations (see Box 27-1).
3. *UAG, UAA, and UGA are Stop codons.* These three codons (also known as **nonsense codons**) do not specify amino acids but signal the ribosome to terminate polypeptide chain elongation.
4. *AUG and GUG are Start codons.* The codons AUG and, less frequently, GUG specify the starting point for polypeptide chain synthesis. However,

Box 27-1 Perspectives in Biochemistry

Evolution of the Genetic Code

Because of the degeneracy of the genetic code, a point mutation in the third position of a codon seldom alters the specified amino acid. For example, a GUU → GUA transversion still codes for Val and is therefore said to be phenotypically silent. Other point mutations, even at the first or second codon positions, producing AUU (Ile) or GCU (Ala), for instance, result in the substitution of a chemically similar amino acid and may have minimal impact on the encoded protein's overall structure or function. This built-in protection against mutation may be more than accidental.

In the 1960s, the perceived universality of the genetic code led Francis Crick to propose the “frozen accident” theory, which holds that codons were allocated to different amino acids entirely by chance. Once assigned, the meaning of a codon could not change because of the high probability of disrupting the structure of the encoded protein. Thus, once established, the genetic code was thought to have ceased evolving.

However, the distribution of codons as presented in Table 27-1 suggests an alternative evolutionary history of the genetic code, in which a few simple codons corresponding to a handful of amino acids gradually became more complex. One scenario begins with an RNA-based world containing only A and U nucleotides. Uracil is almost certainly a primordial base since the pyrimidine biosynthetic pathway yields uracil nucleotides before cytosine or thymine nucleotides (Section 23-2). Adenine would have been required as uracil's complement.

Assuming that a triplet-based genetic code was established at the outset (and it is difficult to envision how any other arrangement could

have given rise to the present-day triplet code), the two bases could have coded for $2^3 = 8$ amino acids. In fact, the contemporary genetic code assigns these all-U/A codons to six amino acids and a stop signal:

UUU = Phe	AAA = Lys
UUA = Leu	AAU = Asn
UAU = Tyr	AUA = Ile
AUU = Ile	UAA = Stop

The AUA codon may well have originally specified the initiating Met (now encoded by AUG), bringing the total to seven amino acids.

When G and C appeared in evolving life-forms, these nucleotides were incorporated into RNA. Codons containing three or four types of bases could specify additional amino acids, but because of selective pressure against introducing disruptive mutations into proteins, the level of codon redundancy increased. An inspection of Table 27-1 shows that triplet codons made entirely of G and C specify only four different amino acids, which is half the theoretical maximum of eight:

GGG, GGC = Gly
GCG, GCC = Ala
CGG, CGC = Arg
CCC, CCG = Pro

This nonrandom allocation of codons to amino acids argues against a completely random origin for the genetic code. The gradual introduction of two new bases (G and C) to a primitive genetic code based on U and A must have allowed greater information capacity (i.e., coding for 20 amino acids) while minimizing the rate of deleterious substitutions.

they also specify the amino acids Met and Val, respectively, at internal positions in polypeptide chains. We will see in Section 27-4A how ribosomes differentiate the two types of codons.

TABLE 27-1 The “Standard” Genetic Code^a

^aNonpolar amino acid residues are gold, basic residues are blue, acidic residues are red, and polar uncharged residues are purple.

^bAUG forms part of the initiation signal as well as coding for internal Met residues.

? What are the consensus nucleotides in the codons for each colored grouping of amino acids?

CHECKPOINT

- Why do frameshift mutations occur with the insertion or deletion of one or two, but not three, nucleotides?
- Describe how the “meaning” of each codon was determined.
- Why must a polypeptide sequence begin with a designated Start codon?
- Explain why codons must consist of at least three nucleotides.
- Which codons serve as punctuation signals?

The “Standard” Genetic Code Is Almost Universal. For many years, it was thought that the “standard” genetic code (that given in Table 27-1) was universal. This assumption was based in part on the observation that one kind of organism (e.g., *E. coli*) can accurately translate the genes for quite different organisms (e.g., humans). Indeed, this phenomenon is the basis of genetic engineering and provides compelling evidence that all current life forms evolved from a common ancestor that employed the “standard” genetic code. DNA studies in 1981 nevertheless revealed that *the genetic codes of certain mitochondria are variants of the “standard” genetic code*. For example, in mammalian mitochondria, AUA, as well as the standard AUG, is a Met/initiation codon; UGA specifies Trp rather than “Stop”; and AGA and AGG are “Stop” rather than Arg. Apparently, mitochondria, which contain their own genes (although only 13 protein-encoding genes; Section 18-1A) and protein-synthesizing systems, are not subject to the same evolutionary constraints as are nuclear genomes (which contain many thousands of protein-encoding genes). An alternate genetic code also appears to have evolved in ciliated protozoa, which branched off very early in eukaryotic evolution. Thus, the “standard” genetic code, although very widely utilized, is not quite universal.

2 Transfer RNA and Its Aminoacylation

KEY CONCEPTS

- tRNA molecules have a characteristic structure.
- An aminoacyl-tRNA synthetase charges each tRNA with the appropriate amino acid.
- The wobble hypothesis explains the ability of a tRNA to recognize more than one codon.

Cells must translate the language of RNA base sequences into the language of polypeptides. In 1955, Crick hypothesized that translation occurs through the mediation of “adaptor” molecules, which we now know are tRNAs that carry a specific amino acid and recognize the corresponding mRNA codon.

A All tRNAs Have Similar Structures

In 1965, after a 7-year effort, Robert Holley reported the first known base sequence of a biologically significant nucleic acid, that of the 76-residue yeast **alanine tRNA (tRNA^{Ala})**. Currently, the base sequences of many thousands of tRNAs from nearly 800 organisms and organelles are known (most from their DNA sequences). They vary in length from 54 to 100 nucleotides (18–28 kD) although most have ~76 nucleotides.

Almost all known tRNAs can be schematically arranged in the so-called cloverleaf secondary structure (**Fig. 27-3**). Starting from the 5′ end, they have the following common features:

1. A 5′-terminal phosphate group.
2. A 7-bp stem that includes the 5′-terminal nucleotide and that may contain non-Watson–Crick base pairs such as G · U. This assembly is known as the **acceptor** or **amino acid stem** because the amino acid residue carried by the tRNA is covalently attached to its 3′-terminal OH group.
3. A 3- or 4-bp stem ending in a 5- to 7-nt loop that frequently contains the modified base **dihydrouridine (D)**. This stem and loop are therefore collectively termed the **D arm**.
4. A 5-bp stem ending in a loop that contains the anticodon. These features are known as the **anticodon arm**.
5. A 5-bp stem ending in a loop that usually contains the sequence TψC (where ψ is the symbol for **pseudouridine**; Section 26-3C). This assembly is called the **TψC** or **T arm**.

FIG. 27-3 The cloverleaf secondary structure of tRNA. Filled circles connected by dots represent Watson–Crick base pairs, and open circles indicate bases involved in non-Watson–Crick base pairing. Invariant positions are indicated: R and Y represent invariant purines and pyrimidines, and ψ represents pseudouridine. The starred nucleotides are often modified. The D and variable arms contain different numbers of nucleotides in the various tRNAs.

6. A 3' CCA sequence with a free 3'-OH group. The —CCA may be genetically specified or enzymatically added to immature tRNA, depending on the species (Section 26-3D).

tRNAs have 15 invariant positions (always have the same base) and 8 **semi-invariant** positions (only a purine or only a pyrimidine) that occur mostly in the loop regions. The purine on the 3' side of the anticodon is invariably modified. The site of greatest variability among the known tRNAs occurs in the so-called **variable arm**. It has from 3 to 21 nucleotides and may have a stem consisting of up to 7 bp.

tRNAs Have Numerous Modified Bases. One of the most striking characteristics of tRNAs is their large proportion, up to 25%, of posttranscriptionally modified bases. Nearly 80 such bases, found at >60 different tRNA positions, have been characterized. A few of them, together with their standard abbreviations, are indicated in Fig. 27-4. None of these modifications is essential for maintaining a tRNA's structural integrity or for its proper binding to the ribosome. However, base modifications may help promote attachment of the proper amino acid to the acceptor stem or strengthen codon–anticodon interactions.

tRNAs Have a Complex Tertiary Structure. As described in Section 24-2C, all tRNA molecules have an L-shape in which the acceptor and T stems form one leg

may also be methylated at their ribose 2' positions to form residues symbolized, for instance, by Cm, Gm, and Um.

? Which of these modifications is likely to affect a nucleotide's ability to form standard base pairs?

FIG. 27-5 The structure of yeast tRNA^{Phe}. (a) The base sequence drawn in cloverleaf form. Tertiary base-pairing interactions are represented by thin red lines connecting the participating bases. Bases that are conserved or semiconserved in all tRNAs are circled by solid and dashed lines, respectively. The 5' terminus is colored bright green, the acceptor stem is yellow, the D arm is white, the anticodon arm is light green, the

variable arm is orange, the TψC arm is cyan, and the 3' terminus is red. (b) The X-ray structure drawn to show how its base-paired stems form an L-shaped molecule. The tRNA is drawn in stick form with C atoms colored as in Part a, N blue, and O red. Adjacent P atoms are connected by rods colored as in Part a. [Based on an X-ray structure by Sung-Hou Kim, PDBid 6TRNA.]

? Why is it important for the anticodon bases not to form intramolecular base pairs?

and the D and anticodon stems form the other (Fig. 27-5). Each leg of the L is ~ 60 Å long and the anticodon and amino acid acceptor sites are at opposite ends of the molecule, some 76 Å apart. The narrow 20- to 25-Å width of tRNA is essential to its biological function: During protein synthesis, three tRNA molecules must simultaneously bind in close proximity at adjacent codons on mRNA (Section 27-4B).

A tRNA's complex tertiary structure is maintained by extensive stacking interactions and base pairing within and between its helical stems. Many of the tertiary base-pairing interactions are non-Watson-Crick associations. Moreover, most of the bases involved in these interactions are either invariant or semi-invariant, consistent with the observation that all tRNAs have similar structures. This is a necessity because all tRNAs interact with ribosomes in similar ways. A tRNA's compact structure renders most of its bases inaccessible to solvent, much like the interior of a protein. The most notable exceptions are the anticodon bases and those of the amino acid-bearing —CCA terminus. Both of these groupings must be accessible in order to carry out their biological functions.

B Aminoacyl-tRNA Synthetases Attach Amino Acids to tRNAs

Ribosomes, as we shall see, cannot distinguish as to whether a correct or incorrect amino acid group is linked to a tRNA. Therefore, accurate translation requires two equally important recognition steps:

1. The correct amino acid must be selected for covalent attachment to a tRNA by an **aminoacyl-tRNA synthetase** (discussed below).

- The correct **aminoacyl-tRNA (aa-tRNA)** must pair with an mRNA codon at the ribosome (discussed in Section 27-4B).

An amino acid-specific aminoacyl-tRNA synthetase (**aaRS**) appends an amino acid to the 3'-terminal ribose residue of its cognate tRNA to form an **aa-tRNA** (Fig. 27-6). Aminoacylation occurs in two sequential reactions that are catalyzed by a single enzyme.

- The amino acid is first "activated" by its reaction with ATP to form an **aminoacyl-adenylate**,

which, with all but three aaRSs, can occur in the absence of tRNA. Indeed, this intermediate can be isolated, although it normally remains tightly bound to the enzyme.

- The mixed anhydride then reacts with tRNA to form the aa-tRNA:

The overall aminoacylation reaction

is driven to completion by the hydrolysis of the PP_i generated in the first reaction step. The aa-tRNA product is a "high-energy" compound (Section 14-2A); for this reason, the amino acid is said to be "activated" and the tRNA is said to be "charged." Amino acid activation resembles fatty acid activation (Section 20-2A); the major difference is that tRNA is the acyl acceptor in amino acid activation whereas CoA performs the function in fatty acid activation.

There Are Two Classes of Aminoacyl-tRNA Synthetases. Most cells have at least one aaRS for each of the 20 amino acids. The similarity of the reaction catalyzed by these enzymes and the structural similarities among tRNAs suggest that all aaRSs evolved from a common ancestor and should therefore be structurally related. This is not the case. In fact, *the aaRSs form a diverse group of enzymes with different sizes and quaternary structures and little sequence similarity*. Nevertheless, these enzymes can be grouped into two classes that each have the same 10 members in nearly all organisms (Table 27-2). **Class I** and **Class II aminoacyl-tRNA synthetases** differ in several ways:

- Structural motifs.** The Class I enzymes share two homologous polypeptide segments that are components of a dinucleotide-binding fold (Rossmann fold, which is also present in many NAD^+ - and ATP-binding proteins; Section 6-2C). The Class II synthetases lack the foregoing sequences but have three other sequences in common.
- Anticodon recognition.** Many Class I aaRSs must recognize the anticodon to aminoacylate their cognate tRNAs. In contrast, several Class II enzymes do not interact with their bound tRNA's anticodon.
- Site of aminoacylation.** All Class I enzymes aminoacylate their bound tRNA's 3'-terminal 2'-OH group, whereas Class II enzymes charge the 3'-OH group. Nevertheless, an aminoacyl group attached at the 2' position rapidly equilibrates between the 2' and 3' positions (it must be at the 3' position to take part in protein synthesis).
- Amino acid specificity.** The amino acids for which the Class I synthetases are specific tend to be larger and more hydrophobic than those for Class II synthetases.

FIG. 27-6 An aminoacyl-tRNA. The amino acid residue is esterified to the tRNA's 3'-terminal nucleotide at either its 3'-OH group, as shown here, or its 2'-OH group.

FIG. 27-7 Experimentally observed identity elements of tRNAs. The tRNA backbone is cyan, and each of its nucleotides is represented by a yellow circle whose diameter is proportional to the fraction of the various tRNA acceptor types for which the nucleotide is an identity element for aaRS recognition.

Aminoacyl-tRNA Synthetases Recognize Unique Structural Features of tRNA. How does an aaRS recognize a tRNA so that it can be charged with the proper amino acid? First, all tRNAs have similar structures, so the features that differentiate them must be subtle variations in sequence or local structure. On the other hand, since the genetic code is degenerate, more than one tRNA may carry a given amino acid. The members of each set of these so-called **isoaccepting tRNAs** must all be recognized by their cognate aaRS. Finally, the tRNA must be charged with only the amino acid that corresponds to its anticodon, and not any of the 19 other amino acids.

Clues to the specificity of synthetase-tRNA interactions have been gleaned from studies using tRNA fragments, mutationally altered tRNAs, chemical cross-linking agents, computerized sequence comparisons, and X-ray crystallography. When the experimentally determined synthetase contact sites, or **identity elements**, for a variety of tRNAs are mapped onto a three-dimensional model of a tRNA molecule, they cluster in the acceptor stem, the anticodon loop, and other points on the inner (concave) face of the L (**Fig. 27-7**). For example, the identity element for *E. coli* tRNA^{Ala} is its G3 · U70 non-Watson-Crick base pair, which is located in its acceptor stem. However, there appears to be little regularity in how the synthetases recognize their cognate tRNAs (the identity elements of most tRNAs have more than two bases), and many enzyme-tRNA interactions do not involve the anticodon at all. Nevertheless, since the correct binding of a tRNA to its corresponding aaRS is as important to accurate translation as is the ribosomal selection of the correct aa-tRNA, the tRNA identity elements are collectively referred to as comprising a second genetic code.

Synthetases that do interact with both the anticodon and the acceptor stem must have a size and structure adequate to bind both legs of the L-shaped tRNA. This is evident in the complex of *E. coli* **glutaminyl-tRNA synthetase (GlnRS)** with tRNA^{Gln} and ATP (**Fig. 27-8**), determined by Thomas Steitz, the first such structure to be elucidated. GlnRS, a 553-residue monomeric Class I enzyme, has an elongated shape so that it binds the anticodon near one end of the protein and the acceptor stem near the other. Genetic and biochemical data indicate that the identity elements for tRNA^{Gln} include all seven bases of the anticodon loop. The bases of the anticodon itself are unstacked and splay outward so as to bind in separate recognition pockets of GlnRS. The 3' end of tRNA^{Gln} plunges deeply into a protein pocket that also binds the enzyme's ATP and glutamine substrates.

Yeast **AspRS**, a Class II enzyme, is a homodimer of 557-residue subunits. Its X-ray structure in complex with tRNA^{Asp}, determined by Dino Moras, reveals that the protein symmetrically binds two tRNA molecules by contacting them principally at their acceptor stem and anticodon regions (**Fig. 27-9**). The anticodon arm of tRNA^{Asp} is bent by as much as 20 Å toward the inside of the L relative to that in the X-ray structure of uncomplexed tRNA^{Asp}, and its anticodon bases are unstacked. The hinge point for the bend is a G30 · U40 base pair in the anticodon stem (nearly all other species of tRNA contain a Watson-Crick base pair at that point). The anticodon bases of tRNA^{Gln} are also unstacked in contacting GlnRS but with a backbone conformation that differs from that in tRNA^{Asp}. Evidently, the conformation of a tRNA in complex with its cognate synthetase is dictated more by its interactions with the protein (induced fit) than by its sequence. This is perhaps one reason why *the members of each set of isoaccepting tRNAs in a cell are recognized by a single aaRS*.

The different modes of tRNA binding by GlnRS and AspRS can be seen by comparing Figs. 27-8 and 27-9. Although both tRNAs approach their synthetases

FIG. 27-8 X-Ray structure of *E. coli* GlnRS · tRNA^{Gln} · ATP. The ATP bound in the protein's active site is drawn in space-filling form with C green, N blue, O red, and P orange. The tRNA is drawn in stick form colored as the ATP but with the C atoms of the anticodon (UCG) and the 3'-CCA end yellow. An orange rod links its successive P atoms. The protein is represented by a semitransparent lavender surface diagram that reveals the buried portions of the tRNA and ATP. Note that both the 3' end of the tRNA (*top right*) and its anticodon bases (*bottom*) are inserted into deep pockets in the protein. [Based on an X-ray structure by Thomas Steitz, Yale University. ? Locate the anticodon and 3' end of each tRNA.

along the inside of the L shapes, tRNA^{Gln} does so from the direction of the minor groove of its acceptor stem, whereas tRNA^{Asp} does so from the direction of its major groove. The 3' end of tRNA^{Asp} thereby continues its helical track as it plunges into AspRS's catalytic site, whereas the 3' end of tRNA^{Gln} bends backward into a hairpin turn as it enters its active site. These structural differences account for the observation that Class I and Class II enzymes aminoacylate different OH groups on the 3' terminal ribose of tRNA.

Proofreading Enhances the Fidelity of Amino Acid Attachment to tRNA. The charging of a tRNA with its cognate amino acid is a remarkably accurate process. Experimental measurements indicate, for example, that at equal concentrations of isoleucine and valine, **IleRS** transfers ~40,000 isoleucines to tRNA^{Ile} for every valine it so transfers. This high degree of accuracy is surprising because valine, which differs from isoleucine only by the lack of a single methylene group, should fit easily into the isoleucine-binding site of IleRS. The binding free energy of a methylene group is estimated to be ~12 kJ · mol⁻¹. Equation 1-17 indicates that the ratio f of the equilibrium constants, K_1 and K_2 , with which two substances bind to a particular site is given by

$$f = \frac{K_1}{K_2} = \frac{e^{-\Delta G_1^{\circ'}/RT}}{e^{-\Delta G_2^{\circ'}/RT}} = e^{-\Delta\Delta G^{\circ'}/RT} \quad [27-1]$$

where $\Delta\Delta G^{\circ'} = \Delta G_1^{\circ'} - \Delta G_2^{\circ'}$ is the difference between the free energies of binding of the two substances. It is therefore estimated that isoleucyl-tRNA synthetase could discriminate between isoleucine and valine by no more than a factor of ~100.

Paul Berg resolved this apparent paradox by demonstrating that, in the presence of tRNA^{Ile}, IleRS catalyzes the quantitative hydrolysis of valine-adenylate, the intermediate of the aminoacylation reaction, to valine + AMP rather than forming Val-tRNA^{Ile}. Thus, *isoleucyl-tRNA synthetase subjects aminoacyl-adenylates to a proofreading or editing step*, a process reminiscent of that carried out by DNA polymerase I (Section 25-2A).

IleRS has two active sites that operate as a double sieve. The first site activates isoleucine and the chemically similar valine. The second active site, which hydrolyzes aminoacylated tRNA^{Ile}, admits only aminoacyl groups that are smaller than isoleucine (i.e., Val-tRNA^{Ile}). The X-ray structure of a bacterial IleRS, a Class I enzyme, determined by Steitz, reveals that the protein contains an additional editing domain inserted into its dinucleotide-binding fold domain (**Fig. 27-10**). The 3' terminus of tRNA^{Ile} appears to shuttle between the aminoacylation and editing sites by a conformational change. *The combined selectivities of the aminoacylation and editing steps are responsible for the high fidelity of translation, a phenomenon that occurs at the expense of ATP hydrolysis.*

FIG. 27-10 X-Ray structure of *Staphylococcus aureus* isoleucyl-tRNA synthetase in complex with tRNA^{Ile}. The tRNA is white, the protein is colored by domain, and **mupirocin**, an antibiotic that binds to IleRS, is drawn in stick form in pink. The four terminal residues of the tRNA are labeled. The 3' terminus of the tRNA is positioned near the editing active site. PDBid 1QU2.

Other aminoacyl-tRNA synthetases discriminate against noncognate amino acids through a variety of noncovalent interactions. In **ValRS**, the side chain of Asp 279 protrudes into the editing active site, where it hydrogen-bonds with the hydroxyl group of threonine. The isosteric (having the same shape) valine lacks this hydroxyl group and is thereby excluded from the editing pocket. **ThrRS** has the opposite problem: It must synthesize Thr-tRNA^{Thr} but not Val-tRNA^{Thr}. Specificity is conferred by the aminoacylation site, which contains a Zn²⁺ ion that is coordinated by the side chain OH group of threonine. Valine cannot coordinate the Zn²⁺ in this way and hence does not undergo adenylation by ThrRS. A separate editing site deals with misacylated Ser-tRNA^{Thr}. **TyrRS** distinguishes between tyrosine and phenylalanine through hydrogen bonding with tyrosine's OH group. Since no other amino acid resembles tyrosine, the enzyme can do without an editing function.

Some Organisms Lack Certain aaRSs. Many bacteria lack the expected complement of 20 aminoacyl-tRNA synthetases. For example, GlnRS is absent in gram-positive bacteria, archaeobacteria, cyanobacteria, mitochondria, and chloroplasts. Instead, glutamate is linked to tRNA^{Gln} by the same GluRS that synthesizes Glu-tRNA^{Glu}. The resulting Glu-tRNA^{Gln} is then converted to Gln-tRNA^{Gln} by **Glu-tRNA^{Gln} amidotransferase** in an ATP-requiring reaction in which glutamine is the amide donor. Some microorganisms that lack **AsnRS** use a similar transamidation pathway for the synthesis of Asn-tRNA^{Asn} from Asp-tRNA^{Asn}.

Certain archaeobacteria lack a gene for **CysRS**. In these cells, Cys-tRNA^{Cys} is produced by a ProRS (called **ProCysRS**). Despite its unusual dual specificity, ProCysRS does not generate either Cys-tRNA^{Pro} or Pro-tRNA^{Cys}. This is because adenylation of Pro does not require the presence of tRNA^{Pro}, but the activation of Cys requires tRNA^{Cys}. Presumably, the binding of Pro-AMP or tRNA^{Cys} elicits conformational changes that are mutually exclusive.

C Most tRNAs Recognize More than One Codon

In protein synthesis, the proper tRNA is selected only through codon-anticodon interactions; the aminoacyl group does not participate in this process (this is one reason why accurate aminoacylation is critical for protein synthesis). The three nucleotides of an mRNA codon pair with the three nucleotides of a complementary tRNA anticodon in an antiparallel fashion. One might naively guess that each of the 61 codons specifying an amino acid would be read by a different tRNA. Yet even though most cells contain numerous groups of isoaccepting tRNAs, *many tRNAs bind to two or three of the codons specifying their cognate amino acids*. For example, yeast tRNA^{Phe}, which has the anticodon GmAA (where Gm indicates G with a 2'-methyl group), recognizes the codons UUC and UUU,

and yeast tRNA^{Ala}, which has the anticodon IGC (where I is inosine), recognizes the codons GCU, GCC, and GCA:

Evidently, non-Watson-Crick base pairing can occur at the third codon-anticodon position (the anticodon's first position is defined as its 3' nucleotide), the site of most codon degeneracy (Table 27-1). Note that the third (5') anticodon position commonly contains a modified base such as Gm or I.

FIG. 27-11 U · G and I · A wobble pairs. Both have been observed in X-ray structures.

TABLE 27-3 Allowed Wobble Pairing Combinations in the Third Codon–Anticodon Position

5'-Anticodon Base	3'-Codon Base
C	G
A	U
U	A or G
G	U or C
I	U, C, or A

The Wobble Hypothesis Accounts for Codon Degeneracy. By combining structural insight with logical deduction, Crick proposed the **wobble hypothesis** to explain how a tRNA can recognize several degenerate codons. He assumed that *the first two codon–anticodon pairings have normal Watson–Crick geometry and that there could be a small amount of play or “wobble” in the third anticodon position to allow limited conformational adjustments in its pairing geometry.* This permits the formation of several non-Watson–Crick pairs such as U · G and I · A (Fig. 27-11). The allowed pairings for the third codon–anticodon position are listed in Table 27-3. An anticodon with C or A in its third position can potentially pair only with its Watson–Crick complementary codon (although, in fact, there is no known instance of a tRNA with an A in its third anticodon position). If U or G occupies the third anticodon position, two codons can potentially be recognized. I at the third anticodon position can pair with U, C, or A.

A consideration of the various wobble pairings indicates that at least 31 tRNAs are required to translate all 61 coding triplets of the genetic code (there are 32 tRNAs in the minimal set because translation initiation requires a separate tRNA; Section 27-4A). Most cells have >32 tRNAs, some of which have identical anticodons. In fact, mammalian cells have >150 tRNAs. Some organisms contain unique tRNAs that are charged with unusual amino acids (Box 27-2).

Frequently Used Codons Are Complementary to the Most Abundant tRNA Species. The analysis of the base sequences of several highly expressed structural genes of baker’s yeast, *Saccharomyces cerevisiae*, has revealed a remarkable bias in their codon usage. Only 25 of the 61 coding triplets are commonly used. *The preferred codons are those that are most nearly complementary, in the Watson–Crick sense, to the anticodons in the most abundant species in each set of isoaccepting tRNAs.* A similar phenomenon occurs in *E. coli*, although several of its 22 preferred codons differ from those in yeast. Consequently, a gene’s level of expression is strongly correlated with the degree with which preferred codons occur in the gene. This has important ramifications for the synthesis of recombinant proteins: For the efficient expression of a recombinant protein, the site-directed mutation of its corresponding codons should be to codons that are abundant in the organism in which the protein is to be expressed. Alternatively, the organism can be engineered to overexpress the tRNAs for normally rare codons.

CHECKPOINT

- Describe the major structural features of tRNA.
- Why is it important for all tRNAs to have similar structures?
- How is ATP used to charge a tRNA?
- What features of tRNA structure are involved in recognition and aminoacylation by an aaRS?
- Why is proofreading necessary during aminoacylation?
- Describe how the double-sieve mechanism of IleRS promotes accurate tRNA aminoacylation.
- Why don’t cells need one tRNA for each codon?
- Which base pairings account for wobble at the third codon–anticodon position?

3. The ribosome mediates the interactions of nonribosomal protein factors that promote polypeptide chain initiation, elongation, and termination.
4. The ribosome catalyzes peptide bond formation.
5. The ribosome undergoes movement so that it can translate sequential codons.

In this section, we discuss the structure of the ribosome, beginning with the smaller and simpler prokaryotic ribosome and ending with the larger and more complicated eukaryotic ribosome.

A The Prokaryotic Ribosome Consists of Two Subunits

Ribosomal components are traditionally described in terms of their rate of sedimentation in an ultracentrifuge, which correlates roughly with their size (Section 5-2E). Thus, the intact *E. coli* ribosome has a sedimentation coefficient of 70S. As James Watson discovered, the ribosome can be dissociated into two unequal subunits (Table 27-4). The small (30S) subunit consists of a 16S rRNA molecule and 21 different proteins, whereas the large (50S) subunit contains a 5S and a 23S rRNA together with 31 different proteins. By convention, ribosomal proteins from the small and large subunits are designated with the prefixes S and L, respectively, followed by a number that roughly increases from the largest to the smallest. These proteins, which range in size from 46 to 557 residues, occur in only one copy per ribosome with the exception of L12, which is present in four copies. Most of these proteins, which exhibit little sequence similarity with one another, are rich in the basic amino acids Lys and Arg and contain few aromatic residues, as is expected for proteins that are closely associated with polyanionic RNA molecules. The up to 20,000 ribosomes in an *E. coli* cell account for ~80% of its RNA content and 10% of its protein.

Ribosomal RNAs Have Complicated Secondary Structures. The *E. coli* 16S rRNA, which was sequenced by Harry Noller, consists of 1542 nucleotides. A computerized search of this sequence for stable double-helical segments yielded many plausible but often mutually exclusive secondary structures. However, the comparison of the sequences of 16S rRNAs from several prokaryotes, under the assumption that their structures have been evolutionarily conserved, and more recently their 3-dimensional structures (see below), led to the flowerlike secondary structure for 16S rRNA seen in Fig. 27-12a. In this four-domain structure, which is 54% base paired, the double-helical stems tend to be short (<8 bp) and

TABLE 27-4 Components of *E. coli* Ribosomes

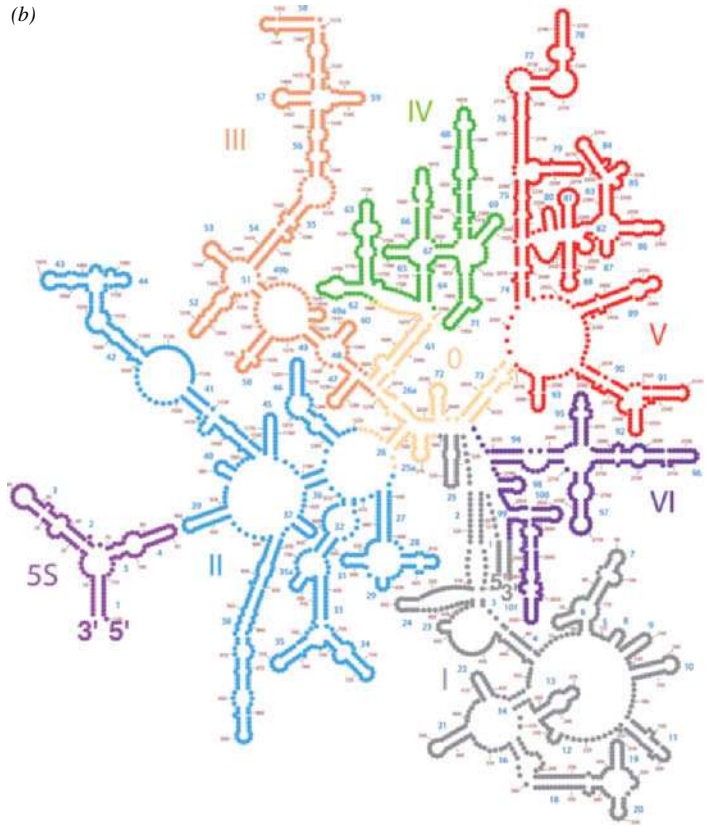

FIG. 27-12 Secondary structures of the *E. coli* ribosomal RNAs as determined from their three-dimensional structures. (a) 16S rRNA and (b) 23S and 5S rRNAs. The rRNAs are colored by domain. The stems, which contain Watson–Crick base pairs, G · U base pairs,

and other non-Watson–Crick base pairs, form flowerlike structures within each domain. The large numbers are helix identifiers and the small numbers are the nucleotide sequence numbers. [Modified from drawings by Loren Williams, Georgia Institute of Technology.]

many of them are imperfect. The large ribosomal subunit’s 5S and 23S rRNAs, which consist of 120 and 2904 nucleotides, respectively, also exhibit extensive secondary structures (Fig. 27-12b).

The Ribosome Has a Complex Three-Dimensional Structure. The structure of the ribosome began to come into focus through electron microscopy (EM; Fig. 27-13a) and later through cryoelectron microscopy (cryo-EM,

which is discussed in Section 6-2B). Cryo-EM studies, carried out largely by Joachim Frank, revealed that the ribosome has an irregular shape, about 250 Å across, with numerous lobes and bulges as well as channels and tunnels (Fig. 27-13b).

The fine structure of the ribosome was determined by X-ray crystallography, a landmark achievement owing to the enormous size of the particle. Ribosomal subunits were first crystallized by Ada Yonath in 1980, but it took another 20 years for improvements in crystal quality and technical advances in crystallography to meet the challenge of determining the X-ray structures of these gargantuan molecular complexes. In 2000, Peter Moore and Steitz reported the X-ray structure of the ~100,000-atom 50S ribosomal subunit of the halophilic (salt-loving) bacterium *Haloarcula marismortui* at atomic (2.4 Å) resolution, and shortly thereafter Venki Ramakrishnan and Yonath independently reported the X-ray structure of the 30S subunit of *T. thermophilus* at ~3 Å resolution. Since then, higher-resolution structures of the entire 70S ribosomes from *T. thermophilus* and *E. coli* have been obtained.

Prokaryotic ribosomes exhibit the following architectural features:

1. Both the 16S and 23S rRNAs are assemblies of helical elements connected by loops, most of which are irregular extensions of helices (Fig. 27-14). These structures, which are in close accord with previous secondary structure predictions, are stabilized by interactions between helices such as minor groove to minor groove packing (recall that A-form RNA has a very shallow minor groove); the insertion of a phosphate ridge into a minor groove; and the insertion of conserved adenines into minor grooves. Similar intramolecular interactions are observed in other complex RNA structures (e.g., Section 26-3C).
2. Each of the 16S rRNA's four domains, which extend out from a central junction (Fig. 27-12a), forms a morphologically distinct portion of the 30S subunit (Fig. 27-14a). In contrast, the 23S rRNA's seven domains (Fig. 27-12b) are intricately intertwined in the 50S subunit (Fig. 27-14b). Since the ribosomal proteins are embedded in the RNA (see below), this suggests that the domains of the 30S subunit can move relative to one another during protein synthesis, whereas the 50S subunit appears to be rigid.

FIG. 27-14 Tertiary structures of the ribosomal RNAs. (a) The 16S rRNA of *T. thermophilus*. (b) The 23S rRNA of *H. marismortui*. The rRNAs are colored according to domain as in Fig. 27-12. The interface view of a ribosomal subunit (left) shows the surface that associates with the other subunit in the whole ribosome and the back view (right) shows the opposite (solvent-exposed) side. Note that the secondary

structure domains of the 16S rRNA fold as separate tertiary structure domains, whereas in the 23S rRNA, the secondary structure domains are more intertwined. FIG. 27-15 Distribution of protein and RNA in the ribosomal subunits. (a) The 30S subunit of *T. thermophilus*. (b) The 50S subunit of *H. marismortui*. The subunits are drawn in space-filling form with their RNAs gray and their proteins in various colors. Note that the interface side of each subunit is largely free of protein. The globular portions of proteins are exposed on the surface of their associated subunit

(Fig. 27-16), whereas their extended segments are largely buried in the RNA. [Part a based on an X-ray structure by Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. Part b based on an X-ray structure by Peter Moore and Thomas Steitz, Yale University. PDBids 1J5E and 1JJ2.]

- The distribution of the proteins in the two ribosomal subunits is not uniform (Fig. 27-15). The vast majority of the ribosomal proteins are located on the back and sides of their subunits. In contrast, the face of each subunit that forms the interface between the two subunits, particularly the region that binds the tRNAs and mRNA (see below), is largely devoid of proteins.
- Most ribosomal proteins consist of a globular domain and a tail. However, there is no significant sequence identity between any of the various ribosomal proteins. The globular domain, when present, is located on a subunit surface (Fig. 27-15). The tail segment, which is largely devoid of secondary structure and unusually rich in basic residues, infiltrates between the RNA helices into the subunit interior (Fig. 27-16). These protein tails make far fewer base-specific interactions than do other known RNA-binding proteins. They tend to interact with the RNA through salt bridges between their positively charged side chains and the RNAs' negatively charged phosphate oxygen atoms, thereby neutralizing the repulsive charge-charge interactions between nearby RNA segments. The sequences of the corresponding ribosomal proteins in different organisms are conserved, but the sequences of these proteins' tails are more highly conserved than their attached globular domains. The functions of these proteins are largely unknown, although it seems likely that many of them have a structural role. All of this is consistent with the hypothesis that the primordial ribosome consisted entirely of RNA (the RNA world) and that the proteins that were eventually

FIG. 27-16 Backbone structures of selected ribosomal proteins. Globular portions of the proteins are green, and extended segments are red. [Courtesy of Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1J5E.]

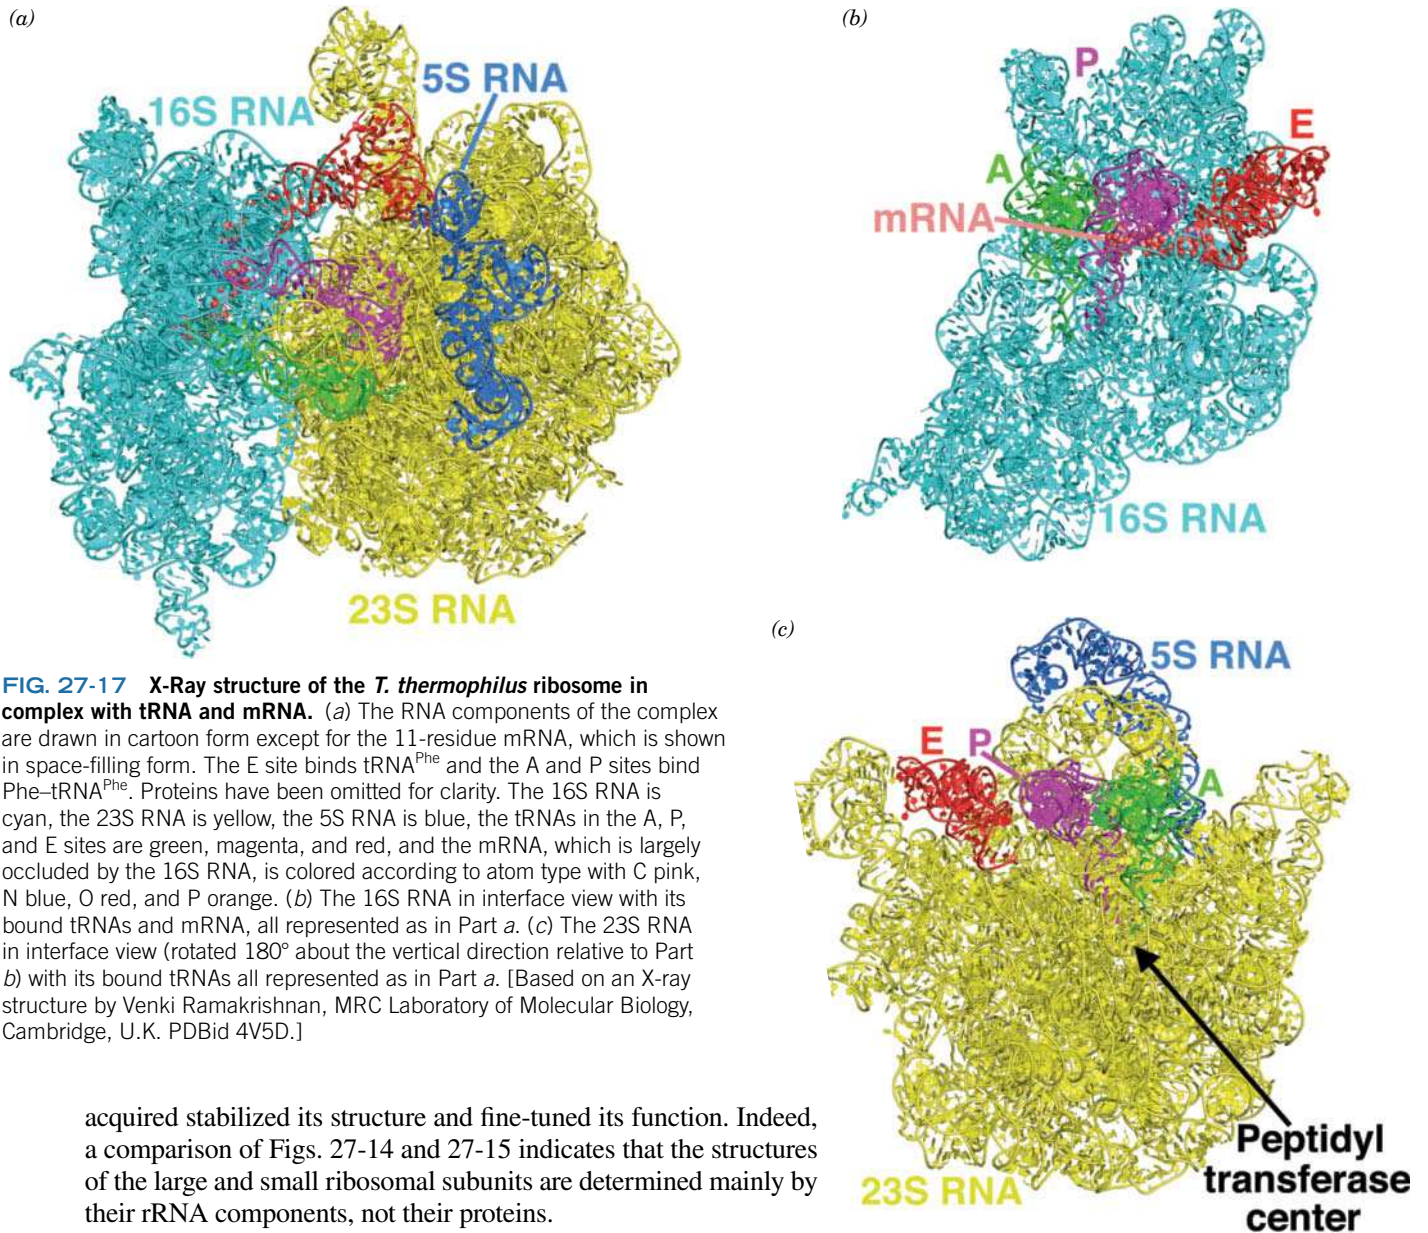

FIG. 27-18 The interactions of tRNAs with mRNA. These RNA structures are part of the ribosomal complex shown in Fig. 27-17. The RNAs are drawn in cartoon form with A-site C green, P-site C magenta, E-site C red, mRNA C pink, N blue, and O red and with successive P atoms connected by orange rods. The Phe residues appended to the A- and P-site tRNAs are represented in space-filling form. Note their close approach. [Based on an X-ray structure by Venki Ramakrishnan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 4V5D.]

? Identify the tRNAs that make close contact with the mRNA.

E or **exit site** (it accommodates a deacylated tRNA that is about to exit the ribosome). The ribosome binds all three tRNAs in a similar manner with their anticodon arms bound to the 30S subunit and their remaining portions bound to the 50S subunit (Fig. 27-17). These interactions, which consist mainly of RNA–RNA contacts, are made to the tRNAs’ universally conserved segments, thereby permitting the ribosome to bind different species of tRNAs in the same way. Nevertheless, the three bound tRNAs have slightly different conformations, with the A-site tRNA most closely resembling the X-ray structure of tRNA^{Phe} (Fig. 27-5b) and the E-site tRNA most distorted.

Only the A-site and P-site tRNAs interact closely with the mRNA through base pairing (Fig. 27-18). In the ribosomal complex, the acceptor ends of these two tRNAs are close together, a necessity for the peptidyl transferase reaction that takes place there.

The growing polypeptide fits into a tunnel on the 50S subunit that extends from the P site to the outer ribosomal surface (the tunnel is visible in Fig. 27-13b). The ~100-Å-long tunnel is lined with mostly hydrophilic residues and has an average diameter of ~15 Å. This is barely large enough to accommodate an α helix, so significant protein folding probably cannot occur until the polypeptide exits the ribosome.

B The Eukaryotic Ribosome Contains a Buried Prokaryotic Ribosome

Eukaryotic ribosomes have particle masses in the range 3.9 to 4.5×10^6 D, at least 40% larger than bacterial ribosomes, and have a nominal sedimentation coefficient of 80S. They dissociate into two unequal subunits, whose compositions are more complex than those of prokaryotes (Table 27-5; compare with Table 27-4). The small (**40S**) subunit of the rat liver cytoplasmic ribosome, a well-characterized eukaryotic ribosome, consists of 33 unique polypeptides and an **18S rRNA**. Its large (**60S**) subunit contains 49 different polypeptides and three rRNAs of 28S, 5.8S, and 5S. The additional complexity of the eukaryotic ribosome relative to its prokaryotic counterpart is presumably due to the eukaryotic ribosome’s additional functions: Its mechanism of translational initiation is more complicated (Section 27-4A); it must be transported from the nucleus, where it is assembled, to the cytoplasm, where translation occurs; and the machinery with which it participates in the secretory pathway is more complex (Section 9-4D).

Sequence comparisons of the corresponding rRNAs from various species indicate that evolution has conserved their secondary structures rather than their base sequences (Fig. 27-12). For example, a G · C in a base-paired stem of *E. coli* 16S rRNA has been replaced by an A · U in the analogous stem of yeast 18S

rRNA, a phenomenon termed **covariance**. The **5.8S rRNA**, a component of the large eukaryotic subunit that forms a base-paired complex with the **28S rRNA**, is homologous in sequence to the 5' end of prokaryotic 23S rRNA. Apparently 5.8S RNA arose through mutations that altered rRNA's posttranscriptional processing to produce a fourth rRNA.

The X-ray structure of the yeast 80S ribosome (**Fig. 27-19**) at near-atomic resolution was determined by Adam Ben-Shem and Marat Yusupov. The shape of the yeast ribosome reveals that there is a high degree of structural conservation between eukaryotic and prokaryotic ribosomes (compare Fig. 27-19 with Fig. 27-17*a*). The greater size and functional complexity of the eukaryotic ribosome is due to additional rRNA sequences called **expansion segments**, 25 proteins that have no prokaryotic counterparts, and extra polypeptide segments inserted into the conserved proteins. The expansion segments are inserted into the helices of the conserved core rRNAs in ways that do not change their conformations, and the proteins with no prokaryotic counterparts associate mainly with the expansion segments. The various sizes of eukaryotic ribosomes from different species are due largely to the differing sizes of four of the expansion segments.

CHECKPOINT

- Summarize the relationship between rRNA and the overall structure of the ribosome.
- Describe the distribution of proteins in the ribosomal subunits.
- Describe the positions and functions of the three tRNA-binding sites in the ribosome.
- Describe the similarities and differences between prokaryotic and eukaryotic ribosomes.

The expansion segments and additional proteins cluster mostly on the solvent-exposed surface of the eukaryotic ribosome rather than in the subunit interface. In essence, *the core of a eukaryotic ribosome is a prokaryotic ribosome that performs the basic processes of polypeptide synthesis* (described in Section 27-4). Moreover, phylogenetic analysis by Loren Williams revealed that 20% of prokaryotic rRNAs are universally conserved and 80% are covariantly conserved. Thus, since all cells contain ribosomes, *the ribosomal core is the most widely conserved structure in all of biology*. In fact, it was sequence comparisons of the 16S RNAs from various organisms that caused Carl Woese to discover that archaea form a different domain of life from those of bacteria and eukaryotes (Section 1-2B).

The yeast ribosome exhibits 16 intersubunit bridges, 12 of which match the 12 that were observed in the X-ray structure of the *T. thermophilus* ribosome, a remarkable evolutionary conservation that indicates the importance of these bridges. The cryo-EM based structures of the more complex human and *Drosophila* 80S ribosomes have been determined at medium resolution by Roland Beckmann.

4 Translation

KEY CONCEPTS

- Initiation factors help to assemble the ribosomal subunits, deliver the initiator tRNA, and in eukaryotes, locate the initiation codon.
- The ribosome selects the correct aminoacyl-tRNA, catalyzes the transpeptidation reaction, and then translocates along the mRNA during the elongation phase of protein synthesis.
- A release factor and ribosome recycling factor participate in terminating polypeptide synthesis.

To appreciate the manner in which the ribosome orchestrates the translation of mRNA to synthesize polypeptides, it is helpful to assimilate the following points:

1. *Polypeptide synthesis proceeds from the N-terminus to the C-terminus*; that is, a **peptidyl transferase** activity appends an incoming amino acid to a growing polypeptide's C-terminus. This was shown to be the case in 1961 by Howard Dintzis, who exposed reticulocytes (immature red blood cells) that were actively synthesizing hemoglobin to ^3H -labeled leucine for less time than it takes to synthesize an entire polypeptide. The extent to which the tryptic peptides from the soluble (completed) hemoglobin molecules were labeled increased with their proximity to the C-terminus (Fig. 27-20), thereby proving that incoming amino acids are appended to the growing polypeptide's C-terminus.

FIG. 27-20 Demonstration that polypeptide synthesis proceeds from the N- to the C-terminus. Rabbit reticulocytes were incubated with [^3H]leucine for the indicated times. The curves show the distribution of [^3H]Leu among the tryptic peptides from the β subunit of soluble rabbit hemoglobin. The numbers on the horizontal axis are peptide identifiers, arranged from the N-terminus to the C-terminus. [After Dintzis, H.M., *Proc. Natl. Acad. Sci.* **47**, 255 (1961).]

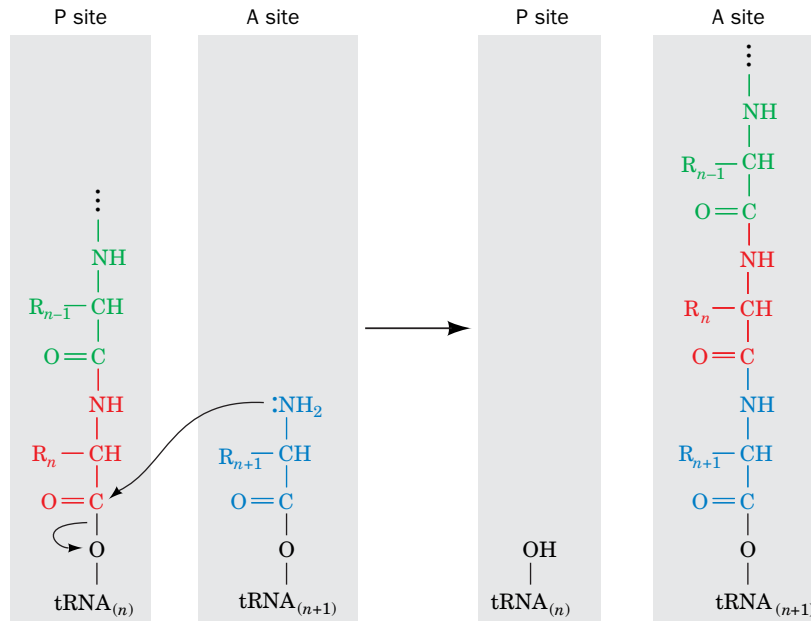

FIG. 27-21 The ribosomal peptidyl transferase reaction forming a peptide bond. The amino group of the aminoacyl-tRNA in the A site nucleophilically displaces the tRNA of the peptidyl-tRNA ester in the P site, thereby forming a new peptide bond and transferring the nascent polypeptide to the A-site tRNA.

? What is the approximate free energy change for the transfer reaction?

- Chain elongation occurs by linking the growing polypeptide to the incoming tRNA's amino acid residue. If the growing polypeptide is released from the ribosome by treatment with high salt concentrations, its C-terminal residue is esterified to a tRNA molecule as a peptidyl-tRNA (at right). The nascent (growing) polypeptide must therefore grow by being transferred from the peptidyl-tRNA in the P site to the incoming aa-tRNA in the A site to form a peptidyl-tRNA with one more residue (Fig. 27-21). After the peptide bond has formed, the new peptidyl-tRNA, which now occupies the A site, is translocated to the P site so that a new aa-tRNA can enter the A site. The uncharged tRNA in the P site moves to the E site before it dissociates from the ribosome (we discuss the details of chain elongation in Section 27-4B).
- Ribosomes read mRNA in the 5'→3' direction. This was shown through the use of a cell-free protein-synthesizing system in which the mRNA was poly(A) with a 3'-terminal C:

Such a system synthesizes a poly(Lys) that has a C-terminal Asn:

Together with the knowledge that AAA and AAC code for Lys and Asn (Table 27-1) and the polarity of peptide synthesis, this established that the mRNA is read in the 5'→3' direction. Because mRNA is also synthesized in the 5'→3' direction, prokaryotic ribosomes can commence translation as soon as a nascent mRNA emerges from RNA polymerase. This, however, is not possible in eukaryotes because the nuclear membrane separates the site of transcription (the nucleus) from the site of translation (the cytosol).

FIG. 27-22 Polysomes. (a) Electron micrograph of polysomes from silk gland cells of the silkworm *Bombyx mori*. The 3' end of the mRNA is on the left. Arrows point to the silk fibroin polypeptides. The bar represents 0.1 μm . (b) Cryo-EM-based image of an *E. coli* polysome. The mRNA (which is mostly occluded) is represented by a red line, the small ribosomal subunits are yellow, the large subunits are cyan, and the red cones point to the polypeptide exit tunnel on each large

subunit. This assembly has a pseudo-helical arrangement of ribosomes in which the center-to-center distance between adjacent ribosomes averages ~ 230 Å. Polysomes with somewhat different although equally densely packed arrangements of ribosomes have also been observed.

? Draw a schematic diagram of the polysome in Part (a) and label its parts.

4. *Active translation occurs on polysomes.* In both prokaryotes and eukaryotes, multiple ribosomes can bind to a single mRNA transcript, giving rise to a beads-on-a-string structure called a **polyribosome (polysome; Fig. 27-22)**. Individual ribosomes are arranged in a helical fashion so that they have a maximum density on the mRNA of ~ 1 ribosome per 80 nt. Polysomes arise because once an active ribosome has cleared its initiation site on mRNA, a second ribosome can initiate translation at that site.

A Chain Initiation Requires an Initiator tRNA and Initiation Factors

The first indication of how ribosomes initiate polypeptide synthesis was the observation that almost half of the *E. coli* proteins begin with the otherwise uncommon amino acid residue Met. In fact, the tRNA that initiates translation is a peculiar form of Met-tRNA^{Met} in which the Met residue is *N*-formylated (*at left*). Because the ***N*-formylmethionine** residue (**fMet**) already has an amide bond, it can only be the N-terminal residue of a polypeptide. *E. coli* proteins are posttranslationally modified by deformylation of their fMet residue, and in many proteins, by the subsequent removal of the resulting N-terminal Met. This processing usually occurs on the nascent polypeptide, which accounts for the observation that mature *E. coli* proteins all lack fMet.

The tRNA that recognizes the initiation codon, tRNA_f^{Met}, differs from the tRNA that carries internal Met residues, tRNA_m^{Met} although they both recognize the same AUG codon. Presumably, the conformations of these tRNAs are different enough to permit them to be distinguished in the reactions of chain initiation and elongation.

In *E. coli*, uncharged tRNA_f^{Met} is aminoacylated with Met by the same MetRS that charges tRNA_m^{Met}. The resulting Met-tRNA_f^{Met} is specifically *N*-formylated to yield fMet-tRNA_f^{Met} by a **transformylase** that employs *N*¹⁰-formyltetrahydrofolate (Section 21-4D) as its formyl donor. This transformylase does not recognize Met-tRNA_m^{Met}.

Translation Initiation

Base Pairing between mRNA and the 16S rRNA Helps Select the Translation Initiation Site. AUG codes for internal Met residues as well as the initiating Met

FIG. 27-23 Some translation initiation sequences recognized by *E. coli* ribosomes. The RNAs are aligned according to their initiation codons (blue shading). Their Shine–Dalgarno sequences (red shading) are complementary, counting G · U pairs, to a portion of the 16S rRNA's 3' end (below). [After Steitz, J.A., in Chambliss, G., Craven, G. R., Davies, J., Davis, K., Kahan, L., and Nomura, M. (Eds.), *Ribosomes. Structure, Function and Genetics*, pp. 481–482, University Park Press (1979).]

residue of a polypeptide. Moreover, mRNAs usually contain many AUGs (and GUGs) in different reading frames. Clearly, a translation initiation site must be specified by more than just an initiation codon.

In *E. coli*, the 16S rRNA contains a pyrimidine-rich sequence at its 3' end. This sequence, as John Shine and Lynn Dalgarno pointed out in 1974, is partially complementary to a purine-rich tract of 3 to 10 nucleotides, the **Shine-Dalgarno sequence**, that is centered ~10 nucleotides upstream from the start codon of nearly all known prokaryotic mRNAs (Fig. 27-23). Base-pairing interactions between an mRNA's Shine–Dalgarno sequence and the 16S rRNA apparently permit the ribosome to select the proper initiation codon.

The X-ray structure of the 70S ribosome reveals, in agreement with Fig. 27-13b, that an ~30-nt segment of the mRNA is wrapped in a groove that encircles the neck of the 30S subunit (Fig. 27-24). The mRNA codons in the A and P sites are exposed on the interface side of the 30S subunit, whereas its 5' and 3' ends are bound in tunnels composed of RNA and protein. The mRNA's Shine–Dalgarno sequence, which is located near its 5' end, is base-paired, as expected, with the 16S rRNA's anti-Shine–Dalgarno sequence, which is situated close to the E site. The proteins that in part form the tunnel through which the mRNA enters the ribosome (green in Fig. 27-24) probably function as a helicase to remove secondary structures from the mRNA that would otherwise interfere with tRNA binding.

Initiation Requires Soluble Protein Factors. Translation initiation in *E. coli* is a complex process in which the two ribosomal subunits and fMet–tRNA^{Met} assemble on a properly aligned mRNA to form a

FIG. 27-24 Path of mRNA through the *T. thermophilus* 30S subunit. The ribosomal subunit is viewed from its interface side. The 16S rRNA is cyan, the mRNA is represented in worm form with its A- and P-site codons orange and red, and the Shine–Dalgarno helix (which includes a segment of 16S rRNA) magenta, and its remaining segments yellow. The ribosomal proteins that in part form the entry and exit tunnels for the mRNA are drawn in green and purple. The remaining ribosomal proteins have been omitted for clarity. complex that can commence chain elongation. This process also requires **initiation factors** that are not permanently associated with the ribosome, designated **IF-1, IF-2, and IF-3** in *E. coli* (Table 27-6).

Translation initiation in *E. coli* occurs in three stages (Fig. 27-25):

1. On completing a cycle of polypeptide synthesis, the 30S and 50S subunits are separated (Section 27-4C). IF-3 binds to the 30S subunit to prevent the reassociation of the 50S complex. The X-ray structure of the 30S subunit in complex with the C-terminal domain of IF-3 (which by itself prevents the association of the 30S and 50S subunits), determined by Yonath and François Franceschi, indicates that IF-3 binds to its solvent-exposed (back) side. Apparently, IF-3 does not function by physically blocking the binding of the 50S subunit.
2. mRNA and IF-2 in a ternary complex with GTP and fMet-tRNA^{Met} along with IF-1, subsequently bind to the 30S subunit in either order. Since the ternary complex containing fMet-tRNA^{Met} can bind to the ribosome before mRNA, fMet-tRNA^{Met} binding must not be mediated by a codon-anticodon interaction; it is the only tRNA-ribosome association that does not require one, although this interaction helps bind fMet-tRNA^{Met} to the ribosome. IF-1 binds in the A site, where it may prevent the inappropriate binding of a tRNA. IF-3 also functions at this stage of the initiation process by preventing the binding of tRNAs other than tRNA^{Met}.
3. Last, in a process that is preceded by IF-1 and IF-3 release, the 50S subunit joins the 30S initiation complex in a manner that stimulates IF-2 to hydrolyze its bound GTP to GDP + P_i. This irreversible reaction

TABLE 27-6 The Soluble Protein Factors of *E. coli* Protein Synthesis

Factor	Number of Residues ^a	Function
Initiation Factors		
IF-1	71	Assists IF-3 binding
IF-2	890	Binds initiator tRNA and GTP
IF-3	180	Releases mRNA and tRNA from recycled 30S subunit and aids new mRNA binding
Elongation Factors		
EF-Tu	393	Binds aminoacyl-tRNA and GTP
EF-Ts	282	Displaces GDP from EF-Tu
EF-G	703	Promotes translocation through GTP binding and hydrolysis
Release Factors		
RF-1	360	Recognizes UAA and UAG Stop codons
RF-2	365	Recognizes UAA and UGA Stop codons
RF-3	528	Stimulates RF-1/RF-2 release via GTP hydrolysis
RRF	185	Together with EF-G, induces ribosomal dissociation to small and large subunits

^aAll *E. coli* translational factors are monomeric proteins.

conformationally rearranges the 30S subunit and releases IF-2 for participation in further initiation reactions.

Initiation results in the formation of an $fMet-tRNA_f^{Met} \cdot mRNA \cdot ribosome$ complex in which the $fMet-tRNA_f^{Met}$ occupies the ribosome's P site while its A site is poised to accept an incoming $aa-tRNA$ (an arrangement analogous to that

PROCESS DIAGRAM

at the conclusion of a round of elongation; Section 27-4B). Note that $\text{tRNA}_f^{\text{Met}}$ is the only tRNA that directly enters the P site. All other tRNAs must first enter the A site during chain elongation.

Initiation in Eukaryotes Is Far More Complicated Than in Prokaryotes. Ribosomal initiation in eukaryotes requires the assistance of at least 12 initiation factors (designated eIFn ; “e” for eukaryotic) that consist of 26 polypeptide chains. Nevertheless, Steps 1 and 3 of the prokaryotic process (Fig. 27-25) are superficially similar in eukaryotes. However, the way in which the mRNA’s initiating codon is identified in eukaryotes is fundamentally different from that in prokaryotes.

The pairing of the initiator tRNA with the initiating AUG in the ribosomal P site begins with **eIF2**, a heterotrimer in complex with GTP, escorting the initiator tRNA to the complex of the 40S subunit with several other initiation factors, thereby forming the **43S preinitiation complex** (a process that resembles Step 2 in prokaryotic initiation but without the mRNA). The initiator tRNA is tRNA_i (“i” for initiator). Its appended Met residue is not formylated as in prokaryotes. Nevertheless, both species of initiator tRNAs are readily interchangeable *in vitro*.

Eukaryotic mRNAs lack the complementary sequences to bind to the 18S rRNA in the Shine–Dalgarno manner. Rather, they have an entirely different mechanism for recognizing the mRNA’s initiating AUG codon. *Eukaryotic mRNAs, nearly all of which have a 7-methylguanosine (m^7G) cap and a poly(A) tail (Section 26-3A), are invariably monocistronic and almost always initiate translation at their leading AUG.* This AUG, which occurs at the end of a 5′-untranslated region of 50 to 70 nt, is embedded in the consensus sequence GCCRCCAUGG. Changes in the purine (R) 3 nt before the AUG and in the G immediately following it each reduce translational efficiency by ~10-fold. The recognition of the initiation site begins by the binding of **eIF4F** to the mRNA’s m^7G cap. eIF4F is a heterotrimeric complex of **eIF4E**, **eIF4G**, and **eIF4A** (all monomers), in which eIF4E (also known as **cap-binding protein**) recognizes the mRNA’s m^7G cap and eIF4G serves as a scaffold to join eIF4E with eIF4A.

The structure of eIF4E in complex with m^7GDP reveals that the protein binds the m^7G base by intercalating it between two highly conserved Trp residues in a region that is adjacent to a positively charged cleft that presumably forms the mRNA-binding site (Fig. 27-26). The m^7G base is specifically recognized by hydrogen bonding to protein side chains in a manner reminiscent of G · C base pairing. eIF4G also binds poly(A)-binding protein (PABP; Section 26-3A), which coats the mRNA’s poly(A) tail, thereby circularizing the mRNA. Although this explains the synergism between an mRNA’s m^7G cap and its

poly(A) tail in stimulating translational initiation, the function of the circle is unclear. However, an attractive hypothesis is that it enables a ribosome that has finished translating the mRNA to reinitiate translation without having to disassemble and then reassemble. Another possibility is that it prevents the translation of incomplete (broken) mRNAs.

The eIF4F–mRNA complex is subsequently joined by several additional initiation factors. The resulting complex joins the 43S preinitiation complex, which then scans down the mRNA in an

FIG. 27-26 X-Ray structure of murine eIF4E in complex with the m^7G cap analog m^7GDP . ATP-driven process until it encounters the mRNA's initiating AUG codon, thereby forming the **48S initiation complex**. The recognition of the AUG occurs mainly through base pairing with the CUA anticodon on the bound Met-tRNA^{Met}, as was demonstrated by the observation that mutating this anticodon results in the recognition of the new cognate codon instead of AUG.

In the analog of Step 3 of prokaryotic initiation (Fig. 27-25), the eIF2-catalyzed hydrolysis of its bound GTP induces the release of all initiation factors from the 48S initiation complex. The resulting 40S subunit-tRNA^{Met} complex is joined by the 60S subunit in a GTP-dependent reaction mediated by **eIF5B** (a monomer and homolog of prokaryotic IF-2), thereby forming the 80S ribosomal initiation complex.

B The Ribosome Decodes the mRNA, Catalyzes Peptide Bond Formation, Then Moves to the Next Codon

Ribosomes elongate polypeptide chains in a three-stage reaction cycle that is highly conserved in all domains of life (Fig. 27-27):

PROCESS DIAGRAM

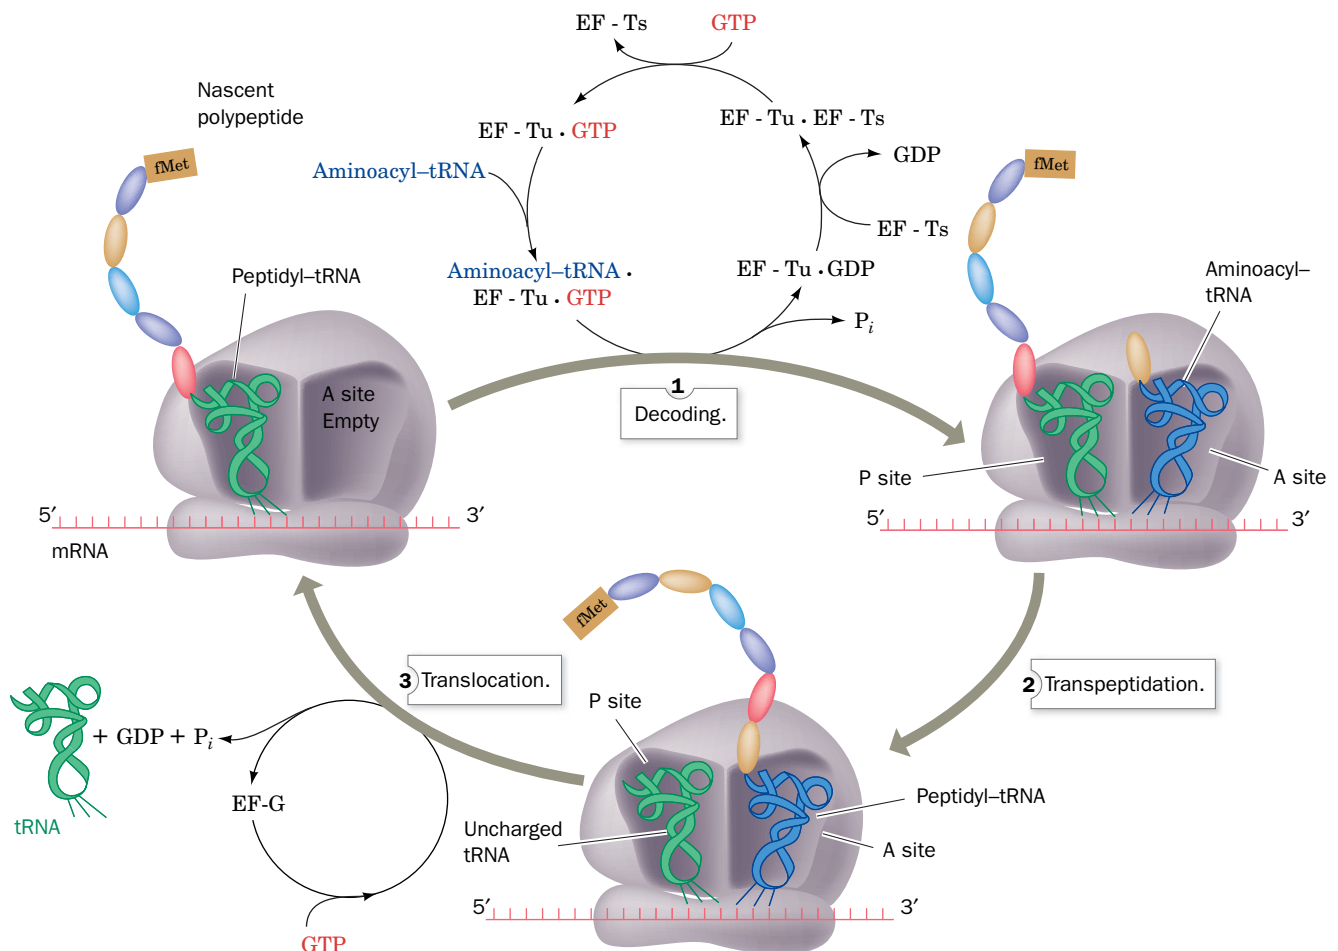

FIG. 27-27 Elongation cycle in *E. coli* ribosomes. The E site is not shown. Eukaryotic elongation follows a similar cycle, but EF-Tu and EF-Ts are replaced by a single multisubunit protein, eEF1, and EF-G is replaced by eEF2. **WPLS See the Animated Process Diagrams.**

? Without looking at the text, summarize the events of translation elongation.

- Transpeptidation**, or peptide bond formation, in which the peptidyl group in the P-site tRNA is transferred to the aminoacyl group in the A site.
- Translocation**, in which the A-site and P-site tRNAs are respectively transferred to the P and E sites, accompanied by their bound mRNA; that is, the mRNA, together with its base-paired tRNAs, is ratcheted through the ribosome by one codon.

This process, which occurs at a rate of 10 to 20 amino acid residues per second, requires several nonribosomal proteins known as **elongation factors** (Table 27-6).

Decoding: An Aminoacyl-tRNA Binds to the Ribosomal A Site. In the first stage of the *E. coli* elongation cycle, a binary complex of GTP and the elongation factor **EF-Tu** combines with an aa-tRNA. The resulting ternary complex binds to the ribosome. Binding of the aa-tRNA in a codon-anticodon complex to the ribosomal A site is accompanied by the hydrolysis of GTP to GDP so that EF-Tu · GDP and P_i are released. The EF-Tu · GTP complex is regenerated when GDP is displaced from EF-Tu · GDP by the elongation factor **EF-Ts**, which in turn is displaced by GTP.

Aminoacyl-tRNAs can bind to the ribosomal A site without EF-Tu but at a rate too slow to support cell growth. The importance of EF-Tu is indicated by the fact that it is the most abundant *E. coli* protein; it is present in ~100,000 copies per cell (>5% of the cell's protein), which is approximately the number of tRNA molecules in the cell. Consequently, *the cell's entire complement of aa-tRNAs is essentially sequestered by EF-Tu.*

The X-ray structure of EF-Tu in complex with Phe-tRNA^{Phe} and the non-hydrolyzable GTP analog **guanosine-5'-(β,γ-imido)triphosphate (GMPPNP at left; alternatively GDPNP)**, was determined by Brian Clark and Jens Nyborg (Fig. 27-28). This complex has a corkscrew-shaped structure in which the EF-Tu and the tRNA's acceptor stem form a knoblike handle and the tRNA's anticodon helix forms the screw. The macromolecules appear to associate rather tenuously via three major regions: (1) The 3'-CCA-Phe segment of the Phe-tRNA^{Phe} binds in the cleft between domains 1 and 2 of EF-Tu · GMPPNP (the blue and green mainly helical domain and the yellow β sheet domain in Fig. 27-28); (2) the 5'-phosphate of the tRNA binds in a depression at the junction of EF-Tu's three domains; and (3) one side of the TψC stem of the tRNA makes contacts with exposed main chain and side chains of EF-Tu domain 3 (the orange β barrel-containing domain in Fig. 27-28).

EF-Tu binds all aminoacylated tRNAs, but not uncharged tRNAs or initiator tRNAs. Evidently, the tight association of the aminoacyl group with EF-Tu greatly increases the affinity of EF-Tu for the otherwise loosely bound tRNA. tRNA_f^{Met} does not bind to EF-Tu because it has a 3' overhang of 5 nt versus 4 nt in an elongator tRNA. This, together with the formyl group attached to the fMet residue, apparently prevents fMet-tRNA_f^{Met} from binding to EF-Tu, thereby explaining why the initiator tRNA never translates internal AUG codons.

EF-Tu is a G protein that undergoes a large conformational change on hydrolyzing GTP. Its N-terminal domain 1 (blue, cyan, and green in Fig. 27-28)

Guanosine-5'-(β,γ-imido)triphosphate (GMPPNP)

? Does this structure resemble the G proteins involved in signal transduction (see Fig. 13-19)?

resembles other G proteins (Sections 13-2B and 13-3B), with Switch I and Switch II regions signaling the state of the bound nucleotide (GTP or GDP). GTP hydrolysis also causes domain 1 to reorient with respect to domains 2 and 3 by a dramatic 91° rotation (Fig. 27-29), a conformational change that eliminates the tRNA-binding site. Since EF-Tu is a G protein, the ribosome can be classified as its GTPase-activating protein (GAP) and EF-Ts functions as its guanine nucleotide exchange factor (GEF).

The X-ray structure of the *T. thermophilus* ribosome in complex with tRNAs and EF-Tu · GDP is shown in Fig. 27-30. The complex was stabilized by the addition of the antibiotic **kirromycin**, which prevents EF-Tu from undergoing conformational changes and dissociating from the ribosome after GTP hydrolysis. The incoming aminoacyl-tRNA has made contact with its codon but, because it is bound to EF-Tu, is distorted relative to its conformation after it has been fully installed in the A site (as in Fig. 27-17).

The Ribosome Monitors Correct Codon-Anticodon Pairing. When EF-Tu · GTP delivers an aa-tRNA to the ribosome, it first inserts the anticodon end of the tRNA into the ribosome. The tRNA's aminoacyl end moves fully into the A site only after GTP is hydrolyzed and EF-Tu dissociates. *This multistep process allows the ribosome to verify that the aa-tRNA has correctly paired with an mRNA codon.* How does the ribosome monitor codon-anticodon pairing?

The X-ray structure of the *T. thermophilus* 30S subunit in complex with a U_6 hexanucleotide “mRNA” and a 17-nt RNA consisting of the tRNA^{Phe} anticodon arm (Fig. 27-5, but with its nucleotides unmodified), determined by Ramakrishnan, reveals how an mRNA-specified tRNA initially binds to the ribosome. The codon-anticodon association is stabilized by its interactions

FIG. 27-30 Model of the ribosome with bound EF-Tu. The *T. thermophilus* ribosome is drawn in ribbon form with its 23S RNA orange, its 50S subunit proteins brown, its 16S RNA cyan, and its 30S proteins blue. The other RNAs are shown as surface models with mRNA black, tRNA^{Phe} in the E site yellow, tRNA^{Phe} in the P site green, and Thr-tRNA^{Thr}, which is bound to EF-Tu (red surface model), magenta. FIG. 27-31 Codon–anticodon interactions in the ribosome. The (a) first, (b) second, and (c) third codon–anticodon base pairs as seen in the X-ray structure of the *T. thermophilus* 30S subunit in complex with U_6 (a model mRNA) and the 17-nt anticodon arm of tRNA^{Phe} (whose anticodon is GAA). The structures are drawn in ball-and-stick

form embedded in their semitransparent van der Waals surfaces. Codons are purple, anticodons are tan, and rRNA is brown or gray with non-C atoms colored according to type (N blue, O red, and P green). Protein segments are gray and Mg^{2+} ions are represented by magenta spheres. PDBid 1IBM.

with three universally conserved ribosomal bases, A1492, A1493, and G530 (Fig. 27-31):

1. The first codon–anticodon base pair, that between mRNA U1 and tRNA A36, is stabilized by the binding of the rRNA A1493 base in the base pair's minor groove (Fig. 27-31a).
2. The second codon–anticodon base pair, that between U2 and A35, is bolstered by A1492 and G530, which both bind in this base pair's minor groove (Fig. 27-31b).
3. The third codon–anticodon base pair (the wobble pair; Section 27-2C), that between U3 and G34, is reinforced through minor groove binding by G530 (Fig. 27-31c). The latter interaction appears to be less stringent than those in the first and second codon–anticodon positions, which is consistent with the need for the third codon–anticodon pairing to tolerate non-Watson–Crick base pairs (Section 27-2C).

Comparison of this structure with that of the 30S subunit alone reveals that the foregoing rRNA nucleotides undergo conformational changes on the formation of a codon–anticodon complex (Fig. 27-32): In the absence of tRNA, the bases of A1492 and A1493 stack in the interior of an RNA loop, whereas in the codon–anticodon complex, these bases have flipped out of the loop and the G530 base has switched from the syn to the anti conformation (Section 24-1B). These interactions enable the ribosome to monitor whether an incoming tRNA is cognate to the codon in the A site; a non-Watson–Crick base pair could not bind these ribosomal bases in the same way. Indeed, any mutation of A1492 or A1493 is lethal because pyrimidines in these positions could not reach far enough to interact with the codon–anticodon complex or G530, and because a G in either position would be unable to form the required hydrogen bonds and its N2 would be subjected to steric collisions. An incorrect codon–anticodon interaction provides insufficient free energy to bind the tRNA to the ribosome and it therefore dissociates from the ribosome, still in its ternary complex with EF-Tu and GTP.

FIG. 27-32 Ribosomal decoding site. The X-ray structures of *T. thermophilus* 30S subunit (a) alone and (b) in its complex with U_6 and the anticodon stem–loop of tRNA^{Phe}. The RNAs are drawn as ribbons with their nucleotides in paddle form with tRNA gold, A-site mRNA purple, P-site mRNA green, rRNA gray, and nucleotides that undergo conformational changes red. Protein S12 is orange and Mg^{2+} ions are represented by red spheres. PDBids (a) 1J5E and (b) 1IBM.

GTP Hydrolysis by EF-Tu Is a Thermodynamic Prerequisite to Ribosomal Proofreading. An aa-tRNA is selected by the ribosome only according to its anticodon, a process that has a measured error rate of only $\sim 10^{-4}$ per residue. Yet the binding energy loss arising from a single base mismatch in a codon-anticodon interaction is estimated to be $\sim 12 \text{ kJ} \cdot \text{mol}^{-1}$, which, according to Eq. 27-1, cannot account for a ribosomal decoding accuracy of less than $\sim 10^{-2}$ errors per codon. Evidently, the ribosome has some sort of proofreading mechanism that increases its overall decoding accuracy.

A proofreading step must be entirely independent of the initial selection step. Only then can the overall probability of error be equal to the product of the probabilities of error of the individual selection steps. We have seen that DNA polymerases and aminoacyl-tRNA synthetases maintain the independence of their two selection steps by carrying them out at separate active sites (Sections 25-2A and 27-2B). Yet the ribosome recognizes the incoming aa-tRNA only according to its anticodon's complementarity to the codon in the A site. Consequently, the ribosome must somehow examine this codon-anticodon interaction in two separate ways. How does this occur?

Cryo-EM studies by Frank indicate that in the ribosome \cdot aa-tRNA \cdot EF-Tu \cdot GTP complex, the aa-tRNA assumes an otherwise energetically unfavorable conformation in which the anticodon arm has moved via a hinge motion toward the inside of the tRNA's L. The formation of a correct codon-anticodon complex results in conformational changes that induce EF-Tu to hydrolyze its bound GTP and thereby dissociate from the aa-tRNA. The aa-tRNA then assumes its energetically more favorable conformation while maintaining its codon-anticodon interaction. This movement swings the acceptor stem with its attached aminoacyl group into the peptidyl transferase center on the 50S subunit (see below). A noncognate (mispaiored) aa-tRNA would presumably have insufficient strength in its codon-anticodon interaction to hold it in place during this conformational change and would therefore dissociate from the ribosome. EF-Tu's irreversible GTPase reaction must precede this proofreading step because otherwise the dissociation of a noncognate aa-tRNA (the release of its anticodon from the codon) would simply be the reverse of the initial binding step; that is, it would be part of the initial selection step rather than proofreading. *GTP hydrolysis therefore provides the second context necessary for proofreading; it is the entropic price the system must pay for accurate tRNA selection.*

Transpeptidation: The Ribosome Is a Ribozyme. In the second (transpeptidation) stage of the elongation cycle (Fig. 27-27), the peptide bond is formed through the nucleophilic displacement of the P site tRNA by the amino group of the 3'-linked aa-tRNA in the A site (Fig. 27-21). The nascent polypeptide chain is thereby lengthened at its C-terminus by one residue and transferred to the A-site tRNA. The rate of this ribosomally-catalyzed reaction is $\sim 10^7$ -fold greater than its spontaneous rate in solution. The reaction occurs without the need of activating cofactors such as ATP because the ester linkage between the nascent polypeptide and the P-site tRNA is a "high-energy" bond relative to the peptide bond that forms during transpeptidation.

The peptidyl transferase center that catalyzes peptide bond formation is located on the large subunit and consists entirely of rRNA. Numerous observations had suggested that the ribosome is indeed a ribozyme rather than a conventional protein enzyme. For example, up to 95% of the protein can be removed from the large subunit without abolishing its peptidyl transferase activity, rRNAs are more highly conserved throughout evolution than are ribosomal proteins, and most mutations that confer resistance to antibiotics that inhibit protein synthesis occur in genes encoding rRNAs rather than ribosomal proteins. However, it was the X-ray structure of the large ribosomal subunit that unambiguously demonstrated that rRNA functions catalytically in protein synthesis. In hindsight, this seems obvious on evolutionary grounds: Since all proteins, including those associated with ribosomes, are ribosomally synthesized, the primordial ribosome must have preceded the primordial proteins and hence consisted entirely of RNA.

The ribosome's active site lies in a highly conserved region in domain V of the 23S rRNA (Figs. 27-12*b*, 27-17, and 27-30). The nearest protein side chain is $\sim 18 \text{ \AA}$ away from the newly formed peptide bond, and the nearest Mg^{2+} ion is $\sim 8.5 \text{ \AA}$ away—both too far to be involved in catalysis. Clearly, *the ribosomal transpeptidase reaction is catalyzed solely by RNA*.

The ribosomal transpeptidase reaction occurs $\sim 10^7$ -fold faster than the uncatalyzed reaction. How does the ribosome catalyze this reaction? Ribosomally mediated peptide bond formation proceeds via the nucleophilic attack of the amino group on the carbonyl group of an ester to form a tetrahedral intermediate that collapses to an amide and an alcohol (Fig. 27-21). However, in the physiological pH range, the attacking amino group is predominantly in its ammonium form (RNH_3^+), which lacks the lone pair necessary to undertake a nucleophilic attack. This suggests that the transpeptidase reaction is catalyzed in part by a general base that abstracts a proton from the ammonium group to generate the required free amino group (RNH_2).

Inspection of the peptidyl transferase active site in *H. marismortui* reveals that the only basic group within 5 \AA of the inferred position of the attacking amino group is atom N3 of the invariant rRNA base A2486 (A2451 in *E. coli*). It is $\sim 3 \text{ \AA}$ from and hence hydrogen bonded to the attacking amino group (Fig. 27-33). This further suggests that the protonated A2486-N3 electrostatically stabilizes the oxyanion of the tetrahedral reaction intermediate and then donates the proton to the leaving group of the P-site tRNA to yield a 3'-OH group (general acid catalysis). However, for A2486-N3 to act as a general base in abstracting the proton from an ammonium group (whose $\text{p}K$ is ~ 10), it must have a $\text{p}K$ of at least 7 (recall that proton transfers between hydrogen-bonded groups occur at physiologically significant rates only when the $\text{p}K$ of the proton donor is no more than 2 or 3 pH units greater than that of the proton acceptor; Section 11-5C). Yet, the $\text{p}K$ of N3 in AMP is < 3.5 . Moreover, the model displayed in Fig. 27-33 indicates that the tetrahedral intermediate's oxyanion would point away from and hence could not be stabilized by protonated A2486-N3.

FIG. 27-33 Model of the substrate complex of the 50S ribosomal subunit. Atoms are colored according to type with the A-site substrate (Tyr-tRNA^{Tyr}) C purple, P-site substrate C green, 23S rRNA C orange, N blue, and O red. The attacking amino group of the A-site aminoacyl residue is held in position for nucleophilic attack (cyan arrow) on the carbonyl C of the P-site aminoacyl ester through hydrogen bonds (dashed black lines) to A2486-N3 and the 2'-O of the P-site A76.

The Ribosome Is an Entropy Trap. The resolution to this conundrum was provided by Marina Rodnina and Richard Wolfenden, who noted that the uncatalyzed reaction of esters with amines to form amides occurs quite readily in aqueous solution. They therefore measured the rates of both uncatalyzed peptide bond formation by model compounds and peptidyl transfer by the ribosome at several different temperatures. This provided values of $\Delta\Delta H_{\text{cat}}^\ddagger$ and $\Delta\Delta S_{\text{cat}}^\ddagger$, the reaction's change in the enthalpy and entropy of activation by the ribosome relative to the uncatalyzed reaction. Here, $\Delta\Delta H_{\text{cat}}^\ddagger - T\Delta\Delta S_{\text{cat}}^\ddagger = \Delta\Delta G_{\text{cat}}^\ddagger = \Delta G_{\text{uncat}}^\ddagger - \Delta G_{\text{cat}}^\ddagger$, where $\Delta\Delta G_{\text{cat}}^\ddagger$ is the change in the reaction's free energy of activation by the ribosome relative to the uncatalyzed reaction, and $\Delta G_{\text{uncat}}^\ddagger$ and $\Delta G_{\text{cat}}^\ddagger$ are the free energies of activation of the uncatalyzed and catalyzed (ribosomal) reactions (Sections 1-3D and 11-2). The measured value of $\Delta\Delta H_{\text{cat}}^\ddagger$ is $-19 \text{ kJ} \cdot \text{mol}^{-1}$, a quantity that would be positive, not negative, if the ribosomal reaction had a significant component of chemical catalysis such as acid-base catalysis and/or the formation of new hydrogen bonds. In contrast, the value of $T\Delta\Delta S_{\text{cat}}^\ddagger$ is $+52 \text{ kJ} \cdot \text{mol}^{-1}$, which indicates that the Michaelis complex (E · S; Section 12-1B) in the ribosomal reaction is significantly more ordered relative to the transition state than is the uncatalyzed reaction. This value of $T\Delta\Delta S_{\text{cat}}^\ddagger$ largely accounts for the observed $\sim 10^7$ -fold rate enhancement of the ribosomal reaction relative to the uncatalyzed reaction (the rate enhancement by the ribosome is given by $e^{\Delta\Delta G_{\text{cat}}^\ddagger/RT}$; Section 11-2). Evidently, *the ribosome enhances the rate of peptide bond formation by properly positioning and orienting its substrates and/or excluding water from the preorganized electrostatic*

FIG. 27-34 A plausible mechanism of ribosome-catalyzed peptidyl transfer. The nucleophilic attack of the α -amino group of the aminoacyl-tRNA (red) on the carbonyl C of the peptidyl-tRNA (blue) occurs in concert with a proton shuttle that involves the O3' and 2'-OH of the

P-site A76 together with the α -amino group of the aminoacyl-tRNA. The reaction proceeds through a transition state (center; enclosed by square brackets) that contains a six-membered ring of partially bonded atoms and which collapses to the reaction products drawn on the right.

environment of the active site (a form of reactant ordering) rather than by chemical catalysis.

The X-ray structures of the large ribosomal subunit in complex with aminoacyl-tRNA and peptidyl-tRNA indicate that the ribosome uses an induced fit mechanism, as occurs in enzymes such as hexokinase (Section 15-2A). Conformational changes in the 23S rRNA, presumably triggered by proper binding of the aminoacyl-tRNA in the A site, orient the ester group of the peptidyl-tRNA for nucleophilic attack. The hydrogen bond between the 2'-OH of the P-site A76 and the attacking amino group (Fig. 27-33) is crucial in doing so, as is indicated by the observations that replacing this 2'-OH group with H or F reduces the reaction rate by $\sim 10^6$ -fold. This suggests that the peptidyl transferase reaction occurs via a substrate-assisted proton shuttle mechanism such as that diagrammed in Fig. 27-34.

In the absence of a tRNA in the A site, the peptidyl-tRNA is held in a position that prevents nucleophilic attack by water (hydrolysis), which would otherwise release the peptidyl group from the ribosome.

Translocation: The Ribosome Moves to the Next Codon. Following transpeptidation, the now uncharged P-site tRNA moves to the E site (not shown in Fig. 27-27), and the new peptidyl-tRNA in the A site, together with its bound mRNA, moves to the P site. These events, which leave the A site vacant, prepare the ribosome for the next elongation cycle. During translocation, the peptidyl-tRNA's interaction with the codon, which is no longer necessary for amino acid specification, acts as a placekeeper so that the ribosome can advance by exactly three nucleotides along the mRNA, as required to preserve the reading frame. An Mg^{2+} -stabilized kink in the mRNA between the A and P codons may help prevent slipping. Indeed, certain mutant tRNA molecules that cause frameshifting induce the ribosome to translocate by four nucleotides, thereby demonstrating that mRNA movement is directly coupled to tRNA movement.

The translocation process requires an elongation factor, **EF-G** in *E. coli*, that binds to the ribosome together with GTP and is released only on hydrolysis of the GTP to GDP + P_i (Fig. 27-27). EF-G release is prerequisite for beginning the next elongation cycle because the ribosomal binding sites of EF-G and EF-Tu partially or completely overlap and hence their ribosomal binding is mutually exclusive. GTP hydrolysis, which precedes translocation, provides free energy for tRNA movement.

FIG. 27-35 X-Ray structure of EF-G from *T. thermophilus* in complex with GMPPNP. The protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The GMPPNP is drawn in space-filling form colored according to atom type with C yellow, N blue, O red, and P orange. An Mg^{2+} ion that is bound to the GMPPNP is represented by a magenta sphere. Portions of the structure are not visible. Note the remarkable resemblance in shape between this structure and that of Phe-tRNA^{Phe} · EF-Tu · GMPPNP (Fig. 27-28). [Based on an X-ray structure by Anders Liljas and Derek Logan, Lund University, Lund, Sweden. PDBid 2BV3.]

EF-G Structurally Mimics the EF-Tu · tRNA Complex. The X-ray structure of EF-G (Fig. 27-35) reveals that the protein has an elongated shape comprising five domains, the first two of which (blue through green in Fig. 27-35) are arranged similarly to the first two domains of the EF-Tu · GMPPNP complex (Fig. 27-28). Most intriguingly, the remaining three domains of EF-G (yellow, orange, and red in Fig. 27-35) have a conformation reminiscent of the shape of tRNA bound to EF-Tu. Such molecular mimicry allows EF-G to drive translocation not just by inducing a conformational change in the ribosome but by actively displacing the peptidyl-tRNA from the A site. The X-ray structure of the ribosome with bound tRNAs and EF-G supports this model (Fig. 27-36). In this complex, EF-G has hydrolyzed its GTP and translocation has occurred, but EF-G cannot dissociate from the ribosome due to the presence of the antibiotic **fusidic acid**. The EF-G occupies a position similar to that of the EF-Tu · tRNA complex bound to the ribosome (Fig. 27-30). The structural similarity between EF-G domains 3 to 5 and tRNA also suggests that in the earliest cells, whose functions were based on RNA, proteins evolved by mimicking shapes already used successfully by RNA.

Translocation Occurs Via Intermediate States. Variations in chemical footprinting patterns during the elongation cycle, together with X-ray and cryo-EM studies, indicate that the translocation of tRNA through the ribosome occurs in several discrete steps (Fig. 27-37):

1. In the **posttranslocational state**, a deacylated tRNA occupies the E site of both the 30S and 50S subunits (the E/E state), a peptidyl-tRNA occupies both P sites (the P/P state), and the A site is vacant. An aa-tRNA in complex with EF-Tu · GTP binds to the ribosome. This yields a complex in which the incoming aa-tRNA is bound in the 30S subunit's A site via a codon-anticodon interaction (recall that the mRNA is bound to the 30S subunit) but with the EF-Tu · GTP preventing the entry of the tRNA's aminoacyl end into the 50S subunit's A site, an arrangement termed the A/T state (T for EF-Tu). This structure is also pictured in Fig. 27-30.
2. As we discussed above, EF-Tu hydrolyzes its bound GTP to GDP + P_i and is released from the ribosome, thereby permitting the aa-tRNA to fully bind to the A site (the A/A state) and releasing the E-site tRNA.
3. The transpeptidation reaction occurs, yielding the **pretranslocational state**.

FIG. 27-36 X-Ray structure of the *T. thermophilus* ribosome with bound EF-G. The structure is drawn and labeled as in Fig. 27-30 with EF-G shown as a red surface model. PDBid 4V5F.

? Compare this structure to the ribosome · EF-Tu complex shown in Fig. 27-30.

4. The acceptor end of the new peptidyl-tRNA shifts to the P site of the 50S subunit, while the tRNA's anticodon end remains associated with the A site of the 30S subunit (yielding the A/P state). The acceptor end of the newly deacylated tRNA simultaneously moves to the E site of the 50S subunit while its anticodon end remains associated with the P site of the 30S subunit (the P/E state). The peptidyl group of peptidyl-tRNA is sterically excluded from the 50S subunit's E site, thereby ensuring that the P/E state can form only after peptidyl transfer has occurred.
5. EF-G · GTP binds to the ribosome and the resulting GTP hydrolysis impels the anticodon ends of the two tRNAs, together with their bound mRNA, to move relative to the small ribosomal subunit such that the peptidyl-tRNA assumes the P/P state and the deacylated tRNA assumes the E/E state (the posttranslocational state), thereby completing the elongation cycle.

FIG. 27-37 Ribosomal binding states in the elongation cycle. Note how this scheme elaborates the classical elongation cycle diagrammed in Fig. 27-27. The drawings are accompanied by 17-Å-resolution cryo-EM-based images of the *E. coli* 70S ribosome in the corresponding binding states in which the 30S subunit is transparent yellow, the 50S subunit is transparent blue, and the tRNAs and elongation factors are colored as in the drawing they accompany.

Courtesy of Knud Nierhaus, Charité-Institute for Medical Physics and Biophysics, Berlin, Germany and Joachim Frank, State University of New York, Albany

The majority of known antibiotics, including a great variety of medically useful substances, block translation in prokaryotes. This situation is presumably a consequence of the translation machinery's enormous complexity, which makes it vulnerable to disruption in many ways. Antibiotics have also been useful in analyzing ribosomal mechanisms because the blockade of a specific function often permits its biochemical dissection into its component steps. For example, the ribosomal elongation cycle was originally characterized through the use of the antibiotic **puromycin**, which resembles the 3' end of Tyr-tRNA:

Puromycin binds to the ribosomal A site without the need of elongation factors. The transpeptidation reaction yields a peptidyl-puromycin in

which puromycin's "amino acid residue" is linked to its "tRNA" via an amide rather than an ester bond. The ribosome therefore cannot catalyze further transpeptidation, and polypeptide synthesis is aborted.

Streptomycin is a medically important member of a family of antibiotics known as **aminoglycosides** that inhibit prokaryotic ribosomes in a variety of ways.

At low concentrations, streptomycin induces the ribosome to characteristically misread mRNA: One pyrimidine may be mistaken for the other

The binding of tRNAs to the A and E sites of the ribosome, as Knud Nierhaus has shown, exhibits negative allosteric cooperativity. In the pre-translocational state, the E site binds the newly deacylated tRNA with high affinity, whereas the now empty A site has low affinity for aa-tRNA. The binding of a new aa-tRNA · EF-Tu · GTP complex induces the ribosome to undergo a conformational change that converts the A site to a high-affinity state and the E site to a low-affinity state that consequently releases the deacylated tRNA. Thus, the E site is not simply a passive holding site for spent tRNAs but performs an essential function in the translation process.

The requirement that the GTP-hydrolyzing proteins EF-Tu and EF-G alternate in their activities ensures that the ribosome cycles unidirectionally through the transpeptidation and translocation stages of translation. Translocation can occur in the absence of GTP, which indicates that the free energy of the transpeptidation reaction is sufficient to drive the entire translational process (this is a further indication that the primordial ribosome consisted only of RNA). However, the GTP hydrolysis catalyzed by EF-Tu and EF-G greatly increases the overall rate of translation, presumably by reducing the activation barriers between successive states. *Because GTP hydrolysis is irreversible, the accompanying conformational changes in the ribosome are also irreversible and hence unidirectional.*

in the first and second codon positions, and either pyrimidine may be mistaken for adenine in the first position. This inhibits the growth of susceptible cells but does not kill them. At higher concentrations, however, streptomycin prevents proper chain initiation and thereby causes cell death.

Chloramphenicol,

Chloramphenicol

the first of the "broad-spectrum" antibiotics, competitively inhibits the peptidyl transferase activity of prokaryotic ribosomes. However, its clinical uses are limited to severe infections because of its toxic side effects, which are caused in part by the chloramphenicol sensitivity of mitochondrial ribosomes. Chloramphenicol binds to the large subunit near the A site, which explains why it competes for binding with puromycin and the 3' end of aminoacyl-tRNA but not with peptidyl-tRNAs.

Tetracycline

Tetracycline

and its derivatives are broad-spectrum antibiotics that bind to the small subunit of prokaryotic ribosomes. Tetracycline binding prevents the entry of aminoacyl-tRNAs into the A site but allows EF-Tu to hydrolyze its GTP. As a result, protein synthesis cannot proceed, and GTP hydrolysis, which occurs every time another aminoacyl-tRNA attempts to enter the ribosome, presents an enormous energetic drain on the cell.

Tetracycline-resistant bacterial strains have become quite common, thereby precipitating a serious clinical problem. Most often, resistance is conferred by a decrease in bacterial cell membrane permeability to tetracycline rather than any alteration of ribosomal components that would overcome the inhibitory effect on translation.

Although it is a protein rather than a small molecule, the enzyme **ricin** can be considered an antibiotic. Ricin is an *N*-glycosidase from castor beans, the source of castor oil. The enzyme inactivates the large subunit of eukaryotic ribosomes by hydrolytically removing the adenine base of a highly conserved residue of 28S rRNA. The modified ribosome is unable to bind elongation factors, and translation ceases. Because it acts catalytically rather than stoichiometrically, a single ricin molecule can inactivate tens of thousands of ribosomes. Its deadliness in minute amounts makes ricin attractive to bioterrorists, but methods for selectively targeting ricin to particular cells, such as cancer cells, raise the possibility of its therapeutic use.

The changes in binding states result in large-scale tRNA movements, in some instances $>50 \text{ \AA}$. Moreover, cryo-EM studies indicate that on binding EF-G \cdot GMPPCP (like GMPPNP but with a CH_2 group rather than an NH group bridging its β and γ phosphates), the 30S subunit rotates with respect to the 50S subunit by 6° clockwise when viewed from the 30S subunit's solvent side, which results in a maximum displacement of $\sim 19 \text{ \AA}$ at the periphery of the ribosome. This rotation, which is referred to as **ratcheting**, is accompanied by many smaller conformational changes in both subunits, particularly in the regions about the entrance and exit to the mRNA channel. Clearly, we are far from fully understanding how the ribosome works at the molecular level. Several of the many antibiotics that disrupt ribosomal functioning are discussed in Box 27-3.

The Eukaryotic Elongation Cycle Resembles That of Prokaryotes. Elongation in eukaryotes closely resembles that in prokaryotes. In eukaryotes, the functions of EF-Tu and EF-Ts are assumed by the eukaryotic elongation factors **eEF1A** and **eEF1B**. Likewise, **eEF2** functions in a manner analogous to prokaryotic EF-G. However, the corresponding eukaryotic and prokaryotic elongation factors are not interchangeable.

FIG. 27-38 The translation termination pathway in *E. coli* ribosomes. RF-1 recognizes the Stop codons UAA and UAG, whereas RF-2 (not shown) recognizes UAA and UGA. Eukaryotic termination

follows an analogous pathway but requires only a single release factor, eRF1, that recognizes all three Stop codons. **WPLS** See the **Animated Process Diagrams**.

? Without looking at the text, summarize the events of translation termination.

C Release Factors Terminate Translation

Polypeptide synthesis under the direction of synthetic mRNAs such as poly(U) results in a peptidyl-tRNA “stuck” in the ribosome. However, the translation of natural mRNAs, which contain the Stop codons UAA, UGA, or UAG, yields free polypeptides. In *E. coli*, the Stop codons, which normally have no corresponding tRNAs, are recognized by protein **release factors** (Table 27-6): **RF-1** recognizes UAA and UAG, whereas the 39% identical **RF-2** recognizes UAA and UGA. In eukaryotes, a single release factor, **eRF1**, recognizes all three Stop codons.

Termination, like initiation and elongation, has several stages. The sequence of events in *E. coli* is diagrammed in Fig. 27-38:

1. RF-1 or RF-2 recognizes a corresponding Stop codon in the ribosome’s A site.
2. The release factor induces the transfer of the peptidyl group from the peptidyl-tRNA to water, rather than to another aa-tRNA, to yield an uncharged tRNA in the P site and a free polypeptide that dissociates from the ribosome.
3. A third factor, **RF-3** (**eRF** in eukaryotes), a G protein, binds to the ribosome in complex with GDP. RF-3 binds to the same site on the ribosome as do EF-Tu and EF-G. In fact, the X-ray structure of RF-3 · GDP resembles that of EF-Tu · GMPPNP (Fig. 27-28). Free RF-3 has a greater affinity for GDP than GTP but on binding to the ribosome–RF-1/2 complex, it exchanges its bound GDP for GTP. The resulting change in the conformation of RF-3, as seen in cryo-EM studies, causes it to bind more tightly to the ribosome and expel the RF-1/2. RF-3 is not required for cell viability although it is necessary for maximum growth rate; RF-3 only accelerates the dissociation of RF-1/2 from the ribosome by ~5-fold.
4. The interaction of RF-3 · GTP with the ribosome stimulates it to hydrolyze its bound GTP, much as occurs with EF-Tu · GTP and EF-G · GTP. The resulting RF-3 · GDP then dissociates from the ribosome. Subsequently, **ribosomal recycling factor (RRF)** (Table 27-6) binds in the ribosomal A site followed by EF-G · GTP. RRF, which was discovered by Akira Kaji, is essential for cell viability.
5. EF-G hydrolyzes its bound GTP, which causes RRF to move to the P site and the tRNAs occupying the P and E sites (the latter not shown in Fig. 27-38) to be released. Finally, the small and large ribosomal subunits separate, a process that is facilitated by the binding of IF-3 (Section 27-4A), and RRF, EF-G · GDP, and mRNA are released. The ribosomal subunits can then participate in a new round of initiation (Fig. 27-25).

RRF Binds in the Ribosomal A Site. The X-ray structure of *T. thermophilus* RRF, determined by Yoshikazu Nakamura, reveals it to be a two-domain structure that resembles tRNA in its overall shape (Fig. 27-39). The comparison of this structure with those of several other bacterial RRFs indicates that the two linkers connecting the RRF domains are flexible such that domain II can rotate about the axis of the three-helix bundle forming domain I.

The X-ray structure of the *T. thermophilus* ribosome in complex with RRF in its A site, the anticodon stem-loop (ASL) of tRNA^{Phe} in its P site, tRNA^{Met} in its E site, and an mRNA with a UAG Stop codon in the A site was determined by

FIG. 27-39 X-Ray structure of *T. thermophilus* RRF. This monomeric protein is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). [Based on an X-ray structure by Yoshikazu Nakamura, The University of Tokyo, Japan. PDBid 1EH1.]

FIG. 27-40 X-Ray structure of the *T. thermophilus* ribosome in complex with RRF. The RRF and an mRNA with a UAG Stop codon are in its A site, the anticodon stem-loop (ASL) of tRNA^{Phe} is in its P site, and tRNA^{Met} is in its E site. The ribosomal RNAs are shown as semitransparent surface diagrams with 23S RNA cyan, 5S RNA blue-green, and 16S RNA yellow. The ribosomal proteins are drawn in ribbon form with 50S subunit proteins blue and 30S subunit proteins orange. The RRF, tRNAs, and mRNA are represented by their surface diagrams with domains I and II of RRF red and blue, the mRNA magenta, the P-site ASL purple, and the E-site tRNA^{Met} gray. PDBid 4V5A.

CHECKPOINT

- How was it determined that peptides are synthesized from their N-terminus to their C-terminus?
- What is the advantage of polysomes?
- Compare prokaryotic and eukaryotic translation initiation with respect to delivering an initiator tRNA to the ribosome and locating the initiation codon.
- Summarize the roles of initiation, elongation, and release factors in translation.
- How does the ribosome catalyze peptide bond formation?
- Summarize the role of GTP hydrolysis in promoting the efficiency of translation initiation, decoding, translocation, and chain termination.
- Which translation protein mimics RNA structures and why?
- How does the ribosome verify correct tRNA–mRNA pairing?
- What mechanism ensures that the ribosome translocates by exactly three nucleotides?

Ramakrishnan (Fig. 27-40). Domain I of the RRF spans the A and P sites of the 50S ribosome, a position in which the tip of its domain I would clash with a tRNA in the P site. This suggests that RRF binding forces a tRNA bound in the P site into the P/E hybrid binding state (Section 27-4B). The lack of a eukaryotic RRF suggests that termination in eukaryotes has a somewhat different mechanism.

Nonsense Suppressors Prevent Termination. A mutation that converts an aminoacyl-coding (sense) codon to a Stop codon is known as a **nonsense mutation** and leads to the premature termination of translation. An organism with such a mutation may be “rescued” by a second mutation in a tRNA gene that causes the tRNA to recognize a Stop (nonsense) codon. This **nonsense suppressor tRNA** carries the same amino acid as its wild-type progenitor and appends it to the growing polypeptide at the Stop codon, thereby preventing chain termination. For example, the *E. coli* suppressor known as *su3* is a tRNA^{Tyr} whose anticodon has mutated from the wild-type GUA (which reads the Tyr codons UAU and UAC) to CUA (which recognizes the Stop codon UAG). An *su3*⁺ *E. coli* cell with an otherwise lethal mutation to UAG in a gene coding for an essential protein would be viable if the replacement of the wild-type amino acid residue by Tyr does not inactivate the protein.

How do cells tolerate a mutation that both eliminates a normal tRNA and prevents the termination of polypeptide synthesis? They survive because the mutated tRNA is usually a minor member of a set of isoaccepting tRNAs and because nonsense suppressor tRNAs must compete with release factors for binding to Stop codons. Consequently, many suppressor-rescued mutants grow more slowly than wild-type cells.

5 Posttranslational Processing

KEY CONCEPTS

- Chaperones bind to polypeptide chains as they emerge from the ribosome.
- The polypeptide chain may be covalently modified and translocated via the secretory pathway.

The tunnel that leads from the peptidyl transferase active site to the exterior of the bacterial ribosome (Fig. 27-13b) is ~100 Å long, enough to shelter a polypeptide of ~30 residues. Once it emerges from the ribosome, the polypeptide faces two

challenges: how to fold properly and how to reach its final cellular destination. Both processes occur with the aid of other proteins. In addition, a nascent polypeptide may be covalently modified before it achieves its mature form. In this section we review some of the events of **posttranslational protein processing**.

A Ribosome-Associated Chaperones Help Proteins Fold

The ribosome's peptide exit tunnel is too narrow ($\sim 15 \text{ \AA}$ wide) to permit the formation of secondary structure other than perhaps helices, so a nascent polypeptide cannot begin to fold until after it emerges from the ribosome. However, folding commences well before translation is complete. Molecular chaperones (Section 6-5B) bind to the N-terminus of nascent polypeptides to prevent their aggregation, to facilitate their folding, and to promote their proper association with other subunits.

A growing body of evidence indicates that ribosomal proteins play a role in protein folding by recruiting chaperones. For example, in *E. coli*, a protein known as **trigger factor (TF)** associates with the ribosomal protein **L23**, which is located at the outlet of the peptide exit tunnel. TF recognizes relatively short hydrophobic protein segments when they first emerge from the ribosome. **DnaK**, a member of the Hsp70 family of chaperones, together with **DnaJ**, an Hsp40 cochaperonin (Section 6-5B), can bind to and protect longer polypeptides (DnaK and DnaJ were so named because they were discovered through the isolation of mutants that do not support the growth of bacteriophage λ and hence were initially assumed to participate in DNA replication). The activities of TF and DnaK/J are somewhat redundant, as *E. coli* can tolerate the deletion of either one. The loss of both, however, is lethal above 30°C and is accompanied by the massive aggregation of newly synthesized proteins. The chaperonins GroEL and GroES facilitate the folding of numerous proteins after their translation termination (Section 6-5B).

The NMR structure of the 432-residue *E. coli* TF in complex with the 471-residue *E. coli* protein PhoA in an unfolded state (Fig 27-41a), determined by Charalamos Kalodimos, reveals that three molecules of TF bind to the largely extended PhoA. Each TF molecule, which consists of four domains, has an elongated conformation with a pronounced hydrophobic cleft along much of its length through which it interacts with PhoA. TF exhibits a high degree of flexibility in binding to the various segments of PhoA, thereby demonstrating how it can bind to a large variety of substrate proteins.

The X-ray structure of TF's 144-residue ribosome-binding N-terminal domain in complex with the 50S subunit from *H. marismortui* reveals that this domain binds near the exit of the ribosome's peptide tunnel. The superposition of this N-terminal domain with that in the X-ray structure of intact TF generated a model of the interaction of TF with the 50S subunit (Fig. 27-41b). In this model, TF hunches over the exit of the ribosome's peptide tunnel with its hydrophobic concave face positioned to interact with a newly synthesized polypeptide segment as it emerges from the tunnel. Moreover, fluorescence energy transfer experiments show that on binding to the ribosome, TF undergoes a conformational expansion that further exposes its hydrophobic surface.

FIG. 27-41 Structures of trigger factor (TF). (a) NMR structure of three TF molecules bound to PhoA in its unfolded and largely extended form. The TF molecules are represented by their surface diagrams (orange) and the PhoA backbone is drawn in worm form embedded in its transparent surface diagram (blue-gray). PDBid 2XXA. (b) Model of the association of TF with the 50S ribosomal subunit. The 50S subunit is shown in a cutaway view that exposes its peptide exit tunnel into which an α helix (magenta) extending from the peptidyl transferase center (PT) has been modeled. The ribosomal RNA is pink and the ribosomal proteins are gray except for L23, which is green. TF is drawn in worm form with its four domains colored, from N- to C-terminus, red, yellow, green, and blue.

Unlike many other chaperones (e.g., DnaK/J and GroEL/ES), TF does not require ATP for its activation. TF dissociates from the ribosome after ~10 s but may remain associated with the elongating polypeptide for >30 s, during which time an additional molecule of TF can bind to the ribosome and shield hydrophobic sequences farther along the nascent polypeptide chain (Fig. 27-41a). Apparently, *TF functions to shield hydrophobic segments of newly synthesized and hence unfolded polypeptides to prevent their misfolding and aggregation.* Subsequently, many of the resulting partially folded proteins are handed off to other chaperones, such as GroEL/ES, to complete the folding process. Eukaryotic cells lack a homolog of TF but contain other small chaperones that likely have similar functions.

B Newly Synthesized Proteins May Be Covalently Modified

The list of known posttranslational modifications is long and includes the removal and/or derivatization of specific residues. For example, a polypeptide's N-terminal Met or fMet residue is usually excised. Other common posttranslational modifications are the hydroxylation of Pro and Lys residues in collagen (Section 6-1C), glycosylation (Sections 8-3C and 16-5), and the prenylation and fatty acylation of membrane-anchored proteins (Section 9-3B). Many covalent modifications, such as phosphorylation (Section 12-3B) and palmitoylation (Section 9-3B), are reversible. Over 150 different types of side chain modifications are known; these involve all side chains except those of Ala, Ile, Leu, and Val. The functions of such modifications are varied and in many cases remain enigmatic.

A growing number of proteins are known to be ubiquitinated. Recall from Section 21-1B that the attachment of the 76-residue protein ubiquitin marks a protein for degradation by the proteasome. A homologous 97-residue protein known as **small ubiquitin-related modifier (SUMO)** can be ligated to a Lys residue, as is ubiquitin, to regulate protein function. But whereas ubiquitination is usually associated with protein degradation, sumoylation appears to play a role in determining protein localization inside cells.

Proteins that are synthesized as inactive precursors, called **proproteins** or proenzymes, are activated by limited proteolysis. The zymogens of serine proteases are converted to active enzymes in that fashion (Section 11-5D). Proteins that are translocated into the endoplasmic reticulum for export from the cell typically contain a signal peptide that must be excised (Section 9-4D). Proteins bearing a signal peptide are known as **preproteins**, or **preproproteins** if they undergo additional proteolysis during their maturation. For example, the hormone insulin (Section 22-2) is synthesized as a preproprotein, which is converted to the proprotein **proinsulin**, a single 84-residue polypeptide. Proteolysis at two sites generates the mature hormone, whose A and B chains remain linked by disulfide bonds (Fig. 27-42). The 33-residue C chain is discarded.

The Signal Recognition Particle Is a Ribonucleoprotein. Many transmembrane and secretory proteins are translocated into or completely through cellular membranes [the endoplasmic reticulum (ER) in eukaryotes and the plasma membrane in prokaryotes] via a series of events known as the secretory pathway

FIG. 27-42 Conversion of proinsulin to insulin. The prohormone, with three disulfide bonds, is proteolyzed at two sites (*arrows*) to eliminate the C chain. The mature hormone insulin consists of the disulfide-linked A and B chains.

FIG. 27-43 Sequence and secondary structure of canine 7S RNA. Its various double-helical segments (denoted H1 through H8) and loops (denoted L1.2 and L2), are drawn in red and yellow with Watson–Crick base pairs represented by connecting lines and non-Watson–Crick base pairs indicated by dots. The positions at which the various SRP proteins bind to the 7S RNA are indicated in cyan, purple, and gray.

(Section 9-4D). As their N-terminal signal sequences emerge from the ribosome, these proteins associate with the signal recognition particle (SRP). Peptide chain elongation ceases on SRP binding to the ribosome but resumes after the SRP docks with its receptor on the ER membrane. The SRP then dissociates from the ribosome, allowing the nascent polypeptide to pass into or through the membrane via a protein pore called the translocon.

Like the ribosome, the spliceosome (Section 26-3B), and RNase P (Section 26-3D), the SRP is a ribonucleoprotein. Mammalian SRPs consist of six polypeptides known as **SRP9**, **SRP14**, **SRP19**, **SRP54**, **SRP68**, and **SRP72** (where the numbers are their molecular masses in kD) and a 7S RNA (~300 nt; **Fig. 27-43**). Many prokaryotic SRPs are much simpler; that in *E. coli* consists of a single polypeptide named **Ffh** that is homologous to SRP54 (Ffh for *Fifty-four* homolog) and a 4.5S RNA (114 nt) that, in part, is predicted to have a secondary structure similar to that portion of the 7S RNA to which SRP54 binds. Indeed, replacing SRP54 with Ffh or vice versa yields functional SRPs, at least *in vitro*, thereby suggesting that the Ffh–4.5S RNA complex is a structurally minimized version of the eukaryotic SRP.

Beckmann and Frank generated a model of the ribosome–SRP complex by fitting the X-ray structures of the yeast ribosome (**Fig. 27-19**) and several SRP fragments to its 12-Å resolution cryo-EM–based image (**Fig. 27-44a**). The model indicates that the so-called S (signal sequence–binding) domain of the ~270-Å-long SRP RNA binds at the base of the large ribosomal subunit next to the exit of the tunnel through which the newly synthesized polypeptide emerges, whereas its Alu domain (so called because it contains *Alu*-like sequences; Section 28-1C) wraps around the large subunit to contact the ribosome at the interface between its large and small subunits. The model indicates that the 7S RNA consists mainly of a long double-helical rod that is bent at two positions, hinge 1 and hinge 2 (**Fig. 27-44b**).

FIG. 27-44 Cryo-EM–based image of the wheat germ ribosome in complex with canine SRP at 12 Å resolution. (a) Surface diagram showing the small ribosomal subunit in blue, the SRP in red, and a tRNA occupying the ribosomal P site in green. The SRP’s S domain interacts with the polypeptide emerging from the ribosome’s exit channel, and its Alu domain binds to the ribosome at the elongation factor–binding site. (b) Molecular model of the SRP. The cryo-EM–based electron density is shown in transparent white and the ribbon diagrams of the X-ray structures of SRP proteins and RNA fragments that have been docked into it are colored as is indicated in **Fig. 27-43**. The signal sequence, modeled as an α helix, is green. Note that no atomic resolution structure of the SRP68/72 heterodimer is available.

(a)

(b)

SRP54 consists of three domains: its N-terminal N domain; its central G domain, which contains the SRP's GTPase function; and its C-terminal M domain [so called because it is rich in Met residues (25 of its 209 residues in humans)]. The N domain, a bundle of four antiparallel α helices, closely associates with the Ras-like G domain to form an assembly named SRP54NG that mediates the SRP's interaction with the SRP receptor. The M domain (SRP54M), which contacts the ribosome near the mouth of its peptide exit tunnel, contains a deep groove that binds the helical signal sequence. The groove is lined almost entirely with hydrophobic residues including many of SRP54's Met residues (the Met side chain has physical properties similar to that of an *n*-butyl group; Section 4-1C). Its flexible unbranched Met side chain "bristles" presumably provide the groove with the plasticity to bind a variety of different signal sequences so long as they are hydrophobic and form an α helix.

Structural and biochemical studies indicate that the eukaryotic SRP first binds to the ribosome via its SRP54 protein. This interaction involves several ribosomal proteins, including L23, to which trigger factor also binds (Section 27-5A). When an emerging signal peptide binds to SRP54M, the SRP alters its conformation in a way that allows its Alu domain to fit into the site on the ribosome's intersubunit interface where elongation factor eEF2 (the eukaryotic counterpart of *E. coli* EF-G) also binds. This presumably interferes with the ribosomal elongation cycle (Fig. 27-27) and explains how the SRP arrests translation. This hypothesis is corroborated by the observation that bacterial SRP's, which do not arrest translation on binding to a ribosome, lack Alu domains.

Protein synthesis resumes after the SRP docks with its transmembrane receptor and its place has been taken by the translocon, whose ribosomal binding site largely overlaps that of the SRP. The central component of the translocon, named **Sec61** (Sec for *secretion*) in eukaryotes and the **SecY** complex in prokaryotes, is a heterotrimeric protein. Its α and γ subunits, but not its β subunit, are essential for channel function and are conserved across all domains of life (these subunits are respectively named Sec61 α , Sec61 β , and Sec61 γ in eukaryotes and SecE, and SecG in bacteria; the X-ray structure of SecY is shown in Fig. 9-38). A cryo-EM-based structure of a porcine ribosome–Sec61 complex (Fig. 27-45), determined by Rebecca Voorhees and Ramanujan Hegde, reveals, as expected, that a single Sec61 channel is positioned over the ribosome's polypeptide exit tunnel.

FIG. 27-45 Cryo-EM-based structure of a porcine ribosome–Sec61 complex at 3.4 Å resolution. The structure is drawn in ribbon form with the 40S rRNA orange, the 40S ribosomal proteins brown, the 60S rRNAs cyan, the 60S ribosomal proteins blue, and Sec61, embedded in its semitransparent surface diagram, red. The regions of the peptidyl transferase center (PTC) and ER membrane are indicated. [Courtesy of Rebecca Voorhees and Ramanujan Hegde, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 3J7O.]

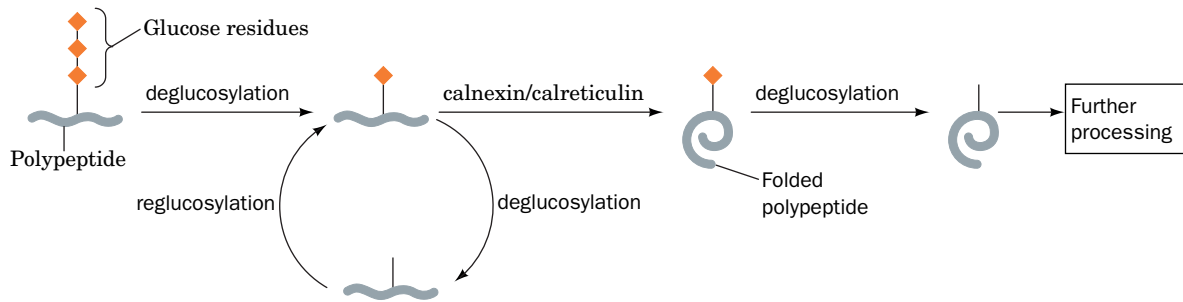

FIG. 27-46 Quality control in oligosaccharide processing. A partially processed glycoprotein bearing one terminal glucose residue can bind to the chaperones calnexin or calreticulin. The bound glycoprotein is then deglucosylated and processed further. An improperly folded

glycoprotein that becomes deglucosylated is reglucosylated by an enzyme that is specific for unfolded glycoproteins. This mechanism promotes the proper folding and oligosaccharide processing of newly synthesized glycoproteins.

Glycosylation Acts as a Quality Control Mechanism. In eukaryotes, polypeptides that are translocated into the ER by the secretory pathway undergo glycosylation. The cotranslational addition of a 14-residue oligosaccharide to an Asn residue is the first step in the production of *N*-linked glycoproteins (Section 8-3C). The attachment of the oligosaccharide verifies that the protein is being successfully translocated from the cytosol to the lumen of the endoplasmic reticulum. The subsequent removal of the two terminal glucose residues allows the protein to interact with a chaperone that recognizes the partially processed oligosaccharide. The membrane-bound 572-residue form of the chaperone, called **calnexin**, or its soluble 400-residue homolog **calreticulin**, binds the immature (unfolded) glycoprotein to assist its folding and to protect it from degradation or premature transfer to the Golgi apparatus (where the late stages of oligosaccharide processing take place; Section 9-4E).

After the folded glycoprotein is released from calnexin/calreticulin, it proceeds through the rest of the oligosaccharide-processing pathway. A glycoprotein that is released before it has adopted its mature conformation can still undergo the next step of processing, which is the removal of another glucose residue. However, when this happens, a glycosyltransferase that recognizes only unfolded glycoproteins reattaches a glucose residue to the immature oligosaccharide. As a result, the glycoprotein can bind again to calnexin/calreticulin for another chance to fold properly (Fig. 27-46). Most glycoproteins undergo reglucosylation at least once.

CHECKPOINT

- What is the function of trigger factor (TF)? Why must the number of TF molecules be at least as great as the number of ribosomes?
- List some posttranslational modifications of proteins.
- Describe the functions of the complexes that interact with the ribosome near its polypeptide exit channel.
- What is the function of the RNA component of the SRP?

Summary

1 The Genetic Code

- The genetic code, by which nucleic acid sequences are translated into amino acid sequences, is composed of three-nucleotide codons that do not overlap and are read sequentially by the protein-synthesizing machinery.
- The standard genetic code of 64 codons includes numerous synonyms, three Stop codons, and one initiation codon.

2 Transfer RNA and Its Aminoacylation

- All tRNAs have numerous chemically modified bases and a similar cloverleaf secondary structure comprising an acceptor stem, D arm, TψC arm, anticodon arm, and variable arm. The three-dimensional structures of tRNAs are likewise similar and are maintained by stacking interactions and non-Watson-Crick hydrogen-bonded cross-links.
- Aminoacyl-tRNA synthetases (aaRSs) catalyze the ATP-dependent attachment of an amino acid to the appropriate tRNA to yield an aminoacyl-tRNA (aa-tRNA). The acceptor stem and anticodon loop are

common identity elements for tRNA-aaRS interactions. The fidelity of aminoacylation is enhanced by proofreading.

- Wobble pairing between mRNA codons and tRNA anticodons at the third position accounts for much of the degeneracy of the genetic code. Within a species, the preferred codons correspond to the most abundant species in each set of isoaccepting tRNAs.

3 Ribosomes

- Ribosomes, which are large complexes of RNA and protein, have a structure that is determined by their RNA components. A small subunit and large subunit associate to form the intact ribosome, which accommodates an aa-tRNA in the A site, a peptidyl-tRNA in the P site, and a deacylated tRNA in the E site.

4 Translation

- During translation initiation, an initiator tRNA charged with fMet (in prokaryotes) or Met (in eukaryotes), an mRNA with an AUG initiation

codon, and the ribosomal subunits assemble. Initiation requires GTP-hydrolyzing initiation factors. The initiating AUG codon is identified in prokaryotes via the mRNA's Shine–Dalgarno sequence. In eukaryotes it is the mRNA's initiating AUG that is identified in a complex process by its proximity to the mRNA's 5' cap.

- A polypeptide chain is elongated from its N- to its C-terminus. An aa-tRNA in complex with a GTP-hydrolyzing elongation factor binds to the A site, where the ribosome senses correct codon–anticodon pairing, a process whose accuracy is enhanced by proofreading. The peptidyl transferase activity of the large subunit's RNA catalyzes the attack of the A-site bound aa-tRNA's amino group on the peptidyl-tRNA in the

P site. Following transpeptidation, a second GTP-hydrolyzing elongation factor promotes the translocation of the new peptidyl-tRNA to the P site.

- Translation termination requires release factors that recognize Stop codons.

5 Posttranslational Processing

- As a polypeptide emerges from the ribosome, it begins to fold with the assistance of chaperones. Proteins may undergo posttranslational processing that includes proteolysis, covalent modification, translocation through a membrane, and glycosylation.

Problems

EXERCISES

1. Could a single nucleotide deletion restore the function of a protein-coding gene interrupted by the insertion of a 4-nt sequence? Explain.

2. When a sequence of deoxynucleotides is entered into a translation program (such as the ExPASy Translate tool at <http://web.expasy.org/translate/>), six possible polypeptide sequences are given as results. Explain.

3. List all possible codons present in a ribonucleotide polymer containing U and G in random sequence. Which amino acids are encoded by this RNA?

4. Which amino acids are specified by codons that can be changed to a UAG Stop codon by a single point mutation?

5. In the genetic code used by mitochondria in many species, UGA codes for tryptophan rather than a Stop signal. How does mitochondrial translation terminate?

6. Some mitochondria use a second codon, in addition to AUG, to specify Met. Which codon(s) is (are) most likely to be used this way?

7. The protein Xpot transports tRNAs out of the nucleus so that they can be aminoacylated in the cytosol. (a) What tRNA structural features is Xpot likely to recognize? (b) How does Xpot distinguish mature tRNAs from pre-tRNAs?

8. The enzyme thiouridylase converts certain tRNA uridine residues to 2-thiouridine. Draw the structure of this modified nucleotide.

9. IleRS uses a double-sieve mechanism to accurately produce Ile-tRNA^{Ile} and prevent the synthesis of Val-tRNA^{Ile}. Which other pairs of amino acids differ in structure by a single carbon and might have aaRSs that use a similar double-sieve proofreading mechanism?

10. Some mutations that do not alter the identity of the encoded amino acid lead to diminished production of the protein. How does the mutation affect translation?

11. Draw the structures of an I · C wobble pair and an I · U wobble pair.

12. In eukaryotes, the primary rRNA transcript is a 45S rRNA that includes the sequences of the 18S, 5.8S, and 28S rRNAs separated by short spacers. What is the advantage of this operon-like arrangement of rRNA genes?

13. Explain the significance of the observation that peptides such as fMet-Leu-Phe “activate” the phagocytotic (particle-engulfing) functions of mammalian leukocytes (white blood cells).

14. Explain why prokaryotic ribosomes can translate a circular mRNA molecule, whereas eukaryotic ribosomes normally cannot, even in the presence of the required cofactors.

15. Explain why the translation of a given mRNA can be inhibited by a segment of its complementary sequence, a so-called **antisense RNA**.

16. Eukaryotic initiation factor eIF2B is a guanine nucleotide exchange factor. Explain why eIF2B would enhance the activity of eIF2.

17. The ribosome can transfer any peptidyl group from the P-site tRNA to any aminoacyl group on the A-site RNA, but the rate may vary with the identities of those groups. Propose an explanation why the ribosome synthesizes poly-Pro sequences extremely slowly compared to other peptide sequences.

18. Mitochondrial ribosomes manufacture 13 proteins, all of which are components of the oxidative phosphorylation machinery. Propose an explanation why the peptide exit tunnel of the mitoribosome is lined with hydrophobic groups rather than hydrophilic groups, as in a cytoplasmic ribosome.

19. Cells can make certain oligopeptides using conventional enzymes rather than mRNA-directed translation by a ribosome. Draw the product of the reaction catalyzed by L-glutamate: L-cysteine gamma-ligase (γ -glutamylcysteine synthetase).

20. The peptidyl transferase activity of the ribosome does not require an additional source of free energy. Is the reaction catalyzed by γ -glutamylcysteine synthetase (Problem 19) also exergonic?

CHALLENGE QUESTIONS

21. One cause of the neurodegenerative disease amyotrophic lateral sclerosis (ALS) is the expansion of the repeating hexanucleotide sequence GGGGCC in the noncoding region of a gene. By unknown mechanisms, the repeating sequence is translated to generate neurotoxic peptides. Predict the sequences of the possible repeating dipeptides.

22. The flu virus maximizes the use of its limited (13.5 kb) genome by using alternative translation initiation sites, overlapping reading frames, and ribosomal frameshifting. For example, part of the viral PA gene includes a rarely used CGU codon. When the ribosome pauses to translate this codon, it may slip ahead by one nucleotide and produce a polypeptide with a different C-terminal sequence. From the partial mRNA sequence shown here, determine the normal polypeptide sequence and the sequence with the frameshift.

– GAUUCUUUCGUCAGUCCGAGA –

23. A double-stranded fragment of viral DNA, one of whose strands is shown below, encodes two peptides, called *vir-1* and *vir-2*. Adding this double-stranded DNA fragment to an *in vitro* transcription and translation system yields peptides of 10 residues (*vir-1*) and 5 residues (*vir-2*).
AGATCGGATGCTCAACTATATGTGATTAACAGAGCATGCGGCATAAACT

- Identify the DNA sequence that encodes each peptide.
- Determine the amino acid sequence of each peptide.
- In a mutant viral strain, the T at position 23 has been replaced with G. Determine the amino acid sequences of the two peptides encoded by the mutant virus.

24. The sequence of the sense strand of a mammalian gene is
TATAATACGCGCAATACAATCTACAGCTTCGCGTAAATC-GTAGGTAAGTTGTAATAAATATAAGTGAGTATGATACAG-GCTTTGGACCGATAGATGCGACCCTGGAGGTAAGTATAGAT-TAATTAAGCACAGGCATGCAGGGATATCCTCCAAAAGGTA-AGTAACCTTACGGTCAATTAATTCAGGCAGTAGATGAATA-AACGATATCGATCGGTTAGGTAAGTCTGAT

Determine the sequences of the mature RNA and the encoded protein. Assume that transcription initiates at a G approximately 25 bp downstream of the TATAATA sequence, that each 5' splice site has the sequence AG/GUAAGU, and that each 3' splice site has the sequence CAG/G (where / marks the location of the splice).

25. EF-Tu binds all aminoacyl-tRNAs with approximately equal affinity so that it can deliver them to the ribosome with the same efficiency. Based on the experimentally determined binding constants for EF-Tu and correctly charged and mischarged aminoacyl-tRNAs (see table), explain how the tRNA-EF-Tu recognition system could prevent the incorporation of the wrong amino acid during translation.

Aminoacyl-tRNA	Dissociation Constant (nM)
Ala-tRNA ^{Ala}	6.2
Gln-tRNA ^{Ala}	0.05
Gln-tRNA ^{Gln}	4.4
Ala-tRNA ^{Gln}	260

Source: [LaRiviere, F.J., Wolfson, A.D., and Uhlenbeck, O.C., *Science* 294, 167 (2001).]

26. The antibiotic **paromomycin** binds to a ribosome and induces the same conformational changes in 16S rRNA residues A1492 and A1493

as are induced by codon-anticodon pairing (Fig. 27-32). Propose an explanation for the antibiotic effect of paromomycin.

27. The rate of the peptidyl transferase reaction increases as the pH increases from 6 to 8. Explain these results in terms of its reaction mechanism.

28. It has been proposed that residue A2486 is protonated and therefore stabilizes the tetrahedral reaction intermediate. Is this mechanistic embellishment consistent with the observed pH effect (Problem 27)? Explain.

29. Explain why a minimum of 32 tRNAs are required to translate the "standard" genetic code.

30. Under conditions of nutrient starvation, bacteria produce a protein that binds to the 3' end of 16S rRNA. What is the result of this interaction and why is it beneficial to the cell?

31. All cells contain an enzyme called **peptidyl-tRNA hydrolase**, and cells that are deficient in the enzyme grow very slowly. What is the probable function of the enzyme and why is it necessary?

32. Genetically engineered mRNAs that code for a stretch of basic residues, such as poly(Lys), induce translation termination and destruction of the nascent polypeptide. Explain how this response would protect cells from the effect of faulty transcription that produces mRNAs with mutated Stop codons.

33. Calculate the energy required, in ATP equivalents, to synthesize a 100-residue protein from free amino acids in *E. coli* (assume that the N-terminal Met remains attached to the polypeptide and that no ribosomal proofreading occurs).

34. Design an mRNA with the necessary prokaryotic control sites that codes for the octapeptide Lys-Pro-Ala-Gly-Thr-Glu-Asn-Ser.

35. How many different types of macromolecules must be minimally contained in a cell-free protein synthesizing system from *E. coli*? Count each type of ribosomal component as a different macromolecule.

36. An antibiotic named fixmycin, which you have isolated from a fungus growing on ripe passion fruit, is effective in curing several types of sexually transmitted diseases. In characterizing fixmycin's mode of action, you have found that it is a bacterial translational inhibitor that binds exclusively to the large subunit of *E. coli* ribosomes. The initiation of protein synthesis in the presence of fixmycin results in the generation of dipeptides that remain associated with the ribosome. Suggest a mechanism of fixmycin action.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1. Viewing and Analyzing Transfer RNA

Exercise 2. Ribosomes, Protein Processing, and the KEGG Database

MORE TO EXPLORE Not all naturally occurring peptides are synthesized by ribosomes that decode messenger RNA. How does nonribosomal peptide synthesis take place? How does it differ from polyketide synthesis (Box 20-3)? What are some functions of these peptides?

Regulation of Gene Expression

Chapter Contents

1 Genome Organization

- A Gene Number Varies among Organisms
- B Some Genes Occur in Clusters
- C Eukaryotic Genomes Contain Repetitive DNA Sequences

2 Regulation of Prokaryotic Gene Expression

- A The *lac* Operon Is Controlled by a Repressor
- B Catabolite-Repressed Operons Can Be Activated
- C Attenuation Regulates Transcription Termination
- D Riboswitches Are Metabolite-Sensing RNAs

3 Regulation of Eukaryotic Gene Expression

- A Chromatin Structure Influences Gene Expression
- B Eukaryotes Contain Multiple Transcriptional Activators
- C Posttranscriptional Control Mechanisms
- D Antibody Diversity Results from Somatic Recombination and Hypermutation

4 The Cell Cycle, Cancer, Apoptosis, and Development

- A Progress through the Cell Cycle Is Tightly Regulated
- B Tumor Suppressors Prevent Cancer
- C Apoptosis Is an Orderly Process
- D Development Has a Molecular Basis

The controlled expression of genetic information requires a multitude of factors that interact specifically and nonspecifically with DNA. This painting schematically diagrams transcription factors in the preinitiation complex whose formation in eukaryotes must precede the transcription of DNA to mRNA.

The faithful replication of DNA ensures that all the descendants of a single cell contain virtually identical sets of genetic instructions. Yet individual cells may differ—sometimes dramatically—from their progenitors, depending on how those instructions are read. The **expression** of genetic information in a given cell or organism, that is, the synthesis of RNA and proteins specified by the DNA sequence, is neither random nor fully preprogrammed. Rather, *the information in an organism's genome must be tapped in an orderly fashion during development and yet must also be available to direct the organism's responses to changes in internal or external conditions.*

Much of the mystery surrounding the regulation of gene expression has to do with how genetic information is organized and how it can be located and accessed on an appropriate time scale. The complexity of the mechanisms for transcribing and translating genes suggests the potential for even more complicated systems for enhancing or inhibiting these processes. Indeed, we have already seen numerous examples of how accessory protein factors influence the rates or specificities of transcription and translation. In this chapter, we consider some additional aspects of gene expression by examining a variety of strategies used by prokaryotes and eukaryotes to control how genetic information specifies cell structures and metabolic functions.

1 Genome Organization

KEY CONCEPTS

- An organism's complexity increases with the number of its genes but not the size of its genome.
- rRNA and tRNA genes occur in clusters.
- Eukaryotic genomes contain segments of repetitive DNA.

Genomics, the study of organisms' genomes, was established as a discipline with the advent of techniques for rapidly sequencing enormous tracts of DNA, such as make up the chromosomes of living things. Studies that once relied on the hybridization of oligonucleotide probes to identify genes can now be conducted by comparing nucleotide sequences deposited in databases (Section 5-3E). In fact, a computerized database is the only practical format for storing the vast amount of information provided by a whole-genome sequence. Even a simplified diagram of the genome of the relatively simple bacterium *Helicobacter pylori* (a major cause of peptic ulcers) reveals a bewildering array of genes (**Fig. 28-1**). Nevertheless, the ability to sequence and map the entire genome of an organism makes it possible to draw far-reaching conclusions about how many genes an organism contains, how they are organized, and how they serve the organism.

A Gene Number Varies among Organisms

The rough correlation between the quantity of an organism's unique genetic material (its **C value**) and the complexity of its morphology and metabolism (Table 3-3) has numerous exceptions, known as the **C-value paradox**. For example, the genomes of lungfishes are 10- to 15-fold larger than those of mammals (**Fig. 28-2**). Some algae have genomes ~10-fold larger still. We know that much of this "extra" DNA is unexpressed, but its function is largely a matter of conjecture. The complete genomic sequences of numerous prokaryotes and eukaryotes, including data from some large, complicated genomes, nevertheless indicate that *the apparent number of genes, like the overall quantity of DNA, roughly parallels the organism's complexity* (**Table 28-1**). Thus, humans have ~21,000 genes compared to *E. coli's* ~4300 genes.

Only a Small Portion of the Human Genome Encodes Proteins. All but about 0.3% of the 3,038,000-kb human genome has been fully sequenced (the remaining

FIG. 28-1 Map of the 1670-kb *H. pylori* circular chromosome. The 1590 predicted protein-coding sequences (91% of the genome) are indicated in different colors on the two outermost rings, which represent the two DNA strands. The third and fourth rings indicate intervening sequence elements and other repeating sequences (2.3% of the genome). The fifth and sixth rings show the genes for tRNAs, rRNAs, and other small RNAs (0.7% of the genome). Intergenic sequences account for 6% of the genome.

FIG. 28-2 Range of haploid genome DNA contents in various categories of organisms. The morphological complexity of the organisms, as estimated from their number of different cell types, increases from bottom to top. Haploid genome size roughly correlates with complexity; exceptions are described by the C-value paradox.

[After Raff, R.A. and Kaufman, T.C., *Embryos, Genes, and Evolution*, p. 314, Macmillan (1983).]

? Identify the vertebrates with the largest and smallest genomes.

DNA includes gene-poor regions near the centromeres and telomeres). *Only about 1.2% of the genome encodes proteins*, and the ~21,000 protein-coding genes are distributed throughout the genome, sometimes in clusters. Identifying the genes in human or other genomes involves several approaches.

A gene can be identified by its homology to a previously described mRNA or protein sequence. A protein-coding gene may also be identified as an **open**

TABLE 28-1 Genome Size and Gene Number in Some Organisms

Organism	Genome Size (kb)	Number of Genes
<i>Haemophilus influenzae</i> (bacterium)	1,830	1,740
<i>Escherichia coli</i> (bacterium)	4,639	4,289
<i>Saccharomyces cerevisiae</i> (yeast)	12,070	6,034
<i>Caenorhabditis elegans</i> (nematode)	97,000	19,099
<i>Oryza sativa</i> (rice)	389,000	~35,000
<i>Arabidopsis thaliana</i> (mustard weed)	119,200	~26,000
<i>Drosophila melanogaster</i> (fruit fly)	180,000	13,061
<i>Mus musculus</i> (mouse)	2,500,000	~22,000
<i>Homo sapiens</i> (human)	3,038,000	~21,000

reading frame (ORF), a sequence that is not interrupted by Stop codons and that exhibits the same codon-usage preferences as other genes in the organism. However, our incomplete knowledge of the features through which cells recognize genes, combined with the fact that human genes consist of relatively short exons (averaging ~123 nt) separated by much longer introns (averaging ~1800 nt and often much longer), has limited the success of computer-based gene identification algorithms. Such algorithms therefore rely on sequence alignments with **expressed sequence tags (ESTs)**; cDNAs that have been reverse-transcribed from mRNAs) together with alignments with known genes from other organisms. Genes may also be revealed by the presence of a **CpG island** (Box 25-4). CpG dinucleotides are present in vertebrate genomes at only about one-fifth their randomly expected frequency (because the spontaneous deamination of m^5C yields a normal T and therefore often results in a $C \cdot G \rightarrow T \cdot A$ mutation), but they appear in clusters or islands at near-normal frequencies in the upstream regions of many genes (~56% of human genes).

The number of human genes is much lower than had once been predicted. The discrepancy between current estimates (~21,000 genes) and earlier estimates of as many as 140,000 protein-coding, or structural, genes is largely attributed to the high prevalence of alternative splicing (Section 26-3B). In addition, variations in posttranslational processing (Section 27-5B) enable a given DNA sequence to give rise to several functionally distinct protein products.

The functions of many human genes have been identified through sequence comparisons at the level both of protein families and of domains (Fig. 28-3). Note that nearly 42% of these genes have unknown functions, as is likewise the case with most other genomes of known sequence, including those of prokaryotes. Genes with no known function are called **orphan genes**. Some of these sequences may represent novel genes whose protein products have not yet been characterized. Others may simply be counterparts of known genes but are too different in sequence to be recognized as such.

About three-quarters of all known human genes appear to have counterparts in other species. About one-quarter are present only in other vertebrates, and one-quarter are present in prokaryotes as well as eukaryotes. As expected, the human genome contains approximately the same number of “housekeeping” genes (genes required for the most fundamental cellular activities) as other eukaryotes. But it includes relatively more genes for vertebrate-specific activities, such as those relevant to the immune system and neuronal and hormonal signaling pathways.

FIG. 28-3 Distribution of molecular functions of the putative structural genes in the human genome. Each wedge of the pie chart lists, in parentheses, the percentage of the genes assigned to the indicated category of molecular function. The outer circle indicates the general functional categories whereas the inner circle provides a more detailed breakdown of the categories. [Courtesy of J. Craig Venter, Celera Genomics, Rockville, Maryland.]

? Which categories would contain fewer genes in a single-celled eukaryote?

A Significant Portion of the Human Genome Is Transcribed to RNA. Although the proportion of exonic DNA in the human genome is relatively small (~1.4%), as much as 80% of the genome may be transcribed. This mass of RNA includes the products of ~4000 identified genes for tRNAs, rRNAs, and other small RNAs, as well as tens of thousands of other **noncoding RNAs (ncRNAs)**, many of which have no known function. Some ncRNAs are polyadenylated, as are mRNAs (Section 26-3A), but do not correspond to any known genes. One possibility is that this RNA represents transcriptional noise arising from promoter-like elements scattered throughout the genome. However, the observation that some ncRNAs exhibit conservation between species and tissue-specific splice variants suggests that such RNAs have regulatory functions.

Many Disease Genes Have Been Identified. The availability of human genomic data has facilitated the identification of sequence variants that are associated with particular diseases. Nearly 15,000 such variants have been catalogued [in the **Online Mendelian Inheritance in Man (OMIM)** database (<http://www.ncbi.nlm.nih.gov/omim/>)], including those for cystic fibrosis (Box 3-1), glycogen storage diseases (Box 16-2), and many hereditary forms of cancer. However, monogenetic diseases are relatively rare. Most diseases result from interactions among several genes and from environmental factors. One goal of genomics is to identify genetic features that can be linked to susceptibility to disease or infection. To that end, a catalog of human DNA sequence variations has been compiled as a database of **single nucleotide polymorphisms (SNPs;** pronounced “snips”). A SNP, or single-base difference between individuals, occurs about every ~1250 bp on average. Over 115 million SNPs have been described. Although less than 1% of them result in protein variants, and probably fewer still have functional consequences, it is becoming increasingly apparent that SNPs are largely responsible for an individual’s susceptibility to many diseases as well as to adverse reactions to drugs (side effects; Section 12-4). Moreover, SNPs can potentially serve as genetic markers for nearby disease-related genes.

Genome-wide association studies (GWAS) attempt to link common genetic variants to specific diseases that have no obvious hereditary component. Such studies typically involve examining the DNA of thousands of individuals to obtain a dataset in which relatively rare sequence variations can be tabulated. For example, 39 loci (sites) have been shown to be associated with type 2 diabetes (Section 22-4B), and 71 loci with **Crohn’s disease**, an autoimmune disorder. Although the increased risk of disease assigned to a particular allele may be low, the entire set of variants can explain up to 50% of the heritability of a disease. Moreover, the discovery of new genes associated with a condition can provide additional targets for drug development (Section 12-4).

B Some Genes Occur in Clusters

Genes are not necessarily randomly distributed throughout an organism’s genome. For example, the average gene frequency in the human genome is ~1 gene per 100 kb but ranges from 0 to 64 genes per 100 kb. Moreover, some protein-coding genes and other chromosomal elements exhibit a certain degree of organization. Prokaryotic genomes, for example, contain numerous operons, in which, as we have seen (Section 26-1B), genes with related functions (e.g., encoding the proteins involved in a particular metabolic pathway) occur close together, sometimes in the same order in which their encoded proteins act in a metabolic reaction sequence, and are transcribed onto a single polycistronic mRNA.

Gene clusters also occur in both prokaryotes and eukaryotes. Although most genes occur only once in an organism’s haploid genome, genes such as those for rRNA and tRNA, whose products are required in relatively large amounts, may occur in multiple copies. As we saw in Section 26-3C, large rRNA

FIG. 28-4 An electron micrograph of tandem arrays of actively transcribing 18S, 5.8S, and 28S rRNA genes from the newt *Notophthalmus viridescens*. The axial fibers are DNA. The fibrillar “Christmas tree” matrices, which consist of newly synthesized RNA strands in complex with proteins, outline each transcriptional unit. Note that the longest ribonucleoprotein branches are only ~10% of the length of their corresponding DNA. Apparently, the RNA strands are compacted through secondary structure interactions and/or protein associations. The matrix-free segments of DNA are the untranscribed spacers.

transcripts are cleaved to yield the mature rRNA molecules. Furthermore, the transcribed blocks of 18S, 5.8S, and 28S eukaryotic rRNA genes are arranged in tandem repeats that are separated by nontranscribed spacers (Fig. 28-4). The rRNA genes, which may be distributed among several chromosomes, vary in haploid number from less than 50 to over 10,000, depending on the species. Humans, for example, have 50 to 200 blocks of rRNA genes spread over five chromosomes. tRNA genes are similarly reiterated and clustered.

Protein-coding genes almost never occur in multiple copies, presumably because the repeated translation of a few mRNA transcripts provides adequate amounts of most proteins. One exception is histone proteins, which are required in large amounts during the short time when eukaryotic DNA synthesis occurs. Not only are histone genes reiterated (up to ~100 times in *Drosophila*), they often occur as sets of each of the five different histone genes separated by nontranscribed sequences (Fig. 28-5). The gene order and the direction of transcription in these quintets are preserved over large evolutionary distances. The spacer sequences vary widely among species and, to a limited extent, among the repeating quintets within a genome. In birds and mammals, which contain 10 to 20 copies of each of the five histone genes, the genes occur in clusters but in no particular order.

Other gene clusters contain genes of similar but not identical sequence. For example, human globin genes are arranged in two clusters on separate chromosomes (Fig. 28-6). The various genes are transcribed at different developmental stages. Adult hemoglobin is an $\alpha_2\beta_2$ tetramer, whereas the first hemoglobin made by the human embryo is a $\zeta_2\varepsilon_2$ tetramer in which ζ and ε are α - and β -like subunits, respectively (Fig. 28-7). At approximately 8 weeks after conception, fetal hemoglobin containing α and γ subunits appears. The γ subunit is gradually supplanted by β starting a few weeks before birth. Adult human blood normally contains ~97% $\alpha_2\beta_2$ hemoglobin, 2% $\alpha_2\delta_2$ (in which δ is a β variant), and 1% $\alpha_2\gamma_2$.

The **α -globin gene cluster** (Fig. 28-6, *top*), which spans 28 kb, contains three functional genes: the embryonic ζ gene and two slightly different α genes, $\alpha 1$ and $\alpha 2$, which encode identical polypeptides. The α cluster also contains four **pseudogenes** (nontranscribed relics of ancient gene duplications): $\psi\zeta$, $\psi\alpha 2$, $\psi\alpha 1$,

FIG. 28-5 The organization and lengths of the histone gene cluster repeating units in a variety of organisms. Coding regions are indicated in color, and spacers are gray. The arrows denote the direction of transcription (the top three organisms are distantly related sea urchins).

FIG. 28-6 The organization of human globin genes. Red boxes represent active genes; green boxes represent pseudogenes; yellow boxes represent repetitive sequences, with the arrows indicating their relative orientations; and triangles represent *Alu* elements in their relative orientations. [After Karlsson, S. and Nienhuis, A.W., *Annu. Rev. Biochem.* **54**, 1074 (1985).]

and $\psi\theta$. The **β -globin gene cluster** (Fig. 28-6, *bottom*), which spans >60 kb, contains five functional genes: the embryonic ϵ gene, the fetal genes $G\gamma$ and $A\gamma$ (duplicated genes encoding polypeptides that differ only by having either Gly or Ala at position 136), and the adult genes δ and β . The β -globin cluster also contains one pseudogene, $\psi\beta$. Both α and β gene clusters also include copies of **repetitive DNA sequences** (see below).

C Eukaryotic Genomes Contain Repetitive DNA Sequences

Approximately 11% of the *E. coli* genome consists of nontranscribed regions, including the regulatory sequences that separate individual genes and sites that govern the origin and termination of replication. In addition, bacterial genomes typically contain insertion sequences (Section 25-6C) and the remnants of integrated bacteriophages.

The small sizes of prokaryotic genomes probably exert selective pressure against the accumulation of useless DNA. Eukaryotic genomes, however, which are usually much larger than prokaryotic genomes, apparently are not subject to the same selective forces. About 30% of the yeast genome consists of nonexpressed sequences, and the proportion is far greater in higher eukaryotes. Much of this DNA consists of repetitive sequences that contribute significantly to the relatively large genomes of certain plants and amphibians. Some repetitive DNA plays a structural role at the **centromeres** of eukaryotic chromosomes, the regions attached to the microtubular spindle during mitosis. These sequences may help align chromosomes and facilitate recombination. The telomeres also

FIG. 28-7 The progression of human globin chain synthesis with fetal development. Note that any red blood cell contains only one type each of α - and β -like subunits. [After Weatherall, D.J. and Clegg, J.B., *The Thalassemia Syndromes* (3rd ed.), p. 64, Blackwell Scientific Publications (1981).]

? Identify the predominant form of hemoglobin 20 weeks before and 20 weeks after birth.

At least 14 human diseases are associated with repeated trinucleotides in certain genes. These **trinucleotide repeats** exhibit an unusual genetic instability: Above a threshold of about 35 to 50 copies (100–150 bp), the repeats tend to expand with successive generations. Because the overall length of the repeat typically correlates with the age of onset of the disease, descendants of an individual with a trinucleotide repeat disease tend to be more severely affected and at an earlier age. The disease is therefore said to exhibit **genetic anticipation**.

Some types of trinucleotide repeat diseases are caused by massive expansion (usually to hundreds of copies) of a trinucleotide in the noncoding region of a gene, for example, in a region upstream of the transcription start site, in a 5' or 3' untranslated region (**UTR**), or in an intron (see table). These expansions generally affect gene expression. For example, **myotonic dystrophy** results from aberrant expression of a protein kinase. The severity of the symptoms, progressive muscle weakness and wasting, correlate with the number of CTG repeats (>2000 in some cases) in its gene's 5' UTR.

Some Diseases Associated with Trinucleotide Repeats

Disease	Repeat	Site of Repeat
Fragile X syndrome	CGG	5' UTR
Myotonic dystrophy	CTG	Upstream region, 3' UTR
Friedrich's ataxia	GAA	Intron
Spinobulbar muscular atrophy	CAG	Exon
Huntington's disease	CAG	Exon

Fragile X syndrome, the most common cause of mental retardation after Down's syndrome, is so named because the tip of the X chromosome's long arm is connected to the rest of the chromosome by a slender thread that is easily broken. As in many trinucleotide repeat diseases, the genetics of fragile X syndrome are bizarre. The maternal grandfathers of individuals having fragile X syndrome may be asymptomatic. Their daughters are likewise asymptomatic, but these daughters' children of either sex may have the syndrome. Evidently, the fragile X defect is activated by passage through a female.

The affected gene in fragile X syndrome, *FMR1* (for fragile X mental retardation 1), encodes a 632-residue RNA-binding protein named **FMRP** (for *FMR* protein), which apparently functions in the transport of certain mRNAs from the nucleus to the cytoplasm. FMRP, which is highly conserved in vertebrates, is heavily expressed in brain neurons, where a variety of evidence indicates that it participates in the proper formation and/or function of synapses. In the general population, the 5' untranslated region of *FMR1* contains a (CGG)_n sequence with *n* ranging from 6 to 60 (such a gene is said to be **polymorphic**). However, in individuals with fragile X syndrome, this triplet repeat has undergone an astonishing expansion to values of *n* ranging from >200 to several thousand. Moreover, these triplet repeats differ in size among siblings and often exhibit heterogeneity within an individual, suggesting that they are somatically generated.

Some trinucleotide repeat diseases result from the moderate expansion of a CAG triplet (which codes for Gln) in the protein-coding region of a gene. For example, in normal individuals, **huntingtin**, a polymorphic, ~3150-residue protein of unknown function, contains a stretch of 11 to 34 consecutive Gln residues beginning 17 residues from its N-terminus. However, in **Huntington's disease (HD)**, this poly(Gln) tract

are composed of repeating DNA sequences (Section 25-3C). A variety of neurological diseases result from excessively reiterated trinucleotide sequences (see Box 28-1).

Highly Repetitive Sequences Are Tandemly Repeated Millions of Times. Nearly identical sequences up to 10 bp long that are tandemly repeated in clusters may be present at >10⁶ copies per haploid genome. Approximately 3% of the human genome consists of **highly repetitive DNA sequences** (also known as **short tandem repeats; STRs**), with the greatest contribution (0.5%) provided by dinucleotide repeats, most frequently CA and TA. STRs appear to have arisen by template slippage during DNA replication. This occurs more frequently with short repeats, which therefore have a high degree of length polymorphism in the human population. Because the number of repeats at a given STR locus varies between individuals, analysis of STRs is widely used for DNA fingerprinting (Box 3-2). **Segmental duplications** are long stretches of DNA (1–200 kb) that are present in at least two locations in the genome.

Moderately Repetitive Sequences Arise from Transposons. Moderately repetitive DNA (<10⁶ copies per haploid genome) occurs in segments of 100 to several thousand base pairs that are interspersed with larger blocks of unique DNA. Most of the repetitive sequences are the remnants of retrotransposons (transposable elements that propagate through the intermediate synthesis of RNA; Section 25-6C). Around 42% of the human genome consists of three types of retrotransposons (**Table 28-2; Fig. 28-8**):

1. **Long interspersed nuclear elements (LINEs)** are 6- to 8-kb-long segments. The great majority of these molecular parasites have accumulated

has expanded to between 37 and 86 repeats. Synthetic poly(Gln) aggregates as β sheets that are linked by hydrogen bonds involving both their main chain and side chain amide groups.

Individuals with HD, an autosomal dominant condition, suffer progressive choreic (jerky and disordered) movements, cognitive decline, and emotional disturbances over a 15- to 20-year course that is invariably fatal. This devastating disease typically develops at around age 40, or earlier in individuals with high numbers of trinucleotide repeats. One of the hallmarks of HD, as well as of other neurodegenerative diseases such as Alzheimer's disease, is the deposition of insoluble protein aggregates in the cytosol and nuclei of neurons (Section 6-5C). The appearance of these intracellular aggregates (presumably huntingtin and/or its proteolytic products in HD) often coincides with the onset of neurological symptoms, although it is unclear whether protein aggregation directly causes neuronal death and its attendant symptoms. The long incubation period before the symptoms of HD become evident is attributed to the lengthy nucleation time for aggregate formation, much like what we have seen occurs in the formation of amyloid fibrils (Section 6-5C).

The expansion of trinucleotide repeats occurs by an unknown mechanism. One theory, that additional nucleotides are introduced by the slippage of DNA polymerases during replication, is inconsistent with the gradual accumulation of trinucleotide repeats over time in cells such as neurons that normally do not divide. Another possibility is that the additional nucleotides are introduced during DNA repair processes (which are ongoing and independent of DNA replication) and may result from hairpin formation within the trinucleotide repeat region. These intrastrand base-paired structures (see figure) may lead to misalignment of DNA strands and the polymerization of additional nucleotides to fill in the gaps.

TABLE 28-2 Moderately Repetitive Sequences in the Human Genome

Type of Repeat	Length (bp)	Number of Copies ($\times 1000$)	Percentage of Genome
LINEs	6000–8000	868	20.4
SINEs	100–300	1558	13.1
LTR retrotransposons	1500–11,000	443	8.3
DNA transposons	80–3000	294	2.8
Total			44.8

Source: International Human Genome Sequencing Consortium, *Nature* **409**, 860 (2001).

FIG. 28-8 The nucleotide sequence content of the human genome. [After Alberts, B., Johnson, A., Lewis, J., Morgan, D., Raff, M., Roberts, K. and Walter, P., *Molecular Biology of the Cell* (6th ed.), p. 218, Garland Science (2015).]

mutations that render them transcriptionally inactive, but a few still appear capable of further transposition. Several hereditary diseases are caused by insertion of a LINE into a gene.

2. **Short interspersed nuclear elements (SINEs)** consist of 100- to 400-bp elements. The most common SINEs in the human genome are members of the *Alu* family, which are so named because most of their ~300-bp segments contain a cleavage site for the restriction endonuclease AluI (AGCT; Table 3-2). The globin gene cluster contains several *Alu* elements (Fig. 28-6).
3. Retrotransposons with **long terminal repeats (LTRs)**.

In addition, the human genome contains DNA transposons that resemble bacterial transposons. Overall, ~45% of the human genome consists of widely dispersed and almost entirely inactive transposable elements.

No function has been unequivocally assigned to **moderately repetitive DNA**, which therefore has been termed **selfish** or **junk DNA**. This DNA apparently is a molecular parasite that, over many generations, has disseminated itself throughout the genome through transposition. The theory of natural selection suggests that the increased metabolic burden imposed by the replication of an otherwise harmless selfish DNA would eventually lead to its elimination. Yet for slowly growing eukaryotes, the relative disadvantage of replicating an additional 100 bp of selfish DNA in an ~1-billion-bp genome would be so slight that its rate of elimination would be balanced by its rate of propagation. *Because unexpressed sequences are subject to little selective pressure, they accumulate mutations at a greater rate than do expressed sequences.*

FIG. 28-9 A phylogenetic tree indicating the lines of descent among 26 representative human populations. The tree is based on the sequences of 29 polymorphic loci. The major groups of human populations are (A) Africans, (B) Caucasians, (C) Greater Asians, (D) Amerindians, and (E) Australopapuans. The number beside each of the branches indicates their relative lengths and is therefore indicative of the genetic distances between the related populations and thus the times between their divergence. [Based on a drawing by Masatoshi Nei, Pennsylvania State University.]

? Which groups are more similar: A and B or C and D?

DNA Polymorphisms Can Establish Genealogies. Unexpressed sequences, which are subject to little selective pressure, evolve so much faster than expressed sequences that they accumulate significant numbers of sequence **polymorphisms** (variations) within a single species. Consequently, the evolutionary relationships among populations within a species can be established by determining how a series of polymorphic DNA sequences are distributed among them. For example, Masatoshi Nei inferred the genealogy of 26 representative human populations from around the world from the sequence variations in 29 polymorphic loci. The resulting phylogenetic tree (**Fig. 28-9**; *opposite*) indicates that non-African (Eurasian) populations are much more closely related to each other than they are to African populations. Fossil evidence indicates that anatomically modern humans arose in Africa ~200,000 years ago and spread throughout that continent. The phylogenetic tree therefore suggests that all Eurasian populations are descended from a surprisingly small “founder population” (perhaps only a few hundred individuals) that left Africa ~100,000 years ago. A similar analysis indicates that the sickle-cell variant of the β -globin gene (Section 7-1E) arose on at least three separate occasions in geographically distinct regions of Africa.

CHECKPOINT

- What is the relationship between genome size and gene number in different organisms?
- What are some factors that allow humans to get by with only slightly more genes than invertebrates?
- What is the purpose of cataloging SNPs and doing genome-wide association studies?
- What are the origins and functions of gene clusters?
- Summarize the relationship between genome size, repetitive DNA, transcribed DNA, and protein-coding exons in the human genome.
- What is the source of the repetitive DNA in the human genome?

2 Regulation of Prokaryotic Gene Expression

KEY CONCEPTS

- The *lac* repressor prevents or allows transcription of the *lac* operon.
- cAMP stimulates transcription of catabolite-repressed operons.
- Attenuation links amino acid availability to operon expression.
- A riboswitch changes its conformation to regulate gene expression.

A complete genome sequence reveals the metabolic capabilities of an organism, but *gene sequences alone do not necessarily indicate when or where the encoded molecules are produced*. The route from gene sequence to fully functional gene product offers many potential points for regulation, but *in prokaryotes, gene expression is primarily controlled at the level of transcription*. This is perhaps because prokaryotic mRNAs have lifetimes of only a few minutes, so translational control is less necessary. In this section, we examine a few well-documented examples of gene regulation in prokaryotes. In the following section, we will consider how eukaryotic cells regulate gene expression.

A The *lac* Operon Is Controlled by a Repressor

Bacteria adapt to their environments by producing enzymes that metabolize certain nutrients only when those substances are available. For example, *E. coli* cells grown in the absence of lactose are initially unable to metabolize the disaccharide. To do so they require two proteins: **β -galactosidase**, which catalyzes the hydrolysis of lactose to its component monosaccharides (*at right*), and **galactoside permease** (also known as **lactose permease**; Section 10-3D), which transports lactose into the cell. Cells grown in the absence of lactose contain only a few molecules of the proteins. Yet a few minutes after lactose is introduced into their medium, the cells increase the rate at which they synthesize the proteins by ~1000-fold and maintain that pace until lactose is no longer available. *This ability to produce a series of proteins only when the substances they metabolize are present permits the bacteria to adapt to their environment without the debilitating need to continuously synthesize large quantities of otherwise unnecessary enzymes.*

WileyPLUS Learning Space

See Guided Exploration

The regulation of gene expression by the *lac* repressor system

Lactose or one of its metabolic products must somehow act as an **inducer** to trigger the synthesis of the above proteins. The physiological inducer of the lactose system, the lactose isomer **1,6-allolactose**,

1,6-Allolactose

arises from lactose's occasional transglycosylation by β -galactosidase. Most *in vitro* studies of lactose metabolism use **isopropylthiogalactoside (IPTG)**,

Isopropylthiogalactoside (IPTG)

a synthetic inducer that structurally resembles allolactose but is not degraded by β -galactosidase. Natural and synthetic inducers also stimulate the synthesis of **thiogalactoside transacetylase**, an enzyme whose physiological role is unknown.

The genes specifying β -galactosidase, galactoside permease, and thiogalactoside transacetylase, designated *Z*, *Y*, and *A*, respectively, are contiguously arranged in the *lac* operon (Fig. 26-5). All three structural genes are translated from a single mRNA transcript. A nearby gene, *I*, encodes the ***lac* repressor**, a protein that inhibits the synthesis of the three *lac* proteins.

***lac* Repressor Recognizes Operator Sequences.** The target of the *lac* repressor is a region of the *lac* operon known as its **operator**, which lies near the beginning of the β -galactosidase gene. *In the absence of inducer, lac repressor specifically binds to the operator to prevent the transcription of mRNA (Fig. 28-10a). On binding inducer, the repressor dissociates from the operator, thereby permitting the transcription and subsequent translation of the lac enzymes (Fig. 28-10b).*

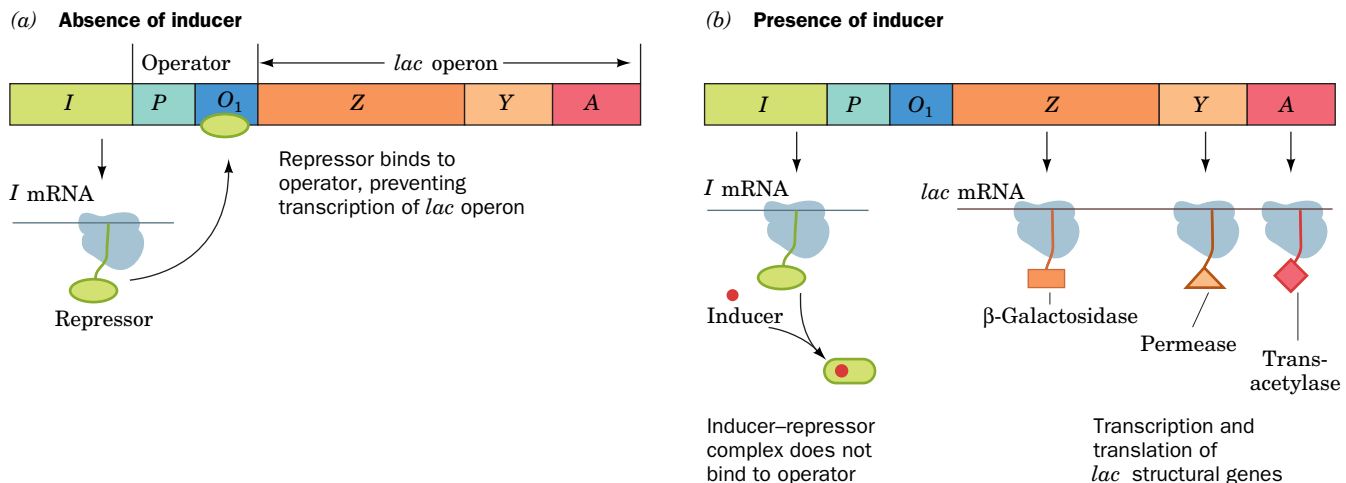

FIG. 28-10 The expression of the *lac* operon. (a) In the absence of inducer, the repressor (the product of the *I* gene) binds to the operator (O_1), thereby preventing transcription of the *lac* operon from the promoter (*P*). (b) On binding inducer, the repressor dissociates from the operator, which permits the transcription and subsequent

translation of the *lac* structural genes (*Z*, *Y*, and *A*, which respectively encode β -galactosidase, lactose permease, and thiogalactoside transacetylase).

? Predict the effect of a mutation in *I*, *P*, O_1 , *Z*, or *Y*.

FIG. 28-11 The base sequence of the *lac* operator O_1 . Its symmetry-related regions, which comprise 28 of its 35 bp, are shaded in red.

The *lac* operon actually contains three operator sequences to which *lac* repressor binds with high affinity, known as O_1 , O_2 , and O_3 . O_1 , the primary repressor-binding site, was identified through its protection by *lac* repressor from nuclease digestion. The 26-bp protected sequence lies within a nearly twofold symmetrical sequence of 35 bp (Fig. 28-11). O_1 overlaps the transcription start site of the *lacZ* gene. The operator sequence O_2 is centered 401 bp downstream, fully within the *lacZ* gene, and O_3 is centered 93 bp upstream of O_1 , at the end of the *lacI* gene. Genetic engineering experiments show that all three operator sequences must be present for maximum repression *in vivo*.

The observed rate constant for the binding of *lac* repressor to *lac* operator is $k \approx 10^{10} \text{ M}^{-1} \cdot \text{s}^{-1}$. This “on” rate is much greater than that calculated for the diffusion-controlled process in solution: $k \approx 10^7 \text{ M}^{-1} \cdot \text{s}^{-1}$ for molecules the size of *lac* repressor. Since it is impossible for a reaction to proceed faster than its diffusion-controlled rate, *lac* repressor must not encounter operator from solution in a random three-dimensional search. Rather, it appears that *lac* repressor finds its operator by nonspecifically binding to DNA and sliding along it in a far more efficient one-dimensional search.

***lac* Repressor Binds Two DNA Segments Simultaneously.** The isolation of *lac* repressor, by Beno Müller-Hill and Walter Gilbert in 1966, was exceedingly difficult because the repressor constitutes only $\sim 0.002\%$ of the protein in wild-type *E. coli*. Molecular cloning techniques (Section 3-5) later made it possible to produce large quantities of *lac* repressor. Nevertheless, it was not until 1996 that Ponzy Lu and Mitchell Lewis reported the complete three-dimensional structure of the protein. Each 360-residue subunit of the repressor homotetramer has four functional units (Fig. 28-12a):

1. An N-terminal “headpiece,” which contains a helix–turn–helix (HTH) motif that resembles those in other prokaryotic DNA-binding proteins (Section 24-4B) and which specifically binds operator DNA sequences.
2. A linker, which contains a short α helix that acts as a hinge and also binds DNA. In the absence of DNA, the hinge helices of the *lac* repressor tetramer are disordered, allowing the headpieces to move freely.
3. A two-domain core, which binds inducers such as IPTG.
4. A C-terminal α helix, which is required for the quaternary structure of *lac* repressor. In the tetramer, all four C-terminal helices associate. Surprisingly, the repressor homotetramer does not exhibit the D_2 symmetry of nearly all homotetrameric proteins of known structure (three mutually perpendicular twofold axes; Section 6-3) but is instead V-shaped (with only twofold symmetry) and is therefore best described as a dimer of dimers (Fig. 28-12b).

FIG. 28-12 X-Ray structure of the *E. coli lac* repressor. (a) Ribbon diagram of the *lac* repressor monomer. The DNA-binding domain containing its helix–turn–helix motif is red; the hinge helix is yellow; the inducer-binding core is light and dark blue; and the tetramerization helix is purple. (b) The *lac* repressor tetramer bound to two 21-bp segments of DNA. The protein subunits are shown in ribbon form in yellow, cyan, green, and orange and the DNA segments are drawn in space-filling form with C white, N blue, O red, and P orange. PDBid 1L8G.

FIG. 28-13 Model of the 93-bp loop formed when the *lac* repressor tetramer binds to O_1 and O_3 . The proteins are represented by their C_α backbones, and the DNA is shown in skeletal form with its sugar–phosphate backbones traced by helical ribbons. The model was constructed from the X-ray structure of *lac* repressor (red) in complex with two 21-bp operator DNA segments (orange) and the X-ray structure of CAP (purple) in complex with its 30-bp target DNA (cyan). The remainder of the DNA loop was generated by applying a smooth curvature to B-DNA (white) with the -10 and -35 regions of the *lac* promoter highlighted in green.

? Where would RNA polymerase bind?

The X-ray structure of a complex between *lac* repressor and a 21-bp synthetic DNA containing a high-affinity binding sequence reveals that each repressor tetramer binds two DNA segments (Fig. 28-12b). The repressor's HTH motif fits snugly into the major groove, bending the DNA so that it has a radius of curvature of 60 Å. The two bound DNA segments are laterally separated by ~25 Å.

IPTG binds to the repressor core at the interface between the two domains colored light and dark blue in Fig. 28-12a. This binding induces a conformational change in the repressor dimer that is communicated through the hinge helices to the headpieces. This causes the two DNA-binding domains in each dimer to separate by ~3.5 Å so that they can no longer simultaneously bind DNA, thereby causing the repressor to dissociate from the DNA.

The *lac* repressor is an allosteric protein: IPTG binding to one subunit alters the DNA-binding activity of its dimeric partner (but not of the other dimer in the repressor tetramer). Since the allosteric transition occurs within the dimer, why does full repressor activity require a tetramer? Model-building studies provide a plausible answer to this puzzle. A *lac* repressor tetramer simultaneously binds to two operators so that it brings them together, forming a loop of DNA either 93 or 401 bp long, depending on whether the repressor binds O_1 and O_3 or O_1 and O_2 . The formation of a stable looped structure may require additional DNA-binding proteins; one candidate is CAP (see below), a DNA-binding protein that binds to the DNA between O_1 and O_3 (Fig. 28-13). In the model shown in Fig. 28-13, the *lac* promoter is part of the looped DNA.

It was widely assumed for years that *lac* repressor simply physically obstructs the binding of RNA polymerase (RNAP) to the *lac* promoter. However, experiments have demonstrated that RNAP can bind to the promoter in the presence of the repressor but cannot properly initiate transcription. Dissociation of the repressor in response to an inducer would allow unimpeded transcription. If RNAP were already bound to the *lac* promoter, transcription could begin immediately. Nevertheless, in the model shown in Fig. 28-13, the contact surface for RNAP is on the inside of the DNA loop, which presumably would preclude the binding of RNAP. Further studies are needed to resolve this apparent contradiction.

B Catabolite-Repressed Operons Can Be Activated

Glucose is *E. coli*'s metabolic fuel of choice; adequate amounts of glucose prevent the full expression of genes specifying proteins involved in the fermentation of numerous other catabolites, including lactose, arabinose, and galactose, even when they are present in high concentrations. This phenomenon, which is known as **catabolite repression**, prevents the wasteful duplication of energy-producing enzyme systems. Catabolite repression is overcome in the absence of glucose by a cAMP-dependent mechanism. cAMP levels are low in the presence of glucose but rise when glucose becomes scarce.

CAP–cAMP Complex Stimulates the Transcription of Catabolite-Repressed Operons. Certain *E. coli* mutants, in which the absence of glucose does not relieve catabolite repression, are missing a cAMP-binding protein that is synonymously named **catabolite gene activator protein (CAP)** or **cAMP receptor protein (CRP)**. CAP is a dimeric protein of identical 210-residue subunits that undergoes a large conformational change on binding cAMP. The CAP–cAMP complex, but not CAP alone, binds to the promoter region of the *lac* operon (among others) and stimulates transcription in the absence of repressor. CAP is therefore a **positive regulator** (it turns transcription on), in contrast to *lac* repressor, which is a **negative regulator** (it turns transcription off).

The X-ray structure of CAP–cAMP in complex with a 30-bp segment of DNA, whose sequence resembles the CAP-binding site, reveals that the CAP

FIG. 28-14 X-Ray structures of CAP–cAMP–dsDNA complexes. The dsDNA and cAMP in these twofold symmetric complexes, viewed here with their twofold axes horizontal, are colored with DNA C white, cAMP C green, N blue, O red, and P orange. (a) CAP–cAMP in complex with a palindromic 30-bp self-complementary DNA. The protein is drawn in ribbon form with its identical subunits pink and blue and with their C-terminal domains in darker shades. The DNA is shown in stick form with successive P atoms in the same strand connected by orange rods and with the cAMP drawn in space-filling form. (b) CAP–cAMP in complex with a 44-bp palindromic DNA and four α CTD subunits. The DNA, CAP, and cAMP are viewed as in Part a with the DNA drawn in space-filling form. The α CTD subunits are drawn in ribbon form with the α CTD^{CAP,DNA} green and the α CTD^{DNA} dark green. [Part a based on an X-ray structure by Thomas Steitz, Yale University. PDBid 1CGP. Part b based on an X-ray structure by Helen Berman and Richard Ebright, Rutgers University. PDBid 1LB2.]

dimer binds in successive turns of DNA's major groove via its two HTH motifs so as to bend the DNA by $\sim 90^\circ$ around the protein dimer (Fig. 28-14a). The bend arises from two $\sim 45^\circ$ kinks in the DNA between the fifth and sixth bases out from the complex's twofold axis in both directions and results in a closing of the major groove and in an enormous widening of the minor groove at each kink.

Why is the CAP–cAMP complex necessary to stimulate the transcription of its target operons? And how does it do so? The *lac* operon has a weak (low efficiency) promoter; its -10 and -35 sequences (TATGTT and TTTACA; Fig. 26-6) differ significantly from the corresponding consensus sequences of strong (high-efficiency) promoters (TATAAT and TTGACA; Fig. 26-6). Such weak promoters evidently require some sort of help for efficient transcriptional initiation.

Richard Ebright has shown that CAP interacts directly with RNAP via the 85-residue C-terminal domain of RNAP's α subunit (α CTD) in a way that stimulates RNAP to initiate transcription from a nearby promoter. The α CTD, which is flexibly linked to the rest of the α subunit, binds dsDNA nonspecifically but does so with higher affinity at A + T-rich sites. The X-ray structure of CAP–cAMP in complex with the *E. coli* α CTD and a 44-bp palindromic DNA containing the 22-bp CAP–cAMP binding site and 5'-AAAAAA-3' at each end, determined by Helen Berman and Ebright, reveals how these components interact (Fig. 28-14b). The twofold symmetric CAP–cAMP– α CTD complex contains two differently located pairs of α CTDs. Each member of the pair designated

$\alpha\text{CTD}^{\text{CAP,DNA}}$ binds both to CAP and in the minor groove of a 6-bp segment of the DNA (5'-AAAAAG-3') centered 19 bp from the center of the DNA (each member of the other pair of αCTDs , designated $\alpha\text{CTD}^{\text{DNA}}$, interacts with the DNA but does not contact other protein molecules). The common portions of the two CAP complexes pictured in Fig. 28-14*a,b* are closely superimposable, thereby indicating that the conformation of CAP and its interaction with DNA are not significantly altered by its association with the αCTD . Evidently, CAP-cAMP transcriptionally activates RNAP via a simple “adhesive” mechanism that facilitates and/or stabilizes its interaction with the promoter DNA.

The model for *lac* repressor binding (Fig. 28-13) paradoxically includes CAP, which is an activator. This dual binding may be a mechanism for conserving cellular energy in the absence of both glucose and lactose. If lactose became available, *lac* repressor would dissociate, and CAP-cAMP would be poised to promote transcription of the *lac* operon.

C Attenuation Regulates Transcription Termination

The *E. coli trp* operon encodes five polypeptides (which form three enzymes) that mediate the synthesis of tryptophan from chorismate (Section 21-5B). The five *trp* operon genes (*A–E*; Fig. 28-15) are coordinately expressed under the control of the *trp* repressor, which binds L-tryptophan to form a complex that specifically binds to the *trp* operator to reduce the rate of *trp* operon transcription 70-fold (Section 24-4B). In this system, tryptophan acts as a **corepressor**; its presence prevents what would be superfluous tryptophan biosynthesis.

The *trp* repressor-operator system was at first thought to fully account for the regulation of tryptophan biosynthesis in *E. coli*. However, the discovery of *trp* deletion mutants located downstream from the operator (*trpO*) that increase *trp*

FIG. 28-15 Genetic map of the *E. coli trp* operon indicating the enzymes it specifies and the reactions they catalyze. The gene product of *trpC* catalyzes two sequential reactions in the synthesis of

tryptophan (Section 21-5B). [After Yanofsky, C., *J. Am. Med. Assoc.* **218**, 1027 (1971).]

operon expression sixfold indicated the existence of an additional transcriptional control element. This element is located ~30 to 60 nucleotides upstream of the structural gene *trpE* in a 162-nucleotide **leader sequence** (*trpL*; Fig. 28-15).

When tryptophan is scarce, the entire 6720-nucleotide polycistronic *trp* mRNA, including the *trpL* sequence, is synthesized. When the encoded enzymes begin synthesizing tryptophan, the rate of *trp* operon transcription decreases as tryptophan binds to *trp* repressor. Of the *trp* mRNA that is transcribed, however, an increasing proportion consists of only a 140-nucleotide segment corresponding to the 5' end of *trpL*. *The availability of tryptophan therefore results in the premature termination of trp operon transcription.* The control element responsible for this effect is consequently termed an **attenuator**.

The *trp* Attenuator's Transcription Terminator Is Masked when Tryptophan Is Scarce. The attenuator transcript contains four complementary segments that can form one of two sets of mutually exclusive base-paired hairpins (Fig. 28-16). Segments 3 and 4 together with the succeeding residues constitute a transcription terminator (Section 26-1D): a G + C-rich hairpin followed by several sequential U's (compare with Fig. 26-10). Transcription rarely proceeds beyond this termination site unless tryptophan is in short supply.

How does a shortage of tryptophan cause transcription to proceed past the terminator? A section of the leader sequence, which includes segment 1 of the attenuator, is translated to form a 14-residue polypeptide that contains two consecutive Trp residues (Fig. 28-16, left). The position of this particularly rare dipeptide (~1% of the residues in *E. coli* proteins are Trp) provided an important clue to the mechanism of attenuation, as proposed by Charles

FIG. 28-16 Alternative secondary structures of *trpL* mRNA. The formation of the base-paired 2 · 3 (antiterminator) hairpin (right) precludes formation of the 1 · 2 and 3 · 4 (terminator) hairpins (left) and vice versa. Attenuation results in the premature termination of

transcription immediately after nucleotide 140 when the 3 · 4 hairpin is present. The arrow indicates the mRNA site past which RNA polymerase pauses until approached by an active ribosome. [After Fisher, R.F. and Yanofsky C., *J. Biol. Chem.* **258**, 8147 (1983).]

FIG. 28-17 Attenuation in the *trp* operon.

(a) When Trp-tRNA^{Trp} is abundant, the ribosome translates *trpL* mRNA. The presence of the ribosome on segment 2 prevents the formation of the 2 · 3 hairpin. The 3 · 4 hairpin, an essential component of the transcriptional terminator, can then form, thus aborting transcription. (b) When Trp-tRNA^{Trp} is scarce, the ribosome stalls on the tandem Trp codons of segment 1. This situation permits the formation of the 2 · 3 hairpin, which precludes the formation of the 3 · 4 hairpin. RNA polymerase therefore transcribes through this unformed terminator and continues transcribing the *trp* operon.

? Could attenuation occur if mRNA segment 1 or segment 4 were missing?

Yanofsky (Fig. 28-17): An RNA polymerase that has escaped repression initiates *trp* operon transcription. Soon after the ribosomal initiation site of the *trpL* sequence has been transcribed, a ribosome attaches to it and begins translating the leader peptide. When tryptophan is abundant (i.e., there is a plentiful supply of Trp-tRNA^{Trp}), the ribosome follows closely behind the transcribing RNA polymerase. Indeed, RNA polymerase pauses past position 92 of the transcript and continues transcribing only on the approach of a ribosome, thereby ensuring the close coupling of transcription and translation. The progress of the ribosome prevents the formation of the 2 · 3 hairpin and permits the formation of the 3 · 4 hairpin, which terminates transcription (Fig. 28-17a). When tryptophan is scarce, however, the ribosome stalls at the tandem UGG codons (which specify Trp) because of the lack of Trp-tRNA^{Trp}. As transcription continues, the newly synthesized segments 2 and 3 form a hairpin because the stalled ribosome prevents the otherwise competitive formation of the 1 · 2 hairpin (Fig. 28-17b). The 3 · 4 hairpin does not form, allowing transcription to proceed past this region and into the remainder of the *trp* operon. Thus, attenuation regulates *trp* operon transcription according to the tryptophan supply.

The leader peptides of the five other amino acid-biosynthesizing operons known to be regulated by attenuation are all rich in their corresponding amino acid residues. For example, the *E. coli his* operon, which specifies enzymes synthesizing histidine, has seven tandem His residues in its 16-residue leader peptide, whereas the *ilv* operon, which specifies enzymes participating in isoleucine, leucine, and valine biosynthesis, has five Ile, three Leu, and six Val residues in its 32-residue leader peptide. The leader transcripts of these operons resemble that of the *trp* operon in their capacity to form two alternative secondary structures, one of which contains a trailing transcription terminator.

D Riboswitches Are Metabolite-Sensing RNAs

We have just seen how the formation of secondary structure in a growing RNA transcript can regulate gene expression through attenuation. The conformational flexibility of mRNA also allows it to regulate genes by directly interacting with certain cellular metabolites, thereby eliminating the need for sensor proteins such as the *lac* repressor, CAP, and the *trp* repressor.

In *E. coli*, the biosynthesis of thiamine pyrophosphate (TPP; Section 15-3B) requires the action of several proteins whose levels vary according to the cell's need for TPP. In at least two of the relevant genes the untranslated regions at the 5' end of the mRNA include a highly conserved sequence called the *thi* box. The susceptibility of the *thi* box to chemical or enzymatic cleavage, as Ronald Breaker

showed, differs in the presence and absence of TPP, suggesting that the RNA changes its secondary structure when TPP binds to it (the binding of a metabolite by RNA is not unprecedented; synthetic oligonucleotides known as **aptamers** bind certain molecules with high specificity and affinity). The TPP-sensing mRNA element has been dubbed a **riboswitch**.

The predicted secondary structure of the TPP-sensing riboswitch and its proposed mechanism are shown in **Fig. 28-18a**. In the absence of TPP, the mRNA assumes a conformation that allows a ribosome to begin translation. In the presence of TPP, an alternative secondary structure masks its Shine–Dalgarno sequence (Section 27-4A) so that the ribosome cannot initiate the mRNA's translation. Thus, *the concentration of a metabolite can regulate the expression of genes required for its synthesis*. The X-ray structure of the 80-nt TPP-binding domain from the *E. coli* TPP-sensing riboswitch, determined by Breaker and Dinshaw Patel, reveals an intricately folded RNA that binds TPP in an extended conformation (**Fig. 28-18b**).

More than 20 types of bacterial riboswitches have as yet been identified, including those that regulate the expression of enzymes involved in the synthesis of coenzyme B₁₂ (Fig. 20-17), riboflavin (Fig. 14-13), and *S*-adenosylmethionine (SAM; Fig. 21-18). These collectively regulate >2% of the genes in certain bacteria. In some cases, metabolite binding to the mRNA controls the formation of an internal transcription termination site so that transcription beyond this site proceeds only when the metabolite is absent. In others, a ribozyme that forms a portion of an mRNA is activated by the binding of a metabolite to self-cleave, thereby inactivating the mRNA. Plants and fungi also contain riboswitches. The fact that the interaction of riboswitches with their effectors does not require the

FIG. 28-18 Structure of the TPP-sensing riboswitch from *E. coli*.

(a) The predicted secondary structure of a 165-residue segment at the 5' end of the *thiM* gene is shown in the absence (*left*) and presence (*right*) of TPP. The TPP-binding conformation masks the Shine–Dalgarno sequence (*purple*) required by the ribosome to initiate translation at the AUG sequence (*red*) just downstream. [After Winkler, W., Nahvi, A., and Breaker, R.R., *Nature* **419**, 952 (2002).] (b) The X-ray structure of the riboswitch's TPP-sensing domain. The RNA is

drawn in cartoon form with its sugar–phosphate backbone represented by an orange rod and its bases represented by paddles with C green, N blue, and O red, and S yellow. The TPP is drawn in space-filling form with C cyan, N blue, O red, and S yellow. Mg²⁺ ions are represented by lavender spheres. [Based on an X-ray structure by Ronald Breaker, Yale University; and Dinshaw Patel, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 2GDI.]

participation of proteins suggests that they are relics of the RNA world (Box 24-3) and hence among the oldest regulatory systems.

Certain riboswitches are the targets of antibiotics. For example, the antibiotic **pyrithiamine** is converted by the bacterial cell to **pyrithiamine pyrophosphate**, a TPP analog,

Pyrithiamine pyrophosphate

Thiamine pyrophosphate (TTP)

which binds to the TPP-sensing riboswitch to inhibit TPP synthesis. Since pyrithiamine pyrophosphate cannot function as a coenzyme (Section 15-3B), this kills the cell.

CHECKPOINT

- What is the regulatory advantage of arranging genes in operons?
- Describe the regulation of the *lac* operon by *lac* repressor and CAP.
- Why does the *lac* operon include more than one operator sequence?
- Compare regulation by the *lac* repressor and the *trp* repressor.
- How does the conformation of mRNA regulate gene expression by attenuation?
- Explain how riboswitches can turn gene expression on and off.

3 Regulation of Eukaryotic Gene Expression

KEY CONCEPTS

- Chromatin structure, as influenced by chromatin-remodeling complexes, histone modification, and DNA methylation, controls gene expression.
- Numerous proteins and DNA elements interact to regulate transcription initiation in eukaryotes.
- mRNA degradation limits gene expression.
- Somatic recombination and hypermutation in immunoglobulin gene segments contributes to antibody diversity.

The general principles that govern the expression of prokaryotic genes apply also to eukaryotic genes: *The expression of specific genes may be actively inhibited or stimulated through the effects of proteins that bind to DNA or RNA.* As in prokaryotes, the majority of known regulatory mechanisms act at the level of gene transcription, but unlike prokaryotic control systems, the eukaryotic mechanisms must contend with much larger amounts of DNA that is packaged in seemingly inaccessible structures. In this section, we describe several of the strategies whereby eukaryotic cells manage their genetic information.

A Chromatin Structure Influences Gene Expression

The majority of DNA in multicellular organisms is not expressed. This includes the portion of the genome that does not encode protein or RNA, as well as the genes whose expression is inappropriate for a particular cell type. Although nearly all the cells in an organism contain identical sets of DNA, genes are expressed in a highly tissue-specific manner. For example, most pancreatic cells synthesize and secrete digestive enzymes, but the pancreatic islet cells synthesize insulin or glucagon instead (Section 22-2).

Nonexpressed DNA is typically highly condensed in a form known as **heterochromatin** (Fig. 28-19). An extreme example of this is the complete inactivation of one of the two X chromosomes in female mammals (Box 28-2).

FIG. 28-19 Electron micrograph of a B lymphocyte. The large body in the center of the cell is the nucleus in which heterochromatin (*black*) adheres to the inner nuclear membrane and the transcriptionally active euchromatin (*gray*) is more centrally located. The small black body at the center of the nucleus is the nucleolus. Also note the extensive rough endoplasmic reticulum filling the cytoplasm of this antibody-producing cell (Section 7-3). Compare this figure with Fig. 1-8.

? Why does an antibody-producing cell have larger amounts of ER and Golgi apparatus than most other types of cells?

Box 28-2 Perspectives in Biochemistry X Chromosome Inactivation

Female mammalian cells contain two X chromosomes, whereas male cells have one X and one Y chromosome. *Female somatic cells, however, maintain only one of their X chromosomes in a transcriptionally active state.* Consequently, both males and females make approximately equal amounts of X chromosome-encoded gene products, a phenomenon known as **dosage compensation**.

The inactive X chromosome is visible as a highly condensed and darkly staining **Barr body** at the periphery of the cell nucleus.

[From Moore, K.L. and Barr, M.L., *Lancet* **2**, 57 (1955).]

In marsupials (pouched mammals, such as kangaroos), the Barr body is always the paternally inherited X chromosome, but in placental mammals, one randomly selected X chromosome in every somatic cell is inactivated when the embryo consists of only a few cells. The progeny of each of these cells maintain the same inactive X chromosome. Female placental animals are therefore mosaics of cloned groups of cells in which the active X chromosome is either paternally or maternally inherited. The calico cat, for example, with its patches of black and orange fur, is almost always a female cat whose two X chromosomes specify the different coat colors.

The X chromosome contains the **X-inactivation center (XIC)**, which has multiple regulatory sites together with the *Xist* gene, which occurs only in placental mammals and is transcribed only from the inactive X chromosome (Xi). The 25-kb *Xist* RNA binds at or near XIC where it induces the heterochromatinization of that region of Xi via a process described below. The resulting heterochromatin recruits additional *Xist* RNA to a neighboring site, which in turn, causes its heterochromatinization. This process propagates in both directions from XIC until Xi is “painted” over its whole length by *Xist* RNA and the entire chromosome is heterochro-

[Hank Delespinasse/Age Fotostock America, Inc.]

matized and thereby transcriptionally inactivated at all sites but *Xist*. XIC is necessary and sufficient to initiate X inactivation as is demonstrated by the observations that the insertion of XIC into an autosome results in its inactivation and X chromosomes that lack XIC are not inactivated.

Localized *Xist* RNA does not by itself inactivate Xi. However, *Xist* RNA recruits enzyme systems that derivatize histones in a way that inactivates their associated genes (histone modification is discussed below). In addition, *Xist* RNA recruits the H2A variant **macroH2A1**, which has a large C-terminal globular domain that H2A lacks. Some or all of these changes are required for X chromosome inactivation and, moreover, are responsible for maintaining Xi's heterochromatic state in subsequent cell generations. In fact, once an X chromosome has been inactivated, *Xist* RNA plays only a minor role in the maintenance of this state.

What is the mechanism through which one X chromosome is inactivated but not the other? XIC also contains a gene named **Tsix** (*Xist* spelled backwards) that overlaps *Xist* but is transcribed from the opposite DNA strand. *Tsix* RNA therefore forms a hybrid RNA–DNA double helix with *Xist* that prevents its transcription and vice versa. Thus Xi expresses *Xist* but not *Tsix*, whereas the active X chromosome (Xa) expresses *Tsix* but not *Xist*. If *Tsix* is inactivated on one X chromosome, that chromosome will be inactivated. Apparently, the balance of transcription between *Xist* and *Tsix* selects which X chromosome is inactivated.

Transcriptionally active DNA, which is known as **euchromatin**, is less condensed, presumably to provide access to the transcription machinery. In fact, Harold Weintraub demonstrated that transcriptionally active chromatin is more susceptible to digestion by pancreatic DNase I than is transcriptionally inactive chromatin. Yet nuclease sensitivity apparently reflects a gene's potential for transcription rather than transcription itself.

For genetic information to be expressed, the transcription machinery must gain access to the DNA, which is packaged in nucleosomes (Section 24-5A). Not surprisingly, nucleosomes are not fixed structures but can undergo remodeling. In addition, histones can be covalently modified to alter how they interact with other cellular components, and the canonical (standard) histones can be replaced by histones with specialized functions.

Chromatin-Remodeling Complexes Shuffle Nucleosomes. Sequence specific DNA-binding proteins must gain access to their target DNAs before they can bind to them. Yet nearly all DNA in eukaryotes is sequestered by nucleosomes if not by higher order chromatin. How then do the proteins that bind to DNA segments gain access to their target DNAs? The answer, which has only become apparent since the mid-1990s, is that *chromatin contains ATP-driven complexes that remodel nucleosomes*, that is, they disrupt the interactions between histones and DNA in nucleosomes to make the DNA more accessible. This may cause the

FIG. 28-20 Model of the RSC with a bound nucleosome. The X-ray structure of the nucleosome (with the proteins shown as orange ribbons and the DNA backbone in light green) was fitted into a cryo-EM–based image of the RSC (gray). The two views show the back and front of the complex. The DNA's dyad (twofold) axis is represented by a blue rod, and two possible binding sites for the ATP-hydrolyzing translocase subunit are indicated.

histone octamer to slide along the DNA strand to a new location or even relocate to a different DNA strand. Thus, *these chromatin-remodeling complexes impose a “fluid” state on chromatin that maintains the DNA’s overall packaging but transiently exposes individual sequences to interacting factors.* They may also partially or fully unwrap the DNA from a nucleosome and exchange the histones in a nucleosome for their subtypes.

Chromatin-remodeling complexes consist of multiple subunits. The first of them to be characterized was the yeast **SWI/SNF** complex, so called because it is essential for mating type switching (SWI for *switching defective*) and for growth on sucrose (SNF for *sucrose nonfermenter*). SWI/SNF, an 1150-kD complex of 11 different types of subunits, is essential for the expression of only ~3% of yeast genes and is not required for cell viability. However, a related complex named **RSC** (for *remodels the structure of chromatin*) is ~100 times more abundant in yeast and is its only chromatin-remodeling complex required for cell viability. RSC shares two of its 17 subunits with SWI/SNF, and many of their remaining subunits are homologs, including their ATPase subunits. All eukaryotes contain multiple chromatin-remodeling complexes.

Biochemical studies indicate that the RSC binds tightly to nucleosomes in a 1:1 complex. Indeed, cryoelectron microscopy–based images of the yeast RSC reveal that it has an irregular shape containing a large central cavity that is remarkably complementary in size and shape to a single nucleosome core particle (Fig. 28-20).

The simultaneous release of all of the many interactions holding DNA to a histone octamer would require an enormous free energy input and hence is unlikely to occur. How, then, do chromatin-remodeling complexes function? Their various ATP-hydrolyzing translocase subunits share a region of homology with helicases (Section 25-2B), although they lack helicase activity. Nevertheless, it seems plausible that, like helicases, chromatin-remodeling complexes “walk” up DNA strands as driven by ATP hydrolysis. If such a complex were somehow tethered to a histone, this would put torsional strain on the DNA in the nucleosome, thereby decreasing its local twist (DNA supercoiling is discussed in Section 24-1C). The region of decreased twist could diffuse along the DNA wrapped around the nucleosome, thereby transiently loosening the histone octamer’s grip on a segment of DNA. The torsional strain might also be partially accommodated as a writhe, which would lift a segment of DNA off the nucleosome’s surface. In either case, the resulting DNA distortion could diffuse around the surface of the nucleosome in a wave that would locally and transiently release the DNA from the histone octamer as it passed (Fig. 28-21). Multiple cycles of ATP hydrolysis would send multiple DNA-loosening waves around the nucleosome, thereby sliding the nucleosome along the DNA and providing DNA-binding proteins access to the DNA.

HMG Proteins Are Architectural Proteins That Help Regulate Gene Expression. The variation of a given gene’s transcriptional activity according to cell type indicates that chromosomal proteins participate in the gene activation process. Yet histones’ chromosomal abundance and lack of variety make it highly unlikely that they have the specificity required for this role. Among the most common

PROCESS DIAGRAM

FIG. 28-21 Model for nucleosome remodeling by chromatin-remodeling complexes. The chromatin-remodeling complex (green) couples the free energy of ATP hydrolysis to the translocation and concomitant twisting of the DNA in the nucleosome (blue, only half

of which is shown for clarity) as depicted by the movement of a fixed point on the DNA (yellow star). [After a drawing by Saha, A., Wittmeyer, J., and Cairns, B.R., *Genes Dev.* **16**, 2120 (2002).] **WPLS** See the Animated Process Diagrams.

nonhistone protein components of chromatin are the members of the **high mobility group (HMG)**, so named because of their high electrophoretic mobilities in polyacrylamide gels. These highly conserved, low molecular mass (<30 kD) proteins, which have the unusual amino acid composition of ~25% basic side chains and 30% acidic side chains, are relatively abundant with ~1 HMG molecule per 10 to 15 nucleosomes.

The yeast HMG protein known as **NHP6A** contains an ~80-residue structural motif called an **HMG box**. Its NMR structure in complex with DNA, determined by Juli Feigon, reveals that it causes the DNA to bend by as much as 70° toward its major groove (**Fig. 28-22**). Such proteins presumably facilitate the binding of

FIG. 28-22 NMR structure of yeast NHP6A protein in complex with a 15-bp DNA. The protein is drawn in ribbon form (cyan) and the DNA is drawn in stick form colored according to atom type (C green, N blue, O red, and P yellow). The three helices of the HMG box form an L shape, with the inside of the L inserted into the DNA's minor groove so as to bend the DNA by ~70° toward its major groove. [Based on an NMR structure by Juli Feigon, University of California at Los Angeles. PDBid 1J5N.]

FIG. 28-23 A selection of histone modifications on the nucleosome core particle. Post-translational modification sites on the four core histones are indicated with colored symbols. The added groups are ac = acetyl, me = methyl, ph = phosphoryl, pr = propionyl, rib = ADP-ribose, and Ub = ubiquitin. Cit represents citrulline (deiminated arginine). Note that some residues can be modified in multiple ways. This diagram is a composite; not all of these modifications occur in all organisms. [After a diagram by Ali Shilatifard, St. Louis University School of Medicine.]

? Which of these modifications significantly changes the charge or size of a histone side chain?

other regulatory proteins to the DNA and are therefore described as **architectural proteins**. Other HMG proteins differ in structure but can also alter DNA conformation by inducing it to bend, straighten, unwind, or form loops. Some HMG proteins compete with histones for DNA, thereby altering nucleosomal structure.

Histones Are Covalently Modified. The posttranslational modifications to which core histones are subject include the acetylation of specific Lys side chains, the methylation of specific Lys and Arg side chains, the phosphorylation of specific Ser and Thr side chains, and the ubiquitination of specific Lys side chains (Fig. 28-23). Moreover, Lys side chains can be mono-, di-, and trimethylated and Arg side chains can be mono- and both symmetrically and asymmetrically dimethylated. All of these modifications can be undone by the action of specific enzymes. Less frequent modifications include ADP-ribosylation of Glu, addition of a propionyl group to Lys, and the conversion of Arg residues to citrullyl residues.

The core histones' N-terminal tails, as we have seen (Section 24-5A), are implicated in stabilizing the structures of both core nucleosomes and higher-order chromatin. Nearly all of the modifications listed above, except methylations, reduce (make more negative) the electronic charge of their attached side chains and hence are likely to weaken histone–DNA interactions so as to promote chromatin decondensation, although as we will see, this is not always the case. Methyl groups, in contrast, increase the basicity and hydrophobicity of the side chains to which they are linked and hence tend to stabilize chromatin structure. Modified histone tails also interact with specific chromatin-associated nonhistone proteins in a way that changes the transcriptional accessibility of their associated genes. Internucleosome and histone–histone interactions are also likely to be affected by covalent modification of the globular cores of the histone proteins, not just their tails.

The characterization of a variety of histone tail modifications led David Allis to hypothesize that *there is a **histone code** in which specific modifications evoke certain chromatin-based functions and that these modifications act sequentially or in combination to generate unique biological outcomes.* For example, Fig. 28-24 indicates the distribution of the various **histone marks** (modifications) on nucleosomes associated with a typical transcriptionally active human gene. It can be seen from Figs. 28-23 and 28-24 that there are a vast number of possible combinations of histone marks, although the way they interact is largely unknown.

Histone Acetyltransferases Are Components of Multisubunit Transcriptional Coactivators. Histone Lys side chains are acetylated in a sequence-specific

FIG. 28-24 Chromatin map of a typical transcriptionally active human gene. The height of each colored strip at a given position indicates the prevalence of the corresponding histone mark(s) on the nucleosome at that position. For example, H3K4me3 (trimethylated H3 Lys 4) and H2BK5ac (acetylated H2B Lys 5) are associated with the nucleosomes flanking the transcriptional start site (*squared off arrow*) as well as portions of enhancers and insulators (Section 28-3B), whereas H3R2me2a (asymmetrically dimethylated H3 Arg 2) is associated with nucleosomes occupying the downstream region of the gene's protein encoding segment. The positions of nucleosomes containing the H2A variant H2A.Z (*yellow*) are also indicated. [Modified from a drawing by Oliver Rando, University of Massachusetts Medical School, and Howard Chang, Stanford University.]

manner by enzymes known as **histone acetyltransferases (HATs)**, all of which employ acetyl-CoA as their acetyl group donor:

Most, if not all, HATs function *in vivo* as members of often large (10–20 subunits) multisubunit complexes, many of which were initially characterized as transcriptional regulators. For example, **TAF1**, the largest subunit of the general transcription factor TFIID (TAF for *TBP-associated factor*, where TBP is *TATA-binding protein*; Section 26-2C), is a HAT. Moreover, many **HAT complexes** share subunits. Thus, the HAT complex named **SAGA** contains **TAF5**, **TAF6**, **TAF9**, **TAF10**, and **TAF12** as does the **PCAF complex** with the exception that TAF5 and TAF6 are replaced in the PCAF complex by their close homologs **PAF65 β** and **PAF65 α** . Portions of TAF6, TAF9, and TAF12 are structural homologs of histones H3, H4, and H2B, respectively (Section 24-5). Consequently, these TAFs probably associate to form an architectural element that is common to TFIID, SAGA, and the PCAF complex and hence these complexes are likely to interact with TBP in a similar manner. The various HAT complexes presumably target their component HATs to the promoters of active genes.

The X-ray structure of the HAT domain of *Tetrahymena thermophila* **GCN5** (residues 48–210 of the 418-residue protein) in complex with a bisubstrate inhibitor was determined by Ronen Marmorstein. The bisubstrate inhibitor

FIG. 28-25 X-Ray structure of *Tetrahymena* GCN5 in complex with an inhibitor. (a) The bisubstrate inhibitor, a peptide–CoA conjugate, consists of CoA covalently linked from its S atom via an isopropionyl group to the side chain of Lys 14 of the 20-residue N-terminal segment of histone H3. (b) The protein is drawn in ribbon form in pink with its core region magenta. The peptide–CoA conjugate is drawn in stick form colored according to atom type (histone C cyan, isopropionyl group C orange, CoA C green, N blue, O red, S yellow, and P gold). [Part *b* based on an X-ray structure by Ronen Marmorstein, University of Pennsylvania. PDBid 1MID.]

(Fig. 28-25a) consists of CoA covalently linked from its S atom via an isopropionyl group (which mimics an acetyl group) to the side chain of Lys 14 (the acetyl group acceptor) of the 20-residue N-terminal segment of histone H3. The enzyme (Fig. 28-25b) is deeply clefted and contains a core region common to all HATs of known structure (magenta in Fig. 28-25b) that consists of a three-stranded antiparallel β sheet connected via an α helix to a fourth β strand that forms a parallel interaction with the β sheet. Only six residues of the histone tail, Gly 12 through Arg 17, are visible in the X-ray structure. The CoA moiety binds in the enzyme's cleft such that it is mainly contacted by core residues. The comparison of this structure with other GCN5-containing structures indicates that the cleft has closed down about the CoA moiety.

Bromodomains Recruit Coactivators to Acetylated Lys Residues in Histone Tails. The different patterns of histone acetylation required for different functions (the histone code) suggest that the function of histone acetylation is more complex than merely attenuating the charge–charge interactions between the cationic histone N-terminal tails and anionic DNA. In fact, specific acetylation patterns appear to be recognized by protein modules of transcriptional **coactivators** in much the same way that specific phosphorylated sequences are recognized by protein modules such as the SH2 domain that mediates signal transduction via protein kinase cascades (Section 13-2B). Thus, nearly all HAT-associated transcriptional coactivators contain ~110-residue modules known as **bromodomains** that specifically bind acetylated Lys residues on histones. For example, GCN5 essentially consists of a HAT domain followed by a bromodomain, whereas TAF1 consists mainly of an N-terminal kinase domain followed by a HAT domain and two tandem bromodomains.

The X-ray structure of human TAF1's double bromodomain (residues 1359–1638 of the 1872-residue protein), determined by Robert Tjian, reveals that it consists of two nearly identical antiparallel four-helix bundles (Fig. 28-26). A variety of evidence, including NMR structures of single bromodomains in complex with their target acetyl-Lys-containing peptides, indicates that the acetyl-Lys-binding

site of each bromodomain occurs in a deep hydrophobic pocket that is located at the end of its four-helix bundle opposite its N- and C-termini. The double bromodomain's two binding pockets are separated by $\sim 25 \text{ \AA}$, which makes them ideally positioned to bind two acetyl-Lys residues that are separated by 7 or 8 residues. In fact, the N-terminal tail of histone H4 contains Lys residues at positions 5, 8, 12, and 16 (Fig. 28-23), whose acetylation is correlated with increased transcriptional activity. Moreover, the 36-residue N-terminal peptide of histone H4, when fully acetylated, binds to the TAF1 double bromodomain in 1:1 ratio with 70-fold higher affinity than to single bromodomains but fails to bind when it is unacetylated.

The foregoing structure suggests that the TAF1 bromodomains serve to target TFIID to promoters that are within or near nucleosomes [in contrast to the previously held notion that TFIID targets PICs (preinitiation complexes) to nucleosome-free regions]. Tjian has therefore postulated that the transcriptional initiation process begins with the recruitment of a HAT-containing coactivator complex by an upstream DNA-binding protein (Fig. 28-27). The HAT could then acetylate the N-terminal histone tails of nearby nucleosomes, which would recruit TFIID to an appropriately located promoter via the binding of its TAF1 bromodomains to the acetyl-Lys residues. Moreover, the TAF1 HAT activity could acetylate other nearby nucleosomes, thereby initiating a cascade of acetylation events that would render the DNA template competent for transcriptional initiation.

Histone acetylation is a reversible process. The enzymes that remove the acetyl groups from histones, the **histone deacetylases (HDACs)**, promote transcriptional repression and gene silencing. Eukaryotic cells from yeast to humans typically contain numerous different HDACs; 10 HDACs have been identified in yeast and 17 in humans. The enzymes that add histone marks to nucleosomes, such as HATs, are collectively known as “writers”; the proteins, such as those containing bromodomains, that recognize histone marks and thereupon recruit other nonhistone proteins are called “readers”; and the enzymes that remove histone marks, such as HDACs, are termed “erasers.”

Histone Methylation May Silence or Activate Genes. Histone methylation at both the Lys and Arg side chains of histone H3 and H4 N-terminal tails (Fig. 28-23)

FIG. 28-26 X-Ray structure of the human TAF1 double bromodomain. Each bromodomain consists of an antiparallel four-helix bundle whose helices are colored, from N- to C-termini, red, yellow, green, and blue, with the remaining portions of the protein orange. The acetyl-Lys binding sites occupy deep hydrophobic pockets at the end of each four-helix bundle opposite its N- and C-termini. [Based on an X-ray structure by Robert Tjian, University of California at Berkeley. PDBid 1EQF.]

FIG. 28-27 Simplified model for the assembly of a transcriptional initiation complex on chromatin-bound templates. Here the DNA is represented by a blue worm, the histone octamers around which the DNA wraps to form nucleosomes are shown as gray spheres, and their N-terminal histone tails are drawn as short beaded chains with the black and red beads representing unacetylated and acetylated Lys residues. The transcription initiation site is represented by the orange segment of the DNA from which the green squared-off arrow points downstream. (a) The process begins by the recruitment of a HAT-containing transcriptional coactivator complex (green) through its interactions with a DNA-binding activator protein (pink) that is bound to an upstream enhancer (yellow). The HAT coactivator complex is thereby positioned to acetylate the N-terminal tail on nearby nucleosomes (curved arrows). (b) The binding of its TAF1's bromodomains to the acetylated histone tails could then help recruit TFIID (pink) to a nearby TATA box (gray). Further acetylation of nearby histone tails by the TAF1's HAT domain could help recruit other basal factors (yellow-green) and RNAP II (green) to the promoter, thus inducing PIC formation.

tends to silence the associated genes by inducing the formation of heterochromatin, although many forms of methylation are instead associated with active genes (Fig. 28-24). The enzymes (writers) mediating histone methylation, the **histone methyltransferases (HMTs)**, all utilize *S*-adenosylmethionine (SAM) as their methyl donor. Thus, the lysine HMTs, the most extensively characterized HMTs, catalyze the following reaction:

These enzymes all have a so-called **SET domain**, which contains their catalytic sites.

The human lysine HMT named **SET7/9** monomethylates Lys 4 of histone H3. The X-ray structure of the SET domain of SET7/9 (residues 108–366 of the 366-residue protein) in complex with SAM and the N-terminal decapeptide of histone H3 in which Lys 4 is monomethylated was determined by Steven Gamblin. Interestingly, SAM and the peptide substrate bind to opposite sides of the protein (Fig. 28-28). However, there is a narrow tunnel through the protein into which the Lys 4 side chain is inserted such that its amine group is properly positioned for methylation by SAM. The arrangement of the hydrogen bonding acceptors for the Lys amino group stabilize the methyl-Lys side chain in its observed orientation about the $C_\epsilon\text{—}N_\zeta$ bond, thus sterically precluding the methyl-Lys group from assuming a conformation in which it could be further methylated by SAM.

Methylated histones are bound by several kinds of protein domains that recognize specific Lys residues with some preference for their mono-, di-, or trimethyl forms. The so-called **chromodomain** (for *chromatin organization modifier*) and the motif known as a **PHD finger** (for *plant homeodomain*) both include binding sites for methylated Lys residues that can be characterized as aromatic cages (Fig. 28-29). Interestingly, the methyl-Lys-binding proteins often include additional readers such as a bromodomain, or erasers such as a deacetylase.

The chromodomain-containing **heterochromatin protein 1 (HP1)**, which binds dimethylated H3 Lys 9, contributes to gene silencing. The bound HP1 recruits the HMT **Suv39h**, which methylates nearby nucleosomes at their H3 Lys 9 residues, thereby recruiting additional HP1, etc. This mechanism could explain why heterochromatin has a tendency to spread so as to silence neighboring genes. In transcriptionally silent chromatin, the DNA itself may also be methylated.

Methyltransferases Flip Their Target Bases Out of the DNA Double Helix. The methylation of DNA, as we have seen (Box 25-4), switches off eukaryotic gene expression. Eukaryotic DNAs are methylated only on their cytosine residues to form 5-methylcytosine ($m^5\text{C}$) residues, a modification that occurs largely on the palindromic CpG islands that commonly occur in the upstream promoter regions of genes (Section 26-2B) and which are typically 300 to 3000 bp long. In fact,

FIG. 28-28 X-Ray structure of the human histone methyltransferase SET7/9 in complex with SAM and the histone H3 N-terminal decapeptide with its Lys 4 monomethylated. The protein is represented by its surface diagram colored according to charge (blue most positive, red most negative, and gray neutral) and the H3 decapeptide is represented by a green ribbon. Note the narrow tunnel through the protein in which the methyl-Lys side chain is inserted. The inset above shows a closeup of this Lys access channel containing the methyl-Lys side chain (green) as viewed from the opposite side of the protein from the SAM-binding site. PDBid 1O9S.

FIG. 28-29 Binding sites for histone trimethyl-Lys residues. (a) H3 trimethyl-Lys 9 bound to the chromodomain of *Drosophila* heterochromatin protein 1 (HP1) and (b) H3 trimethyl-Lys 4 bound to a human PHD finger. The H3 trimethyl-Lys residues are drawn with C green and N blue and with the peptide backbone yellow. The aromatic side chains of HP1 and the PHD finger that cage the trimethylammonium group are drawn with C cyan, N blue, and O red. The dot surfaces delineate the van der Waals surfaces of the aromatic side chains and the trimethylammonium groups. [Part a based on an X-ray structure by Sepideh Khorasanizadeh, University of Virginia. PDBid 1KNE. Part b based on an X-ray structure by David Allis, Rockefeller University, and Dinshaw Patel, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 2F6J.]

60% to 80% of the ~30 million CpG dinucleotides in the human genome are methylated. The enzymes (writers) that mediate these modifications, the **DNA methyltransferases (DNA MTases)**, all use SAM as their methyl donor. Cells also contain **demethylases**, which catalyze the reaction

In DNA MTase reactions, SAM reacts with the enzyme's targeted cytosine base to form a tetrahedral intermediate in which the cytosine C5 is substituted by both its original hydrogen atom and the donated methyl group. This requires that the attacking methyl group approach C5 from above or below the cytosine ring. Yet the faces of nucleic acid bases are inaccessible within the DNA double helix. Consequently, a DNA MTase must induce its target cytosine base to flip out of the double helix to where it can be methylated by SAM. Such a flipped-out intermediate is observed in the X-ray structure of the DNA MTase from *Haemophilus haemolyticus* (**M.HhaI**), determined by Richard Roberts and Xiaodong Cheng, in which the target cytosine base has been replaced by 5-fluorocytosine (**Fig. 28-30**). Although the normally present

FIG. 28-30 X-Ray structure of the M.HhaI DNA methyltransferase. The protein, represented by a semitransparent ribbon, is shown in complex with *S*-adenosylhomocysteine and a dsDNA containing a methylated 5-fluorocytosine base at the enzyme's target site. The DNA is drawn in stick form colored with C green, N blue, O red, and P orange. Its methylated 5-fluorocytidine residue (C atoms cyan) has swung out of the DNA helix into the enzyme's active site pocket, where its C6 forms a covalent bond with the S atom of an enzyme Cys residue (C atoms magenta and S yellow). The methyl group and a fluorine atom at C5 (which prevents the methylation reaction from going to completion) are represented by magenta and yellow-green spheres, respectively. The position of the flipped-out cytosine base in the DNA double helix is occupied by the side chain of a Gln residue (shown in space-filling form with C yellow), which hydrogen bonds to the "orphaned" guanine base. The *S*-adenosylhomocysteine, which is SAM without its methyl group, is drawn in stick form with its C atoms pink. [Based on an X-ray structure by Richard Roberts, New England Biolabs, Beverly, Massachusetts, and Xiaodong Cheng, Cold Spring Harbor Laboratory, Cold Spring Harbor, New York. PDBid 1MHT.]

FIG. 28-31 Maintenance methylation. The pattern of methylation on a parental DNA strand induces the corresponding methylation pattern in the complementary strand. In this way, a stable methylation pattern may be maintained in a cell line.

? Why is it necessary for methylation to occur at palindromic sequences?

C5—H atom is eliminated from the foregoing tetrahedral intermediate as H⁺ to yield the methylation reaction's m⁵C product, the high electronegativity of fluorine prevents the C5—F atom from being eliminated as F⁺, thereby trapping the tetrahedral intermediate on the enzyme (here the 5-fluorouracil residue is a suicide substrate; Box 23-1). Certain DNA repair enzymes that act on individual DNA bases also operate by flipping their target base out of the DNA helix (Section 25-5A).

DNA Methylation in Eukaryotes Is Self-Perpetuating. The palindromic nature of DNA methylation sites in eukaryotes permits the methylation pattern on a parental DNA strand to direct the generation of the same pattern in its daughter strand (Fig. 28-31). This **maintenance methylation** would result in the stable “inheritance” of a methylation pattern in a cell line and hence cause these cells to all have the same differentiated phenotype. Such changes to the genome are described as being **epigenetic** (Greek: *epi*, on or beside) because they provide an additional layer of information that specifies when and where specific portions of the otherwise fixed genome are expressed [epigenetic changes that we have already encountered are the lengthening of telomeres in germ cells (Section 25-3C) and the inactivation of a specific X chromosome in female mammals (Box 28-2)]. Epigenetic characteristics, as we will see, are not bound by the laws of Mendelian inheritance.

There is considerable experimental evidence favoring the existence of maintenance methylation, including the observation that artificially methylated viral DNA, when taken up by eukaryotic cells, maintains its methylation pattern for at least 30 cell generations. Maintenance methylation in mammals appears to be mediated mainly by **DNMT1** protein, which has a strong preference for methylating hemimethylated substrate DNAs. In contrast, prokaryotic DNA MTases such as *M.HhaI* do not differentiate between hemimethylated and fully methylated substrate DNAs. The importance of maintenance methylation is demonstrated by the observation that mice that are homozygous for the deletion of the *DNMT1* gene die early in embryonic development.

The pattern of DNA methylation in mammals varies in early embryonic development. DNA methylation levels are high in mature gametes (sperm and ova) but are nearly eliminated by the time a fertilized ovum has become a **blastocyst** (a hollow ball of cells, the stage at which the embryo implants into the uterine wall). After that stage, however, the embryo's DNA methylation levels globally rise until, by the time the embryo has reached the developmental stage known as a **gastrula**, its DNA methylation levels have risen to adult levels, where they remain for the lifetime of the animal. This *de novo* (new) methylation appears to be mediated by two DNA MTases distinct from DNMT1 named **DNMT3a** and **DNMT3b**. An important exception to this remethylation process is that the CpG islands of germline cells (cells that give rise to sperm or ova) remain unmethylated. This ensures the faithful transmission of the CpG islands to the succeeding generation in the face of the strong mutagenic pressure of m⁵C deamination (which yields T, a mutation that mismatch repair occasionally fails to correct; Box 25-5). In female mammals, the inactivation of the same X chromosome from cell generation to cell generation (Box 28-2) is, at least in part, preserved by maintenance methylation.

The change in DNA methylation levels (epigenetic reprogramming) during embryonic development suggests that the pattern of genetic expression differs in embryonic and somatic cells. This explains the observed high failure rate in cloning mammals (sheep, mice, cattle, etc.) by transferring the nucleus of an adult cell into an enucleated oocyte (immature ovum). Few of these animals survive to birth, many of those that do so die shortly thereafter, and most of the ~1% that do survive have a variety of abnormalities, most prominently an unusually large size. However, the survival of any embryos at all indicates that the oocyte has

the remarkable capacity to epigenetically reprogram somatic chromosomes (although it is rarely entirely successful in doing so) and that mammalian embryos are relatively tolerant of epigenetic abnormalities. Presumably, the reproductive cloning of humans from adult nuclei would result in similar abnormalities and for this reason (in addition to social and ethical prohibitions) should not be attempted.

Genomic Imprinting Results from Differential DNA Methylation. It has been known for thousands of years that maternal and paternal inheritance can differ. For example, a mule (the offspring of a mare and a male donkey) and a hinny (the offspring of a stallion and a female donkey) have obviously different physical characteristics, a hinny having shorter ears, a thicker mane and tail, and stronger legs than a mule. This is because, in mammals only, certain maternally and paternally supplied genes are differentially expressed, a phenomenon termed **genomic imprinting**. The genes that are subject to genomic imprinting are, as Rudolph Jaenisch has shown, differentially methylated in the two parents during gametogenesis, and the resulting different methylation patterns are resistant to the wave of demethylation that occurs during the formation of the blastocyst and to the wave of *de novo* methylation that occurs thereafter.

The importance of genomic imprinting is demonstrated by the observation that an embryo derived from the transplantation of two male or two female pronuclei into an ovum fails to develop (pronuclei are the nuclei of mature sperm and ova before they fuse during fertilization). Inappropriate imprinting is also associated with certain diseases. For example, **Prader-Willi syndrome (PWS)**, which is characterized by the failure to thrive in infancy, small hands and feet, marked obesity, and variable mental retardation, is caused by a >5000-kb deletion in a specific region of the paternally inherited chromosome 15. In contrast, **Angelman syndrome (AS)**, which is manifested by severe mental retardation, a puppetlike ataxic (uncoordinated) gait, and bouts of inappropriate laughter, is caused by a deletion of the same region from the maternally inherited chromosome 15. These syndromes are also exhibited by those rare individuals who inherit both their chromosomes 15 from their mothers for PWS and from their fathers for AS. Evidently, certain genes on the deleted chromosomal region must be paternally inherited to avoid PWS and others must be maternally inherited to avoid AS. Several other human diseases are also associated with either maternal or paternal inheritance or lack of it. Aberrant epigenetic programming may also play a role in tumor growth, as cancer cells often exhibit abnormal patterns of DNA methylation.

B Eukaryotes Contain Multiple Transcriptional Activators

In addition to the six general transcription factors described in Section 26-2C, eukaryotic cells contain a host of other proteins that interact with DNA and/or other transcription factors to stimulate or repress the transcription of class II genes (genes that are transcribed by RNAP II). Some of these proteins bind to any available DNA containing their target sequences, whereas others must be activated and deactivated, often as part of a signal transduction pathway (Section 13-2B). The target DNA sites to which these transcription factors bind are known as **enhancers**. Enhancers are often referred to as **cis-acting regulatory elements** (Latin: *cis*, on this side) because they are located on the same DNA molecule as the genes they control. In contrast, transcription factors are called **trans-acting factors** (Latin: *trans*, across) because they are diffusible substances that influence the expression of genes that may be on different chromosomes from those encoding them. *The human genome contains an estimated one million enhancers (although only a small subset of them is functional in any cell type) and encodes over one thousand transcription factors for class II genes* (Fig. 28-3).

An enhancer typically is not essential for transcription but significantly increases its rate. Unlike promoters, which are necessarily located a short distance from the transcription start site, *enhancers need not have fixed positions and orientations* (Section 26-2B). For example, William Rutter linked the upstream (5'-flanking) sequences of either the insulin or the chymotrypsin gene to the sequence encoding **chloramphenicol acetyltransferase (CAT)**, an easily assayed enzyme not normally present in eukaryotic cells. A plasmid containing the insulin gene sequences elicits expression of the CAT gene only when introduced into cultured cells that normally produce insulin. Likewise, the chymotrypsin recombinants are active only in chymotrypsin-producing cells. Dissection of the insulin gene control sequence indicates that the enhancer lies between positions 2103 and 2333 and, in insulin-producing cells only, it stimulates the transcription of the CAT gene with little regard to its position and orientation relative to the promoter.

Transcription Factors Act Cooperatively with Each Other and the PIC. How do transcription factors stimulate (or inhibit) transcription? *Evidently, when these proteins bind to their target DNA sites in the vicinity of a PIC (in some cases, many thousands of base pairs distant), they somehow activate (or repress) its component RNAP II to initiate transcription.* Transcription factors may bind cooperatively to each other and/or the PIC, thereby synergistically stimulating (or repressing) transcriptional initiation. Indeed, molecular cloning experiments indicate that many enhancers consist of segments (modules) whose individual deletion reduces but does not eliminate enhancer activity. *Such complex arrangements presumably permit transcriptional control systems to respond to a variety of stimuli in a graded manner.* In some cases, however, several transcription factors together with so-called **architectural proteins** cooperatively assemble on an ~100-bp enhancer to form a multisubunit complex known as an **enhanceosome**, in which the absence of a single subunit all but eliminates its ability to stimulate transcriptional initiation at the associated promoter. Thus, enhanceosomes function more like on/off switches rather than providing a graded response. Enhanceosomes may also contain coactivators and/or corepressors, proteins that do not bind to DNA but, rather, interact with proteins that do so to activate or repress transcription.

The functional properties of many transcription factors are surprisingly simple. They typically consist of (at least) two domains:

1. A DNA-binding domain that specifically binds to the protein's target DNA sequence (several such domains are described in Section 24-4C).
2. A domain containing the transcription factor's activation function. Sequence analysis indicates that many of these **activation domains** have conspicuously acidic surface regions whose negative charges, if mutationally increased or decreased, respectively raise or lower the transcription factor's activity. This suggests that the associations between these transcription factors and a PIC are mediated by relatively nonspecific electrostatic interactions rather than by conformationally more demanding hydrogen bonds. Other types of activation domains have also been characterized, including those with Gln-rich regions and those with Pro-rich regions.

The DNA-binding and activation functions of eukaryotic transcription factors can be physically separated (which is why they are thought to occur on different domains). In fact, a genetically engineered hybrid protein, containing the DNA-binding domain of one transcription factor and the activation domain of a second, activates the same genes as the first transcription factor. Moreover,

it makes little functional difference as to whether the activation domain is placed on the N-terminal side of the DNA-binding domain or on its C-terminal side. This geometric permissiveness in the binding between the activation domain and its target protein is also indicated by the observation that transcription factors are largely insensitive to the orientations and positions of their corresponding enhancers relative to the transcriptional start site. Of course, *the DNA between an enhancer and its distant transcriptional start site must be looped around for an enhancer-bound transcription factor to interact with the promoter-bound PIC* (Section 26-2C).

The synergy (cooperativity) of multiple transcription factors in initiating transcription may be understood in terms of a simple recruitment model. Suppose an enhancer-bound transcription factor increases the affinity with which a PIC binds to the enhancer's associated promoter so as to increase the rate at which the PIC initiates transcription there by a factor of 10. Then, if another transcription factor binding to a different enhancer subsite likewise increases the initiation rate by a factor of 20, both transcription factors acting together will increase the initiation rate by a factor of 200. *In this way, a limited number of transcription factors can support a much larger number of transcription patterns.* Transcriptional activation, according to this model, is essentially a mass action effect: The binding of a transcription factor to an enhancer increases the transcription factor's effective concentration at the associated promoter (the DNA holds the transcription factor in the vicinity of the promoter), which consequently increases the rate at which the PIC binds to the promoter. This explains why a transcription factor that is not bound to DNA (or even lacks a DNA-binding domain) inhibits transcriptional initiation. Such unbound transcription factors compete with DNA-bound transcription factors for their target sites and thereby reduce the rate at which the PIC is recruited to the associated promoter. This phenomenon, which is known as **sqelching**, is apparently why transcription factors in the nucleus are almost always bound to inhibitors unless they are actively engaged in transcriptional initiation.

Mediator Links Transcriptional Activators and RNAP II. Transcriptional activators fail to stimulate transcription by a reconstituted PIC *in vitro*. Evidently, an additional factor is required to do so. *Indeed, genetic studies in yeast by Roger Kornberg led him to discover an ~25-subunit, ~1200-kD complex named Mediator, whose presence is required for transcription from nearly all class II gene promoters in yeast.* Mediator, which is therefore considered to be a coactivator, binds to the C-terminal domain (CTD) of RNAP II's β' subunit (Section 26-2A). Further investigations revealed that multicellular organisms have similarly functioning Mediators, many of whose numerous subunits (~30 in humans, although this number is variable) are related, albeit distantly, to those of yeast Mediator. *Mediators apparently function as adaptors that bridge DNA-bound transcriptional regulators and RNAP II so as to influence (induce or inhibit) the formation of a stable PIC at the associated promoter. They thereby function to integrate the various signals implied by the binding of these transcriptional regulators to their target DNAs.*

The cryo-EM image of yeast Mediator (**Fig. 28-32**), determined by Francisco Asturias, reveals that Mediator consists of three intricately shaped modules named its head, middle, and tail, which can be dissociated from each other *in vitro*. Further studies indicate that the connections between these modules vary conformationally with the presence of RNAP II and transcriptional activators. In many cases, the individual deletion of a Mediator subunit affects the expression of only a small subset of genes, which indicates that different transcription factors interact with different Mediator subunits. Evidently, multiple transcription factors can simultaneously bind to Mediator. Moreover, there is mounting

FIG. 28-32 Cryo-EM-based structure of yeast Mediator at ~18 Å resolution. The head, middle, and tail domains are differently colored and, where available, the X-ray structures of its various subunits, represented as ribbon diagrams, have been docked into it. The four images are related by clockwise-successive 90° rotations about the vertical axis.

evidence that the binding of one transcription factor to Mediator facilitates its interactions with other transcription factors.

Including Mediator, the transcriptional machinery for class II genes comprises ~75 polypeptides with an aggregate molecular mass of ~3.7 million D. Nevertheless, as we have seen (Section 28-3A), this ribosome-sized assembly (the eukaryotic ribosome has a molecular mass of ~4.2 million D; Table 27-5) requires considerable assistance from other large particles to gain access to the DNA in chromatin.

Insulators Limit the Effects of Enhancers and Stop Heterochromatin Spreading.

Enhancers function independently of their position relative to the promoter. So what prevents an enhancer from affecting the transcription of all the genes in its chromosome? Conversely, heterochromatin, as we have seen (Section 28-3A), appears to be self-nucleating. What prevents heterochromatin from spreading into neighboring segments of euchromatin? Experiments in which DNA sequences near *Drosophila* genes were rearranged revealed that short (<2 kb) segments of DNA known as **insulators** define the boundaries of functional units for transcription. Inserting an insulator between a gene and its upstream enhancer blocks the effect of the enhancer on transcription. Insulators may also prevent heterochromatin from spreading. For example, the **HS4** insulator in the chicken β -globin gene cluster recruits HATs that acetylate H3 Lys 9 on nearby nucleosomes (which is associated with transcriptional activity; Fig. 28-24), thereby blocking their methylation (which induces heterochromatin formation). The mechanism of action of insulators is enigmatic. Presumably, it is not the insulators themselves but the proteins that bind to them that form the active insulator elements. Indeed, the HAT-recruiting activity of HS4 is distinct from its enhancer-blocking function, which is mediated by the binding of an 11-zinc finger protein named **CTCF** (for *CCCTC-binding factor*) to a different subsite of HS4 than that to which HATs bind.

Many Signal Transduction Pathways Activate Transcription Factors. A variety of signaling pathways, including some involving steroid hormones, heterotrimeric G proteins, receptor tyrosine kinases (RTKs), and phosphoinositide cascades (Chapter 13), result in the activation (or inactivation) of transcription factors. In this way, extracellular factors such as hormones can influence gene expression inside a cell. We have already seen that the Ras signaling cascade (Fig. 13-7) results in the phosphorylation of several transcription factors, including Fos, Jun, and Myc, thereby modulating their activities. The sterol regulatory element binding protein (SREBP), which regulates the expression of the genes involved in cholesterol biosynthesis by binding to their sterol regulatory elements (SREs; Section 20-7B), is also an inducible transcription factor. In the following paragraphs, we discuss two additional examples of signaling pathways that activate transcription factors.

The JAK-STAT Pathway Relays Cytokine-Based Signals. The protein growth factors that regulate the differentiation, proliferation, and activities of numerous types of cells, most conspicuously white blood cells, are known as **cytokines**. The signal that certain cytokines have been extracellularly bound by their cognate receptors is transmitted within the cell, as James Darnell elucidated, by the **JAK-STAT pathway**. **Cytokine receptors** form complexes with proteins of the **Janus kinase (JAK)** family of **nonreceptor tyrosine kinases (NRTKs)**, so named because each of its four ~1150-residue members has two tyrosine kinase domains (Janus is the two-faced Roman god of gates and doorways), although only the C-terminal domain is functional. **STATs** (for signal transducers and activators of transcription) comprise a family of seven ~800-residue proteins that are the only known transcription factors whose activities are regulated by Tyr phosphorylation and that have SH2 domains.

The JAK-STAT pathway, which is conserved from worms to mammals (but is absent in plants and fungi), functions as is diagrammed in **Fig. 28-33**:

1. Ligand binding induces the cytokine receptor to dimerize (or, in some cases, to trimerize or even tetramerize) or for a pre-existing dimer to change conformation (Section 13-1D).
2. The cytokine receptor's two associated JAKs are thereby brought into apposition, whereon they reciprocally phosphorylate each other and then their associated receptors, a process resembling the autophosphorylation of dimerized RTKs (Section 13-2A).

PROCESS DIAGRAM

FIG. 28-33 The JAK-STAT pathway for the intracellular relaying of cytokine signals. [After Carpenter, L.R., Yancopoulos, G.D., and Stahl, N., *Adv. Prot. Chem.* 52, 109 (1999).] **WPLS** See the Animated Process Diagrams.

FIG. 28-34 X-Ray structure of the Stat3 β homodimer bound to a 17-bp DNA containing its 9-bp target sequence. The complex is viewed along the helix axis of the DNA, which is represented by a purple ribbon. The protein's various domains are drawn in different colors. The phosphorylatable Tyr residues are located in the SH2 domains (yellow), which mediate the protein's dimerization. Note how the STAT dimer binds the DNA in a sort of scissors grip. PDBid 1BG1.

Courtesy of Christoph W. Müller, EMBL Heidelberg, Germany. From *Nature* 394:1, 145–151 (1998), p. 147, Fig. 2a.

3. STATs bind to the phospho-Tyr group on their cognate activated receptor via their SH2 domain and are then phosphorylated on a conserved Tyr residue by the associated JAK.
4. Following their dissociation from the receptor, the phosphorylated STATs homo- or heterodimerize via the association of their phospho-Tyr residue with the SH2 domain on the opposing subunit.
5. The STAT dimers are then translocated to the nucleus, where the now functional transcription factors specifically bind to their target DNA sequences, thereby inducing the transcription of the associated genes. Mammals have seven genetically distinct STATs, each specific for a different DNA sequence.

Like many other components of signal transduction pathways, the STAT signal is inactivated through the action of phosphatases so that a STAT typically remains active for only a few minutes. The X-ray structure of the STAT named **Stat3 β** , determined by Christoph Müller, is shown in [Fig. 28-34](#).

Nuclear Receptors Are Activated by Hormones. The **nuclear receptor superfamily**, which occurs in animals ranging from worms to humans, is composed of >150 proteins that bind a variety of hormones including steroids (glucocorticoids, mineralocorticoids, estrogens, and androgens; Sections 9-1E and 13-1C), **thyroid hormones** such as thyroxine (Fig. 4-15) that stimulate metabolism, and vitamin D (Section 9-1E), all of which are nonpolar molecules. The nuclear receptors, many of which activate distinct but overlapping sets of genes, share a conserved modular organization that includes, from N- to C-terminus, a poorly conserved activation domain, a highly conserved DNA-binding domain, a connecting hinge region, and a ligand-binding domain. The DNA-binding domains each contain eight Cys residues that, in groups of four, tetrahedrally coordinate two Zn²⁺ ions.

Many members of the nuclear receptor superfamily recognize specific DNA segments known as **hormone response elements (HREs)** that have the half-site consensus sequences 5'-AGAACA-3' for steroid receptors and 5'-AGGTCA-3' for other nuclear receptors. These sequences are arranged in direct repeats ($\rightarrow n \rightarrow$), inverted repeats ($\rightarrow n \leftarrow$), and everted repeats ($\leftarrow n \rightarrow$), where n represents a 0- to 8-bp spacer (usually 1–5 bp) to whose length a specific receptor is targeted. **Steroid receptors** bind to their hormone response elements as homodimers, whereas other nuclear receptors do so as homodimers, as heterodimers, and in a few cases as monomers.

Steroid hormones, being nonpolar, readily pass through cell membranes into the cytosol or nucleus, where they bind to their receptors (although in some

FIG. 28-35 X-Ray structure of the dimeric glucocorticoid receptor DNA-binding domain in complex with DNA. The complex is viewed with its approximate twofold molecular axis horizontal. Its 18-bp DNA is drawn in paddle form with the C atoms of its two 6-bp GRE half-sites magenta, the C atoms of the remaining nucleotides green, N blue, O red, and P orange and with successive P atoms connected by orange rods. The protein is shown in ribbon form with its lower subunit colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) and upper subunit pink. Each subunit contains a zinc finger (Section 24-4C), whose two Zn^{2+} ions (*cyan spheres*) are tetrahedrally liganded by Cys side chains shown in stick form with C green and S yellow. Note how the receptor's two N-terminal helices are inserted into adjacent major grooves of the DNA. However, only the lower subunit binds to the DNA in a sequence-specific manner; the upper subunit binds to the palindromic DNA one base pair closer to the center of the DNA molecule than does the lower subunit and hence does not make sequence-specific contacts with the DNA. [Based on an X-ray structure by Paul Sigler, Yale University. PDBid 1GLU.]

cases, they may also interact with cell-surface receptors). In the absence of their cognate steroid, these receptors are part of large multiprotein complexes. Steroid binding releases these receptors, whereon they dimerize and, if they are cytoplasmic, enter the nucleus, where they bind to their target HREs so as to induce, or in some cases repress, the transcription of the associated genes.

The X-ray structure of the 86-residue DNA-binding domain of rat **glucocorticoid receptor (GR)**; which regulates carbohydrate, protein, and lipid metabolism) in complex with DNA containing two ideal 6-bp **glucocorticoid response element (GRE)** half-sites arranged in inverted repeats was determined by Paul Sigler and Keith Yamamoto (Fig. 28-35). The protein forms a symmetric dimer involving protein–protein contacts even though it exhibits no tendency to dimerize in the absence of DNA (NMR measurements indicate that the contact region is flexible in solution). Each protein subunit consists of two structurally distinct modules, each nucleated by a Zn^{2+} coordination center, that closely associate to form a compact globular fold. The C-terminal module provides the entire dimerization interface and also makes several contacts with the phosphate groups of the DNA backbone. The N-terminal module, which is also anchored to the phosphate backbone, makes all of the GR's sequence-specific interactions with the GRE via three side chains that extend from the N-terminal α helix, its recognition helix, which is inserted into the GRE's major groove.

Afterword. As we have seen, eukaryotic transcriptional initiation is an astoundingly complex process that involves large segments of DNA as well as the synergistic participation of numerous multisubunit complexes comprising several hundred often loosely or sequentially interacting polypeptides (i.e., histones, the PIC, Mediator, transcription factors, architectural factors, coactivators, corepressors, chromatin-remodeling complexes, histone-modifying enzymes, and DNA methylases and demethylases). Moreover, as we shall see below (Section 28-3C), multiple RNA molecules have been implicated in regulating gene expression. Despite the extensive characterization of many of these factors, we are far from having a more than rudimentary understanding of how the various components interact *in vivo* to transcribe only those genes required by their cell under its particular circumstances in the appropriate amounts and with the proper timing. Nevertheless, an increase in the complexity of transcriptional regulation—rather than an increase in gene number per se—is likely to be at least partially responsible for the vast differences in morphology and behavior among nematodes, fruit flies, and humans, which have comparable numbers of genes (Table 28-1).

C Posttranscriptional Control Mechanisms

Although much of the regulation of gene expression in eukaryotes occurs at the level of transcription, additional control mechanisms act after an RNA transcript has been synthesized. In this section, we consider several of these mechanisms, including mRNA degradation, RNA interference, the roles of lncRNAs, and control

of translation initiation. We have already discussed alternative mRNA splicing (Section 26-3B) as a posttranscriptional mechanism for modulating gene expression through the selection of different exons.

mRNAs Are Degraded at Different Rates. The range of mRNA stability in eukaryotic cells, measured in half-lives, varies from a few minutes to many hours or days. The mRNA molecules themselves appear to contain elements that dictate their decay rates. These elements include the poly(A) tail, the 5' cap, and sequences that are located within the coding region.

A major route for mRNA degradation begins with the progressive removal of its poly(A) tail, a process catalyzed by **deadenylases** that appear to be located throughout the cytosol. When the residual poly(A) tail is less than ~10 nt long and hence no longer capable of interacting with poly(A)-binding protein (Section 26-3A), the mRNA becomes a substrate for a **decapping enzyme**, which hydrolytically excises the mRNA's m⁷GDP cap. This is possible because, as we have seen (Section 27-4A), the translational initiation factor eIF4G interacts with both poly(A)-binding protein and cap-binding protein, thereby circularizing the mRNA so that events at its 3' end can be coupled to events at its 5' end. The decapped and deadenylated mRNA is then degraded by exonucleases, mainly the 1706-residue 5' → 3' exonuclease **Xrn1** and the 3' → 5' exonuclease complex named the **exosome** (which, confusingly, has the same name as vesicles that are secreted by mammalian cells). A decapping enzyme, 5' → 3' exonucleases, and accessory proteins form complexes called **P bodies** (P for *processing*) that are visible in the light microscope and function both to degrade mRNA and to store it in an inactive form.

Proteins that bind to **AU-rich elements (AREs)** in the 3' untranslated region of the mRNA also appear to increase or decrease the rate of mRNA degradation, although their exact action is not understood. RNA secondary structure and RNA-binding proteins, which may be susceptible to modification by cellular signaling pathways, play a role in regulating mRNA stability. mRNAs that cannot be translated due to the presence of a premature Stop codon are specifically targeted for degradation (Box 28-3).

In addition to their mRNA degrading function, eukaryotic exosomes have been implicated in the 3'-end processing of stable functional RNAs such as ribosomal RNAs (rRNAs), small nuclear RNAs (snRNAs), and small nucleolar RNAs (snoRNAs). The eukaryotic core exosome consists of single copies of nine different subunits. Its X-ray structure (Fig. 28-36), determined by Christopher

Box 28-3 Perspectives in Biochemistry

Nonsense-Mediated Decay

Errors during DNA replication, transcription, or mRNA splicing can give rise to a Stop codon either through substitution of one nucleotide for another or through frameshifting. “Premature” Stop codons that interrupt a coding sequence may account for as many as one-third of human genetic diseases. Interestingly, eukaryotic mRNAs with premature Stop codons rarely produce the corresponding truncated polypeptide because the mRNA is destroyed through **nonsense-mediated decay (NMD)** soon after its synthesis.

How do cells distinguish a premature Stop codon from a normal Stop codon at the end of the coding sequence? Experiments suggest that the signal for NMD depends on RNA splicing. Following intron removal, an **exon-junction protein complex (EJC)** containing splicing factors and other components remains associated with each exon–exon junction, even after the mRNA has been exported to the cytosol for translation. An EJC following a Stop codon apparently marks the transcript for destruction.

A revised model for NMD proposes that quality control occurs before the mRNA leaves the nucleus. Although the bulk of

translation occurs in the cytosol, *an estimated 10 to 15% of total translation in mammalian cells takes place inside the nucleus.* During nuclear translation, a ribosome paused at a Stop codon may be converted to a “surveillance” complex that then scans the rest of the mRNA for the presence of an EJC. If an EJC is detected, the mRNA is degraded by removal of its 5' cap and 3' poly(A) tail and by the action of exonucleases.

Two other quality-control mechanisms also depend on translation. mRNAs that lack Stop codons entirely are subject to **nonstop decay**. When the ribosome reaches the 3' end of the defective mRNA, a protein known as **Ski7p**, which structurally resembles the release factor eRF3, binds to the A site and recruits an exosome to degrade the mRNA. In yeast, a mechanism known as **no-go decay** deals with mRNAs that include an obstacle such as a stable stem-loop that halts translation. In this case, the mRNA is cleaved by an endonuclease associated with the stalled ribosome.

FIG. 28-36 X-Ray structure of the human core exosome. The protein complex is drawn in ribbon form embedded in its semitransparent molecular surface, with each of its nine different subunits differently colored. The view is toward the face of the six-membered ring of subunits opposite that to which the three other subunits bind. [Based on an X-ray structure by Christopher Lima, Sloan-Kettering Institute, New York, New York. PDBid 2NN6.]

Lima, reveals that six of these subunits, **Rrp41** (Rpr for *rRNA processing*), **Rrp42**, **Mtr3**, **Rrp43**, **Rrp45**, and **Rrp46**, form a six-membered ring with the remaining three subunits, **Rrp4**, **Csl4**, and **Rrp40**, bound to the same face of the ring. The subunits are arranged such that the core exosome contains an $\sim 9\text{-\AA}$ -wide central channel that allows the entrance of only single-stranded RNAs.

The archaeal exosome appears to be a simpler version of the eukaryotic core exosome. Its six-membered ring consists of only two types of subunit, Rrp41 and Rrp42, that alternate around the ring, with three copies of Rrp4 bound to the same face of the ring. Only Rrp41 contains an active site although Rrp42 is required for activity. Not surprisingly, eukaryotic Rrp4, Mtr3, and Rrp46 are homologs of archaeal Rrp41, eukaryotic Rrp42, Rrp43, and Rrp45 are homologs of archaeal Rrp42, and eukaryotic Rrp4, Csl4, and Rrp40 are homologs of archaeal Rrp4. Nevertheless, despite the fact that each of its core subunits is essential for viability, eukaryotic core exosomes, from yeast to humans, are catalytically inactive. However, the core exosome associates with two 3'-exonucleases, **Rrp6** and **Rrp44**, whose catalytically inactive mutants are individually viable in yeast but lethal in combination. Moreover, the core exosome interacts with numerous mostly multisubunit cofactors that carry out a variety of RNA processing activities in both the nucleus and the cytosol. Thus, the eukaryotic core exosome appears to be a structural platform on which many RNA processing enzymes can be mounted.

RNA Interference Is a Type of Posttranscriptional Gene Silencing. Since the 1990s, it has become increasingly clear that *noncoding RNAs can have important roles in controlling gene expression*. One of the first indications of this phenomenon occurred in Richard Jorgensen's attempt to genetically engineer more vividly purple petunias by introducing extra copies of the gene that directs the synthesis of the purple pigment. Unexpectedly, the resulting transgenic plants had variegated or entirely white flowers. Apparently, the purple-making genes switched each other off. This result was at first attributed to the well-known phenomenon in which **antisense RNA** (RNA that is complementary to a portion of an mRNA) prevents the translation of the corresponding mRNA because the ribosome cannot translate double-stranded RNA. However, injecting **sense RNA** (RNA with the same sequence as the mRNA) into experimental organisms such as the nematode worm *C. elegans* also blocked protein production. Since the added RNA somehow interferes with gene expression, this phenomenon is known as **RNA interference (RNAi)**. RNAi is now known to occur in all eukaryotes except baker's yeast.

Further experiments by Andrew Fire and Craig Mello revealed that double-stranded RNA is even more effective than either of its component strands alone at interfering with gene expression. In fact, RNAi can be induced by just a few molecules of double-stranded RNA, indicating that RNAi is a catalytic rather than a stoichiometric phenomenon.

RNA interference is not merely an artifact of genetic engineering. In many cells, naturally occurring small RNA molecules, called **short interfering RNAs (siRNAs)** or **microRNAs (miRNAs)**, depending on their origin, down-regulate gene expression by binding to complementary mRNA molecules. Thousands of miRNAs, ranging in length from 18 to 25 nucleotides, have been identified in mammals, although their mRNA targets are only beginning to be characterized.

Several Nucleases Participate in RNAi. Work with exogenous double-stranded RNA in *C. elegans* and *Drosophila* has led to the elucidation of the following pathway for RNAi (**Fig. 28-37**):

1. The trigger double-stranded RNA, as Phillip Zamore discovered, is chopped up into ~21- to 23-nt fragments (that is, siRNAs), each of whose

PROCESS DIAGRAM

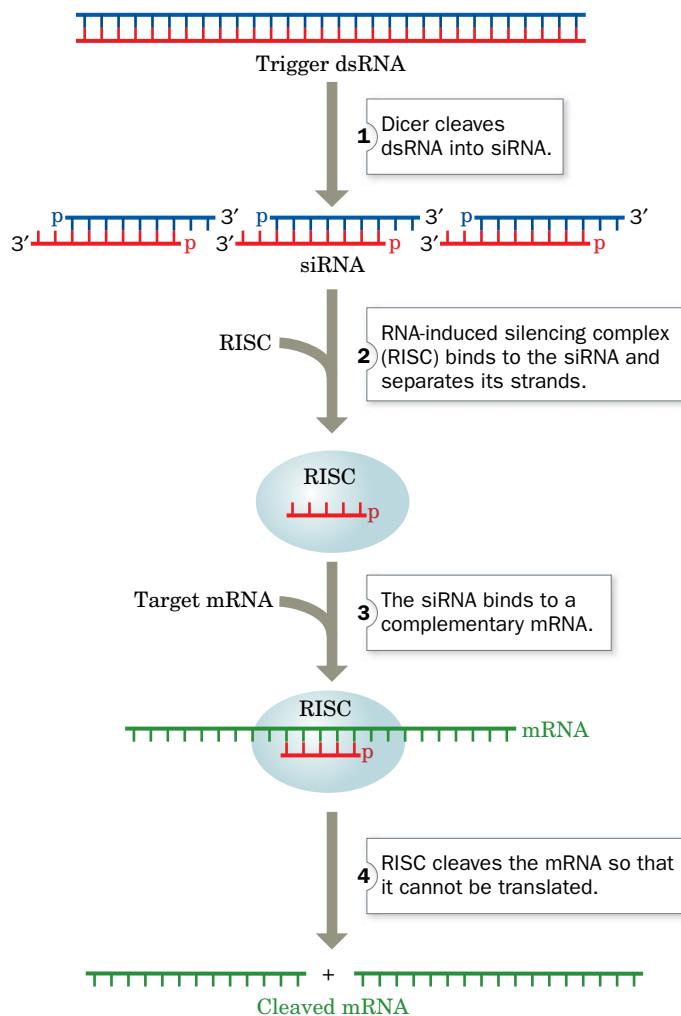

FIG. 28-37 A mechanism of RNA interference. ATP is required for Dicer-catalyzed cleavage of RNA and for RISC-associated helicase unwinding of double-stranded RNA. Depending on the species, the

mRNA may not be completely degraded. **WPLS** See the **Animated Process Diagrams**.

? Explain why RNAi is a mechanism for “silencing” genes.

strands has a 5' phosphate and a 2-nt overhang at its 3' end. The cleavage reaction is catalyzed by an ATP-dependent RNase named **Dicer**, a homodimer of ~1900-residue subunits in animals that is a member of the **RNase III** family of double-strand-specific RNA endonucleases.

2. An siRNA is transferred to a 250- to 500-kD enzyme complex known as the **RNA-induced silencing complex (RISC)**. RISC has at least four protein components, one of which is an ATP-dependent RNA helicase that separates the two strands of the siRNA. The strand whose 5' end has the lower free energy of binding, the **guide RNA**, is bound by the RISC whereas its complementary strand, the **passenger RNA**, is cleaved and discarded. In some species, but apparently not in humans, the original siRNA signal is amplified by the action of an **RNA-dependent RNA polymerase**.
3. The **guide RNA** recruits the RISC complex to an mRNA with the complementary sequence.
4. An RNase III component of RISC known as **Argonaute (Ago; also called Slicer)** cleaves the mRNA opposite the bound guide RNA. The cleaved mRNA is then further degraded by cellular nucleases, thereby preventing its translation.

Although the molecular machinery involved in RNAi is highly conserved from yeast to humans, variations abound, even within a single organism. For example, different Dicer enzymes can potentially generate different lengths of siRNAs, which may differ in their gene-silencing activities. The exact length of the siRNA produced by Dicer, or the degree to which its sequence exactly complements the mRNA sequence, may determine whether a corresponding mRNA is completely degraded or just rendered nontranslatable.

The X-ray structure of Dicer from the parasitic protozoan *Giardia intestinalis*, determined by Jennifer Doudna, reveals a hatchet-shaped enzyme with two RNase active sites, each of which includes four conserved acidic residues that bind two Mg^{2+} ions. The active sites are 17.5 Å apart, the width of dsRNA's major groove, and thus appear positioned to cleave the two strands of a bound dsRNA (Fig. 28-38). The so-called PAZ domain (bottom of Fig. 28-38) specifically binds dsRNA ends that have a 3' two-nucleotide overhang. The distance between this binding site and the closest RNase active site is 65 Å, the length of a 25-bp dsRNA.

The X-ray structure of the 859-residue human Argonaute2 (Ago2) in complex with an 8-nt segment of guide RNA, determined by Ian MacRae, reveals a bilobal protein that binds the guide RNA in a deep cleft (Fig. 28-39). The RNA,

FIG. 28-40 The generation of miRNAs from pri-miRNAs and their RISC-mediated binding to target mRNAs. See the text for details.

which apparently originated from 10- to 20-nt cellular RNAs in the crystallization preparation and was modeled as poly(A), assumes an A-like conformation in which bases 2 to 6 are splayed out to pre-order them for base pairing with a complementary segment of mRNA.

The ease with which RNAi can be induced by exogenous RNAs suggests that the pathway may have arisen as a defense against viruses. In many eukaryotes, the major source of double-stranded RNA is RNA viruses, many of which encode their own RNA-dependent RNA polymerase to convert their single-stranded genome into double-stranded RNA. In fact, many plant viruses contain genes that suppress various steps of RNAi and that are therefore essential for pathogenesis.

Micro RNAs Regulate Gene Expression. A wide variety of eukaryotes, including plants, nematodes, flies, fish, and mammals, use RNAi to control gene expression. Certain mRNAs expressed by these organisms contain ~70-nt, imperfectly base-paired, stem-loop structures that are excised by the so-called **microprocessor complex**, which consists of a 1374-residue RNase III named **Drosha** and the 772-residue **DGCR8** (for DiGeorge syndrome critical region gene 8), a protein that contains two double-stranded RNA-binding domains (Fig. 28-40). The stem-loops are exported from the nucleus to the cytosol where they are cleaved by Dicer to liberate ~22-bp dsRNAs known as **micro RNAs (miRNAs)**; so called to differentiate these endogenous RNAs from the exogenous siRNAs). The transcripts from which miRNAs are derived are known as **pri-miRNAs** (pri for primary), whereas the stem-loops are called **pre-miRNAs** (pre for precursor). Pre-miRNAs can be located within both the introns and, less commonly, the exons of a pri-miRNA. The miRNAs bind to RISC in which they function to identify the tens to hundreds of mRNAs containing segments that are partially complementary to the miRNA.

The RISC-bound miRNA binds to its target site, which is usually in the 3' untranslated region (3'UTR) of an mRNA. A lack of perfect complementarity prevents Argonaute from cleaving the mRNA (Argonaute catalyzes slicing only if there is perfect complementarity to the miRNA's so-called **seed sequence**, which consists of nucleotides 2 to 6 from its 5' end), and in fact, many species of Argonaute lack the catalytic residues to do so (of the four human Argonautes, only Ago2 is catalytically active). Instead, miRNA-mediated silencing is thought to occur through the removal of its target mRNA's poly(A) tail or its m⁷G cap, which leads to the mRNA's degradation, and/or the RISC-mediated repression of the target mRNA's translation by interfering with ribosomal initiation (Section 27-4A) and sequestering or degrading the mRNA in P bodies.

In 1993, Victor Ambros discovered the first known miRNA, which is encoded by the *lin-4* gene of *C. elegans* (Fig. 28-41a). The *lin-4* gene was known to control the timing of larval development, although at the time it was thought that it encoded a protein that repressed the expression of the *lin-14* gene. In fact, the *lin-4* miRNA is complementary to seven sites on the 3'UTR of the *lin-14* gene, which had previously been shown to mediate the repression of *lin-14* by the *lin-4* gene product. A puzzling observation at the time was that this regulation greatly reduces the amount of LIN-14 protein produced without altering the level of *lin-14* mRNA. These findings were eventually followed by the discovery that the *C. elegans let-7* gene encodes what is now known to be an miRNA (Fig. 28-41b) that controls the transition from larval to adult stages of development. Subsequently, *let-7* homologs were identified in the *Drosophila* and human genomes and *let-7* RNA was detected in these organisms as well as in numerous other animals.

Both the *lin-4* and *let-7* miRNAs were discovered by genetic analyses. However most of the nearly 10,000 miRNAs in plants and animals that are now known, including those in Fig. 28-41c, were identified through bioinformatic approaches (Section 6-2E). Nearly all miRNAs are conserved among closely related animals (e.g., mice and humans) and many are more broadly conserved

throughout animal lineages (e.g., more than one-third of the 174 *C. elegans* miRNAs have homologs in humans). *The significance of miRNAs is indicated by the fact that humans express >1000 miRNAs that participate in regulating at least 30% of their protein-coding genes.*

RNAi Has Numerous Applications. The exquisite specificity of RNAi has made it a widely used method for “knocking out” specific genes in plants and invertebrates. For example, in *C. elegans*, RNAi has been used to systematically inactivate over 16,000 of its ~19,000 protein-coding genes in an attempt to assign a function to each gene. *C. elegans* is particularly amenable to the RNAi approach, since these worms eat *E. coli* cells, and it is relatively easy to genetically engineer the bacterial cells to express double-stranded RNA that becomes part of the worms’ diet. One limitation of the RNAi method is that only gene inactivation—rather than gene activation—can be examined.

Manipulating the RNAi pathway in mammals is more problematic, mainly due to the difficulty of delivering double-stranded RNA to cells and eliciting more than transient gene silencing. To complicate matters, mammalian cells have additional pathways for dealing with foreign RNA, which result in non-specific degradation of RNA and cessation of all translation (these responses probably also help prevent infection by RNA viruses). Nevertheless, experiments have demonstrated that it is possible to use RNAi to block the liver’s inflammatory response to a hepatitis virus, at least in mice, and to prevent HIV replication in cultured human cells. One challenge for the future is to devise protocols for more specific and longer-lasting gene silencing that would make it possible to prevent viral infections or to block the effects of disease-causing mutant genes.

lncRNAs Have Essential Regulatory Functions. Long noncoding RNAs (lncRNAs; also called **lincRNAs for **long intervening noncoding RNAs**)** are RNAs of >200 nt (to distinguish them from short regulatory RNAs such as miRNAs) that, like mRNAs, are transcribed by RNAP II, 5'-capped, polyadenylated, and spliced, but do not encode proteins. For many years, it was assumed that lncRNAs are nonfunctional and arose through spurious transcription (transcriptional “noise”). However, it is becoming increasingly evident that many lncRNAs have crucial regulatory functions. Indeed, we have already met two such lncRNAs, *Xist* and *Tsix* RNAs, which participate in X chromosome inactivation (Box 28-2).

The large-scale sequencing of cDNA libraries by next-generation sequencing techniques (Section 3-4D) has unexpectedly shown that mammals transcribe tens of thousands of lncRNAs, the majority of which are likely to be functional, although only a small fraction of them have yet been characterized. For example, John Rinn has shown that a lncRNA named HOTAIR [for *Hox* transcript anti-sense RNA; *Hox* genes organize the body plans of bilateral organisms (Section 28-4D)] binds to **Polycomb Repressive Complex 2 (PRC2)**, which functions to di- and trimethylate Lys 27 of histone H3, a transcriptionally repressive mark. PRC2 is thereby targeted to the *HoxD* gene cluster via base pairing between segments of HOTAIR and *HoxD* DNA. This silences the transcription of the *HoxD* genes, thus regulating the epigenetic differentiation of the skin over different parts of the body as well as the skeleton and other tissues. *Xist* RNA similarly recruits PRC2 to the X chromosome, resulting in its inactivation through histone H3 Lys 27 methylation. In fact, PRC2 has been shown to bind hundreds of lncRNAs, which presumably permits PRC2 to influence the transcription of a wide variety of specific genes.

Other lncRNAs regulate transcription by binding to the general transcription factors, Mediator, or RNAP II. Some bind directly to their target mRNAs so as to influence pre-mRNA processing, transport, translation, and degradation. Clearly, *lncRNAs have critical and widespread roles in the regulation of eukaryotic gene expression.*

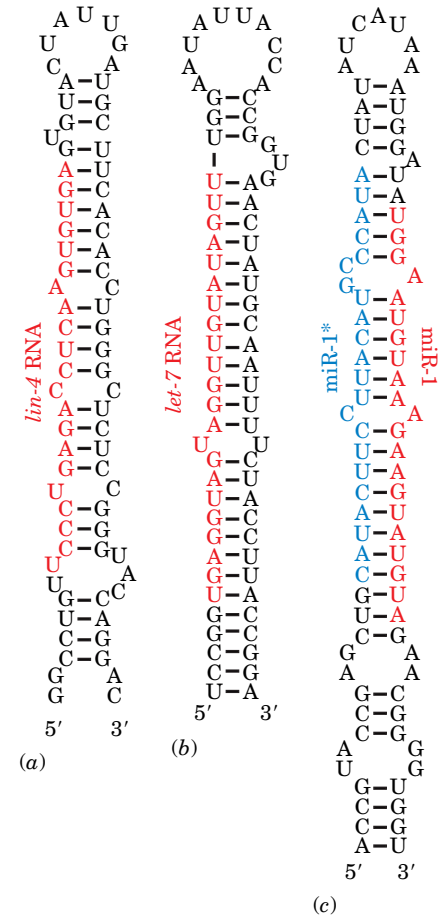

FIG. 28-41 The predicted stem-loops of some pre-miRNAs. The miRNAs contained in these pre-mRNAs, all of which are from *C. elegans*, are red. (a) *lin-4*, (b) *let-7*, and (c) *miR-1* and *miR-1** (in blue), which are largely complementary to each other.

mRNA Translation May Be Controlled. In some cells, altering the rates of mRNA production or degradation does not provide the necessary level of control. For example, the early embryonic development of sea urchins, insects, and frogs depends on the rapid translation of mRNA that has been stockpiled in the oocyte. The mRNA is stored in inactive form in association with proteins but on fertilization becomes available for translation. This permits embryogenesis to commence immediately, without waiting for mRNAs from paternally supplied genes to be synthesized.

Globin synthesis in reticulocytes (immature red blood cells) also proceeds rapidly, but only if heme is available. The inhibition of globin synthesis occurs at the level of translation initiation. In the absence of heme, reticulocytes accumulate a protein, **heme-regulated inhibitor (HRI)**. HRI is a kinase that phosphorylates a specific Ser residue, Ser 51, on the α subunit of eIF2 (the initiation factor that delivers GTP and Met-tRNA^{Met} to the ribosome; Section 27-4A).

Phosphorylated eIF2 participates in translation initiation in much the same way as unphosphorylated eIF2, but it is not regenerated normally. At the completion of the initiation process, unmodified eIF2 exchanges its bound GDP for GTP in a reaction mediated by another initiation factor, **eIF2B**:

Phosphorylated eIF2 forms a much tighter complex with eIF2B than does unphosphorylated eIF2. This sequesters eIF2B (Fig. 28-42), which is present in lesser amounts than is eIF2, thereby preventing regeneration of the eIF2 • GTP required for translation.

In the presence of heme, the heme-binding sites in HRI are occupied, which inactivates the kinase. The eIF2 molecules that are already phosphorylated are reactivated through the action of **eIF2 phosphatase**, which is unaffected by heme. The reticulocyte thereby coordinates its synthesis of globin and heme.

D Antibody Diversity Results from Somatic Recombination and Hypermutation

As described in Section 7-3B, an individual can generate an extraordinary number of different antibody molecules from a limited number of immunoglobulin

FIG. 28-42 A model for heme-controlled protein synthesis in reticulocytes.

gene segments. This feat is accomplished through an unusual mutation process and through **somatic recombination** in differentiating cells of the immune system. Homologous recombination (Section 25-6A), a fundamental feature of reproduction in multicellular organisms, occurs only in germline cells. The mechanism whereby a developing B lymphocyte “selects” light and heavy chain gene segments for expression is described below. Similar events occur in T lymphocytes to generate a large number of unique T cell receptors.

Immunoglobulin Chain Genes Are Assembled from Multiple Gene Segments.

One of the two types of immunoglobulin light chains, the **κ chain**, is encoded by four exons (Fig. 28-43):

1. A **leader** or L_{κ} **segment**, which encodes a 17- to 20-residue hydrophobic signal peptide. This polypeptide directs newly synthesized κ chains to the endoplasmic reticulum and is then excised (Section 9-4D).
2. A V_{κ} **segment**, which encodes the first 95 residues of the κ chain’s 108-residue variable region.
3. A **joining** or J_{κ} **segment**, which encodes the variable region’s remaining 13 residues.
4. The C_{κ} **segment**, which encodes the κ chain’s constant region.

In embryonic tissues (which do not make antibodies), the exons occur in clusters. The human κ chain gene family contains ~40 functional L_{κ} and V_{κ} segments, separated by introns, with the L_{κ} - V_{κ} units separated from each other by ~7-kb spacers. This sequence of exon pairs is followed, well downstream, by 5 J_{κ} segments at intervals of ~300 bp, a 2.4-kb spacer, and a single C_{κ} segment.

The assembly of a κ chain mRNA is a complex process involving both somatic recombination and selective mRNA splicing (Section 26-3B) over several cell generations. The first step of this process, which occurs in B cell progenitor cells, is an intrachromosomal recombination that joins an L_{κ} - V_{κ} unit to a J_{κ} segment and deletes the intervening DNA sequences (Fig. 28-43). Then, in later cell generations, the entire modified gene is transcribed and the resulting transcript is selectively spliced so as to join the L_{κ} - V_{κ} - J_{κ} unit to the C_{κ} segment. The L_{κ} and V_{κ} segments are also spliced together in this step, yielding an mRNA that encodes one of each of the four elements of a κ chain gene.

The joining of 1 of 40 functional V_{κ} segments to 1 of 5 J_{κ} segments can generate only $40 \times 5 = 200$ different κ chains, far less than the number observed. However, studies of many joining events involving the same V_{κ} and J_{κ} segments revealed that *the V/J recombination site is not precisely defined; the two gene segments can join at different points* (Fig. 28-44). Consequently, the amino acids

FIG. 28-44 Variation at the V_{κ}/J_{κ} joint. The point at which the V_{κ} and J_{κ} sequences somatically recombine varies by several nucleotides, thereby giving rise to different nucleotide sequences in the active κ gene. In this example of junctional flexibility, the second amino acid can be Ser, Gly, or Asp.

specified by the codons in the vicinity of the V/J joint, which corresponds to the third hypervariable loop (Fig. 7-40), depend on which nucleotides are supplied by the germline V_{κ} segment and which are supplied by the germline J_{κ} segment. Assuming that this junctional flexibility increases the possible κ chain diversity 10-fold, the expected number of possible different κ chains is increased to around $40 \times 5 \times 10 = 2000$.

The other type of immunoglobulin light chain, the λ chain, is similarly encoded by a gene family containing L_{λ} , V_{λ} , J_{λ} , and C_{λ} segments whose recombination likewise yields a large number of possible polypeptides.

Heavy chain genes are assembled in much the same way as are light chain genes but with the additional inclusion of an ~13-bp **diversity** or **D segment** between their V_H and J_H segments. The human heavy chain gene family consists of clusters of ~65 different functional L_H-V_H units, ~27 D segments, 6 J_H segments, and 9 C_H segments (Fig. 28-45). Germline V_H , D , and J_H segments are joined in a particular order (D is joined to J_H before V_H is joined to DJ_H), and the joining sites are subject to the same junctional flexibility as are light chain V/J sites. Thus the number of possible different heavy chains is around $65 \times 27 \times 6 \times 9 \times 10^2 = 9.5 \times 10^6$.

Somatic Recombination Occurs at Specific Sequences. Highly conserved sequences flanking the V , D , and J gene segments act as **recombination signal sequences (RSS; Fig. 28-46a)**. Each RSS consists of a palindromic heptamer and an AT-rich nonamer separated by either 12 bp (corresponding to ~1 turn of the DNA helix) or 23 bp (corresponding to ~2 helical turns). The recombination machinery joins a segment with a so-called 12-RSS to a segment with a 23-RSS. Because each V_{κ} gene segment only has a 12-RSS and each J_{κ} segment only has a 23-RSS, somatic recombination cannot join two V_{κ} segments or two J_{κ} segments. Similarly the distribution of 12-RSS and 23-RSS elements in heavy chain gene segments is such that V_H must join to D , and D to J_H , which precludes V_H/J_H joining (Fig. 28-46b).

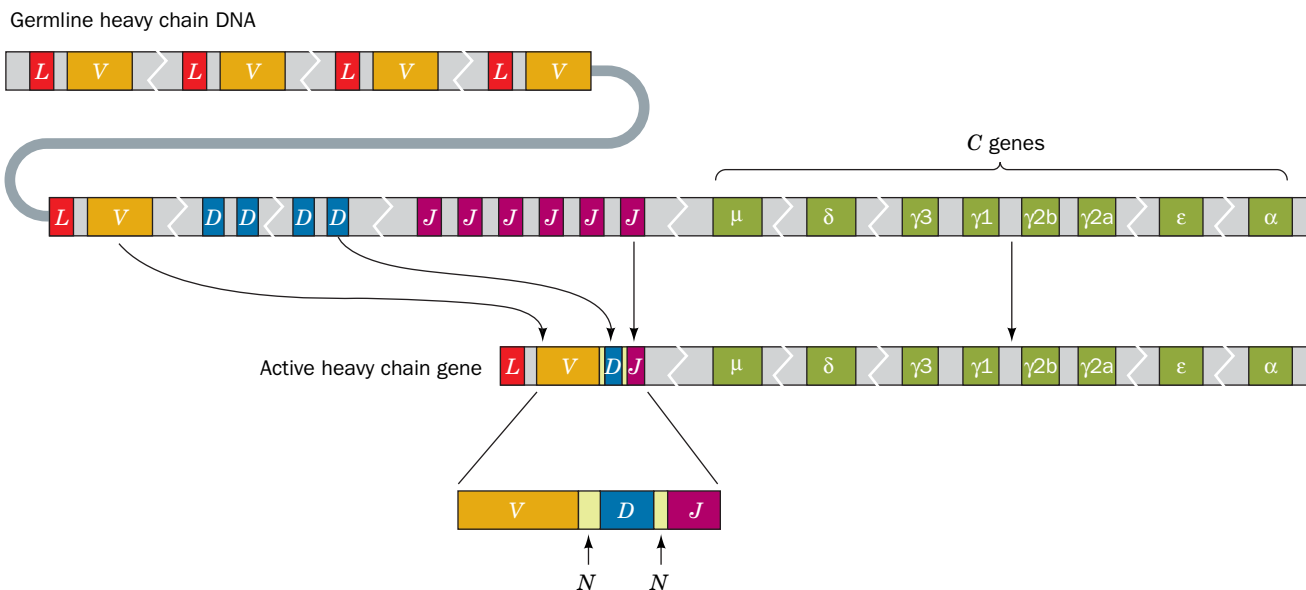

FIG. 28-45 The organization and rearrangement of the heavy chain gene family in humans. This gene family consists of ~65 sequential pairs of L_H and V_H gene segments followed by ~27 D segments, 6 J_H segments, and 9 C_H segments (one for each class or subclass of heavy chains; Table 7-2). During lymphocyte differentiation, an L_H-V_H unit is

joined to a D segment and a J_H segment. In the process, the D segment becomes flanked by short stretches of random sequence called N regions. In the B cell and its progeny, transcription and splicing join the $L_H-V_H-N-D-N-J_H$ unit to one of the 9 C_H gene segments. This diagram is not drawn to scale.

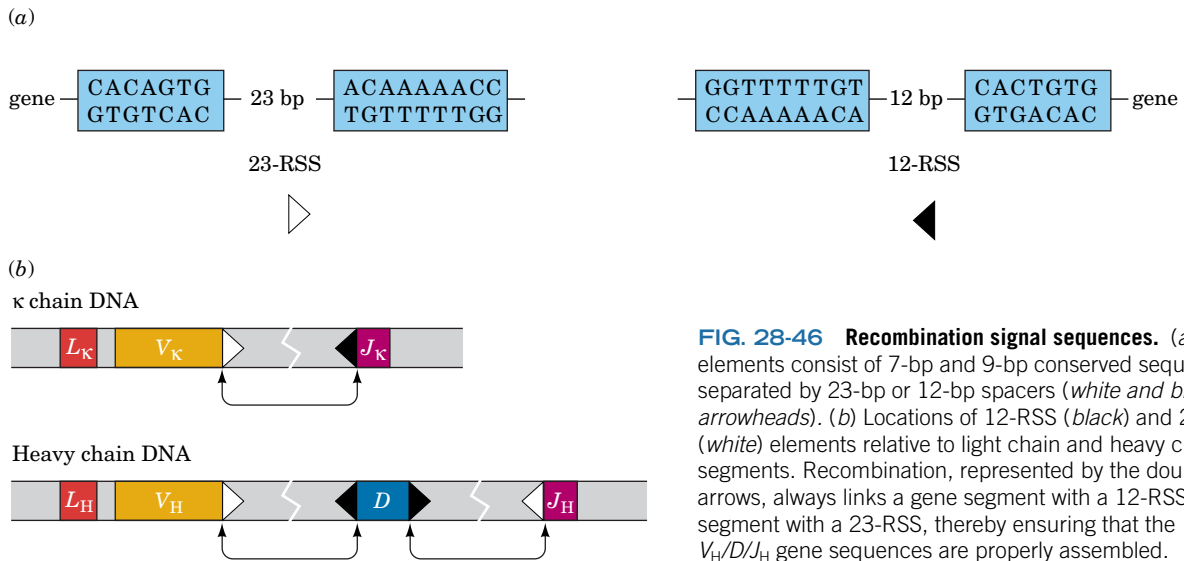

FIG. 28-46 Recombination signal sequences. (a) The RSS elements consist of 7-bp and 9-bp conserved sequences separated by 23-bp or 12-bp spacers (*white and black arrowheads*). (b) Locations of 12-RSS (*black*) and 23-RSS (*white*) elements relative to light chain and heavy chain gene segments. Recombination, represented by the double-headed arrows, always links a gene segment with a 12-RSS to a gene segment with a 23-RSS, thereby ensuring that the V_{κ}/J_{κ} and $V_H/D/J_H$ gene sequences are properly assembled.

Recombination requires enzymes that are synthesized only in developing lymphocytes, as well as ubiquitous DNA repair proteins. All ***V(D)J joining*** reactions are catalyzed by an evolutionarily conserved ***V(D)J recombinase*** system. Indeed, David Baltimore discovered two proteins, **RAG1** and **RAG2** (RAG for *recombination activating genes*), that work in concert to recognize the RSS elements of two different gene segments, align them, and catalyze DNA cleavage. This process is assisted by HMG proteins **HMG1** and **HMG2**, which appear to bend the DNA. Under laboratory conditions, RAG1 and RAG2 can catalyze transposition, that is, the relocation of a DNA segment to another DNA molecule (Section 25-6C), consistent with the proposal that the RAG proteins originated as a transposon that appeared in vertebrates around 450 million years ago.

During recombination, the two RSS elements are neatly excised, but their adjacent coding sequences may be trimmed by nucleases and unevenly joined, thereby contributing to junctional flexibility (Fig. 28-44). The trimming and ligating reactions are not unique to lymphocytes but apparently make use of a variety of DNA repair enzymes that function in all cells (Section 25-5).

In addition, a few nucleotides may be added to the recombination joints, either as part of the DNA-repair process or, in the case of heavy chain gene assembly, by the action of the lymphocyte-specific enzyme **terminal deoxynucleotidyl transferase**. This DNA polymerase is unusual in that it does not require a template. It may add up to 15 nucleotides at the V_H/D_H and D_H/J_H joints, which, of course, greatly increases the potential for sequence diversity in the encoded variable region of the immunoglobulin chain.

Hypermutation Is a Further Source of Antibody Diversity. Despite the enormous antibody diversity generated by somatic recombination, immunoglobulins are subject to even more variation that arises as the B cells undergo cell division. The amino acid sequences of the variable regions of both heavy and light chains are more diverse than is expected from their original germline nucleotide sequences. Indeed, these regions mutate at rates of up to 10^{-3} base changes per nucleotide per cell generation, rates that are at least a millionfold higher than the rates of spontaneous mutation in other genes. This **somatic hypermutation** of immunoglobulin gene segments is initiated by the expression, in proliferating B

CHECKPOINT

- Why is chromatin remodeling necessary for efficient gene expression?
- List some ways that histones can be covalently modified.
- Describe how histone modifications can affect the structure of nucleosomes and the function of transcription factors.
- Summarize the role of DNA methylation in epigenetic inheritance and imprinting.
- Explain why eukaryotic gene expression requires proteins in addition to the six general transcription factors.
- Why is the spacing between enhancers and promoters variable?
- What is the role of Mediator in transcription?
- How is hormone signaling linked to gene expression?
- Describe the steps of RNA interference.
- Compare gene silencing by siRNA and miRNA.
- Describe how antibody diversity is generated. List the responsible enzymatic activities that are unique to lymphocytes.

cells, of a cytidine deaminase named **activation-induced deaminase (AID)**. The resulting uracil may then participate in normal DNA replication, yielding a C · G to T · A transition (Section 25-4A). More frequently, however, the uracil is excised by uracil–DNA glycosylase (Section 25-5B) and replaced by a base excision repair (BER; Section 25-5B), a process that employs error-prone translesion DNA polymerases (Section 25-5E). The mutations occur throughout the *V/J* and *V/D/J* regions but are concentrated at the sequences corresponding to the three hypervariable loops of each chain. DNA sequences in other genes do not seem to be affected.

Somatic hypermutation acts over many cell generations after antigen stimulation. Because B cells producing antibodies with high affinity for their antigen tend to proliferate faster than B cells producing poorly binding antibodies, the pool of antibody molecules becomes exquisitely tailored to a particular antigen over time. The diversity arising from somatic recombination, with its junctional flexibility, and from hypermutation thereby permits an individual's immune system to cope, in a kind of Darwinian struggle, with the rapid mutation rates of pathogenic microorganisms.

4 The Cell Cycle, Cancer, Apoptosis, and Development

KEY CONCEPTS

- Cyclins and cyclin-dependent kinases regulate progress through the cell cycle.
- Tumor suppressors such as p53 alter gene expression to arrest the cell cycle.
- Apoptosis leads to cell death in response to internal or external signals.
- Development programs are genetically controlled in a sequential fashion.

In addition to selecting *which* genes to express from among the thousands that are present in its genome, a cell must decide *when* to express them. Thus a cell can undertake a particular developmental program or respond effectively to changing conditions. The events of the eukaryotic cell cycle, encompassing normal and abnormal cell reproduction, as well as cell death, illustrate how particular gene products regulate a cell's activities at different times.

A Progress through the Cell Cycle Is Tightly Regulated

The **cell cycle**, the general sequence of events that occur during the lifetime of a eukaryotic cell, is divided into four distinct phases (Fig. 28-47):

1. Mitosis and cell division occur during the relatively brief **M phase** (for *mitosis*).
2. This is followed by the **G₁ phase** (for *gap*), which covers the longest part of the cell cycle.
3. G₁ gives way to the **S phase** (for *synthesis*), which, in contrast to events in prokaryotes, *is the only period in the cell cycle when DNA is synthesized*.
4. During the relatively short **G₂ phase**, the now tetraploid cell prepares for mitosis. It then enters M phase once again and thereby commences a new round of the cell cycle.

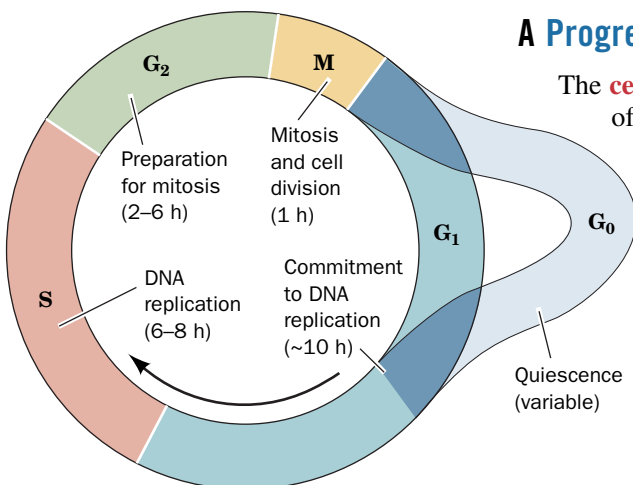

FIG. 28-47 The eukaryotic cell cycle. Cells may enter a quiescent phase (G₀) rather than continuing about the cycle.

? Describe the types of activities that likely occur during each phase.

The cell cycle for cells in culture typically occupies a 16- to 24-h period. In contrast, cell cycle times for the different types of cells in a multicellular organism may vary from as little as 8 h to >100 days. Most of this variation occurs in the G_1 phase. Moreover, many terminally differentiated cells, such as neurons or muscle cells, never divide; they assume a quiescent state known as the **G_0 phase**.

Progression through the cell cycle is triggered by external as well as internal signals. In addition, the cell cycle has a series of **checkpoints** that monitor its progress and the health of the cell and arrest the cell cycle if certain conditions have not been satisfied. For example, G_2 has a checkpoint that prevents the initiation of M until all of the cell's DNA has been replicated, thereby ensuring that both daughter cells will receive a full complement of DNA. Similarly, a checkpoint in M prevents mitosis until all chromosomes have properly attached to the mitotic spindle (if this were not the case, even for one chromosome, one daughter cell would lack this chromosome and the other would have two, both deleterious, if not lethal, conditions). Checkpoints in G_1 and S also arrest the cell cycle in response to damaged DNA to give the cell time to repair the damage (Section 25-5). In the cells of multicellular organisms, if after a time the checkpoint conditions have not been met, the cell may be directed to commit suicide, a process named **apoptosis** (see below), thereby preventing the proliferation of an irreparably damaged and hence dangerous (e.g., cancerous) cell.

The Activities of Cyclin-Dependent Protein Kinases Change throughout the Cell Cycle. The progression of a cell through the cell cycle is regulated by proteins known as **cyclins** and **cyclin-dependent protein kinases (Cdks)**. Cyclins are so named because they are synthesized during one phase of the cell cycle and are completely degraded during a succeeding phase (protein degradation is discussed in Section 21-1). A particular cyclin specifically binds to and thereby activates its corresponding Cdk(s), which are Ser/Thr protein kinases, to phosphorylate their target nuclear proteins. These proteins, which include histone H1, several oncogene proteins (see below), and proteins involved in nuclear disassembly and cytoskeletal rearrangement, are thereby activated to carry out the processes making up that phase of the cell cycle.

The human Cdk named **Cdk2** is activated by the binding of **cyclin A** and by phosphorylation of its Thr 160 as catalyzed by **Cdk-activating kinase (CAK)**; this kinase is itself a complex of **cyclin H** and **Cdk7**. Phosphorylation of Cdk2 residues Thr 14 and Tyr 15 negatively regulates Cdk2 activity. The X-ray structure of unphosphorylated Cdk2 in complex with ATP but in the absence of cyclin A (**Fig. 28-48a**) closely resembles that of the catalytic subunit of protein kinase A (PKA; Fig. 13-21). However, Cdk2 is inactive as a kinase in part because access of protein substrates to the γ -phosphate of the bound ATP is blocked by a 19-residue protein loop dubbed the **T loop** (which contains Thr 160). Phosphorylation of Thr 160 and binding of cyclin A alter the conformation of Cdk2 (**Fig. 28-48b**). In particular, the N-terminal α helix of Cdk2, which contains the PSTAIRE sequence motif characteristic of the Cdk family, rotates about its axis by 90° and moves several angstroms in order to position several residues in a catalytically active arrangement. In addition, Cdk2's T loop undergoes a dramatic reorganization, involving position shifts of up to 21 Å, that allows protein substrates access to the active site. The phosphate group on Thr 160 fits snugly into a positively charged pocket composed of three Arg residues that forms, in part, on cyclin A binding.

In addition to their control by phosphorylation/dephosphorylation and by the binding of the appropriate cyclin, *Cdk activities are regulated by **cyclin dependent kinase inhibitors (CKIs)**, which arrest the cell cycle in response to such antiproliferative signals as contact with other cells, DNA damage, terminal differentiation, and senescence (in which cell cycle arrest is permanent)*. The importance of CKIs is indicated by their frequent alterations in cancer, which is

FIG. 28-48 X-Ray structure of human cyclin-dependent kinase 2 (Cdk2). (a) Cdk2 in complex with ATP. The protein is shown in the “standard” protein kinase orientation with its N-terminal lobe pink, its C-terminal lobe cyan, its PSTAIRE helix (residues 45–56) magenta, and its T loop (residues 152–170) orange. The ATP is shown in space-filling form and the phosphorylatable side chains of Thr 14, Tyr 15, and Thr 160 are shown in stick form, all colored with C green, N blue, O red, and P yellow. [Based on an X-ray structure by Sung-Hou Kim, University of California at Berkeley. PDBid 1HCK.] (b) The complex of Thr 160-phosphorylated Cdk2 with cyclin A and ATP. The Cdk2 and ATP are represented as in Part a and viewed similarly. The cyclin A is

colored light and dark green. The phosphoryl group at Thr 160 of Cdk2 is drawn in space-filling form. Note how the binding of cyclin A together with the phosphorylation of Thr 160 has caused a major structural reorganization of the T loop and the Cdk2 N-terminal lobe, including its PSTAIRE helix. Also note the different conformations of the ATP triphosphate group in the two structures. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1JST.]

? Compare the structure of Cdk2 with that of protein kinase A (PKA; Fig. 13-21).

manifest as uncontrolled cell division. The pathways by which sensor proteins monitor cellular conditions and activate or inactivate Cdks are not yet fully understood. However, considerable information has been provided by studies of proteins, including p53 and pRb (see below), whose mutations are associated with loss of cell cycle control.

B Tumor Suppressors Prevent Cancer

Individuals with the rare inherited condition known as **Li-Fraumeni syndrome** are highly susceptible to a variety of malignant tumors, particularly breast cancer, which they often develop before their thirtieth birthdays. These individuals have germline mutations in their *p53* gene, which suggests that its normal protein product, **p53** (a polypeptide with a nominal mass of 53 kD), is a **tumor suppressor**. In other words, *p53 functions to restrain the uninhibited cell proliferation that is characteristic of cancer*. Indeed, the *p53* gene is the most commonly altered gene in human cancers; ~50% of human cancers contain a mutation in *p53*, and many other oncogenic (cancer-causing) mutations occur in genes that encode proteins that directly or indirectly interact with p53. Evidently, p53 functions as a “molecular policeman” in monitoring genome integrity.

p53 Arrests the Cell Cycle in G₂. Despite the central role of p53 in preventing tumor formation, the way it does so has only gradually come to light. p53 is specifically bound by **Mdm2** protein, a ubiquitin-protein ligase (E3) that specifically ubiquitinates p53, thereby marking it for proteolytic degradation by the proteasome (Section 21-1). Consequently, the amplification (generation of several copies) of the *mdm2* gene, which occurs in >35% of human **sarcomas** (none of which have a mutated *p53* gene; sarcomas are malignancies of connective tissues such as muscle, tendon, and bone), results in an increased rate of degradation of p53, thereby predisposing cells to malignant transformation. Thus, *an additional way that oncogenes (cancer-causing genes; Box 13-3) can cause cancer is by inactivating normal tumor suppressors.*

p53 is an efficient transcriptional activator. Indeed, all point-mutated forms of p53 that are implicated in cancer have lost their sequence-specific DNA-binding properties. How, then, does p53 function as a tumor suppressor? A clue to this riddle came from the observation that the treatment of cells with DNA-damaging ionizing radiation results in the accumulation of normal p53. This led to the discovery that the activated protein kinases **ATM** and **Chk2** both phosphorylate p53 [ATM for *ataxia telangiectasia mutated (ataxia telangiectasia* is a rare genetic disease characterized by a progressive loss of motor control, growth retardation, premature aging, and a greatly increased risk of cancer); Chk for *checkpoint kinase*]. ATM and Chk2 had previously been shown to be activated by and participate in a phosphorylation cascade that induces cell cycle arrest at the G₂ checkpoint on the detection of damaged or unreplicated DNA. The phosphorylation of p53 prevents its binding by Mdm2 and hence increases the otherwise low level of p53 in the nucleus. *Although p53 does not initiate cell cycle arrest in G₂, its presence is required to prolong this process. It does so by activating the transcription of the gene encoding the cyclin-dependent kinase inhibitor (CKI) named p21^{Cip1}, which binds to several Cdk–cyclin complexes so as to inhibit both the G₁/S and G₂/M transitions.*

Cells that are irreparably damaged synthesize excessive levels of p53, which in turn induces these cells to commit suicide by activating the expression of several of the proteins that participate in apoptosis (see below). In the absence of p53 activation, cells control the level of p53 through a feedback loop in which p53 stimulates the transcription of the *mdm2* gene.

In addition to the foregoing, p53 represses the expression of numerous genes. One mechanism through which it does so is by directly or indirectly stimulating the transcription of certain microRNAs (miRNAs), which in turn repress the expression of a variety of pro-proliferative proteins (Section 28-3C). The most conspicuous of these miRNAs is **miR-34a**, which is implicated in inducing senescence and facilitating apoptosis (cell death; see below).

A second repressive mechanism involves a lincRNA named **lincRNA-p21** (because its gene neighbors that of p21, although the significance of this, if any, is unknown). The transcription of lincRNA-p21, as Rinn discovered, is induced by p53. LincRNA-p21 forms a complex with **heterogeneous nuclear ribonucleoprotein K (hnRNP-K; hnRNPs are proteins that bind hnRNAs and influence their posttranscriptional processing)** that targets it to hundreds of genes, many of which are pro-proliferative, thereby repressing their transcription.

The X-Ray Structure of p53 Explains Its Oncogenic Mutations. p53 is a tetramer of identical 393-residue subunits, which each contain a sequence-specific DNA-binding core. The X-ray structure of this domain (residues 102–313) in complex with a 21-bp target DNA sequence, determined by Nikola Pavletich, is shown in **Fig. 28-49**. The p53 DNA-binding motif does not resemble any other that has previously been characterized (Sections 24-4B and 24-4C). It makes sequence-specific contacts with the bases of the DNA in its major groove (lower right of Fig. 28-49). In addition, the side chain of Arg 248 extends into the DNA's minor groove (upper right of Fig. 28-49). The protein also contacts the

FIG. 28-49 X-Ray structure of the DNA-binding domain of human p53 in complex with its target DNA. The DNA is drawn in stick form colored according to atom type (C green, N blue, O red, and P orange) with its successive P atoms joined by orange rods. The protein is shown in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). A tetrahedrally liganded Zn^{2+} ion is represented by a magenta sphere, and the side chains of the six most frequently mutated residues in human tumors are shown in stick form with C yellow and identified with their one-letter codes. [Based on an X-ray structure by Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1TSR.]

DNA backbone between the major and minor grooves in this region (notably with Arg 273).

The structure's most striking feature is that *its DNA-binding motif consists of conserved regions comprising the most frequently mutated residues in the >1000 p53 variants found in human tumors*. Among them are one Gly and five Arg residues (highlighted in yellow in Fig. 28-49) whose mutations collectively account for over 40% of the *p53* variants in tumors. The two most frequently mutated residues, Arg 248 and Arg 273, as we saw, directly contact the DNA. The other four “mutational hotspot” residues appear to play a critical role in structurally stabilizing p53's DNA-binding surface. The relatively sparse secondary structure in the polypeptide segments forming this surface (one helix and three loops) accounts for this high mutational sensitivity: Its structural integrity mostly relies on specific side chain–side chain and side chain–backbone interactions.

p53 Is a Sensor That Integrates Information from Several Pathways. p53 may be activated by several other pathways. For example, aberrant growth signals, including those generated by oncogenic variants of Ras signaling cascade components (Fig. 13-7) such as Ras, cause the inappropriate activation of a variety of transcription factors. One of them, **Myc**, activates the transcription of the gene encoding **p14^{ARF}**, which binds to Mdm2 and thereby inhibits its activity. This prevents the degradation of p53 and hence triggers the p53-dependent transcriptional programs leading to cell cycle arrest as well as apoptosis. Evidently, p14^{ARF} acts as part of a p53-dependent fail-safe system to counteract hyperproliferative signals.

A third activation pathway for p53 is induced by a wide variety of DNA-damaging chemotherapeutic agents, protein kinase inhibitors, and UV radiation. These activate a protein kinase named **ATR** to phosphorylate p53 so as to reduce its affinity for Mdm2 in much the same way as do ATM and Chk2. p53 is also subject to a rich variety of reversible posttranslational modifications that markedly

influence the expression of its target genes, including acetylation at several Lys residues, glycosylation, and sumoylation (Section 27-5B), in addition to its phosphorylation at multiple Ser/Thr residues and ubiquitination.

p53, as we have only glimpsed, is the recipient of a vast number of intracellular signals and, in turn, controls the activities of a large number of downstream regulators. One way to understand the operation of this highly complex and interconnected network is in analogy with the Internet. In the Internet (cell), a small number of highly connected servers or hubs (“master” proteins) transmit information to/from a large number of computers or nodes (other proteins) that directly interact with only a few other nodes (proteins). In such a network, overall performance is largely unperturbed by the inactivation of one of the nodes (other proteins). However, the inactivation of a hub (“master” protein) will greatly impact system performance. p53 is a “master” protein, that is, it is analogous to a hub. Inactivation of one of the many proteins that influences its performance or one of the many proteins whose activity it influences usually has little effect on cellular events due to the cell’s redundant and highly interconnected components. However, the inactivation of p53 or several of its most closely associated proteins (e.g., Mdm2) disrupts the cell’s responses to DNA damage and tumor-predisposing stresses, thereby leading to tumor formation.

 **Loss of pRb Protein Leads to Cancer.** **Retinoblastoma**, a cancer of the developing retina that affects infants and young children, is associated with the loss of the *Rb* gene, which encodes the tumor suppressor **pRb**. This 928-residue DNA-binding protein interacts with the **E2F** family of transcription factors, which has six members in mammals. E2F proteins induce the transcription of genes that encode proteins required for entry into S phase. pRb can be phosphorylated at as many as 16 of its Ser/Thr residues by various Cdk–cyclin complexes (the various complexes phosphorylate different sets of sites on pRb). In nonproliferating cells (those in early G₁), pRb is hypophosphorylated. In that state, it binds to E2F to prevent it from activating transcription at the promoters to which it is bound. In response to a mitogenic signal (a signal that induces mitosis), the levels of D-type cyclins increase, which triggers phosphorylation of pRb by **Cdk4/6–cyclin D** complexes. Hyperphosphorylated pRb releases E2F, which then induces the expression of genes that promote cell cycle progression, including genes for additional cyclins and Cdks. The E2F-binding site of pRb is the major site of *Rb* gene alterations in tumors.

C Apoptosis Is an Orderly Process

Programmed cell death or **apoptosis** (Greek: falling off, as leaves from a tree), which was first described by John Kerr in the late 1960s, is a normal part of development as well as maintenance and defense of the adult animal body. For example, in many vertebrates, the digits of the developing hands and feet are initially connected by webbing that is eliminated by programmed cell death (Fig. 28-50), as are the tails of tadpoles and the larval tissues of insects (Section 28-4D) during their metamorphoses into adults. In the adult human body, which consists of nearly 10^{14} cells, an estimated 10^{11} cells are eliminated each day through programmed cell death (which closely matches the number of new cells produced by mitosis). Indeed, the

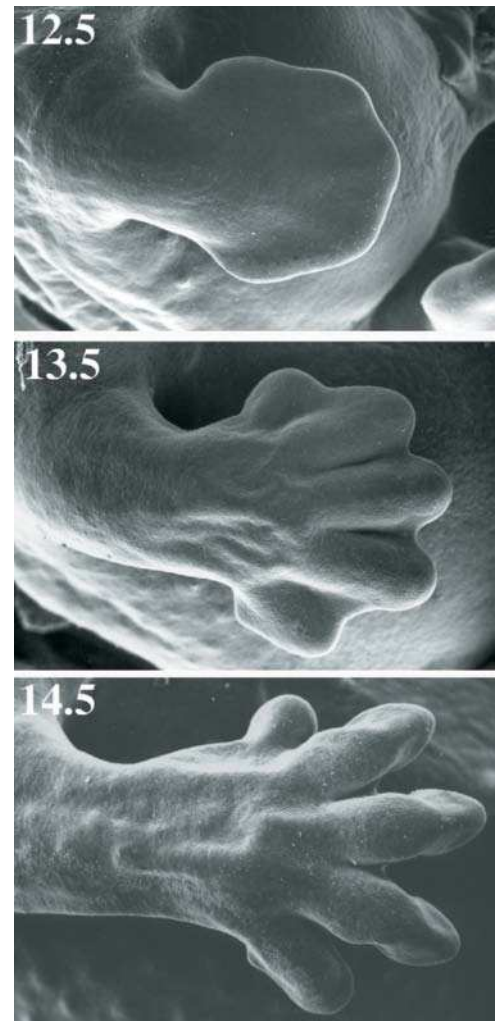

FIG. 28-50 **Programmed cell death in the embryonic mouse paw.** At day 12.5 of development, its digits are fully connected by webbing. At day 13.5, the webbing has begun to die. By day 14.5, the apoptotic process is complete.

mass of the cells that we annually lose in this manner approaches that of our entire body. The immune system eliminates virus-infected cells, in part by inducing them to undergo apoptosis, in order to prevent viral replication. Cells with irreparably damaged DNA and hence at risk for malignant transformation undergo apoptosis, thereby protecting the entire organism from cancer. In fact, as Martin Raff pointed out, *apoptosis appears to be the default option for animal cells: Unless they continually receive external hormonal and/or neuronal signals not to commit suicide, they will do so.* Thus, adult organs maintain their constant size by balancing cell proliferation with apoptosis. Not surprisingly, therefore, inappropriate apoptosis has been implicated in several neurodegenerative diseases including Alzheimer's disease (Section 6-5C), Parkinson's disease (Section 21-6B), and Huntington's disease (Box 28-1), as well as much of the damage caused by stroke and heart attack.

Apoptosis is qualitatively different from **necrosis**, the type of cell death caused by trauma (e.g., lack of oxygen, extremes of temperature, and mechanical injury). Cells undergoing necrosis essentially explode: They and their membrane-enclosed organelles swell as water rushes in through their compromised membranes, releasing lytic enzymes that digest the cell contents until the cell lyses, spilling its contents into the surrounding region (Box 18-5). The cytokines that the cell releases often induce an inflammatory response (which can damage surrounding cells). In contrast, apoptosis begins with the loss of intercellular contacts by an apparently healthy cell followed by its shrinkage, the condensation of its chromatin at the nuclear periphery, the collapse of its cytoskeleton, the dissolution of its nuclear envelope, the fragmentation of its DNA, and violent blebbing (blistering) of its plasma membrane. Eventually, the cell disintegrates into numerous membrane-enclosed **apoptotic bodies** that are phagocytosed (engulfed) by neighboring cells as well as by roving macrophages without spilling the cell contents and hence not inducing an inflammatory response. The phagocytotic cells recognize the apoptotic bodies through "eat me" signals. In mammals, this signal is the phospholipid phosphatidylserine, which in the plasma membrane of healthy cells occurs only in its inner leaflet (Fig. 9-32) but in apoptotic cells is translocated to the outer leaflet.

Caspases Participate in Apoptosis. Apoptosis involves a family of proteases known as **caspases** (for cysteinyl *aspartate*-specific *proteases*), which are **cysteine proteases** whose mechanism resembles that of serine proteases (Section 11-5) but with Cys replacing the active site Ser. Caspases cleave target polypeptides after an Asp residue.

Caspases are $\alpha_2\beta_2$ heterotetramers that consist of two large α subunits (~300 residues) and two small β subunits (~100 residues). They are expressed as single-chained zymogens (**procaspases**) that are activated by proteolytic excision of their N-terminal prodomains and proteolytic separation of their α and β subunits. The activating cleavage sites all follow Asp residues and are, in fact, targets for caspases, suggesting that caspase activation may either be autocatalytic or be catalyzed by another caspase.

The X-ray structure of human **caspase-7** (Fig. 28-51), determined by Keith Wilson and Paul Charifson, reveals that each $\alpha\beta$

FIG. 28-51 X-Ray structure of caspase-7 in complex with a tetrapeptide aldehyde inhibitor. The $\alpha_2\beta_2$ heterotetrameric enzyme is viewed along its twofold axis with its large (α) subunits orange and gold and its small (β) subunits cyan and light blue. The acetyl-Asp-Glu-Val-Asp-CHO inhibitor is drawn in stick form with C green, N blue, and O red. [Based on an X-ray structure by Keith Wilson and Paul Charifson, Vertex Pharmaceuticals, Cambridge, Massachusetts. PDBid 1F1J.]

heterodimer contains a six-stranded β sheet flanked by five α helices that are approximately parallel to the β strands. The β sheet is continued across the enzyme's twofold axis to form a twisted 12-stranded β sheet. The active site of each $\alpha\beta$ heterodimer is located at the C-terminal ends of its parallel β strands. The structures of other caspases differ mainly in the conformations of the four loops forming their active sites. In the inactive **procaspase-7**, these loops are folded so as to obliterate the active site.

More than 60 cellular proteins have been identified as caspase substrates. These include cytoskeletal proteins, proteins involved in cell cycle regulation (including cyclin A, p21^{Cip1}, ATM, and pRb), proteins that participate in DNA replication, transcription factors, and proteins that participate in signal transduction. Nevertheless, how the cleavage of these numerous proteins causes the morphological changes that cells undergo during apoptosis is unclear. The induction of apoptosis also causes the rapid degradation of DNA by the action of **caspase-activated DNase**. Presumably, DNA degradation prevents the genetic transformation of other cells that subsequently phagocytose apoptotic bodies containing viral DNA or damaged chromosomal DNA.

Apoptosis Is Triggered Extracellularly or Intracellularly. *Apoptosis in a given cell may be induced either by externally supplied signals in the so-called **extrinsic pathway** (death by commission) or by the absence of external signals that inhibit apoptosis in the so-called **intrinsic pathway** (death by omission).* The extrinsic pathway is initiated by the association of a cell destined to undergo apoptosis with a cell that has selected it to do so. In what is perhaps the best characterized such pathway (Fig. 28-52), a transmembrane protein named **Fas ligand (FasL)** that projects from the plasma membrane of the inducing cell, a so-called **death ligand**, binds to a transmembrane protein known as **Fas** that projects from the plasma membrane of the apoptotic cell, a so-called **death receptor**. Fas ligand is a homotrimeric protein whose binding to three Fas molecules causes the Fas cytoplasmic domains to trimerize. The trimerized Fas recruits three molecules of a 208-residue adaptor protein named **FADD** (for *Fas*-associating *death* domain-containing protein), which in turn recruits **procaspase-8** and **procaspase-10**. The consequent clustering of procaspase-8 and procaspase-10 results in the proteolytic autoactivation of these zymogens, thereby generating **caspases-8** and **-10**, which are termed **initiator caspases**. This is because these enzymes then activate **caspase-3**, which is known as an **effector (executioner) caspase** because its actions cause the cell to undergo apoptosis.

The intrinsic pathway for initiating apoptosis follows a slightly different route to caspase-3 activation. Most animal cells are continuously bathed in an extracellular soup, generated in part by neighboring cells, that contains a wide variety of substances that regulate the cell's growth, differentiation, activity, and survival. The withdrawal of this chemical support for its survival or the loss of direct cell–cell interactions induces a cell to undergo apoptosis via the intrinsic pathway. The initial step of this pathway appears to be the activation of one or more members of the **Bcl-2** family (so named because its founding member is involved in *B* cell lymphoma). Association of certain Bcl-2 proteins with the mitochondrion causes it to release cytochrome *c* (Section 18-2E) from the intermembrane space into the cytosol. It is not clear how cytochrome *c* exits the mitochondrion. It may traverse the outer membrane via a newly formed pore or via an existing pore whose conformation is altered to accommodate the ~12-kD cytochrome, or the outer membrane may rupture as a result of Bcl-2 activity.

The cytochrome *c* combines with a 1248-residue protein called **Apaf-1** (for apoptosis protease-activating factor-1) and ATP or dATP to form an ~1100-kD

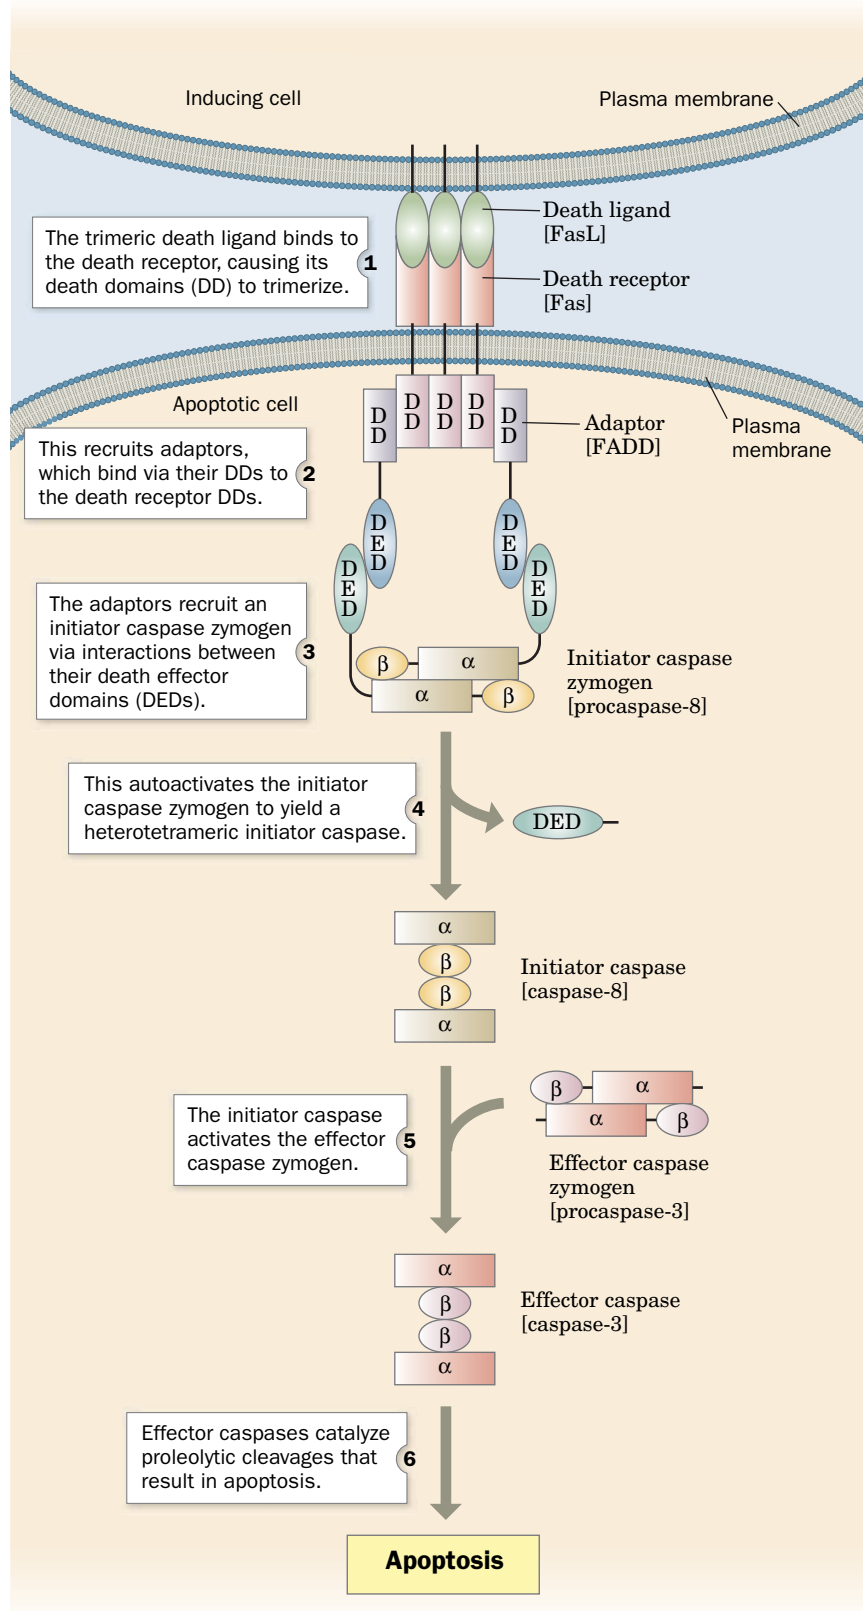

FIG. 28-52 The extrinsic pathway of apoptosis. The square brackets contain specific examples of the indicated protein types. **WPLS** See the Animated Process Diagrams.

? What features of this pathway would help prevent the accidental triggering of apoptosis?

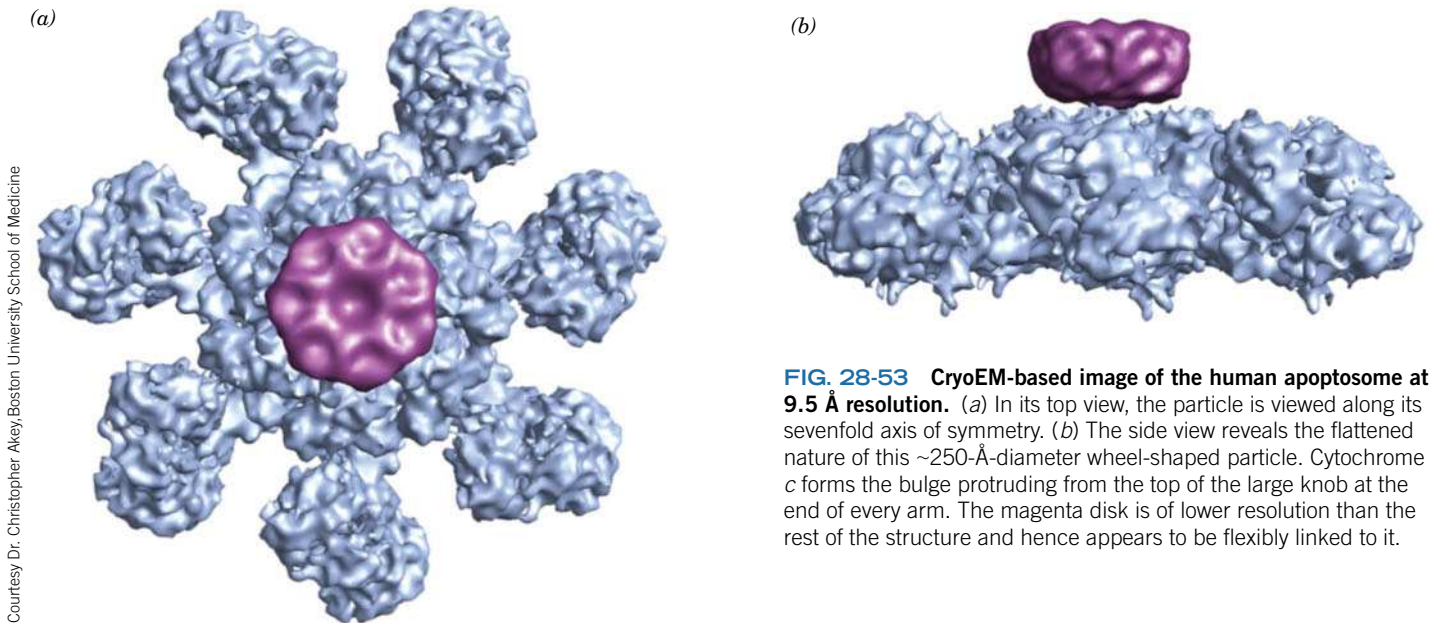

FIG. 28-53 CryoEM-based image of the human apoptosome at **9.5 Å resolution**. (a) In its top view, the particle is viewed along its sevenfold axis of symmetry. (b) The side view reveals the flattened nature of this ~ 250 -Å-diameter wheel-shaped particle. Cytochrome *c* forms the bulge protruding from the top of the large knob at the end of every arm. The magenta disk is of lower resolution than the rest of the structure and hence appears to be flexibly linked to it.

wheel-shaped complex named the **apoptosome** (Fig. 28-53). The apoptosome binds several molecules of **procaspase-9** in a manner that induces their autoactivation. The resulting **caspace-9**, still bound to the apoptosome, then activates procaspase-3 to instigate cell death.

D Development Has a Molecular Basis

Perhaps the most awe-inspiring event in biology is the growth and development of a fertilized ovum to form an extensively differentiated multicellular organism. No outside instruction is required to do so; *fertilized ova contain all the information necessary to form complex multicellular organisms such as human beings*. Much of what we know about the molecular basis of cell differentiation is based on studies of the fruit fly *Drosophila melanogaster*. We therefore begin this section with a synopsis of *Drosophila* embryogenesis.

The *Drosophila* Embryo Is Divided into Segments. Almost immediately after the *Drosophila* egg (Fig. 28-54a) is laid (which, rather than the earlier fertilization, triggers development), it commences a series of rapid, synchronized nuclear divisions, one every 6 to 10 min (the fastest known nuclear divisions in animals). Here, the nuclear division process is not accompanied by the formation of new cell membranes; the nuclei continue sharing their common cytoplasm to form a so-called **syncytium** (Fig. 28-54b). After the eighth round of nuclear division, the ~ 256 nuclei begin to migrate toward the cortex (outer layer) of the egg. Up until this point, all of the nuclei are **totipotent**; that is, they can form any type of adult cell (the germ-cell progenitors, the pole cells, are set aside after the ninth division). But subsequently, the location of each nucleus determines its developmental fate (see below). By around the eleventh nuclear division, the ~ 2000 nuclei have formed a single layer surrounding a yolk-rich core (Fig. 28-54c). At this stage, the mitotic cycle time begins to lengthen while the nuclear genes, which have heretofore been fully engaged in DNA replication, become transcriptionally active (a freshly laid egg contains an enormous store of mRNA that has been contributed by the developing oocyte's surrounding "nurse" cells). In the fourteenth nuclear division cycle, which lasts ~ 60 min, the egg's plasma membrane invaginates around each of the ~ 6000 nuclei to yield a cellular monolayer called a **blastoderm** (Fig. 28-54d). At this point, after ~ 2.5 h of development, transcriptional activity reaches its maximum and mitotic synchrony is lost.

FIG. 28-54 Development in *Drosophila*. The various stages are explained in the text. Note that the embryos and newly hatched larva are all the same size, ~0.5 mm long. The adult is, of course, much larger. The approximate numbers of cells in the early stages of development are given in parentheses.

During the next few hours, the embryo undergoes **gastrulation** (migration of cells to form a triple-layered structure) and organogenesis. A striking aspect of this remarkable process, in *Drosophila* as well as in higher animals, is the division of the embryo into a series of segments corresponding to the adult organism's organization (Fig. 28-54e). The *Drosophila* embryo has at least three segments that eventually merge to form its head (Md, Mx, and Lb for mandibular, maxillary, and labial), three thoracic segments (T1–T3), and eight abdominal segments (A1–A8). As development continues, the embryo elongates and several of its abdominal segments fold over its thoracic segments (Fig. 28-54f). At this stage, the segments become subdivided into anterior (forward) and posterior (rear) compartments. The embryo then shortens and unfolds to form a larva that hatches 1 day after beginning development (Fig. 28-54g). Over the next 5 days, the larva feeds, grows, molts twice, pupates, and commences metamorphosis to form an adult (Fig. 28-54h). In the latter process, the larval epidermis is almost entirely replaced (through apoptosis) by the outgrowth of apparently undifferentiated patches of larval epithelium known as **imaginal disks** that are committed to their developmental fates as early as the blastoderm stage. These structures, which maintain the larva's segmental boundaries, form the adult's legs, wings, antennae, eyes, etc. About 10 days after commencing development, the adult emerges and, within a few hours, initiates a new reproductive cycle.

Developmental Patterns Are Genetically Mediated. What is the mechanism of embryonic pattern formation? Much of what we know about this process stems from genetic analyses of a series of bizarre mutations in three classes of *Drosophila* genes that normally specify progressively finer regions of cellular specialization in the developing embryo:

1. **Maternal-effect genes**, which define the embryo's polarity, that is, its anteroposterior (head-to-tail) and dorsoventral (back-to-belly) axes. Mutations of these genes globally alter the embryonic body pattern, producing, for example, nonviable embryos with two anterior or two posterior ends pointing in opposite directions.
2. **Segmentation genes**, which specify the correct number and polarity of embryonic body segments. Investigations by Christiane Nüsslein-Volhard and Eric Wieschaus led to their subclassification as follows:
 - (a) **Gap genes**, the first of a developing embryo's to be transcribed, are so named because their mutations result in gaps in the embryo's segmentation pattern. Embryos with defective ***hunchback* (*hb*)** genes, for example, lack mouthparts and thorax structures.
 - (b) **Pair-rule genes** specify the division of the embryo's broad gap domains into segments. These genes are so named because their mutations usually delete portions of every second segment.

(c) **Segment polarity genes** specify the polarities of the developing segments. Thus, homozygous *engrailed* (*en*) mutants lack the posterior compartment of each segment.

3. **Homeotic selector genes**, which specify segmental identity. Mutations of homeotic selector genes transform one body part into another. For instance, *Antennapedia* (*antp*, antenna-foot) mutants have legs in place of antennae (Fig. 28-55a), whereas the mutations *bithorax* (*bx*), *anteriorbithorax* (*abx*), and *postbithorax* (*pbx*) each transform sections of halteres (vestigial wings that function as balancers), which normally occur only on segment T3, to the corresponding sections of wings, which normally occur only on segment T2 (Fig. 28-55b).

The properties of maternal-effect gene mutants suggest that maternal-effect genes specify substances known as **morphogens** whose distributions in the egg cytoplasm define the future embryo's spatial coordinate system. Indeed, immunofluorescence studies by Nüsslein-Volhard have demonstrated that the product of the *bicoid* (*bcd*) gene is distributed in a gradient that decreases toward the posterior end of the normal embryo (Fig. 28-56a), whereas embryos with *bcd*-deficient mothers lack this gradient. The gradient arises through the secretion, by ovarian nurse cells, of *bcd* mRNA into the anterior end of the oocyte during oogenesis. The *nanos* gene mRNA is similarly deposited near the egg's posterior pole. The *bcd* and *nanos* gene products regulate the expression of specific gap genes. Some other maternal-effect genes specify proteins that trap the localized mRNAs in their area of deposition. This explains why early embryos produced by females homozygous for maternal-effect mutations can often be "rescued" by the injection of cytoplasm, or sometimes just the mRNA, from early wild-type embryos.

The mRNA of the gap gene *hunchback* (*hb*) is deposited uniformly in the unfertilized egg (Fig. 28-56a). However, **Bicoid protein** activates the transcription of the embryonic *hb* gene, whereas **Nanos protein** inhibits the translation of *hb* mRNA. Consequently, **Hunchback protein** becomes distributed in a gradient that decreases from anterior to posterior (Fig. 28-56b). Footprinting studies have demonstrated that Bicoid protein binds to five homologous sites (consensus sequence TCTAATCCC) in the *hb* gene's upstream promoter region.

Hunchback protein controls the expression of several other gap genes (Fig. 28-56c, d): High levels of Hunchback protein induce *giant* expression; **Krüppel** (German: cripple) is expressed where the level of Hunchback protein begins to decline; *knirps* (German: pigmy) is expressed at even lower levels of Hunchback protein; and *giant* is again activated in regions where Hunchback protein is undetectable. These patterns of gene expression are stabilized and maintained by additional interactions. For example, **Krüppel protein** binds to the promoters of the *hb* gene, which it activates, and the *knirps* gene, which it represses. Conversely, **Knirps protein** represses the *Krüppel* gene. This mutual repression is thought to be responsible for the sharp boundaries between the various gap domains.

Pair-rule genes are expressed in sets of seven stripes, each just a few nuclei wide, along the early embryo's anterior–posterior axis (Fig. 28-57). The gap gene products directly control three **primary pair-rule genes**: *hairy*, *even-skipped* (*eve*), and *runt*. The promoters of most primary pair-rule genes consist of a series of modules, each of which contains a particular arrangement of activating and inhibitory binding sites for the various gap gene proteins. As a result, the expression of a pair-rule gene reflects the combination of gap gene proteins present, giving rise to a "zebra stripe" pattern. As with the gap genes, the patterns

(b)

FIG. 28-55 Developmental mutants of *Drosophila*. (a) Head and thorax of a wild-type adult fly (left) and one that is homozygous for a mutant form of the homeotic *Antennapedia* (*antp*) gene (right). The mutant gene is inappropriately expressed in the imaginal disks that normally form antennae (where the wild-type *antp* gene is not expressed) so that they develop as the legs that normally occur only on segment T2. (b) A four-winged *Drosophila* (it normally has two wings) that results from the presence of three mutations in the bithorax complex. These mutations cause the normally haltere-bearing segment T3 to develop as if it were the wing-bearing segment T2.

FIG. 28-56 The formation and effects of the Hunchback protein gradient in *Drosophila* embryos. (a) The unfertilized egg contains maternally supplied *bicoid* and *nanos* mRNAs placed at its anterior and posterior poles, together with a uniform distribution of *hunchback* mRNA. (b) On fertilization, the three mRNAs are translated. Bicoid and Nanos proteins are not bound in place as are their mRNAs and hence their gradients are broader than those of the mRNAs. Bicoid protein stimulates the translation of *hunchback* mRNA whereas Nanos protein inhibits its translation, resulting in a gradient of Hunchback protein that decreases nonlinearly from anterior to posterior. (c) Specific concentrations of Hunchback protein induce the transcription of the *giant*, *Krüppel*, and *knirps* genes. The gradient of Hunchback protein thereby specifies the positions at which the latter mRNAs are synthesized. (d) A photomicrograph of a *Drosophila* embryo (anterior end left) that has been immunofluorescently stained for both Hunchback (green) and Krüppel proteins (red). The region where the proteins overlap is yellow. [Parts a, b, and c after Gilbert, S.F., *Developmental Biology* (5th ed.), pp. 550 and 565, Sinauer Associates (1997); Part d courtesy of Stephen W. Paddock, Jim Langeland, and Sean Carroll, Howard Hughes Medical Institute, University of Wisconsin–Madison.]

of expression of the primary pair-rule genes become stabilized through interactions among themselves. The primary pair-rule gene products also induce or inhibit the expression of five **secondary pair-rule genes** including *fushi tarazu* (*ftz*; Japanese for not enough segments). Thus, as Walter Gehring demonstrated, *ftz* transcripts first appear in the nuclei lining the cortical cytoplasm during the embryo's tenth nuclear division cycle. By the fourteenth division cycle, when the cellular blastoderm forms, *ftz* is expressed in a pattern of seven belts around the blastoderm, each 3 or 4 cells wide (Fig. 28-57).

The expression of eight known segment polarity genes is initiated by pair-rule gene products. For example, by the thirteenth nuclear division cycle, as Thomas Kornberg demonstrated, *engrailed* (*en*) transcripts become detectable but are more or less evenly distributed throughout the embryonic cortex. However, since *en* is preferentially expressed in nuclei containing high concentrations of either Eve or Ftz proteins, by the fourteenth cycle they form a striking pattern of 14 stripes around the blastoderm (half the spacing of *ftz* expression). The *en* gene product thereby induces the posterior half of each segment to develop in a different fashion from its anterior half.

FIG. 28-57 *Drosophila* embryo stained for pair-rule genes. The Fushi tarazu protein (Ftz) is stained brown, and the Eve protein is stained gray. These proteins are each expressed in seven stripes.

FIG. 28-58 The correspondence between *Drosophila* antennae and legs. [After Postlethwait, J.H. and Schneiderman, H.A., *Dev. Biol.* **25**, 622 (1971).]

Homeotic Genes Direct Development of Individual Body Parts. The structural components of developmentally analogous body parts, say *Drosophila* antennae and legs, are nearly identical; only their organizations differ (Fig. 28-58). Consequently, developmental genes must control the pattern of structural gene expression rather than simply turning the genes on or off.

The *Drosophila* homeotic selector genes map into two large gene families: the **bithorax complex (BX-C)**, which controls differentiation in the thoracic and abdominal segments, and the **antennapedia complex (ANT-C)**, which primarily affects head and thoracic segments. Homozygous mutations in BX-C cause one or more segments to develop as if they were more anterior segments (e.g., segment T3 develops as if it were segment T2; Fig. 28-55b). The entire deletion of BX-C causes all segments posterior to T2 to resemble T2; apparently T2 is the developmental “ground state” of the more distal segments. The evolution of homeotic gene families, it is thought, permitted arthropods (the phylum containing insects) to arise from the more primitive annelids (segmented worms) in which all segments are nearly alike.

Detailed genetic analysis of BX-C led Edward B. Lewis to formulate a model for segmental differentiation (Fig. 28-59): BX-C, Lewis proposed, contains at least one gene for each segment from T3 to A8 (numbered 0 to 8 in Fig. 28-59). Starting with segment T3, progressively more posterior segments express successively more BX-C genes until, in segment A8, all of the genes are expressed. Such a pattern of gene expression may result from a gradient in the concentration of a BX-C repressor that decreases from the anterior to the posterior end. The developmental fate of a segment is thereby determined by its position in the embryo. Subsequent sequence analysis revealed that the nine “genes” in the Lewis model are actually enhancer elements on three BX-C genes.

In characterizing the *Antennapedia (antp)* gene, Gehring and Matthew Scott independently discovered that *antp* cDNA hybridizes to both the *antp* and the *ftz* genes, indicating that these genes share a common base sequence. Subsequent experiments revealed that a similar sequence, called a **homeodomain** or **homeobox**, occurs in many *Drosophila* homeotic genes. These sequences, which are 70 to 90% identical to one another, encode even more identical 60-residue polypeptide segments.

Further hybridization studies using homeodomain probes led to the truly astonishing finding that homeodomains are also present in the genomes of many animals. Homeodomain-containing genes have collectively become known as **Hox genes**. In vertebrates, they are organized in four clusters of 9 to 11 genes, each located on a separate chromosome and spanning more than 100 kb. In

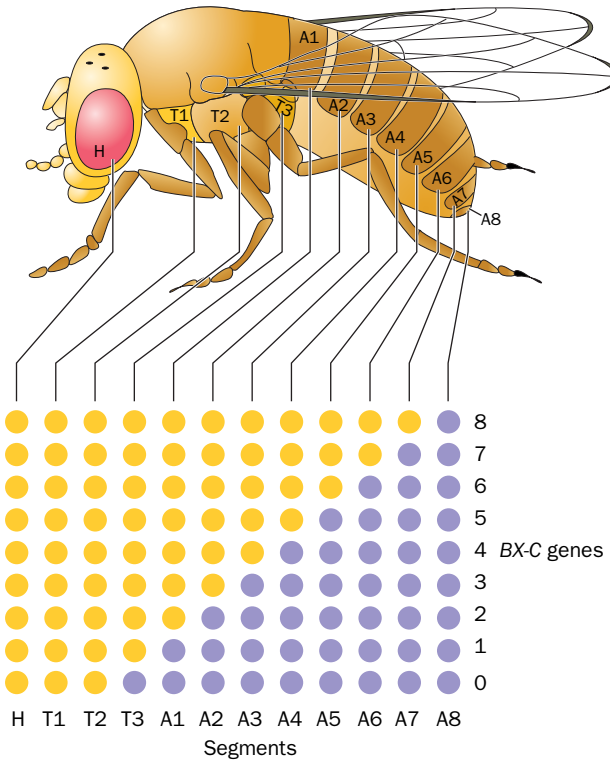

FIG. 28-59 Model for the differentiation of embryonic segments in *Drosophila*. Segments T2, T3, and A1–8, as the lower drawing indicates, are each characterized by a unique combination of active (purple circles) and inactive (yellow circles) *BX-C* “genes.” These “genes” (which are really enhancer elements), here numbered 0 to 8, are thought to be sequentially activated from anterior to posterior in the embryo so that segment T2, the developmentally most primitive segment, has no active *BX-C* genes, while in segment A8, all of them are active. [After Ingham, P., *Trends Genet.* 1, 113 (1985).]

contrast, *Drosophila*, as we saw, have two *Hox* clusters, whereas nematodes, which are evolutionarily more primitive than insects, have only one *Hox* cluster. The various *Hox* clusters, as well as their component genes, almost certainly arose through a series of gene duplications.

***Hox* Genes Encode Transcription Factors.** Some *Hox* genes are remarkably similar; for example, the homeodomains of the *Drosophila antp* gene and the frog *MM3* gene encode polypeptides that have 59 of their 60 amino acids in common. Since vertebrates and invertebrates diverged over 600 million years ago, this strongly suggests that the product of the homeodomain has an essential function.

The polypeptide encoded by the homeodomain of the *Drosophila engrailed* gene specifically binds to the DNA sequences just upstream from the transcription start sites of both the *en* and the *ftz* genes. Moreover, fusing the *ftz* gene’s upstream sequence to other genes imposes *ftz*’s pattern of stripes (Fig. 28-57) on the expression of these genes in *Drosophila* embryos. *These observations suggest that homeodomain-containing genes encode transcription factors that regulate the expression of other genes.*

Thomas Kornberg and Carl Pabo determined the X-ray structure of the 61-residue homeodomain from the *Drosophila* Engrailed protein in complex with a 21-bp DNA (Fig. 28-60). The homeodomain consists largely of three α helices, the last two of which form an

FIG. 28-60 X-Ray structure of the Engrailed protein homeodomain in complex with its target DNA. The protein is shown in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The DNA is shown in stick form colored according to atom type (C green, N blue, O red, and P orange) with the nucleotides forming its TAAT subsite highlighted with C atoms cyan. Successive P atoms in the same chain are linked by orange rods. Note that the protein’s recognition helix, its C-terminal helix (red and orange), is bound in the DNA’s major groove, and that the protein’s N-terminal segment (blue) is inserted into the DNA’s minor groove. FIG. 28-61 Pattern of expression of the *Hox-3.1* gene in a 12.5-day-old mouse embryo.

The protein-coding portion of the *Hox-3.1* gene was replaced by the *lacZ* gene. The regions of this transgenic embryo in which *Hox-3.1* is expressed are revealed by soaking the embryo in a buffer containing a substance (X-gal; Section 3-5A) that turns blue when hydrolyzed by the *lacZ* gene product, β -galactosidase.

HTH motif that is closely superimposable on the HTH motifs of prokaryotic repressors (Section 24-4B).

Vertebrate *Hox* genes, like those of *Drosophila*, are expressed in specific patterns and at particular stages during embryogenesis. That the *Hox* genes directly specify the identities and fates of embryonic cells was shown, for example, by the following experiment. Mouse embryos were made transgenic for the *Hox-1.1* gene that had been placed under the control of a promoter that is active throughout the body even though *Hox-1.1* is normally expressed only below the neck. The resulting mice had severe craniofacial abnormalities, such as a cleft palate and an extra vertebra and an intervertebral disk at the base of the skull. Some also had an extra pair of ribs in the neck region. Thus, the altered expression of the *Hox-1.1* gene induced a homeotic mutation, that is, a change in the development pattern, analogous to those observed in *Drosophila* (Fig. 28-55).

Homozygotic mice whose *Hox-3.1* coding sequence has been replaced with that of *lacZ* are born alive but usually die within a few days. They exhibit skeletal deformities in their trunk regions in which several skeletal segments are transformed into the likenesses of more anterior segments. The pattern of β -galactosidase activity, as colorimetrically detected through the use of a substrate analog whose hydrolysis products are blue (Fig. 28-61), indicates that *Hox-3.1* deletion modifies the properties but not the positions of the embryonic cells that normally express *Hox-3.1*.

CHECKPOINT

- Summarize the stages of the cell cycle. What is the role of cyclins?
- Explain how p53 and pRb suppress tumor formation.
- Summarize the events of apoptosis.
- Why is apoptosis preferable to necrosis?
- Summarize the sequence of events in *Drosophila* embryogenesis and explain the functions of the substances that control these events.

Summary

1 Genome Organization

- Genomic DNA sequence data reveal the total number of genes, their probable functions, and possible links to disease.
- Certain genes are found in clusters, for example, those in bacterial operons, rRNA and tRNA genes, and eukaryotic histone genes. The human globin gene clusters contain genes expressed at different developmental stages.
- Prokaryotic genomes contain small amounts of nontranscribed DNA, which include control regions for replication and transcription. The

genomes of higher eukaryotes contain much larger proportions of nontranscribed DNA in the form of repetitive sequences, many of them the remnants of transposons.

2 Regulation of Prokaryotic Gene Expression

- Prokaryotic gene expression is controlled primarily at the level of transcription. Regulation of the *lac* operon is mediated by the binding of the *lac* repressor to its operator sequences. This binding, which prevents transcription of the operon, is reversed by the binding to the

lac repressor of an inducer whose presence signals the availability of lactose, the substrate for the *lac* operon–encoded enzymes.

- In catabolite repression, a complex of CAP and cAMP, which signals the scarcity of glucose, binds to its target DNA to stimulate the transcription of genes encoding proteins that participate in the metabolism of other sugars.
- Attenuation is a mechanism whereby the translation-dependent formation of alternate mRNA secondary structures in an operon's leader sequence determines whether transcription proceeds or terminates. In a riboswitch, metabolite binding to an mRNA regulates gene expression.

3 Regulation of Eukaryotic Gene Expression

- The expression of eukaryotic genetic information involves the repositioning of nucleosomes and the covalent modification of histones as part of the histone code that is read by regulatory proteins. DNA methylation allows epigenetic inheritance.
- In eukaryotes, activators and repressors, which bind to DNA enhancers, act cooperatively to regulate the rate of transcription initiation. Some of these transcription factors are activated by hormone signaling.
- Eukaryotic gene expression may also be controlled by variable rates of mRNA degradation and regulation of translation initiation. RNA interference (RNAi) is a posttranscriptional gene silencing pathway in which an RNA segment directs the selective degradation of a complementary

mRNA. MicroRNAs (miRNAs) and long noncoding RNAs (lncRNAs) are transcriptional regulators.

- Antibody diversity results from somatic recombination involving the selection of individual members of clustered gene sequences encoding the different segments of the immunoglobulin light and heavy chains. Diversity is augmented by imprecise V/D/J joining and by somatic hypermutation.

4 The Cell Cycle, Cancer, Apoptosis, and Development

- The eukaryotic cell cycle is governed by cyclin-dependent kinases, whose targets include the tumor suppressors p53 and pRb. p53 functions as a transcriptional activator that detects a variety of pathological states such as DNA damage and thereon helps maintain cell cycle arrest and, if the damage cannot be repaired, apoptosis (programmed cell death).
- Extracellular or intracellular signals may trigger apoptosis, a cell-suicide pathway that requires the activities of various caspases.
- The development of the *Drosophila* embryo is controlled by maternal-effect genes, which define the embryo's polarity; gap, pair-rule, and segment polarity genes, which specify the number and polarity of embryonic body segments; and homeotic selector genes (*Hox* genes), which encode transcription factors that regulate the expression of genes and therefore govern cell differentiation. *Hox* genes similarly regulate vertebrate development.

Key Terms

gene expression 1033	polymorphism 1043	genomic imprinting 1063	somatic hypermutation 1079

Problems

EXERCISES

1. DNA isolated from an organism can be sheared into fragments of uniform size (~1000 bp), heated to separate the strands, then cooled to allow complementary strands to reanneal. The renaturation process can be followed over time. Explain why the renaturation of *E. coli* DNA is a monophasic process, whereas the renaturation of human DNA is biphasic (an initial rapid phase followed by a slower phase).
2. Explain why the organization of genes in operons facilitates the assignment of functions to previously unidentified ORFs in a bacterial genome.

3. The genome of *Daphnia pulex*, a small freshwater crustacean, includes approximately 30,000 genes in ~200,000 kb of DNA. How does the genome compare to that of *Drosophila melanogaster*, another arthropod, and to that of humans?

4. The marine alga *Ostreococcus tauri* has an unusually high gene density for a eukaryote: ~8000 genes in an ~13,000-kb genome. Assuming that intergene distances are negligible, what is the average size of an *O. tauri* gene? How does this compare to the average gene size in the prokaryote *E. coli*?

5. A possible mechanism for the pathology of trinucleotide repeat diseases is aberrant translation, in which all three reading frames are used. Which repeating amino acid residues will result from the translation of transcripts made from repeating DNA sequences of (a) CAG and (b) CTG?
6. In addition to SNPs, humans exhibit copy-number polymorphisms (CNPs), which result from relatively large deletions or insertions of certain segments of the genome. One study showed that individuals differed by 11 CNPs with an average length of 465 kb. Calculate the fraction of the human genome represented by copy-number variants.
7. Explain why inactivation of the O_1 sequence of the *lac* operator almost completely abolishes repression of the *lac* operon.
8. Explain why (a) inactivation of the O_2 or O_3 sequence of the *lac* operon causes only a twofold loss in repression, and (b) inactivation of both O_2 and O_3 reduces repression ~70-fold.
9. Why do *E. coli* cells with a defective *lacZ* gene fail to show galactoside permease activity after the addition of lactose in the absence of glucose?
10. Describe the probable genetic defect that abolishes the sensitivity of the *lac* operon to the absence of glucose when other metabolic operons continue to be sensitive to the absence of glucose.
11. Why can't eukaryotic transcription be regulated by attenuation?
12. Predict the effect of deleting the leader peptide sequence on regulation of the *trp* operon.
13. Draw the molecular formula of the covalently modified histone side chain of acetyllysine. How does this modification alter the chemical properties of the side chain?
14. Draw the molecular formulas of the covalently modified histone side chains of methyllysine and methylarginine. How do these modifications alter the chemical properties of the side chains?
15. Monomethylation of histone Arg residues can be reversed by the action of a peptidylarginine deiminase, which requires water to remove the methyl group along with the imino group of Arg. Draw the structure of the resulting amino acid side chain and identify this nonstandard amino acid.
16. Is it possible for a transcription enhancer to be located within the protein-coding sequence of a gene? Explain.
17. Explain why natural selection has favored the instability of RNA.
18. How many different heavy chain variable regions can theoretically be generated by somatic recombination in humans (ignore junctional flexibility)? If each of these heavy chains could combine with any of the ~2000 κ light chains, how many different immunoglobulins could be produced?
19. V/D/J recombination frequently yields a gene whose mRNA cannot be successfully translated into an immunoglobulin chain. What aspect of somatic recombination is likely to produce nonproductive gene rearrangement?
20. Explain what might happen if the activation-induced cytidine deaminase (AID) were activated in a cell other than a B cell.
21. Why is it disadvantageous for single-celled eukaryotes such as yeast to undergo apoptosis?
22. During apoptosis, phosphatidylserine (Section 9-1C) undergoes transverse movement (flip-flop). Explain why this could help identify apoptotic cells to phagocytic cells for engulfment and disposal.

23. In *Drosophila*, an *esc*⁻ homozygote develops normally unless its mother is also an *esc*⁻ homozygote. Explain.
24. Describe the appearance of a *Drosophila* embryo, in which the *knirps* gene protein-coding sequence has been replaced by *lacZ*, following incubation in a solution of X-gal.

CHALLENGE QUESTIONS

25. Red–green color blindness is caused by an X-linked recessive genetic defect. Hence females rarely exhibit the red–green colorblind phenotype but may be carriers of the defective gene. When a narrow beam of red or green light is projected onto some areas of the retina of such a female carrier, she can readily differentiate the two colors, but on other areas she has difficulty in doing so. Explain.
26. Why is transcriptionally active chromatin ~10 times more susceptible to cleavage by DNase I than transcriptionally silent chromatin?
27. Explain why a deficiency of the vitamin folic acid could lead to undermethylation of histones and DNA.
28. Proliferation and differentiation of T and B lymphocytes during an immune response are mediated by signaling that leads to phosphorylation of a protein called I κ B. Unphosphorylated I κ B binds to and inhibits the transcription factor NF- κ B. Phosphorylated I κ B releases NF- κ B and is then ubiquitinated and degraded by a proteasome. (a) Explain why this mechanism for activating NF- κ B allows rapid changes in gene expression. (b) Explain why directly phosphorylating NF- κ B might not be an effective mechanism for altering gene expression. (c) A protein produced by *Yersinia pestis* (the bacterium that causes plague) removes the ubiquitin molecules from I κ B. How would this affect the immune response to the *Yersinia* infection?
29. Explain why RNAi would be a less efficient mechanism for regulating the expression of specific genes if Dicer hydrolyzed double-stranded RNA every 11 bp rather than every 22 bp.
30. B cells suppress the expression of all but one heavy chain allele and one light chain allele, a process known as allelic exclusion, by inhibiting the further somatic recombination of heavy and light chain genes after a productive recombination has occurred. Describe the aberrant properties of immunoglobulins produced by a B cell in which allelic exclusion is defective.
31. The fusion of cancer cells with normal cells often suppresses the expression of the tumorigenic phenotype. Explain.

BIOINFORMATICS

Brief Exercises Brief, online bioinformatics homework exercises can be found in WileyPLUS Learning Space.

Exercise 1. Viewing and Analyzing the *lac* Repressor

Exercise 2. Apoptosis and the KEGG Database

MORE TO EXPLORE Even relatively compact bacterial genomes include some noncoding DNA between genes; large eukaryotic genomes are mostly noncoding DNA. How have genome comparisons helped identify noncoding sequences that have some biological function? Have the functions of any of these sequences been identified? Where are such sequences located?

SOLUTIONS TO ODD PROBLEMS

Chapter 1

- An amino or imino group gives a molecule a positive charge; a carboxylate or phosphoryl group gives a molecule a negative charge.
- Hydrolysis reactions tend to occur with an increase in entropy, because the highly ordered polymer is broken down into separate units.
- The data indicate that eukaryotes are more similar to the archaea than to the eubacteria.
- (a) Decreases; (b) increases; (c) increases; (d) no change.
- (a) False. A spontaneous reaction occurs in only one direction.
(b) False. Thermodynamics does not specify the rate of a reaction.
(c) True. (d) True. A reaction is spontaneous as long as $\Delta S > \Delta H/T$.

11. $\Delta G = \Delta H - T\Delta S$

$$\Delta G = -7000 \text{ J} \cdot \text{mol}^{-1} - (298 \text{ K})(-25 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})$$

$$\Delta G = -7000 + 7450 \text{ J} \cdot \text{mol}^{-1} = 450 \text{ J} \cdot \text{mol}^{-1}$$

The reaction is not spontaneous because $\Delta G > 0$. The temperature must be decreased in order to decrease the value of the $T\Delta S$ term.

13. $\Delta G^{\circ'} = -RT \ln K_{\text{eq}} = -RT \ln([C][D]/[A][B])$
 $= -(8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K}) \ln[(3 \times 10^{-6})(5 \times 10^{-6}) / (10 \times 10^{-6})(15 \times 10^{-6})]$
 $= 5700 \text{ J} \cdot \text{mol}^{-1} = 5.7 \text{ kJ} \cdot \text{mol}^{-1}$

Since $\Delta G^{\circ'}$ is positive, the reaction is endergonic under standard conditions.

15. From Eq. 1-17, $K_{\text{eq}} = [\text{G6P}]/[\text{G1P}] = e^{-\Delta G^{\circ'}/RT}$
 $[\text{G6P}]/[\text{G1P}] = e^{-(-7100 \text{ J} \cdot \text{mol}^{-1})/(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K})}$
 $[\text{G6P}]/[\text{G1P}] = 17.6$
 $[\text{G1P}]/[\text{G6P}] = 0.057$

17. Membrane-enclosed cellular compartments are typical of eukaryotic but not prokaryotic cells.

19. Number of molecules = (molar conc.)(volume) $(6.022 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1})$
 $= (1.0 \times 10^{-3} \text{ mol} \cdot \text{L}^{-1})(5.24 \times 10^{-16} \text{ L})$
 $(6.022 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1})$
 $= 3.2 \times 10^5 \text{ molecules}$

21. (a) Because $K_{\text{eq}} = \frac{[\text{R}]}{[\text{Q}]} = 25$, at equilibrium, the concentration of

R is 25 times greater than the concentration of Q. When equal concentrations of Q and R are mixed, molecules of Q will be converted to molecules of R.

(b) Let x = amount of Q converted to R, so that [R] will be $50 \mu\text{M} +$

x and [Q] will be $50 \mu\text{M} - x$. Since $K_{\text{eq}} = \frac{[\text{R}]}{[\text{Q}]} = 25$,

$$50 + x = 25(50 - x)$$

$$50 + x = 1250 - 25x$$

$$26x = 1200$$

$$x = 46.15$$

$$[\text{R}] = 50 \mu\text{M} + 46.15 \mu\text{M} = 96.15 \mu\text{M}$$

$$[\text{Q}] = 50 \mu\text{M} - 46.15 \mu\text{M} = 3.85 \mu\text{M}$$

23. This strategy will *not* work because Reaction 1 has a negative enthalpy change, releasing heat, and will therefore become more favorable with decreasing temperature, whereas Reaction 2, which has a positive enthalpy change, will become less favorable. Thus decreasing the

temperature will favor Reaction 1, not Reaction 2. To make Reaction 2 more favorable, the temperature must be raised.

To calculate the amount that the temperature must be raised, Equation 1-18 may be used as follows:

$$\ln K_{\text{eq}} = \frac{-\Delta H^{\circ}}{R} \left(\frac{1}{T} \right) + \frac{\Delta S^{\circ}}{R}$$

$$\ln \frac{K_1^{T_1}}{K_1^{T_2}} = \frac{-\Delta H_1^{\circ}}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)$$

$$\ln \frac{K_2^{T_1}}{K_2^{T_2}} = \frac{-\Delta H_2^{\circ}}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)$$

On subtraction of the previous two equations, and taking into

account that $\frac{K_2^{T_1}}{K_1^{T_1}} = 1$, we get

$$\ln \left[\frac{K_1^{T_1} K_2^{T_2}}{K_1^{T_2} K_2^{T_1}} \right] = \ln \frac{K_2^{T_2}}{K_1^{T_2}} = \frac{\Delta H_2^{\circ} - \Delta H_1^{\circ}}{R} \left(\frac{1}{T_1} - \frac{1}{T_2} \right)$$

We would like $\frac{K_2^{T_2}}{K_1^{T_2}} = 10$. Substituting in all values and solving for T_2 we get

$$\ln \frac{K_2^{T_2}}{K_1^{T_2}} = \ln 10 = 2.3 = \frac{28,000 + 28,000}{8.31} \left(\frac{1}{298} - \frac{1}{T_2} \right)$$

Solving for T_2 we get

$$T_2 = \frac{1}{\frac{1}{298} - \frac{2.3 \times 8.31}{56,000}} = 332 \text{ K}$$

Hence, to increase K_2/K_1 from 1 to 10, the temperature must be raised from 298 K to 332 K.

Chapter 2

- (a) Donors: NH_1 , NH_2 at C2, NH_9 ; acceptors: N_3 , O at C6, N_7 .
(b) Donors: NH^+ , NH_2 at C4; acceptors: O at C2, N_3 . (c) Donors: NH_3^+ group, OH group; acceptors: COO^- group, OH group.
- 18 mL of water has a mass of about 18 g; one mole contains about 6×10^{23} molecules, and the molecular mass of H_2O is about $18 \text{ g} \cdot \text{mol}^{-1}$. Therefore, the spoon holds $(18 \text{ g})(6 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1}) / (18 \text{ g} \cdot \text{mol}^{-1}) = 6 \times 10^{23}$ molecules.
- (a) Water; (b) water.
- Water molecules move from inside the dialysis bag to the surrounding seawater by osmosis. Ions from the seawater diffuse into the dialysis bag. At equilibrium, the compositions of the solutions inside and outside the dialysis bag are identical. If the membrane were solute-impermeable, essentially all the water would leave the dialysis bag.

11. pH 4, NH_4^+ ; pH 8, NH_4^+ ; pH 11, NH_3 .

SP-2

13. The increase in $[H^+]$ due to the addition of HCl is $(50 \text{ mL})(1 \text{ mM}) / (250 \text{ mL}) = 0.2 \text{ mM} = 2 \times 10^{-4} \text{ M}$. Because the $[H^+]$ of pure water, 10^{-7} M , is relatively insignificant, the pH of the solution is equal to $-\log(2 \times 10^{-4})$ or 3.7.

15. The pK corresponding to the equilibrium between $H_2PO_4^-$ (HA) and HPO_4^{2-} (A^-) is 6.82 (Table 2-4). The concentration of A^- is $(50 \text{ mL})(2.0 \text{ M}) / (200 \text{ mL}) = 0.5 \text{ M}$, and the concentration of HA is $(25 \text{ mL})(2.0 \text{ M}) / (200 \text{ mL}) = 0.25 \text{ M}$. Substitute these values into the Henderson–Hasselbalch equation (Eq. 2-10):

$$\begin{aligned} \text{pH} &= \text{p}K + \log \frac{[A^-]}{[HA]} \\ \text{pH} &= 6.82 + \log \frac{0.5}{0.25} \\ \text{pH} &= 6.82 + \log 2 \\ \text{pH} &= 6.82 + 0.30 = 7.12 \end{aligned}$$

17. (a) At pH 7.0, $[H^+] = 10^{-7} \text{ M}$, so 10^{-7} moles of water molecules have ionized. This is equivalent to $(10^{-7} \text{ mol})(6 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1}) = 6 \times 10^{16}$ molecules.

(b) If the concentration of water is 55.5 M, then there are $(55.5 \text{ mol})(6 \times 10^{23} \text{ molecules} \cdot \text{mol}^{-1}) = 3.3 \times 10^{25}$ molecules of water in 1 L. The fraction of ionized molecules is $(6 \times 10^{16} \text{ molecules}) / (3.3 \times 10^{25} \text{ molecules}) = 1.8 \times 10^{-9}$ or $1.8 \times 10^{-7}\%$.

19. U , the energy of association of two charged particles, is equal to Kq_1q_2/Dr . Because D , the dielectric constant, for a hydrocarbon is <3 and D for H_2O is 78.5, U is at least 26 times greater ($78.5 \div 3$) in benzene than in water.

21. A protonated (and therefore positively charged) nitrogen would promote the separation of charge in the adjacent C—H bond so that the C would have a partial negative charge and the H would have a partial positive charge. This would make the H more likely to be donated to a hydrogen bond acceptor group.

23. The high solute concentration of honey tends to draw water out of microorganisms by osmosis, thereby preventing their growth.

25. The high concentration of bicarbonate in the dialysate means that some bicarbonate will diffuse from the dialysate across the dialysis membrane into the patient's blood, where it will combine with and neutralize excess protons.

27. The tomato juice is mildly acidic, with a pH of about 4.4 (Table 2-3). The protons in the juice react with the calcium carbonate, eventually producing H_2O and CO_2 , which evaporate, leaving a scar on the marble surface.

29. Let HA = sodium succinate and A^- = disodium succinate.

$$[A^-] + [HA] = 0.05 \text{ M, so } [A^-] = 0.05 \text{ M} - [HA]$$

From Eq. 2-10 and Table 2-4,

$$\log([A^-] / [HA]) = \text{pH} - \text{p}K = 6.0 - 5.64 = 0.36$$

$$[A^-] / [HA] = 10^{0.36} = 2.29$$

$$(0.05 \text{ M} - [HA]) / [HA] = 2.29$$

$$[HA] = 0.015 \text{ M}$$

$$[A^-] = 0.05 \text{ M} - 0.015 \text{ M} = 0.035 \text{ M}$$

grams of sodium succinate = $(0.015 \text{ mol} \cdot \text{L}^{-1})(140 \text{ g} \cdot \text{mol}^{-1}) \times (1 \text{ L}) = 2.1 \text{ g}$

grams of disodium succinate = $(0.035 \text{ mol} \cdot \text{L}^{-1})(162 \text{ g} \cdot \text{mol}^{-1}) \times (1 \text{ L}) = 5.7 \text{ g}$

31. The dissociation of TrisH^+ to its basic form and H^+ is associated with a large, positive enthalpy change. Consequently, heat is taken up by the reactant on dissociation. When the temperature is lowered,

there is less heat available for this process, shifting the equilibrium constant toward the associated form (the effect of temperature on the equilibrium constant of a reaction is given by Eq. 1-18). To avoid this problem, the buffer should be prepared at the same temperature as its planned use.

Chapter 3

1. Guanosine 5'-diphosphate

3.

5-Methylcytosine

5. (a) Yes; (b) no.

7. Since the haploid genome contains 21% G, it must contain 21% C (because $G = C$) and 58% A + T (or 29% A and 29% T, because $A = T$). Each cell is diploid, containing 90,000 kb or 9×10^7 bases. Therefore,

$$A = T = (0.29)(9 \times 10^7) = 2.61 \times 10^7 \text{ bases}$$

$$C = G = (0.21)(9 \times 10^7) = 1.89 \times 10^7 \text{ bases}$$

9. The high pH tends to eliminate the hydrogen-bonding protons between bases, making it easier to separate the strands of DNA.

11. According to the central dogma, DNA serves as a template for RNA synthesis. The HIV enzyme, called reverse transcriptase, works in reverse by synthesizing DNA from an RNA template.

13. Because each amino acid corresponds to three nucleotides (a codon), a minimum of 90 nucleotides are required. The corresponding gene is likely much larger than that, since it must contain additional sequences—before and after the coding sequence—to facilitate transcription and translation.

17. In *O. tauri*, the gene density is 8000 genes/13,000 kb = 0.62, a value that is somewhat lower than that of the prokaryote *E. coli* (4300 genes/4639 kb = 0.93) but more than that of the plant *A. thaliana* (25,500 genes/119,200 kb = 0.21).

19. Use of the enzymes NarI, BglII, MstI, PvuI, and PvuII would interfere with β -galactosidase production.

21. The genomic library contains DNA sequences corresponding to all the organism's DNA, which includes genes and nontranscribed sequences. A cDNA library represents only the DNA sequences that are transcribed into mRNA.

23.

*N*⁶-methyladenosine

25.

27. The energy of N1 in a purine ring is lowest when it is in its uncharged trivalent form. Thus, protonated and therefore tetravalent and positively charged N1 in adenine readily gives up its proton to water (has a low pK value) to yield its uncharged trivalent form. In contrast, the trivalent N1 of neutral guanine resists donating its proton to water (has a high pK value) to yield a divalent and therefore negatively charged ion.

29.

Hypoxanthine

Adenine

31. (a) Newly synthesized chains would be terminated less frequently, so the bands representing truncated fragments on the sequencing gel would appear faint.

(b) Chain termination would occur more frequently, so longer fragments would be less abundant.

33. The *C. elegans* genome contains 97,000 kb, so

$$f = 5/97,000 = 5.2 \times 10^{-5}$$

Using Eq. 3-2,

$$N = \log(1 - P)/\log(1 - f)$$

$$N = \log(1 - 0.99)/\log(1 - 5.2 \times 10^{-5})$$

$$N = -2/(-2.24 \times 10^{-5}) = 8.91 \times 10^4$$

35. (a) Only single DNA strands of variable length extending from the remaining primer would be obtained. The number of these strands would increase linearly with the number of cycles rather than geometrically.

(b) PCR would yield a mixture of DNA segments whose lengths correspond to the distance between the position of the primer with a single binding site and the various sites where the multispecific primer binds.

37. ATAGGCATAGGC and CTGACCAGCGCC.

Chapter 4

1. Gly and Ala, Ser and Thr; Val, Leu and Ile; Asn and Gln; Asp and Glu.

5.

7. Hydrogen bond donors: α -amino group, amide nitrogen. Hydrogen bond acceptors: α -carboxylate group, amide carbonyl.

9. (a) +1; (b) 0; (c) -1; (d) -2.

11. (a) chiral; (b) nonchiral; (c) chiral; (d) chiral; (e) nonchiral; (f) chiral; (g) chiral.

13. (a) Glutamate; (b) aspartate

15. Glutamate

17. Isopeptide bonds can form from the side chain amino group of Lys and from the side chain carboxylate groups of Asp and Glu.

21. The polypeptide would be even less soluble than free Tyr, because most of the amino and carboxylate groups that interact with water and make Tyr at least slightly soluble are lost in forming the peptide bonds in poly(Tyr).

23. (a) $pI = (2.35 + 9.87)/2 = 6.11$

- (b) $pI = (6.04 + 9.33)/2 = 7.68$

- (c) $pI = (2.10 + 4.07)/2 = 3.08$

25.

- (a) The pK 's of the ionizable side chains (Table 4-1) are 3.90 (Asp) and 10.54 (Lys); assume that the C-terminal Lys carboxyl group has a pK of 3.5 and the N-terminal Ala amino group has a pK of 8.0 (Section 4-1D). The pI is approximately midway between the pK 's of the two ionizations involving the neutral species (the pK of Asp and the N-terminal pK):

$$pI \approx \frac{1}{2} (3.90 + 8.0) \approx 5.95$$

- (b) The net charge at pH 7.0 is 0 (as drawn above).

27.

29.

31. (a) Serine (*N*-acetylserine); (b) lysine (5-hydroxylysine); (c) methionine (*N*-formylmethionine)

33.

Chapter 5

- There are 8^{10} or about 1 billion possibilities.
- Peptide B, because it contains more Trp and other aromatic residues.
- Lowering the pH from 7.0 to 5.0 would promote the precipitation of protein Q because the protein will be least soluble when its net charge is zero (when $\text{pH} = \text{pI}$).
- (a) Leu, His, Arg. (b) Lys, Val, Glu.
- The protein behaves like a larger protein during gel filtration, suggesting that it has an elongated shape. The mass determined by SDS-PAGE is more accurate since the mobility of a denatured SDS-coated protein depends only on its size.
- The protein aggregates at the higher salt concentration.
- Dansyl chloride reacts with primary amino groups, including the ϵ -amino group of Lys residues.
- The mass of an asparagine (N) residue is $114 \text{ g} \cdot \text{mol}^{-1}$ and the mass of a lysine (K) residue is $128 \text{ g} \cdot \text{mol}^{-1}$ (Table 4-1). Since an intact peptide contains an additional O atom at its C-terminus and two additional H atoms at its N-terminus, the mass of the pentapeptide is $(4 \times 114) + 128 + 16 + 2 \text{ g} \cdot \text{mol}^{-1} = 602 \text{ g} \cdot \text{mol}^{-1}$.
- Because the side chain of Gly is only an H atom, it often occurs in a protein at a position where no other residue can fit. Consequently, Gly can take the place of a larger residue more easily than a larger residue, such as Val, can take the place of Gly.

- Add a salt such as ammonium sulfate to the dilute protein solution to reach a final salt concentration that is somewhat higher than the salting-out point for the protein. Centrifuge the solution, collect the protein precipitate, and then dissolve the precipitate in a small volume of buffer.
- Because protein 1 has a greater proportion of hydrophobic residues (Ala, Ile, Pro, Val) than do proteins 2 and 3, hydrophobic interaction chromatography could be used to isolate it.
- (a)

Purification step	mg		Specific activity		Fold purification
	total protein	$\mu\text{mol Mb}$	$(\mu\text{mol Mb/mg total protein})$	% yield	
1. Crude extract	1550	0.75	4.8×10^{-4}	100	1
2. DEAE-cellulose chromatography	550	0.35	6.4×10^{-4}	47	1.3
3. Affinity chromatography	5.0	0.28	5.6×10^{-2}	80 from affinity chromatography (37 overall)	117-fold overall, (87-fold from affinity chromatography)

- (b) The DEAE chromatography step results in only a 47% yield, while the affinity chromatography step results in an 80% yield from the

step before it. The DEAE chromatography step therefore results in the greatest loss of Mb.

- The DEAE chromatography step results in a 1.3-fold purification, while the affinity chromatography step results in a 87-fold purification from the previous step. The affinity chromatography step therefore results in the greatest purification of Mb.
 - The affinity chromatography step is the best choice for a one-step purification of Mb in this example.
 - Thermolysin would yield the most fragments (9) and endopeptidase V8 would yield the fewest (2).
 - (a) The positive charges are caused by the protonation of basic side chains (H, K, and R) and the N-terminal amino groups of the protein.
(b) There are 1 H, 6 K, 11 R, and 1 NH_2 at the N-terminus. Therefore, the maximum number of positive charges that can be obtained is 19.
31. Gln-Ala-Phe-Val-Lys-Gly-Tyr-Asn-Arg-Leu-Glu
- 33.

Chapter 6

-
- The large side chains of the amino acids all project from the side of the helix but would still sterically interfere with each other.
- The reducing conditions promote cleavage of the disulfide bonds that cross-link α keratin molecules. This helps the larvae digest the wool clothing that they eat.
- Collagen's primary structure is its amino acid sequence, which is a repeating triplet of mostly Gly-Pro-Hyp. Its secondary structure is the left-handed helical conformation characteristic of its repeating sequence. Its tertiary structure is essentially the same as its secondary structure, as most of the protein consists of one type of secondary structure, but with the addition of its side chains. Collagen's quaternary structure is the arrangement of its three chains in a right-handed triple helix.
- A fibrous protein such as α keratin does not have a discrete globular core. Most of the residues in its coiled coil structure are exposed to the solvent. The exception is the strip of nonpolar side chains at the interface of the two coils.
- In a protein crystal, the residues at the end of a polypeptide chain may experience fewer intramolecular contacts and therefore tend to be less ordered (more mobile in the crystal). If their disorder prevents them from generating a coherent diffraction pattern, it may be impossible to map their electron density.
- (a) α ; (b) α/β
- (a) Phe. Ala and Phe are both hydrophobic, but Phe is much larger and might not fit as well in Val's place.
(b) Asp. Replacing a positively charged Lys residue with an oppositely charged Asp residue is likely to be more disruptive.
(c) Glu. The amide-containing Asn would be a better substitute for Gln than the acidic Glu.

(d) His. Pro's constrained geometry is best approximated by Gly, which lacks a side chain, rather than a residue with a bulkier side chain such as His.

17. The brains of the Alzheimer's-prone mice were already burdened with accumulated A β , so the PrP^{Sc} aggregation augmented the brain damage, leading to earlier onset of symptoms than in mice whose brains were not already damaged by A β accumulation. (There is also some evidence that A β oligomers may interact directly with PrP.)

Pyroglutamate

21. (a) 3.6₁₃; (b) steeper.
23. Peptide c is most likely to form an α helix with its three charged residues (Lys, Glu, and Arg) aligned on one face of the helix. Peptide a has adjacent basic residues (Arg and Lys), which would destabilize a helix. Peptide b contains Gly and Pro, both of which are helix-breaking (Table 6-1).
25. Each backbone N—H group in an α helix normally forms a hydrogen bond to the carbonyl oxygen atom four residues back along the chain (toward the N-terminus; Fig. 6-7). Pro, which lacks a backbone N—H group, cannot do so and hence its presence in an interior position of an α helix destabilizes the helix through the loss of hydrogen bonding to the otherwise carbonyl acceptor. However, the four most N-terminal residues of an α helix cannot donate hydrogen bonds within the α helix. In addition, the pyrrolidine ring of a Pro residue in the interior of an α helix sterically interferes with the residue one turn towards the N-terminus. Pro residues in the N-terminal turn of an α helix do not have such steric clashes. Hence Pro residues can occupy the N-terminal turn of an α helix.
27. D₆
29. No.
31. At physiological pH, the positively charged Lys side chains repel each other. Increasing the pH above their pK (>10.5) would neutralize the side chains and allow an α helix to form.
33. The molecular mass of O₂ is 32 D. Hence the ratio of the masses of hemoglobin and 4 O₂, which is equal to the ratio of their volumes, is 65,000/(4 × 32) = 508. The 70-kg office worker has a volume of 70 kg × 1 cm³/g × (1000 g/kg) × (1 m/100 cm)³ = 0.070 m³. Hence the ratio of the volumes of the office and the office worker is (4 × 4 × 3)/0.070 = 686. These ratios are similar in magnitude, which you may not have expected.
35. (a) In one subunit there are 386 residues, each with a (1 - 1/3000) probability of being correctly inserted. For the entire subunit this is (1 - 1/3000)³⁸⁶ = 0.879. For the entire coat of 180 subunits, the number of subunits that will have to be synthesized, on average, to form a perfect coat is 180/0.879 = 205.
- (b) If the coat were one polypeptide chain, it would have 180 × 386 = 69,480 residues. The probability of such a coat being perfectly synthesized is (1 - 1/3000)⁶⁹⁴⁸⁰ = 8.71 × 10⁻¹¹. Consequently, 1/(8.71 × 10⁻¹¹) = 1.14 × 10¹⁰ coats would have to be synthesized in order to obtain an average of one perfect coat.
37. Oxidation can cause a protein to unfold, so cells increase the production of heat shock proteins to help the damaged proteins refold. Under the same conditions, the level of reduced glutathione (GSH)

decreases and the level of oxidized glutathione (GSSG) increases as oxidized proteins are restored to a reduced state.

39. The GroEL/ES system behaves analogously to a wheel equipped with a ratchet that only permits the wheel to rotate in one direction. Thus, in Step 1 of Fig. 6-45, the binding of GroES to the GroEL-(ATP)⁷ complex to yield the cis ring induces conformational changes in GroEL that ensure the hydrolysis of the ATP bound to the cis rings, while preventing the binding of ATP to the trans ring. The ensuing hydrolysis of the cis ring-bound ATP to ADP + P_i and the subsequent release of P_i in Step 2 weakens these interactions, thereby permitting 7ATP to bind to the trans ring in Step 3. The resulting conformational changes in GroEL further weaken the interactions in the cis ring, leading to the release of its bound 7ADP + GroES in Step 4. At this point, the cis and trans rings of GroEL have exchanged roles and the cycle repeats. What prevents this process from going backward (the ratchet) are: in Step 1, the free energy of binding of GroES to the cis ring of GroEL; in Step 2, the irreversibility of ATP hydrolysis; in Step 3, the free energy of binding of ATP to the trans ring of GroEL; and in Step 4, the low affinity of the GroEL cis ring for GroES and ADP. Thus, all four steps are irreversible (exergonic). The free energy for this process is ultimately supplied by the irreversible hydrolysis of the ATP.

Chapter 7

1.

3. For hemoglobin, $p_{50} = 26$ torr. Let the Hill constant, n , equal 3.

$$Y_{O_2} = \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n}$$

(a)

$$Y_{O_2} = \frac{(20)^3}{(26)^3 + (20)^3} = \frac{8000}{17,576 + 8000} = 0.31$$

(b)

$$Y_{O_2} = \frac{(40)^3}{(26)^3 + (40)^3} = \frac{64,000}{17,576 + 64,000} = 0.78$$

(c)

$$Y_{O_2} = \frac{(60)^3}{(26)^3 + (60)^3} = \frac{216,000}{17,576 + 216,000} = 0.92$$

5. (a) Vitamin O is useless because the body's capacity to absorb oxygen is not limited by the amount of oxygen available, but by the ability of hemoglobin to bind and transport O₂. Furthermore, oxygen is normally introduced into the body via the lungs, so it is unlikely that the gastrointestinal tract would have an efficient mechanism for extracting oxygen.

SP-6

(b) The fact that oxygen delivery in vertebrates requires a dedicated O₂-binding protein (hemoglobin) indicates that dissolved oxygen by itself cannot attain the high concentrations required. Moreover, a few drops of vitamin O would make an insignificant contribution to the amount of oxygen already present in a much larger volume of blood.

7. (a) Lower; (b) higher. The Asp 99β → His mutation of hemoglobin Yakima disrupts a hydrogen bond at the α₁-β₂ interface of the T state (Fig. 7-9a), causing the T ⇌ R equilibrium to shift toward R state (lower p₅₀). The Asn 102β → Thr of hemoglobin Kansas causes the opposite shift in the T ⇌ R equilibrium by abolishing an R-state hydrogen bond (Fig. 7-9b).
9. The increased BPG helps the remaining erythrocytes deliver O₂ to tissues. However, BPG stabilizes the T conformation of hemoglobin, so it promotes sickling and therefore aggravates the disease.
11. Myosin is both fibrous and globular. Its two heads are globular, with several layers of secondary structure. Its tail, however, consists of a lengthy, fibrous coiled coil.
13. Because many myosin heads bind along a thin filament where it overlaps a thick filament, and because the myosin molecules do not execute their power strokes simultaneously, the thick and thin filaments can move past each other by more than 100 Å in the interval between power strokes of an individual myosin molecule.
15. Because cell volume is constant, the sarcomeres must widen as they shorten. As a result, the distance from each myosin head to its binding site on an actin filament increases, diminishing the ability of the myosin heads to pull on the thin filament.
17. (a) 150–200 kD; (b) 150–200 kD; (c) ~23 kD and 53–75 kD
19. The loops are on the surface of the domain, so they can tolerate more amino acid substitutions. Amino acid changes in the β sheets would be more likely to destabilize the domain.
21. According to Eq. 7-6,

$$Y_{O_2} = \frac{pO_2}{K + pO_2}$$

When pO₂ = 10 torr,

$$Y_{O_2} = \frac{10}{2.8 + 10} = 0.78$$

When pO₂ = 1 torr,

$$Y_{O_2} = \frac{1}{2.8 + 1} = 0.26$$

The difference in Y_{O₂} values is 0.78 – 0.26 = 0.52. Therefore, in active muscle cells, myoglobin can transport a significant amount of O₂ by diffusion from the cell surface to the mitochondria.

23.

25. (a) Hyperventilation eliminates CO₂, but it does not significantly affect the O₂ concentration, since the hemoglobin in arterial blood is already essentially saturated with oxygen.
(b) The removal of CO₂ also removes protons, according to the reaction
$$H^+ + HCO_3^- \rightleftharpoons H_2O + CO_2$$

The resulting increase in blood pH would increase the O₂ affinity of hemoglobin through the Bohr effect. The net result would be that less oxygen could be delivered to the tissues until the CO₂ balance was restored. Thus, hyperventilation has the opposite of the intended effect (note that since hyperventilation suppresses the urge to breathe, doing so may cause the diver to lose consciousness due to lack of O₂ and hence drown).
27. In the case of anemia, the Hb that is present functions normally and is presumably present in sufficient quantity to carry the required amount of O₂ (at least under conditions of low exertion). In the CO poisoning case, half the O₂ binding sites of Hb bind CO essentially irreversibly. This converts most of the Hb to the R state which greatly increases its O₂ affinity over that of normal Hb. Therefore, at the tissues, little of the O₂ carried by this Hb will be discharged, resulting in the asphyxiation of the victim.
29. Microfilaments consist entirely of actin subunits that are assembled in a head-to-tail fashion so the polarity of the subunits is preserved in the fully assembled fiber. In keratin filaments, however, successive heterodimers align in an antiparallel fashion, so that in a fully assembled intermediate filament, half the molecules are oriented in one direction and half are oriented in the opposite direction (Fig. 6-16).
31. The antigenic site in the native protein usually consists of several peptide segments that are no longer contiguous when the tertiary structure of the protein is disrupted.
33. Cleaving the IgA molecules into separate Fab fragments destroys their ability to cross-link antigens. Although the Fab fragments can still bind to the bacteria, the bacteria will not become trapped in a cross-linked network and can still initiate an infection.

Chapter 8

1. (a) 4; (b) 8; (c) 16
3. (a)
- 5.

7.

9. Tagatose is derived from galactose.

11.

13. One

15. Glucosamine is a building block of certain glycosaminoglycan components of proteoglycans (Fig. 8-12). Boosting the body's supply of glucosamine might slow the progression of the disease osteoarthritis, which is characterized by the degradation of proteoglycan-rich articular (relating to a joint) cartilage. [Note, however, that clinical trials indicate that glucosamine does not affect the progress of osteoarthritis.]

17. -200

19.

21.

23. 19. C1 of one glucopyranose can form α or β glycosidic linkages with C1, C2, C3, C4, or C6 of a second glucopyranose, which can also be in the α or β form. However, α -glucose-(1 \rightarrow 1)- β -glucose is identical to β -glucose-(1 \rightarrow 1)- α -glucose, so the total is 19 rather than 20.

25. (a) α -D-glucose-(1 \rightarrow 1)- α -D-glucose. (b) The numerous hydrogen-bonding —OH groups of the disaccharide act as substitutes for water molecules. Because trehalose is a nonreducing sugar, it is

unlikely to participate in oxidation–reduction reactions with other biomolecules when it is present at high concentrations.

27.

29. (a) One

(b)

31. The cationic Ca^{2+} ions shield the negative charges of the glycosaminoglycans in the proteoglycans, so that they can be stored in a relatively small volume inside the cell. When the Ca^{2+} ions are pumped out, the repulsion between the glycosaminoglycan chains causes them to expand in the extracellular space.

33.

The filled circles represent the glucose residues that can be cleaved away by β -amylase. The remainder is the limit dextrin.

Chapter 9

1. *trans*-Oleic acid has a higher melting point because, in the solid state, its hydrocarbon chains pack together more tightly than those of *cis*-oleic acid.

3.

5. Of the $4 \times 4 = 16$ pairs of fatty acid residues at C1 and C3, only 10 are unique because a molecule with different substituents at C1 and C3 is identical to the molecule with the reverse substitution order. However, C2 may have any of the four substituents for a total of $4 \times 10 = 40$ different triacylglycerols.

7. All except choline can form hydrogen bonds.

SP-8

9. This lipid is ceramide-1-phosphate, produced by the phosphorylation of the ceramide derived from a sphingomyelin.
11. Eicosanoids synthesized from arachidonic acid are necessary for intercellular communication. Cultured cells do not need such communication and therefore do not require linoleic acid.
13. Triacylglycerols lack polar head groups, so they do not orient themselves in a bilayer with their acyl chains inward and their glycerol moiety toward the surface.
15. (a) Saturated; (b) long-chain. By increasing the proportion of saturated and long-chain fatty acids, which have higher melting points, the bacteria can maintain constant membrane fluidity at the higher temperature.
17. (a) $(1 \text{ turn}/5.4 \text{ \AA})(30 \text{ \AA}) = 5.6 \text{ turns}$
 (b) $(3.6 \text{ residues/turn})(5.6 \text{ turns}) = 20 \text{ residues}$
 (c) The additional residues form a helix, which partially satisfies backbone hydrogen bonding requirements, where the lipid head groups do not offer hydrogen bonding partners.
19. (a) Inner; (b) outer. See Fig. 9-32.
21. (a)

- (b) To convert sphingomyelin to sphingosine-1-phosphate, a portion of the head group (typically choline or ethanolamine) must be hydrolytically cleaved, leaving a phosphate group, and the amide linkage to the fatty acyl group must be hydrolyzed.
23. Both DNA and phospholipids have exposed phosphate groups that are recognized by the antibodies.
25. The monosaccharide groups are glucosamine-4-phosphate (left) and glucosamine-1-phosphate (right). Four 3-hydroxy-tetradecanoyl (β -hydroxy-myristoyl) groups are attached via ester or amide bonds to the glucosamine groups, and two of these chains have additional tetradecanoyl (myristoyl) groups esterified to their hydroxyl groups.
27. Proteins that are tethered to membranes via *N*-myristoylation would be set free by the action of an enzyme that cleaved away the *N*-terminal glycine to which the fatty acyl group was attached. [This is just one event during infection by *Shigella*, which produces ~20 proteins that interfere with host cell function.]
29. (a) Both the intra- and extracellular portions will be labeled. (b) Only the extracellular portion will be labeled. (c) Only the intracellular portion will be labeled.
31. An overactive endocytic pathway would require large amounts of membrane material to form the numerous intracellular vesicles. The cell cannot keep up with the demand, so its membranes become attenuated and rupture, which kills the cell.
33. The mutant signal peptidase would cleave many preproteins within their signal peptides, which often contain Leu–Leu sequences. This would not affect translocation into the ER, since signal peptidase acts after the signal peptide enters the ER lumen. Proteins lacking the Leu–Leu sequence would retain their signal peptides. These proteins, and those with abnormally cleaved signal sequences, would be more likely to fold abnormally and therefore function abnormally.
35. Since all subunits must have the same orientation with respect to the membrane, the only allowed rotational symmetry axes must be perpendicular to the membrane plane. This constraint eliminates all but cyclic symmetries; that is, C_2 , C_3 , C_4 , etc.

Chapter 10

$$1. \Delta G = RT \ln \frac{[\text{glucose}]_{in}}{[\text{glucose}]_{out}}$$

$$= (8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K}) \ln \frac{(0.003)}{(0.005)}$$

$$= -1270 \text{ J} \cdot \text{mol}^{-1} = -1.27 \text{ kJ} \cdot \text{mol}^{-1}$$

3. Use Equation 10-3 and let $Z = 2$ and $T = 310 \text{ K}$:

$$(a) \Delta G = RT \ln \frac{[\text{Ca}^{2+}]_{in}}{[\text{Ca}^{2+}]_{out}} + Z\mathcal{F}\Delta\Psi$$

$$= (8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K}) \ln (10^{-7}/10^{-3})$$

$$+ (2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(-0.050 \text{ V})$$

$$= -23,700 \text{ J} \cdot \text{mol}^{-1} - 9600 \text{ J} \cdot \text{mol}^{-1}$$

$$= -33,300 \text{ J} \cdot \text{mol}^{-1} = -33.3 \text{ kJ} \cdot \text{mol}^{-1}$$

The negative value of ΔG indicates a thermodynamically favorable process.

$$(b) \Delta G = RT \ln \frac{[\text{Ca}^{2+}]_{in}}{[\text{Ca}^{2+}]_{out}} + Z\mathcal{F}\Delta\Psi$$

$$= (8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K}) \ln (10^{-7}/10^{-3})$$

$$+ (2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(+0.150 \text{ V})$$

$$= -23,700 \text{ J} \cdot \text{mol}^{-1} + 28,900 \text{ J} \cdot \text{mol}^{-1}$$

$$= +5,200 \text{ J} \cdot \text{mol}^{-1} = +5.2 \text{ kJ} \cdot \text{mol}^{-1}$$

The positive value of ΔG indicates a thermodynamically unfavorable process.

5. (a) Nonmediated; (b) mediated; (c) nonmediated; (d) mediated.
7. An eight-stranded β barrel has a solid core. A β barrel with 16 or 18 strands has a diameter large enough to accommodate a pore for solute transport.
9. The presence of a series of K^+ ions within the channel prevents water molecules from forming a hydrogen-bonded chain.
11. A channel provides an open pore across the membrane, whereas a pump operates by changing its conformation in an ATP-dependent manner. The additional time required for ATP hydrolysis and protein conformation changes causes ion movement through a pump to be slower than through a channel.
13. In the absence of ATP, Na^+ extrusion by the $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ would cease, so no glucose could enter the cell by the Na^+ –glucose symport. The glucose in the cell would then exit via the passive-mediated glucose transporter, and the cellular [glucose] would decrease until it matched the extracellular [glucose] (of course, the cell would probably osmotically burst before this could occur).
15. (a) The phosphate transporter is more likely to function like the transport protein GLUT1, because a channel large enough to accommodate phosphate ions would be unable to prevent the transmembrane movement of smaller ions such as Cl^- . (b) The phosphate transporter is a symport system. (c) There are more H^+ ions inside the cell than outside, so phosphate transport cannot be driven by a pH gradient, which would require a higher extracellular $[\text{H}^+]$.
17. K^+ transport ceases because the ionophore- K^+ complex cannot diffuse through the membrane when the lipids are immobilized in a gel-like state.
19. (a) No; there is no glycerol backbone.
 (b) Miltefosine is amphipathic and therefore cannot cross the parasite cell membrane by diffusion. Since it is not a normal cell component, it probably does not have a dedicated active transporter. It most likely enters the cell via a passive transport protein.
 (c) This amphipathic molecule most likely accumulates in membranes, with its hydrophobic tail buried in the bilayer and its polar head group exposed to the solvent.
 (d) The protein recognizes the phosphocholine head group, which also occurs in some sphingolipids and some glycerophospholipids.

Since the protein does not bind all phospholipids or triacylglycerols, it does not recognize the hydrocarbon tail.

21. (a) The data do not indicate the involvement of a transport protein, since the rate of transport does not approach a maximum as $[X]$ increases. (b) To verify that a transport protein is involved, increase $[X]$ to demonstrate saturation of the transporter at high $[X]$, or add a structural analog of X to compete with X for binding to the transporter, resulting in a lower flux of X .
23. (a) $\text{pH} = -\log[\text{H}^+] = -\log(0.15) = 0.82$

The pH of the secreted HCl is more than 6 pH units lower than the cytosolic pH, which corresponds to a $[\text{H}^+]$ of $\sim 4 \times 10^{-8} \text{ M}$.

(c)

25. CO_2 is converted to carbonic acid, which dissociates to form bicarbonate and protons. The protons block the pain signals that would otherwise be triggered by high $[\text{CO}_2]$. This allows the animals to tolerate the crowded conditions in its burrows.

Chapter 11

1. b
3. (a) isomerase (alanine racemase); (b) lyase (pyruvate decarboxylase).
5. There are three transition states (X^\ddagger) and two intermediates (I). The reaction is not thermodynamically favorable because the free energy of the products is greater than that of the reactants.

7. At 25°C , every 10-fold increase in rate corresponds to a decrease of about $5.7 \text{ kJ} \cdot \text{mol}^{-1}$ in ΔG^\ddagger . For the nuclease, with a rate enhancement on the order of 10^{14} , ΔG^\ddagger is lowered about $14 \times 5.7 \text{ kJ} \cdot \text{mol}^{-1}$, or about $80 \text{ kJ} \cdot \text{mol}^{-1}$. Alternatively, since the rate enhancement, k , is given by $k = e^{\Delta\Delta G_{\text{cat}}^\ddagger/RT}$,
 $\ln k = \ln(10^{14}) = \Delta\Delta G_{\text{cat}}^\ddagger/8.3145 \times (273 + 25)$
Hence $\Delta\Delta G_{\text{cat}}^\ddagger = 80 \text{ kJ} \cdot \text{mol}^{-1}$.
9. As the temperature increases, thermal energy boosts the proportion of reactants that can achieve the transition state per unit time, so the rate increases. Above an optimal temperature, the enzyme becomes

denatured and rapidly loses catalytic activity (recall that proteins are typically only marginally stable; Section 6-4).

11. Glu has a $\text{p}K$ of ~ 4 and, in its ionized form, acts as a base catalyst. Lys has a $\text{p}K$ of ~ 10 and, in its protonated form, acts as an acid catalyst.
13. Inhibition by various metal ions suggests that urease requires a metal ion for catalysis, whose replacement by Hg, Co, or Cd inactivates the enzyme. However, the inhibitory metal ions could also disrupt the enzyme's structure by binding somewhere other than the active site, so this inhibitory effect does not prove that urease acts via metal ion catalysis. (In fact, urease activity requires two catalytic Ni ions.)
15. The lysozyme active site is arranged to cleave oligosaccharides between the fourth and fifth residues. Moreover, since the lysozyme active site can bind at least six monosaccharide units, $(\text{NAG})_6$ would be more tightly bound to the enzyme than $(\text{NAG})_4$, and this additional binding free energy would be applied to distorting the D ring to its half-chair conformation, thereby facilitating the reaction.

Tosyl-L-alanine chloromethylketone or

Tosyl-L-valine chloromethylketone

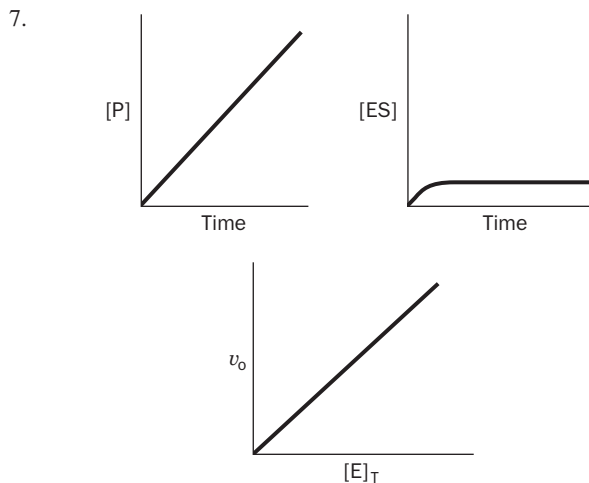

SP-10

23. The ability of RNA molecules to form complex tertiary structures allows them to bind substrates and catalyze reactions through proximity and orientation effects as well as by transition state stabilization, even though RNA lacks a wide variety of functional groups. In addition, the Mg^{2+} ions that RNA normally binds may also have catalytic functions. DNA lacks the 2'-OH functional group that is present in RNA. Moreover, in its double helical form, DNA is conformationally rigid and is therefore unable to form the required complex tertiary structures.
25. Asp 101 and Arg 114 form hydrogen bonds with the substrate molecule (Fig. 11-19). Ala cannot form these hydrogen bonds, so the substituted enzyme is less active.
27. Yes. An enzyme decreases the activation energy barrier for both the forward and the reverse directions of a reaction.
29. If the soybean trypsin inhibitor were not removed from tofu, it would inhibit the trypsin in the intestine. At best, this would reduce the nutritional value of the meal by rendering its protein indigestible. It might very well also lead to intestinal upset.
31. Activated factor IXa leads, via several steps, to the activation of the final coagulation protease, thrombin. The absence of factor IX therefore slows the production of thrombin, delaying clot formation, and causing the bleeding of hemophilia. Although activated factor XIa also leads to thrombin production, factor XI plays no role until it is activated by thrombin itself. By this point, coagulation is already well underway, so a deficiency of factor XI does not significantly delay coagulation.

Chapter 12

1. (a) $v = k[A]$
 $k = v/[A]$
 $k = (5 \mu\text{M} \cdot \text{min}^{-1})/(20 \text{ mM})$
 $= (0.005 \text{ mM} \cdot \text{min}^{-1})/(20 \text{ mM})$
 $= 2.5 \times 10^{-4} \text{ min}^{-1}$
 (b) The reaction has a molecularity of 1.
3. From Eq. 12-7, $[A] = [A]_0 e^{-kt}$. Since $t_{1/2} = 0.693/k$, $k = 0.693/14 \text{ d} = 0.05 \text{ d}^{-1}$. (a) 7 mmol; (b) 5 μmol ; (c) 3.5 μmol ; (d) 0.3 μmol .
5. Only a plot of $1/[\text{reactant}]$ versus t gives a straight line, so the reaction is second order. The slope, k , is $0.15 \text{ mM}^{-1} \cdot \text{s}^{-1}$.

Time (s)	$1/[\text{reactant}](\text{mM}^{-1})$
0	0.16
1	0.32
2	0.48
3	0.62
4	0.78
5	0.91

9. $v_0 = V_{\max}[S]/(K_M + [S])$
 $v_0/V_{\max} = [S]/(K_M + [S])$
 $0.95 = [S]/(K_M + [S])$
 $[S] = 0.95 K_M + 0.95[S]$
 $0.05[S] = 0.95 K_M$
 $[S] = (0.95/0.05)K_M = 19 K_M$
11. Construct a Lineweaver-Burk plot.

- $$K_M = -1/x\text{-intercept} = -1/(-4 \mu\text{M}^{-1}) = 0.25 \mu\text{M}$$
- $$V_{\max} = 1/y\text{-intercept} = 1/(0.8 \text{ mM}^{-1} \cdot \text{s}) = 1.25 \text{ mM} \cdot \text{s}^{-1}$$
13. (a) *N*-Acetyltyrosine ethyl ester, with the lower value of K_M , has greater apparent affinity for chymotrypsin. (b) The value of V_{\max} is not related to the value of K_M , so no conclusion can be drawn.
 15. A^* will appear if the reaction follows a Ping Pong mechanism, since a double-displacement reaction can exchange an isotope from P back to A in the absence of B.
 17. By irreversibly reacting with chymotrypsin's active site, DIFP would decrease $[E]_T$. The apparent V_{\max} would decrease since $V_{\max} = k_{\text{cat}}[E]_T$. K_M would not be affected since the uninhibited enzyme would bind substrate normally.
 19. The lines of the double-reciprocal plots intersect to the left of the $1/v_0$ axis (on the $1/[S]$ axis). Hence, inhibition is mixed (with $\alpha = \alpha'$).

[S]	1/[S]	$1/v_0$	$1/v_0$ with I
1	1.00	0.7692	1.2500
2	0.50	0.5000	0.8333
4	0.25	0.3571	0.5882
8	0.125	0.2778	0.4545
12	0.083	0.2500	0.4167

21. Velocity measurements can be made using any convenient unit of change per unit of time. K_M is, by definition, a substrate concentration (the concentration when $v_o = V_{\max}/2$), so its value does not reflect how the velocity is measured.
23. Comparing the two data points, since a 100-fold increase in substrate concentration only produces a 10-fold increase in reaction velocity, it appears that when $[S] = 100 \text{ mM}$, the velocity is close to V_{\max} . Therefore, assume that $V_{\max} \approx 50 \mu\text{M} \cdot \text{s}^{-1}$ and use the other data point to estimate K_M using the Michaelis-Menten equation:

$$v_o = \frac{V_{\max} [S]}{K_M + [S]}$$

$$K_M + [S] = \frac{V_{\max} [S]}{v_o}$$

$$K_M = \frac{V_{\max} [S]}{v_o} - [S]$$

$$K_M = \frac{(50 \mu\text{M} \cdot \text{s}^{-1})(1 \mu\text{M})}{(5 \mu\text{M} \cdot \text{s}^{-1})} - (1 \mu\text{M}) = 9 \mu\text{M}$$

The true V_{\max} must be greater than the estimated value, so the value of K_M is an underestimate of the true K_M .

25. The enzyme concentration is comparable to the lowest substrate concentration and therefore does not meet the requirement that $[E] \ll [S]$. You could fix this problem by decreasing the amount of enzyme used for each measurement.
27. If an irreversible inhibitor is present, the enzyme solution's activity would be exactly 100 times lower when the sample is diluted 100-fold. Dilution would not significantly change the enzyme's degree of inhibition.
29. (a) Inhibition is most likely mixed (noncompetitive) with $\alpha = \alpha'$ since it is reversible and only V_{\max} is affected.
 (b) Since $V_{\max}^{\text{app}} = 0.8 V_{\max}$, 80% of the enzyme remains uninhibited. Therefore, 20% of the enzyme molecules have bound inhibitor.
 (c) As indicated in Table 12-2 for mixed inhibition, $V_{\max}^{\text{app}} = V_{\max}/\alpha'$. Thus,

$$\alpha' = \frac{V_{\max}}{V_{\max}^{\text{app}}} = \frac{1}{0.8} = 1.25$$

From Eq. 12-32,

$$1.25 = 1 + \frac{[I]}{K'_I}$$

$$K'_I = \frac{5 \text{ nM}}{1.25 - 1} = 20 \text{ nM}$$

31. Since the molecular mass of methanol (MeOH) is 32 D, 100 mL of methanol in 40 L of solution has the concentration

$$[\text{MeOH}] = \frac{100 \text{ mL} \times 0.79 \text{ g} \cdot \text{mL}^{-1}}{32 \text{ g} \cdot \text{mol}^{-1} \times 40 \text{ L}} = 0.062 \text{ M}$$

Ethanol (EtOH) is a competitive inhibitor of methanol with LADH.

$$v_o(\text{uninhibited}) = \frac{V_{\max} [S]}{K_M + [S]}$$

$$v_o(\text{inhibited}) = \frac{V_{\max} [S]}{\alpha K_M + [S]}$$

where $\alpha = \left(1 + \frac{[I]}{K_I}\right)$, $[\text{MeOH}] = [S]$, and $K_M = 0.01 \text{ M}$.

We require that

$$\frac{v_o(\text{inhibited})}{v_o(\text{uninhibited})} = 0.05 = \frac{K_M + [\text{MeOH}]}{\alpha K_M + [\text{MeOH}]}$$

$$0.05 = \frac{0.01 + 0.062}{0.01\alpha + 0.062}$$

$$0.0005\alpha + 0.0031 = 0.072$$

$$\alpha = 138 = \left(1 + \frac{[I]}{K_I}\right)$$

$$[I] = (138 - 1)K_I = 137K_I = 137 \times 1.0 \times 10^{-3}$$

$$[I] = 0.137 \text{ M} = [\text{EtOH}]$$

Mol EtOH = $0.137 \text{ M} \times 40 \text{ L} = 5.48 \text{ mol}$

Molecular mass EtOH = 46 D

$$\text{Mass EtOH} = 46 \text{ g} \cdot \text{mol}^{-1} \times 5.48 \text{ mol} = 252 \text{ g}$$

$$\text{Volume pure EtOH} = \frac{252 \text{ g}}{0.79 \text{ g} \cdot \text{mL}^{-1}} = 319 \text{ mL}$$

Since 100 proof whiskey is 50% ethanol by volume, it is necessary to imbibe $2 \times 319 \text{ mL} = 638 \text{ mL}$ (which is about 5/6 of a "fifth" of whiskey).

Chapter 13

- Somatostatin is a 14-residue peptide hormone and is not lipid-soluble, so it would require a cell-surface receptor.
- (a) Norepinephrine is synthesized by the decarboxylation of Tyr and by hydroxylation of its β carbon and its phenyl group. (b) Epinephrine is derived from norepinephrine by *N*-methylation.
- A plot of fractional saturation (Y) versus $[L]$ yields a hyperbola where the estimated value of 0.5 Y corresponds to a ligand concentration, or K_L , of about $3.5 \mu\text{M}$.

SP-12

9. The SH2 domain allows the enzyme to bind to phospho-Tyr residues on its target proteins. Because targets typically contain more than one phospho-Tyr group, the phosphatase can recognize and bind to one site on the target protein while dephosphorylating another site on the same protein.
11. Transformation to the cancerous state results from several genetic changes in a cell. Thus, a single oncogene supplied to an otherwise normal cell will be insufficient to transform it. However, an immortalized cell already has some of the genetic changes necessary for transformation (malignant cells are also immortal). In such cells, the additional oncogene may be all they require to complete their transformation.
13. Because the GTP analog cannot be hydrolyzed, G_{α} remains active. Analog binding to G_s therefore increases cAMP production. Analog binding to G_i decreases cAMP production.
15. Like cholera toxin, *B. anthracis* EF leads to the overproduction of cAMP which triggers the release of fluid from cells. The result is edema.
17. Diacylglycerol kinase converts DAG to phosphatidic acid (Section 9-1C).
19. Li^+ blocks the conversion of phosphorylated inositol species to inositol, thereby preventing the recycling of IP_3 and its degradation products back to inositol. This in turn prevents the synthesis of phosphatidylinositol and PIP_2 , the precursor of the IP_3 second messenger.
21. Use Equation 13-8, letting $[L] = 1 \mu M$ and $[B] = [I_{50}] = 2.5 \mu M$,

$$K_I = \frac{[I_{50}]}{\left(1 + \frac{[L]}{K_L}\right)} = \frac{(2.5 \times 10^{-6})}{\left(1 + \frac{(1 \times 10^{-6})}{(5 \times 10^{-6})}\right)} = \frac{2.5 \times 10^{-6}}{1.2} = 2.1 \mu M$$

23. The PH domain allows the IRS to be localized to the intracellular leaflet of the cell membrane, close to the insulin receptor and ready to participate in signal transduction. The PTB domain, like an SH2 domain, recognizes phospho-Tyr residues, in this case on the autophosphorylated insulin receptor. As a result, the IRS can be activated following insulin binding to its receptor. The phospho-Tyr residues on the IRS itself are recognition points for SH2-containing proteins, which can thereby become activated.
25. (a) Yes, because the binding of Src's SH3 domain to the linker that connects its SH2 domain to the N-terminal lobe of its PTK domain is required for Src to maintain its autoinhibited conformation. Hence, the deletion of this SH3 domain would constitutively activate Src, thereby driving the cell with this mutation to a state of unrestrained proliferation.
- (b) No, because the phosphorylation of Tyr 416 is required for the activation of Src and hence the Y416F mutation would inhibit the mutant cell's proliferation.
27. When $G_{s\alpha}$ catalyzes the hydrolysis of its bound GTP to $GDP + P_i$, the Arg side chain that cholera toxin ADP-ribosylates functions to

stabilize the transition state's developing negative charge. The ADP-ribosylated $G_{s\alpha}$ therefore hydrolyzes its bound GTP at a greatly reduced rate and hence remains activated far longer than normal $G_{s\alpha}$. Mutating this Arg will have a similar effect. Consequently, in cells in which a $G_{s\alpha}$ GTP functions to induce cell proliferation, mutating this Arg will drive the cell into a state of unrestrained proliferation, a requirement for the malignant transformation of the cell. The gene encoding such a $G_{s\alpha}$ subunit is a proto-oncogene and the mutation of its Arg residue converts it to an oncogene.

29. No. Although the diacylglycerol second messengers are identical, phosphatidylethanolamine does not generate an IP_3 second messenger that triggers the release of Ca^{2+} , which in turn alters protein kinase C activity.
31. (a) The positively charged Ca^{2+} ions bind to negatively charged lipids at the membrane surface. This disrupts the electrostatic interactions between CD3 and the membrane so that the proteins dissociate from the membrane and expose their Tyr side chains to the NRTKs for phosphorylation. (b) This is an example of feed-forward activation: the binding of antigen initiates signaling that leads to Ca^{2+} influx, which in turn promotes additional events (phosphorylation of the CD3 proteins); the two-step mechanism means a stronger cellular response to the antigen.

Chapter 14

1. A heterotroph relies on other organisms for food, which may include substances the heterotroph cannot synthesize (including vitamins). An autotroph can produce all the molecules it needs.
3. Arsenic, which resembles phosphorus, is incorporated into nucleic acids and other compounds that ordinarily contain phosphate groups.
5. C, D, A, E, B
7. (a) $K = e^{-\Delta G^{\circ}/RT}$
 $K = e^{-(-31,500 \text{ J}\cdot\text{mol}^{-1})/(8.3145 \text{ J}\cdot\text{K}^{-1}\cdot\text{mol}^{-1})(310 \text{ K})}$
 $K = 2.0 \times 10^5$
- (b) The large change in free energy makes the citrate synthase reaction irreversible, so it could (and does; Section 17-4B) serve as a control point for the citric acid cycle.
9. We can assume that ATP's three phosphoryl groups behave like phosphoric acid, which has three pK values (2.15, 6.82, and 12.38). At physiological pH (7.4), ionization of the first proton on each phosphoryl group is complete (since its pK value is 2.15), and ionization of the second proton (if present) is more than halfway complete (since pH 7.4 is greater than the pK value of 6.82). Therefore the net charge of an ATP molecule is between -3.5 and -4 .
11. The theoretical maximum yield of ATP is equivalent to $(\Delta G^{\circ} \text{ for fuel oxidation})/(\Delta G^{\circ} \text{ for ATP synthesis}) = (-2850 \text{ kJ}\cdot\text{mol}^{-1})/(-30.5 \text{ kJ}\cdot\text{mol}^{-1}) \approx 93 \text{ ATP}$
13. The exergonic hydrolysis of PP_i by pyrophosphatase ($\Delta G^{\circ} = -19.2 \text{ kJ}\cdot\text{mol}^{-1}$) drives fatty acid activation.
15. The more positive the reduction potential, the greater the oxidizing power. From Table 14-4,

Compound	$\mathcal{E}^{\circ}(\text{V})$
SO_4^{2-}	-0.515
Acetoacetate	-0.346
NAD^+	-0.315
Pyruvate	-0.185
Cytochrome <i>b</i> (Fe^{3+})	0.077

17. Using the data in Table 14-4:

$$\begin{aligned}\Delta \mathcal{E}^{\circ'} &= \mathcal{E}^{\circ'}(e^- \text{ acceptor}) - \mathcal{E}^{\circ'}(e^- \text{ donor}) = \mathcal{E}^{\circ'}(\text{fumarate}) - \mathcal{E}^{\circ'}(\text{NAD}^+) \\ &= 0.031 \text{ V} - (-0.315 \text{ V}) = 0.346 \text{ V}\end{aligned}$$

Because $\Delta \mathcal{E}^{\circ'} > 0$, $\Delta G^{\circ'} < 0$ and the reaction will spontaneously proceed as written.

19. Probably not. Although all cells carry out a similar set of basic metabolic reactions, the enzymes that catalyze the reactions have different amino acid sequences and hence different gene sequences. cDNAs produced from mammalian mRNAs would be unlikely to hybridize with bacterial DNA segments.

21. Unlike nucleic acids, metabolites cannot be amplified, and metabolite structures are not encoded by genetic information. In addition, attaching a large fluorescent molecule to a metabolite might alter its biological activity.

23. (a) Since $\Delta G^{\circ'} = -RT \ln K$,

$$\begin{aligned}K &= e^{-\Delta G^{\circ'}/RT} \\ K &= e^{-(7500 \text{ J} \cdot \text{mol}^{-1})/(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K})} \\ K &= 0.048\end{aligned}$$

$$(b) \Delta G = \Delta G^{\circ'} + RT \ln \frac{[B]}{[A]}$$

$$\begin{aligned}\Delta G &= 7500 \text{ J} \cdot \text{mol}^{-1} \\ &+ (8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K}) \ln \frac{(0.0001)}{(0.0005)}\end{aligned}$$

$$\begin{aligned}\Delta G &= 7500 \text{ J} \cdot \text{mol}^{-1} - 4150 \text{ J} \cdot \text{mol}^{-1} \\ \Delta G &= 3350 \text{ J} \cdot \text{mol}^{-1} = 3.35 \text{ kJ} \cdot \text{mol}^{-1}\end{aligned}$$

The reaction is not spontaneous since $\Delta G > 0$.

(c) The reaction can proceed in the cell if the product B is the substrate for a second reaction such that the second reaction continually draws off B, causing the first reaction to continually produce more B from A.

25. At pH 6, the phosphate groups are more ionized than they are at pH 5, which increases their electrostatic repulsion and therefore increases the magnitude of ΔG for hydrolysis (makes it more negative).

27. Calculating ΔG for the reaction $\text{ATP} + \text{creatine} \rightleftharpoons \text{phosphocreatine} + \text{ADP}$, using Eq. 14-1:

$$\begin{aligned}\Delta G &= \Delta G^{\circ'} + RT \ln \left(\frac{[\text{phosphocreatine}][\text{ADP}]}{[\text{creatine}][\text{ATP}]} \right) \\ &= 12.6 \text{ kJ} \cdot \text{mol}^{-1} + (8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K}) \\ &\quad \ln \left(\frac{(2.5 \text{ mM})(0.15 \text{ mM})}{(1 \text{ mM})(4 \text{ mM})} \right) \\ &= 12.6 \text{ kJ} \cdot \text{mol}^{-1} - 5.9 \text{ kJ} \cdot \text{mol}^{-1} = 6.7 \text{ kJ} \cdot \text{mol}^{-1}\end{aligned}$$

Since $\Delta G > 0$, the reaction will proceed in the opposite direction as written above, that is, in the direction of ATP synthesis.

31. The ubiquinone half-reaction has a higher reduction potential (0.045 V) than the NAD^+ half-reaction (-0.315 V). Therefore, electrons will flow from NADH (which becomes oxidized) to ubiquinone (which becomes reduced).

33. The balanced equation is

Using the data in Table 14-4,

$$\begin{aligned}\Delta \mathcal{E}^{\circ'} &= \mathcal{E}^{\circ'}(e^- \text{ acceptor}) - \mathcal{E}^{\circ'}(e^- \text{ donor}) = 0.235 \text{ V} - 0.045 \text{ V} \\ &= 0.190 \text{ V}\end{aligned}$$

$$\begin{aligned}\Delta G^{\circ'} &= -n\mathcal{F}\Delta \mathcal{E}^{\circ'} = -(2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(0.190 \text{ V}) \\ &= -36.7 \text{ kJ} \cdot \text{mol}^{-1}\end{aligned}$$

Chapter 15

1. (a) Reactions 1, 3, 7, and 10; (b) Reactions 2, 5, and 8; (c) Reaction 6; (d) Reaction 9; (e) Reaction 4.

3. This reaction resembles Step 4 of glycolysis and is carried out by an aldolase, which links dihydroxyacetone phosphate to an aldehyde (erythrose-4-phosphate).

5. C1 of DHAP and C1 of GAP are achiral but become chiral in FBP (as C3 and C4). There are four stereoisomeric products that differ in configuration at C3 and C4: fructose-1,6-bisphosphate, psicose-1,6-bisphosphate, tagatose-1,6-bisphosphate, and sorbose-1,6-bisphosphate (see Fig. 8-2).

7. The reaction intermediate is glucose-1,6-bisphosphate (G1,6P).

9. Alcoholic fermentation, unlike homolactic fermentation, includes a step (the pyruvate decarboxylase reaction) in which a carbon is lost as CO_2 . Because the CO_2 diffuses (bubbles) away, the reaction cannot proceed in reverse.

11. ΔG values differ from $\Delta G^{\circ'}$ values because $\Delta G = \Delta G^{\circ'} + RT \ln[\text{products}]/[\text{reactants}]$ and cellular reactants and products are not in their standard states.

13. Pyruvate kinase regulation is important for controlling the flux of metabolites, such as fructose (in liver), which enter glycolysis after the PFK step.

15. The high glycolytic flux rapidly generates the ATP needed for cell growth and division.

17. The three glucose molecules that proceed through glycolysis yield 6 ATP. The bypass through the pentose phosphate pathway results in a yield of 5 ATP.

1,2-Enediolate intermediate

21. Transketolase transfers 2-carbon units from a ketose to an aldose, so the products are a 3-carbon sugar and a 7-carbon sugar.

23. (a) $\text{Glucose} + 2 \text{ NAD}^+ + 2 \text{ ADP} + 2 \text{ P}_i \rightarrow 2 \text{ pyruvate} + 2 \text{ NADH} + 2 \text{ ATP} + 2 \text{ H}_2\text{O}$

(b) $\text{Glucose} + 2 \text{ NAD}^+ + 2 \text{ ADP} + 2 \text{ AsO}_4^{3-} \rightarrow 2 \text{ pyruvate} + 2 \text{ NADH} + 2 \text{ ADP} + 2 \text{ AsO}_3^{2-} + 2 \text{ H}_2\text{O}$

Overall: $\text{Glucose} + 2 \text{ NAD}^+ \rightarrow 2 \text{ pyruvate} + 2 \text{ NADH}$

SP-14

- (c) Arsenate is a poison because it uncouples ATP generation from glycolysis. Consequently, glycolytic energy generation cannot occur.
25. (a) The volume of the balloon would increase as the yeast produce CO₂ by fermenting the sugar. (b) The balloon would not inflate because iodoacetate inhibits the activity of GAPDH and prevents fermentation. (c) Because yeast do not normally metabolize lactose (milk sugar), the balloon would inflate much more slowly than if sucrose were present.
27. When [GAP] = 10⁻⁴ M, [DHAP] = 5.5 × 10⁻⁴ M. According to Eq. 1-17,

$$K = e^{-\Delta G^{\circ}/RT}$$

$$\frac{[\text{GAP}][\text{DHAP}]}{[\text{FBP}]} = e^{-(22,800 \text{ J} \cdot \text{mol}^{-1})/(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol})(310 \text{ K})}$$

$$\frac{(10^{-4})(5.5 \times 10^{-4})}{[\text{FBP}]} = 1.4 \times 10^{-4}$$

$$[\text{FBP}] = 3.8 \times 10^{-4} \text{ M}$$

$$[\text{FBP}]/[\text{GAP}] = (3.8 \times 10^{-4} \text{ M})/(10^{-4} \text{ M}) = 3.8$$

29. Galactokinase, which catalyzes a highly exergonic reaction, is a possible control point. Because galactose enters the glycolytic pathway as glucose-6-phosphate, the PFK reaction is also likely to be a major control point.
31. (a) Glycerol can be converted to the glycolytic intermediate DHAP by the activity of glycerol kinase and glycerol phosphate dehydrogenase (Fig. 15-27). (b) One ATP is consumed by the glycerol kinase reaction, but two ATP are produced (by the PGK and PK reactions), for a net yield of one ATP per glycerol (this does not count the ATP that might be generated through oxidative phosphorylation from the NADH produced in the glycerol phosphate dehydrogenase reaction).
33. Even when the flux of glucose through glycolysis and hence the citric acid cycle is blocked, glucose can be oxidized by the pentose phosphate pathway, with the generation of CO₂.
35. (a) Reaction 8, (b) Reaction 5, (c) Reaction 1, (d) Reaction 2, (e) Reaction 3.

Chapter 16

- Glycogen is broken down when the cell needs to catabolize glucose to produce ATP. The G1P generated by the glycogen phosphorylase reaction is quickly isomerized to G6P and enters glycolysis. The continual consumption of G1P “pulls” the phosphorylase reaction forward, making it thermodynamically favorable.
- Phosphoglucokinase activity generates G1,6P, which is necessary to “prime” phosphoglucomutase that has become dephosphorylated and thereby inactivated through the loss of its G1,6P reaction intermediate.
- The conversion of circulating glucose to lactate in the muscle generates 2 ATP. If muscle glycogen could be mobilized, the energy yield would be 3 ATP, since phosphorylase of glycogen bypasses the hexokinase-catalyzed step that consumes ATP in the first stage of glycolysis.
- A glycogen molecule with 28 tiers would represent the most efficient arrangement for storing glucose, and its outermost tier would contain considerably more glucose residues than a glycogen molecule with only 12 tiers. However, densely packed glucose residues would be inaccessible to phosphorylase. In fact, such a dense glycogen molecule could not be synthesized because glycogen synthase and branching enzyme would have no room to operate (see Box 16-3 for a discussion of glycogen structure).

- (a) Circulating [glucose] is high because cells do not respond to the insulin signal to take up glucose. (b) Insulin is unable to activate phosphoprotein phosphatase-1 in muscle, so glycogen synthesis is not stimulated. Moreover, glycogen synthesis is much reduced by the lack of available glucose in the cell.
- During the domestication process, wolves, which are carnivores, would have been provided with grain-based (starchy) foods produced by humans. Additional amylase genes would have made starch digestion more efficient, giving the animals a survival advantage.
- The equation for glycolysis is
Glucose + 2 NAD⁺ + 2 ADP + 2 P_i →
2 pyruvate + 2 NADH + 4 H⁺ + 2 ATP + 2 H₂O
The equation for gluconeogenesis is
2 Pyruvate + 2 NADH + 4 H⁺ + 4 ATP + 2 GTP + 6 H₂O →
glucose + 2 NAD⁺ + 4 ADP + 2 GDP + 6 P_i
For the two processes operating sequentially,
2 ATP + 2 GTP + 4 H₂O → 2 ADP + 2 GDP + 4 P_i
- (a) +9 ATP, (b) +6 ATP, (c) -18 ATP.
- (a) At the beginning of a fast, blood glucose levels are normal, because dietary sources or glycogenolysis can supply glucose. (b) After a fast, the blood glucose levels are very low, because dietary glucose and glycogen have been depleted and gluconeogenesis is impaired due to the fructose-1,6-bisphosphatase deficiency.
- PFK-2 converts fructose-6-phosphate to fructose-2,6-bisphosphate, an allosteric activator of PFK-1. The result is increased glycolytic flux to generate the ATP to power cell division during angiogenesis.
- (a) Microorganisms that produce fucosidase can cleave fucose residues from the glycoproteins, thereby obtaining a source of free energy from the host. (b) The pathogens cannot use this food source and therefore are less likely to survive when no other food is available.
- In the course of glucose catabolism, a detour through glycogen synthesis and glycogen breakdown begins and ends with G6P. The energy cost of this detour is 1 ATP equivalent, consumed in the UDP-glucose pyrophosphorylase step. The overall energy lost is therefore 1/32 or ~3%.
- (a) Aspartate can be transaminated to produce oxaloacetate, a gluconeogenic precursor. (b) To convert 2 aspartate to glucose, 2 GTP are consumed in the PEPCK reaction and 2 ATP are consumed in the phosphoglycerate kinase reaction, for a total of 4 ATP equivalents.
- The reactions catalyzed by pyruvate carboxylase and phosphoenolpyruvate carboxykinase are phosphate transfer reactions.
- A high level of AMP results from a high rate of ATP consumption in the cell, so it would act to promote flux through ATP-generating pathways such as glycolysis. Therefore, AMP would be expected to inhibit the activity of the gluconeogenic enzyme fructose-1,6-bisphosphatase.
- UDP-Glucose + fructose-6-phosphate

33. The first tier has $2^1 - 1 = 1$ branch; the 2nd tier has $2^{2-1} = 2$ branches for a total of $2 + 1 = 3 = 2^2 - 1$ branches through that tier; the 3rd tier has $2^{3-1} = 4$ branches for a total of $4 + 3 = 7 = 2^3 - 1$ branches through that tier; etc. Hence in n tiers, there are a total of $2^n - 1$ branches. The particle therefore has a total of $2^{12} - 1$ branches of 13 residues each for a total of $(2^{12} - 1) \times 13 = 53,235$ glucose residues.

Chapter 17

- The labeled carbon becomes C4 of the succinyl moiety of succinyl-CoA. Because succinate is symmetrical, the label appears at C1 and C4 of succinate. When the resulting oxaloacetate begins the second round, the labeled carbons appear as $^{14}\text{CO}_2$ in the isocitrate dehydrogenase and the α -ketoglutarate dehydrogenase reactions (see Fig. 17-2).
- In mammals, pyruvate can be converted to lactate (reduction), to alanine (transamination), to acetyl-CoA (oxidative decarboxylation), and to oxaloacetate (carboxylation). In yeast, pyruvate is also converted to acetaldehyde (decarboxylation).
- The decarboxylation step is most likely to be metabolically irreversible since the CO_2 product is rapidly hydrated to bicarbonate. The reverse reaction, a carboxylation, requires the input of free energy to become favorable (Section 16-4A). The other four reactions are transfer reactions or oxidation–reduction reactions (transfer of electrons) that are more easily reversed.
- Unlike the CO_2 generated by the pyruvate dehydrogenase complex, the formate produced in the reaction is a charged molecule and therefore does not diffuse out of the cell. Instead, it can be used for other biosynthetic reactions.

- Competitive inhibition can be overcome by adding more substrate—in this case, succinate. Oxaloacetate overcomes malonate inhibition because it is converted to succinate by the reactions of the citric acid cycle.
- The $\Delta G^{\circ'}$ value is the sum of the $\Delta G^{\circ'}$ values for the malate dehydrogenase reaction ($29.7 \text{ kJ} \cdot \text{mol}^{-1}$) and the citrate synthase reaction ($-31.5 \text{ kJ} \cdot \text{mol}^{-1}$): $-1.8 \text{ kJ} \cdot \text{mol}^{-1}$.
- From Table 17-2, for the succinate dehydrogenase reaction, $\Delta G^{\circ'} = 6 \text{ kJ} \cdot \text{mol}^{-1}$ and $\Delta G = \sim 0$.

$$\Delta G = \Delta G^{\circ'} + RT \ln \left(\frac{[\text{fumarate}]}{[\text{succinate}]} \right)$$

$$\Delta G^{\circ'} = -RT \ln \left(\frac{[\text{fumarate}]}{[\text{succinate}]} \right)$$

$$\left(\frac{[\text{fumarate}]}{[\text{succinate}]} \right) = e^{-\Delta G^{\circ'}/RT}$$

$$= e^{-(6000 \text{ J} \cdot \text{mol}^{-1})/(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(310 \text{ K})}$$

$$= e^{-2.33} = 0.10$$

- When pyruvate concentrations rise, indicating a need for increased flux through the citric acid cycle, some of the pyruvate is carboxylated to produce oxaloacetate to boost the cycle's capacity. If this step cannot occur, then excess pyruvate is converted to lactate instead.
- (a) Because citric acid cycle intermediates such as citrate and succinyl-CoA are precursors for the biosynthesis of other compounds, anaerobes must be able to synthesize them.
(b) These organisms do not need a complete citric acid cycle, which would yield reduced coenzymes that must be reoxidized.

- NAD^+ ($\mathcal{E}^{\circ'} = -0.315 \text{ V}$) does not have a high enough reduction potential to support oxidation of succinate to fumarate ($\mathcal{E}^{\circ'} = +0.031 \text{ V}$); that is, the succinate dehydrogenase reaction has insufficient free energy to reduce NAD^+ . Enzyme-bound FAD ($\mathcal{E}^{\circ'} \approx 0$) is more suitable for oxidizing succinate.
- The phosphofructokinase reaction is the major flux-control point for glycolysis. Inhibiting phosphofructokinase slows the entire pathway, so the production of acetyl-CoA by glycolysis followed by the pyruvate dehydrogenase complex can be decreased when the citric acid cycle is operating at maximum capacity and the citrate concentration is high. As citric acid cycle intermediates are consumed in synthetic pathways, the citrate concentration drops, relieving phosphofructokinase inhibition and allowing glycolysis to proceed in order to replenish the citric acid cycle intermediates.

- To synthesize citrate, pyruvate must be converted to oxaloacetate by pyruvate carboxylase:

A second pyruvate is converted to acetyl-CoA by pyruvate dehydrogenase:

The acetyl-CoA then combines with oxaloacetate to produce citrate:

The net reaction is

- The malic enzyme reaction yields reducing power in the form of NADPH, which is required for many biosynthetic processes (Section 15-6).
- First, the six-carbon isocitrate is decarboxylated to α -ketoglutarate. Next, glutamate dehydrogenase catalyzes reductive amination to produce glutamate. Finally, glutamate is isomerized to methylaspartate.

- Mitochondria with more cristae have more surface area and therefore more proteins for electron transport and oxidative phosphorylation. Tissues with a high demand for ATP synthesis (such as heart) contain mitochondria with more cristae than tissues with lower demand for oxidative phosphorylation (such as liver).
- When NADH participates in the glycerophosphate shuttle, the electrons of NADH flow to FAD and then to CoQ, bypassing Complex I. Thus, about 1.5 ATP are synthesized per NADH.
- If the mitochondrial electron-transport chain cannot function normally, then cells cannot rely on oxidative phosphorylation to meet their ATP needs. Instead, glycolysis occurs at a high rate, which helps generate the necessary ATP but also produces lactate as an end product.
- The relevant half-reactions (Table 14-4) are

$$\text{FAD} + 2 \text{H}^+ + 2 e^- \rightleftharpoons \text{FADH}_2 \quad \mathcal{E}^{\circ'} = -0.219 \text{ V}$$

$$\frac{1}{2} \text{O}_2 + 2 \text{H}^+ + 2 e^- \rightleftharpoons \text{H}_2\text{O} \quad \mathcal{E}^{\circ'} = 0.815 \text{ V}$$

Since the $\text{O}_2/\text{H}_2\text{O}$ half-reaction has the more positive $\Delta\mathcal{E}^{\circ'}$, the FAD half-reaction is reversed and the overall reaction is

$$\frac{1}{2} \text{O}_2 + \text{FADH}_2 \rightleftharpoons \text{H}_2\text{O} + \text{FAD}$$

$$\Delta\mathcal{E}^{\circ'} = 0.815 \text{ V} - (-0.219 \text{ V}) = 1.034 \text{ V}$$

Since $\Delta G^{\circ'} = -n\mathcal{F}\Delta\mathcal{E}^{\circ'}$,

$$\Delta G^{\circ'} = -(2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(1.034 \text{ V}) = -200 \text{ kJ} \cdot \text{mol}^{-1}$$

The maximum number of ATPs that could be synthesized under standard conditions is therefore $200 \text{ kJ} \cdot \text{mol}^{-1}/30.5 \text{ kJ} \cdot \text{mol}^{-1} = 6.6 \text{ mol ATP/mol FADH}_2$ oxidized by O_2 .
- Vitamin K resembles ubiquinone and is likely to play a similar role as a membrane-soluble carrier that delivers electrons from Complexes I and II to Complex III.
- Cytochrome *c* has several positively charged lysine residues on its surface (Fig. 18-16), which would allow it to interact electrostatically with cardiolipin, which has a net charge of -2 (Table 9-2).
- NO_3^- is the electron acceptor and NADH is the electron donor. Their standard reduction potentials are listed in Table 14-4.

$$\begin{aligned} \Delta\mathcal{E}^{\circ'} &= \mathcal{E}^{\circ'}_{(\text{NO}_3^-)} - \mathcal{E}^{\circ'}_{(\text{NADH})} \\ &= (0.42 \text{ V}) - (-0.315 \text{ V}) = 0.735 \text{ V} \\ \Delta G &= -n\mathcal{F}\Delta\mathcal{E} \\ &= -(2)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(0.735 \text{ V}) \\ &= -142,000 \text{ J} \cdot \text{mol}^{-1} = -142 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$

Since the standard free energy change for ATP synthesis is $30.5 \text{ kJ} \cdot \text{mol}^{-1}$, approximately $142/30.5 = 4.6$ ATP could be synthesized.

- \mathcal{E} may differ from $\mathcal{E}^{\circ'}$, depending on the redox center's micro-environment and the concentrations of reactants and products. In addition, the tight coupling between successive electron transfers within a complex may "pull" electrons so that the overall process is spontaneous.

- The import of ADP (net charge -3) and the export of ATP (net charge -4) represents a loss of negative charge from inside the mitochondrion. This decreases the difference in electrical charge across the membrane, since the outside is positive due to the translocation of protons during electron transport. Consequently, the electrochemical gradient is diminished by the activity of the ADP-ATP translocator. The activity of the $\text{P}_i\text{-H}^+$ symport protein diminishes the proton gradient by allowing protons from the intermembrane space to re-enter the matrix.
- The protonation and subsequent deprotonation of Asp 61 of the F_1F_0 -ATPase's *c* subunits induces the rotation of the *c*-ring, which in turn, mechanically drives the synthesis of ATP. DCCD reacts with Asp 61 in a manner that prevents it from binding a proton and thereby prevents the synthesis of ATP.
- DNP and related compounds dissipate the proton gradient required for ATP synthesis. The dissipation of the gradient decreases the rate of synthesis of ATP, decreasing the ATP mass action ratio. Decreasing this ratio relieves the inhibition of the electron transport chain, causing an increase in metabolic rate.
- The switch to aerobic metabolism allows ATP to be produced by oxidative phosphorylation. The phosphorylation of ADP increases the $[\text{ATP}]/[\text{ADP}]$ ratio, which then increases the $[\text{NADH}]/[\text{NAD}^+]$ ratio because a high ATP mass action ratio slows electron transport. The increases in $[\text{ATP}]$ and $[\text{NADH}]$ inhibit their target enzymes in glycolysis and the citric acid cycle (Fig. 18-30) and thereby slow these processes.
- Glucose is shunted through the pentose phosphate pathway to provide NADPH, whose electrons are required to reduce O_2 to O_2^- .

(a) O_2 consumption ceases because amytal blocks electron transport in Complex I.

(b) Electrons from succinate bypass the amytal block by entering the electron-transport chain at Complex II and thereby restore electron transport through Complexes III and IV.

- For the transport of a proton from outside to inside (Eq. 18-1),

$$\Delta G = 2.3 RT [\text{pH}(\text{side } 1) - \text{pH}(\text{side } 2)] + Z\mathcal{F}\Delta\Psi$$

The difference in pH is -1.4 . Since an ion is transported from the positive to the negative side of the membrane, $\Delta\Psi$ is negative.

$$\begin{aligned} \Delta G &= (2.3)(8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K})(-1.4) \\ &\quad + (1)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(-0.06 \text{ V}) \end{aligned}$$

$$\Delta G = -7980 \text{ J} \cdot \text{mol}^{-1} - 5790 \text{ J} \cdot \text{mol}^{-1} = -13.8 \text{ kJ} \cdot \text{mol}^{-1}$$

- (a) NAD^+ and NADP^+ have similar standard reduction potentials ($\mathcal{E}^{\circ'}$ values of -0.315 V and -0.320 V , respectively; Table 14-4), so it is unlikely that the value of $\Delta\mathcal{E}$ under cellular conditions would generate a large value of ΔG . (b) The NNT reaction reduces the efficiency of oxidative phosphorylation by consuming NADH that could otherwise pass electrons to the electron-transport chain, and by translocating a proton that could otherwise help drive the rotation of ATP synthase.

35. In an ATP synthase with more c subunits, more proton translocation events are required to drive one complete rotation of the c -ring. Consequently, more substrate oxidation (O_2 consumption) is required to synthesize three ATP (the yield of one cycle of the rotary engine), and the P/O ratio is lower.
(b) $15/3 = 5$ protons are required to synthesize 1 ATP.
37. Oxygen consumption will decrease when α -ketoglutarate levels increase because the activity of ATP synthase is coupled to the activity of the electron transport chain, which includes the O_2 -consuming Complex IV.
39. The dead algae are a source of food for aerobic microorganisms lower in the water column. As the growth of these organisms increases, the rate of respiration and O_2 consumption increase to the point where the concentration of O_2 in the water becomes too low to sustain larger aerobic organisms.
41. (a) Antimycin A binds to the Q_i site of cytochrome bc_1 . This blocks the binding of CoQ to this site and hence prevents its reduction by heme b_H . However, a simplistic interpretation of the Q cycle (Fig. 18-15) might suggest that this would not prevent $CoQH_2$ at the Q_o site from reducing cytochrome c_1 via the iron-sulfur protein (ISP) and shedding its two protons in the intermembrane space, thereby pumping 50% of the four protons that it does in the absence of inhibitor.
(b) The foregoing scenario implicitly assumes that either (1) CoQ^- is released from the Q_o site to allow subsequent rounds of the Q cycle's first cycle and that the CoQ^- is then reconverted to $CoQH_2$ by Complex I and/or Complex II without binding protons from the intermembrane space; or (2) that CoQ^- is able to reduce the ISP (which, in turn, reduces cytochrome c_1) and is then released as CoQ. However, since CoQ^- binds in a different subsite of Q_o than does $CoQH_2$, it is both unlikely that CoQ^- would be readily released by Q_o and that the ISP would be in a position to be reduced by CoQ^- . Hence neither of these scenarios appears to be correct.

Chapter 19

- $2 H_2O + 2 NADP^+ \rightarrow 2 NADPH + 2 H^+ + O_2$
- The color of the seawater indicates that the photosynthetic pigments of the algae absorb colors of visible light other than red.
- The energy per photon is $E = hc/\lambda$, so the energy per mole of photons ($\lambda = 700 \text{ nm}$) is

$$\begin{aligned} E &= Nhc/\lambda \\ &= (6.022 \times 10^{23} \text{ mol}^{-1})(6.626 \times 10^{-34} \text{ J} \cdot \text{s}) \\ &\quad (2.998 \times 10^8 \text{ m} \cdot \text{s}^{-1})/(7 \times 10^{-7} \text{ m}) \\ &= 1.71 \times 10^5 \text{ J} \cdot \text{mol}^{-1} \\ &= 171 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$
- The order of action is water-plastoquinone oxidoreductase (Photosystem II), plastoquinone-plastocyanin oxidoreductase (cytochrome b_6f), and plastocyanin-ferredoxin oxidoreductase (Photosystem I).
- Both systems mediate cyclic electron flows. The photooxidized bacterial reaction center passes electrons through a series of electron carriers so that electrons return to the reaction center (e.g., P960⁺) and restore it to its original state. During cyclic electron flow in PSI, electrons from photooxidized P700 are transferred to cytochrome b_6f and, via plastoquinone and plastocyanin, back to P700. In both cases, there is no net change in the redox state of the reaction center, but the light-driven electron movements are accompanied by the transmembrane movement of protons.
- The change in reduction potential is about -1.5 V (Fig. 19-10).
Since $\Delta G^\circ = -n\mathcal{F}\Delta\mathcal{E}^\circ$,

$$\begin{aligned} \Delta G &= -(1)(96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1})(-1.5 \text{ V}) \\ &= 140,000 \text{ J} \cdot \text{mol}^{-1} = 140 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$
- Because the light-dependent reactions (measured as O_2 produced by PSII) and the light-independent reactions (measured as CO_2 fixed by the Calvin cycle) are only indirectly linked via ATP and NADPH, they may vary. Cyclic electron flow, which increases ATP production without increasing NADPH production, may increase the amount of O_2 produced without increasing CO_2 fixation.
- Because chloroplast cytochrome b_6f is functionally and structurally similar to mitochondrial Complex III, myxothiazol would be expected to block electron transport in the chloroplast. As a result, the Q cycle would not function and no proton gradient would be generated. No ATP would be produced and no electrons would reach $NADP^+$.
- Using Equation 18-1,

$$\begin{aligned} \Delta G &= 2.3 RT [\text{pH}(\text{side 1}) - \text{pH}(\text{side 2})] \\ \Delta G &= 2.3(8.3145 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1})(298 \text{ K})(-3.4) \\ &= -19,400 \text{ J} \cdot \text{mol}^{-1} = -19.4 \text{ kJ} \cdot \text{mol}^{-1} \end{aligned}$$
- An uncoupler dissipates the transmembrane proton gradient by providing a route for proton translocation other than ATP synthase. Therefore, chloroplast ATP production would decrease.
- By allowing K^+ ions to cross the thylakoid membrane from the lumen to the stroma, the channel would dissipate a portion of the membrane potential ($\Delta\Psi$) without affecting ΔpH . This would help maintain electrical neutrality and fine-tune the protonmotive force needed for ATP synthesis.
- After the light is turned off, ATP and NADPH levels fall as these substances are used up in the Calvin cycle without being replaced by the light reactions. The RuBP level drops because it is consumed by the RuBP carboxylase reaction (which requires neither ATP nor NADPH) and its replenishment is blocked by the lack of ATP for the phosphoribulokinase reaction.
- The carbonic anhydrase catalyzes the conversion of bicarbonate to CO_2 , which is the substrate for RuBP carboxylase.
- The cyanobacterial enzyme is more efficient at carboxylation but is still limited by the amount of CO_2 available. Hence augmenting the CO_2 supply by introducing bicarbonate transporters is beneficial (carbonic anhydrase converts the bicarbonate to CO_2).
- These plants store CO_2 by CAM. At night, CO_2 reacts with PEP to form malate. By morning, so much malate (malic acid) has accumulated that the leaves have a sour taste (the taste of H^+). During the day, the malate is converted to pyruvate + CO_2 . The leaves therefore become less acidic and hence tasteless. Late in the day, when all the malate is consumed, the leaves become slightly basic; that is, bitter.
- The increased concentration of CO_2 would mean that plants would need to open their stomata less to obtain the CO_2 needed for the Calvin cycle. Consequently, less water would be lost through the stomata and the plants' water consumption would decrease.
- The longer-wavelength absorption maximum allows the bacteria to collect more low-energy (longer-wavelength) light to use for photosynthesis.
- One mole of photons of red light ($\lambda = 700 \text{ nm}$) has an energy of 171 kJ. Therefore, $438/171 = 2.6$ moles of photons are theoretically required to drive the oxidation of H_2O by $NADP^+$ to form one mole of O_2 .

SP-18

37. The buildup of the proton gradient is indicative of a high level of activity of the photosystems. A steep gradient could therefore trigger photoprotective activity to prevent further photooxidation when the proton-translocating machinery is operating at maximal capacity.
39. The net synthesis of 2 GAP from 6 CO₂ in the initial stage of the Calvin cycle (Fig. 19-26) consumes 18 ATP and 12 NADPH (equivalent to 30 ATP). The conversion of 2 GAP to glucose-6-phosphate (G6P) by gluconeogenesis does not require energy input (Section 16-4B), nor does the isomerization of G6P to glucose-1-phosphate (G1P). The activation of G1P to its nucleotide derivative consumes 2 ATP equivalents (Section 16-5), but ADP is released when the glucose residue is incorporated into starch. These steps represent an overall energy investment of 18 + 30 + 1 = 49 ATP.
- Starch breakdown by phosphorolysis yields G1P, whose subsequent degradation by glycolysis yields 3 ATP, 2 NADH (equivalent to 5 ATP), and 2 pyruvate. Complete oxidation of 2 pyruvate to 6 CO₂ by the pyruvate dehydrogenase reaction and the citric acid cycle (Section 17-1) yields 8 NADH (equivalent to 20 ATP), 2 FADH₂ (equivalent to 3 ATP), and 2 GTP (equivalent to 2 ATP). The overall ATP yield is therefore 3 + 5 + 20 + 3 + 2 = 33 ATP.
- The ratio of energy spent to energy recovered is 49/33 = 1.5.
41. If nighttime warming exceeds daytime warming, then respiration (which occurs day and night) might proceed at a rate greater than could be sustained by photosynthesis (which occurs only during the day). As a result, plant growth would be slowed.
43. The partial pressure of CO₂ at which a C₄ plant can photosynthesize is much lower than that of a C₃ plant. Moreover, at very low partial pressures of CO₂, the C₃ plant reverses the effects of photosynthesis by photorespiration. In the sealed box, the C₄ plant maintains the CO₂ partial pressure so low that the C₃ plant wastes away through photorespiration. In effect, the C₄ plant devours the C₃ plant.

Chapter 20

9. The first three steps of β oxidation resemble the reactions that convert succinate to oxaloacetate (Sections 17-3F–17-3H).

11. Because ACP carries the growing acyl chain between the separate enzymes of the bacterial fatty acid synthesis pathway, it must accommodate reaction intermediates, which are mostly hydrophobic.
13. Six rounds of β oxidation are required to convert the 16-carbon palmitate to the 4-carbon butyrate.
15. There are not as many usable nutritional calories per gram in unsaturated fatty acids as there are in saturated fatty acids. This is because oxidation of fatty acids containing double bonds yields fewer reduced coenzymes whose oxidation drives the synthesis of ATP. In the oxidation of fatty acids with a double bond at an odd-numbered carbon, the enoyl-CoA isomerase reaction bypasses the acyl-CoA dehydrogenase reaction and therefore does not generate FADH₂ (equivalent to 1.5 ATP). A double bond at an even-numbered carbon must be reduced by NADPH (equivalent to the loss of 2.5 ATP).
17. Oxidation of odd-chain fatty acids generates succinyl-CoA, an intermediate of the citric acid cycle. Because the citric acid cycle operates as a multistep catalyst to convert acetyl groups to CO₂, increasing the concentration of a cycle intermediate can increase the catalytic activity of the cycle.
19. 3-Ketoacyl-CoA transferase is required to convert ketone bodies to acetyl-CoA. If the liver contained this enzyme, it would be unable to supply ketone bodies as fuels for other tissues.
21. The label does not appear in palmitate because ¹⁴CO₂ is released in Reaction 2b of fatty acid synthesis (Fig. 20-26).
23. The breakdown of glucose by glycolysis generates the dihydroxyacetone phosphate that becomes the glycerol backbone of triacylglycerols (Fig. 20-29).
25. ACC catalyzes the first committed step of fatty acid synthesis, so blocking this step might decrease the fatty acids available for storage as triacylglycerols (fat). The malonyl-CoA produced in the ACC reaction inhibits import of fatty acyl-CoA into the mitochondria, so lowering the level of malonyl-CoA might help promote fatty acid oxidation and reduce fat accumulation.
27. (a) Yes; the egg phosphatidylcholine is a source of choline that is eventually converted to TMAO. (b) No; excess phosphatidylcholine would increase the concentration of TMAO and promote atherosclerosis. Atherosclerosis is a progressive disease that often accompanies aging, so this condition would only worsen with increased intake of phosphatidylcholine.
29. This molecule consists of palmitate that has been esterified to 12-hydroxy stearate.

31. The products are heptadecane ($C_{17}H_{36}$) and pentadecane ($C_{15}H_{32}$).
33. (a) Phytanate can be esterified to CoA, but the methyl group at the β position prevents the dehydrogenation catalyzed by hydroxyacyl-CoA dehydrogenase (reaction 3 of the β oxidation pathway).
- (b)

(c)

35. Palmitate (C_{16}) synthesis requires 14 NADPH. The transport of 8 acetyl-CoA to the cytosol by the tricarboxylate transport system supplies 8 NADPH (Fig. 20-23), which represents $8/14 \times 100 = 57\%$ of the required NADPH.
37. The synthesis of stearate (18:0) from mitochondrial acetyl-CoA requires 9 ATP to transport 9 acetyl-CoA from the mitochondria to the cytosol. Seven rounds of fatty acid synthesis consume 7 ATP (in the acetyl-CoA carboxylase reaction) and 14 NADPH (equivalent to 35 ATP). Elongation of palmitate to stearate requires 1 NADH and 1 NADPH (equivalent to 5 ATP). The energy cost is therefore $9 + 7 + 35 + 5 = 56$ ATP.

The degradation of stearate to 9 acetyl-CoA consumes 2 ATP (in the acyl-CoA synthetase reaction) but generates, in eight rounds of β oxidation, 8 $FADH_2$ (equivalent to 12 ATP) and 8 NADH (equivalent to 20 ATP). Thus, the energy yield is $12 + 20 - 2 = 30$ ATP. This represents only about half of the energy consumed in synthesizing stearate (30 ATP versus 56 ATP).

39. Palmitate biosynthesis consumes 7 ATP and 14 NADPH (equivalent to 35 ATP). The addition of four more 2-carbon units as acetyl-CoA in the mitochondrion (Fig. 20-28) consumes 4 NADH (equivalent to 10 ATP) and 4 NADPH (equivalent to 10 ATP), so that a total of 62 ATP are consumed.
41. Statins inhibit the HMG-CoA reductase reaction, which produces mevalonate, a precursor of cholesterol. Although lower cholesterol levels induce the synthesis of HMG-CoA reductase to make up for the loss in activity, some decrease in activity may still be present. Because mevalonate is also the precursor of ubiquinone (coenzyme Q), supplementary ubiquinone may be necessary.
43. The patient is suffering from a deficiency of lipoprotein lipase (an inherited disease), which normally functions to hydrolyze the triacylglycerols of chylomicrons and VLDL. The symptoms of the disease may be minimized by maintaining a low fat diet since chylomicrons are intestinally packaged dietary lipids.

Chapter 21

- Proteasome-dependent proteolysis requires ATP to activate ubiquitin in the first step of linking ubiquitin to the target protein (Fig. 21-2) and for denaturing the protein as it enters the proteasome.
- The proteasome would facilitate the degradation of intracellular proteins that have been damaged or denatured by heat or oxidation and would therefore help the cell eliminate these nonfunctional and

possibly toxic proteins so that they could be replaced by newly synthesized proteins.

- A glutamate receptor would have helped human ancestors recognize protein-rich foods, because foods containing significant amounts of protein also contain relatively large amounts of glutamate, one of the most abundant amino acids.
- (a) Ala, Arg, Asn, Asp, Cys, Gln, Glu, Gly, His, Met, Pro, Ser, and Val
(b) Leu and Lys
(c) Ile, Phe, Thr, Trp, and Tyr
- Since the three reactions converting tiglyl-CoA to acetyl-CoA and propionyl-CoA are analogous to those of fatty acid oxidation (β oxidation; Fig. 20-12), the reactions are

- Tyrosine is derived from the essential amino acid phenylalanine, and cysteine is derived from the essential amino acid methionine. A diet lacking sufficient phenylalanine and methionine will lead to shortages of tyrosine and cysteine also.
- Glutamate dehydrogenase, glutamine synthetase, and carbamoyl phosphate synthetase.
- In the absence of uridylyl-removing enzyme, adenylyltransferase $\cdot P_{II}$ will be fully uridylylated, since there is no mechanism for removing the uridylyl groups once they are attached. Uridylylated adenylyltransferase $\cdot P_{II}$ adenylylates glutamine synthetase, which activates it. Hence, the defective *E. coli* cells will have a hyperactive glutamine synthetase and thus a higher than normal glutamine concentration. Reactions requiring glutamine will therefore be accelerated, thereby depleting glutamate and the citric acid cycle intermediate α -ketoglutarate. Consequently, biosynthetic reactions requiring transamination, as well as energy metabolism, will be suppressed.
- Glycine

SP-20

19. 2-Phenylethanol is derived from phenylalanine by removal of the amino group and reduction of the carboxylate group to a hydroxide group.
21. Agmatine is derived by decarboxylation from arginine.
23. A methyl group is added to the hydroxyl group of the phenyl ring, and the amino group is replaced by a carboxylate group by oxidative deamination.
25. The pigment coloring skin and hair is melanin, which is synthesized from tyrosine. When tyrosine is in short supply, as when dietary protein is not available, melanin cannot be synthesized in normal amounts, and the skin and hair become depigmented.
27. The standard nitrogenase reaction, $N_2 \rightarrow NH_3$, also produces H_2 . This H_2 is used to reduce CO to C_2H_6 and C_3H_8 .
29. The urea cycle transforms excess nitrogen from protein breakdown to an excretable form, urea. In a deficiency of a urea cycle enzyme, the preceding urea cycle intermediates may build up to a toxic level. A low-protein diet minimizes the amount of nitrogen that enters the urea cycle and therefore reduces the concentrations of the toxic intermediates.
31. (a) Three ATP are converted to 2 ADP and AMP + PP_i , for a total of 4 ATP equivalents.
(b) The fumarate produced in the urea cycle can be converted to malate and then to pyruvate by malic enzyme, generating NADPH (equivalent to 2.5 ATP). Conversion of pyruvate to acetyl-CoA generates NADH (2.5 ATP equivalents), and the oxidation of the acetyl-CoA by the citric acid cycle yields another 10 ATP, for a total of 15 ATP.
33. The ϵ -amino group is removed by the addition of α -ketoglutarate followed by the departure of glutamate (Fig. 21-22, Reactions 1 and 2). The α -amino group is eliminated when α -amino adipate undergoes transamination with α -ketoglutarate (Fig. 21-22, Reaction 4).
35. *a* bond cleavage: transaminases (Fig. 21-8) and serine–threonine dehydratase (Fig. 21-15). *b* bond cleavage: amino acid decarboxylases (Section 21-6B). *c* bond cleavage: serine hydroxymethyltransferase (Fig. 21-14).
37. Yes; one product of the glycine cleavage system is N^5, N^{10} -methylene-THF, which provide the one-carbon group for converting dUMP to dTMP.
39. Threonine dehydrogenase converts threonine to α -amino- β -ketobutyrate (Fig. 21-14), which is then broken down to acetyl-CoA and glycine. The glycine cleavage system transfers a one-carbon group to THF. Homocysteine reacts with methyl-THF to yield methionine (Fig. 21-18), which is a precursor for *S*-adenosylmethionine.
41. Ferrochelatase is a homodimer. Thus in heterozygotes for a defective ferrochelatase, if it is expressed in normal amounts, 25% of the dimers will have both subunits defective, 50% will have one subunit defective and the other normal, and 25% will have both subunits normal. Apparently, only a dimer with two normal subunits is enzymatically active, thereby accounting for the observed activity of ferrochelatase in heterozygotes.

Chapter 22

1. At high altitude, less oxygen is available for aerobic metabolism, so glycolysis, an anaerobic pathway, would become relatively more important in active muscles. An increase in GLUT1 would increase the intracellular glucose concentration, and an increase in PFK would increase the flux of glucose through the pathway.
3. Cardiac muscle relies on oxidation of fatty acids to supply ATP for muscle contraction. The muscle performs poorly when β oxidation is inhibited, and the blood glucose concentration drops as the heart takes up glucose instead to meet its need for ATP through glycolysis.
5. GLUT2 has a higher K_M than GLUT1 so that the rate of glucose entry into liver cells can vary directly with the concentration of glucose in the blood. A transporter with a high K_M is less likely to be saturated with its ligand and therefore would not limit the rate of transport.
7. The portal vein delivers NH_4^+ -rich blood from the intestine directly to the liver, which can convert it to urea (only the liver carries out the urea cycle; Section 21-3). The remaining NH_4^+ is carried through the circulation to other tissues, where glutamine synthetase converts glutamate to glutamine (Section 21-5A).
9. The availability of nutrients in the colon is limited, so organisms that can extract more free energy from metabolic fuels through nitrate-based respiration have an advantage over organisms that are strictly limited to fermentation.
11. Insulin promotes the uptake of glucose via the increase in GLUT4 receptors on the adipocyte surface. A source of glucose is necessary to supply the glycerol-3-phosphate backbone of triacylglycerols.
13. Insulin activates ATP-citrate lyase, which is the enzyme that converts citrate to oxaloacetate and acetyl-CoA (Section 20-4A). The activity of this enzyme is essential for making acetyl units available for fatty acid biosynthesis in the cytosol. The acetyl units, generated from pyruvate in the mitochondria, combine with oxaloacetate to form citrate, which can then be transported from the mitochondria to the cytosol for reconversion to acetyl-CoA.
15. Adipose tissue synthesizes and releases the polypeptide hormones adiponectin, leptin, and resistin.
17. Since PYY₃₋₃₆ is a peptide hormone, it would be digested if taken orally. Introducing it directly into the bloodstream avoids degradation.
19. Adiponectin is a polypeptide hormone (247 residues) that exists as multimers *in vivo*, so it is difficult to prepare a form of the hormone that is stable and whose concentration can be accurately monitored. A small molecule agonist would be easier to evaluate and to use as a drug. Moreover, if taken orally, adiponectin would be digested, whereas a small molecule agonist could survive the digestive tract.
21. Type 1 diabetics lack β cells that produce insulin, so providing the hormone is an effective treatment for the disorder. In type 2 diabetes, cells do not respond efficiently to insulin. Increasing the availability of the hormone may boost its signaling activity in some patients, but in the majority of type 2 diabetics, insulin levels are already elevated and further increases are ineffective.
23. PFK-2 catalyzes the production of fructose-2,6-bisphosphate, so increasing PFK-2 activity would increase the concentration of this activator of phosphofruktokinase. The effect would be increased flux of glucose through glycolysis, which would help lower the concentration of glucose in the blood.
25. 3-Phosphoglycerate is an intermediate of glycolysis; its concentration increases when glycolytic flux slows. By inhibiting 6-phosphogluconate dehydrogenase, 3PG slows pentose phosphate pathway activity also. Slower consumption of glucose would tend to slow the growth of the cancer cell.
27. ATP generating pathways such as glycolysis and fatty acid oxidation require an initial investment of ATP (the hexokinase and phosphofruktokinase steps of glycolysis and the acyl-CoA synthetase activation step that precedes β oxidation). This “priming” cannot occur when ATP has been exhausted.
29. Because fatty acids, like glucose, are metabolic fuels, it makes metabolic sense for them to stimulate insulin release, which is a signal of abundant fuel.

31. Leucine is an essential amino acid; it cannot be synthesized by humans. Circulating leucine therefore serves as a marker of sufficient food intake.
33. Ingesting glucose while in the resting state causes the pancreas to release insulin. This stimulates the liver, muscle, and adipose tissue to synthesize glycogen, fat, and protein from the excess nutrients while inhibiting the breakdown of these metabolic fuels. Hence, ingesting glucose before a race will gear the runner's metabolism for resting rather than for running.
35. An intermediate in the biosynthesis of triacylglycerols is diacylglycerol (DAG), a second messenger responsible for activating PKC.
37. Physical inactivity would lead to a decreased need for ATP in muscle, which would be reflected by a decreased AMP to ATP ratio. A decrease in the ratio would lead to a decrease in AMPK activity. AMPK activity is positively associated with glucose uptake by cells due to an increase in GLUT4 activity. GLUT4 activity is also increased by insulin. A decrease in AMPK activity causes a decrease in GLUT4 activity, making insulin's job more difficult.
39. The liver is the only organ capable of urea biosynthesis so that, upon liver failure, the ammonia level in the blood rises, leading to ammonia toxicity. Severe hypoglycemia also ensues because the liver normally functions to maintain blood glucose levels between meals via gluconeogenesis. Many toxic substances will accumulate in the blood because the liver is unable to detoxify them.

Chapter 23

1. Following aspartate addition to IMP, adenylosuccinate lyase removes fumarate, leaving an amino group. In the urea cycle, following the addition of aspartate to citrulline, argininosuccinase removes fumarate, leaving an amino group.
3. Guanine has an amino group attached to C2; in azahypoxanthine, nitrogen is part of the ring structure.
5. Amidophosphoribosyl transferase (step 2 of IMP synthesis), FGAM synthetase (step 5 of IMP synthesis), GMP synthetase (GMP synthesis), carbamoyl phosphate synthetase II (step 1 of UMP synthesis), and CTP synthetase (CTP synthesis).
7. (a) 7 ATP; (b) 8 ATP; (c) 7 ATP
9. Hydroxyurea destroys the tyrosyl radical that is essential for the activity of ribonucleotide reductase. Tumor cells are generally fast-growing and cannot survive without this enzyme, which supplies dNTPs for nucleic acid synthesis. In contrast, most normal cells grow slowly, if at all, and hence have less need for nucleic acid synthesis.
11. Serine donates a hydroxymethyl group to THF in order to regenerate the cofactor for the conversion of dUMP to dTMP by thymidylate synthase (Fig. 23-16).
13. The synthesis of histidine and methionine requires THF. The cell's THF is converted to DHF by the thymidylate synthase reaction, but in the presence of methotrexate, THF cannot be regenerated.
15. Trimethoprim binds to bacterial dihydrofolate reductase but does not permanently inactivate the enzyme. Therefore, it is not a mechanism-based inhibitor.
17. Allopurinol is oxidized by xanthine oxidase to a product that irreversibly binds to the enzyme. It is therefore a mechanism-based inhibitor of xanthine oxidase.
19. Uracil and thymine accumulate in the urine because they cannot be further degraded in the absence of the dihydropyrimidine dehydrogenase (Fig. 23-25).

21.

23. The kinase-catalyzed phosphorylation of riboflavin consumes one "high-energy" bond. In the second reaction, an AMP group is transferred from ATP to FMN (thereby breaking a second "high-energy" bond), leaving PP_i , whose subsequent hydrolysis breaks a third "high-energy" bond.
25. UTP functions as a feedback inhibitor of its own synthesis, to prevent the cell from synthesizing too many pyrimidine nucleotides. ATP activates pyrimidine nucleotide synthesis so that when ATP concentrations are high, the production of other nucleotides will increase to match it.
27. Threonine is broken down to acetyl-CoA and glycine, either directly via the serine hydroxymethyltransferase reaction (reaction 5 in Fig. 21-14) or through the intermediacy of α -amino- β -ketobutyrate via the threonine dehydrogenase reaction (reaction 6 of Fig. 21-14) followed by the α -amino- β -ketobutyrate lyase reaction (reaction 7 of Fig. 21-14). The acetyl-CoA can enter the citric acid cycle to produce considerable ATP via oxidative phosphorylation. The glycine is a substrate of the glycine cleavage system, which generates N^5,N^{10} -methylene-THF (reaction 3 of Fig. 21-14), the methyl-group donor required for thymidylate synthesis.
29. In muscles, the purine nucleotide cycle functions to convert aspartate to fumarate to boost the capacity of the citric acid cycle. If glutamate dehydrogenase activity were high, then it would combine the NH_4^+ produced by the purine nucleotide cycle with α -ketoglutarate to yield glutamate, a reaction that depletes a citric acid cycle intermediate.
31. Meat contains relatively large quantities of nucleic acids, which are broken down to yield, among other products, uric acid. This additional uric acid may increase the uric acid concentration beyond the solubility limit in some otherwise gout-free individuals, thereby precipitating a gout attack.
33. (a) The recovered deoxycytidylate would be equally labeled in its base and ribose components (i.e., the same labeling pattern as in the original cytidine).
(b) The recovered deoxycytidylate would be unequally labeled in its base and ribose components because the separated ^{14}C -cytosine and ^{14}C -ribose would mix with the different-sized

SP-22

pools of unlabeled cellular cytosine and ribose before recombining as the deoxycytidylate that becomes incorporated into DNA. [This experiment established that deoxyribonucleotides, in fact, are synthesized from their corresponding ribonucleotides (alternative a).]

Chapter 24

1. Hypoxanthine pairs with cytosine in much the same way as does guanine.

3. Since amino acids have an average molecular mass of ~110 D, the 50-kD protein contains $50,000 \text{ D} \div 110 \text{ D/residue} = \sim 455$ residues. These residues are encoded by $455 \times 3 = 1365$ nucleotides. In B-DNA, the rise per base pair is 3.4 Å, so the contour length of 1365 bp is $3.4 \text{ Å/bp} \times 1365 \text{ bp} = 4641 \text{ Å}$, or 0.46 μm.

5.

7.

9. Assuming all the DNAs in Figure 24-8 contain the same number of base pairs, the most supercoiled structure would move farthest during electrophoresis, because its compact structure allows it to move fastest through the agarose matrix.

11. Its T_m decreases because the charges on the phosphate groups are less shielded from each other at lower ionic strength and hence repel each other more strongly, thereby destabilizing the double helix.
13. The segment with 20% A residues (i.e., 40% A · T base pairs) contains 60% G · C base pairs and therefore melts at a higher temperature than a segment with 30% A residues (i.e., 40% G · C base pairs).

15.

17.

19. The target sequence consists of 6 symmetry-related base pairs. Since there are 4 possible base pairs (A · T, T · A, G · C, and C · G), the probability that any two base pairs are randomly related by symmetry is 1/4. Hence, the probability of finding all 6 pairs of base pairs by random chance is $(1/4)^6 = 2.4 \times 10^{-4}$.

21. Because they interact closely with DNA, protamines must be rich in basic amino acids. In fact, they are particularly rich in arginine.

23. (a) Increased ion concentrations would interfere with the electrostatic interactions between M1 and histones and would weaken binding. (b) Decreasing the pH would protonate and neutralize negatively charged carboxylate groups, which are important for interacting with the positively charged groups on the histones. Neutral M1 would then bind to histones less tightly.

25. (a) The contour length is $5 \times 10^7 \text{ bp} \times 3.4 \text{ Å/bp} = 1.7 \times 10^8 \text{ Å} = 17 \text{ mm}$.

(b) A nucleosome, which binds ~200 bp, compresses the DNA to an 80-Å-high supercoil. The length of the DNA is therefore $(80 \text{ Å} / 200 \text{ bp}) \times (5 \times 10^7 \text{ bp}) = 2 \times 10^7 \text{ Å} = 2 \text{ mm}$.

27. Histones are required in large amounts during a relatively short period when DNA is replicated prior to cell division. The large number of histone genes allows the efficient production of histones.

29.

The helix diameter is smaller in this alternate arrangement (Hoogsteen base pairing).

31.

33. The bonds opposite atoms C2' and C3' in the ribose ring both contain O1'. Since O1' has no extra-annular substituents, none of the substituents to the ribose ring will be eclipsed if either C2' or C3' is out of the plane of the other ring atoms. This minimizes the steric interference between ring substituents.

35. $L = T + W$. For the constrained DNA circle, $W = 0$ so that $L = T = 207$. For the unconstrained DNA circle, $L = 207$ since this quantity is invariant, $T = 2310 \text{ bp}/(10.5 \text{ bp/turn}) = 220$, and $W = L - T = 207 - 220 = -13$. For the constrained DNA circle, $\sigma = W/T = 0/207 = 0$. For the unconstrained DNA circle, $\sigma = -13/220 = -0.059$ (a value that is typical of naturally occurring DNA circles *in vivo*).

37. Type I is closed circular duplex DNA, type II is a nicked circular duplex DNA, and type III is linear duplex DNA. Type I DNA has such a broad melting curve and a high T_m because its strands cannot separate from each other without breaking a covalent bond (its ΔS of melting is unusually small). The bases therefore tend to remain paired above the T_m for the equivalent linear DNA.

The slightly greater sedimentation coefficient of type I in comparison with type II DNA indicates that type I is supercoiled, which makes it more compact than type II. The relaxed circles of type II DNA are more compact than type III, the linear duplex, and hence type II DNA sediments faster than type III.

At pH 13, which denatures duplex DNA, type III DNA undergoes strand separation to yield linear single strands of 16S. Type II DNA also undergoes strand separation to yield a 16S linear single strand and a slightly more compact 18S single-stranded circle. Type I DNA denatures but its strands cannot unwind from each other (L remains constant). However, the stiff double-helical structure has collapsed so that denatured type I DNA is a highly compact entity. This accounts for its 53S sedimentation coefficient.

Chapter 25

- Okazaki fragments are 1000 to 2000 nt long, and the *E. coli* chromosome contains 4.6×10^6 bp. Therefore, *E. coli* chromosomal replication requires 2300 to 4600 Okazaki fragments.
- The drug would inhibit DNA synthesis because the polymerization reaction is accompanied by the release and hydrolysis of PP_i . Failure to hydrolyze the PP_i would remove the thermodynamic driving force for polymerization, that is, it would be reversible.
- When DNA polymerase begins synthesizing a new strand, it binds the template DNA to which an RNA primer is already base paired. In order to extend the primer, the polymerase active site must accommodate the DNA-RNA hybrid helix, which has an A-DNA-like structure (Fig. 24-4).
- AT-rich DNA is less stable than GC-rich DNA and therefore would more readily melt apart, a requirement for initiating replication.
- DNA polymerase could extend a primer that entered its active site, but polymerization would not be highly processive unless the sliding clamp was in place. If the primer first associates with the clamp, which then interacts with DNA polymerase, the primer can be extended in a processive and therefore more efficient manner.
- The *E. coli* replication system can fully replicate only circular DNAs. Bacteria do not have a mechanism (e.g., telomerase-catalyzed extension of telomeres) for replicating the extreme 3' ends of linear template strands.
- After adding the 6-nt telomere sequence, telomerase translocates to the new 3' end to add another repeat. The RNA template includes

a region of overlap (~3 nt) that helps position the enzyme and template for the next addition of nucleotides (see Fig. 25-27).

15. (a)

5BU
(enol tautomer) **Guanine**

(b) When 5BU incorporated into DNA pairs with G, the result is an $\text{A} \cdot \text{T} \rightarrow \text{G} \cdot \text{C}$ transition after two more rounds of DNA replication:

- (a) The original $\text{A} \cdot \text{T}$ base pair becomes an $\text{I} \cdot \text{T}$ base pair. When the DNA replicates, the template T will pair with A, and the template I will pair with C. Thus, one daughter cell will be normal and one will have an abnormal $\text{I} \cdot \text{C}$ base pair. (b) After the second round of cell division, two cells will be normal ($\text{A} \cdot \text{T}$ base pairs). One cell will have an abnormal $\text{I} \cdot \text{C}$ base pair, and one will have a normal but mutated $\text{C} \cdot \text{G}$ base pair.
- The triphosphatase destroys nucleotides containing the modified base before they can be incorporated into DNA during replication.
- (a) Without an active site Cys residue, the alkyl transfer reaction cannot occur.
(b) Although the proteins cannot remove the alkyl group attached to the guanine by direct repair, they can still bind to the modified residue, thereby marking this region of DNA for repair by NER enzymes.
- When 5-methylcytosine residues deaminate, they form thymine residues.

Since thymine is a normal DNA base, the repair systems cannot determine whether such a T or its opposing G is the mutated base. Consequently, only about half of the deaminated 5-methylcytosines are correctly repaired.

- Base excision repair. The deaminated base can be recognized because hypoxanthine does not normally occur in DNA.
- First, an endoribonuclease must cleave one of the two phosphodiester bonds involving the ribonucleotide, then a second endonuclease must cleave the other bond to completely remove the ribonucleotide. The resulting gap can be filled in by DNA polymerase, and the nick sealed by DNA ligase.
- Topoisomerases maintain the appropriate degree of supercoiling during DNA replication. These enzymes act by cleaving one or both DNA strands and covalently linking the 3'- or 5'-phosphate to an enzyme Tyr residue (Section 24-1D). If the catalytic cycle is not completed, the enzyme remains associated with the cut DNA and impedes replication and transcription. A tyrosyl-DNA phosphodiesterase frees the trapped topoisomerase so that the DNA can be repaired by other enzymes.

SP-24

31. Pol V is less processive than Pol III. When the progress of Pol III is arrested by the presence of a thymine dimer, Pol V can take over, allowing replication to continue at a high rate, although with a greater incidence of mispairings. The damage is minimal, however, since Pol V soon dissociates from the DNA, allowing the more accurate Pol III to resume replicating DNA.
33. In conjugation, the ssDNA becomes incorporated into the recipient's DNA through homologous recombination. RecBCD includes nuclease and helicase activity, which are necessary to nick and unwind the recipient dsDNA so that the incoming ssDNA can be introduced.
35. As indicated in Fig. a (below), nucleotides would be added to a polynucleotide strand by attack of the 3'-OH of the incoming nucleotide on the 5' triphosphate group of the growing strand with the elimination of PP_i . The hydrolytic removal of a mispaired nucleotide by the 5' → 3' exonuclease activity (Fig. b, below) would leave only an OH group or a monophosphate group at the 5' end of the DNA chain. This would require an additional activation step before further chain elongation could commence.

(a) 3' → 5' Polymerase

(b) 5' → 3' Exonuclease

37. The conversion factor between the real and expanded systems is $1 \text{ m}/20 \text{ \AA} = 0.05 \text{ m/\AA}$.
- (a) The length of B-DNA is $3.4 \text{ \AA}/\text{bp}$. The replisome replicates DNA at the rate of $\sim 1000 \text{ bp/s}$. Hence, the rate of travel of the expanded replisome is
- $$3.4 \text{ \AA}/\text{bp} \times 1000 \text{ bp/s} \times 0.05 \text{ m/\AA} \times 3600 \text{ s/hr} \times 0.001 \text{ km/m} = 610 \text{ km/hr}$$
- (b) The *E. coli* genome consists of ~ 4.6 million bp (Table 3-3). Each replisome in *E. coli*'s bidirectional replication fork replicates half this DNA. Hence the distance each replisome must travel is
- $$1/2 \times 4.6 \times 10^6 \text{ bp} \times 3.4 \text{ \AA}/\text{bp} \times 0.05 \text{ m/\AA} \times 0.001 \text{ km/m} = 390 \text{ km}$$
- (c) Okazaki fragments in *E. coli* range in length from 1000 to 2000 nt. Hence their expanded lengths would be
- $$(1000 \text{ to } 2000) \text{ nt} \times 3.4 \text{ \AA}/\text{nt} \times 0.05 \text{ m/\AA} \times 0.001 \text{ km/m} = (0.17 \text{ to } 0.34) \text{ km}$$
- (d) The *E. coli* replisome makes around one error for every 10 million bases it correctly replicates. Hence the distance between errors that it would travel in our expanded system is
- $$10^7 \text{ nt} \times 3.4 \text{ \AA}/\text{nt} \times 0.05 \text{ m/\AA} \times 0.001 \text{ km/m} = 1700 \text{ km}$$
39. The Klenow fragment, which lacks 5' → 3' exonuclease activity (and therefore cannot catalyze nick translation), is used to ensure that all the replicated DNA chains have the same 5' terminus. For the chain terminator method of sequencing DNA, this is a necessity because a sequence is assigned according to fragment length. For pyrosequencing or Illumina sequencing, the DNA segments at a particular

position on the sequencing well or slide must all be identical or the identification of each nucleotide in the sequence will be ambiguous.

41. Use Equation 12-6,

$$\ln[A] = \ln[A]_0 - kt$$

where $[A]_0 = 6.0 \times 10^9$, $[A] = [A]_0 - 2 \times 10^4 = 5.99998 \times 10^9$, and $t = 1 \text{ d}$. Solve the equation for k :

$$k = \left(\ln \frac{[A]_0}{[A]} \right) / t = \left(\ln \frac{6 \times 10^9}{5.99998 \times 10^9} \right) / 1 \text{ d}$$

$$k = \ln(1.0000033) / 1 \text{ d} = 0.0000033 \text{ d}^{-1}$$

Using Equation 12.9,

$$t_{1/2} = 0.693/k = 0.693/0.0000033 \text{ d}^{-1} = 2.08 \times 10^5 \text{ d} \times (1 \text{ y}/365 \text{ d}) = 570 \text{ y}$$

43. By aligning its identical tracts of DNA side by side, *D. radiodurans* has prepared these sequences for rapid recombinational repair, the only nonmutagenic mode for restoring the double-strand breaks that ionizing radiation frequently induces in DNA.

Chapter 26

- (a) Cordycepin is the 3'-deoxy analog of adenosine.
(b) Because it lacks a 3'-OH group, the cordycepin incorporated into a growing RNA chain cannot support further chain elongation in the 5' → 3' direction.
- The probe should have a sequence complementary to the consensus sequence of the 6-nt Pribnow box: 5'-ATTATA-3'.
- (a) Operons allow cells to turn sets of related genes on and off together, thereby maximizing efficiency, since all the necessary genes are expressed at the same time and in the same amount.
(b) In eukaryotes, genes in different locations can be turned on or off at the same time if they share the same transcriptional regulatory sequences, such as core promoter elements and enhancers that interact with the same transcription factors.
- Increasing the error rate of transcription increases the chances of introducing a mutation that prevents the virus from completing its life cycle in the host cell.
- In the presence of bicyclomycin, transcription of Rho-dependent genes does not terminate, causing read-through into adjacent coding regions. This results in the transcription of the adjacent gene(s), often causing the inappropriate expression of the corresponding protein(s).
- The cell lysates can be applied to a column containing a matrix with immobilized poly(dT). The poly(A) tails of processed mRNAs will bind to the poly(dT) while other cellular components are washed away. The mRNAs can be eluted by decreasing the salt concentration to destabilize the A · T base pairs.
- DNA polymerase needs a primer; poly(A) polymerase uses the pre-mRNA as a primer; CCA-adding polymerase uses the immature tRNA as a primer; and RNA polymerase does not require a primer. Both DNA polymerase and RNA polymerase require a DNA template, but neither poly(A) polymerase nor CCA-adding polymerase uses a template. The four polymerases use different sets of nucleotides: DNA polymerase uses all four dNTPs; RNA polymerase uses all four NTPs; poly(A) polymerase uses only ATP; and CCA-adding polymerase uses ATP and CTP.
- The mechanism of RNase hydrolysis requires a free 2'-OH group to form a 2',3'-cyclic phosphate intermediate (Figure 11-10).

Nucleotide residues lacking a 2'-OH group would therefore be resistant to RNase-catalyzed hydrolysis.

17. The mRNA splicing reaction, which requires no free energy input and results in no loss of phosphodiester bonds, is theoretically reversible *in vitro*. However, the degradation of the excised intron makes the reaction irreversible in the cell.
19. Histone genes lack introns, so their mRNAs do not undergo splicing, and their mRNAs do not have a poly(A) tail.
21. Inhibition of snRNA processing interferes with mRNA splicing. As a result, host mRNA cannot be translated, so the host ribosomes will synthesize only viral proteins.
23. The top strand is the sense strand. Its TATGAT segment differs by only one base from the TATAAT consensus sequence of the promoter's -10 sequence; its TTTACA sequence differs by only one base from the TTGACA consensus sequence of the promoter's -35 sequence and is appropriately located ~25 nt to the 5' side of the -10 sequence; and the initiating G nucleotide is the only purine that is located ~10 nt downstream of the -10 sequence.

25. Promoter elements for RNA polymerase II include sequences at -27 (the TATA box) and between -50 and -100. The insertion of 10 bp would separate the promoter elements by the distance of the turn of the DNA helix, thereby diminishing the binding of proteins required for transcription initiation. However, the protein-binding sites would still be on the same side of the helix. Inserting 5 bp (half of a helical turn) would move the protein-binding sites to opposite sides of the helix, making it even more difficult to initiate transcription.
27. Because TFIIB can bind directly to DNA at the promoter and indirectly to DNA at the end of the gene, it can cause the intervening DNA to form a loop. As a result, an RNA polymerase that has finished transcribing a gene will be positioned near the promoter so that transcription can be quickly reinitiated.
29. Enhancers are recognized by specific transcription factors that stimulate RNAP II to bind to the associated promoter. Enhancers are usually distant from the promoter on the same DNA and hence the interaction between the enhancer-bound transcription factor and the promoter-bound RNAP II requires that the DNA loop around. If the enhancer and promoter are on different but catenated plasmids, the enhancer-bound transcription factor and the promoter-bound RNAP II can arrange themselves to contact one another and thus stimulate translational initiation at the promoter. However, if the two plasmids are not catenated, the transcription factor and the RNAP II are unlikely to find each other and hence transcription initiation will not occur.

Chapter 27

1. A 4-nt insertion would add one codon and shift the gene's reading frame by one nucleotide. The proper reading frame could be restored by deleting a nucleotide. Gene function, however, would not be restored if (a) the 4-nt insertion interrupted the codon for a functionally critical amino acid; (b) the 4-nt insertion created a codon for a structure-breaking amino acid; (c) the 4-nt insertion introduced a Stop codon early in the gene; or (d) the 1-nt deletion occurred far from the 4-nt insertion so that even though the reading frame was restored, a long stretch of frame-shifted codons separated the insertion and deletion points.

3. The possible codons are UUU, UUG, UGU, GUU, UGG, GUG, GGU, and GGG. The encoded amino acids are Phe, Leu, Cys, Val, Trp, and Gly (Table 27-1).
5. There are still two other Stop codons, UAA and UAG, to terminate translation.
7. (a) Like an aaRS, Xpot must recognize features of tRNA structure that are present in all tRNAs, such as the acceptor stem and the T ψ C loop. (b) Xpot can distinguish mature and pre-tRNAs because mature tRNAs have a processed 5' end with a single phosphate group, and the 3' end must be a —CCA sequence (see Fig. 27-3).
9. Gly and Ala; Val and Leu; Ser and Thr, Asn and Gln; and Asp and Glu.

11.

13. Only newly synthesized bacterial polypeptides have fMet at their N-terminus. Consequently, the appearance of fMet in a mammalian system signifies the presence of invading bacteria. Leukocytes that recognize the fMet residue can therefore combat these bacteria through phagocytosis.
15. Ribosomes cannot translate double-stranded RNA, so the base pairing of a complementary antisense RNA to an mRNA prevents its translation.
17. The constrained geometry of Pro could affect the efficiency of peptidyl transfer, or the poly-Pro segment could fit poorly in the ribosome exit tunnel, slowing the rate of chain lengthening.

19.

21. The repeating sequence can be translated as GGG-GCC, GGG-CCG, and GGC-CGG, which correspond to the repeating peptides —Gly—Ala—, —Gly—Pro—, and —Gly—Arg—.
23. (a) Each ORF begins with an initiation codon (ATG) and ends with a Stop codon (TGA):
ATGCTCAACTATATGTGA encodes *vir-2* and ATGCCGCATGCTCTGTTAATCACATATAGTTGA on the complementary strand encodes *vir-1*.
(b) *vir-1*: MPHALLITYS; *vir-2*: MLNYM.
(c) *vir-1*: MPHALLIPYS; *vir-2*: MLNYMGLTEHAA.
25. As expected, the correctly charged tRNAs (Ala-tRNA^{Ala} and Gln-tRNA^{Gln}) bind to EF-Tu with approximately the same affinity, so they are delivered to the ribosomal A site with the same efficiency.

SP-26

The mischarged Ala-tRNA^{Gln} binds to EF-Tu much more loosely, indicating that it may dissociate from EF-Tu before it reaches the ribosome. The mischarged Gln-tRNA^{Ala} binds to EF-Tu much more tightly, indicating that EF-Tu may not be able to dissociate from it at the ribosome. These results suggest that either a higher or a lower binding affinity could affect the ability of EF-Tu to carry out its function, which would decrease the rate at which mischarged aminoacyl-tRNAs bind to the ribosomal A site during translation.

27. Transpeptidation involves the nucleophilic attack of the amino group of the aminoacyl-tRNA on the carbonyl carbon of the peptidyl-tRNA. As the pH increases, the amino group becomes more nucleophilic (less likely to be protonated).

29. From Table 27-2: The 2 amino acids specified by only one codon each require a tRNA. The 12 amino acids that are specified by PQX where X may be either purine or else either pyrimidine can each be specified by a single tRNA according to the wobble pairing rules (Table 27-3). Ile, which is specified by AU \bar{Y} , where Y = U, C or A, also requires a single tRNA. However, the 8 amino acids that are specified by RSZ, where Z = U, C, A or G, must each have 2 tRNAs specifying them (Leu, Arg and Ser are specified by both PQX and RSZ). Finally, an initiator tRNA is required. Thus,

$$2 + 12 + 1 + 2 \times 8 + 1 = 32 \text{ tRNAs are minimally required}$$

31. The enzyme hydrolyzes peptidyl-tRNA molecules that dissociate from a ribosome before normal translation termination takes place. Because peptide synthesis is prematurely halted, the resulting polypeptide, which is still linked to tRNA, is likely to be nonfunctional. Peptidyl-tRNA hydrolase is necessary for recycling the amino acids and the tRNA.

33. Aminoacylation occurs via pyrophosphate cleavage of ATP, and hence the aminoacylation of 100 tRNAs requires 200 ATP equivalents; translation initiation requires 1 GTP (1 ATP equivalent); 99 cycles of elongation require 99 GTP (99 ATP equivalents) for EF-Tu action; 99 cycles of ribosomal translocation require 99 GTP (99 ATP equivalents) for EF-G action; and translation termination requires 1 GTP (1 ATP equivalent), bringing the total energy cost to $200 + 1 + 99 + 99 + 1 = 400$ ATP equivalents.

35. The *E. coli* ribosome contains 52 proteins + 3 RNAs.

A minimum of 31 noninitiating tRNAs and their 20 cognate aminoacyl-tRNA synthetases is required.

tRNA^{Met} is also required (it is charged by the aminoacyl-tRNA synthetase for Met).

Initiation requires 3 factors: IF-1, IF-2, and IF-3.

Elongation requires 3 factors: EF-Tu, EF-Ts, and EF-G.

Termination requires 4 factors: RF-1, RF-2, RF-3, and RRF.

mRNA is also required.

Thus, the total number of macromolecules is:

$$52 + 3 + 31 + 20 + 1 + 3 + 3 + 4 + 1 = 118 \text{ different macromolecules.}$$

Chapter 28

1. Virtually all the DNA sequences in *E. coli* are present as single copies, so the reassociation of *E. coli* DNA is a straightforward process of each fragment reassociating with its complementary strand. In contrast, the human genome contains many repetitive DNA sequences. The many DNA fragments containing these sequences find each other to form double-stranded regions (renature) much faster than the single-copy DNA sequences that are also present, giving rise to a biphasic renaturation curve.

3. The *Daphnia* and *Drosophila* genomes are similar in size (200,000 kb versus 180,000 kb), but *Daphnia* contains far more genes (~30,000 versus ~13,000). The *Daphnia* genome is much smaller than the human genome (200,000 kb versus 3,038,000 kb) but appears to contain more genes (~30,000 versus ~21,000).

5. (a) Translation of CAG repeats will yield polypeptides containing polyglutamine (from the CAG codon), polyserine (from the AGC codon), and polyalanine (from the GCA codon). (b) Translation of CTG repeats will yield polypeptides containing polyisoleucine (from the CUG codon), polycysteine (from the UGC codon), and polyalanine (from the GCU codon).

7. O₁ is the primary repressor-binding site, so *lac* repressor cannot stably bind to the operator in its absence and repression cannot occur.

9. In the absence of β-galactosidase (the product of the *lacZ* gene), lactose is not converted to the inducer allolactose. Consequently, *lac* enzymes, including galactoside permease, are not synthesized.

11. In eukaryotes, transcription takes place in the nucleus and translation occurs in the cytoplasm. Hence, in eukaryotes, ribosomes are never in contact with nascent mRNAs, an essential aspect of the attenuation mechanism in prokaryotes.

13.

In acetyllysine, the cationic side chain of Lys has been converted to a polar but uncharged side chain.

15. The product is a citrulline side chain (Fig. 21-9).

17. The susceptibility of RNA to degradation *in vivo* makes it possible to regulate gene expression by adjusting the rate of mRNA degradation. If mRNA were very stable, it might continue to direct translation even when the cell no longer needed the encoded protein.

19. The imprecise joining of *V*, *D*, and *J* segments, along with nucleotide addition or removal at the junction, can generate a Stop codon (yielding a truncated and hence nonfunctional immunoglobulin chain) or create a shift in the reading frame (yielding a misfolded and nonfunctional protein).

21. In multicellular organisms, apoptosis of damaged cells minimizes damage to the entire organism. For a single-celled organism, survival of a genetically damaged cell is preferable (in a Darwinian sense) to its death.

23. The *esc* gene is apparently a maternal-effect gene. Thus, the proper distribution of the *esc* gene product in the fertilized egg, which is maternally specified, is sufficient to permit normal embryonic development regardless of the embryo's genotype.

25. Red-green color blindness is conferred by a mutation in an X-linked gene so female carriers of the condition, who do not appear to be red-green colorblind, have one wild-type gene and one mutated

gene. In placental mammals such as humans, females are mosaics of clones of cells in which only one of their two X chromosomes is transcriptionally active. Hence in a female carrier of red–green color blindness, the transcriptionally active X chromosome in some clones will contain the wild-type gene and the others will contain the mutated gene. The former type of retinal clone is able to differentiate red and green light, whereas the latter type of retinal clone is unable to do so. Apparently, these retinal clones are small enough so that a narrow beam of light is necessary to separately interrogate them.

27. Histone and DNA methylation requires *S*-adenosylmethionine (SAM), which becomes *S*-adenosylhomocysteine after it gives up its methyl group (Fig. 21-18). *S*-Adenosylhomocysteine is converted back to methionine, the precursor of SAM, in a reaction in which the methyl group is donated by the folic acid derivative tetrahydrofolate (THF; Fig. 21-18). A shortage of this cofactor could limit cellular production of SAM, which would result in the undermethylation of histones and DNA.
29. A 22-bp segment of RNA, incorporating all four nucleotides, has $4^{22} = 1.8 \times 10^{13}$ possible unique sequences. An RNA half this size would have only 4^{11} or 4.2×10^6 possible sequences. The shorter the siRNA, the greater the probability that it could hybridize with more than one complementary mRNA, thereby making it less efficient in silencing a specific gene. (In the 3.0×10^9 -bp human genome, a sequence of 16 bp has a high probability of randomly occurring at least once.)
31. If the cancer cell's transformed state results, at least in part, from the absence of a functional tumor suppressor gene such as that expressing pRb, and if the chromosomes that the normal cell contribute to the fused cell express that tumor suppressor gene, then the fused cell will have a nontumorigenic phenotype. This is because tumor suppressor gene products suppress uncontrolled cell proliferation (cancer) so that cells requiring such a gene product for normal growth, but lacking it, will assume the cancerous state.

GLOSSARY

Numbers and Greek letters are alphabetized as if they were spelled out.

aaRS. See aminoacyl-tRNA synthetase.

aa-tRNA. See aminoacyl-tRNA.

ABC transporter. A member of a large family of transmembrane proteins that use the free energy of ATP to mediate the transport of polar or nonpolar substances across a membrane.

ABO blood group antigens. The oligosaccharide components of glycolipids on the surfaces of erythrocytes and other cells.

Absolute configuration. The spatial arrangement of chemical groups around a chiral center.

Absorbance (A). A function of the amount of light transmitted through a solution (I) relative to the incident light (I_0) at a given wavelength: $A = \log(I_0/I)$. Also called optical density.

Absorptivity (ϵ). A constant that relates the absorbance of a solution to the concentration of the solute at a given wavelength. Also called the extinction coefficient.

Acceptor stem. The base-paired region of a tRNA molecule that contains the 5' end and the 3' end, to which an amino acid is attached.

Accessory pigment. A molecule in a photosynthetic system that absorbs light at wavelengths other than those absorbed by chlorophyll.

Acid. A substance that can donate a proton.

Acidic solution. A solution whose pH is less than 7.0 ($[H^+] > 10^{-7} M$).

Acidosis. A pathological condition in which the pH of the blood drops below its normal value of 7.4.

Action potential. The wave of transient depolarization and repolarization that constitutes the electrical signal generated by a nerve cell.

Active site. The region of an enzyme in which catalysis takes place.

Active transport. The transmembrane movement of a substance from low to high concentrations by a protein that couples this endergonic transport to an exergonic process such as ATP hydrolysis.

Activity. A solute's concentration, corrected for its nonideal behavior at concentrations greater than infinite dilution.

Acyl-carrier protein (ACP). A phosphopantetheine-containing protein that binds the intermediates of fatty acid synthesis as thioesters.

Acyl-enzyme intermediate. An intermediate of peptide bond hydrolysis in which the carbonyl carbon of the scissile bond is covalently bound to the enzyme nucleophile that attacked it.

Adenylation. Addition of an adenylyl (AMP) group.

Adipocyte. Fat cell, which is specialized for the synthesis and storage of triacylglycerols from free fatty acids.

Adipose tissue. Fat cells; distributed throughout an animal's body.

ADP-ATP translocator. A membrane transport protein with an adenine nucleotide-binding site that alternately allows ADP to enter and ATP to exit the mitochondrial matrix.

Adrenergic receptor. A cell-surface receptor that binds and responds to adrenal hormones such as epinephrine and norepinephrine. Also called an adrenoreceptor.

Aerobic glycolysis. The rapid consumption of glucose that is directed toward anabolic processes to support the rapid growth of cells such as cancer cells.

Affinity chromatography. A procedure in which a molecule is separated from a mixture of other molecules by its ability to bind specifically to an immobilized ligand. See also metal chelate affinity chromatography.

Affinity labeling. A technique in which a labeled substrate analog reacts irreversibly with, and can thereby be used to identify, a group in an enzyme's active site.

Agarose. Linear carbohydrate polymers, made by red algae, that form a loose mesh.

Agonist. A substance that binds to a receptor to evoke a cellular response.

Alcoholic fermentation. A metabolic pathway that synthesizes ethanol from pyruvate through decarboxylation and reduction.

Alditol. A sugar produced by reduction of an aldose or ketose to a polyhydroxy alcohol.

Aldol cleavage. A carbon-carbon cleavage reaction of an aldol (an aldehyde or ketone with a β hydroxyl group) that yields smaller carbonyl compounds.

Aldonic acid. A sugar produced by oxidation of an aldose aldehyde group to a carboxylic acid group.

Aldose. A sugar whose carbonyl group is an aldehyde.

Alkalosis. A pathological condition in which the pH of the blood rises above its normal value of 7.4.

Allele. An alternate form of a gene; diploid organisms contain two alleles for each gene, which may or may not be identical.

Allosteric effector. A small molecule whose binding to a protein affects the function of another site on the protein.

Allosteric interaction. The binding of ligand at one site in a macromolecule that affects the binding of other ligands at other sites in the molecule. See also cooperative binding.

α motif. A protein motif consisting of two α helices packed against each other with their axes inclined.

α -amino acid. See amino acid.

α anomer. See anomers.

α/β barrel. A β barrel in which successive parallel β strands are connected by α helices such that a barrel of α helices surrounds the β barrel.

α carbon. The carbon atom of an amino acid to which the amino and carboxylic acid groups are attached.

α -glycoside. See glycoside.

α helix. A regular secondary structure of polypeptides, with 3.6 residues per right-handed turn, a pitch of 5.4 Å, and hydrogen bonds between each backbone N-H group and the backbone C=O group that is four residues earlier.

Alternative gene splicing. The tissue-specific patterns of splicing of a given pre-mRNA that result in variations in the excision and retention of introns and exons.

Alternative splicing. The tissue-specific patterns of splicing of a given pre-mRNA that result in variations in the excision and retention of introns and exons.

Alzheimer's disease. A neurodegenerative disease characterized by the precipitation of β amyloid protein in the brain.

Ames test. A method for assessing the mutagenicity of a compound from its ability to cause genetically defective strains of bacteria to revert to normal growth.

Amino acid. A compound consisting of a carbon atom to which are attached a primary amino group, a carboxylic acid group, a side chain (R group), and an H atom. Also called an α -amino acid.

Aminoacyl site (A site). The ribosomal site where a tRNA with an attached aminoacyl group binds during protein synthesis.

Aminoacyl-tRNA (aa-tRNA). The covalent ester complex between an "activated" amino acid and a tRNA molecule.

Aminoacyl-tRNA synthetase (aaRS). An enzyme that catalyzes the ATP-dependent esterification of an amino acid to a tRNA with high specificity for the amino acid and the tRNA molecule.

Amino sugar. A sugar in which one or more OH groups are replaced by an amino group, which is often acetylated.

Amino terminus. The end of a polypeptide that has a free amino group. Also called the N-terminus.

Amphibolic. A term to describe a metabolic process that can be either catabolic or anabolic.

G-2

Amphipathic substance. See amphiphilic substance.

Amphiphilic substance. A substance that contains both polar and nonpolar regions and is therefore both hydrophilic and hydrophobic. Also called an amphipathic substance.

Amyloid. Insoluble extracellular aggregates of fibrous protein that characterize such diseases as Alzheimer's disease and the transmissible spongiform encephalopathies.

Anabolism. The reactions by which biomolecules are synthesized from simpler components.

Anaerobe. An organism that does not use O_2 as an oxidizing agent for nutrient breakdown. An obligate anaerobe cannot grow in the presence of O_2 , whereas a facultative anaerobe can grow in the presence or absence of O_2 .

Anaplerotic reaction. A reaction that replenishes the intermediates of a metabolic pathway.

Androgen. A steroid that functions primarily as a male sex hormone.

Angina pectoris. Chest pain due to insufficient blood supply to the heart. Often just called angina.

Anion exchanger. A cationic matrix used to bind anionic molecules in ion exchange chromatography.

Anneal. To maintain conditions that allow loose base pairing between complementary single polynucleotide strands so that properly paired double-stranded segments form.

Anomeric carbon. The carbonyl carbon of a monosaccharide unit, which becomes a chiral center when the sugar cyclizes to a hemiacetal or hemiketal.

Anomers. Sugars that differ only in the configuration around the anomeric carbon. In the α anomer, the OH substituent of the anomeric carbon is on the opposite side of the ring from the CH_2OH group at the chiral center that designates the D or L configuration. In the β anomer, the OH substituent is on the same side.

Antagonist. A substance that binds to a receptor but does not elicit a cellular response.

Antenna chlorophyll. A chlorophyll group that absorbs light energy and passes it on to a photosynthetic reaction center by exciton transfer.

Antibody. A protein produced by an animal's immune system in response to the introduction of a foreign substance (an antigen); it contains at least one pair each of identical heavy and light chains. Also called an immunoglobulin (Ig).

Anticodon. The sequence of three nucleotides in tRNA that recognizes an mRNA codon through complementary base pairing.

Anticodon arm. The conserved stem-loop structure in a tRNA molecule that includes the anticodon.

Anti conformation. A purine or pyrimidine nucleotide conformation in which the ribose and the base point away from each other. See also syn conformation.

Antigen. A substance that elicits an immune response (production of antibodies) when introduced into an animal; it is specifically recognized by an antibody.

Antioxidant. A substance that destroys reactive oxygen species such as O_2^- or $\cdot OH$.

Antiparallel. Extending in opposite directions.

Antiport. A transmembrane channel that simultaneously transports two molecules or ions in opposite directions. See also symport and uniport.

Antisense RNA. A single-stranded RNA molecule that forms a double-stranded structure with a complementary mRNA to block its translation into protein.

Antisense strand. The DNA strand that serves as a template for transcription; it is complementary to the RNA. Also called the noncoding strand.

Apoenzyme. An enzyme that is inactive due to the absence of a cofactor.

Apolipoprotein. A protein component of a lipoprotein. Also called an apoprotein.

Apoprotein. A protein without the prosthetic group or metal ion that renders it fully functional. See also apoenzyme and apolipoprotein.

Apoptosis. Cell death by a regulated process in which the cell shrinks and fragments into membrane-bounded portions for phagocytosis by other cells. See also necrosis.

Aptamer. A nucleic acid whose conformation allows it to bind a particular ligand with high specificity and high affinity.

Aquaporin. A membrane protein that mediates the rapid diffusion of water molecules but not protons or other ions across a membrane.

Archaea. One of the two major groups of prokaryotes (the other is eubacteria). Also known as archaeobacteria.

Archaeobacteria. See archaea.

A site. See aminoacyl site.

Assay. A laboratory technique for detecting, and in many cases quantifying, a macromolecule or its activity.

Asymmetric center. See chiral center.

Atherosclerosis. A disease characterized by the formation of cholesterol-containing fibrous plaques in the walls of blood vessels, leading to loss of elasticity and blockage of blood flow.

Atomic force microscopy (AFM). A technique for determining molecular topography at subnanometer resolution by passing a mechanical probe over a surface and monitoring its deflection by optical or electronic means.

ATPase. An enzyme that catalyzes the hydrolysis of ATP to ADP + P_i or the reverse reaction.

ATP mass action ratio. The ratio $[ATP]/[ADP][P_i]$, which influences the rate of electron transport and oxidative phosphorylation.

Attenuator. A prokaryotic control element that governs transcription of an operon according to the availability of an amino acid synthesized by the proteins encoded by the operon.

Autocatalytic reaction. A reaction in which a product molecule can act as a catalyst for the same reaction; the reactant molecule therefore appears to catalyze its own reaction.

Autoimmune disease. A disease in which the immune system has lost some of its self-tolerance and attacks certain self-antigens.

Autophagy. The process in which damaged or unneeded organelles are enclosed by a membrane and the resulting vesicle fuses with a lysosome that digests its contents.

Autophosphorylation. The kinase-catalyzed phosphorylation of itself or an identical molecule.

Autoradiography. A process in which X-ray film records the positions of radioactive entities, such as proteins or nucleic acids, that have been immobilized in a matrix such as a nitrocellulose membrane or an electrophoretic gel.

Autotroph. An organism that can synthesize all its cellular components from simple molecules using the energy obtained from sunlight (photoautotroph) or from the oxidation of inorganic compounds (chemolithotroph).

Axial substituent. A group that extends approximately perpendicularly from the plane of the ring to which it is bonded. See also equatorial substituent.

Backbone. The atoms that form the repeating linkages between successive residues of a polymeric molecule, exclusive of the side chains. Also called the main chain.

Bacteria. The organisms comprising the two major groups of prokaryotes, the archaea and the eubacteria.

Bacterial artificial chromosome (BAC). A plasmid-derived DNA molecule that can replicate in a bacterial cell. BACs are commonly used as cloning vectors.

Bacteriophage. A virus specific for bacteria. Also known as a phage.

Barr body. The condensed and darkly staining inactive X chromosome in the nucleus of a female mammalian cell.

Base. (1) A substance that can accept a proton. (2) A purine or pyrimidine component of a nucleoside, nucleotide, or nucleic acid.

Base excision repair (BER). The removal and replacement of a damaged nucleotide in DNA that is initiated by the removal of its base.

Base pair. The specific hydrogen-bonded association between nucleic acid bases. The Watson-Crick base pairs are A • T and G • C.

- Basic helix–loop–helix (bHLH) motif.** A eukaryotic protein motif that includes a basic DNA-binding region followed by two amphipathic helices connected by a loop. The second helix, which mediates protein dimerization, is often continuous with a leucine zipper motif.
- Basic solution.** A solution whose pH is greater than 7.0 ($[H^+] < 10^{-7}$ M).
- Beer–Lambert law.** The equation that describes the relationship between a solute's absorbance (A) and its concentration (c): $A = \epsilon cl$ where ϵ is the solute's molar absorptivity and l is the length of the light path.
- Beriberi.** A disease caused by a deficiency of thiamine (vitamin B₁), which is a precursor of the cofactor thiamine pyrophosphate.
- $\beta\alpha\beta$ motif.** A protein motif consisting of an α helix connecting two parallel strands of a β sheet.
- β anomer.** See anomers.
- β barrel.** A protein motif consisting of a β sheet rolled into a cylinder.
- β bend.** See reverse turn.
- β bulge.** An irregularity in a β sheet resulting from an extra residue that is not hydrogen bonded to a neighboring chain.
- β -glycoside.** See glycoside.
- β hairpin.** A protein motif in which two antiparallel β strands are connected by a reverse turn.
- β sheet.** A regular secondary structure in which extended polypeptide chains form interstrand hydrogen bonds. In parallel β sheets, the polypeptide chains all run in the same direction; in antiparallel β sheets, neighboring chains run in opposite directions.
- bHLH motif.** See basic helix–loop–helix motif.
- Bilayer.** An ordered, double layer of amphiphilic molecules in which polar segments point toward the two solvent-exposed surfaces and the nonpolar segments associate in the center.
- Bile acid (bile salt).** An amphiphilic cholesterol derivative that acts as a detergent to solubilize lipids for digestion and absorption.
- Binding change mechanism.** The mechanism whereby the subunits of the F₁F₀-ATP synthase adopt three successive conformations to convert ADP + P_i to ATP as driven by the dissipation of the transmembrane proton gradient.
- Bioavailability.** A measure of the fraction of a drug that reaches its target tissue, which depends on the drug's dosage and pharmacokinetics.
- Biochemical standard state.** A set of conditions including unit activities of the species of interest, a temperature of 25°C, a pressure of 1 atm, and a pH of 7.0.
- Biofilm.** A surface-associated aggregate of bacterial cells and extracellular polysaccharides that protect the cells from environmental assault.
- Bioinformatics.** The study of biological information in the form of molecular sequences and structures; e.g., structural bioinformatics.
- Blastoderm.** The single layer of cells surrounding a yolklake core that forms during the early development of an insect larva.
- Blunt ends.** The fully base-paired ends of a DNA fragment that has been cleaved by a restriction endonuclease that cuts the DNA strands at opposing sites.
- Bohr effect.** The decrease in O₂ binding affinity of hemoglobin in response to a decrease in pH.
- bp.** Base pair, the two hydrogen-bonded bases that form the repeating units of double helical nucleic acids. Thousands of base pairs (kilobase pairs) are abbreviated kb.
- Branch migration.** The movement of a crossover point in a Holliday junction during DNA recombination.
- Breathing.** The small conformational fluctuations of a protein molecule.
- Bromodomain.** A protein module that binds acetylated Lys residues in histones.
- Brownian ratchet.** A molecular mechanism in which random thermal (Brownian) back-and-forth fluctuations are converted to coherent forward motion by inhibiting the backward motion.
- Buffer.** A solution of a weak acid and its conjugate base in approximately equal quantities. Such a solution resists changes in pH on the addition of acid or base.
- Buffering capacity.** The ability of a buffer solution to resist pH changes on addition of acid or base. Buffers are most useful when the pH is within one unit of its component acid's pK.
- Cahn–Ingold–Prelog system (RS system).** A system for unambiguously describing the configurations of molecules with one or more asymmetric centers by assigning a priority ranking to the substituent groups of each asymmetric center.
- Calmodulin (CaM).** A small Ca²⁺-binding protein that binds to other proteins in the presence of Ca²⁺ and thereby regulates their activities.
- Calvin cycle.** The sequence of photosynthetic dark reactions in which ribulose-5-phosphate is carboxylated, converted to three-carbon carbohydrate precursors, and regenerated. Also called the reductive pentose phosphate cycle.
- cAMP.** 3',5'-Cyclic AMP, an intracellular second messenger.
- CaM.** See calmodulin.
- CAM.** See crassulacean acid metabolism.
- Cap.** A 7-methylguanosine residue that is posttranscriptionally appended to the 5' end of a eukaryotic mRNA.
- Capillary electrophoresis (CE).** Electrophoretic procedures carried out in small-diameter capillary tubes.
- Carbamate.** The product of a reaction between CO₂ and an amino group: —NH—COO[−].
- Carbohydrate.** A compound with the formula (C · H₂O)_n where $n \geq 3$. Also called a saccharide.
- Carboxyl terminus.** The end of a polypeptide that has a free carboxylate group. Also called the C-terminus.
- Carcinogen.** An agent that damages DNA to induce a mutation that leads to uncontrolled cell proliferation (cancer).
- Caspase.** A heterotetrameric cysteine protease that hydrolyzes cellular proteins, including caspase zymogens, as part of the process of apoptosis.
- Catabolism.** The degradative metabolic reactions in which nutrients and cell constituents are broken down for energy and raw materials.
- Catabolite repression.** A phenomenon in bacteria in which the presence of glucose prevents the expression of genes involved in the metabolism of other fuels.
- Catalyst.** A substance that promotes a chemical reaction without itself undergoing permanent change. A catalyst increases the rate at which a reaction approaches equilibrium but does not affect the free energy change of the reaction.
- Catalytic perfection.** The ability of an enzyme to catalyze a reaction as fast as diffusion allows it to bind its substrates.
- Catalytic triad.** The hydrogen-bonded Ser, His, and Asp residues that participate in catalysis in serine proteases and related enzymes.
- Cataplerotic reaction.** A reaction that drains the intermediates of a metabolic pathway.
- Catecholamine.** A hydroxylated tyrosine derivative, such as dopamine, norepinephrine, or epinephrine.
- Catenate.** To interlink circular DNA molecules like the links of a chain.
- Cation exchanger.** An anionic matrix used to bind cationic molecules in ion exchange chromatography.
- CCAAT box.** A eukaryotic promoter element with the consensus sequence CCAAT that, in many structural genes, is located 70 to 90 nucleotides upstream from the transcription start site.
- cdNA.** See complementary DNA.
- Cell cycle.** The sequence of events between eukaryotic cell divisions; it includes mitosis and cell division (M phase), a gap stage (G₁ phase), a period of DNA synthesis (S phase), and a second gap stage (G₂ phase) before the next M phase.
- Cellular immunity.** Immunity mediated by T lymphocytes (T cells).
- Central dogma of molecular biology.** The paradigm that DNA directs its own replication as well as its transcription to RNA, which is then translated into a polypeptide. The flow of information is from DNA to RNA to protein.

G-4

- Centromere.** The eukaryotic chromosomal region that attaches to the mitotic spindle during cell division; it contains high concentrations of repetitive DNA.
- Ceramide.** A sphingosine derivative with an acyl group attached to its amino group.
- Cerebroside.** A ceramide with a sugar residue as a head group.
- Chain-terminator method.** A technique for determining the nucleotide sequence of a DNA using dideoxy nucleotides so as to yield a collection of daughter strands of all different lengths. Also called the dideoxy method.
- Channeling.** The transfer of an intermediate product from one enzyme active site to another in such a way that the intermediate remains protected by the protein.
- Chaotropic agent.** A substance that increases the solubility of nonpolar substances in water and thereby tends to denature proteins.
- Chargaff's rules.** The observation, first made by Erwin Chargaff, that duplex DNA has equal numbers of adenine and thymine residues and equal numbers of guanine and cytosine residues.
- Chemical potential.** The partial molar free energy of a substance.
- Chemiosmotic theory.** The postulate, now known to be correct, that the free energy of electron transport is conserved by the formation of a transmembrane proton gradient. The electrochemical potential of the gradient is used to drive ATP synthesis.
- Chemolithotroph.** An autotrophic organism that obtains energy from the oxidation of inorganic compounds.
- Chimera.** See recombinant.
- Chiral center.** An atom whose substituents are arranged such that it is not superimposable on its mirror image. Also called an asymmetric center.
- Chirality.** The property of having one or more chiral centers. A chiral molecule cannot be superimposed on its mirror image.
- Chloroplasts.** The plant organelles in which photosynthesis takes place.
- Chromatin-remodeling complex.** An ATP-dependent multisubunit protein in eukaryotes that transiently disrupts DNA-histone interactions so as to alter the accessibility of DNA in nucleosomes.
- Chromatin.** The complex of DNA and protein that comprises the eukaryotic chromosomes.
- Chromatography.** A technique for separating the components of a mixture of molecules based on their partition between a mobile solvent phase and a porous matrix (stationary phase).
- Chromodomain.** A protein module that binds methylated Lys residues in histones.
- Chromophore.** A light-absorbing group or molecule.
- Chromosome.** The complex of protein and a single DNA molecule that comprises some or all of an organism's genome.
- Chromosome territory.** The region of the nucleus occupied by a single chromosome.
- Chylomicrons.** Lipoprotein particles that transport dietary triacylglycerols and cholesterol from the intestines to the tissues.
- Cis conformation.** An arrangement of the peptide group in which successive C_{α} atoms are on the same side of the peptide bond.
- Cistron.** An archaic term for a gene.
- Citric acid cycle.** A set of eight enzymatic reactions, arranged in a cycle, in which free energy in the form of ATP, NADH, and $FADH_2$ is recovered from the oxidation of the acetyl group of acetyl-CoA to CO_2 . Also called the Krebs cycle and the tricarboxylic acid (TCA) cycle.
- Clathrin.** A three-legged protein that polymerizes to form a polyhedral structure defining the shape of membranous vesicles that travel between the plasma membrane and intracellular organelles such as the Golgi apparatus.
- Clinical trials.** A three-phase series of tests of a drug's safety, effectiveness, and side effects in human subjects.
- Clone.** A collection of identical cells derived from a single ancestor.
- Cloning.** The production of exact copies of a DNA segment or the organism that harbors it.
- Closed system.** A thermodynamic system that can exchange energy but not matter with its surroundings.
- Coated vesicle.** A membranous intracellular transport vesicle that is encased by clathrin or another coat protein.
- Coding strand.** See sense strand.
- Codon.** The sequence of three nucleotides in DNA or RNA that specifies a single amino acid.
- Coenzyme.** A small organic molecule that is required for the catalytic activity of an enzyme. A coenzyme may be either a cosubstrate or a prosthetic group.
- Coenzyme Q (CoQ).** An isoprenoid that functions in electron-transport pathways as a lipid-soluble electron carrier. Also called ubiquinone.
- Cofactor.** A small organic molecule (coenzyme) or metal ion that is required for the catalytic activity of an enzyme.
- Coiled coil.** An arrangement of polypeptide chains in which two α helices wind around each other, as in α keratin.
- Cointegrate.** The product of the fusion of two plasmids, which occurs as an intermediate in transposition.
- Colligative property.** A physical property, such as freezing point depression or osmotic pressure, that depends on the concentration of a dissolved substance rather than on its chemical nature.
- Colony hybridization.** A procedure in which DNA from multiple cell colonies is transferred to a membrane or filter and incubated with a DNA or RNA probe to test for the presence of a desired DNA fragment in the cell colonies. Also called *in situ* hybridization.
- Combinatorial chemistry.** A method for rapidly and inexpensively synthesizing large numbers of related compounds by systematically varying a portion of their structure.
- Compartmentation.** The division of a cell into smaller functionally discrete systems.
- Competitive inhibition.** A form of enzyme inhibition in which a substance competes with the substrate for binding to the enzyme active site and thereby appears to increase its K_M .
- Complementary DNA (cDNA).** A DNA molecule, usually synthesized by the action of reverse transcriptase, that is complementary to an mRNA molecule.
- Composite transposon.** A genetic sequence that may include a variety of genes and is flanked by IS-like elements; such transposons apparently arose by the association of two independent IS elements.
- Condensation reaction.** The formation of a covalent bond between two molecules, during which the elements of water are lost; the reverse of hydrolysis.
- Conjugate acid.** The compound that forms when a base accepts a proton.
- Conjugate base.** The compound that forms when an acid donates a proton.
- Conjugate redox pair.** An electron donor and acceptor that form a half-reaction. Also called a redox couple.
- Conservative replication.** A hypothetical mode of DNA duplication in which the parental molecule remains intact and both strands of the daughter duplex are newly synthesized.
- Conservative substitution.** A change of an amino acid residue in a protein to one with similar properties, e.g., Leu to Ile or Asp to Glu.
- Constant region.** The C-terminal portion of an antibody (immunoglobulin) subunit, which does not exhibit the high sequence variability of the antigen-recognizing (variable) region of the antibody.
- Constitutive enzyme.** An enzyme that is synthesized at a more or less steady rate and that is required for basic cell function. Also called a housekeeping enzyme. See also inducible enzyme.
- Contour length.** The end-to-end length of a stretched-out polymer molecule.
- Convergent evolution.** The independent development of similar characteristics in unrelated species or proteins.
- Cooperative binding.** A situation in which the binding of a ligand at one site on a macromolecule affects the affinity of other sites for the same ligand. Both negative and positive cooperativity occur. See also allosteric interaction.
- Corepressor.** A substance that acts together with a protein repressor to block gene transcription.
- Cori cycle.** An interorgan metabolic pathway in which lactate produced by glycolysis in the muscles is transported via the bloodstream to the liver,

- where it is used for gluconeogenesis. The resulting glucose returns to the muscles.
- Cosubstrate.** A coenzyme that is only transiently associated with an enzyme so that it functions as a substrate.
- Coupled enzymatic reaction.** A technique in which the activity of an enzyme is measured by the ability of a second enzyme to use the product of the first enzymatic reaction to produce a detectable product.
- Covalent catalysis.** A catalytic mechanism in which the transient formation of a covalent bond between the catalyst and a reactant lowers the free energy of a reaction's transition state.
- CpG island.** A cluster of CG dinucleotides located just upstream of many vertebrate genes; such sequences occur elsewhere in the genome at only one-fifth their randomly expected frequency.
- Crassulacean acid metabolism (CAM).** A variation of the C₄ photosynthetic cycle in which CO₂ is temporarily stored as malate.
- CRISPR–Cas.** A prokaryotic system in which short RNA transcripts direct the hydrolysis of complementary DNA sequences; components of this system are used to alter specific eukaryotic genes.
- Cristae.** The invaginations of the inner mitochondrial membrane.
- Crosstalk.** The interactions of different signal transduction pathways through activation of the same signaling components, generation of a common second messenger, or similar patterns of target protein phosphorylation.
- Cryo-electron microscopy (cryo-EM).** A technique in electron microscopy in which a sample is rapidly frozen to very low temperatures so it retains its native shape to a greater extent than in conventional electron microscopy.
- C-terminus.** See carboxyl terminus.
- C2'-endo.** A ribose conformation in which C2' is displaced toward the same side of the ring as C5'.
- C3'-endo.** A ribose conformation in which C3' is displaced toward the same side of the ring as C5'.
- Curved arrow convention.** A notation for indicating the movement of an electron pair in a chemical reaction by drawing a curved arrow emanating from the electrons and pointing to the electron-deficient center that attracts the electron pair.
- C value.** A measure of the quantity of an organism's unique genetic material.
- C-value paradox.** The occurrence of exceptions to the rule that an organism's DNA content (C value) is correlated with the complexity of its morphology and metabolism.
- Cyanosis.** A bluish skin color indicating the presence of deoxyhemoglobin in the arterial blood.
- Cyclic symmetry.** A type of symmetry in which the asymmetric units of a symmetric object are related by a single axis of rotation.
- Cyclin.** A member of a family of proteins that participate in regulating the stages of the cell cycle and whose concentrations change dramatically over the course of the cell cycle.
- Cytochrome.** A redox-active protein that carries electrons via a prosthetic Fe-containing heme group.
- Cytochromes P450.** Heme-containing monooxygenases that catalyze the addition of OH groups to drugs and toxins in order to detoxify them and facilitate their excretion.
- Cytoplasm.** The entire contents of a cell, excluding the nucleus.
- Cytoskeleton.** The network of intracellular fibers that gives a cell its shape and structural rigidity.
- Cytosol.** The contents of a cell excluding its nucleus and other membrane-bounded organelles.
- D.** Dalton, a unit of molecular mass; 1/12th the mass of a ¹²C atom.
- D arm.** A conserved stem-loop structure in a tRNA molecule that usually contains the modified base dihydrouracil.
- Dark reactions.** The portion of photosynthesis in which NADPH and ATP produced by the light reactions are used to incorporate CO₂ into carbohydrates.
- ddNTP.** An abbreviation for any dideoxynucleoside triphosphate.
- Deamination.** The hydrolytic removal of an amino group.
- Debranching.** The enzymatic removal of side chains from a branched polymer such as glycogen.
- Degenerate code.** A code in which more than one "word" encodes the same entity.
- Δℰ.** Electromotive force. Change in reduction potential.
- ΔG‡.** See free energy of activation.
- ΔΨ.** See membrane potential.
- Denature.** To disrupt the native conformation of a polymer.
- Density gradient.** A solution used in ultracentrifugation, in which the concentration of a substance such as sucrose or CsCl increases from the top to the bottom of the centrifuge tube.
- Deoxynucleotide.** See deoxyribonucleotide.
- Deoxyribonucleic acid.** See DNA.
- Deoxyribonucleotide.** A nucleotide in which the pentose is 2'-deoxyribose. Also known as a deoxynucleotide.
- Deoxy sugar.** A monosaccharide produced by replacement of an OH group by H.
- Desaturase.** An enzyme that introduces double bonds into a fatty acid.
- Desensitization.** A cell's or organism's adaptation to a long-term stimulus through a reduced response to the stimulus.
- Dextrorotatory.** Rotating the plane of plane-polarized light clockwise from the point of view of the observer; the opposite of levorotatory.
- Diabetes mellitus.** A disease in which the pancreas does not secrete sufficient insulin (also called type 1, insulin-dependent, or juvenile-onset diabetes) or in which the body has insufficient response to circulating insulin (type 2, non-insulin-dependent, or maturity-onset diabetes). Diabetes is characterized by elevated levels of glucose in the blood.
- Dialysis.** A procedure in which solvent molecules and solutes smaller than the pores in a semipermeable membrane freely exchange with the bulk medium, while larger solutes are retained, thereby changing the solution in which the larger molecules are dissolved.
- Diazotroph.** A bacterium that can fix nitrogen.
- Dideoxy method.** See chain-terminator procedure.
- Diet-induced thermogenesis.** See thermogenesis.
- Diffraction pattern.** The record of the destructive and constructive interferences of radiation scattered from an object. In X-ray crystallography, this takes the form of a series of discrete spots resulting from a collimated beam of X-rays scattering from a single crystal.
- Diffusion.** The transport of molecules through their random movement.
- Diffusion-controlled limit.** The theoretical maximum rate of an enzymatic reaction in solution; about 10⁸ to 10⁹ M⁻¹ · s⁻¹.
- Dihedral angle.** See torsion angle.
- Dihedral symmetry.** A type of symmetry in which the asymmetric units are related by a twofold rotation axis that intersects another rotation axis at a right angle.
- Dimer.** An assembly consisting of two monomeric units (protomers).
- Dinucleotide binding fold.** A protein structural motif consisting of two βαβαβ units, which binds a dinucleotide such as NAD⁺. Also called a Rossmann fold.
- Dipeptide.** A polypeptide consisting of two amino acids.
- Diploid.** Having two equivalent sets of chromosomes.
- Dipolar ion.** A compound bearing oppositely charged groups. Also called a zwitterion.
- Disaccharide.** A carbohydrate consisting of two monosaccharides linked by a glycosidic bond.
- Dissociation constant (K).** The ratio of the products of the concentrations of the dissociated species to those of their parent compounds at equilibrium.
- DNA.** Deoxyribonucleic acid. A polymer of deoxynucleotides whose sequence of bases encodes genetic information in all living cells.
- DNA chip.** See DNA microarray.
- DNA fingerprinting.** A technique for distinguishing individuals on the basis of DNA polymorphisms, such as the number of short tandem repeats (STR).

G-6

DNA microarray. A set of DNA segments of known sequence that are immobilized on a solid support for the purpose of hybridizing them with nucleic acids in test samples. Also called a DNA chip.

dNTP. A deoxyribonucleoside triphosphate.

Dolichol. A long-chain polyisoprenoid that serves as a lipid-soluble carrier of an *N*-linked oligosaccharide during its synthesis in the endoplasmic reticulum.

Domain. A group of one or a few polypeptide segments of about 40–200 residues that folds into a globular unit.

Double-displacement reaction. A reaction in which a substrate binds and a product is released in the first stage, and another substrate binds and another product is released in the second stage.

Double-reciprocal plot. See Lineweaver–Burk plot.

Drug–drug interactions. Increases or decreases in the bioavailability of a drug caused by the metabolic effects of another drug.

ℰ. See reduction potential.

EC classification. The Enzyme Commission's system for classifying and numbering enzymes according to the type of reaction catalyzed.

Edman degradation. A chemical reaction that is used for the stepwise removal and identification of the N-terminal residues of a polypeptide.

EF hand. A widespread helix–loop–helix structural motif that forms a Ca^{2+} -binding site.

Eicosanoids. C_{20} compounds derived from the C_{20} fatty acid arachidonic acid and which act as local mediators. Prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins are eicosanoids.

Electrochemical cell. A device in which two half-reactions occur in separate compartments linked by a wire for transporting electrons and a salt bridge for maintaining electrical neutrality; the simultaneous activity of the half-reactions forms a complete oxidation–reduction reaction.

Electrochemical potential. The partial molar free energy of a substance (chemical potential) in the presence of an electrical potential.

Electromotive force (emf), $\Delta\mathcal{E}$. Change in reduction potential.

Electron crystallography. A technique for determining molecular structure, in which the electron beam of an electron microscope is used to elicit diffraction from a two-dimensional crystal of the molecules of interest.

Electron density. The distribution of electrons that gives rise to a diffraction pattern in X-ray crystallography.

Electron Transport. The metabolic pathway through which NADH and FADH_2 are oxidized by O_2 with the concomitant translocation of protons through the membrane.

Electrospray ionization (ESI). A method for vaporizing macromolecules for their mass spectrometry in which a macromolecular solution is sprayed from a narrow capillary at high voltage to produce fine, highly charged droplets that rapidly evaporate, leaving the now charged macromolecule in the gas phase.

Electrostatic catalysis. A catalytic mechanism in which the distribution of charges about the catalytic site lowers the free energy of a reaction's transition state.

Elementary reaction. A simple one-step chemical process, several of which may occur in sequence in a chemical reaction.

Elongase. An enzyme that adds acetyl units to a fatty acid previously synthesized by fatty acid synthase.

Elongation factor. A protein that interacts with tRNA and/or the ribosome during polypeptide synthesis.

Eluant. The solution used to wash material through a chromatographic column.

Elution. The process of dislodging a molecule that has bound to a chromatographic matrix.

Emergent property. A property of a complex system that is not attributable to any of its individual components but becomes apparent when all components are present.

emf. Electromotive force. Change in reduction potential.

Enantiomers. Molecules that are nonsuperimposable mirror images of one another. Enantiomers are a type of stereoisomer.

Endergonic process. A process that has an overall positive free energy change (a nonspontaneous process).

Endocrine gland. A tissue in higher animals that synthesizes and releases hormones into the bloodstream.

Endocytosis. The internalization of extracellular material through the formation of a vesicle that buds off from the plasma membrane; the opposite of exocytosis. See also receptor-mediated endocytosis.

Endoglycosidase. An enzyme that catalyzes the hydrolysis of the glycosidic bonds between two monosaccharide units within a polysaccharide.

Endonuclease. An enzyme that catalyzes the hydrolysis of the phosphodiester bonds between two nucleotide residues within a polynucleotide strand.

Endopeptidase. An enzyme that catalyzes the hydrolysis of a peptide bond within a polypeptide chain.

Endoplasmic reticulum (ER). A labyrinthine membranous organelle in eukaryotic cells in which membrane lipids are synthesized and proteins destined for secretion, membrane insertion, and residence in certain organelles undergo posttranslational modification.

Endosome. A membrane-bounded vesicle that receives materials that the cell ingests via receptor-mediated endocytosis and passes them to lysosomes for degradation.

Enediol intermediate. A reaction intermediate containing a carbon–carbon double bond and a hydroxyl group attached to each carbon.

Energy coupling. The conservation of the free energy of electron transport in a form that can be used to synthesize ATP from $\text{ADP} + \text{P}_i$.

Enhanceosome. A complex containing several transcription factors that regulates gene expression in eukaryotes.

Enhancer. A eukaryotic DNA sequence located some distance from the transcription start site, where an activator of transcription may bind.

Enthalpy (H). A thermodynamic quantity, $H = U + PV$, that is equivalent to the heat absorbed at constant pressure (q_p).

Entropy (S). A measure of the degree of randomness or disorder of a system. It is defined as $S = k_B \ln W$, where k_B is the Boltzmann constant and W is the number of equivalent ways the system can be arranged in its particular state.

Enzyme. A biological catalyst. Most enzymes are proteins; a few are RNA.

Enzyme-linked immunosorbent assay (ELISA). A technique in which a molecule is detected, and in many cases quantified, by its ability to bind an antibody to which an enzyme with an easily detected reaction product is attached.

Epigenetics. The inheritance of patterns of gene expression that are maintained from generation to generation independent of DNA's base sequence. This occurs, for example, through the methylation of DNA.

Epimers. Sugars that differ only by the configuration at one C atom (excluding the anomeric carbon).

Equatorial substituent. A group that extends largely in the plane of the ring to which it is bonded. See also axial substituent.

Equilibrium. The point in a process at which the forward and reverse reaction rates are exactly balanced so that it undergoes no net change.

Equilibrium constant (K_{eq}). The ratio, at equilibrium, of the product of the concentrations of reaction products to those of its reactants. K_{eq} is related to ΔG° for the reaction: $\Delta G^\circ = -RT \ln K_{\text{eq}}$. Usually abbreviated K .

ER. See endoplasmic reticulum.

Erythrocyte. A red blood cell, which functions to transport O_2 to the tissues. It is essentially a membranous sack of hemoglobin.

ES complex. The enzyme–substrate complex, whose formation is a key component of the Michaelis–Menten model of enzyme action. Also called the Michaelis complex.

E site. See exit site.

Essential amino acid. An amino acid that an animal cannot synthesize and must therefore obtain in its diet.

Essential fatty acid. A required fatty acid that an animal cannot synthesize and must therefore obtain in its diet.

- EST.** See expressed sequence tag.
- Estrogen.** A steroid that functions primarily as a female sex hormone.
- Eubacteria.** One of the two major groups of prokaryotes (the other is archaea).
- Euchromatin.** The transcriptionally active, relatively uncondensed chromatin in a eukaryotic cell.
- Eukarya.** See eukaryote.
- Eukaryote.** An organism consisting of a cell (or cells) whose genetic material is contained in a membrane-bounded nucleus.
- Evolution.** The gradual alteration of an organism or one of its components through natural selection as a result of genetic changes that are passed from parent to offspring.
- Exciton transfer.** A mode of decay of an energetically excited molecule, in which electronic energy is transferred to a nearby unexcited molecule. Also known as resonance energy transfer.
- Ergonic process.** A process that has an overall negative free energy change (a spontaneous process).
- Exit site (E site).** The ribosomal binding site that accommodates a tRNA molecule that has previously transferred its peptidyl group to an incoming aminoacyl-tRNA and is ready to dissociate from the ribosome.
- Exocytosis.** The release outside the cell of a vesicle's contents through the fusion of the vesicle membrane with the plasma membrane; the opposite of endocytosis.
- Exoglycosidase.** An enzyme that catalyzes the hydrolytic excision of a monosaccharide unit from the end of a polysaccharide.
- Exome.** A complete set of a cell's mRNAs.
- Exon.** A portion of a gene that appears in both the primary and mature mRNA transcripts. Also called an expressed sequence.
- Exonuclease.** An enzyme that catalyzes the hydrolytic excision of a nucleotide residue from one end of a polynucleotide strand.
- Exopeptidase.** An enzyme that catalyzes the hydrolytic excision of an amino acid residue from one end of a polypeptide chain.
- Expressed sequence.** See exon.
- Expressed sequence tag (EST).** A cDNA segment corresponding to a cellular mRNA, that can be used to identify genes that are transcribed.
- Expression vector.** A plasmid containing the transcription and translation control sequences required for the production of a foreign DNA gene product (RNA or protein) in a host cell.
- Extinction coefficient.** See absorptivity.
- Extrinsic protein.** See peripheral protein.
- \mathcal{F} . Faraday, the electrical charge of one mole of electrons ($96,485 \text{ C} \cdot \text{mol}^{-1}$).
- Fab fragment.** A proteolytic fragment of an antibody molecule that contains the antigen-binding site. See also Fc fragment.
- Facilitated diffusion.** See passive-mediated transport.
- Familial hypercholesterolemia.** See hypercholesterolemia.
- Fat.** A mixture of triacylglycerols that is solid at room temperature.
- Fatty acid.** A carboxylic acid with a long-chain hydrocarbon side group.
- Fc fragment.** A proteolytic fragment of an antibody molecule that contains the two C-terminal domains of its two heavy chains. See also Fab fragment.
- Feedback inhibition.** The inhibition of an early step in a reaction sequence by the product of a later step.
- Feedforward activation.** The activation of a later step in a reaction sequence by the product of an earlier step.
- Fibrous protein.** A protein characterized by a stiff, elongated conformation, that tends to form fibers.
- First-order reaction.** A reaction whose rate is proportional to the concentration of a single reactant.
- Fischer convention.** A system for describing the absolute configurations of chiral molecules by relating their structures to that of D- or L-glyceraldehyde.
- Fischer projection.** A graphical convention for specifying molecular configuration in which horizontal lines represent bonds that extend above the plane of the drawing and vertical lines represent bonds that extend below the plane of the drawing.
- FISH.** See fluorescence *in situ* hybridization.
- 5' end.** The terminus of a polynucleotide whose C5' is not esterified to another nucleotide residue.
- Flip-flop.** See transverse diffusion.
- Flippase.** An enzyme that catalyzes the translocation of a membrane lipid across a lipid bilayer (a flip-flop).
- Fluid mosaic model.** A model of biological membranes in which integral membrane proteins float and diffuse laterally in a fluid lipid bilayer.
- Fluorescence.** A mode of decay of an excited molecule, in which electronic energy is emitted in the form of a photon.
- Fluorescence *in situ* hybridization (FISH).** A microscopic technique in which a fluorescently labeled DNA or RNA probe is allowed to bind to a complementary segment of chromosomal DNA in an intact cell.
- Fluorescence recovery after photobleaching (FRAP).** A technique for assessing the diffusion of membrane components from the rate at which the fluorescently labeled component moves into an area previously bleached by an intense pulse of laser light.
- Fluorophore.** A fluorescent group or molecule.
- Flux.** (1) The rate of flow of metabolites through a metabolic pathway, J . (2) The rate of transport per unit area.
- Footprinting.** A procedure in which the DNA sequence to which a protein binds is identified by determining which bases are protected by the protein from chemical or enzymatic modification.
- Fractional saturation (Y).** The fraction of a protein's ligand-binding sites that are occupied by ligand. For example, Y_{O_2} is the fractional saturation of a protein's oxygen-binding sites.
- Fractionation procedure.** A laboratory technique for separating the components of a mixture of molecules through differences in their chemical and physical properties.
- Frameshift mutation.** An insertion or deletion of nucleotides in DNA that alters the sequential reading (the frame) of sets of three nucleotides (codons) during translation.
- FRAP.** See fluorescence recovery after photobleaching.
- Free energy (G).** A thermodynamic quantity, $G = H - TS$, whose change at constant pressure is indicative of the spontaneity of a process. For spontaneous processes, $\Delta G < 0$, whereas for a process at equilibrium, $\Delta G = 0$. Also called the Gibbs free energy.
- Free energy of activation (ΔG^\ddagger).** The free energy of the transition state minus the free energies of the reactants in a chemical reaction.
- Free radical.** A molecule with an unpaired electron.
- Functional group.** A portion of a molecule that participates in interactions with other substances. Common functional groups in biochemistry are acyl, amido, amino, carbonyl, carboxyl, diphosphoryl (pyrophosphoryl), ester, ether, hydroxyl, imino, phosphoryl, and sulfhydryl groups.
- Furanose.** A sugar with a five-membered ring.
- Futile cycle.** See substrate cycle.
- Ganglioside.** A ceramide whose head group is an oligosaccharide containing at least one sialic acid residue.
- Gap genes.** See segmentation genes.
- Gap junction.** An intercellular channel for ions and small molecules that is formed by protein complexes in the membranes of apposed cells.
- Gastrulation.** The stage of embryonic development in which cells migrate to form a triple-layered structure.
- Gates and fences model.** A model for membrane structure that includes cytoskeletal proteins that prevent or limit the free diffusion of other membrane proteins.
- Gating.** The opening and closing of a transmembrane channel in response to a signal such as mechanical stimulation, ligand binding, presence of a signaling molecule, or change in membrane voltage.
- Gel electrophoresis.** A procedure in which macromolecules are separated on the basis of charge or size by their differential migration through a gel-like matrix under the influence of an applied electric field. In polyacrylamide gel electrophoresis (PAGE), the matrix is cross-linked polyacrylamide. Agarose gels are used to separate molecules of very

G-8

- large masses, such as DNAs. See also SDS-PAGE and pulsed-field gel electrophoresis.
- Gel filtration chromatography.** A procedure in which macromolecules are separated on the basis of their size and shape. Also called size exclusion or molecular sieve chromatography.
- Gene.** A unique sequence of nucleotides that encodes a polypeptide or RNA; it may include nontranscribed and nontranslated sequences, some of which have regulatory functions.
- Gene cluster.** A region of DNA containing multiple copies of genes, usually tRNA or rRNA genes, whose products are required in large amounts.
- Gene duplication.** An event, such as aberrant crossover, that gives rise to two copies of a gene on the same chromosome, each of which can then evolve independently.
- Gene expression.** The decoding, via transcription and translation, of the information contained in a gene to yield a functional RNA or protein product.
- Gene knockout.** A genetic engineering process that deletes or inactivates a specific gene in an animal.
- Gene product.** The RNA or protein that is encoded by a gene and that is the end point of the gene's expression through transcription and translation.
- Gene therapy.** The transfer of genetic material to the cells of an individual in order to produce a therapeutic effect.
- General acid catalysis.** A catalytic mechanism in which partial proton transfer from an acid lowers the free energy of a reaction's transition state.
- General base catalysis.** A catalytic mechanism in which partial proton abstraction by a base lowers the free energy of a reaction's transition state.
- General transcription factor (GTF).** One of a set of eukaryotic proteins that are required for the synthesis of all mRNAs.
- Genetic anticipation.** A pattern of inheritance of a genetic disease, in which the age of onset of symptoms decreases with each generation.
- Genetic code.** The correspondence between the sequence of nucleotides in a nucleic acid and the sequence of amino acids in a polypeptide; a series of three nucleotides (a codon) specifies an amino acid.
- Genome.** The complete set of genetic instructions in an organism.
- Genome-wide association study (GWAS).** A systematic examination of genetic differences between individuals with and without a disease in order to identify DNA sequence variations that might contribute to the disease.
- Genomic library.** A set of cloned DNA fragments representing an organism's entire genome.
- Genomics.** The study of the size, organization, and gene content of organisms' genomes.
- Gibbs free energy.** See free energy.
- Globin.** The polypeptide components of myoglobin and hemoglobin.
- Globular protein.** A water-soluble protein characterized by a compact, highly folded structure.
- Glucocorticoid.** A steroid hormone that affects a range of metabolic pathways and the inflammatory response.
- Gluconeogenesis.** The synthesis of glucose from noncarbohydrate precursors.
- Glucose-alanine cycle.** An interorgan metabolic pathway that transports nitrogen to the liver, in which pyruvate produced by glycolysis in the muscles is converted to alanine and transported to the liver. There the alanine is converted back to pyruvate and its amino group is used to synthesize urea for excretion. The pyruvate is converted, via gluconeogenesis, to glucose, which is returned to the muscles.
- Glucose-fatty acid cycle.** The downregulation of glycolysis by fatty acid oxidation, caused by the acetyl-CoA-induced inhibition of phosphofructokinase by citrate. Also called the Randle cycle (although it is not actually a cycle).
- Glycan.** See polysaccharide.
- Glycerophosphate shuttle.** A metabolic pathway that uses the interconversion of dihydroxyacetone phosphate and 3-phosphoglycerol to transport cytosolic reducing equivalents into the mitochondria.
- Glycerophospholipid.** An amphiphilic lipid in which two fatty acyl groups are attached to a glycerol-3-phosphate whose phosphate group is linked to a polar group. Also called a phosphoglyceride.
- Glycoconjugate.** A molecule, such as a glycolipid or glycoprotein, that contains covalently linked carbohydrate.
- Glycoforms.** Glycoproteins that differ in the sequence, location, and number of covalently attached carbohydrates.
- Glycogen.** An $\alpha(1\rightarrow6)$ branched polymer of $\alpha(1\rightarrow4)$ -linked glucose residues that serves as a glucose storage molecule in animals.
- Glycogenolysis.** The enzymatic degradation of glycogen to glucose-6-phosphate.
- Glycogen storage disease.** An inherited disorder of glycogen metabolism affecting the size and structure of glycogen molecules or their mobilization in the muscle and/or liver.
- Glycolipid.** A lipid to which carbohydrate is covalently attached.
- Glycolysis.** The 10-reaction pathway by which glucose is broken down to 2 pyruvate with the concomitant production of 2 ATP and the reduction of 2 NAD^+ to 2 NADH.
- Glycomics.** The study of the structures and functions of all of a cell's carbohydrates, including large glycans and the small oligosaccharides of glycoproteins.
- Glycoprotein.** A protein to which carbohydrate is covalently attached.
- Glycosaminoglycan.** An unbranched polysaccharide consisting of alternating residues of uronic acid and hexosamine.
- Glycosidic bond.** The covalent linkage (acetal or ketal) between the anomeric carbon of a saccharide and an alcohol (*O*-glycosidic bond) or an amine (*N*-glycosidic bond). Glycosidic bonds link the monosaccharide residues of a polysaccharide.
- Glycosylation.** The attachment of carbohydrate chains to a protein or lipid through *N*- or *O*-glycosidic linkages.
- Glyoxysome.** A membrane-bounded plant organelle in which the reactions of the glyoxylate cycle take place. It is a specialized type of peroxisome.
- Golgi apparatus.** A eukaryotic organelle consisting of a set of flattened membranous sacs in which newly synthesized proteins and lipids are modified.
- Gout.** A disease characterized by elevated levels of uric acid, usually the result of impaired uric acid excretion. Its most common manifestation is painful arthritic joint inflammation caused by the deposition of sodium urate.
- GPCR.** G-protein-coupled receptor, a cell-surface protein with seven transmembrane helices that interacts with an associated G protein on ligand binding.
- GPI-linked protein.** A protein that is anchored in a membrane via a covalently linked glycosylphosphatidylinositol (GPI) group.
- G protein.** A guanine nucleotide-binding protein, most of which are involved in signal transduction, that is inactive when it binds GDP and active when it binds GTP. The GTPase activity of the G protein limits its own activity. Heterotrimeric G proteins consist of three subunits, which dissociate to form G_α (to which GTP binds) and $G_{\beta\gamma}$ components on activation.
- G-quartet.** A cyclic tetramer of hydrogen-bonded guanine groups. Stacks of G-quartets result from the antiparallel association of G-rich telomeric DNA hairpin structures.
- Gram-negative bacterium.** A bacterium that does not take up Gram stain, indicating that its cell wall is surrounded by a complex outer membrane that excludes Gram stain.
- Gram-positive bacterium.** A bacterium that takes up Gram stain, indicating that its outermost layer is a cell wall.
- Grana (sing. granum).** The stacked disks of the thylakoid in a chloroplast.
- gRNA.** See guide RNA.
- Group I intron.** An intron in an rRNA molecule whose self-splicing reaction requires a guanine nucleotide and generates a cyclized intron product.
- Group II intron.** An intron in a eukaryotic rRNA molecule whose self-splicing reaction does not require a free nucleotide and generates a lariat intron product.

- Growth factor.** A protein hormone that stimulates the proliferation and differentiation of its target cells.
- GTF.** See general transcription factor.
- GTPase.** An enzyme that catalyzes the hydrolysis of GTP to GDP + P_i.
- Guide RNA (gRNA).** Small RNA molecules that pair with an immature mRNA to direct its posttranscriptional editing.
- GWAS.** See genome-wide association study.
- H.** See enthalpy.
- Half-life.** See half-time.
- Half-reaction.** The single oxidation or reduction process, involving an electron donor and its conjugate electron acceptor, that occurs in electrical cells but requires direct contact with another such reaction to form a complete oxidation–reduction reaction.
- Half-time ($t_{1/2}$).** The time required for half the reactant initially present to undergo reaction. Also called half-life.
- Halobacteria.** Bacteria that thrive in (and may require) high salinity.
- Haploid.** Having one set of unique chromosomes.
- HAT.** See histone acetyltransferase.
- Haworth projection.** A representation of a sugar ring in which ring bonds that project in front of the plane of the paper are drawn as thick lines and ring bonds that project behind the plane of the paper are drawn as thin lines.
- HDL.** High density lipoprotein; see lipoprotein.
- Heat shock protein (Hsp).** See molecular chaperone.
- Helicase.** An enzyme that unwinds a double-stranded nucleic acid.
- Helix cap.** A protein structural element in which the side chain of a residue preceding or succeeding a helix folds back to form a hydrogen bond with the backbone of one of the helix's four terminal residues.
- Helix–turn–helix (HTH) motif.** An ~20-residue protein motif that forms two α helices that cross at an angle of ~120°. The motif, which occurs in numerous prokaryotic DNA-binding proteins, binds in DNA's major groove to specific base sequences.
- Heme.** A porphyrin derivative whose central Fe(II) atom is the site of reversible oxygen binding (in myoglobin and hemoglobin) or oxidation–reduction (in cytochromes).
- Hemiacetal.** The product of the reaction between an alcohol and the carbonyl group of an aldehyde.
- Hemiketal.** The product of the reaction between an alcohol and the carbonyl group of a ketone.
- Hemolytic anemia.** Loss of red blood cells through their lysis (destruction) in the bloodstream.
- Henderson–Hasselbalch equation.** The mathematical expression of the relationship between the pH of a solution of a weak acid and its pK:

$$\text{pH} = \text{pK} + \log\left(\frac{[\text{A}^-]}{[\text{HA}]}\right)$$
- Heptad repeat.** A repeating sequence, *a-b-c-d-e-f-g*, in an α -helical polypeptide in which residues *a* and *d* are hydrophobic and thus line one face of the helix, thereby inducing the formation of a coiled coil with a second similar helix.
- Heterochromatin.** Highly condensed, nonexpressed eukaryotic DNA.
- Heterogeneous nuclear RNA (hnRNA).** Eukaryotic mRNA primary transcripts whose introns have not yet been excised.
- Heterologous DNA.** A segment of DNA consisting of imperfectly complementary strands.
- Heterolytic cleavage.** Cleavage of a bond in which one of two chemically bonded atoms acquires both of the electrons that formed the bond.
- Heteropolysaccharide.** A polysaccharide consisting of more than one type of monosaccharide.
- Heterotrimeric G protein.** See G protein.
- Heterotroph.** An organism that obtains free energy from the oxidation of organic compounds produced by other organisms.
- Heterozygous.** Having one each of two gene variants.
- Hexose monophosphate shunt.** See pentose phosphate pathway.
- “High-energy” intermediate.** A substance whose degradation is highly exergonic (yields at least as much free energy as is required to synthesize ATP from ADP + P_i; $\geq 30.5 \text{ kJ} \cdot \text{mol}^{-1}$ under standard biochemical conditions). Also called an “energy-rich” compound.
- High-performance liquid chromatography (HPLC).** An automated chromatographic procedure for fractionating molecules using precisely fabricated matrix materials and pressurized flows of precisely mixed solvents.
- Highly repetitive DNA.** Clusters of nearly identical sequences of up to 10 bp that are repeated thousands of times; the sequences are present at $> 10^6$ copies per haploid genome. Also known as short tandem repeats (STRs).
- Hill equation.** A mathematical expression for the degree of saturation of ligand binding to a molecule with multiple binding sites as a function of the ligand concentration.
- Histone acetyltransferase (HAT).** An enzyme that catalyzes the sequence-specific acetylation of histones to regulate gene transcription.
- Histone code.** The correlation between the pattern of histone modification and the transcriptional activity of the associated DNA.
- Histones.** Highly conserved basic proteins that constitute the protein core to which DNA is bound to form a nucleosome.
- HIV.** Human immunodeficiency virus, the causative agent of acquired immunodeficiency syndrome (AIDS).
- HMG protein.** A member of the high mobility group (HMG) of nonhistone chromosomal proteins whose abundant charged groups give them high electrophoretic mobility.
- hnRNA.** See heterogeneous nuclear RNA.
- Holliday junction.** The four-stranded structure that forms as an intermediate in DNA recombination.
- Holoenzyme.** A catalytically active enzyme–cofactor complex.
- Homeobox.** See homeodomain.
- Homeodomain.** An ~60-amino acid DNA-binding motif common to many genes that specify the identities and fates of embryonic cells; such genes encode transcription factors. Also called a homeobox.
- Homeostasis.** The maintenance of a steady state in an organism. See also metabolic homeostasis.
- Homeotic selector genes.** Insect genes that specify the identities of body segments.
- Homolactic fermentation.** The reduction of pyruvate to lactate with the concomitant oxidation of NADH to NAD⁺.
- Homologous end-joining.** A pathway in which DNA with double-strand breaks is repaired nonmutagenically through recombination with an intact homologous chromosome.
- Homologous proteins.** Proteins that resemble each other due to their evolution from a common ancestor.
- Homologous recombination.** See recombination.
- Homology-directed repair (HDR).** See homologous end-joining.
- Homolytic cleavage.** Cleavage of a bond in which each participating atom acquires one of the electrons that formed the bond.
- Homopolysaccharide.** A polysaccharide consisting of one type of monosaccharide unit.
- Homozygous.** Having two identical copies of a particular gene.
- Hoogsteen base pair.** A form of base pairing in which thymine or uracil atom N3 hydrogen bonds to adenine atom N7 and adenine N6 hydrogen bonds to thymine or uracil O4. See also Watson–Crick base pair.
- Hormone.** A substance (e.g., a peptide or a steroid) that is secreted by one tissue and induces a physiological response (e.g., growth and metabolism) in other tissues.
- Hormone response element (HRE).** A DNA sequence to which a hormone–receptor complex binds so as to enhance or repress the transcription of an associated gene.
- Hormone-sensitive lipase.** An adipose tissue enzyme that releases fatty acids from triacylglycerols in response to a hormonally generated increase in cAMP. Also known as hormone-sensitive triacylglycerol lipase.
- Hox gene.** A gene encoding a transcription factor that includes a homeodomain and which specifies segmental identity.
- HRE.** See hormone response element.
- HTH motif.** See helix–turn–helix motif.
- Humoral immunity.** Immunity mediated by antibodies (immunoglobulins) produced by B lymphocytes (B cells).

G-10

Hybridization. The formation of double-stranded segments of complementary DNA and/or RNA sequences.

Hybridoma. The cell clones produced by the fusion of an antibody-producing lymphocyte and an immortal myeloma cell. These are the cells that produce monoclonal antibodies.

Hydration. The molecular state of being surrounded by and interacting with several layers of solvent water molecules, that is, solvated by water.

Hydrogen bond. A largely electrostatic interaction between a weakly acidic donor group such as O—H or N—H and a weakly basic acceptor atom such as O or N.

Hydrolysis. The cleavage of a covalent bond accomplished by adding the elements of water; the reverse of a condensation.

Hydronium ion. A proton associated with a water molecule, H_3O^+ .

Hydrophathy. A measure of the combined hydrophobicity and hydrophilicity of an amino acid residue; it is indicative of the likelihood of finding that residue in a protein interior.

Hydrophilic substance. A substance whose high polarity allows it to readily interact with water molecules and thereby dissolve in water.

Hydrophobic collapse. A driving force in protein folding, resulting from the tendency of hydrophobic residues to avoid contact with water and hence form the protein core.

Hydrophobic effect. The tendency of water to minimize its contacts with nonpolar substances, thereby inducing the substances to aggregate.

Hydrophobic interaction chromatography. A procedure in which molecules are selectively retained on a nonpolar matrix by virtue of their hydrophobicity.

Hydrophobic substance. A substance whose nonpolar nature reduces its ability to be solvated by water molecules. Hydrophobic substances tend to be soluble in nonpolar solvents but not in water.

Hydroxide ion. OH^- , a product of the ionization of a water molecule.

Hyperammonemia. Elevated levels of ammonia in the blood, a toxic situation.

Hypercholesterolemia. High levels of cholesterol in the blood, a risk factor for heart disease. Familial hypercholesterolemia usually results from an inherited defect in the LDL receptor.

Hyperchromic effect. The increase in duplex DNA's ultraviolet absorbance resulting from the loss of stacking interactions as the DNA denatures.

Hyperglycemia. Elevated levels of glucose in the blood.

Hyperpolarization. The decrease of membrane potential below the resting state that occurs during the latter portion of an action potential in nerve cells.

Hypervariable residue. An amino acid residue occupying a position in a protein that is occupied by many different residues among evolutionarily related proteins. The opposite of a hypervariable residue is an invariant residue.

Hypoxia. A condition in which the oxygen level in the blood is lower than normal.

I-cell disease. A hereditary deficiency in a lysosomal hydrolase that causes the accumulation of glycosaminoglycan and glycolipid inclusions in the lysosomes.

IDL. Intermediate density lipoprotein; see lipoprotein.

Ig. Immunoglobulin. See antibody.

Imaginal disk. A patch of apparently undifferentiated but developmentally committed cells in an insect larva that ultimately gives rise to a specific external structure in the adult.

Immune system. The cells and organs that respond to infection by producing antibodies and by killing pathogens and infected host cells.

Immunoaffinity chromatography. A procedure in which a molecule is separated from a mixture of other molecules by its ability to bind specifically to an immobilized antibody.

Immunoassay. A procedure for detecting, and in some cases quantifying, the activity of a macromolecule by using an antibody or mixture of antibodies that reacts specifically with that substance.

Immunoblot. A technique in which a molecule immobilized on a membrane filter can be detected through its ability to bind to an antibody directed against it. A Western blot is an immunoblot to detect an immobilized protein after electrophoresis.

Immunofluorescence microscopy. A technique in microscopy in which a fluorescently-tagged antibody is used to reveal the presence of the antigen to which it binds.

Immunoglobulin (Ig). See antibody.

Immunoglobulin fold. A disulfide-linked domain consisting of a sandwich of a three-stranded and a four-stranded antiparallel β sheet that occurs in antibody molecules and other proteins.

Inactivator. An inhibitor that reacts irreversibly with an enzyme to inactivate it.

Indirect readout. The ability of a DNA-binding protein to detect its target base sequence through the sequence-dependent conformation and/or flexibility of its DNA backbone rather than through direct interaction with its bases.

Induced fit. An interaction between a protein and its ligand, which induces a conformational change in the protein that increases the protein's affinity for the ligand.

Inducer. A substance that facilitates gene expression.

Inducible enzyme. An enzyme that is synthesized only when required by the cell. See also constitutive enzyme.

Inhibition constant (K_i). The dissociation constant for an enzyme-inhibitor complex.

Inhibitor. A substance that reduces an enzyme's activity by affecting its substrate binding or turnover number.

Initiation factor. A protein that interacts with mRNA and/or the ribosome and which is required to initiate translation.

Insertion sequence. A simple transposon that is flanked by short inverted repeats. Also called an IS element.

Insertion/deletion mutation. A genetic change resulting from the addition or loss of nucleotides; also called an indel.

in situ hybridization. See colony hybridization.

Insulator. A segment of DNA that delimits the effective range of a transcription-regulating element.

Insulin resistance. The decreased ability of cells to respond to insulin, which results in a decrease in their ability to take up glucose.

Integral protein. A membrane protein that is embedded in the lipid bilayer and can be separated from it only by treatment with agents that disrupt membranes. Also called an intrinsic protein.

Intercalation agent. A substance, usually a planar aromatic cation, that slips in between the stacked bases of a double-stranded polynucleotide.

Interfacial activation. The increase in activity when a lipid-specific enzyme contacts the lipid-water interface.

Intermembrane space. The compartment between the inner and outer mitochondrial membranes. Because of the porosity of the outer membrane, the intermembrane space is equivalent to the cytosol in its small-molecule composition.

Internal conversion. A mode of decay of an excited molecule, in which electronic energy is converted to heat (the kinetic energy of molecular motion).

Intervening sequence. See intron.

Intrinsic protein. See integral protein.

Intrinsic terminator. A conserved G + C-rich hairpin followed by a U-rich segment that causes Rho-independent transcription termination in *E. coli*.

Intron. A portion of a gene that is transcribed but excised prior to translation. Also called an intervening sequence.

Invariant residue. A residue in a protein that is the same in all evolutionarily related proteins. The opposite of an invariant residue is a hypervariable residue.

in vivo. In a living organism.

Ion exchange chromatography. A fractionation procedure in which ions are selectively retained by a matrix bearing oppositely charged groups.

Ion pair. An electrostatic interaction between two ionic groups of opposite charge. In proteins, it is also called a salt bridge.

Ionophore. An organic molecule, often an antibiotic, that increases the permeability of a membrane to a particular ion. A carrier ionophore diffuses with its ion through the membrane, whereas a channel-forming ionophore forms a transmembrane pore.

Iron–sulfur protein. A protein that contains a prosthetic group consisting most commonly of equal numbers of iron and sulfur ions (i.e., [2Fe–2S] and [4Fe–4S]) and that usually participates in oxidation–reduction reactions.

Ischemia. The blockage of blood flow to a tissue or organ.

IS element. See insertion sequence.

Isoaccepting tRNA. A tRNA that carries the same amino acid as another tRNA.

Isoelectric focusing (IEF). Electrophoresis through a stable pH gradient such that a charged molecule migrates to a position corresponding to its isoelectric point.

Isoelectric point (pI). The pH at which a molecule has no net charge and hence does not migrate in an electric field.

Isoforms. See isozymes.

Isolated system. A thermodynamic system that cannot exchange matter or energy with its surroundings.

Isomerase. An enzyme that catalyzes an isomerization reaction.

Isopeptide bond. An amide linkage between an α -carboxylate group of an amino acid and the ϵ -amino group of Lys, or between the α -amino group of an amino acid and the β - or γ -carboxylate group of Asp or Glu.

Isoprenoid. A lipid consisting of five-carbon units with the same carbon skeleton as isoprene.

Isozymers. Restriction endonucleases that cleave at the same nucleotide sequence.

Isozymes. Enzymes that catalyze the same reaction but are encoded by different genes. Also called isoforms.

JAK-STAT pathway. A signal transduction pathway involving a JAK (Janus kinase) protein and a STAT (signal transducer and activator of transcription) protein that relays cytokine-based signals.

Jaundice. A yellowing of the skin and whites of the eyes as a result of the deposition of the heme degradation product bilirubin in those tissues. It is a symptom of liver dysfunction, bile-duct obstruction, or a high rate of red cell destruction.

Junk DNA. See selfish DNA.

k. See rate constant.

k_B . Boltzmann constant ($1.3807 \times 10^{-23} \text{ J} \cdot \text{K}^{-1}$); it is equivalent to R/N , where R is the gas constant and N is Avogadro's number.

kb. Kilobase pair; 1 kb = 1000 base pairs (bp).

k_{cat} . The catalytic constant for an enzymatic reaction, equivalent to the ratio of the maximal velocity (V_{max}) and the enzyme concentration ($[E]_T$). Also called the turnover number.

k_{cat}/K_M . The apparent second-order rate constant for an enzyme-catalyzed reaction; it is a measure of an enzyme's catalytic efficiency.

kD. Kilodaltons; 1000 daltons (D).

Ketogenesis. The synthesis of ketone bodies from acetyl-CoA.

Ketone bodies. Acetoacetate, D- β -hydroxybutyrate, and acetone; these compounds are produced from acetyl-CoA by the liver for use as metabolic fuels in peripheral tissues.

Ketose. A sugar whose carbonyl group is a ketone.

Ketosis. A potentially pathological condition in which ketone bodies are produced in excess of their utilization.

K_I . See inhibition constant.

Kinase. An enzyme that transfers a phosphoryl group between ATP and another molecule.

Kinase cascade. A set of reactions in which kinase-catalyzed phosphorylation activates the next kinase in a series, thereby amplifying the effect of the initial kinase.

K_M . See Michaelis constant.

K_M^{app} . The apparent (observed) Michaelis constant for an enzyme-catalyzed reaction, which may differ from the true value due to the presence of an enzyme inhibitor.

Krebs cycle. See citric acid cycle.

K_w . The ionization constant of water; equal to 10^{-14} .

L. See linking number.

Lactose intolerance. The inability to digest the disaccharide lactose due to a deficiency of the enzyme β -galactosidase (lactase).

Lagging strand. A newly synthesized DNA strand that extends $3' \rightarrow 5'$ in the direction of travel of the replication fork. This strand is synthesized as a series of discontinuous fragments that are later joined.

Lateral diffusion. The movement of a lipid within one leaflet of a bilayer.

LBHB. See low-barrier hydrogen bond.

LDL. Low density lipoprotein; see lipoprotein.

Lead compound. A drug molecule that serves as the starting point for the development of more effective drug molecules.

Leader sequence. (1) A nucleotide sequence that precedes the coding region of an mRNA. (2) A signal sequence.

Leading strand. A newly synthesized DNA strand that extends $5' \rightarrow 3'$ in the direction of travel of the replication fork. This strand is synthesized continuously.

Le Châtelier's principle. The phenomenon that a change in concentration, temperature, volume, or pressure in a system at equilibrium causes the equilibrium position to shift so as to counteract the change.

Lectin. A protein that binds to a specific saccharide.

Lesch–Nyhan syndrome. A genetic disease caused by the deficiency of hypoxanthine–guanine phosphoribosyltransferase (HGPRT), an enzyme required for purine salvage reactions. Affected individuals produce excessive uric acid and exhibit neurological abnormalities.

Leucine zipper. A protein structural motif in which two α helices, each with a hydrophobic strip along one side, associate as a coiled coil. This motif, which has a Leu at nearly every seventh residue, mediates the association of many types of DNA-binding proteins.

Leukocyte. White blood cell.

Levorotatory. Rotating the plane of polarized light counterclockwise from the point of view of the observer; the opposite of dextrorotatory.

Ligand. (1) A small molecule that binds to a larger molecule. (2) A molecule or ion bound to a metal ion.

Ligand-gated channel. A channel whose opening and closing (gating) is controlled by the binding of a specific molecule (ligand). Also called a signal-gated channel.

Ligation. The joining together of two molecules such as two DNA segments.

Light-harvesting complex (LHC). A pigment-containing membrane protein that collects light energy and transfers it to a photosynthetic reaction center.

Light reactions. The portion of photosynthesis in which specialized pigment molecules capture light energy and are thereby oxidized. Electrons are transferred to generate NADPH and a transmembrane proton gradient that drives ATP synthesis.

Limited proteolysis. A technique in which a polypeptide is incompletely digested by proteases.

lincRNA. See long intergenic noncoding RNA.

Lineweaver–Burk plot. A graph of a rearrangement of the Michaelis–Menten equation to a linear form that permits the determination of K_M and V_{max} . Also called a double-reciprocal plot.

Linker DNA. The ~ 55 -bp segment of DNA that links nucleosome core particles in chromatin.

Linking number (*L*). The number of times that one strand of a covalently closed circular double-stranded DNA winds around the other; it cannot be changed without breaking covalent bonds.

Lipid. Any member of a broad class of biological molecules that are largely or wholly hydrophobic and therefore tend to be insoluble in water but soluble in organic solvents such as hexane.

Lipid bilayer. See bilayer.

Lipid-linked protein. A protein that is anchored to a biological membrane via a covalently attached lipid such as a farnesyl, geranylgeranyl, myristoyl, palmitoyl, or glycosylphosphatidylinositol group.

G-12

Lipid raft. A semicrystalline region of a cell membrane containing tightly packed glycosphingolipids and cholesterol.

Lipid storage disease. A defect in a lipid-degrading enzyme that causes the substrate for the enzyme to accumulate in lysosomes.

Lipoprotein. A globular particle consisting of a nonpolar lipid core surrounded by an amphiphilic coat of protein, phospholipid, and cholesterol. Lipoproteins, which transport lipids between tissues via the bloodstream, are classified by their density as high, low, intermediate, and very low density lipoproteins (HDL, LDL, IDL, and VLDL).

Liposome. A synthetic vesicle bounded by a single lipid bilayer.

Lipoyllysyl arm. An extended structure, consisting of lipoic acid linked to a lysine side chain, that delivers intermediates between active sites in multienzyme complexes such as the pyruvate dehydrogenase complex.

London dispersion forces. The weak attractive forces between electrically neutral molecules in close proximity, which arise from electrostatic interactions among their fluctuating dipoles.

Long intervening noncoding RNA (lincRNA). Large nontranslated eukaryotic RNAs that are transcribed by RNA polymerase II.

Low-barrier hydrogen bond (LBHB). An unusually short and strong hydrogen bond that forms when the donor and acceptor groups have nearly equal pK values so the hydrogen atom is equally shared between them.

Lung surfactant. The amphipathic protein and lipid mixture that prevents collapse of the lung alveoli (microscopic air spaces) on the expiration of air.

Lysis. The disintegration of cells by rupturing their cell walls.

Lysophospholipid. A glycerophospholipid derivative lacking a fatty acyl group at position C2 whose detergentlike properties can disrupt cell membranes.

Lysosome. A membrane-bounded organelle in a eukaryotic cell that contains a battery of hydrolytic enzymes and which functions to digest ingested material and to recycle cell components.

Macronutrient. A nutrient that is required in relatively large amounts, such as proteins, carbohydrates, and fats. See also micronutrient.

Main chain. See backbone.

Major groove. The groove on a DNA double helix whose bounding glycosidic bonds from each base pair form an angle of $>180^\circ$. In B-DNA, this groove is wider than the minor groove.

Malaria. A mosquito-borne disease caused by protozoa of the genus *Plasmodium*, most notably *Plasmodium falciparum*, which reside in red blood cells during much of their life cycle.

Malate-aspartate shuttle. A metabolic circuit that uses the malate and aspartate transporters and the interconversion of malate, oxaloacetate, and aspartate to ferry reducing equivalents into the mitochondrion.

Malignant tumor. A mass of cells that proliferate uncontrollably; a cancer.

Mass spectrometry. A technique for identifying molecules by measuring the mass-to-charge ratios of molecular ions in the gas phase.

Maternal-effect genes. Insect genes whose mRNA or protein products are deposited by the mother in the ovum and which define the polarity of the embryonic body.

Matrix. The gel-like solution of enzymes, substrates, cofactors, and ions in the interior of the mitochondrion.

Mechanism-based inhibitor. A molecule that chemically inactivates an enzyme only after undergoing part or all of its normal catalytic reaction. Also called a suicide substrate.

Mechanosensitive channel. A channel whose opening and closing (gating) is controlled by mechanical stimuli such as touch, sound, and changes in osmotic pressure.

Mediated transport. The transmembrane movement of a substance through the action of a specific carrier protein; the opposite of nonmediated transport.

Melting temperature (T_m). The midpoint temperature of the melting curve for the thermal denaturation of a macromolecule.

Membrane-enveloped virus. A virus produced by budding from the surface of a host cell such that the viral particle is surrounded by a membrane derived from the host cell.

Membrane potential ($\Delta\Psi$). The electrical potential difference across a membrane.

Memory B cell. A B cell that can recognize its corresponding antigen and rapidly proliferate to produce specific antibodies weeks to years after the antigen was first encountered.

Mercaptan. A compound containing an —SH group.

Messenger RNA (mRNA). A ribonucleic acid whose sequence is complementary to that of a protein-coding gene in DNA. In the ribosome, mRNA directs the polymerization of amino acids to form a polypeptide with the corresponding sequence.

Metabolic homeostasis. The ability of an organism to maintain a balance between energy inflow and output.

Metabolic syndrome. An obesity-related disorder that includes insulin resistance, hypertension, and atherosclerosis.

Metabolism. The total of all degradative and biosynthetic cellular reactions.

Metabolite. A reactant, intermediate, or product of a metabolic reaction.

Metabolomics. The study of all the metabolites produced by a cell under a given set of conditions, including their concentrations and functions.

Metabolon. A loose complex of the enzymes that catalyze the steps of a metabolic pathway such that intermediates can be efficiently transferred between enzymes.

Metagenomic sequencing. The analysis of all the DNA sequences in a sample containing multiple organisms.

Metal chelate affinity chromatography. A procedure in which a molecule bearing metal-chelating groups is separated from a mixture of other molecules by its ability to bind to metal ions attached to a chromatographic matrix.

Metalloenzyme. An enzyme that contains a tightly bound metal ion cofactor, typically a transition metal ion such as Fe^{2+} , Zn^{2+} , or Mn^{2+} .

Methanogen. An organism that produces CH_4 .

Micelle. A globular aggregate of amphiphilic molecules in aqueous solution that are oriented such that polar segments form the surface of the aggregate and the nonpolar segments form a core that is out of contact with the solvent.

Michaelis complex. See ES complex.

Michaelis constant (K_M). For an enzyme that follows the Michaelis–Menten model, $K_M = (k_{-1} + k_2)/k_1$; K_M is equal to the substrate concentration at which the reaction velocity is half-maximal.

Michaelis–Menten equation. A mathematical expression that describes the initial rate of an enzymatic reaction (v_0) in terms of the substrate concentration ($[S]$), the enzyme's maximal velocity (V_{\max}), and its Michaelis constant (K_M): $v_0 = V_{\max}[S]/(K_M + [S])$.

Microbiome. The collection of microorganisms that live in or on the human body.

Microfilament. A 70-Å-diameter cytoskeletal element composed of actin.

Microheterogeneity. The variability in carbohydrate composition in glycoproteins.

Micronutrient. A nutrient that is required in relatively small amounts, such as vitamins and minerals. See also macronutrient.

Micro RNA (miRNA). An endogenous RNA of ~22 nucleotides that inhibits gene expression through RNA interference. See also short interfering RNA (siRNA).

Mineral. An inorganic substance required for metabolic activity, including sodium, potassium, chloride, and calcium. Minerals such as iron, copper, and zinc, which are required in small amounts, are known as trace elements.

Mineralocorticoid. A steroid hormone that regulates the excretion of salt and water by the kidneys.

Minor groove. The groove on a DNA double helix whose bounding glycosidic bonds from each base pair form an angle of $<180^\circ$. In B-DNA, this groove is narrower than the major groove.

(–) **end.** The end of a polymeric filament where growth is slower. See also (+) end.

miRNA. See micro RNA.

Mismatch repair (MMR). A postreplication process, in which mispaired nucleotides are excised and replaced, that distinguishes between the parental (correct) and daughter (incorrect) strands of DNA.

Mitochondrial matrix. See matrix.

- Mitochondria** (*sing.* **mitochondrion**). The double-membrane-enveloped eukaryotic organelles in which aerobic metabolic reactions occur, including those of the citric acid cycle, fatty acid oxidation, and oxidative phosphorylation.
- Mixed inhibition**. A form of enzyme inhibition in which an inhibitor binds to both the enzyme and the enzyme–substrate complex and thereby differentially affects K_M and V_{max} . Also called noncompetitive inhibition.
- MMR**. See mismatch repair.
- Moderately repetitive DNA**. Segments of hundreds to thousands of base pairs that are present at $<10^6$ copies per haploid genome.
- Modification methylase**. A bacterial enzyme that methylates a specific sequence of DNA as part of a restriction–modification system.
- Molecular chaperone**. A protein that binds to unfolded or misfolded proteins to promote normal folding and the formation of native quaternary structure. Also known as a heat shock protein (Hsp).
- Molecular cloning**. See recombinant DNA technology.
- Molecularity**. The number of molecules that participate in an elementary chemical reaction.
- Molecular sieve chromatography**. See gel filtration chromatography.
- Molecular weight**. See M_r .
- Molten globule**. A collapsed but conformationally mobile intermediate in protein folding that has much of the native protein's secondary structure but little of its tertiary structure.
- Monoclonal antibody**. A single species of antibody molecule produced by a clone of hybridoma cells, which are derived by the fusion of a myeloma cell with a lymphocyte producing that antibody.
- Monomer**. (1) A structural unit from which a polymer is built up.
(2) A single subunit or protomer of a multisubunit protein.
- Monosaccharide**. A carbohydrate consisting of a single saccharide (sugar).
- Morphogen**. A substance whose distribution in an embryo directs, in part, the embryo's developmental pattern.
- Motif**. See supersecondary structure.
- Motor protein**. An intracellular protein that couples the free energy of ATP hydrolysis to molecular movement relative to another protein that often acts as a track for the linear movement of the motor protein.
- M_r . Relative molecular mass. A dimensionless quantity that is defined as the ratio of the mass of a particle to 1/12th the mass of a ^{12}C atom. Also known as molecular weight. It is numerically equal to the grams/mole of a compound.
- Multienzyme complex**. A group of noncovalently associated enzymes that catalyze two or more sequential steps in a metabolic pathway.
- Multiple myeloma**. A disease in which a cancerous B cell proliferates and produces massive quantities of a single antibody known as a myeloma protein.
- Multisubunit protein**. A protein consisting of more than one polypeptide chain (subunit).
- Mutagen**. An agent that induces a mutation in an organism.
- Mutase**. An enzyme that catalyzes the transfer of a functional group from one position to another on a molecule.
- Mutation**. A heritable alteration in an organism's genetic material.
- Myocardial infarction**. The death of heart tissue caused by the loss of blood supply (a heart attack).
- Myofibril**. The bundle of fibers that are arranged in register in striated muscle cells.
- Myristoylation**. The attachment of a myristoyl group to a protein to form a lipid-linked protein.
- Native structure**. The fully folded conformation of a macromolecule.
- Natural selection**. The evolutionary process by which the continued existence of a replicating entity depends on its ability to survive and reproduce under the existing conditions.
- ncRNA**. See noncoding RNA.
- NDP**. A ribonucleoside diphosphate.
- Near-equilibrium reaction**. A reaction whose ΔG value is close to zero, so that it can operate in either direction depending on the substrate and product concentrations.
- Necrosis**. Trauma-induced cell death that results in the unregulated disintegration of the cell and the release of proinflammatory substances. See also apoptosis.
- Negative cooperativity**. See cooperative binding.
- N-end rule**. The correlation between the identity of a polypeptide's N-terminal residue and its half-life in the cell.
- Nernst equation**. An expression of the relationship between reduction potential difference ($\Delta\mathcal{E}$) and the concentrations of the electron donors and acceptors (A, B): $\Delta\mathcal{E} = \Delta\mathcal{E}^\circ - RT/n\mathcal{F} \ln ([A_{red}][B_{ox}]/[A_{ox}][B_{red}])$.
- Neurotransmitter**. A substance released by a nerve cell that alters the activity of a neighboring nerve cell.
- Neutral drift**. Evolutionary changes that become fixed at random rather than through natural selection.
- Neutral solution**. A solution whose pH is equal to 7.0 ($[\text{H}^+] = 10^{-7} \text{ M}$).
- Nick translation**. The progressive movement of a single-strand break (nick) in duplex DNA through the coordinated actions of a $5' \rightarrow 3'$ exonuclease function that removes residues from the $5'$ side of the break and a polymerase function that adds residues to the $3'$ side.
- Nitrogen cycle**. The series of reactions in which N_2 and ammonia are interconverted, often via nitrate and nitrite, by various organisms.
- Nitrogen fixation**. The process by which atmospheric N_2 is converted to a biologically useful form such as NH_3 .
- NMD**. See nonsense-mediated decay.
- Noncoding RNA (ncRNA)**. An RNA molecule, such as rRNA, tRNA, or another small RNA, that is not translated.
- Noncoding strand**. See antisense strand.
- Noncompetitive inhibition**. (1) A synonym for mixed inhibition.
(2) A special case of mixed inhibition in which the inhibitor binds to the enzyme and enzyme–substrate complex with equal affinities ($K_i = K'_i$), thereby reducing the apparent value of V_{max} but leaving K_M unchanged.
- Noncooperative binding**. A situation in which binding of a ligand to a macromolecule does not affect the affinities of other binding sites on the same molecule.
- Nonessential amino acid**. An amino acid that animals can synthesize from common intermediates.
- Nonhomologous end-joining (NHEJ)**. An error-prone pathway for repairing DNA with double-strand breaks.
- Nonmediated transport**. The transmembrane movement of a substance through simple diffusion; the opposite of mediated transport.
- Nonreceptor tyrosine kinase**. An intracellular tyrosine kinase that is indirectly activated by ligand binding to a receptor.
- Nonsense codon**. See Stop codon.
- Nonsense-mediated decay (NMD)**. The degradation of an mRNA that contains a premature Stop codon.
- Nonsense mutation**. A mutation that converts a codon that specifies an amino acid to a Stop codon, thereby causing the premature termination of translation.
- Nonsense suppressor tRNA**. A mutated tRNA that recognizes a Stop codon so that its attached aminoacyl group is appended to the polypeptide chain; it mitigates the effect of a nonsense mutation in a structural gene.
- Northern blotting**. A procedure for identifying an RNA containing a particular base sequence through its ability to hybridize with a complementary single-stranded segment of DNA or RNA. See also Southern blotting.
- nt**. Nucleotide.
- N-terminus**. See amino terminus.
- NTP**. A ribonucleoside triphosphate.
- Nuclear magnetic resonance (NMR)**. A spectroscopic method for characterizing atomic and molecular properties based on the signals emitted by radiofrequency-excited atomic nuclei in a magnetic field. It can be used to determine the three-dimensional molecular structure of a protein or nucleic acid.
- Nuclease**. An enzyme that hydrolytically degrades nucleic acids.
- Nucleic acid**. A polymer of nucleotide residues. The major nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Also known as a polynucleotide.

G-14

Nucleolus (*pl. nucleoli*). The dark-staining region of the eukaryotic nucleus, where ribosomal RNA (rRNA) is transcribed and processed and where ribosomes are assembled.

Nucleoside. A compound consisting of a nitrogenous base and a five-carbon sugar (ribose or deoxyribose) in *N*-glycosidic linkage.

Nucleosome core particle. The complex of histones and ~146 bp of DNA that forms a compact disk-shaped particle in which the DNA is wound in ~2 helical turns around the outside of the histone octamer.

Nucleosome. The complex of a histone octamer and ~200 bp of DNA that forms the lowest level of DNA organization in the eukaryotic chromosome.

Nucleotide. A compound consisting of a nucleoside esterified to one or more phosphate groups. Nucleotides are the monomeric units of nucleic acids.

Nucleotide excision repair (NER). A multistep process in which a portion of DNA containing a lesion is excised and replaced by normal DNA.

Nucleotide sugar. A saccharide linked to a nucleotide by a phosphoester bond, the cleavage of which drives the formation of a glycosidic bond.

Nucleus. The membrane-enveloped organelle in which the eukaryotic cell's genetic material is located.

Nutrition. The intake and utilization of food as a source of raw materials and free energy.

OEC. See oxygen-evolving center.

Oil. A mixture of triacylglycerols that is liquid at room temperature.

Okazaki fragments. The short segments of DNA formed in the discontinuous lagging-strand synthesis of DNA.

Oligomer. (1) A short polymer consisting of a few linked monomer units.

(2) A protein consisting of a few protomers (subunits).

Oligopeptide. A polypeptide containing a few amino acid residues.

Oligosaccharide. A polymeric carbohydrate containing a few monosaccharide residues.

Oncogene. A mutant version of a normal gene (a proto-oncogene), which may be acquired through viral infection; it interferes with the mechanisms that normally control cell growth and differentiation and thereby contributes to uncontrolled proliferation (cancer).

Open reading frame (ORF). A portion of the genome that potentially codes for a protein. This sequence of nucleotides begins with a Start codon, ends with a Stop codon, contains no internal Stop codons, is flanked by the proper control sequences, and exhibits the same codon-usage preference as other genes in the organism.

Open system. A thermodynamic system that can exchange matter and energy with its surroundings.

Operator. A DNA sequence at or near the transcription start site of a gene, to which a repressor binds so to control transcription of the gene.

Operon. A prokaryotic genetic unit that consists of several genes with related functions that are transcribed as a single mRNA molecule.

Optical activity. The ability of a molecule to rotate the plane of polarized light. Molecules with optical activity are chiral.

Optical density. See absorbance.

Ordered mechanism. A sequential reaction with a compulsory order of substrate addition to the enzyme.

ORF. See open reading frame.

Organelle. A differentiated structure within a eukaryotic cell, such as a mitochondrion, ribosome, or lysosome, that performs specific functions.

Organic compound. A compound that contains the element carbon.

Orphan gene. A gene, usually identified through genome sequencing, with no known function.

Orthologous genes. Evolutionarily related genes in different species that have the same function.

Orthophosphate cleavage. The hydrolysis of ATP that yields ADP + P_i.

Osmosis. The movement of solvent across a semipermeable membrane from a region of low solute concentration to a region of high solute concentration.

Osmotic pressure. The pressure that must be applied to a solution containing a high concentration of solute to prevent the net flow of solvent across a semipermeable membrane separating it from a solution with a lower concentration of solute. The osmotic pressure of a 1 M solution

of any solute separated from solvent by a semipermeable membrane is ideally 22.4 atm.

Overproducer. A genetically engineered organism that produces massive quantities of a foreign DNA gene product.

Oxidation. The loss of electrons. Oxidation of a substance is accompanied by the reduction of another substance.

Oxidative phosphorylation. The process by which the free energy obtained from the oxidation of metabolic fuels is used to generate ATP from ADP + P_i.

Oxidizing agent. A substance that can accept electrons from other substances, thereby oxidizing them and becoming reduced.

Oxonium ion. A resonance-stabilized and oxygen-containing carbocation such as occurs during the lysozyme-catalyzed hydrolysis of a glycoside.

Oxyanion hole. A structure in an enzyme active site that preferentially binds and thereby stabilizes the oxyanionic tetrahedral transition state of the reaction.

Oxygen debt. The postexertion continued elevation in O₂ consumption that is required to replenish the ATP consumed by the liver during operation of the Cori cycle.

Oxygen-evolving center (OEC). The portion of photosystem II that contains a Mn₄CaO₅ complex where 2 H₂O is converted to O₂ during photosynthesis.

Pair-rule genes. See segmentation genes.

Palindrome. A word or phrase or a nucleotide sequence that reads the same forward or backward.

Palmitoylation. The attachment of a palmitoyl group to a protein to form a lipid-linked protein.

Paralogous genes. Related genes in the same organism derived from a gene duplication event.

Partial oxygen pressure (pO₂). The concentration of gaseous O₂ in units of pressure (e.g., torr).

Passive-mediated transport. The thermodynamically spontaneous carrier-mediated transmembrane movement of a substance from high to low concentration. Also called facilitated diffusion.

Pasteur effect. The greatly increased sugar consumption of yeast grown under anaerobic conditions compared to that of yeast grown under aerobic conditions.

Pathogen. A disease-causing microorganism.

P body. A complex of proteins that stores or degrades eukaryotic mRNAs.

Pellagra. The vitamin deficiency disease resulting from a lack of niacin (nicotinic acid) or nicotinamide, precursors of the nicotinamide-containing cofactors NAD⁺ and NADP⁺.

Pentose phosphate pathway. A pathway for glucose degradation that yields ribose-5-phosphate and NADPH. Also called the hexose monophosphate shunt.

Peptidase. An enzyme that hydrolyzes peptide bonds. Also called a protease.

Peptide. A polypeptide of less than about 40 residues.

Peptide bond. An amide linkage between the α-amino group of one amino acid and the α-carboxylate group of another. Peptide bonds link the amino acid residues in a polypeptide.

Peptide group. The planar —CO—NH— group that encompasses the peptide bond between amino acid residues in a polypeptide.

Peptidoglycans. The cross-linked bag-shaped macromolecules consisting of polysaccharide and polypeptide chains that form bacterial cell walls.

Peptidyl site (P site). The ribosomal site that accommodates a tRNA with an attached peptidyl group during protein synthesis.

Peptidyl-tRNA. The covalent complex between a tRNA molecule and a growing polypeptide chain during protein synthesis.

Peripheral protein. A protein that is weakly associated with the surface of a biological membrane. Also called an extrinsic protein.

Peroxisome. A eukaryotic organelle with specialized oxidative functions.

Perutz mechanism. A model for the cooperative binding of oxygen to hemoglobin, in which O₂ binding causes the protein to shift conformation from the deoxy (T state) to the oxy (R state).

PFGE. See pulsed-field gel electrophoresis.

p_{50} . For a gaseous ligand, the ligand concentration, in units of pressure (e.g., torr), at which a binding protein such as hemoglobin is half-saturated with ligand.

pH. A quantity used to express the acidity of a solution, equal to $-\log[H^+]$.

Pharmacogenomics. The study of how an individual's genetic makeup influences a drug's effectiveness.

Pharmacokinetics. The behavior of a drug in the body over time, including its tissue distribution and rate of elimination or degradation.

Phenotype. An organism's physical characteristics.

ϕ (phi). The torsion angle that describes the rotation around the $C_\alpha-N$ bond in a peptide group; the dihedral angle made by the bonds connecting the $C-N-C_\alpha-C$ atoms in a peptide chain.

Phosphagen. A phosphoguanidine whose phosphoryl group-transfer potential is greater than that of ATP; these compounds can therefore phosphorylate ADP to generate ATP.

Phosphatase. An enzyme that hydrolyzes phosphoryl ester groups. See also protein phosphatase.

Phosphatidic acid. The simplest glycerophospholipid, consisting of two fatty acyl groups attached to glycerol-3-phosphate.

Phosphodiester bond. The linkage in which a phosphate group is esterified to two alcohol groups, e.g., the phosphate groups that join the adjacent nucleoside residues in a polynucleotide.

Phosphoglyceride. See glycerophospholipid.

Phospholipase. An enzyme that hydrolyzes one or more bonds of a glycerophospholipid.

Phosphorolysis. The cleavage of a chemical bond by the substitution of a phosphate group rather than water.

Phosphoryl group-transfer potential. A measure of the tendency of a phosphorylated compound to transfer its phosphoryl group to water; the negative of its free energy of hydrolysis.

Photoautotroph. An autotrophic organism that obtains energy from sunlight.

Photon. A packet (quantum) of light energy. See also Planck's law.

Photooxidation. A mode of decay of an excited molecule, in which oxidation occurs through the transfer of an electron to an acceptor molecule.

Photophosphorylation. The synthesis of ATP from $ADP + P_i$ coupled to the dissipation of a proton gradient that has been generated through light-driven electron transport.

Photoreactivation. The conversion of pyrimidine dimers, a form of DNA damage, to monomers using light energy.

Photorespiration. The consumption of O_2 and evolution of CO_2 by plants (a dissipation of the products of photosynthesis), resulting from the competition between O_2 and CO_2 for binding to ribulose biphosphate carboxylase.

Photosynthesis. The reduction of CO_2 to $(CH_2O)_n$ in plants and bacteria as driven by light energy.

Photosynthetic reaction center. The pigment-containing protein complex that undergoes photooxidation during the light reactions of photosynthesis.

Phylogenetic tree. A reconstruction of the probable paths of evolution of a set of related organisms, usually based on sequence variations among their homologous proteins and nucleic acids; a sort of family tree.

Phylogeny. The study of the evolutionary relationships among organisms.

pI . See isoelectric point.

PIC. See preinitiation complex.

Ping Pong reaction. A group-transfer reaction in which one or more products are released before all substrates have bound to the enzyme.

Pitch. The distance a helix rises along its axis per turn; 5.4 Å for an α helix, 34 Å for B-DNA.

pK . A quantity used to express the tendency for an acid to donate a proton (dissociate); equal to $-\log K$, where K is the acid's dissociation constant. Also known as pK_a .

Planck's law. An expression for the energy (E) of a photon: $E = hc/\lambda = h\nu$, where c is the speed of light in vacuum, λ is its wavelength, ν is its frequency, and h is Planck's constant ($6.626 \times 10^{-34} \text{ J} \cdot \text{s}$).

Plaque. (1) A region of lysed cells on a "lawn" of cultured bacteria, which indicates the presence of infectious bacteriophage. (2) A deposit of insoluble material in an animal's tissues.

Plasmalogen. A glycerophospholipid in which the $C1$ substituent is attached via an ether rather than an ester linkage.

Plasmid. A small circular DNA molecule that autonomously replicates in a bacterial or yeast cell. Plasmids are often modified for use as cloning vectors.

(+) end. The end of a polymeric filament where growth is faster. See also (−) end.

pmf. See protonmotive force.

Point mutation. The substitution of one base for another in DNA. Point mutations may arise from mispairing during DNA replication or from chemical alterations of existing bases.

Point mutation. The substitution of one base for another in DNA. Point mutations may arise from mispairing during DNA replication or from chemical alterations of existing bases.

Polarimeter. A device that measures the optical rotation of a solution. It can be used to determine the optical activity of a substance.

Polar molecule. A molecule with one or more groups that have permanent dipoles.

Polyacrylamide gel electrophoresis (PAGE). See gel electrophoresis.

Polycythemia. A condition characterized by an increased number of erythrocytes.

Polyelectrolyte. A macromolecule that bears multiple charged groups.

Polyketide. A molecule produced by the stepwise condensation and modification of 2- to 4-carbon units, catalyzed by an enzyme containing multiple active sites arranged in modular fashion.

Polymer. A molecule consisting of numerous smaller units that are linked together in an organized manner. Polymers may be linear or branched and may consist of one or more kinds of structural units (monomers).

Polymerase. An enzyme that catalyzes the addition of nucleotide residues to a polynucleotide through nucleophilic attack of the chain's 3'-OH group on the α -phosphoryl group of the incoming nucleoside triphosphate. DNA- and RNA-directed polymerases require a template molecule with which the incoming nucleotide must base pair.

Polymerase chain reaction (PCR). A procedure for amplifying a segment of DNA by repeated rounds of replication centered between primers that hybridize with the two ends of the DNA segment of interest.

Polymorphism. A variation in DNA or amino acid sequences between individuals.

Polynucleotide. See nucleic acid.

Polypeptide. A polymer consisting of amino acid residues linked in linear fashion by peptide bonds.

Polyprotic acid. A substance with more than one proton that can ionize. Polyprotic acids have multiple ionization states.

Polyribosome. An mRNA transcript bearing multiple ribosomes in the process of carrying out translation. Also called a polysome.

Polysaccharide. A polymeric carbohydrate consisting of multiple monosaccharide residues. Also called a glycan.

Polysome. See polyribosome.

Polyunsaturated fatty acid. A fatty acid that contains more than one double bond in its hydrocarbon chain.

P/O ratio. The ratio of the number of molecules of ATP synthesized from $ADP + P_i$ to the number of atoms of oxygen reduced.

Porphyrias. Genetic defects in heme biosynthesis that result in the accumulation of porphyrins.

Positive cooperativity. See cooperative binding.

Posttranscriptional modification. The removal or addition of nucleotide residues or their modification following the synthesis of RNA.

Posttranslational processing. The removal or derivatization of amino acid residues following their incorporation into a polypeptide, or the cleavage of a polypeptide.

Prebiotic era. The period of time between the formation of the earth ~ 4.6 billion years ago and the appearance of living organisms at least 3.5 billion years ago.

G-16

Precursor. An entity that gives rise, through a process such as evolution or chemical reaction, to another entity.

Preinitiation complex (PIC). An assembly of eukaryotic transcription factors bound to DNA that renders the DNA available for transcription by RNA polymerase.

Prenylation. The attachment of an isoprenoid group to a protein to form a lipid-linked protein.

Preprotein. A protein bearing both a signal peptide (preprotein) and a propeptide (proprotein).

Preprotein. A protein bearing a signal peptide that is cleaved off following the translocation of the protein through the endoplasmic reticulum membrane.

pre-rRNA. An immature rRNA transcript.

Pribnow box. The prokaryotic promoter element with the consensus sequence TATAAT that is centered at around the -10 position relative to the transcription start site.

Primary active transport. Transmembrane transport that is driven by the exergonic hydrolysis of ATP.

Primary structure. The sequence of residues in a polymer.

Primary transcript. The immediate product of transcription, which may be modified before becoming fully functional.

Primase. The RNA polymerase responsible for synthesizing the RNA segment that primes DNA synthesis.

Primer. An oligonucleotide that serves as a starting point for additional polymerization reactions catalyzed by DNA polymerase to form a polynucleotide. A primer base pairs with a segment of a template polynucleotide strand to form a short double-stranded segment that can then be extended through template-directed polymerization.

Primosome. The protein complex that synthesizes the RNA primers in DNA synthesis.

Prion. A protein whose misfolding causes it to aggregate and produce the neurodegenerative symptoms of transmissible spongiform encephalopathies and related diseases. Prions act as infectious agents by inducing their corresponding properly folded proteins to misfold and thereby form more prions.

Probe. A labeled single-stranded DNA or RNA segment that can hybridize with a DNA or RNA of interest in a screening procedure.

Processive enzyme. An enzyme that catalyzes many rounds of a polymerization reaction without dissociating from the growing polymer.

Prochirality. A property of certain nonchiral molecules such that they contain a group whose substitution by another group yields a chiral molecule.

Product inhibition. A case of enzyme inhibition in which product that accumulates during the course of the reaction competes with substrate for binding to the active site.

Proenzyme. An inactive precursor of an enzyme.

Prokaryote. A unicellular organism that lacks a membrane-bounded nucleus. All bacteria are prokaryotes.

Promoter. The DNA sequence at which RNA polymerase binds to initiate transcription.

Proofreading. An additional catalytic activity of an enzyme, which acts to correct errors made by the primary enzymatic activity.

Proprotein. The inactive precursor of a protein that, to become fully active, must undergo limited proteolysis to excise its propeptide.

Prostaglandin. See eicosanoids.

Prosthetic group. A cofactor that is permanently (often covalently) associated with an enzyme.

Protease. See peptidase.

Protein. A macromolecule that consists of one or more polypeptide chains.

Protein kinase. An enzyme that catalyzes the transfer of a phosphoryl group from ATP to the OH group of a protein Ser, Thr, or Tyr residue.

Protein phosphatase. An enzyme that catalyzes the hydrolytic excision of phosphoryl groups from proteins.

Proteoglycan. An extracellular aggregate of protein and glycosaminoglycan.

Proteomics. The study of all of a cell's proteins, including their quantitation, localization, modifications, interactions, and activities.

Protomer. One of two or more identical units of an oligomeric protein. A protomer may consist of one or more polypeptide chains.

Proton jumping. The sequential transfer of protons between hydrogen-bonded water molecules. Proton jumping is largely responsible for the rapid rate at which hydronium and hydroxyl ions appear to move through an aqueous solution.

Protonmotive force (pmf). The free energy of the electrochemical proton gradient that forms during electron transport.

Proton wire. A group of hydrogen-bonded protein groups and water molecules that serves as a conduit for protons to traverse a transmembrane protein via proton jumping.

Proto-oncogene. The normal cellular analog of an oncogene; the mutation of a proto-oncogene may yield an oncogene that contributes to uncontrolled cell proliferation (cancer).

Proximity effect. A catalytic mechanism in which a reaction's free energy of activation is reduced by the prior bringing together of its reacting groups.

Pseudo-first-order reaction. A bimolecular reaction whose rate appears to be proportional to the concentration of only a single reactant because the second reactant is present in large excess.

Pseudogene. An unexpressed sequence of DNA that is apparently the defective remnant of a duplicated gene.

ψ (psi). The torsion angle that describes the rotational position around the $C_{\alpha}-C$ bond in a peptide group; the dihedral angle made by the bonds connecting the $N-C_{\alpha}-C-N$ atoms in a peptide chain.

P site. See peptidyl site.

Pulse labeling. A technique for tracing metabolic fates, in which cells or a reacting system are exposed briefly to high levels of a labeled compound.

Pulsed-field gel electrophoresis (PFGE). An electrophoretic procedure in which electrodes arrayed around the periphery of an agarose slab gel are sequentially pulsed so that DNA molecules must continually reorient, thereby allowing very large molecules to be separated by size.

Purine nucleotide cycle. The conversion of aspartate to fumarate, which replenishes citric acid cycle intermediates, through the deamination of AMP to IMP.

Purines. Derivatives of the compound purine, a planar aromatic, heterocyclic compound. Adenine and guanine, two of the nitrogenous bases of nucleotides, are purines.

Pyranose. A monosaccharide with a six-membered ring.

Pyrimidine dimer. The cyclobutane-containing structure resulting from UV irradiation of adjacent thymine or cytosine residues in the same strand of DNA.

Pyrimidines. Derivatives of the compound pyrimidine, a planar aromatic, heterocyclic compound. Cytosine, uracil, and thymine, three of the nitrogenous bases of nucleotides, are pyrimidines.

Pyrophosphate cleavage. The hydrolysis of ATP that yields AMP + PP_i .

Pyrosequencing. A procedure for determining the sequence of nucleotides in DNA by copying a DNA strand in such a way that a flash of light is generated when the correct nucleotide is incorporated.

Q cycle. The cyclic flow of electrons accompanied by the transport of protons, involving a stable semiquinone intermediate of CoQ in Complex III of mitochondrial electron transport and in photosynthetic electron transport.

Quantum (pl. quanta). A packet of energy. See also photon.

Quantum yield. The ratio of molecules reacted to photons absorbed in a light-induced reaction.

Quaternary structure. The spatial arrangement of a macromolecule's individual subunits.

Racemic mixture. A sample of a compound in which both enantiomers are present in equal amounts.

Radioimmunoassay (RIA). A technique for measuring the concentration of a molecule based on its ability to block the binding of a small amount of the radioactively labeled molecule to its corresponding antibody.

Radionuclide. A radioactive isotope.

Ramachandran diagram. A plot of ψ versus ϕ that indicates the sterically allowed conformations of a polypeptide.

- Randle cycle.** See glucose–fatty acid cycle.
- Random coil.** A totally disordered and rapidly fluctuating polymer conformation.
- Random mechanism.** A sequential reaction without a compulsory order of substrate addition to the enzyme.
- Rate constant (k).** The proportionality constant between the velocity of a chemical reaction and the concentration(s) of the reactant(s).
- Rate-determining step.** The step with the highest transition state free energy in a multistep reaction; the slowest step.
- Rate enhancement.** The ratio of the rates of a catalyzed to an uncatalyzed chemical reaction.
- Rational drug design.** See structure-based drug design.
- Reaction coordinate.** The path of minimum free energy for the progress of a reaction.
- Reaction order.** The sum of the exponents of the concentration terms that appear in a reaction's rate equation.
- Reactive oxygen species (ROS).** Partially reduced forms of O_2 , such as superoxide ($O_2^{\cdot-}$) and the hydroxyl radical ($\cdot OH$), that react with and therefore damage cellular components.
- Reading frame.** The grouping of nucleotides in sets of three whose sequence corresponds to a polypeptide sequence.
- Receptor-mediated endocytosis.** A process in which an extracellular ligand binds to a specific cell-surface receptor and the resulting receptor–ligand complex is engulfed by the cell.
- Receptor tyrosine kinase.** A hormone receptor whose intracellular domain is activated, as a result of hormone binding, to phosphorylate tyrosine residues on other proteins and/or on other subunits of the same receptor.
- Recombinant.** A DNA molecule constructed by combining DNA from different sources. Also called a chimera.
- Recombinant DNA technology.** The isolation, amplification, and modification of specific DNA sequences. Also called molecular cloning or genetic engineering.
- Recombination.** The exchange of polynucleotide strands between separate DNA segments. Homologous recombination occurs between DNA segments with extensive homology, whereas site-specific recombination occurs between two short, specific DNA sequences.
- Recombination repair.** A mechanism for repairing damaged DNA, in which recombination exchanges a portion of a damaged strand for a homologous segment that can then serve as a template for the replacement of the damaged bases.
- Redox center.** A group that can undergo an oxidation–reduction reaction.
- Redox couple.** See conjugate redox pair.
- Reducing agent.** A substance that can donate electrons, thereby reducing another substance and becoming oxidized.
- Reducing equivalent.** A term used to describe the number of electrons that are transferred from one molecule to another during a redox reaction.
- Reducing sugar.** A saccharide bearing an anomeric carbon that has not formed a glycosidic bond and can therefore reduce mild oxidizing agents.
- Reduction.** The gain of electrons. Reduction of a substance is accompanied by the oxidation of another substance.
- Reduction potential (\mathcal{E}).** A measure of the tendency of a substance to gain electrons.
- Reductive pentose phosphate cycle.** See Calvin cycle.
- Regular secondary structure.** A segment of a polymer in which the backbone adopts a regularly repeating conformation.
- Release factor.** A protein that recognizes a Stop codon and thereby helps induce ribosomes to terminate polypeptide synthesis.
- Renaturation.** The refolding of a denatured macromolecule so as to regain its native conformation.
- Repetitive DNA.** Stretches of DNA of up to several thousand bases that occur in multiple copies in an organism's genome; they are often arranged in tandem.
- Replica plating.** The transfer of yeast colonies, bacterial colonies, or phage plaques from a culture plate to another culture plate, a membrane, or a filter in a manner that preserves the distribution of the cells on the original plate.
- Replication.** The process of making an identical copy of a DNA molecule. During DNA replication, the parental polynucleotide strands separate so that each can direct the synthesis of a complementary daughter strand, resulting in two complete DNA double helices.
- Replication fork.** The branch point in a replicating DNA molecule at which the two strands of the parental molecule are separated and serve as templates for the synthesis of the daughter strands.
- Replicon.** A unit of eukaryotic DNA that is replicated from one replication origin.
- Replisome.** The DNA polymerase–containing protein assembly that catalyzes the synthesis of both the leading and lagging strands of DNA at the replication fork.
- RER.** See rough endoplasmic reticulum.
- Residue.** A term for a monomeric unit of a polymer.
- Resonance energy transfer.** See exciton transfer.
- Respiratory distress syndrome.** Difficulty in breathing in prematurely born infants, caused by alveolar collapse resulting from insufficient synthesis of lung surfactant.
- Restriction endonuclease.** A bacterial enzyme that recognizes a specific DNA sequence and cleaves the DNA as part of a restriction–modification system.
- Restriction–modification system.** A matched pair of bacterial enzymes that recognize a specific DNA sequence: a modification methylase that methylates bases in that sequence, and a restriction endonuclease that cleaves the DNA if it has not been methylated in that sequence. It is a defensive system that eliminates foreign (e.g., viral) DNA.
- Reticulocyte.** An immature red blood cell, which actively synthesizes hemoglobin.
- Retrotransposon.** A transposon whose sequence and mechanism of transposition suggest that it arose from a retrovirus.
- Retrovirus.** A virus whose genetic material is RNA that must be reverse-transcribed to double-stranded DNA during host cell infection.
- Reverse transcriptase.** A DNA polymerase that uses RNA as its template.
- Reverse transcriptase (RT).** A DNA polymerase that uses RNA as its template.
- Reverse turn.** A polypeptide conformation in which the chain makes an abrupt reversal in direction; usually consisting of four successive residues. Also called a β bend.
- R group.** A symbol for a variable portion of an organic molecule, such as the side chain of an amino acid.
- Rho factor.** A prokaryotic helicase that separates DNA and RNA to promote transcription termination.
- Ribonucleic acid.** See RNA.
- Ribonucleoprotein.** A complex of protein and RNA.
- Ribonucleotide.** A nucleotide in which the pentose is ribose.
- Ribosomal RNA (rRNA).** The RNA molecules that constitute the bulk of the ribosome, the site of polypeptide synthesis. rRNA provides structural scaffolding for the ribosome and catalyzes peptide bond formation.
- Ribosome.** The organelle that synthesizes polypeptides under the direction of mRNA. It consists of around two-thirds RNA and one-third protein.
- Riboswitch.** An mRNA segment that regulates gene expression through alterations in its structure triggered by the presence of the metabolite that is synthesized by the encoded protein.
- Ribozyme.** An RNA molecule that has catalytic activity.
- Rickets.** A vitamin D-deficiency disease in children that is characterized by stunted growth and deformed bones.
- Rigor mortis.** The stiffening of muscles after death due to lack of ATP.
- RNA.** Ribonucleic acid. A polymer of ribonucleotides. The major forms of RNA include messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA).
- RNA editing.** The posttranscriptional insertion, deletion, or alteration of bases in mRNA.
- RNA interference (RNAi).** A form of posttranscriptional gene regulation in which a short double-stranded RNA segment triggers the degradation of the homologous mRNA molecule.

G-18

RNAi. See RNA interference.

RNAP. RNA polymerase, the enzyme that synthesizes RNA using a DNA template.

Rossmann fold. See dinucleotide binding fold.

Rotational symmetry. A type of symmetry in which the asymmetric units of a symmetric object can be brought into coincidence through rotation.

Rough endoplasmic reticulum (RER). That portion of the endoplasmic reticulum associated with ribosomes; it is the site of synthesis of membrane proteins and proteins destined for secretion or residence in certain organelles.

R state. One of two conformations of an allosteric protein; the other is the T state. The R state is customarily the catalytically more active state.

RS system. See Cahn–Ingold–Prelog system.

S. See entropy.

Saccharide. See carbohydrate.

Salt bridge. See ion pair.

Salting in. The increase in solubility of a protein (or other molecule) with increasing (low) salt concentration.

Salting out. The decrease in solubility of a protein (or other molecule) with increasing (high) salt concentration.

Salvage pathway. A metabolic pathway for converting free purines and pyrimidines to their nucleotide forms.

Sarcomere. The repeating unit of a myofibril, which contains thin and thick filaments that slide past each other during muscle contraction.

Saturated fatty acid. A fatty acid that does not contain any double bonds in its hydrocarbon chain.

Saturation. The state in which all of a macromolecule's ligand-binding sites are occupied by ligand. See also enzyme saturation and saturated fatty acid.

Schiff base. An imine that forms between an amine and an aldehyde or ketone.

SCID. See severe combined immunodeficiency disease.

Scrapie. See transmissible spongiform encephalopathy.

Screening. A technique for identifying clones that contain a desired gene.

Scurvy. A disease caused by vitamin C (ascorbic acid) deficiency, which results in inadequate formation of 4-hydroxyprolyl residues in collagen, thereby reducing collagen's stability.

SDS-PAGE. Polyacrylamide gel electrophoresis (PAGE) in the presence of the detergent sodium dodecyl sulfate (SDS), which denatures and imparts a uniform charge density to polypeptides and thereby permits them to be fractionated on the basis of size rather than inherent charge.

Secondary active transport. Transmembrane transport that is driven by the energy stored in an electrochemical gradient, which itself is generated utilizing the free energy of ATP hydrolysis or electron transport.

Secondary structure. The local spatial arrangement of a polymer's backbone atoms without regard to the conformations of its substituent side chains. α helices and β sheets are common secondary structural elements of proteins.

Second messenger. An intracellular ion or molecule that acts as a signal for an extracellular event such as ligand binding to a cell-surface receptor.

Second-order reaction. A reaction whose rate is proportional to the square of the concentration of one reactant or to the product of the concentrations of two reactants.

Secretory pathway. The series of steps in which a protein destined for secretion, membrane insertion, or residence in certain organelles is recognized by the signal recognition particle as it emerges from the ribosome, has its signal peptide excised by a signal peptidase, and is translocated across the endoplasmic reticulum membrane or inserted into it via a translocon.

Segmentation genes. Insect genes that specify the correct number and polarity of body segments. Gap genes, pair-rule genes, and segment polarity genes are all segmentation genes.

Segment polarity genes. See segmentation genes.

Selectable marker. A gene whose product has an activity, such as antibiotic resistance, such that, under the appropriate conditions, cells harboring the gene can be distinguished from those that lack the gene.

Selfish DNA. Genomic DNA that has no apparent function. Also called junk DNA.

Semiconservative replication. The natural mode of DNA duplication in which each new duplex molecule contains one strand from the parent molecule and one newly synthesized strand.

Semidiscontinuous replication. The mode of DNA replication in which one strand is replicated as a continuous polynucleotide strand (the leading strand) while the other is replicated as a series of discontinuous fragments (Okazaki fragments) that are later joined (the lagging strand).

Sense strand. The DNA strand complementary to the strand that is transcribed; it has the same base sequence (except for the replacement of U with T) as the synthesized RNA. Also called the coding strand.

Sequential model of allostery. A model for allosteric behavior in which the subunits of an oligomeric protein change conformation in a stepwise manner as the number of bound ligands increases.

Sequential reaction. A reaction in which all substrates must combine with the enzyme before a reaction can occur; it can proceed by an Ordered or Random mechanism.

Severe combined immunodeficiency disease (SCID). An inherited disease that greatly impairs the immune system. One such defect is a deficiency of the enzyme adenosine deaminase.

Shear degradation. The fragmentation of DNA by the mechanical force of shaking or stirring.

Shine–Dalgarno sequence. A purine-rich sequence ~ 10 nucleotides upstream from the start codon of many prokaryotic mRNAs that is partially complementary to the 3' end of the 16S rRNA. This sequence helps position the ribosome to initiate translation.

Short interfering RNA (siRNA). An exogenous RNA of 18 to 25 nucleotides that inhibits gene expression through RNA interference. See also microRNA.

Short tandem repeat (STR). See highly repetitive DNA.

Shotgun cloning. The cloning of an organism's genome in the form of a set of random fragments.

Sickle-cell anemia. An inherited disease in which erythrocytes are deformed and damaged by the presence of a mutant hemoglobin (Glu 6 β \rightarrow Val) that in its deoxy form polymerizes into fibers.

σ factor. A subunit of the bacterial RNA polymerase holoenzyme that recognizes a gene's promoter and is released once chain initiation has occurred.

Sigmoidal curve. The S-shaped graphical representation of the cooperative binding of a ligand to a molecule.

Signal-gated channel. See ligand-gated channel.

Signal peptide. A short (13–36 residues) N-terminal peptide sequence that targets a nascent secretory or transmembrane protein to the endoplasmic reticulum (in eukaryotes) or plasma membrane (in prokaryotes). This leader peptide is subsequently cleaved away by a signal peptidase.

Signal recognition particle (SRP). A protein–RNA complex that binds to the signal peptide of a nascent transmembrane or secretory protein and escorts it to the endoplasmic reticulum (in eukaryotes) or plasma membrane (in prokaryotes) for translocation through the membrane.

Signal transduction. The transmittal of an extracellular signal to the cell interior by the binding of a ligand to a receptor so as to elicit a cellular response through the activation of a sequence of intracellular events that often include the generation of second messengers.

Single-displacement reaction. A reaction in which a group is transferred from one molecule to another in a concerted fashion (with no intermediates).

Single nucleotide polymorphism (SNP). A single base difference in the genomes of two individuals; such differences occur every 1250 bp, on average, in the human genome.

Single-strand binding protein (SSB). A tetrameric protein, many molecules of which coat single-stranded DNA during replication to prevent the re-formation of double-stranded DNA.

siRNA. See short interfering RNA.

- Site-directed mutagenesis.** A technique in which a cloned gene is mutated in a specific manner.
- Site-specific recombination.** See recombination.
- Size exclusion chromatography.** See gel filtration chromatography.
- Sliding filament model.** A mechanism for muscle contraction in which interdigitated thin and thick filaments move past each other to shorten the overall length of a sarcomere.
- Small nuclear ribonucleoprotein (snRNP).** A complex of protein and small nuclear RNA that participates in mRNA splicing.
- Small nuclear RNA (snRNA).** Highly conserved 60- to 300-nt RNAs that participate in mRNA splicing.
- Small nucleolar RNA (snoRNA).** Eukaryotic RNA molecules of 70 to 100 nt that pair with immature rRNAs to direct their sequence-specific methylation.
- SNARE.** A membrane-associated protein that participates in vesicle fusion; SNAREs from the two fusing membranes form bundles of four helices that bring the membranes together.
- snoRNA.** See small nucleolar RNA.
- SNP.** See single nucleotide polymorphism.
- snRNA.** See small nuclear RNA.
- snRNP.** See small nuclear ribonucleoprotein.
- Solvation.** The state of being surrounded by several layers of ordered solvent molecules. Hydration is solvation by water.
- Somatic hypermutation.** The greatly increased rate of mutation that occurs in the immunoglobulin genes of proliferating B lymphocytes and leads, over several cell generations, to antibodies with higher antigen affinity.
- Somatic recombination.** Genetic rearrangement that occurs in cells other than germline cells.
- Sonication.** Irradiation with high-frequency sound waves. Such treatment is used to mechanically disrupt cells and subcellular membranous structures.
- SOS response.** A bacterial system that recognizes damaged DNA, halts its replication, and repairs the damage, although in an error-prone fashion.
- Southern blotting.** A procedure for identifying a DNA base sequence after electrophoresis, through its ability to hybridize with a complementary single-stranded segment of labeled DNA or RNA. See also Northern blotting.
- Special pair.** The set of two closely spaced chlorophyll molecules in a photosynthetic system that undergo photooxidation.
- Spherocytosis.** A hereditary abnormality in the erythrocyte cytoskeleton that renders the cells rigid and spheroidal and which causes hemolytic anemia.
- Sphingolipid.** A derivative of the C₁₈ amino alcohol sphingosine. Sphingolipids include the ceramides, cerebrosides, and gangliosides. Sphingolipids with phosphate head groups are called sphingophospholipids.
- Spliceosome.** A ~60S particle containing proteins, snRNPs, and pre-mRNA; it carries out the splicing reactions whereby a pre-mRNA is converted to a mature mRNA.
- Splicing.** The usually ribonucleoprotein-catalyzed process by which introns are removed and exons are joined to produce a mature transcript. Some RNAs are self-splicing.
- Spontaneous process.** A thermodynamic process that occurs without the input of free energy from outside the system. Spontaneity is independent of the rate of a process.
- Squelching.** The inhibition of the activity of a transcription factor by another transcription factor that competes with it for binding to DNA.
- SRP.** See signal recognition particle.
- SRP receptor (SR).** The endoplasmic reticulum protein that serves as a docking site for the signal recognition particle (SRP) during the synthesis of a transmembrane or secretory protein.
- SSB.** See single-strand binding protein.
- Stacking interactions.** The stabilizing van der Waals interactions between successive (stacked) bases and base pairs in a polynucleotide.
- Standard state.** A set of conditions including unit activity of the species of interest, a temperature of 25°C, a pressure of 1 atm, and a pH of 0.0. See also biochemical standard state.
- Starch.** A mixture of linear and branched glucose polymers that serve as the principal energy reserves of plants.
- STAT.** See JAK-STAT.
- State function.** Quantities such as energy, enthalpy, entropy, and free energy, whose values depend only on the current state of the system, not on how they reached that state.
- Steady state.** A set of conditions in an open system under which the formation and degradation of individual components are balanced such that the system does not change over time.
- Steady state assumption.** A condition for the application of the Michaelis-Menten model to an enzymatic reaction, in which the concentration of the ES complex remains unchanged over the course of the reaction.
- Stem-loop.** A secondary structural element in a single-stranded nucleic acid, in which two complementary segments form a base-paired stem whose strands are connected by a loop of unpaired bases.
- Stereoisomers.** Chiral molecules with different configurations about at least one of their asymmetric centers but that are otherwise identical.
- Steroid.** Any of numerous naturally occurring lipids composed of four fused rings; many are hormones that are derived from cholesterol.
- Sterol.** An alcohol derivative of a steroid.
- Sticky end.** The single-stranded extension of a DNA fragment that has been cleaved at a specific sequence (often by a restriction endonuclease) in a staggered cut such that the single-stranded extension is complementary to those of similarly cleaved DNAs.
- Stop codon.** A sequence of three nucleotides that does not specify an amino acid but instead causes the termination of translation. Also called a nonsense codon.
- STR.** Short tandem repeat. See highly repetitive DNA.
- Striated muscle.** The voluntary or skeletal muscles, which have a striped microscopic appearance.
- Stroma.** The concentrated solution of enzymes, small molecules, and ions in the interior of a chloroplast; the site of carbohydrate synthesis.
- Stromal lamellae.** The membranous assemblies that connect grana in a chloroplast.
- Strong acid.** An acid that is essentially completely ionized in aqueous solution. A strong acid has a dissociation constant much greater than unity ($pK < 0$).
- Structural bioinformatics.** See bioinformatics.
- Structural gene.** A gene that encodes a protein.
- Structure-based drug design.** The synthesis of more effective drug molecules as guided by knowledge of the target protein's structure. Also called rational drug design.
- Substrate.** A reactant in an enzymatic reaction.
- Substrate cycle.** Two opposing sets of metabolic reactions that, in many cases, function together to hydrolyze ATP, but provide a control point for regulating metabolic flux. Also called a futile cycle.
- Substrate-level phosphorylation.** The direct transfer of a phosphoryl group to ADP to generate ATP.
- Subunit.** One of several polymer chains that make up a macromolecule.
- Suicide substrate.** See mechanism-based inhibitor.
- Supercoiling.** The topological state of covalently closed circular double helical DNA in which the double helix is twisted around itself. It arises through the over- or underwinding of the double helix. Also called superhelicity.
- Superhelicity.** See supercoiling.
- Superoxide radical.** O₂^{-•}, a partially reduced oxygen species that can damage biomolecules through free-radical reactions.
- Supersecondary structure.** A common grouping of secondary structural elements. Also called a motif.
- Suppressor mutation.** A mutation that cancels the effect of another mutation.
- Surface labeling.** A technique in which a lipid-insoluble protein-labeling reagent is used to identify the portion of a membrane protein that is exposed to solvent.
- Surroundings.** In thermodynamics, the universe other than the particular system that is of interest.

G-20

Svedberg (S). Equivalent to 10^{-13} s; used to describe a particle's sedimentation velocity per unit of centrifugal force in an ultracentrifuge.

Symbiosis. A mutually dependent relationship between two organisms.

Symmetry model of allostereism. A model for allosteric behavior in which all the subunits of an oligomeric protein are constrained to change conformation in a concerted manner so as to maintain the symmetry of the oligomer.

Symport. A transmembrane channel that simultaneously transports two different molecules or ions in the same direction. See also antiport and uniport.

Syn conformation. A purine nucleotide conformation in which the ribose and the base are eclipsed. See also anti conformation.

Syncytium. A single cell containing multiple nuclei that results from repeated nuclear division without the formation of new plasma membranes.

Synonymous codons. Codons that specify the same amino acid.

System. In thermodynamics, the part of the universe that is of interest; the rest of the universe is the surroundings. See also closed system, isolated system, and open system.

Systems biology. The computer-based collection and analysis of data sets for the purpose of discerning relationships between dynamic or multifactorial biological entities.

T. See twist.

T state. One of two conformations of an allosteric protein; the other is the R state. The T state is customarily the catalytically less active state.

TAFs. TBP-associated factors, which, along with TBP, constitute the general transcription factor TFIID required for the transcription of eukaryotic structural genes.

TATA box. A eukaryotic promoter element with the consensus sequence TATA \hat{A} \hat{A} located 10 to 27 nucleotides upstream from the transcription start site.

Tautomers. Isomers that differ only in the positions of their hydrogen atoms and double bonds.

Taxonomy. The study of biological classification.

Tay–Sachs disease. A fatal sphingolipid storage disease caused by a deficiency of hexosaminidase A, the lysosomal enzyme that breaks down ganglioside G_{M2}.

TBP. TATA-binding protein, a DNA-binding protein that is required for transcription of all eukaryotic genes.

TCA cycle. Tricarboxylic acid cycle. See citric acid cycle.

Telomerase. An RNA-containing DNA polymerase that, using the RNA as a template, catalyzes the repeated addition of a specific G-rich sequence to the 3' end of a eukaryotic DNA molecule to form a telomere.

Telomere. The end of a linear eukaryotic chromosome, which consists of tandem repeats of a short G-rich sequence on the 3'-ending strand and its complementary sequence on the 5'-ending strand.

Tertiary structure. The entire three-dimensional structure of a single-chain polymer, including that of its side chains.

Tetrahedral intermediate. An intermediate of peptide bond hydrolysis in which the carbonyl carbon of the scissile bond has undergone nucleophilic attack so that it has four substituents.

Tetramer. An assembly consisting of four monomeric units.

Therapeutic index. The ratio of the dose of a drug that produces toxicity to the dose that produces the desired effect.

Thermodynamics. The study of the relationships among various forms of energy.

Thermophile. An organism that thrives at high temperatures.

3' end. The terminus of a polynucleotide whose C3' is not esterified to another nucleotide residue.

θ structure. The appearance of a circular DNA molecule undergoing replication by the progressive separation of its two strands.

Thick filament. The sarcomere element that is composed primarily of several hundred myosin molecules.

Thin filament. The sarcomere element that is composed primarily of actin, together with tropomyosin and troponin.

Thylakoid. The innermost compartment in chloroplasts, which is formed by invaginations of the chloroplast's inner membrane. The thylakoid membrane is the site of the light reactions of photosynthesis.

Titration curve. The graphical presentation of the relationship between the pH of an acid- or base-containing solution and the degree of proton dissociation (roughly equal to the number of equivalents of strong base or strong acid that have been added to the solution).

Topoisomerase. An enzyme that alters DNA supercoiling by catalyzing breaks in one or both strands, passing DNA through the break, and resealing the break.

Topology. The study of the geometric properties of an object that are not altered by deformations such as bending and stretching.

Torsion angle. The dihedral angle described by the bonds between four successive atoms. The torsion angles ϕ and ψ indicate the backbone conformation of a peptide group in a polypeptide.

T ψ C arm. A conserved stem–loop structure in a tRNA molecule that usually contains the sequence T ψ C, where ψ is pseudouridine.

Trans conformation. An arrangement of the peptide group in which successive C α atoms are on opposite sides of the peptide bond.

Transamination. The transfer of an amino group from an amino acid to an α -keto acid to yield a new α -keto acid and a new amino acid.

Transcription. The process by which RNA is synthesized under the direction of a DNA template, thereby transferring genetic information from the DNA to the RNA. Transcription is catalyzed by RNA polymerase as facilitated by numerous other proteins.

Transcription factor. A protein that promotes the transcription of a gene by binding to DNA sequences at or near the gene or by interacting with other proteins that do so.

Transcriptomics. The study of all the RNA molecules that a cell transcribes.

Transfer RNA (tRNA). The small L-shaped RNAs that deliver specific amino acids, which have been esterified to the tRNA's 3' ends, to ribosomes according to the sequence of a bound mRNA. The proper tRNA is selected through the complementary base pairing of its three-nucleotide anticodon with the mRNA's codon, and the growing polypeptide is transferred to its aminoacyl group.

Transformation. (1) The permanent alteration of a bacterial cell's genetic message through the introduction of foreign DNA. (2) The genetic changes that convert a normal cell to a cancerous cell.

Transgene. A foreign gene that is stably expressed in a host organism.

Transition. A mutation in which one purine (or pyrimidine) replaces another.

Transition state. A molecular assembly at the point of maximal free energy in the reaction coordinate diagram of a chemical reaction.

Transition state analog. A stable substance that geometrically and electronically resembles the transition state of a reaction.

Transition temperature. The temperature at which a lipid bilayer shifts from a gel-like solid to a more fluid liquid crystal form.

Translation. The process by which a polypeptide is synthesized under the direction of the sequence information contained in a messenger RNA as specified by the genetic code. Translation is catalyzed by ribosomes and requires the additional participation of messenger RNA, transfer RNA, and a variety of protein factors.

Translocation. (1) The movement of a polypeptide through a membrane during the synthesis of a secreted protein. (2) The movement, by one codon, of the ribosome relative to the mRNA after peptide bond synthesis.

Translocon. A multisubunit protein that forms an aqueous pore across the endoplasmic reticulum membrane that functions to translocate a nascent polypeptide across the membrane or to install it in the membrane as part of the secretory pathway.

Transmembrane (TM) protein. An integral protein that completely spans the membrane.

Transmissible spongiform encephalopathy (TSE). An invariably fatal neurodegenerative disease resulting from a prion infection, such as scrapie in sheep.

Transpeptidation. The ribosomal process in which a tRNA-bound nascent polypeptide is transferred to a tRNA-bound aminoacyl group so as to form a new peptide bond, thereby lengthening the polypeptide by one residue at its C-terminus.

Transposable element. See transposon.

- Transposition.** The movement (copying) of genetic material from one part of the genome to another or, in some cases, from one organism to another.
- Transposon.** A genetic unit that can move (be copied) from one position to another in a genome; some transposons carry genes. Also called a transposable element.
- Transverse diffusion.** The movement of a lipid from one leaflet of a bilayer to the other. Also called flip-flop.
- Transversion.** A mutation in which a purine is replaced by a pyrimidine or vice versa.
- Treadmilling.** The addition of monomeric units to one end of a linear assembly, such as an actin filament, and their simultaneous removal from the opposite end such that the length of the assembly remains unchanged.
- Triacylglycerol.** A lipid in which three fatty acids are esterified to a glycerol backbone. Also called a triglyceride.
- Tricarboxylic acid (TCA) cycle.** See citric acid cycle.
- Triglyceride.** See triacylglycerol.
- Trimer.** An assembly consisting of three monomeric units.
- Tripeptide.** A polypeptide containing three amino acids.
- Tumor suppressor.** A protein whose loss or inactivation may lead to cancer.
- Turnover number.** See k_{cat} .
- Twist (T).** The number of complete revolutions that one strand of a covalently closed circular double helical DNA makes around the duplex axis. It is positive for right-handed superhelical coils and negative for left-handed superhelical coils.
- Two-dimensional (2D) gel electrophoresis.** A technique in which proteins are first subjected to isoelectric focusing, which separates them by net charge, and then to SDS-PAGE in a perpendicular direction, which separates them by size.
- Ubiquinone.** See coenzyme Q.
- Ubiquitin.** A small, highly conserved protein that is covalently attached to a eukaryotic intracellular protein to mark it for degradation by a proteasome.
- Ultracentrifugation.** A procedure that subjects macromolecules to a strong centrifugal force (in an ultracentrifuge), thereby separating them by size and/or density and providing a method for determining their mass and subunit structure.
- Uncompetitive inhibition.** A form of enzyme inhibition in which an inhibitor binds to the enzyme–substrate complex and thereby decreases its apparent K_M and its apparent V_{max} by the same factor.
- Uncoupler.** A substance that allows the proton gradient across a membrane to dissipate without ATP synthesis so that electron transport proceeds without oxidative phosphorylation.
- Uniport.** A transmembrane channel that transports a single molecule or ion. See also antiport and symport.
- Unsaturated fatty acid.** A fatty acid that contains at least one double bond in its hydrocarbon chain.
- Urea cycle.** A catalytic cycle in which amino groups donated by ammonia and aspartate combine with a carbon atom from HCO_3^- to form urea for excretion and which provides the route for the elimination of nitrogen from protein degradation.
- Uridylylation.** Addition of a uridylyl (UMP) group.
- Uronic acid.** A sugar produced by oxidation of an aldose primary alcohol group to a carboxylic acid group.
- Vacuole.** An intracellular vesicle for storing water or other molecules.
- van der Waals distance.** The distance of closest approach between two nonbonded atoms.
- van der Waals forces.** The noncovalent associations between molecules that arise from the electrostatic interactions among permanent and/or induced dipoles.
- van't Hoff plot.** A graph of K_{eq} versus $1/T$ that is used to determine ΔH° and ΔS° and therefore ΔG° for a chemical reaction.
- Variable arm.** A nonconserved region of a tRNA molecule that contains 3 to 21 nucleotides and that may include a base-paired stem.
- Variable region.** The N-terminal portions of an antibody molecule, where antigen binding occurs and which are characterized by high sequence variability.
- Variant.** A naturally occurring mutant form.
- Vector.** See cloning vector.
- Vesicle.** A fluid-filled sac enclosed by a membrane.
- Virulence.** The disease-evoking power of a microorganism.
- Virus.** A nonliving entity that co-opts the metabolism of a host cell to reproduce.
- Vitamin.** A metabolically required organic substance that cannot be synthesized by an animal and must therefore be obtained from its diet.
- VLDL.** Very low density lipoprotein; see lipoprotein.
- V_{max} . Maximal velocity of an enzymatic reaction.
- Voltage-gated channel.** A channel whose opening and closing (gating) is controlled by a change in membrane potential.
- W.** (1) See writhing number. (2) The number of energetically equivalent ways of arranging the components of a system.
- Water of hydration.** The shell of relatively immobile water molecules that surrounds and interacts with (solvates) a dissolved molecule.
- Watson–Crick base pair.** A stable pairing of nucleotide bases, either adenine with thymine or guanine with cytosine, that occurs in DNA and, to a lesser extent, in RNA (in which thymine is replaced by uracil). See also Hoogsteen base pair.
- Weak acid.** An acid that is only partially ionized in aqueous solution. A weak acid has a dissociation constant less than unity ($\text{p}K > 0$).
- Western blot.** See immunoblot.
- Wild type.** The naturally occurring version of an organism or gene.
- Wobble hypothesis.** An explanation for the permissive tRNA–mRNA pairing at the third anticodon position that includes non-Watson–Crick base pairs. This allows many tRNAs to recognize two or three different (degenerate) codons.
- Writhing number (W).** The number of turns that the duplex axis of a covalently closed circular double helical DNA makes around the superhelix axis. It is a measure of the DNA's superhelicity.
- Xenobiotic.** A molecule that is not normally present in an organism.
- X-ray crystallography.** A method for determining three-dimensional molecular structures from the diffraction pattern produced by exposing a crystal of a molecule to a beam of X-rays.
- Yeast artificial chromosome (YAC).** A linear DNA molecule that contains the chromosomal structures required for normal replication and segregation in a yeast cell. YACs are commonly used as cloning vectors.
- Ylid.** A molecule with opposite charges on adjacent atoms.
- Zero-order reaction.** A reaction whose rate does not vary with the concentration of any of its reactants.
- Zinc finger.** A protein structural motif, often involved in DNA binding, that consists of 25 to 60 residues that include His and/or Cys residues to which one or two Zn^{2+} ions are each tetrahedrally coordinated.
- Z-scheme.** A Z-shaped diagram indicating the sequence of events and their reduction potentials in the two-center photosynthetic electron-transport system of plants and cyanobacteria.
- Zwitterion.** See dipolar ion.
- Zymogen.** The inactive precursor (proenzyme) of a proteolytic enzyme.

INDEX

Page numbers in **bold** refer to a major discussion of the entry. F after a page number refers to a figure. T after a page number refers to a table. Positional and configurational designations in chemical names (e.g., 3-, α , *N*-, *p*-, *trans*, *D*-) are ignored in alphabetizing. Numbers and Greek letters are otherwise alphabetized as if they were spelled out.

 Tth RNAP holoenzyme, 940, 940F
 Tumor necrosis factor- α , 788
 Tumor suppressors, **1082–1085**
 Turnover number, 368
tus gene, 896
 Tus protein, 896, 896F
 TVGYG (signature sequence), 299
 20S proteasome, 721–723
 23S rRNA, 973, 997–999
 26S proteasome, 721, 721F, 722F
 28S rRNA, 973
 Twist, supercoiled DNA, 841, 841F
 [2Fe–2S] clusters, 598
 Two-center electron transport, photosynthesis, **639–650**
 cytochrome *b_f*, 645–646
 plastocyanin, 645–646
 PSI-activated electrons, 648–650
 PSII and P680, 641–643
 PSI RC and PSII RC, 646–648
 water-splitting reaction, 643–644
 Two-dimensional (2D) gel electrophoresis, 108, 108F
 Two-dimensional (2D) nuclear magnetic resonance spectroscopy, 148
 Two-step reactions, 328–329, 328F
 TxB₂, 258F
 Type I diabetes mellitus, 793
 Type 2 diabetes mellitus, 793–795
 Type I glycogen storage disease, 531
 Type I restriction endonucleases, 54
 Type II restriction endonucleases, 54–56, 55F
 Type III restriction endonucleases, 54
 Type I topoisomerases, 842–845, 845F
 Type IA topoisomerases, 842–844, 843F, 844F
 Type IB topoisomerases, 842, 844, 845, 845F
 Type II topoisomerases, 842, 845–848, 846F, 847F
 Type III topoisomerases, 843–844, 843F
 Type IV topoisomerases, 897
 Tyramine, 771
 Tyrosine (Tyr):
 acid-base catalysis by, 332
 biosynthesis, 755, 755F
 breakdown, **745**, **746**, 747F
 in neurotransmitter synthesis, 762–763, 763F
 in phenylalanine breakdown, 471F, 745F
 uncharged polar side chain, 85
 UV absorbance spectra, 102F
 Tyrosine kinase-associated receptors, 418
 Tyrosyl-tRNA, 1020
 TyrRS, 994
 TZDs (thiazolidinediones), 795
 U, *see* Uracil
 U, *see* Energy
 U1-70K, 967
 U1-A, 967
 U1-C, 967, 968F
 U1-snRNA, 966, 967
 U2-snRNP, 966, 967
 U2-snRNP auxiliary factor (U2AF), 970, 971
 U4-snRNP, 966, 967
 U5-snRNP, 966, 967
 U6-snRNP, 966
 Ubiquinone, *see* Coenzyme Q
 Ubiquitin, **720–721**, 720F
 Ubiquitin-activating enzyme (E1), 720
 Ubiquitin-conjugating enzyme (E2), 720
 Ubiquitin isopeptidases, 720
 Ubiquitin-protein ligase (E3), 720
 UCP1, 620, 790
 UCP2, 620
 UCP3, 620
 UDG (uracil-DNA glycosylase), 911–912, 911F
 UDP (uridine diphosphate), 510
 UDPG (UDP-glucose), 511F, 532
 UDP-galactose, 510, 511F
 UDP-galactose (uridine diphosphate galactose), 552
 UDP-galactose-4-epimerase, 510
 UDP-glucose (UDPG), 511F, 532
 UDP-glucose pyrophosphorylase, **532–533**, 533F
 Ultracentrifugation, **106–108**
 Ultracentrifuge, 109
 Umami, 747
 UMP (uridine monophosphate), **809–811**, 809F, 827F

- Uncharged polar side chains, amino acid, 83T, 85, 85F, 150

APPLICATIONS INDEX

Diet & Nutrition

artificial sweeteners 229
essential amino acids 752
essential fatty acids 695
fructose 509
lactose intolerance 228
pellagra 444
riboflavin 463
scurvy 142
starvation 790
thiamine deficiency 500
threonine 81
trans fats 249
vitamin B₁₂ deficiency 680
vitamin D disorders 256

Drugs & Toxins

adrenergic receptor inhibitors 406
anabolic steroids 407
antibiotics and protein synthesis 1020
antibiotics and transcription 950
antifolates 821
arsenic poisoning 568
aspirin 705
bacitracin 555
cardiac glycosides 312
COX-2 inhibitors 705
diabetes drugs 795
drug design 392
drug resistance 314
drug–drug interactions 395
enantiomeric drugs 91
fatty acid synthase inhibitors 693
heparin 234
HIV enzyme inhibitors 376
influenza drugs 375
lead poisoning 758
malaria drugs 391
methanol poisoning 378
nerve poisons 346
oral rehydration therapy 316
penicillin and vancomycin 238
purine derivatives 826
sulfa drugs 740
tetanus and botulinum toxins 286
topoisomerase inhibitors 848
viagra 432

Evolution & Comparative Biochemistry

aerobic metabolism 558
 α/β barrel enzymes 488
anaerobic metabolism 443
bacterial electron transport 612
citric acid cycle evolution 582
cytochrome *c* evolution 120
domains of life 9
endosymbiosis 10
fatty acid synthase evolution 689
gene duplication 124
genetic code evolution 986

protein misfolding diseases 173
retinoblastoma 1085
severe combined immunodeficiency 823
spina bifida and anencephaly 740
sudden infant death syndrome 675
Tangier disease 714
Tay–Sachs disease 706
thermogenesis 507
toxoplasmosis 810
trinucleotide repeat diseases 1040
xeroderma pigmentosum 913
Zellweger syndrome 684

Laboratory & Clinical Tools

clinical trials 393
CRISPR–Cas system 927
DNA fingerprinting 73
expanding the genetic code 996
gastric bypass surgery 796
gene therapy 75
green fluorescent protein 93
kidney dialysis 31
monoclonal antibodies 216
organ transplants 423
polyketide synthesis 694
protein design 167
protein sequencing 112
radioimmunoassay 404
receptor–ligand binding 410
recombinant DNA technology, ethical aspects 75
transaminase assays 726

Some Common Biochemical Abbreviations

A	adenine	F2,6P	fructose-2,6-bisphosphate
aaRS	aminoacyl-tRNA synthetase	F6P	fructose-6-phosphate
ACAT	acyl-CoA:cholesterol acyltransferase	FAD	flavin adenine dinucleotide, oxidized form
ACP	acyl-carrier protein	FADH•	flavin adenine dinucleotide, radical form
ADA	adenosine deaminase	FADH ₂	flavin adenine dinucleotide, reduced form
ADP	adenosine diphosphate	FBP	fructose-1,6-bisphosphate
AIDS	acquired immunodeficiency syndrome	FBPase	fructose-1,6-bisphosphatase
ALA	δ-aminolevulinic acid	Fd	ferredoxin
AMP	adenosine monophosphate	FH	familial hypercholesterolemia
ATCase	aspartate transcarbamoylase	fMet	<i>N</i> -formylmethionine
ATP	adenosine triphosphate	FMN	flavin mononucleotide
BChl	bacteriochlorophyll	G	guanine
bp	base pair	G1P	glucose-1-phosphate
BPG	D-2,3-bisphosphoglycerate	G6P	glucose-6-phosphate
BPheo	bacteriopheophytin	G6PD	glucose-6-phosphate dehydrogenase
BPTI	bovine pancreatic trypsin inhibitor	GABA	γ-aminobutyric acid
C	cytosine	Gal	galactose
CaM	calmodulin	GalNAc	<i>N</i> -acetylgalactosamine
CAM	crassulacean acid metabolism	GAP	glyceraldehyde-3-phosphate
cAMP	3',5'-cyclic AMP	GAPDH	glyceraldehyde-3-phosphate dehydrogenase
CAP	catabolite gene activator protein	GDH	glutamate dehydrogenase
CDK	cyclin-dependent protein kinase	GDP	guanosine diphosphate
cDNA	complementary DNA	Glc	glucose
CDP	cytidine diphosphate	GlcNAc	<i>N</i> -acetylglucosamine
CE	capillary electrophoresis	GMP	guanosine monophosphate
Chl	chlorophyll	GPI	glycosylphosphatidylinositol
CM	carboxymethyl	GSH	glutathione
CMP	cytidine monophosphate	GSSH	glutathione disulfide
CoA or		GTF	general transcription factor
CoASH	coenzyme A	GTP	guanosine triphosphate
CoQ	coenzyme Q (ubiquinone)	Hb	hemoglobin
COX	cyclooxygenase	HDL	high density lipoprotein
CPS	carbamoyl phosphate synthetase	HIV	human immunodeficiency virus
CTP	cytidine triphosphate	HMG-CoA	β-hydroxy-β-methylglutaryl-CoA
D	dalton	hnRNA	heterogeneous nuclear RNA
d	deoxy	HPLC	high performance liquid chromatography
DAG	1,2-diacylglycerol	Hsp	heat shock protein
DCCD	dicyclohexylcarbodiimide	HTH	helix-turn-helix
dd	dideoxy	Hyl	5-hydroxylysine
ddNTP	2',3'-dideoxynucleoside triphosphate	Hyp	4-hydroxyproline
DEAE	diethylaminoethyl	IDL	intermediate density lipoprotein
DHAP	dihydroxyacetone phosphate	IF	initiation factor
DHF	dihydrofolate	IgG	immunoglobulin G
DHFR	dihydrofolate reductase	IMP	inosine monophosphate
DNA	deoxyribonucleic acid	IP ₃	inositol-1,4,5-trisphosphate
DNP	2,4-dinitrophenol	IPTG	isopropylthiogalactoside
dNTP	2'-deoxynucleoside triphosphate	IR	infrared
E4P	erythrose-4-phosphate	IS	insertion sequence
EF	elongation factor	ISP	iron-sulfur protein
ELISA	enzyme-linked immunosorbent assay	kb	kilobase pair
EM	electron microscopy	kD	kilodalton
emf	electromotive force	<i>K_M</i>	Michaelis constant
ER	endoplasmic reticulum	LDH	lactate dehydrogenase
ESI	electrospray ionization	LDL	low density lipoprotein
ETF	electron-transfer flavoprotein	LHC	light-harvesting complex
F1P	fructose-1-phosphate	Man	mannose

(table continued on following page)

Mb	myoglobin	PP _i	pyrophosphate
mRNA	messenger RNA	PRPP	5-phosphoribosyl- α -pyrophosphate
MS	mass spectrometry	PS	photosystem
MurNAc	N-acetylmuramic acid	PTK	protein tyrosine kinase
NAD ⁺	nicotinamide adenine dinucleotide, oxidized form	PTP	protein tyrosine phosphatase
NADH	nicotinamide adenine dinucleotide, reduced form	Q	ubiquinone (CoQ) or plastoquinone
NADP ⁺	nicotinamide adenine dinucleotide phosphate, oxidized form	QH ₂	ubiquinol or plastoquinol
NADPH	nicotinamide adenine dinucleotide phosphate, reduced form	r	ribo
NAG	N-acetylglucosamine	R5P	ribose-5-phosphate
NAM	N-acetylmuramic acid	RER	rough endoplasmic reticulum
NANA	N-acetylneuraminic (sialic) acid	RF	release factor
NDP	nucleoside diphosphate	RFLP	restriction fragment length polymorphism
NER	nucleotide excision repair	RIA	radioimmunoassay
NeuNAc	N-acetylneuraminic acid	RNA	ribonucleic acid
NMN	nicotinamide mononucleotide	RNAi	RNA interference
NMR	nuclear magnetic resonance	rRNA	ribosomal RNA
nt	nucleotide	RS	aminoacyl-tRNA synthetase
NTP	nucleoside triphosphate	RT	reverse transcriptase
OEC	oxygen-evolving center	RTK	receptor tyrosine kinase
OMP	orotidine monophosphate	Ru5P	ribulose-5-phosphate
ORF	open reading frame	RuBP	ribulose-1,5-bisphosphate
P or p	phosphate	S	Svedberg unit
PAGE	polyacrylamide gel electrophoresis	S7P	sedoheptulose-7-phosphate
PBG	porphobilinogen	SAM	S-adenosylmethionine
PC	plastocyanin	SCID	severe combined immunodeficiency disease
PCNA	proliferating cell nuclear antigen	SDS	sodium dodecyl sulfate
PCR	polymerase chain reaction	siRNA	small interfering RNA
PDB	protein data bank	SNAP	soluble NSF attachment protein
PDBid	PDB identification code	SNARE	SNAP receptor
PDI	protein disulfide isomerase	snRNA	small nuclear RNA
PE	phosphatidylethanolamine	snRNP	small nuclear ribonucleoprotein
PEP	phosphoenolpyruvate	SOD	superoxide dismutase
PEPCK	PEP carboxykinase	SRP	signal recognition particle
PFGE	pulsed-field gel electrophoresis	SSB	single-strand binding protein
PFK	phosphofructokinase	STAT	signal transducer and activator of transcription
2PG	2-phosphoglycerate	T	thymine
3PG	3-phosphoglycerate	TAF	TBP-associated factor
PGI	phosphoglucose isomerase	TBP	TATA box-binding protein
PGK	phosphoglycerate kinase	TCA	tricarboxylic acid
PGM	phosphoglycerate mutase	THF	tetrahydrofolate
Pheo	pheophytin	TIM	triose phosphate isomerase
P _i	orthophosphate	TNBS	trinitrobenzenesulfonic acid
PIC	preinitiation complex	TPP	thiamine pyrophosphate
PIP ₂	phosphatidylinositol-4,5-bisphosphate	tRNA	transfer RNA
PK	pyruvate kinase	TTP	thymidine triphosphate
PKA	protein kinase A	U	uracil
PKB	protein kinase B	UDP	uridine diphosphate
PKU	phenylketonuria	UDPG	uridine diphosphate glucose
PLP	pyridoxal-5'-phosphate	UMP	uridine monophosphate
pmf	protonmotive force	UTP	uridine triphosphate
PMP	pyridoxamine-5'-phosphate	UV	ultraviolet
PNP	purine nucleotide phosphorylase	VLDL	very low density lipoprotein
Pol	DNA polymerase	V _{max}	maximal velocity
		XMP	xanthosine monophosphate
		Xu5P	xylulose-5-phosphate
		YAC	yeast artificial chromosome
		YADH	yeast alcohol dehydrogenase
