Fractures

Key Points

- Always obtain two different radiographic perspectives of a bone or joint when evaluating for fractures.
- Always examine the joint above and below a fracture to look for associated injuries.
- Open fractures are orthopedic emergencies and need to be urgently washed out in the operating room.
- Be particularly alert for growth plate fractures in children.

One of the most common reasons for not identifying a fracture is the failure to examine or radiograph the area or extremity appropriately. When evaluating a patient for a fracture, the primary care physician must be sure to palpate and examine the joint above and below the fracture for potential concomitant injuries. Always obtain orthogonal views from at least two perspectives (e.g., anteroposterior [AP] and lateral). Additional radiographs are necessary only if a fracture is suspected. When communicating about fractures, health care professionals require a similar vocabulary to visualize the description accurately. This is especially true when family physicians and emergency physicians communicate with orthopedic consultants to make treatment decisions. Specific locations of the fracture or fracture fragments are important. They can be proximal or distal, anterior or posterior, medial or lateral. It is also helpful to describe them in relationship (how many centimeters?) to the nearest joint.

Fractures can be oriented in a variety of planes, and certain patterns are associated with a greater risk of instability or complications. Typical fracture orientations are transverse, spiral, oblique, or compression, but they can also be described as buckle, avulsion, stress, or greenstick. Additional features include the specific bone; region within the bone (diaphysis, metaphysis, epiphysis) (Figure 30-1); and whether the fracture is complete or incomplete, open or closed (is bleeding present or bone exposed?), intraarticular or extraarticular, displaced or nondisplaced (if so, how many centimeters?), angulated (if so, pointing in which direction?), shortened (if so, how much?), or comminuted

(if so, how many pieces?). In children, physal involvement is a special concern.

Open fractures are surgical emergencies and require immediate irrigation and debridement, tetanus prophylaxis, and antibiotic coverage. Orthopedists typically refer to the Gustilo-Anderson classification for open fractures, which is based on the size of skin wound, soft tissue damage, and bone comminution (Table 30-1). Even a small puncture wound over a fracture may allow skin flora to infiltrate the fracture site and initiate an infection. Any open fracture warrants an immediate referral to an emergency department (ED) for orthopedic evaluation.

GROWTH PLATE FRACTURES

The physal plate is a cartilaginous plate present in ends of long bones adjacent to the metaphysis. This is the area that provides longitudinal growth to bones and eventually matures into bone. During growth, the physal cartilaginous plate is weaker than the surrounding bone and often weaker than the ligaments and tendons that attach nearby, causing it to fracture before other areas. The Salter-Harris classification system describes these injuries (Figure 30-2).

Salter-Harris Type I

The epiphysis is separated from the metaphysis along the physis without an associated fracture through the metaphyseal or epiphyseal bone. The injury goes directly through the cartilaginous physal plate. These injuries can be displaced or nondisplaced. A nondisplaced Salter-Harris I fracture has a normal-appearing growth plate on radiographs, but patients have pain on palpation directly over the growth plate. Stress radiographs or magnetic resonance imaging (MRI) may be necessary to reveal the injury. Displaced type I injuries are typically easy to reduce because the periosteal attachment remains intact. These injuries have an excellent chance of normal healing with full growth of the injured bone. Despite this, growth delay and growth arrest are complications of growth plate injuries, which should be discussed with the patient and family.

Salter-Harris Type II

The fracture line incompletely extends through the physal plate and then turns into the metaphysis in an extraarticular fracture pattern. The Salter-Harris II fracture is the most

common type of growth plate fracture. The periosteum remains intact on the concave side of the injury, creating a “hinge” and making reduction relatively easy. The prognosis is excellent for future growth when anatomically reduced, with only a minor risk of angular deformity.

Figure 30-1 Bone regions: the diaphysis, metaphysis, and epiphysis.

Salter-Harris Type III

The fracture line extends incompletely along the physis and then turns through the epiphyseal bone into the joint. Salter-Harris III fractures are intraarticular injuries that imply an increased risk of arthritis, especially if they are not anatomically reduced. Alignment of the joint surface is the

Table 30-1 Gustilo-Anderson Open-Fracture Classification

Type I	<ul style="list-style-type: none"> Wound is smaller than 1 cm, with minimal soft tissue injury. Wound bed is clean. Fracture is usually a simple transverse, short oblique fracture, with minimal comminution.
Type II	<ul style="list-style-type: none"> Wound is larger than 1 cm, with moderate soft tissue injury. Fracture is usually a simple transverse, short oblique fracture, with minimal comminution.
Type III	<ul style="list-style-type: none"> Fracture involves extensive damage to the soft tissues, including muscle, skin, and neurovascular structures. Fracture is often accompanied by a high-velocity injury or a severe crushing component. Special patterns classified as type III: <ul style="list-style-type: none"> Open segmental fracture, regardless of the size of the wound Gunshot wounds: high-velocity and short-range shotgun injuries Open fracture with neurovascular injury Farm injuries, with soil contamination, regardless of size of wound Traumatic amputations Open fractures more than 8 hours after injury Mass casualties (e.g., war, tornado victims)
Subtype IIIA	<ul style="list-style-type: none"> Adequate soft tissue coverage despite soft tissue laceration or flaps or high-energy trauma, regardless of size of wound; includes segmental fractures or severely comminuted fractures.
Subtype IIIB	<ul style="list-style-type: none"> Extensive soft tissue lost with periosteal stripping and bony exposure; usually associated with massive contamination.
Subtype IIIC	<ul style="list-style-type: none"> Fracture with major arterial injury requiring repair for limb salvage.

Figure 30-2 Types of growth plate injury (I to V) as classified by Salter and Harris. (From Salter RB, Harris WR. Injuries involving the epiphyseal plate. *J Bone Joint Surg Am.* 1963;45:587.)

top priority, and open reduction is often necessary. The prognosis is good, provided the blood supply to the fracture fragment remains intact.

Salter-Harris Type IV

This intraarticular fracture pattern extends from the epiphysis, across the physal plate, and through a portion of the metaphysis. Open reduction and internal fixation (ORIF) is usually needed to ensure anatomic alignment of the joint surface and perfect alignment and apposition of the physal plate. Premature growth arrest and angular deformities can occur with Salter-Harris IV fractures. The prognosis can be good but depends on the ability to restore growth plate.

Salter-Harris Type V

Salter-Harris V fractures are crushing injuries in which an axial load compresses the epiphysis into the metaphysis, squeezing the actively growing physis between them. The prognosis for future growth is poor, with a high rate of premature closure of the physis and resultant joint deformity. Fortunately, these are rare injuries.

Shoulder

Key Points

- The diagnosis of joint injuries is usually clinically based and depends on good knowledge of anatomy. Special care should be taken to rule out injury to associated neurovascular structures for all joint injuries.
- Baseline imaging studies of the shoulder should *always* include a second tangential view of the scapula and glenoid. The best radiographic screening series is an AP view in internal rotation, AP view in external rotation, and axillary view of shoulder. The axillary view is the simplest to assess for joint dislocation.
- Impingement, rotator cuff injuries, and shoulder instability are best diagnosed with a complete physical examination supported by appropriate imaging studies rather than a single isolated maneuver.
- Performance, injury prevention, and injury recovery related to the shoulder are optimized when the entire kinetic chain is addressed, including a sound base, core strength, scapular stability, antagonist capsular and muscle stretching, and classic rotator cuff-strengthening program.

The true functional shoulder joint comprises the glenohumeral joint, scapular thoracic joint, acromioclavicular (AC) joint, and sternoclavicular (SC) joint. Problems around the shoulder can be acute or chronic and include pain, weakness, dysfunction, stiffness, and instability. To ensure optimal outcome of treatment, an accurate, anatomic-based diagnosis is necessary. Less targeted treatment regimens tend to be less successful because the specific problem may not be treated. Several evidence-based reviews remain inconclusive regarding specific interventions when a non-specific diagnosis such as “shoulder pain” is targeted.

INJURIES OF CLAVICULAR COMPLEX

Key Points

- Most clavicle fractures can be definitively treated nonsurgically with a sling or a figure-8 dressing if they are minimally displaced or nondisplaced.
- Grade 1 (tenderness) and grade 2 (tenderness and displacement with intact coracoclavicular [CC] ligaments) AC injuries are managed conservatively with ice, pain control, and a sling for comfort.
- Anterior shoulder dislocations are more common than posterior shoulder dislocations, but posterior dislocations are more commonly missed.

The diagnosis of clavicle, AC, and SC injuries is straightforward; direct palpation along the clavicular complex should lead to an area of focal pain. Imaging studies should include the entire clavicle and a clear view of the targeted area from at least two planes. All injuries around the shoulder should include examination of the cervical spine and distal neurovascular evaluation. The brachial plexus, subclavian vein, and axillary artery lie immediately beneath the clavicle and can be at risk of injury.

Clavicle fractures account for 5% to 10% of all fractures and can be classified as either displaced or nondisplaced as well as by their specific location (proximal-distal) on the clavicle. Most fractures involve the midshaft (80%); however, distal third (15%) and proximal third (5%) fractures are also possible. Fortunately, most clavicle fractures can be definitively treated nonoperatively with a sling or a figure-8 dressing if they are minimally displaced or nondisplaced. Figure-8 bracing has been linked with skin necrosis over the fracture site, indicating the need for careful observation of skin integrity when used. In most cases, a simple sling for comfort is adequate over the first few weeks followed by progressive range of motion (ROM) activities. More significant displacement (>100%), any tenting of the skin, significant comminution, or excessive shortening (>2 cm) may warrant surgical intervention. Referral to an orthopedic surgeon is recommended. Distal clavicle fractures have a higher rate of nonunion with nonsurgical treatment than midshaft or medial fracture patterns, so careful follow-up is necessary (Khan et al., 2009; McKee et al., 2004).

Acromioclavicular Joint

Acromioclavicular joint injuries are classified by the ligamentous structures involved and the degree of separation of the AC joint (Figure 30-3). A *grade 1* injury involves only a partial injury to the AC ligaments, no displacement occurs, and the CC ligaments are intact. A *grade 2* injury involves the complete injury of the AC ligaments; therefore, mild superior translation of the distal clavicle occurs (<100% translation), and the CC ligaments are intact. Both grade 1 and grade 2 injuries have an excellent prognosis with conservative treatment, which includes local application of ice, reduction of stresses, and a sling for comfort. Most patients have substantial active motion and functional use of the arm within 6 weeks. A *grade 3* involves the complete rupture of both the AC and CC ligaments. The distal end of the clavicle and acromion are now separated by more

Figure 30-3 Progressive severity of acromioclavicular (AC) joint injuries. Grade 1 indicates incomplete injury of ligaments. Grade 2 has complete injury of the AC ligaments but intact coracoclavicular (CC) ligaments. Grade 3 injuries have complete injury of both AC and CC ligaments. Grade 4, 5, and 6 injuries are progressively severe, with posterior displacement of clavicle, severe superior displacement of clavicle, and inferior displacement of clavicle beneath the coracoid process.

than a full clavicular width (>100% displacement). Stress radiographic views may magnify this separation even further; however, stress views rarely alter the treatment plan and are painful to patients and thus no longer considered required diagnostic images.

Treatment of grade 3 AC injuries is controversial and ranges from surgical to conservative treatment with a sling. With conservative treatment, the distal clavicle may ultimately heal in a superiorly translated position, leaving a prominent bump over the lateral aspect of the shoulder. However, nonelite athletes can function well and have a full return to activities. Acute repair of grade 3 injuries is suggested for some elite athletes but has not been proved in randomized controlled trials (RCTs) because subtle changes occur at this important point in the kinetic chain. Chronic reconstructions have been suggested in patients who have grade 3 injuries but with residual pain or dysfunction. The more severe injuries of the AC joint have significant posterior, superior, or inferior displacement and require surgical reduction and repair.

A *grade 4* AC separation is a complete injury of both AC and CC ligaments with a posterior subluxation of the distal clavicle relative to the acromion. These are frequently missed on routine AP radiographs but can be easily identified if routine axillary shoulder views are obtained. Fundamental management of bone and joint injuries requires a view from two perspectives. *Grade 5* injuries are basically equivalent to severe grade 3 injuries in which the distal clavicle is riding so high that it either buttonholes through the fascia or tents beneath the skin (300% translation). The fascial injury prevents reduction, and the pressure on the undersurface of the skin risks skin slough or an open injury. Finally, *grade 6* AC injuries are extremely rare and are associated with an inferior dislocation of the distal clavicle beneath the coracoid.

STERNOCLAVICULAR JOINT

Patients with SC injury present with a history of trauma (e.g., landing on lateral aspect of shoulder) or a history of chronic overuse that has led to popping and pain over the medial aspect of the clavicle (Matava et al., 2005). Acute

SC joint dislocations can be identified clinically with localized tenderness over the medial clavicular aspect, and gross deformity may be present. More often, however, patients present with a subtle, chronic situation caused by esthetic findings with a palpable or gross asymmetry. The examination should always include an assessment of the patient's airway and circulation, including cervical (jugular) venous distention, because the great vessels and trachea lie immediately posterior to the SC joints and may be compressed or injured (Figure 30-4). Imaging studies should include an AP radiograph of the chest, views of the entire clavicle, and a tangential or serendipity view of the SC joint (Figure 30-5). Because of overlapping shadows, these studies may be difficult to interpret. When suspicious, the best test is computed tomography (CT).

Traumatic SC joint dislocations can be either anterior or posterior. *Anterior dislocations* are generally easily palpated, with the proximal clavicle anteriorly displaced and painful. Anterior injuries may be reduced by placing a rolled towel or beanbag between the shoulder blades and then creating a distraction force along the arm in extension. Anterior dislocations tend to be unstable and to redisplace after

Figure 30-4 Schematic showing the proximity of major neurovascular structures to the sternoclavicular joint.

Figure 30-5 Technique in obtaining a tangential radiographic image, the serendipity view, to assess sternoclavicular joint injuries.

Figure 30-6 Medial clavicle injuries in patients younger than 23 to 25 years are likely physeal injuries and have the potential to remodel. **A**, The initial injury with periosteal sleeve delimitation. **B**, The new callous and bone healing over time.

attempted reduction. Fortunately, anterior injuries usually heal uneventfully, leaving an asymptomatic medial prominence and occasional popping, with minimal effect on the patient's activities of daily living (ADLs). *Posterior dislocations* can be dangerous because of proximity to the great vessels posteriorly. If patients have venous engorgement in the neck and difficulty breathing, closed reduction may be attempted. A towel clip is used at the medial end of the clavicle, pulling anteriorly and creating the reduction. If this is attempted, it is best done in the operating room with a vascular surgeon immediately available in case the proximal clavicle was actually tamponading an injury to the great vessels. This reduction should never be performed on the sideline in the absence of immediate cardiothoracic surgical response unless the patient's life is at risk and there is no other option.

When treating injuries to the proximal clavicle, the age of the patient and normal maturation of the proximal epiphysis are also important considerations. The medial clavicle epiphysis is one of the last to appear, at 19 to 23 years of age, and then the last to fuse, at 23 to 25 years of age. In patients younger than 23 years of age, these injuries are generally physeal injuries and not true dislocations, reducing the need for aggressive treatment (Figure 30-6).

KEY TREATMENT

- Subacromial injection for rotator cuff disease or intra-articular injection for adhesive capsulitis may be effective, although the effect may be minimal and not well maintained (Buchbinder et al., 2003) (SOR: A).
- The use of some physiotherapy interventions is indicated in specific and circumscribed cases of shoulder pain (Green et al., 2003) (SOR: B).

- Little evidence supports the benefit of manual therapy for adhesive capsulitis, shoulder pain, or subacromial impingement syndrome (Ho et al., 2009) (SOR: A).
- The use of acupuncture for shoulder pain can be neither recommended nor refuted (Green et al., 2005) (SOR: A).

SHOULDER IMPINGEMENT AND ROTATOR CUFF DISEASE

Key Points

- Tests to diagnose impingement syndrome include a positive Hawkins test, a painful arc of motion, and weakness with external rotation.
- Tests to diagnose a complete cuff tear include a positive drop-arm test, a painful arc of motion, and weakness to external rotation.
- Incomplete tears of the rotator cuff improve with physical therapy, antiinflammatory medications, or subacromial injection.

By far the two most common diagnostic categories of the shoulder are rotator cuff impingement and shoulder instability. The rotator cuff is a group of four muscles—the supraspinatus, infraspinatus, teres minor, and subscapularis—that originate from the scapular surface, traverse just outside of the glenohumeral capsule, and insert onto the tuberosities of the humerus (Figure 30-7). The rotator cuff initiates motion in the shoulder and stabilizes the humeral head in the glenohumeral joint.

When making the diagnosis of rotator cuff impingement, the clinician should look at the problem as a continuum of progressively more severe pathologies, including subacromial bursitis, AC joint hypertrophy and spurring, rotator cuff tendinosis, partial rotator cuff tears, complete or massive rotator cuff tears, and ultimately, rotator cuff arthropathy (i.e., degenerative disease related to chronic rotator cuff insufficiency) (Almekinders, 2001). Patients generally present with shoulder pain exacerbated by repetitive overhead activities, weakness, and occasionally difficulty sleeping on the shoulder. Physical examination of the shoulder includes provocative maneuvers that exacerbate impingement findings and evaluate the function of each rotator cuff muscle (Tennent et al., 2003a, 2003b). Impingement testing includes straight, forward flexion of the shoulder (Neer sign), abduction and internal rotation of the shoulder (Hawkins sign), and adduction of the shoulder in a 90-degree, forward-flexed position (Figures 30-8 and 30-9). The examiner must be cautious with the latter test because the result may be positive with impingement but also with AC joint hypertrophy alone or with degenerative change of the AC joint.

Isolated testing of the rotator cuff is performed in sequence. To isolate the supraspinatus muscle, the examiner should perform the "empty can" test. This is performed with the arm slightly forward flexed in the plane of the scapula, abducted to 90 degrees, with full internal rotation (i.e., with the thumbs down, or empty can). The examiner should then place resistance on the patient's distal hand in an inferior direction. If this exacerbates pain, it is a positive finding of impingement or rotator cuff tendinopathy. If the

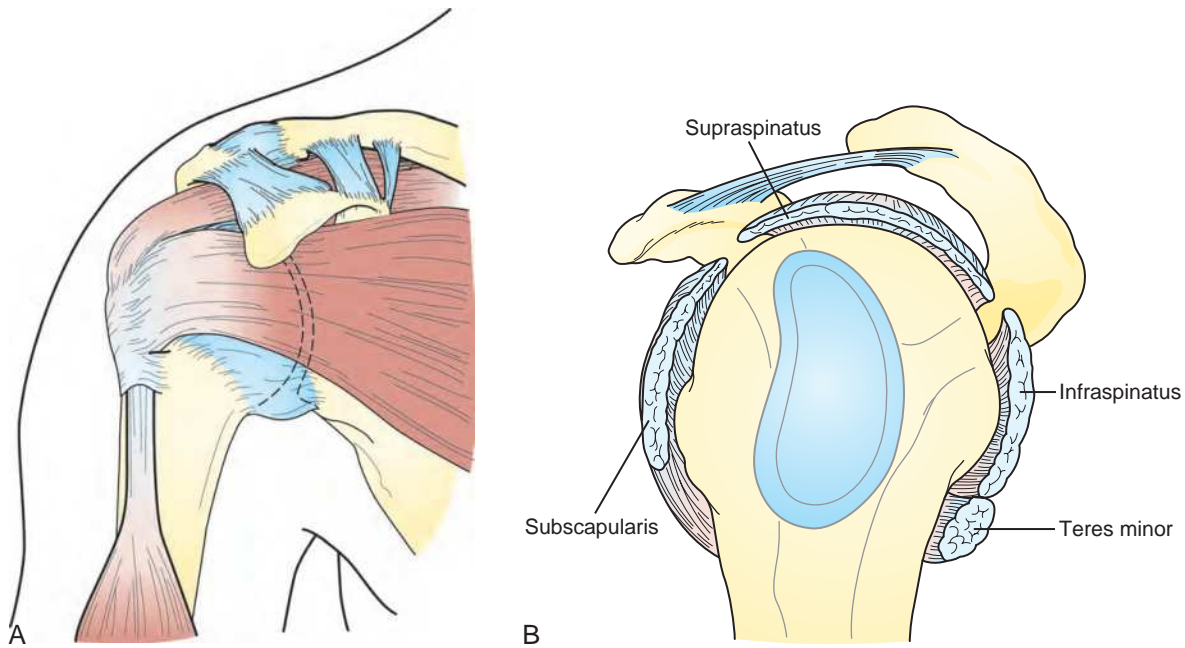

Figure 30-7 Anteroposterior (A) and lateral cross-sectional (B) schematics of the shoulder demonstrate the relationship of the rotator cuff muscles (supraspinatus, infraspinatus, teres minor, and subscapularis) to the bony structure of the shoulder.

Figure 30-8 The Hawkins test for shoulder impingement is performed by forward elevating the humerus against the fixed scapula. Pain indicates anterior impingement. (Courtesy Mark R. Hutchinson, MD.)

Figure 30-9 The Neer test for shoulder impingement is performed with abduction and internal rotation of the shoulder. Pain indicates lateral impingement. (Courtesy Mark R. Hutchinson, MD.)

patient has a positive “drop arm” sign and is unable to maintain the arm in this position, a complete rotator cuff tear should be suspected. However, this does not confirm a complete rotator cuff tear because the patient may be guarding secondary to pain. Clinically, the examiner can clarify the difference by performing a diagnostic subacromial injection with lidocaine. The injection should significantly diminish pain complaints but not affect the motor function of an intact rotator cuff (Park et al., 2005).

To evaluate the infraspinatus and teres minor muscles, the examiner should evaluate external rotation against resistance. This is best done with the arm at the side, keeping the elbows near the torso, and asking the patient to rotate externally against resistance. Isolating the subscapularis muscle is more difficult. Resisted internal rotation with the

arms at the side will recruit the pectoralis muscles and not isolate the subscapularis. To isolate the subscapularis, two tests have been described. In the *lift-off test*, the patient places the arm behind the back and lifts the hand into further internal rotation against resistance (Figure 30-10). If able to do this, the patient’s subscapularis muscle is likely intact. Modification of this test has been described as the “tummy pat” or the “Napoleon” test, in which the patient abducts the elbow, which must be away from the body in the plane of the torso, and is then asked to pat the stomach against resistance (Figure 30-11). Weakness or inability to press against resistance is considered to be a positive test result. After the diagnosis is made clinically, AP and axillary shoulder radiography studies can be obtained to evaluate the extent of injury further or assess for concomitant

Figure 30-10 The lift-off test is used to assess subscapularis muscle function. Patients are asked to lift their hands off their backs against resistance. Weakness or pain indicates subscapularis pathology. (Courtesy Mark R. Hutchinson, MD.)

Figure 30-11 The “Napoleon” or “tummy pat” test is a modified lift-off test to evaluate subscapularis function. Patients are asked to maintain their elbow laterally while pressing into their bellies. (Ensure that patients do not drop their arm and use the humerus extensors to mimic subscapularis function.) (Courtesy Mark R. Hutchinson, MD.)

injuries. MRI is not routinely indicated with an intact rotator cuff clinically, and we usually recommend trying a course of physical therapy for 6 to 12 weeks before ordering MRI (Park et al., 2005).

If the patient has symptomatic shoulder pain with overhead motion and cross-body adduction with an intact rotator cuff function on clinical examination and otherwise normal findings on radiographs, a conservative course of physical therapy is indicated for the impingement symptoms. Ninety percent to 95% of patients with incomplete tears of the rotator cuff improve with the course of physical therapy, antiinflammatory medications, or a subacromial injection, although some may require surgery eventually (Matava et al., 2005). Physical therapy should focus on rotator cuff strengthening, ROM, posterior capsular

stretching, and scapular stabilization. If patients fail a 6- to 12-week course of conservative treatment, a corticosteroid injection should be considered before surgery. If a patient is refractory to both corticosteroids and physical therapy, surgical intervention may be indicated. This is a more appropriate time to order MRI because preoperative MR scanning can evaluate the extent of rotator cuff pathology, associated spurring, and degeneration within the shoulder joint. Although not necessary for making the diagnosis, MRI can assist the surgeon at surgery. Platelet-rich plasma injections for partial rotator cuff tears and subacromial bursitis have not been proven in the literature, and only small case reports with short-term follow-up have been reported.

For incomplete rotator cuff tears (<50% of surface), a partial debridement and subacromial decompression using arthroscopy can provide effective, long-term relief of impingement pain. Management of rotator cuff tears greater than 50% or complete with clinical dysfunction is generally surgical. If the tear is identified before chronic retraction and muscle changes, primary arthroscopic or open repair has been effective in reducing pain and improving function. Rehabilitation after rotator cuff repair requires at least 6 weeks of passive ROM only, to protect the repair, followed by a gradual increase to resistance activities for the rotator cuff. Patients usually begin strengthening at 12 weeks. In patients with nonreparable chronic rotator cuff tears or those with advanced rotator arthropathy and degenerative disease, surgical interventions include muscle transfers, soft tissue grafts, hemiarthroplasties, and reverse shoulder hemiarthroplasties.

EVIDENCE-BASED SUMMARY

- In a review of eight clinical trials (>390 patients), no definitive evidence supports or refutes the efficacy of common interventions, including physiotherapy, nonsteroidal antiinflammatory drugs (NSAIDs), corticosteroid injections, or open and arthroscopic surgery, for rotator cuff tears in adults (Ejnisman et al., 2003) (SOR: A).
- Based on limited data from two quality RCTs, no evidence supports the superiority of conservative versus surgical treatment for subacromial impingement syndrome (Dorrestijn et al., 2009) (SOR: B).
- A review of 14 RCTs evaluating rotator cuff surgery showed no long-term pain benefit of surgical decompression versus exercise programs (Coghlan et al., 2009) (SOR: A).

SHOULDER INSTABILITY

Bony anatomy provides minimal stability to the glenohumeral joint; therefore, the primary stability depends on both static and dynamic soft tissue structures. The static soft tissue structures include the fibrocartilaginous labrum, glenohumeral ligaments, and capsule. The labrum attaches to the periphery of the glenoid and serves to deepen the socket, reducing translation out of the socket. The glenohumeral ligaments attach to the labrum, are thickenings in the capsule, and connect to the humeral head. The intrinsic dynamic stabilizers are the rotator cuff and biceps, which help maintain the humeral head in the glenoid socket. The extrinsic dynamic stabilizers include the rhomboid, levator

Figure 30-12 The apprehension test is performed with the arm in full abduction and external rotation. A sensation of impending subluxation is a positive finding. (Courtesy Mark R. Hutchinson, MD.)

scapulae, serratus, and trapezius muscles, which position the glenoid beneath the humeral head.

The diagnosis of shoulder instability begins with the patient's history and mechanism of injury, which often include episodes of subluxation, dislocation, or apprehension. Classically, anterior instability is appreciated when the arm is placed in abduction and external rotation (Tennent et al., 2003a, 2003b) (Figure 30-12). Inferior instability is appreciated when the patient tries to hold a heavy object and the shoulder subluxes inferiorly. Posterior instability is frequently associated with a fall on an outstretched arm or occasionally with weightlifters who lock out their arms in extension while bench pressing. The clinical examination targets these specific pathologies with the classic *apprehension test* for anterior instability, which is performed with the arm in abduction and external rotation and the patient having the sensation of the arm going out of place. In the *relocation test*, the examiner then presses the humeral head back into a reduced position, thus eliminating the sensation of apprehension. Posterior instability is assessed in a supine position with the arm forward flexed 90 degrees with a posteriorly directed force. Inferior instability is assessed by pulling inferiorly on the arm and looking for or feeling the humerus come out the socket and looking for a concavity just below the acromion, called the "sulcus sign" (Figure 30-13).

Some patients may have generalized ligamentous laxity, but laxity itself is not a painful process and is therefore not pathologic. However, some patients with generalized ligamentous laxity do have symptoms of instability and pathology that can be assessed by comparison with the opposite side or looking at the elbows, fingers or thumb, or knees for excessive recurvatum (hyperextension). In general, patients with generalized ligamentous laxity should undergo an extensive course of conservative treatment because of the increased risk of failure associated with most surgical interventions compared with simple unidirectional instability.

The conservative treatment of shoulder instability is targeted at balancing the flexibility, optimizing the motor strength, and optimizing the function of the kinetic chain. The core component is rotator cuff–strengthening exercises

Figure 30-13 The presence or absence of a sulcus sign is evaluated by distracting the arm inferiorly to sublux the humeral head out of the socket. If a sulcus is appreciated as the glenoid is emptied of the humeral head, the clinician should suspect multidirectional instability. (Courtesy Mark R. Hutchinson, MD.)

as well as scapular stabilizer exercises. Controversy surrounds the ideal treatment for a first-time shoulder anterior dislocation. In young athletes or military populations, the risk of recurrence and future shoulder problems approaches 90%. Surgical treatment with repair of labral detachments has led to a high rate of return to play and return to performance, with a low risk (<10%) of recurrent instability for a first dislocation. Older nonathletic patients (>40) with first-time dislocations have a reduced risk of recurrent instability (<50%), so surgical treatment is unnecessary. However, if any patient has recurrent instability or pain, surgery to repair the torn capsule or labral lesions is strongly recommended, with good to excellent outcomes occurring 75% to 95% of the time. The Bankart procedure is most often performed and involves direct repair of the torn labrum back to the glenoid from which it was detached (Figure 30-14). Classically, this procedure was performed open, although the current trend is toward arthroscopic assistance.

Posterior instability accounts for only 10% to 15% of isolated instability of the shoulder. The classic treatment for posterior instability is to initiate a course of conservative treatment focused on strengthening the posterior capsular muscles, including the infraspinatus and teres minor. It is important to carefully review a complete series of shoulder images to assess bone anatomy and look for associated glenoid fracture. If a conservative course fails, surgical treatment can again address either capsular laxity or posterior labral injuries.

Multidirectional instability is usually not secondary to a single acute traumatic event. More frequently, the patient will have underlying generalized ligamentous laxity that may or may not be exacerbated by a single traumatic event. These patients are generally loose jointed in all directions and in other joints. Initially, treatment is conservative, although in resistant cases, surgical capsular tightening can be successful in improving symptoms. A thorough

Figure 30-14 **A**, Detachment of the anterior inferior labrum (a Bankart lesion). **B**, Subsequent suture repair.

history is necessary to rule out psychologic factors (e.g., voluntary dislocation for attention or a party trick). These patients have an extremely high failure rate with surgical intervention.

KEY TREATMENT

- Primary surgical repair is indicated for young athletes engaged in highly demanding physical activities who have sustained their *first* shoulder dislocation (Handoll et al., 2004) (SOR: A).
- Surgical repair of shoulder instability from dislocation results in significantly lower recurrent instability than conservative treatment, especially for younger athletes and those in collision sports (Brophy and Marx, 2009) (SOR: B).
- No significant difference exists between arthroscopic and open techniques in the surgical treatment of recurrent shoulder instability in adults (Pulavarti et al., 2009) (SOR: B).

Elbow

Key Points

- Chronic lateral epicondylopathy (tennis elbow) is a degenerative process of the collagen and not an inflammatory process within the tendon.
- Topical or oral NSAIDs and corticosteroid injections provide short-term relief of lateral epicondylopathy pain but do not treat the underlying tendinopathy.
- Steroids must not be injected into an infectious olecranon bursitis.
- Steroid injections into the medial epicondyle and medial collateral ligament (MCL) can weaken the ligament and increase the risk of rupture.

LATERAL ELBOW TENDINOPATHY

Lateral elbow tendinopathy, commonly called *lateral epicondylitis* or “tennis elbow,” is caused by repetitive overuse of the wrist extensor and forearm supinator muscles that originate at the lateral epicondyle of the humerus—more specifically, the extensor carpi radialis brevis tendon. Once thought to result from inflammation, lateral elbow tendinosis is caused by chronic degenerative changes in the collagen fibers themselves (Nirschl, 1992), with minimal inflammation present. Microtears, chronic granulation tissue, and scar tissue formation are often seen in pathologic specimens of surgical cases of tennis elbow. Peritendinous soft tissue inflammation can occur, which may respond to ice and antiinflammatory medications, but these treatments do not address the collagen fiber degeneration.

Patients present because of pain in the lateral aspect of the elbow and less commonly complain of weakness or restricted elbow motion. Pain is made worse by gripping, turning handles, and lifting activities, particularly with the hand in a palm-down position, as in lifting a suitcase, briefcase, or purse. Common positive physical examination findings include tenderness to palpation of the lateral epicondyle of the elbow and over the proximal wrist extensor and forearm supinator muscle tendons just distal to the lateral epicondyle. Pain is intensified with resisted wrist extension and forearm supination. Pain can also limit patient strength. There should be no tenderness directly over the radial head, with normal ligamentous stability and normal neurovascular evaluation. Plain radiographs are not needed to make an accurate diagnosis of lateral epicondylopathy but should be considered in patients with a history of trauma, motion loss, or locking, or those with a prolonged period of pain.

Management focuses on pain control and restoration of normal elbow function. Cryotherapy, ice massage, and NSAIDs or acetaminophen are excellent pain relievers. NSAIDs and corticosteroid injection have been mainstays

of treatment, but their use is now questioned because inflammation no longer seems a main factor in the injury process. There seems to be a component of neovascularization, and the tendon is in a chronic state of injury. Corticosteroid injections help quickly reduce the pain of lateral elbow tendinosis related to peripheral peritendinous inflammation but do not alter the long-term outcome (Smidt et al., 2002). Cortisone injection may lead to a short-lived increase in pain in a large percentage of patients (Wang et al., 2003). For recalcitrant cases, treatments such as prolotherapy and extracorporeal shock wave therapy have been studied, but short-term follow-up and isolated reports of effectiveness are mixed (Rabago et al., 2013). Platelet-rich plasma injections for chronic tennis elbow have not been thoroughly evaluated or proven and only small case reports with short term follow-up have been studied.

Counterforce straps can effectively reduce discomfort in some patients (Figure 30-15). The strap is applied just distal to the area of maximal tenderness. The strap may relieve some of the tension exerted on the affected muscle tendon units during activities, thereby reducing pain. However, straps, medications, and injections should not replace therapeutic exercises, which include massage, stretching, and strengthening exercises. The most effective stretch is performed with the elbow extended, forearm fully pronated,

Figure 30-15 Lateral elbow counterforce brace. Note that wide, non-elastic support is curved to fit the conical forearm shape. This does not allow for full muscular expansion, thereby diminishing intrinsic muscular force on the lateral epicondyle. (From Morrey BF, ed. *The elbow and its disorders*. Philadelphia: Saunders; 1985.)

and wrist flexed. From this position, gentle traction is applied to the middle and ring fingers toward the olecranon. Strengthening exercises with light weights for wrist extension and forearm supination can be done.

Most patients with lateral elbow tendinopathy will obtain excellent relief of symptoms with the program just described, although minimal evidence exists to support these plans (Bisset et al., 2005). If these measures do not lead to adequate relief, other protocols can be added. Formal physical therapy is often used in recalcitrant cases. Treatments such as prolotherapy, dry needling, platelet-rich plasma injections, and extracorporeal shock wave therapy are still experimental, and studies have not fully proved their effectiveness. Surgical intervention is sometimes needed and has excellent results.

KEY TREATMENT

- No specific physical therapy modality is preferred over another in the treatment of lateral elbow tendinopathy (Smidt et al., 2003) (SOR: A).
- Topical and oral NSAIDs are both effective in providing short-term pain relief from lateral epicondylopathy; topical NSAIDs have fewer adverse effects (Green et al., 2002) (SOR: A).
- Corticosteroid injections are helpful in reducing pain from lateral epicondylopathy but do not alter the long-term outcome (Smidt et al., 2002) (SOR: A).
- Little evidence exists to support the use of therapeutic exercises or braces in the treatment of lateral epicondylopathy (Bisset et al., 2005) (SOR: A).
- Extracorporeal shock wave therapy provides little or no benefit in terms of pain and function in lateral elbow pain (nine placebo-controlled trials, 1006 participants; Buchbinder et al., 2009) (SOR: A).

MEDIAL ELBOW TENDINOPATHY

Medial elbow tendinopathy, commonly called *medial epicondylitis* or “golfer’s elbow,” is caused by repetitive overuse of the wrist flexor and forearm pronator muscles that originate at the medial epicondyle of the humerus. Patients present because of pain in the medial aspect of the elbow, rarely weakness, and loss of ROM. Pain is worsened by gripping and lifting activities, particularly with the hand in a palm-up position. Common positive findings include tenderness to palpation of the medial epicondyle of the elbow and over the proximal wrist flexor and forearm pronator muscle tendons. Pain is intensified with resisted wrist flexion and forearm pronation (Figure 30-16). Patient discomfort often limits strength. Elbow motion, ligamentous stability, and neurovascular status are typically intact.

As with lateral elbow tendinopathy, plain radiographs are not needed to make an accurate diagnosis of medial elbow tendinopathy but should be considered with a history of trauma, motion loss, locking, or chronic pain. Also similar to lateral epicondylopathy, management of medial epicondylopathy includes ice, medication, prolotherapy or platelet-rich plasma injections, and strapping. Corticosteroid injections are not recommended because of possible ulnar nerve injury and weakening of the MCL. In medial elbow

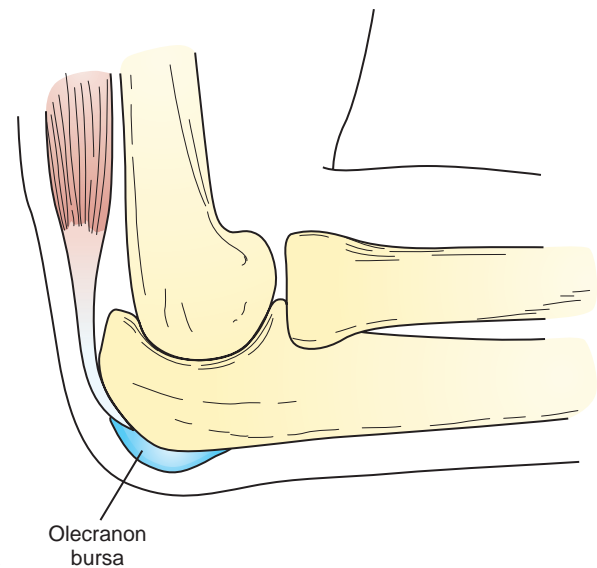

Figure 30-16 Medial epicondylitis may be diagnosed clinically by pain localized to the medial epicondyle during wrist flexion and pronation against resistance. Pain is often elicited after making a tight fist, and grip strength is usually diminished on the affected side. (From Morrey BF, ed. *The elbow and its disorders*. Philadelphia: Saunders; 1985.)

tendinopathy, the most effective stretch is performed with the elbow extended and the wrist and fingers gently pulled into full extension. The forearm can be pronated or supinated. Strengthening focuses on wrist flexion and forearm pronation exercises.

OLECRANON BURSITIS

Olecranon bursitis is a common cause of painless elbow swelling from repetitive friction of the olecranon against a firm surface or traumatic impact. Patients most often present with a painless swelling at the dorsal tip of the elbow, described as “a golf ball” or “goose egg” (Figure 30-17). With trauma-induced swelling, pain and a hematoma may be present. Pain, redness, warmth, and lymphadenopathy may accompany septic bursitis. ROM loss, instability, neurovascular compromise, and strength loss are uncommon. On examination, there is a soft, fluctuant area of swelling directly over the olecranon. Diagnostic studies are generally not necessary to make a diagnosis of olecranon bursitis. However, plain radiographs should be obtained if trauma preceded the bursitis or fracture or dislocation is suspected.

Classic treatment for aseptic bursitis includes compression, ice, and avoidance of impact at the olecranon. NSAIDs may help to reduce swelling. If the fluid collection within the bursa is large or infection is suspected, aspiration of the bursa can be done in the office with a large-bore needle under sterile conditions. The bursa fluid should be clear and straw colored but may be bloody in a traumatic injury. If an infection is not suspected clinically when the fluid is withdrawn, a corticosteroid can be injected. Corticosteroids should never be injected if infection is a possibility. Oral antibiotics can be started if an infection is present. A local incision and drainage may be required in the presence of an infection and abscess. Aspiration does not replace compression wrap, ice, and avoidance of impact. Fluid may reaccumulate but should decrease. Serial aspirations are an option in a recurrent aseptic bursitis, but bursectomy is occasionally needed for definitive treatment.

A Olecranon bursa

Figure 30-17 **A**, Relationship of the olecranon bursa to the skin and olecranon. **B**, An enlarged olecranon bursa. (From Singer KM, Butters KP. Olecranon bursitis. In DeLee JC, Drez D, eds. *Orthopedic sports medicine: principles and practice*. vol 1. Philadelphia: Saunders; 1994:890, 892.)

Wrist and Hand

Key Points

- Both bracing and cortisone injection may reduce carpal tunnel syndrome (CTS) pain in the short term.
- Surgical treatment of CTS leads to better symptom relief than bracing.
- Immobilization of suspected scaphoid injuries should be instituted while the workup is completed.
- Initial immobilization of any scaphoid fracture should be in a thumb spica cast.
- Proximal pole and displaced scaphoid fractures should be treated by an orthopedic surgeon.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is the most common nerve entrapment syndrome encountered in primary care. CTS is more

Figure 30-18 Cross-sectional anatomy of the carpal tunnel bounded on three sides by the carpal bones and volarly by the transverse carpal ligament. Nine flexor tendons and the median nerve pass through the tunnel. Anything that causes increased pressure in this canal can produce the symptoms of carpal tunnel syndrome. (From McCue FC, Bruce VF: Hand and wrist. In DeLee JC, Drez D, eds. *Orthopedic sports medicine: principles and practice*. vol 1. Philadelphia: Saunders; 1994:997.)

common in women than men and affects about 3% of the adult American population. Of the many possible etiologies, the most common is tenosynovitis of the hand flexors, leading to median nerve compression. CTS can develop during pregnancy as well. Nine flexor tendons course through the carpal tunnel along with the median nerve (Figure 30-18).

Patients typically present because of pain, numbness, paresthesias, and loss of grip strength in the wrist and hand. Symptoms may even radiate into the shoulder region. Symptoms usually involve the radial 3½ digits as supplied by the median nerve and are noted more with repetitive hand motion activities and at night. Physical examination may reveal thenar atrophy and decreased sensation over the radial 3½ digits. These two clinical findings, along with a history of pain in the distribution of the median nerve, are highly suggestive of CTS and correlate to positive nerve conduction study findings (D'Arcy and McGee, 2000).

The Tinel test (sign) at the wrist is performed by tapping over the flexor retinaculum and having increased or reproducible symptoms of pain, numbness, and tingling in the radial 3½ digits. The most sensitive test is the carpal compression test, in which direct compression over the tunnel elicits the symptoms. The Phalen maneuver is performed by having the patient flex the wrists to a 90-degree position, holding the dorsal aspects of the hands back to back. The patient maintains this position up to 1 minute, until symptoms develop.

Diagnostic imaging is not necessary to make a diagnosis of CTS. Electrodiagnostic tests can be used to confirm the diagnosis but are not needed to initiate or direct early treatment in most patients. Although up to 25% are false-negative results in patients with clinical CTS, electrodiagnostic tests should be done before surgery.

Treatment begins with attempts to avoid or at least modify activities known to cause pain for the patient. This may include ergonomic changes in the workplace, such as wrist support pads for computer use. Wrist splinting,

particularly at night, may prove helpful. Nerve gliding exercises are routinely prescribed and can provide relief (Figure 30-19). Oral analgesic and NSAID use may also lead to relief, although studies show these are no more effective than placebo. Corticosteroid injection is a helpful adjunct in many patients and may relieve symptoms better than placebo. A majority of patients will experience good relief of symptoms if these conservative measures are followed. Unfortunately, most of these patients will have a return of symptoms in 1 year (Kanaan and Sawaya, 2001). Surgery is considered in patients who have recurrence of symptoms despite adequate conservative measures, and outcomes are excellent. Both open and endoscopic techniques are available, with equivalent long-term results.

KEY TREATMENT

- Oral analgesics and NSAIDs used to treat symptoms of CTS are no more effective than placebo (Gerritsen et al., 2002) (SOR: A).
- Corticosteroid injection is more effective than placebo in relieving symptoms (short term) (Gerritsen et al., 2002) (SOR: A).
- Bracing for CTS may lead to significant short-term pain reduction (O'Connor et al., 2003) (SOR: A).
- Surgery relieves CTS symptoms significantly better than bracing (Verdugo et al., 2005) (SOR: A).

DEQUERVAIN TENOSYNOVITIS

DeQuervain tenosynovitis is a painful repetitive and overuse condition of the abductor pollicis longus and extensor pollicis brevis along the dorsal radial aspect of the wrist. Patients present because of pain and swelling along the dorsal radial side of the wrist, which is worsened with activities. Physical examination reveals tenderness with palpation, and the classic clinical finding is a positive Finkelstein test result. This is performed by having the patient flex and adduct the thumb to the palm and then close the remaining fingers over the thumb. The examiner then passively takes the patient's wrist into ulnar deviation. Pain along the tendons with this maneuver is considered a positive test result (Finkelstein, 1930). Radiographic tests are not necessary to make an accurate diagnosis.

Treatment begins with avoidance of the inciting activities. Ice may reduce pain and swelling, and analgesic medications are often used as well. Thumb spica splinting is very helpful, allowing the irritated tendons to rest (Winzeler and Rosenstein, 1996). Prolonged splinting may be needed to reduce pain significantly. Corticosteroid injection along the tendon sheath is often used to reduce pain more acutely (Peters-Veluthamaningal et al., 2009a; Wood and Dobyns, 1986). In refractory cases, surgical decompression of the tendons can be performed.

DIGITAL FLEXOR TENOSYNOVITIS

Tenosynovitis of a digital flexor tendon, also called "trigger finger," is quite common. Patients present with the complaint of a finger that "sticks" with motion, primarily flexion, and they must painfully force the finger back into

Figure 30-19 Carpal tunnel nerve glide exercises.

extension. Usually, a painful palpable nodule on the flexor tendon is present along the distal palmar crease or at the base of the thumb, at the level of the metacarpophalangeal (MCP) joint (Figure 30-20). Motion and activities may be associated with pain. Radiographs and other diagnostic tests are not needed to make an accurate diagnosis.

Treatment options for digital flexor tenosynovitis include antiinflammatory medications, modification of activities, ice, massage, stretching of the flexor tendons, and gentle-grip strength exercises, although these usually provide little relief. Corticosteroid injections are often used to relieve pain and triggering symptoms (Marks and Gunther, 1989; Peters-Veluthamaningal et al., 2009b). Symptoms may return, and repeat injections are considered if the first injection provided reasonable pain relief. However, surgery may be needed in patients with frequent recurrence.

SCAPHOLUNATE SPRAINS

Ligament sprains of the wrist usually result from falls on an outstretched hand. Most are mild and resolve with splinting and symptomatic treatment. However, the clinician must be careful not to miss potentially catastrophic injuries that could compromise a patient's hand and wrist function,

including carpal dislocations, carpal instability (more specifically, scapholunate ligament instability), scaphoid fractures, and displaced intraarticular distal radius fractures. Injury to the scapholunate joint may be missed by physicians who do not consider it in their differential diagnosis of wrist injuries (Figure 30-21).

Patients with scapholunate sprains have pain in the wrist with motion, gripping, and lifting and along the dorsal aspect of the wrist at the scapholunate joint just distal to the Lister tubercle (bump on dorsal aspect of distal radius). Physical examination typically reveals no gross deformities, although dorsal swelling may be noted. The pain may be exacerbated by flexion and extension while palpating directly over the scapholunate joint on the dorsal aspect of the wrist.

Impacts strong enough to cause scapholunate sprain are sufficient to cause fracture. Therefore, plain radiographs should be obtained in all patients with suspected scapholunate sprain to look for associated fracture or avulsion. The series should include a standard AP view, AP with a clenched fist (accentuates scapholunate joint widening), standard lateral view, and posteroanterior (PA) view in ulnar deviation (assesses scaphoid bone for fracture). It is often helpful to obtain a comparison AP view of the

Figure 30-20 Flexor tendon nodule. **A**, Classic trigger finger with a flexor tendon nodule trapped proximal to the A1 pulley. **B**, Classic clinical presentation of a patient with a locked trigger finger.

Figure 30-21 **A**, Disruption of scapholunate and radiocarpal ligaments leads to progressive dissociation between scaphoid and rest of carpal bones. This injury is frequently mistaken for a persistent wrist sprain. **B**, Chronic dissociation of scapholunate joint allows the scaphoid to rotate downward toward the palm. This increases the angle between scaphoid axis and radiolunate–capitate axis. The capitate then slowly migrates toward the radius, and osteoarthritis rapidly develops. (From Connolly JF. *DePalma's the management of fractures and dislocations: an atlas*. 3rd ed. Philadelphia: Saunders; 1981.)

opposite wrist. An increased gap between the scaphoid and lunate bones of 2 to 3 mm on the AP projection (e.g., “Terry Thomas” [United Kingdom] or “David Letterman” [United States] sign because of their gapped-tooth grin) is indicative of scapholunate dissociation (Figure 30-22).

Patients with a “simple” scapholunate sprain require protection and rest with a period of splinting. This can be accomplished with a custom fiberglass or plaster splint or a prefabricated cock-up wrist splint until the patient is asymptomatic. After initial treatment, the patient is weaned from the wrist splint and begins active ROM and hand-strengthening therapy. In patients with scapholunate

dissociation, surgical consultation should be considered early, and referral to a hand specialist is encouraged. Fixation of the joint is often needed to maximize future wrist function (Figure 30-23).

DISTAL RADIUS FRACTURES

Patients with distal radius fractures most often present with wrist pain and deformity immediately after a fall. All patients with wrist pain after a fall should have AP, lateral, and oblique radiographs of the wrist. Deformity may or may not be present, and some patients may complain of paresthesias in the affected extremity. A patient’s ability to move the wrist does not rule out a fracture. It is important to palpate the entire extremity to assess any injury above or below the primary injury site for concomitant fractures. If suspected, radiographs should be taken of those areas as well. Neurovascular status should always be evaluated and documented.

Treatment is based on fracture type, patient age, and demand. A nondisplaced or minimally displaced fracture can be initially treated in a splint for 5 to 7 days until swelling subsides and then casted in a short-arm cast. The average healing time is 4 to 8 weeks, and repeat radiographs should be obtained during the healing process at an interval of every 2 to 3 weeks. An extraarticular, angulated fracture is initially treated with closed reduction with block (lidocaine injection into fracture hematoma). If postreduction alignment is adequate, a splint can be placed for 5 to 7 days to maintain the alignment pending casting. Because displacement or angulation of fracture fragments is a high risk even when appropriately splinted or casted, radiographic follow-up is important. Comminuted or displaced intra-articular fractures usually require closed reduction with percutaneous pinning or ORIF to maintain position and articular surface integrity; orthopedic surgery referral is recommended.

Figure 30-22 **A**, Posteroanterior radiograph of left wrist in 27-year-old soccer player who fell, landed on his left palm, and complained of pain. Note the abnormal widening of the scapholunate interval. **B**, Comparison view of the uninjured right wrist demonstrates the same scapholunate separation (>3 mm) (the "David Letterman" sign). The patient recovered with only splint support. (From Nicholas J, Hershman E. *The upper extremity in sports medicine*. 2nd ed. St. Louis: Mosby; 1995:456.)

Figure 30-23 Postoperative radiograph with scapholunate joint reduced and two K wires properly positioned to stabilize the joint. (From Nicholas J, Hershman E. *The upper extremity in sports medicine*. 2nd ed. St. Louis: Mosby; 1995:393.)

SCAPHOID FRACTURE

Patients typically present after a fall onto an outstretched hand and complain of pain and swelling in the radial aspect of the wrist, worsened by motion. Gross deformity is not usually seen. The most common physical examination finding is tenderness with palpation over the scaphoid tubercle or in the anatomic snuffbox. Radiographs should be obtained in all patients with suspected scaphoid injury, including AP, lateral, and oblique views, as well as PA ulnar deviation or scaphoid views (Figure 30-24). Importantly, radiographic findings are often negative shortly after immediate injury and may still be negative up to 14 days after the injury; radiographs should be repeated in 2 weeks if suspicion remains high. Because a fracture is suspected, interim splinting or casting is necessary. Other diagnostic tests may be obtained if repeat radiographic results are negative after 2 weeks and the patient is still symptomatic or if definitive diagnosis is needed sooner than the planned 2-week follow-up. These tests may include radionuclide bone scan (usually positive within 2-3 days of injury), CT, or MRI.

Immobilization of a potential scaphoid fracture is initiated if suspicion is high even though radiographic results are initially negative. If fracture is ruled out at follow-up visits, treatment is adjusted accordingly. Nondisplaced scaphoid fractures are treated with cast immobilization. Thumb spica casting is essential, but whether the initial cast needs to be a long- or short-arm variety is controversial. Studies have shown decreased time to union and reduced rates of delayed union and nonunion with a long-arm thumb spica cast (Gellman et al., 1989). However, union rates of up to 95% with short-arm casting have been reported. A combination, with a long-arm cast for the initial 6 weeks followed by short-arm casting from 6 weeks until

Figure 30-24 Transverse fracture through the waist of the scaphoid. (Courtesy James L. Moeller, MD.)

radiographic healing is present, addresses both of these key issues.

Healing rates and average healing time depend on location of the fracture because the blood supply differs throughout the scaphoid. Nondisplaced distal pole fractures tend to receive a better blood supply and have a healing rate of close to 100%, with average healing time of 10 to 12 weeks. Scaphoid waist fractures have a healing rate of 80% to 90%, with average healing also 10 to 12 weeks. Proximal pole fractures have a healing rate of only 60% to 70%, with average healing time of 12 to 20 weeks. Poor outcomes (i.e., nonunion, malunion) in any scaphoid fracture are more likely to occur if the diagnosis or appropriate treatment is delayed; this is why it is important to initiate treatment based on suspicion of injury with normal radiographs. Displaced fractures (≥ 1 mm) should be referred to an orthopedic surgeon for consideration of surgical fixation.

EVIDENCE-BASED SUMMARY

- One controlled study showed significant benefit of steroid injections for DeQuervain tenosynovitis. Because of a limited number of patients and limited quality supportive studies, however, definitive recommendations cannot be made (Peters-Veluthamaningal et al., 2009a) (SOR: B).
- Pain and symptoms of people with “trigger finger” may improve with a corticosteroid injection (Peters-Veluthamaningal et al., 2009b) (SOR: A).
- Bone scintigraphy and MRI have equally high sensitivity and high diagnostic value for excluding scaphoid fracture. However, MRI is more specific and better for confirming scaphoid fracture (Yin et al., 2009) (SOR: A). We believe additional studies are needed to assess diagnostic performance of CT.

Hip

Key Points

- Hip osteoarthritis (OA) commonly presents as groin and anterior thigh pain. AP pelvis and lateral hip radiography is recommended for comparison with the other side.
- Greater trochanteric bursitis commonly presents as lateral hip pain that can be reproduced by palpation.
- Avascular necrosis (AVN) of the hip is most commonly associated with prolonged corticosteroid use, alcoholism, and sickle cell disease.
- Hip pain can be referred pain from the lumbar spine.
- Hip fractures are commonly related to osteoporosis, and routine screening should be initiated. Guidelines for screening are updated periodically and based on the United States Preventative Task Force Services Guidelines, <http://www.uspreventiveservicestaskforce.org>.
- Slipped capital femoral epiphysis (SCFE) is a femoral head growth plate fracture found in adolescent patients. Treatment should be protected weight bearing and urgent referral to an orthopedist for possible surgical intervention.

DEGENERATIVE HIP OSTEOARTHRITIS

An estimated 25% of adults may develop symptomatic hip OA (Murphy, 2010). Degenerative OA of the hip is caused by loss of the hyaline cartilage along the hip joint surfaces. Weight-bearing AP and lateral hip radiographs are strongly recommended to evaluate joint space narrowing and OA extent. MRI is not routinely required and should not be ordered instead of plain radiographs. Radiographic findings include loss of the joint space, presence of osteophytes, subchondral sclerosis, and cysts (Figure 30-25).

Figure 30-25 Radiograph demonstrating hip arthritis, including joint space narrowing, and superior migration of the femur within the acetabulum. (Reused with permission from Frontera WR, Silver JK, Rizzo TD. *Essentials of physical medicine and rehabilitation*. 2nd ed. Philadelphia: Elsevier; 2008:F48-2.)

Patients with hip OA may complain of groin and anterior thigh pain initially as a deep stiffness or pain when they first get up from a seated position. After a few steps, the pain may subside in the early stages of OA but persist in more severe OA. Additional symptoms include stiffness with walking, difficulty putting on socks and shoes, limping, and difficulty with stair climbing. Physical examination findings often reveal decreased hip ROM (internal rotation and adduction). Logrolling of the hip in a supine position will typically reproduce the symptoms. Additionally, performing the Stinchfield test, resisted supine hip flexion, should reproduce the patient's hip symptoms in the groin and thigh.

Treatment of OA is based on the patient's age, demand, comorbidities, and severity of OA. Conservative treatment for hip arthritis should include a generalized low-impact conditioning program, activity modification to avoid sports or activities that exacerbate the symptoms, weight loss, use of a cane to improve proprioceptive control, use of cushioned shoes, and NSAIDs. Oral supplementation with glucosamine and chondroitin sulfate may also be considered. If these do not provide relief after 4 to 6 weeks, corticosteroid injections can be administered, typically with variable pain relief and duration. Injections may be repeated depending on the patient response. The newest recommendations from the American Academy of Orthopaedic Surgeons (AAOS) do not recommend the routine use of glucosamine

in a routine regimen of approaching patient with OA. Others argue that because they are very low risk, a trial to assess their effectiveness is reasonable. Studies evaluating glucosamine sulfate appear to have better results than those using glucosamine HCl. The dose of glucosamine sulfate is 750 mg twice daily (Sawitzke et al., 2010). Chondroitin is more controversial but may prove helpful in hand OA at a dose of 1200 mg/day (Gabay et al., 2011). In severe OA and resistant cases, a hip replacement can provide excellent pain relief and improve function.

HIP GREATER TROCHANTERIC BURSITIS

Greater trochanteric bursitis is a combination of the inflammation of the bursa surrounding the hip abductor muscles and tendons that attach to the greater trochanteric region of the femur. Typically, this is caused from repetitive overuse or is related to changes in the patient's gait patterns. Evaluate the patient for other musculoskeletal ailments that have changed his or her postures or walking gait (i.e., low back pain, painful ankle, painful knee). The symptoms are typically lateral hip pain with walking and tenderness over the lateral upper part of the femur, which may result in the inability to lie on the affected side.

The diagnosis can be made with a complete history and physical examination and radiography of the hip. Radiography is useful to rule out underlying hip arthritis. MRI is not routinely ordered. The patient will have well-circumscribed area of tenderness over the lateral upper part of the femur. He or she typically has less groin pain, buttock pain, and back pain compared with the lateral areas.

Treatments are based on prevention and correcting body posture and gait patterns, strengthening lower extremity muscles, and increasing flexibility. The primary treatments should start with activity modification, avoiding actions that result in aggravation of the pain; antiinflammatory oral medications; and icing the area. In addition, physical therapy is prescribed for 4 to 6 weeks to work on strengthening and flexibility of the core hip and lumbar spine postural muscles. If these are ineffective, a corticosteroid injection into the inflamed bursal area can be given, which can provide varying amounts of relief. The cortisone shot can be repeated at a minimum of every 3 to 4 months. However, repeated injections of cortisone can weaken and damage the underlying tendons. In rare cases, when the pain does not improve after physical therapy, cortisone shots, and antiinflammatory medication, the inflamed bursa can be removed surgically.

HIP AVASCULAR NECROSIS

Avascular necrosis refers to cellular death of the bone and cartilage due to damage of the blood supply. Most commonly hip femoral head AVN is highly associated with prolonged corticosteroid use, alcoholism, or sickle cell disease (Jacobs, 1978). Specifically, prolonged corticosteroid use for treatment of rheumatologic diseases, asthma, chronic obstructive pulmonary disease, or inflammatory bowel diseases can account for up to 30% of all hip AVN cases (Jacobs, 1978). Alcoholism has been reported to be related to up to 40% of cases of femoral head AVN in several case series (Arlet, 1992; Jacobs, 1978). However, a number of

Table 30-2 Federative Committee on Anatomical Terminology Classification of Avascular Necrosis

	Radiography	MRI	Bone Scan	Clinical Symptoms
Stage 0	Normal	Normal	—	—
Stage I	Normal or minor osteopenia	Edema	Increased uptake	Pain typically in the groin
Stage II	Mixed osteopenia or sclerosis	Geographic defect	Increased uptake	Pain and stiffness
Stage III	Crescent sign and eventual cortical collapse	Same as radiography	+/- Pain and stiffness	Radiation to knee and limp
Stage IV	End stage with evidence of secondary degenerative change	Same as radiography		Pain and limp

MRI, Magnetic resonance imaging.

Figure 30-26 Magnetic resonance image of avascular necrosis. A T1-weighted coronal view of both hips demonstrates normal high signal from the fatty marrow in the right femur (*dotted white arrow*) but decreased signal in the left femoral head extending to the subchondral bone of the left hip joint (*solid white arrow*). The joint space is preserved. (Reused with permission from Herring W. *Learning radiology: recognizing the basics*. 2nd ed. Philadelphia: Elsevier; 2011:F21-8.)

medical conditions have been associated with AVN, including posttraumatic hip fractures, hemoglobinopathies, hyperuricemia, malignancy, hyperlipidemia, and caisson disease (Arlet, 1992; Jacobs, 1978). AVN often leads to secondary arthritis. Pain is the usual presenting symptoms, most often reported in the groin, radiating to the anterior thigh. Pain is present at rest but worse with weight bearing and hip ROM.

Radiographs of the hip in the AP and lateral plane are recommended. Early stages may not show any changes. Late stages will show cystic and sclerotic changes in the femoral head, subchondral collapse, flattening of the femoral head, and joint space loss. An MRI of the hip without contrast is also recommended in the diagnostic workup to help with the staging. The MRI helps determine the amount or percentage of the femoral head involvement as well as the presence of subchondral collapse, which help determine treatment options (Figure 30-26) (Steinberg, 2001). Hip AVN is a disabling and progressive condition; surgical hip-preserving treatments are successful in the early stages, but more severe cases require a total hip replacement. The key to successful treatment lies in early diagnosis and timely treatments. The FICAT staging system is commonly used to look at the presence or absence of subchondral collapse (Table 30-2). Patients have a more favorable prognosis with hip-preserving procedures such as a core decompression in FICAT stages 1 and 2. After the subchondral bone has collapsed and secondary arthritis has developed, patients typically require a total hip

Table 30-3 Indications for Bone Mineral Density Testing

- Consider bone mineral density testing in the following individuals:
- Women age 65 years and older and men age 70 years and older regardless of clinical risk factors
 - Younger postmenopausal women, women in the menopausal transition, and men age 50 to 69 years with clinical risk factors for fracture
 - Adults who have a fracture after age 50 years
 - Adults with a condition (e.g. rheumatoid arthritis) or taking a medication (e.g. glucocorticoids in a daily dose ≥ 5 mg prednisone or equivalent for ≥ 3 months) associated with low bone mass or bone loss

From National Osteoporosis Foundation. Having a Bone Density Test. <http://nof.org/articles/743>.

replacement. The treatment of each patient with hip AVN will depend on the amount and extent of the AVN, presence of subchondral collapse, presence of arthritis, and underlying cause of the AVN.

HIP FRACTURES

Hip fractures in elderly adults pose a significant health care problem worldwide, with a 1-year mortality rate estimated at 30% (Miyamoto, 2008). Hip fractures are most commonly associated from mechanical falls associated with osteoporosis. Osteoporosis is a progressive bone disease characterized by a decrease in bone mass and density, which can lead to an increased risk of fracture. Osteoporosis is defined by the World Health Organization (WHO) as a bone mineral density (BMD) of 2.5 standard deviations or more below the mean peak bone mass (average of young, healthy adults) as measured by dual-energy x-ray absorptiometry (DEXA scan). The National Osteoporosis Foundation (NOF) estimates that more than 10 million people older than age 50 years in the United States have osteoporosis, and another 34 million are at risk for the disease (NOF, 2013). In 2013, the NOF updated its clinical screening guidelines and treatments for patients (NOF, 2013) (Table 30-3).

Treatment focuses on fall prevention and increasing BMD. Modifiable risks fractures to prevent falls can focus on balance and gait training through physical therapy and use of an ambulatory aid such as a cane or a walker. In addition, removal of obstacles and loose carpets in the living environment may substantially reduce falls. Proper nutrition and exercise have been shown to increase bone quality.

Figure 30-27 Femoral acetabular impingement types. The reduced clearance during joint motion leads to repetitive abutment between the proximal part of the femur and the anterior acetabular rim. **A**, The normal clearance of the hip. **B**, Reduced femoral head and neck offset (cam impingement). **C**, Excessive overcoverage of the femoral head by the acetabulum (pincer impingement). **D**, A combination of reduced head and neck offset and excessive anterior overcoverage (combined impingement). (Reused with permission from Clohisy JC, Beaulé PE, O'Malley A, et al. AOA Symposium: hip disease in the young adult: current concepts of etiology and surgical treatment. *J Bone Joint Surg Am*. 2008;90(suppl A):2267-2281.)

Bisphosphonate medications are useful in decreasing the risk of future fractures; this benefit is present when taken for 3 to 5 years, with evidence of little benefit when used for more than 3 to 5 years (Suresh, 2014; Wells, 2008; Whitaker, 2012). With the potential adverse events, it may be appropriate to stop treatment after this time in some.

HIP FEMORAL ACETABULAR IMPINGEMENT

Femoral acetabular impingement (FAI) is a developmental incongruity of the femoral head ball and acetabular socket joint that can cause pain and cartilage damage and lead to secondary hip OA. There are three types of FAI: pincer, cam, and combined impingement (Figures 30-27 to 30-29). Pincer FAI occurs when the acetabulum rim extends too far over the femoral head, providing “overcoverage.” The overcoverage of the femoral head from the acetabulum leads to impingement on femoral head and neck bone, with hip flexion, adduction, and internal rotation, which can cause pain. In addition, the hip labrum can be compressed and tear from the abnormal articulation. The hip labrum is a fibrocartilaginous extension of the acetabulum that aids in hip stability. CAM FAI occurs when the femoral head contour is asymmetric or “overgrown” in one area and cannot rotate in the socket freely. Typically, it is the anterolateral aspect of the femoral head and neck, causing pain with hip flexion, internal rotation, and adduction. The third type of FAI, known as mixed impingement, is a combination of both pincer and CAM FAI.

Femoral acetabular impingement develops from incongruent and asymmetric development of the ball and socket during childhood. It is the deformity of the two bones that leads to FAI, subsequent cartilage damage, and hip pain. Patients with FAI usually have pain in the groin area that

Figure 30-28 Cam-type femoral–acetabular impingement. Frontal radiograph of the pelvis shows osseous prominence (arrows) at the anterolateral femoral head–neck junction on the left (compare with normal femoral neck concavity on the right, arrowhead). (Reused with permission from Miller MD, Sanders TG. *Presentation, imaging and treatment of common musculoskeletal conditions: MRI–arthroscopy correlation*. Philadelphia: Elsevier; 2011:F69-1.)

Figure 30-29 Pincer type femoral–acetabular impingement. Frontal radiograph of the pelvis (and coronal magnetic resonance image, inset) show a relatively deep acetabular fossa that can lead to overhanging margins and impingement. Note that the medial wall of the acetabulum (arrow) extends beyond the margin of the ilioischial line (arrowheads). (Reused with permission from Morrison W, Salvo JP, Busconi B, Wallace R. *Presentation, imaging and treatment of common musculoskeletal conditions*. Philadelphia: Elsevier; 2012:337-344.)

is worse with activities such as twisting at the hip and hip flexion. It can be described as a dull ache or sharp stabbing pain.

Physical examination testing commonly performed involves having the patient lie supine, flexing the hip up to 90 degrees, and internally rotating the hip with combined adduction. This should reproduce the patient’s symptoms. FAI can be diagnosed with a radiographic evaluation. The radiographs should include AP and lateral radiographs of the affected hip and possibly the unaffected hip for comparison. CT scans are not routinely ordered. MRI of the hip can be useful and is typically ordered for evaluation of the labrum.

Treatment of FAI varies depending on the severity of FAI, activity level of the patient, age of the patient, and whether secondary OA has developed in the hip joint. Nonsurgical treatment should always be considered first when treating FAI. Nonsurgical treatment will not change the underlying bone incongruity, but FAI symptoms can often be resolved

Figure 30-30 Frog-leg lateral radiographic images of the right hip before (A) and after (B) femoral neck osteoplasty. The arrow points to the cam lesion before resection and to the area of bony resection thereafter. (Reused with permission from Chow RM, Kuzma SA, Krych AJ, Levy BA. Arthroscopic femoral neck osteoplasty in the treatment of femoroacetabular impingement. *Arthrosc Tech.* 3(1):e21-5.)

with rest, modifying one's behavior, and a physical therapy or antiinflammatory regimen (or both). An intraarticular hip cortisone injection can also provide relief. Such conservative treatments have been successful in reducing the pain and swelling in the joint. If the pain persists after conservative management, surgery may be recommended. Surgery for FAI varies depending on the severity of the FAI, activity level of the patient, age of the patient, and if secondary OA has developed in the hip joint. Surgery for FAI involves reshaping of the acetabulum and femoral head to remove the impingement. Additional repair of the labrum may be required. Surgery to reshape the femoral head and acetabulum is known as "osteoplasty" and can be done via an open technique or arthroscopically (Figure 30-30). However, if the patient has already developed secondary arthritis because of the FAI, a surgeon may not recommend osteoplasty but rather a total hip replacement. Surgery can successfully reduce symptoms caused by impingement and can prevent future damage to the hip joint. However, sometimes not all of the damage can be completely fixed by surgery, especially if treatment has been put off and the damage is severe and it is possible that more problems may develop in the future (Bedi, 2013).

HIP SLIPPED CAPITAL FEMORAL EPIPHYSIS

SCFE is a fracture through the femoral head growth plate that occurs most commonly in adolescents aged 11 to 15 years. SCFE affects approximately one to 10 per 100,000 children, has a higher prevalence in African American patients, and affects boys twice as often as girls (Kliegman, 2011; Novais et al., 2012). The incidence varies by geographic location, season of the year, and ethnicity. It is strongly linked to obesity, endocrine disorders, trauma, and family history (Kliegman, 2011; Novais et al., 2012). There is a relationship of hypothyroid and short stature specifically with SCFE (Kliegman, 2011; Novais et al., 2012). SCFEs usually cause groin pain on the affected side and can radiate to the knee or thigh. Symptoms include the gradual, progressive onset of hip, thigh, or knee pain with a painful limp. Clinical examination will show obligate external rotation with hip flexion and loss of internal rotation.

Radiographic evaluation should include an AP and frog-leg lateral radiograph of bilateral hips (Figure 30-31).

Figure 30-31 Radiographic representation of a slipped capital femoral epiphysis on the left hip. (Reused with permission from Miller MD, Hart J, MacKnight JM. *Essential orthopaedics*. Philadelphia: Elsevier; 2009:F221-1.)

Bilateral involvement occurs in up to 30% of patients. Klein's line is a line drawn along the superior border of the femoral neck and should cross at least a portion of the femoral epiphysis. A slip must be suspected if a straight line drawn up the lateral surface of the femoral neck does not touch the femoral head on the lateral view (Figures 30-32 and 30-33).

Treatment of SCFE is surgical, and the goal is to prevent any additional slipping of the femoral head until the growth plate closes. Surgical treatment will vary depending on the degree of the slip and age of the patient. In mild slips, a single screw can be placed percutaneously across the femoral physis to stabilize the slip in situ and facilitate physeal closure (Figure 30-34). More severe slips with greater deformity may require open reduction and stabilization. Patients should be made non-weight bearing, given crutches, and referred to an orthopedic surgeon urgently. Treatment should be immediate. Early diagnosis of SCFE provides the best chance to achieve the treatment goal of stabilizing the hip.

Knee

Key Points

- In clinical examination of ligament injuries about the knee, the Lachman test is the most sensitive for anterior cruciate ligament (ACL) instability.
- The clinician should maintain a high level of suspicion of associated ligament injuries, especially the lateral collateral ligament (LCL) and posterolateral corner. Acute surgical intervention (within 3 weeks) of LCL and posterolateral corner injuries significantly improves prognosis.

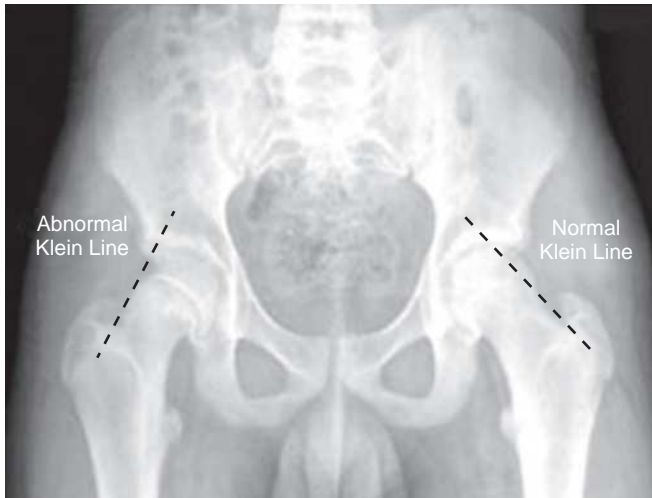

Figure 30-32 Anteroposterior pelvis radiograph demonstrating the Klein line intersecting the epiphysis on the right hip. In the left hip, which shows a slipped capital femoral epiphysis, the Klein line passes just lateral to the epiphysis. (Reused with permission from Aronsson DD, Loder RD, Brerur GJ, Weinstein ST. Slipped capital femoral epiphysis: current concepts. *J Am Acad Orthop Surg*. 2006;14(12):666-679.)

- Viscosupplementation (injection of hyaluronate), corticosteroids injections, therapeutic exercise, and oral supplementation with glucosamine and chondroitin sulfate may all provide some symptomatic relief and functional improvement for generalized knee arthritis. Arthroscopic debridement alone (in the absence of loose bodies, cartilage flaps, and meniscus tears) may not provide relief.
- Vertical, peripheral meniscus tears in the vascular zone of the meniscus of young patients should be treated with meniscus repair whenever possible to avoid focal increased pressures in the articular surface and future risk of degenerative joint disease.
- In older patients with degenerative meniscus pathology and no locking, prevention of arthritic progression may be surgical or nonsurgical. When performed, partial is preferred to complete meniscectomy.

Figure 30-33 Left hip showing a slipped capital femoral epiphysis in the frog-leg lateral, right hip normal position.

Figure 30-34 Anteroposterior (A) and frog-leg lateral (B) radiographs of a left in situ pinning of a left slipped capital femoral epiphysis (SCFE). Note that in the image on the left, the relationship between the epiphysis and metaphysis would be considered normal. However, on the lateral view, a large posterior displacement of the epiphysis is seen, thus confirming the SCFE. This emphasizes the necessity of lateral radiographs in making this diagnosis. (Reused with permission from Miller MD, Hart J, MacKnight JM. *Essential orthopaedics*. Philadelphia: Elsevier; 2009:F221-3.)

Figure 30-35 Weight-bearing knee radiographs showing osteoarthritis.

DEGENERATIVE OSTEOARTHRITIS

Degenerative OA of the knee is caused by loss of the hyaline cartilage along the knee joint surfaces. This can occur in an isolated compartment or diffusely throughout all three compartments of the knee. OA more often develops in the medial side or medial compartment of the knee, first leading to joint space narrowing and varus, or bowleg, deformity. Loss of articular cartilage and joint space on the lateral aspect of the knee leads to valgus or knock-knee deformity. Weight-bearing (standing flexed-knee PA) radiographs are strongly recommended to evaluate joint space narrowing and OA extent. Lateral and patella sunrise tangential views complete the study (Figure 30-35). MRI is not routinely required and should not be ordered instead of plain radiography. MRI is best reserved for mechanical pathology or preoperative planning. Radiographic findings include loss of the joint space, presence of osteophytes, subchondral sclerosis, and cysts.

Patients with OA typically complain of knee pain and stiffness with walking after prolonged sitting, descending stairs, and early in the morning. Swelling of knees and worse symptoms are typical with weather changes. Physical examination findings often reveal decreased ROM (flexion contractures), knee varus or valgus deformity, joint line tenderness, and crepitus with palpation during ROM.

Treatment of OA is based on the patient's age, demand, comorbidities, and severity of OA. Conservative treatment for knee arthritis should include a generalized conditioning program, weight loss, a knee brace to improve the proprioceptive control, cushioned shoes, and NSAIDs. Oral supplementation with glucosamine and chondroitin sulfate may also be considered. If these do not provide relief after 4 to 6 weeks, corticosteroid or viscosupplement injections can be administered, typically with variable pain relief and duration. Injections may be repeated depending on patient response. The newest recommendations from the AAOS do not recommend the routine use of glucosamine or viscosupplementation in a routine regimen of approaching patients with OA. Others argue that because they are very low risk, a trial to assess their effectiveness is reasonable. In resistant cases, total or partial knee replacement can provide excellent pain relief and improve function. The

effect of arthroscopy in patients with degenerative arthritis remains controversial (Hunt et al., 2002; Mosely et al., 2002). However, arthroscopy in the absence of loose bodies, cartilage flaps, or meniscal pathology is unlikely to be unsuccessful (Sihvonen et al., 2013).

EVIDENCE-BASED SUMMARY

- The short-term benefit of intraarticular corticosteroid in treatment of knee OA is well established; however, longer-term benefits have not been confirmed, and the response to viscosupplemental hyaluronic products may have more durability (Bellamy et al., 2005a) (SOR: A).
- Based on a single RCT, bracing for OA may provide additional benefit compared with medical treatment alone (Brouwer et al., 2005) (SOR: B).
- Land-based therapeutic exercise programs reduce pain and improve physical function for patients with OA of the knee (Brosseau et al., 2003; Fransen et al., 2001) (SOR: A).
- Viscosupplementation (injection of hyaluronate) is an effective treatment for OA of the knee, with beneficial effects on pain and function (Bellamy et al., 2005b) (SOR: A).
- Nonglucosamine preparations failed to show benefit, but glucosamine preparations were superior to placebo in the treatment of pain and functional impairment resulting from symptomatic OA (Towhead et al., 2009) (SOR: A).
- Arthroscopic debridement has no benefit for undiscriminated OA with mechanical or inflammatory causes (Laupattarakasem et al., 2009; Sihvonen et al., 2013) (SOR: A).
- In OA patients, exercise results in a modest reduction in pain and a modest improvement in physical function (Fransen and McConnell, 2009) (SOR: B).
- The newest recommendations from the AAOS based on an evidence-based review of the literature do not recommend the inclusion of glucosamine or viscosupplementation in the treatment regimen for OA.

INFECTIONS

Intraarticular joint infections are orthopedic emergencies and require urgent surgical irrigation and debridement as well as long-term antibiotic therapy. The most common source of infection is *Staphylococcus aureus*, which aggressively and quickly destroys cartilage and leaves the patient with permanent OA. Patients with a knee joint infection present with increased pain, swelling, warmth, redness, fever, and decreased ability to ambulate on that leg. Most patients will not want to move their knee at all. The knee should be aspirated and the fluid inspected and sent for laboratory analysis (Gram stain, cell count, culture, crystal evaluation). Crystalline arthropathy such as gout should always be considered because the aspirated fluid often appears cloudy and may mimic a joint infection. C-reactive protein and erythrocyte sedimentation rate should also be obtained. Appropriate antibiotic treatment is initiated based on the offending organism. Although proposed in the medical literature for low-virulent organisms, serial aspiration is discouraged in the orthopedic literature, with surgical irrigation being the preferred treatment.

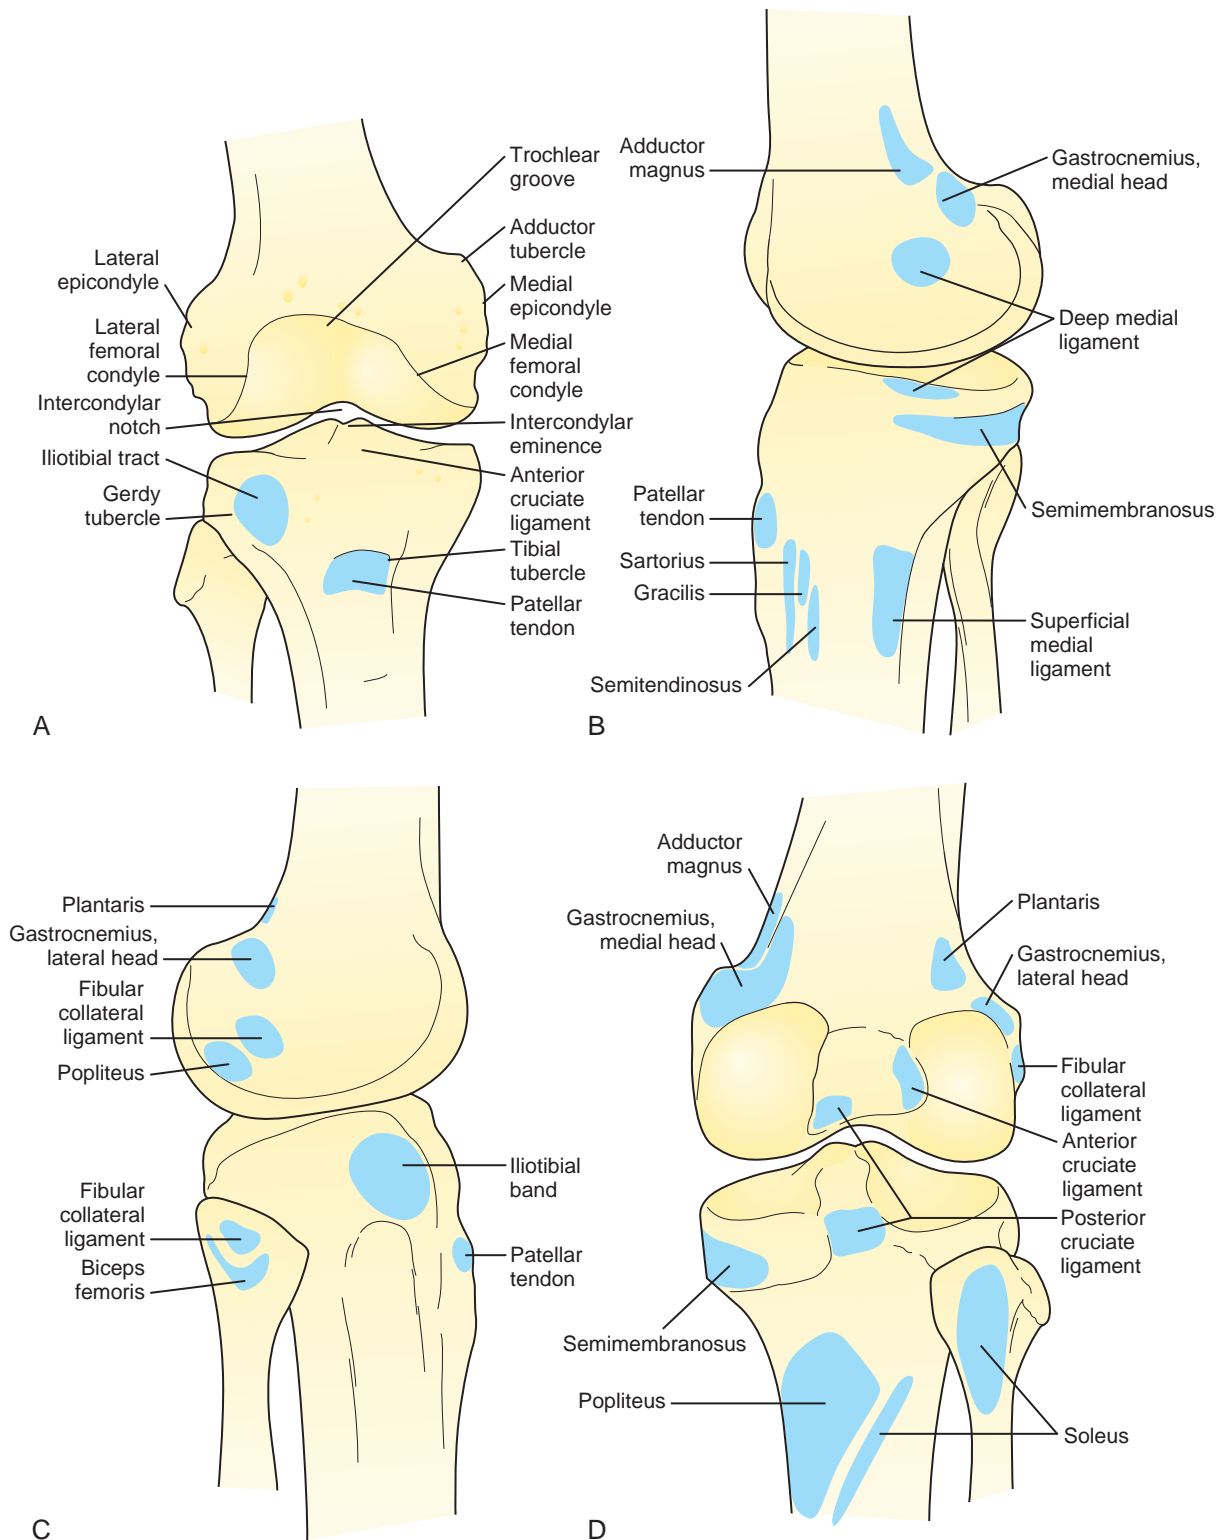

Figure 30-36 Schematic showing anatomic sites of bursae around the knee. **A**, Anterior view. **B**, Medial view. **C**, Lateral view. **D**, Posterior view.

INFLAMMATORY CONDITIONS

Bursae are synovial fluid–filled structures or “cushions” that pad bony prominences as protection against repetitive impact from external forces or snapping anatomic structures, such as ligaments or tendons. Several bursae around

the knee can become inflamed; irritated; and rarely, infected, including the prepatellar bursa, infrapatellar bursa, pes anserine bursa, and iliotibial (IT) band bursa (beneath the IT band laterally). Knowing their anatomic location is important so that these bursae can be palpated directly (Figure 30-36).

Treatment of *bursitis* includes compression, ice, protective padding, and avoidance of impact on the bursa. NSAIDs may help to reduce swelling. If the fluid collection is large or an infection is suspected, aspiration of the bursa can be performed in the office with a large-bore needle under sterile conditions. The bursa fluid should be clear and straw colored; it may be bloody in a traumatic injury. If an infection is not suspected clinically after the fluid is withdrawn, a corticosteroid can be injected. Corticosteroids should never be injected if infection is a possibility. Oral antibiotics can be started if an infection is present. Local incision and debridement may be required with infection and abscess. Aspiration does not replace compression wrap, ice, and avoidance of impact. Reaccumulation of fluid may occur, but total volume usually decreases. Serial aspirations are an option in patients with recurrent aseptic bursitis.

EXTENSOR MECHANISM PROBLEMS

The extensor mechanism comprises the quadriceps muscle, quadriceps tendon, patella, and patellar tendon. The differential diagnosis of problems in the extensor mechanism is broad, including muscle or tendon rupture, patellar fracture, patellar tendinopathy, patellofemoral syndrome, patellar instability, Osgood-Schlatter disease, and symptomatic medial plica. Examination of patients with anterior knee pain or extensor mechanism problems should always include a careful evaluation of the lumbar spine and hip to rule out referred pain, as well as assessment of the antagonist hamstring muscles posteriorly. Cores of gluteal weakness as well as hamstring tightness can exacerbate problems of tendinosis, patellofemoral syndrome, and instability.

If the patient presents with focal tenderness over the patellar tendon at the distal pole of the patella, or potentially at the quadriceps insertion onto the patella, the likely diagnosis is tendinopathy. Numerous studies show that chronic repetitive overuse does not actually lead to inflammation of the tendon itself but rather to a central degeneration or tendinosis of the fibers of the tendon (Fithian, 2002). Steroid injections into patellar tendinosis are highly discouraged because they may predispose the tendon to complete failure. Treatment protocols for patellar tendinosis, or “jumper’s knee,” should include hamstring stretching, quadriceps strengthening with eccentric loading, and occasionally the use of a counterforce brace (Figure 30-37).

Alternative treatments, including deep friction massage, prolotherapy, platelet-rich plasma injections, topical anti-inflammatory drugs, ultrasonic waves, and radiofrequency probes, show mixed results. Although no RCTs have yet proved their efficacy, these modalities have had some success. Surgical intervention for debridement of the tendinosis is uncommon but may be necessary to provide long-term relief. In a skeletally immature patient, tenderness at the distal pole of the patella may represent an avulsion apophysitis called Sinding-Larsen-Johansson disease. If a skeletally immature patient has pain at the insertion of the patellar tendon on the tibia, the most likely diagnosis is an apophysitis of the tibial tubercle, or Osgood-Schlatter disease. Both problems are more common during active phases of growth and are generally treated conservatively with rest, flexibility exercises, and a gradual return to activity. Complete failure or rupture of the extensor mechanism

Figure 30-37 A counterforce brace (Cho-Pat strap) can be effective in reducing symptoms of patellar tendinosis (jumper’s knee).

at the patellar or quadriceps tendon requires surgical repair (Ilan et al., 2002).

PATELLOFEMORAL SYNDROME

Anterior knee pain has been variously termed patellofemoral syndrome and chondromalacia patellae. When treating anterior knee pain, the physician should identify the specific pathology to initiate targeted treatment. *Chondromalacia patellae*, or degenerative changes on the undersurface of the patella, is more common in young females. Pain complaints related to chondromalacia are exacerbated by sitting for an extended period with a flexed knee, doing deep squats, or going up and down stairs. Each of these activities increases the posteriorly directed forces of the patella, directing increased pressure onto the chondral surfaces.

Treatment of these early arthritic changes is typically rehabilitation. Surgical intervention, such as cartilage scraping and debridement, has not been shown to provide long-term relief or benefit. In rare patients who have associated tight lateral retinacular structures and patellar tilt, surgical release of the lateral retinaculum can provide benefit. Conservative treatment of patellofemoral syndrome includes cushioned shoes, rehabilitation focused on the vastus medialis obliquus muscle, reductive taping techniques, hamstring stretches, and NSAIDs. Correction of the foot alignment with orthotic devices is also a treatment option, but supportive evidence is limited. Seventy percent to 80% of patients will improve with this conservative

treatment. Unfortunately, the remaining patients with resistant symptoms can have a frustrating long-term therapeutic course, with a guarded prognosis for any surgical intervention. Ultrasound therapy had no clinically important effect on patients with patellofemoral pain syndrome (Brosseau et al., 2001).

MENISCUS INJURIES

The menisci are fibrocartilaginous structures situated on the tibial plateau both medially and laterally that help disperse the weight-bearing contact forces across the knee joint cartilage surfaces (Figure 30-38). In the presence of a meniscus tear or the complete absence of a meniscus, focal

stresses increase. This in turn increases the loading of the hyaline cartilage and early progressive degenerative arthritis (Sherman, 1996). Meniscus tears can occur with axial loading but primarily occur because of twisting, cutting, or rotational forces. In older patients, meniscus tears may simply be a progression of the normal degenerative process. On physical examination, patients have pain over the medial or lateral joint line and may complain of snapping, popping, or catching within the knee (Greis et al., 2002a, 2002b). Varus or valgus loading may exacerbate pain as the meniscus is squeezed between the bony structures. Recurrent effusions may also represent intraarticular pathology. The most common test for meniscus injury is the McMurray test (Figure 30-39). The knee is hyperflexed, stressed with varus

Figure 30-38 Medial and lateral meniscus anatomy as viewed from above (A) and via cross-section (B). Note the circulation provided to the peripheral third of the meniscus only.

Figure 30-39 Classic examination for meniscal pathology. **A**, The medial McMurray test is performed by palpating along the medial joint line (thin arrow) while creating a varus force (solid triangle), ranging the knee through flexion and extension and internally and externally rotating the leg (yellow arrows). A positive finding is noted when the maneuver recreates the symptoms and the examiner feels a palpable click. **B**, The lateral McMurray test is done in a similar manner with valgus stress. (Courtesy Mark R. Hutchinson, MD.)

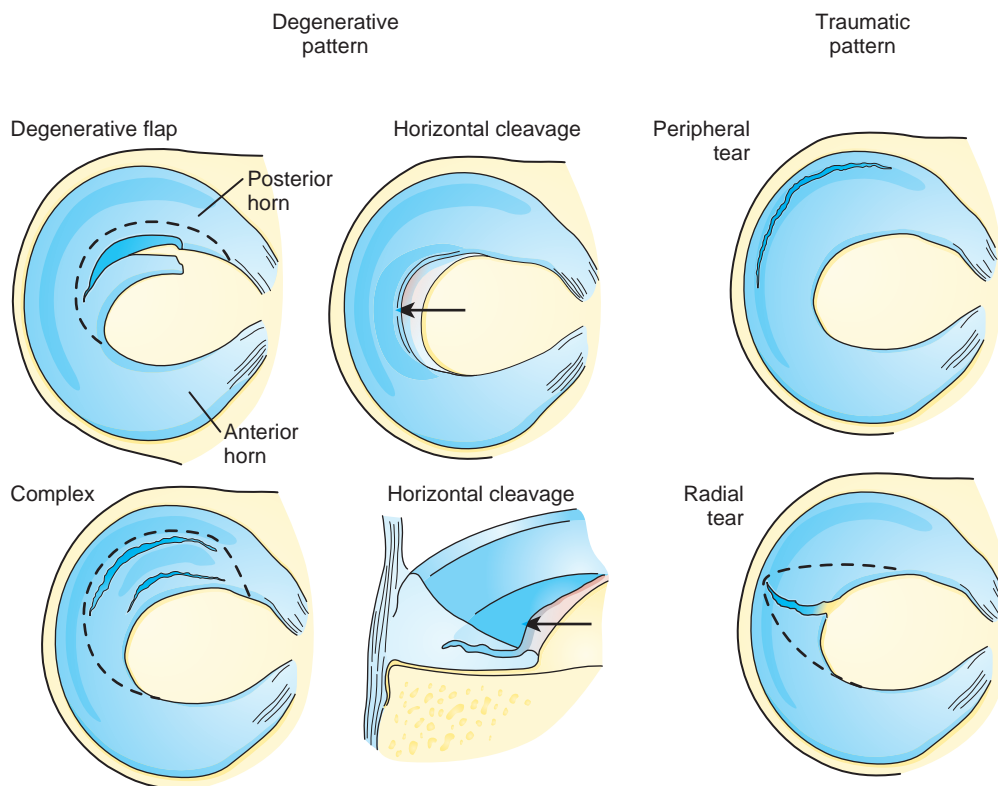

Figure 30-40 Representations of meniscus pathology. Degenerative tears tend to be complex, fibrinous, and horizontal. Acute tears that are vertical in the periphery may be repairable.

or valgus load, and internally and externally rotated as the knee is brought into full extension. More simply, the examiner uses the lower leg and tibia to try to trap the torn meniscus between the tibia and the femur through a full knee ROM. If the examiner feels a snapping or a pop along the joint line and the patient simultaneously complains of pain, the test result is considered positive and highly indicative of a meniscus tear. A single finding may raise suspicion of a tear but does not confirm its presence. Indeed, sensitivity of both findings, the pop and pain, is greater than 90%. MRI can be used to confirm the diagnosis or assist with preoperative planning but should never replace a thorough physical examination.

Definitive treatment of meniscus pathology depends on the actual pattern and location of the meniscus injury on MRI, age of the patient, activity level of the patient, and if coexisting OA is present in the knee. (Greis et al., 2002a, 2002b; Katz et al., 2013; Sherman, 1996; Sihovenon, 2013) (Figure 30-40). Treatment options can be nonsurgical and surgical depending on all of the above factors. Initial treatment may include physical therapy, activity modification, NSAIDs, analgesics, ice, and cortisone injections. If initial conservative treatment fails, then surgery may be indicated. However, surgery may be indicated sooner in younger, more active patients with more substantial meniscus tears. The meniscus can either be repairable or nonrepairable depending on the size, location, and patient's age. Because of its essential role in sharing load and preventing the progression of degenerative arthritis, salvageable meniscus tears should always be repaired if possible. After

debridement, patients can bear weight as tolerated and usually return to full activities by about 3 or 4 weeks. With meniscus repair, recovery is extended and requires restricted weight bearing for 3 to 6 weeks, with 2 to 3 months needed before a return to unrestricted activities.

EVIDENCE-BASED SUMMARY

- Definitive treatment of a meniscus tear depends on the actual pattern and location of the meniscus injury on MRI, additional ligament or cartilage injuries, the age of the patient, and the activity level of the patient. If coexisting OA is present in the knee, nonsurgical and surgical options both have a role depending on the aforementioned factors (Greis et al., 2002; Katz et al., 2013; Sherman, 1996; Sihvonen et al., 2013) (SOR: B).
- In a meta-analysis, sensitivity and specificity were 70% and 71% for the McMurray test, 60% and 70% for the Apley test, and 63% and 77% for joint line tenderness, respectively; no single test appears to diagnose a torn tibial meniscus accurately (Hegedus et al., 2007) (SOR: A).

LIGAMENTOUS INJURIES

Four major ligaments keep the knee stable: the ACL, posterior cruciate ligament (PCL), MCL, and LCL. They can be injured in isolation or in combinations related to knee dislocations. Most ligament injuries about the knee are

Figure 30-41 Valgus stress is used to assess function of the medial collateral ligament (MCL). To best isolate the MCL, the knee is unlocked to 30 degrees of flexion when stress is applied. If the knee is still unstable in full extension, other structures (posterior cruciate ligament, anterior cruciate ligament, posterior capsule) have been injured. *Black arrowheads* represent a valgus, or medially directed, force, and *white arrowheads* represent a varus, or laterally directed, force. (Courtesy Mark R. Hutchinson, MD.)

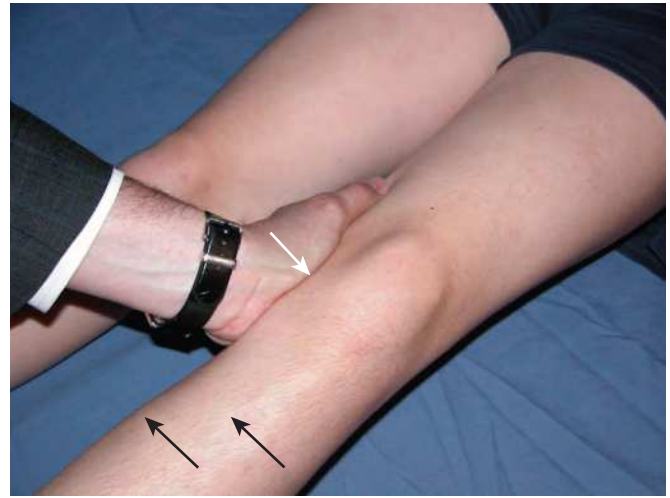

Figure 30-42 Varus stress is used to assess function of the lateral collateral ligament. Varus laxity noted in an acute knee injury should *always* be referred to an orthopedic surgeon; urgent primary repair of injured structures has a better prognosis than delayed reconstruction. *Black arrows* represent a valgus, or medially directed, force, and the *white arrow* represents a varus, or laterally directed, force. (Courtesy Mark R. Hutchinson, MD.)

not urgent. However, the primary care physician must remember (1) always to look out for the potential of a multi-ligament knee injury and the possibility of an arterial injury and (2) always to assess the LCL based on the significantly poorer prognosis if the diagnosis and treatment are delayed beyond 4 to 6 weeks. Early identification and surgical repair of acute LCL injuries improve patient outcomes from 50% to 90%.

Medial Collateral Ligament

The MCL is the most frequently injured ligament of the knee and is often associated with concomitant ligamentous injuries; 95% are associated ACL ruptures. The MCL is the primary knee restraint to valgus loads. The MCL is tested in isolation at 30 degrees of knee flexion with a valgus load (**Figure 30-41**); at 0 degrees, bony constraints contribute to stability. Valgus laxity at near or full extension implies concurrent injury to the posteromedial capsule or cruciate ligaments. Grade 1 injuries have pathologic laxity, indicated by increased medial joint space widening, of 1 to 4 mm; grade 2, laxity of 5 to 9 mm; and grade 3, more than 10 mm of increased laxity compared to the contralateral side.

Imaging studies should include AP and lateral radiographs looking for associated bone injury or avulsions. MRI may be of benefit in more severe injuries to look for additional associated soft tissue injuries. The initial treatment is nonsurgical for grade 1, 2, and 3 ligament sprains. Protected weight bearing is allowed with crutches and a hinged knee brace until pain resolves medially. Unrestricted ROM is allowed and encouraged. Most patients with MCL injuries do well with conservative treatment. Occasionally, patients with grade 3 injuries who do not respond to nonoperative treatment may require surgery. Timing of return to sports or function is related to severity of injury: grade 1 injuries, usually 1 week; grade 2, 2 to 4 weeks; and grade 3, 4 to 8 weeks.

Lateral Collateral Ligament and Posterolateral Ligament Complex

When evaluating the lateral side of the knee, the physician should evaluate the function of the LCL but also the stability of the knee to posterolateral rotation. The LCL is assessed with the knee unlocked at about 20 to 30 degrees of flexion with varus stress (**Figure 30-42**). The posterolateral corner is tested by externally rotating the tibia when the knee is flexed at 30 and 90 degrees. If an increased spinout to external rotation is visualized compared with the opposite knee at 30 and 90 degrees, the patient has a posterolateral corner and PCL injury. If the knee spins out only at 30 degrees compared with the opposite side, an isolated posterolateral corner injury is present (**Figure 30-43**). Imaging usually includes AP and lateral radiographs and MRI. Perhaps the simplest rule for primary care physicians is that any patient with acute varus instability (injury of LCL) should be referred to an orthopedic surgeon as soon as possible.

Treatment is based on the severity of the injury. Nonsurgical treatment with protected weight bearing and protected ROM early for a few weeks is recommended for isolated grade 1 or 2 LCL; grade 1 is an opening of the lateral joint line less than 5 mm, and grade 2 is an opening of 6 to 10 mm. Progressive ROM and functional rehabilitation are initiated. Return to sports can be expected in 6 to 8 weeks. Surgical indications are recommended for isolated grade 3 LCL injuries (>10 mm gapping) and any rotator instability of the posterolateral corner. Acute surgery has more favorable outcomes, and early referral to an orthopedic surgeon is recommended.

Posterior Cruciate Ligament

The PCL is the primary restraint to posterior tibial translation in the knee. The most sensitive test for the PCL is the posterior drawer, which is a posterior-directed force on the

Figure 30-43 The dial test is used to assess the posterior cruciate ligament (PCL) and posterolateral corner and is best done with patient prone and knees together. **A**, A normal examination result should reveal symmetry with forced external rotation. **B**, If increased external rotation is identified with knee flexed 30 degrees, an injury to the posterolateral corner is identified. If asymmetry persists as knee is flexed to 90 degrees, the PCL is likely also involved. (Courtesy Mark R. Hutchinson, MD.)

knee with the knee flexed to about 90 degrees (Figure 30-44). The PCL is usually injured secondary to a posteriorly directed force on the tibia, from a fall, or potentially from a dashboard injury during a motor vehicle crash. Grading of the PCL injury is based on the posterior drawer test and the relationship of the proximal tibia to the femoral condyles. In grade I PCL injuries, the tibial plateau is slightly anterior to the femoral condyles; in grade II, the plateau and condyles sit flush at the same level; and in grade III, the tibia is posterior to the level. Treatment of a PCL injury is guided by injury severity and associated ligamentous injuries (Cosgarea and Jay, 2001; Wind and Bergfield, 2004).

Figure 30-44 The posterior drawer test is the most sensitive test for evaluating posterior cruciate ligament function. Place the thumbs on the femoral condyles, feeling the tibial offset at the level of the joint line (black arrow). Then create a posteriorly directed force (white arrows) and reassess the tibial step-off. (Courtesy Mark R. Hutchinson, MD.)

Typically, grades I, II, and III are treated nonsurgically with bracing and functional rehabilitation to focus on quadriceps strengthening. PCL ruptures, unlike ACL ruptures, tend to heal, and often a grade III will heal as a grade II and a grade II as a grade I, with appropriate bracing and protection. Mild PCL laxity is usually not symptomatic for patients. If the knee becomes unstable over time, reconstruction can be performed with exactly the same technique that would have been used if performed acutely.

Anterior Cruciate Ligament

The ACL is perhaps the most famous of knee ligaments because of its notoriety in twisting and cutting sports. The common presentation of an ACL injury is an athlete landing in a twisting and cutting sport, feeling a pop, and having an acute hemarthrosis within 24 hours. The most sensitive test for ACL rupture is a Lachman test, which is basically an anterior translation of the tibia on the femur with the knee flexed 20 to 30 degrees (Figure 30-45). The anterior drawer test is also used but is less sensitive (Figure 30-46). The most specific test is the “pivot shift.”

The initial treatment of ACL injury focuses on rehabilitation to regain ROM and strengthen the knee. Surgical indications are based on the patient’s function as well as future demands (Beynon et al., 2005). For young athletes who want to play a twisting or cutting sport more than two or three times per week, ACL reconstruction is strongly recommended. The key reason for that indication is the absolute requirement to avoid the current instability or pivoting. Recurrent wobbling or pivoting of the knee leads to an increase in stress along the meniscus, meniscal failure, meniscal degeneration, hyaline cartilage degeneration, and degenerative changes in the knee. If the athlete is willing to give up his or her sport, with no complaints of instability performing ADLs, surgical ACL reconstruction is not always necessary.

Figure 30-45 The Lachman test is the most sensitive approach to assess anterior cruciate ligament function. The femur is stabilized (*white arrows*) with the knee flexed about 15 to 20 degrees and the tibia drawn anteriorly (*white arrow*). Comparison with the opposite side and assessment of a ropelike end point are key.

Figure 30-46 The anterior drawer test is less sensitive for isolating anterior cruciate ligament injuries but may assist in diagnosing associated pathology. The knee is flexed 90 degrees, and the tibia is drawn anteriorly. The *white arrowheads* represent an anteriorly directed force as the examiner pulls the tibia anteriorly with respect to the femur. (Courtesy Mark R. Hutchinson, MD.)

Skeletally immature athletes pose a unique challenge because of their open growth plates. Treatment options include delay of definitive surgical reconstruction until maturity, extraarticular reconstruction, and reconstruction with soft tissue across the physis (Bates et al., 2004). Most studies have shown that children are not fully cooperative with programs that have them reduce activities until skeletal maturity. This leads to recurrent episodes of instability with associated meniscal and cartilage damage. Based on this, there has been a strong trend to surgically stabilize these young athletes to reduce the risk of arthrosis at a young age.

EVIDENCE-BASED SUMMARY

- No RCTs have compared surgical and nonsurgical outcomes in reduction of future osteoarthritic change for PCL injuries (Peccin et al., 1995) (SOR: A).
- Based on two clinical trials in the 1980s and insufficient RCTs, no conclusions can be drawn about conservative versus surgical treatment of ACL ruptures in adults (Linko et al., 2005).
- Surgical stabilization should be considered for skeletally immature patients with ACL injuries because they carry a high risk of recurrent instability and subsequent injury and damage to the meniscus (Bates et al., 2004) (SOR: B).

Ankle and Foot

Key Points

- Radiographs for foot and ankle imaging should be weight bearing if a fracture does not preclude it.
- Radiographs are not necessary in all cases of suspected ankle sprain.
- Early mobilization with an external supportive device usually leads to a quicker recovery from ankle sprain, although it may not affect the long-term outcome.
- Although corticosteroid injections can provide short-term relief of plantar fasciitis pain, no single intervention appears superior to another.
- Fractures through the watershed area of blood supply in the proximal fifth metatarsal (Jones fracture) have a high risk of nonunion or malunion.

The foot and ankle are complex structures that provide the foundation to gait and the upright musculoskeletal structure. They are intimately related to a person's ability to ambulate, run, jump, and traverse unstable and variable terrain. Optimal foot and ankle function implies a higher level of function for ADLs. Thorough examination and imaging should consider a broad differential diagnosis of common problems, including ligament sprains, stress fractures, fractures and avulsions, chronic tendinopathies, and tendon ruptures. A more expansive differential diagnosis includes nerve entrapment, circulatory dysfunction, and systemic disease, as well as congenital and developmental problems. All radiographic imaging of the foot and ankle for pain should be weight-bearing views, in the absence of suspicion of a fracture, to allow a more accurate clinical picture because the patient usually experiences pain when weight bearing and not at rest (Stiell et al., 1992, 1993).

ANKLE SPRAINS

Sprains are injuries to the ligamentous structures of the ankle. About 85% of ankle sprains involve the lateral ligaments; medial and syndesmosis sprains make up the remaining 15%. The diagnosis is based primarily on the history and physical examination, although radiographs are often helpful. Advanced diagnostic testing is not usually

Figure 30-47 Anatomy of lateral ankle ligaments. (From Nicholas J, Hershman E. *The lower extremity and spine in sports medicine*. Vol 1, 2nd ed. St. Louis: Mosby; 1995:424.)

Figure 30-48 Forceful inversion of the hindfoot with a plantarflexed ankle, possibly tearing the anterior talofibular and interosseous talocalcaneal ligaments. (From Meyer JM, Garcia J, Hoffmeyer P, et al. The subtalar sprain: a roentgenographic study. *Clin Orthop*. 1988;226:169-173.)

necessary. The family physician must be aware of the many potential pitfalls in the diagnosis of ankle sprains as well.

Lateral Ankle Sprains

The anterior talofibular ligament (ATFL), calcaneofibular ligament (CFL), and posterior talofibular ligament (PTFL) are the three ligaments of the lateral ankle (Figure 30-47). The ATFL primarily restricts anterior motion of the talus within the ankle mortise, the CFL restricts inversion, and the PTFL restricts posterior translation. The most common mechanism of lateral ankle sprain is an *inversion* ankle injury. Inversion events with the ankle in a plantarflexed position often lead to ATFL injury (Figure 30-48); inversion events with the ankle in a dorsiflexed position more often lead to CFL injury (Figure 30-49). Patients present because of ankle pain that may be associated with swelling,

Figure 30-49 Forceful inversion of the hindfoot with a dorsiflexed ankle, possibly tearing the calcaneofibular, cervical, and interosseous talocalcaneal ligaments. The curved pink area describes a rotational inversion force as the calcaneus/hindfoot is rotated beneath the ankle mortis, causing tension and failure of the lateral ligamentous structures. (From Meyer JM, Garcia J, Hoffmeyer P, et al. The subtalar sprain: a roentgenographic study. *Clin Orthop*. 1988;226:169-173.)

bruising, decreased motion, and increased pain with weight bearing if they are able.

Examination begins with observing the patient's gait; a limp is often noted. Gross observation of the foot and ankle often reveals lateral edema and ecchymosis. Active motion may be severely restricted. Neurovascular structures are usually normal. Along with palpation of the ATFL, CFL, and PTFL, important structures to palpate on the lateral aspect of the ankle include the fibula (entire length), peroneal tendons, lateral process of the talus, neck of the talus, cuboid, and base of the fifth metatarsal. Stress testing is performed to assess the integrity of ligamentous structures. The anterior drawer test translates the talus within the mortise and assesses the ATFL, performed with the ankle in slight plantarflexion to place the ATFL under tension while decreasing CFL tension. Both the amount of excursion compared with the opposite side and the end-point feel to the test are important determinants in the evaluation. The CFL is tested by the talar tilt. The ankle is placed in a neutral position, putting tension on the CFL and decreasing tension on the ATFL. The talus is then inverted within the mortise while the examiner assesses excursion and end-point feel. Again, these findings are compared with the opposite side to determine the severity of injury.

In the United States, patients presenting for ankle injury often undergo radiographic evaluation, but the utility of routine radiographs to evaluate ankle injuries is under debate. Well-designed studies from Canada have shown that many patients with ankle injuries can be managed safely without routine radiographs. Indications for lateral ankle radiograph include age younger than 18 or older than 55 years; inability to bear weight for four consecutive steps, either immediately after injury or in the examination room; and pain over the posterior portion of the distal 6 cm or at the tip of the fibula (Stiell et al., 1992, 1993). If pain is noted in the proximal or midshaft fibula, tibia and fibula radiographs should be obtained, and pain over

the base of the fifth metatarsal indicates the need for foot radiographs.

Various scales are available to grade ankle injuries, and inter- and intraexaminer variability is high. The most common scale is mild (grade 1), moderate (grade 2), and severe (grade 3). However, grading does not significantly affect treatment, complication rates, or long-term outcomes. Grading may have a predictive role in duration of recovery.

Treatment of lateral ankle sprains has changed drastically over the past 25 years. Complete immobilization and rest were once thought to be important initial components of treatment. Currently, early mobilization with an external support device and rehabilitation are common therapies. Early immobilization may lead to greater stability and patient compliance, and the risk for early reinjury is low. In the early mobilization and rehabilitation plan, recovery tends to occur slightly more quickly (based on full return to work), and early discomfort may be decreased (Eiff et al., 1994; Karlsson et al., 1996). With immobilization, the ankle joint can become stiff and lead to muscle atrophy. This may require a prolonged postimmobilization program focused on regaining motion and strength. Long-term outcomes of early mobilization and immobilization treatment plans are not significantly different.

Basic stages of treatment include early external support and, depending on severity, limited weight bearing, pain control, reducing swelling with ice and elevation, and maintaining motion. After the initial acute injury subsides, weaning from supportive devices such as crutches, walking boots, or casts should be done and formal rehabilitation initiated. Rehabilitation should focus on motion, strength, and proprioception activities. The final phase of rehabilitation is reintroduction of sport-specific tasks and return to sports. Participation in a prevention-based training program with a focus on balance and proprioception reduces the incidence of ankle sprain without increasing the incidence of other injuries (Bahr et al., 1997). Bracing the ankle on return to sports may reduce the risk of recurrent injury. Whether bracing reduces the risk of an initial sprain is under debate (Sitler et al., 1994; Surve et al., 1994).

When treating skeletally immature patients, it is important to remember that physeal plate fractures through the distal fibula result from the same mechanism as an ankle sprain. If the physical examination reveals tenderness along the distal fibular growth plate, a growth plate fracture must be considered even if the radiographic results are negative. In this case, a short period of immobilization followed by repeat imaging in 2 weeks is appropriate.

Medial Ankle Sprains

The main ligament on the medial side of the ankle is the deltoid ligament (Figure 30-50). Deltoid injuries are typically caused by an eversion mechanism. Medial ankle examination is similar to that of the lateral ankle. Observation of gait usually reveals a limp, and gross observation of the ankle often reveals medial edema but no other deformity. Active motion may be severely restricted, and neurovascular status should be normal. Careful palpation of bony, tendinous, and ligamentous structures of the medial ankle include the deltoid ligament, medial malleolus, medial process of the talus, neck of the talus, medial cuneiform,

Figure 30-50 Anatomy of medial ankle ligaments. (From Nicholas J, Hershman E. *The lower extremity and spine in sports medicine*. Vol 1, 2nd ed. St. Louis: Mosby; 1995:424.)

cuboid, navicular, and medial ankle tendons (posterior tibi-
alis, flexor digitorum longus, and flexor hallucis longus).

Stress testing of the deltoid ligament is performed by an eversion stress test, usually performed with the ankle in neutral position. The amount of excursion compared with the opposite side and the end-point feel determine the severity of the injury. Deltoid function should be carefully assessed with eversion stressing the ankle in eversion as well as translation stressing from side to side. Mortis widening indicates an injury of the syndesmosis. Any offset increases the stresses on the articular cartilage and increases the risk of arthritis. Obtaining radiographs in the patient with medial ankle injury is decided on a case-by-case basis but should be done more readily than for the typical lateral ankle sprain. Treatment plans are similar to those for lateral ankle sprains. It is widely believed that medial sprains take longer to heal than their lateral counterparts.

Syndesmosis Ankle Sprains (High Ankle Sprains)

The ankle *syndesmosis* is the area of the distal tibia–fibula joint. The five soft tissue structures in the syndesmosis region include the anterior tibiofibular, posterior tibiofibular, transverse tibiofibular, and interosseous ligaments and the interosseous membrane; of these, the anterior tibiofibular ligament is most often injured. Syndesmosis sprains account for 1% to 18% of ankle sprains, with a higher incidence in high-level athletes. Syndesmosis sprains are generally thought to take longer to heal than lateral or medial sprains (Hopkinson et al., 1990), and persistent ankle pain and persistent dysfunction are more common (Gerber et al., 1998); syndesmosis injuries are often associated with fractures. The mechanism of injury is different than for the more common lateral and medial sprains; syndesmosis sprains are most often caused by forceful external rotation and hyperdorsiflexion injuries.

Physical examination often reveals an antalgic gait limp and anterolateral ankle swelling over the anterior

Figure 30-51 The squeeze test. (From Hopkinson WJ, St. Pierre P, Ryan IB, et al. Syndesmosis sprains of the ankle. *Foot Ankle Int.* 1990;10:325-330. Copyright American Orthopedic Foot and Ankle Society, 1990.)

tibiofibular ligament just proximal to the joint line. Ecchymosis is often a delayed finding and is usually noted proximal to the ankle joint in contrast to that noted in lateral and medial sprains, which is often below the ankle and occasionally throughout the foot. Careful palpation reveals tenderness directly over the anterior tibiofibular ligament. Syndesmosis injuries may be present along with medial ankle injury, so tenderness over the deltoid ligament may be noted as well. Be sure to palpate the proximal fibula because extreme forced external rotation may lead to a Maisonneuve fracture (proximal fibular fracture). Strength testing is often limited by pain, and neurovascular status remains intact.

Special stress tests to evaluate the syndesmosis include the squeeze, external rotation, and dorsiflexion-compression tests. The squeeze test is performed by compressing the fibula and tibia above the midpoint of the calf (Hopkinson et al., 1990) (Figure 30-51). The test result is positive if compression causes pain in the region of the syndesmosis ligament. The external rotation test is performed with the knee at 90-degree flexion and the ankle in neutral position. An external rotation force is applied to the foot while the remainder of the leg is stabilized. Pain in the anterior tibiofibular region is a positive test result. The external rotation test is thought to be the most reliable of the common clinical tests used to diagnose syndesmosis sprains.

Because of the risk of concurrent fracture with syndesmosis sprains, radiographs should be obtained. Plain

radiographs are adequate to assess for frank *diastasis* (widening between fibula and tibia). Stress radiographs may be necessary to discover latent diastasis. The three major radiographic considerations are the (1) *tibiofibular clear space*, the distance between the medial border of fibula and the lateral border of the posterior tibia, measured 1 cm above tibial plafond; (2) *tibiofibular overlap*, the maximum amount of overlap of the distal fibula and anterior tibial tubercle; and (3) *medial clear space*, the distance between medial malleolus and the medial border of the talus, measured 1 cm below the tibial plafond (Figure 30-52).

Additional testing such as CT can be helpful early in the workup to look for occult fracture and later to assess for heterotopic ossification, a common complication of syndesmosis sprains. MRI is sometimes used and has a high sensitivity and specificity for detecting anterior and posterior tibiofibular ligament injuries (Oae et al., 2003).

The initial treatment begins with protection of the joint, relative rest, ice, compression, and elevation. Various modalities to reduce swelling and inflammation can be used. Rehabilitation includes ROM exercises, strengthening and balance exercises, and proprioception training. Activities can be advanced when pain is reduced, and rehabilitation exercises can be performed pain free. Return to full activities can be entertained when the patient has full motion, full strength, no tenderness on examination, and no functionally limiting pain.

Minimal diastasis can be treated nonoperatively if reduction can be achieved. Therapy includes immobilization with non-weight bearing followed by progressive weight bearing beginning at about 4 weeks and full weight bearing by 2 months. Surgery is needed if reduction cannot be achieved or if diastasis recurs despite immobilization. Frank diastasis is treated surgically.

A common adverse outcome of syndesmosis sprain is heterotopic ossification. Plain radiographs are adequate to make the diagnosis in patients with persistent pain (Figure 30-53). Affecting 25% to 90% of patients, heterotopic ossification may or may not be symptomatic. Ossification may cause pain without causing frank synostosis. The discomfort comes from an inflammatory response in early stages and then from pressure on adjacent bones. Fracture of the ossification is also a potential cause of pain. Frank synostosis can occur. Pain typically results from restricted tibiofibular motion, particularly during full ankle dorsiflexion. Conservative treatment may reduce the pain, but surgical excision may be required (Hopkinson et al., 1990; Taylor et al., 1992).

ACHILLES TENDINOPATHY

Achilles tendinopathy is a common problem, especially in running and jumping athletes. The Achilles tendon consists of the distal ends of the gastrocnemius and soleus muscles and attaches broadly across the posterior aspect of the calcaneus. Contraction of the Achilles results in plantarflexion of the ankle. Activities that cause eccentric loading of the tendon may result in tendonitis. Achilles tendonitis is considered an overuse injury.

Patients present with pain in the posterior aspect of the distal lower leg or heel. Pain is worsened with push-off activities, such as walking up hills or stairs, running, and

Figure 30-52 A, Normal anteroposterior radiograph of the ankle revealing (1) a normal tibiofibular clear space, (2) normal tibiofibular overlap, and (3) normal medial clear space. Significant mortise widening is noted with widening of all three of these parameters. Note the distal fibula fracture. This injury is best treated with internal fixation of the fracture and stabilization of the ankle mortise with a syndesmosis screw. **B**, A football eversion injury shows widening medial mortise with associated deltoid tear, widening distal tibiofibular syndesmosis, a high fibular fracture, and a small posterior malleolus fracture (not seen here). (Part A courtesy James L. Moeller, MD; part B from Nicholas J. Hershman E. *The lower extremity and spine in sports medicine*. Vol 1, 2nd ed. St. Louis: Mosby; 1995:465.)

jumping. Examination reveals tenderness to palpation of the distal portion of the tendon. A palpable area of swelling and firmness may be noted as well as “wet crepitus” from fluid in the peritenon. Strength may be limited because of discomfort. This can be assessed by direct manual testing or

Figure 30-53 Heterotopic ossification noted after a syndesmosis ankle sprain. (Courtesy James L. Moeller, MD.)

by having the patient perform repeated single-foot toe-raise exercises.

Assessment of the integrity of the Achilles tendon is essential and best done by the Thompson test. Asking the patient simply to plantarflex the ankle actively is not sufficient because there are several secondary plantarflexors. The patient should lie prone on the examination table with the knee flexed to 90 degrees and the ankle in neutral position. Squeeze the midgastrocnemius area and observe for passive ankle plantarflexion. If the Achilles is intact, the ankle will plantarflex (negative test result). If the Achilles is torn, the ankle will remain in a neutral position (positive test result).

Radiographs generally are not necessary to make an accurate diagnosis of Achilles tendinopathy or to initiate treatment. Radiographs are considered in chronic cases, primarily to rule out calcific tendinopathy and Haglund deformity (a bump on the back of the calcaneus near the Achilles insertion). Ultrasonography and MRI are not routinely needed early on but may be used to assess for partial tears, as well as assess the vascular integrity of the injured area. Ultrasonography and MRI changes in the tendon can persist even after functional recovery (Khan et al., 2003).

Treatment of Achilles tendinopathy is similar to that for other forms of tendinopathy and includes ice treatment, relative rest, NSAIDs, stretching and strengthening programs, and proprioception exercises. An exercise program focused on eccentric training has been described and

renders promising results in many cases (Alfredson et al., 1998). Most experts agree that corticosteroid injection should not be considered because of the risk of tendon rupture. For recalcitrant cases, treatments such as prolotherapy and extracorporeal shock wave therapy have been studied, but short-term follow-up and isolated reports of effectiveness are mixed. Platelet-rich plasma injections for chronic Achilles tendinopathy have no benefit over saline injections. Surgical debridement is reserved for chronic cases and involves debridement of the diseased tendon and may require tendon transfers for grafting.

ACHILLES TENDON RUPTURE

Tears of the Achilles tendon are most often encountered in men 40 to 60 years old. The most common mechanism of injury is sudden, forceful eccentric loading of the tendon. This can occur from a sudden forceful push-off from a single foot or landing on a single foot. Patients present because of a sudden onset pain in the posterior heel and decreased push-off strength. Patients often describe a feeling of being kicked or hit in the heel, often hearing or feeling a pop at the time of injury. Examination may reveal a palpable gap in the tendon, usually distally. The Thompson test result is positive, with no ankle plantarflexion when the examiner squeezes the calf. Imaging studies are not typically needed to make an accurate diagnosis of Achilles tendon rupture.

Both surgical and nonsurgical treatment options exist (McComis et al., 1997; Weber et al., 2003). Patient selection and including the patient in the decision-making process are important. Generally, younger patients who desire or require greater posttreatment push-off power are likely to be good surgical candidates, and older patients or patients who require less push-off power are nonsurgical candidates. The nonoperative risk of repeat rupture is as high as 10% versus up to 2% with surgery. Skin necrosis of the surgical wound occurs in 5% to 10% of patients.

Conservative treatment entails a period of immobilization accomplished through casting or brace use, usually for 8 to 10 weeks; early weight bearing is controversial. After immobilization, progressive rehabilitation to regain motion, strength, and proprioception is initiated. Surgery is associated with improved push-off power and a reduced rate of repeat rupture and generally allows for the best functional recovery (Wong et al., 2002).

PLANTAR FASCIITIS

Plantar fasciitis is the most common cause of plantar heel pain in active individuals. The plantar fascia is a fibrous band of tissue that originates at the medial calcaneal tubercle, fans out across the plantar aspect of the foot, and then splits before inserting into the plantar aspects of the proximal phalanges. Plantar fasciitis is an overuse injury often seen in people who stand for prolonged periods, as well as in runners and regular exercisers. Many believe plantar fasciitis is an inflammatory condition, but it is more likely caused by chronic changes and microtears of the fascia.

The most common clinical presentation is plantar heel pain. Pain has often been present for several months before

presentation. The pain can be described as sharp and stabbing and tends to be worst in the morning, on arising from prolonged sitting, and after standing for prolonged periods. Other symptoms, such as bruising, swelling, weakness, numbness, and tingling, are uncommon. The primary finding on physical examination reveals tenderness over the origin of the plantar fascia.

Treatment protocols are variable, and it may take several months for the patient to feel significant pain relief. Most treatment plans include plantar fascia stretching, ice or ice massage, heel cushioning, and analgesic medication. NSAIDs are often used but are helpful most likely because of their analgesic, not antiinflammatory, effects. Other common treatment options include night splints, physical therapy, orthotic devices, and cortisone injection. Cortisone injection reduces pain from plantar fasciitis, but the mechanism is unclear (Hunt and Sevier, 2004). Cortisone is a potent antiinflammatory, but as previously stated, chronic plantar fasciitis is probably not an inflammatory problem. Risks with cortisone injection include plantar fascia rupture and necrosis of the plantar fat pad, the natural heel cushion. These adverse outcomes should be reviewed with patients before injection.

New modalities for the treatment of plantar fasciitis are under investigation. Extracorporeal shock wave therapy has shown mixed results (Rompe et al., 2002, 2003). Prolotherapy and autologous blood injection involve injecting substances into the area of pathology. Dry needling is also being studied. None of these options has proved to be consistently helpful. Surgical intervention is sometimes needed in recalcitrant cases.

METATARSAL FRACTURES

Nondisplaced fractures of the midshaft and distal portions of the metatarsals are treated with immobilization. Short-leg casting and immobilizer boots can lead to adequate healing in 6 to 8 weeks in most cases. Postoperative shoe use without formal immobilization can also lead to adequate healing of metatarsal fractures, although the risk of adverse outcome is higher. Displaced, angulated, and rotated fractures may require operative fixation.

Fractures of the proximal portion of the metatarsal (first through fourth metatarsals) should be approached with great care. Nondisplaced fractures may be associated with injury to the intermetatarsal ligaments, leading to widening of these joints; surgical consultation is recommended in these cases. If there is no apparent injury to the tarsometatarsal (Lisfranc) joint, cast immobilization typically leads to adequate fracture healing.

Fractures of the base of the fifth metatarsal deserve special discussion. A watershed area of blood flow in the proximal portion of the fifth metatarsal puts it at particular risk for malunion and nonunion. Avulsion fractures off the most proximal portion of the bone have an opportunity to heal with conservative management. Fractures that occur in the watershed area, so-called Jones fractures, have a high chance for malunion and nonunion that should be discussed with the patient. Jones fractures occur in the proximal third of the metatarsal and do not involve the tarsometatarsal joint. Screw fixation of Jones fractures often leads to more acceptable outcomes.

EVIDENCE-BASED SUMMARY

- Early mobilization with an external support device after ankle sprain leads to better short-term outcomes (reduction of pain and return to work and sport activities) compared with early immobilization; long-term outcomes are similar (Eiff et al., 1994; Karlsson et al., 1996; Kerkhoffs et al., 2004) (SOR: A).
- Use of an external ankle brace after ankle sprain reduces the risk of recurrent sprain. Evidence also supports balance and proprioception training for reducing risk of recurrent sprain (Bahr et al., 1997; Surve et al., 1994) (SOR: B).
- An eccentric training program is effective in treating chronic Achilles tendinopathy (Alfredson et al., 1998) (SOR: B).
- Surgery for acute Achilles tendon ruptures reduces the risk of repeat rupture compared with nonsurgical treatment but produces a significantly higher risk of other complications, including wound infection (Khan et al., 2004) (SOR: A).
- Corticosteroid injection can reduce plantar fasciitis pain in the short term (Hunt and Sevier, 2004) (SOR: B).
- For acute Jones fractures in recreationally active patients, early intramedullary screw fixation results in lower failure rates and shorter times to both clinical union and return to sports than non-weight-bearing short-leg casting (Vu et al., 2006) (SOR: B).

Introduction

Neck and lower back pain are common, often frustrating, presenting complaints for primary care physicians. Up to 85% of patients have low back pain at some point in their lives, and it is the fifth most common reason for visiting a physician (Manusov, 2012). Neck pain has an estimated prevalence of 30% to 50% (Manchikanti, 2009). The cost of spinal pain to the United States alone is enormous, accounting for \$89 billion in 2005 (Martin et al., 2008). Furthermore, chronic low back pain is the leading cause of opioid prescriptions for noncancer pain (Chou et al., 2009).

Spinal pain is a frustrating problem for clinicians and patients. Factors associated with pain include mood, coping skills, relationship problems, and sleep disorders. Physicians identify chronic pain as a factor contributing to a patient being labeled “difficult” (Edgoose, 2012). Patients turn to complementary therapies for pain more than any other diagnosis, often because of dissatisfaction with their treatment choices (National Institutes of Health, National Center of Complementary and Alternative Medicine, 2004). In addition, the overall societal burden of these conditions is increasing because of unnecessary imaging, unjustified procedures, and the effects of increasing opioid prescribing.

Family physicians are ideally suited to manage the complex problem of spinal pain. They have an understanding of the patient’s psychosocial milieu, comorbidities, and functional status. However, many family physicians do not feel equipped to effectively diagnose and treat spinal pain. Multiple guidelines do exist addressing these areas, but they are often not used in routine clinical care (Manusov, 2012).

This section can serve as a framework to the diagnostic and therapeutic challenge of spinal pain. With improved understanding of these conditions, we can better partner with patients, helping them become active in their care and improve their quality of life.

HISTORY

The initial assessment is focused on questions that elucidate the history of the presenting pain condition, including location, quality, severity, duration, timing, context, modifying factors, and associated signs and symptoms. Of particular importance in the initial history are the acuity of pain and

a description of any inciting trauma. Further questioning has several goals: identifying an underlying etiology when possible, identifying urgent medical or surgical issues, and assessing psychosocial barriers to successful treatment (Table 31-1).

Emergent conditions are rare but essential considerations in the evaluation of spinal pain. Emergencies such as cauda equina syndrome and spinal infections are examples of conditions that must be identified as quickly as possible. Physicians can efficiently evaluate for these conditions by considering “red flag” symptoms (Table 31-2).

It is also important to consider and assess the psychosocial aspects of pain. Clinicians should ask about the impact of the pain on daily activities, any recent life stressors, and any history of psychiatric disorders.

PHYSICAL EXAMINATION

The physical evaluation of neck and lower back pain begins with inspection of the spine and assessment of motion. Inspection is focused on alignment of major bony landmarks and assessment of the normal spinal curves. The skin should be directly assessed because dermatologic conditions such as herpes zoster can be a cause of neck or back pain. Both the cervical and lumbar spine normally have a lordotic curve. Absence of this can indicate underlying muscular pathology. Range of motion (ROM) should be tested in flexion, extension, side bending, and rotation. Specific muscle testing can also be useful, such as testing hamstring and psoas muscle motion.

The examination should include palpation of bony landmarks and soft tissue structures related to the area of pain. Checking for costovertebral angle tenderness can help rule out renal involvement. A neurologic examination is of particular importance in assessing for more urgent concerns. This should include assessment of gait, strength, sensation, and reflexes. This information can then be correlated with history findings of radicular pain, subjective weakness, or numbness. Finally, special tests can be done to further clarify the differential diagnosis. Several special tests for spinal pain may be appropriate (Table 31-3). They are of limited utility when taken in isolation, so they should always be considered in the context of the entire evaluation. Finally, it may be necessary to evaluate the adjacent joint structures, most commonly the temporomandibular joint,

Table 31-1 Top 10 Questions to Assess Spinal Pain

1. Is this the first episode or a recurrence?
2. Was there any inciting trauma?
3. What increases and decreases your pain?
4. What is your pain pattern over a 24-hour period?
5. Can you diagram the pain pathway?
6. Is there any focal weakness or numbness?
7. Are there any new bowel or bladder symptoms?
8. What previous treatments have been used? Did they help?
9. Did you have any joint problems or sports injuries in childhood?
10. How is this pain affecting your daily life?

Table 31-2 Historical Red Flags

Fever, weight loss, nausea	History of IV drug use
Saddle anesthesia	History of cancer
Recent trauma	History of immune suppression
Bowel or bladder incontinence or retention	History of chronic steroid use
Recent UTIs	History of tuberculosis

IV, Intravenous; UTI, urinary tract infection.

Table 31-3 Physical Exam Testing of the Spine

Test	Description	Purpose
GENERAL		
Inspection, including posture		
Gait assessment		
Range of motion		
Neurologic testing		
Palpation		
Adjacent joint testing		
SPECIAL TESTS		
Spurling test	The neck is passively extended and then side bent toward the symptomatic side. A compressive force is then applied through the top of the patient's head.	Tests for cervical radiculopathy. A positive test result is an increase in pain and radicular symptoms. This test has a low sensitivity but a high specificity (Rubinstein et al., 2007).
Cervical distraction test	The patient is supine. The examiner has one hand on the chin and another on the occiput. The head is then gently lifted and cervical traction applied.	Tests for cervical radiculopathy. A positive test result is an improvement in pain and radicular symptoms. This test has a low sensitivity but a high specificity (Rubinstein et al., 2007).
Upper limb tension test	The patient is supine. The examiner uses one hand to compress the scapula. The other hand places the patient's shoulder in flexion and abduction and then extends the elbow, wrist, and fingers. The neck is side bent toward the contralateral side.	Tests for cervical radiculopathy. A positive test result is an increase in pain and radicular symptoms. This test has a sensitivity of more than 90% but a low specificity (Rubinstein et al., 2007).
Straight-leg raise	The patient is supine with the legs straight. The leg on the symptomatic side is lifted with the knee in extension.	Tests for lumbar disc herniation. A positive test result is pain between 30 and 70 degrees in the low back or leg. Sensitivity has been published at 91% and specificity at 26% (Deville et al., 2000).
Standing flexion test	The patient is standing with the examiner behind the patient. The examiner places the thumbs on the base of the sacrum and asks the patient to forward flex.	A positive test result is one thumb tracking asymmetrically higher on one side; this indicates iliosacral dysfunction. Thoracic and lumbar ROM can also be assessed from this position.
Psoas muscle test	The patient is prone. The knee is flexed to 90 degrees and then lifted off the table to assess ROM.	Tightness in one or both psoas muscles can contribute to low back pain through attachments on the lumbar spine. Asymmetry in ROM or reproducing low back pain symptoms may indicate psoas involvement in the underlying etiology.
Piriformis test	The patient lies on his or her side. The lower leg is flexed at the hip and knee for stability. The upper leg is straightened off the table. The examiner stabilizes at the pelvis and then pushes down on the upper leg.	Tests for piriformis muscle involvement. A positive test result is pain in the buttocks. If pain radiates down the leg, the test is suggestive of sciatic nerve impingement at the piriformis.

ROM, Range of motion.

shoulder joint, or hip joint, to assess for nonspinal sources of pain.

IMAGING

A history and physical examination are adequate for making a diagnosis and determining a treatment plan for the vast majority of patients with neck or low back pain. The potential benefits of imaging in spinal pain are to advance the diagnosis, exclude urgent medical and surgical pathology, or guide evidence-based treatment. In most

cases, imaging does not add useful information or value. Despite this, use of magnetic resonance imaging (MRI) in lower back pain increased by 307% from 1994 to 2005 with no evidence of improved outcomes (Maus, 2010).

In acute neck pain, the presence or absence of trauma guides the decision-making process for imaging. Acute neck trauma is a special consideration because of the concern for catastrophic spinal injury. The National Emergency X-Radiography Utilization Study (NEXUS) criteria provide a clinical guideline to aid in selecting patients for imaging. If a patient meets the criteria listed in Table 31-4, no acute

imaging is required (Hoffman et al., 1998). For patients in acute neck pain without trauma or neurologic findings, imaging is not indicated. Chronic neck pain warrants radiographic imaging according to consensus guidelines, but its usefulness remains controversial (Daffner, 2010). If initial radiographic results are normal and there are no neurologic findings, then no further imaging is required. If neurologic findings are present on examination or there is history of significant whiplash injury, MRI is indicated to evaluate further.

Early imaging in acute back pain has not been shown to improve either short- or long-term outcomes and is not recommended by several clinical guidelines (Davis et al., 2009; Maus, 2010). This has been shown to be costly and can be harmful, and findings do not correlate to clinical course (Maus, 2010). Avoiding the use of imaging in the early evaluation of low back pain has been identified as one of the top five ways to improve value in primary care (Good Stewardship Working Group, 2011). Without red flag symptoms or concerning neurologic findings, imaging before 6 weeks of symptoms is discouraged.

Table 31-4 The NEXUS Low-Risk Criteria

Cervical spine imaging is recommended in acute trauma unless all of the following criteria exist:

No posterior midline tenderness

A normal level of alertness

No focal neurologic deficits

No evidence of intoxication

No distracting injuries (other injuries that are large enough as to possibly distract from cervical injury)

NEXUS, National Emergency X-Radiography Utilization Study.
From Hoffman JR, Wolfson AB, Todd K, Mower WR. Selective cervical spine radiography in blunt trauma: methodology of the National Emergency X-Radiography Utilization Study (NEXUS). *Ann Emerg Med.* 1998;32:461-469.

Even after the acute period, patients should undergo imaging only if it may reasonably guide treatment decisions. Several limitations are associated with the use of radiographic and MRI testing that can lead to increased risks to patients. A major problem is the poor correlation between anatomic abnormalities and the underlying source of pain. For example, even if a patient has a known disc abnormality on imaging, there is no standard to identify the disc as the source of the patient's symptoms. Also, MRI findings of degenerative changes in facet joints are not predictive of a patient benefiting from a facet joint injection (Maus, 2010). The same is true of degenerative changes in the sacroiliac joints. This makes interpreting studies difficult and may overestimate the importance of imaging studies when trying to correlate information to the patient presentation. Potential harms of advanced imaging include unnecessary subsequent procedures and "labeling" a patient with a condition, such as degenerative disc disease, that may ultimately have no bearing on the course of his or her clinical symptoms. If the decision is made to proceed with imaging in low back pain, radiographs are recommended initially (Figure 31-1). If there is a specific neurologic concern or the patient is considering interventional treatments, an MRI may help guide treatment.

Cervical Sprains and Whiplash Syndromes

Key Points

- It is important to rule out fracture, joint instability, and neurologic deficit early in the evaluation process
- Long-term comprehensive treatment should include patient education, lifestyle modifications, and use of psychological interventions to aid in pain coping mechanisms.

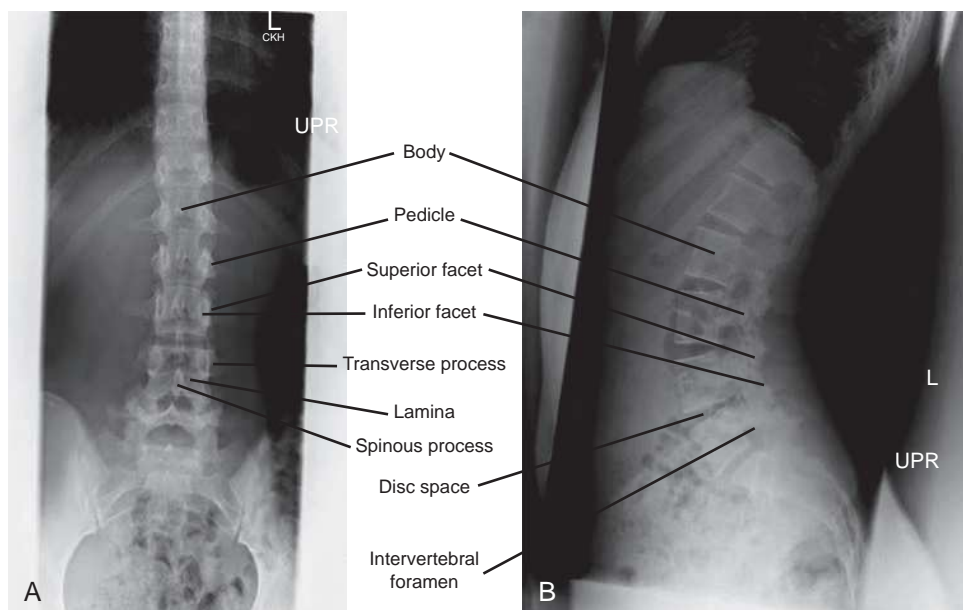

Figure 31-1 Standing lumbar anteroposterior (A) and lateral (B) radiographs. Note the important labeled bony and soft tissue structures of the vertebrae.

Figure 31-2 Neck retraction used to correct head protraction and to self-mobilize facets.

Whiplash is a term coined by Crowe in 1928. Before that, the term *railway spine* was used to describe these types of injuries (Otte, 2001). The mechanism of injury is due to a combination of forces, including flexion-extension, dynamic loading, shear, and others (Nordin et al., 2008). Abnormal neck postures or axial rotation at the time of the collision increases the risk of structural injury. Pain generators include facets, dorsal root ganglia, discs, ligaments, muscles, vertebral artery, psychosocial factors, and generalized hyperalgesia (Nordin et al., 2008). Fractures, ligamentous instability, significant disc herniation, and degenerative changes such as osteophytes can be identified on imaging studies. Subtle microscopic injuries to facets, nerves, muscles, and bone are not seen on these studies, relegating patients with these types of injuries to the subjective pain category (Curatolo et al., 2011).

CLINICAL FEATURES

Symptoms vary but frequently include neck pain and stiffness, dizziness, headache, radiating pain, numbness, and weakness in the upper extremities and may include cognitive impairment (Walton et al., 2013). It is important to document the onset of symptoms in relation to the time of injury and the presence or absence of preexisting symptoms before the injury. Of note, evidence indicates that factors related to the collision itself, such as amount of vehicle damage, are not reliably predictive of the degree of pain and injury to the individual (Walton et al., 2013).

Evaluation includes review of posture, gait, ROM of the spine and extremities, and neurologic tests (including cranial nerves and cognitive function when indicated). In addition, special tests such as the Spurling test, manual

cervical traction, and palpation are done to assess the cervical spine. The Spurling test is done by slightly extending the cervical spine and bending the neck toward the painful side. Pressure is then applied through the top of the head (axial loading). A positive test result is increased pain and radicular symptoms, suggestive of a cervical radiculopathy. The maneuver is thought to be specific but not sensitive for cervical radiculopathy (Tong et al., 2002). With any area of injury, the proximal and distal joints should be evaluated. For a cervical injury, this includes the temporal–mandibular joint above and the scapula and glenohumeral joint below (Hol, 2008). In the acute setting, imaging should be done based on the NEXUS criteria (see Table 31-4).

TREATMENT

With acute injuries, emphasis is initially placed on pain control, mechanisms to decrease inflammation, and passive modalities. As the patient tolerates more activity, emphasis should shift to more active approaches such as aerobic and joint-specific exercise (Figures 31-2 and 31-3), and sport-specific activity. Cervical collars and supportive devices should be reserved for short-term use only when no instability is present (Hurwitz et al., 2008).

Risk factors for poor recovery include female gender, a low level of education, higher baseline scores for neck pain intensity and somatization, and lower baseline scores for work-related activities. Of these, neck pain intensity and work disability are the most consistent predictors (Hendriks, 2005; Walton et al., 2013). Most rigorous studies suggest that half of those with whiplash-associated disorders report neck symptoms 1 year after their injury (Carroll et al., 2008).

Figure 31-3 Isometric cervical strengthening. This is done in four quadrants as part of a general cervical strengthening program.

Cervical and Lumbar Disc Syndromes

Key Points

- Disc herniations are usually the result of a long-standing degenerative process.
- A careful neurologic examination is mandatory to determine the clinical level of involvement.

Although a cervical or lumbar radiculopathy can be a result of a specific incident or injury, it is usually a manifestation of an ongoing degenerative process. There is a fine balance between the vertebrae–disc complex and the two facet joints. The combination of muscle imbalances, coordination issues, postural abnormalities, and disc degeneration alters the center of axis of motion of this three-joint complex. Dysfunctional movement can result in tissue damage, such as fraying of the annulus fibrosis, and micro-trauma to the facet joints and their fluid-filled capsules.

In addition, Wolff's law states that bone responds to the stressors placed on it by hypertrophy, an example of form following function. As the spine seeks a more stable state, facet and ligamentum flavum hypertrophy may result in a central, lateral recess or foraminal stenosis (Kirkaldy-Willis, 1988; Wolff, 1986). In the cervical spine, the uncus is a unique structure that is a site of osteophyte formation (Figure 31-4). A combination of disc herniation, uncovertebral hypertrophy (disc–osteophyte complex), and facet hypertrophy may result in stenosis of the foramen, lateral recess, or central canal (White and Panjabi, 1990) (Figure 31-5).

The result of these processes in either the cervical or lumbar spine is an unstable joint that eventually may result in disc herniation caused by joint laxity (Kirkaldy-Willis, 1988). Describing disc herniation as the end result of a multifactorial, chronic process rather than an isolated event is helpful in counseling patients and planning effective treatments.

CLINICAL FEATURES

A pain diagram and a through history and physical are key to defining a radicular pattern. Other structures such as facet joints, myofascial trigger points, or the sacroiliac joint may have a radiating pain that mimics a compressed nerve root pattern (Kellgren, 1939). In the lumbar spine, disc

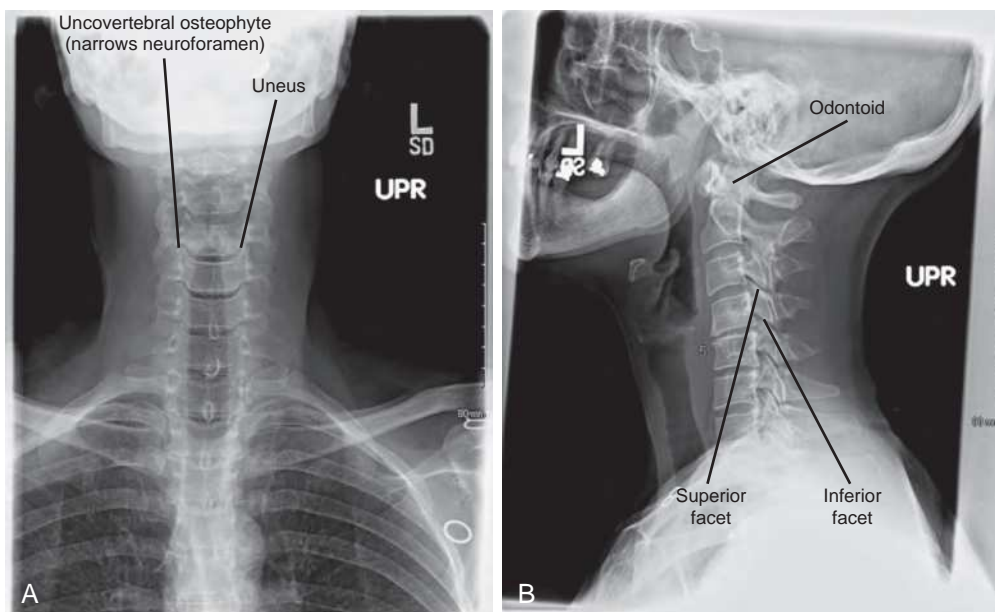

Figure 31-4 Cervical anteroposterior (A) and lateral (B) radiographs. Note the uncus and upward pointing lateral projection of the vertebral body. Osteophytes are prone to develop here (note right C4-C5 level), and frequently project into the neural foramen, impinging the exiting nerve root.

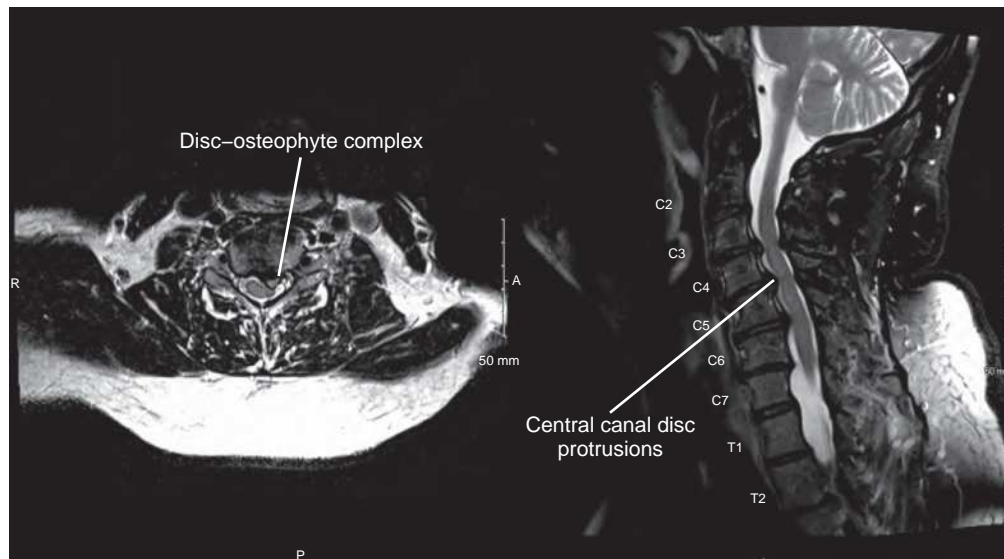

Figure 31-5 Cervical MRI axial and sagittal views. Note the disc–osteophyte complex to the left of center at C4 to C5 that impinges on both the spinal cord and the exiting nerve root.

Table 31-5 Common Radiculopathies

Level of Disc Herniation	Nerve Root Involved	Muscle to Be Tested	Area of Sensory Loss	Reflex
C5-C6	C6	Biceps	Lateral forearm	Biceps
C6-C7	C7	Triceps	Index finger	Triceps
L3-L4	L4	Tibialis anterior	Medial calf	Patellar
L4-L5	L5	Extensor hallucis longus	Lateral calf	None
L5-S1	S1	Gastrosoleus	Lateral foot	Achilles
Cauda equina syndrome	S2-S3-S4	External anal sphincter	Perirectal	None

herniations most frequently increase pain with sitting (Nachemson, 1981; White and Panjabi, 1990).

Lumbar herniations are more frequently noted to be central or in the paramedian position in the spinal canal. This results in the compression of the nerve root exiting at the next lower level (e.g., an L4-L5 herniation compressing the L5 nerve root) (Table 31-5 and Figure 31-6). The exception is when there is a far lateral herniation into the neuroforamen (e.g., an L4-L5 foraminal protrusion compressing the exiting L4 nerve root).

In the cervical spine, disc herniations usually compress the nerve root at the same level (e.g., a C5-C6 herniation compressing the C6 nerve root) (Figure 31-7). The amount of compression of the nerve root varies according to the degree of disc herniation (i.e., protrusion, extrusion, sequestered fragment).

Although the extent of the herniation can be visualized on MRI, the process is dynamic and subject to pressure and positional influences. Therefore, the clinical picture takes precedent over the imaging studies. Thorough neurologic examinations are required to define any deficit that exists, including any potential cauda equina involvement.

TREATMENT

Although treatment guidelines are available, evidence-based rules are not well defined. The absolute indication for

surgery is loss of bowel or bladder control or progressive neurologic involvement. Relative indications for surgery include static motor loss or intractable pain that causes debilitating functional loss. Other potential indications include neoplasm, infection, congenital conditions, or deformity (Cole and Herring, 2003).

Conservative approaches are multiple. The major categories of these are listed in Table 31-6. After an initial short period of rest, aerobic exercise should be one major component of the program. Recommendations for spine-specific exercises vary, but family physicians should feel comfortable initiating a few commonly effective exercises. In the cervical spine, these include neck retraction and isometric strengthening (see Figures 31-2 and 31-3). In the lumbar spine, rehabilitation can include the supine knee-to-chest and prone extension initially (Figures 31-8 and 31-9). As the patient progresses, strengthening exercises such as the four-point balance exercise and lateral plank are good options (Figures 31-10 and 31-11). Other specific exercises can be included based on individual needs, often with the help of a physical therapist.

Although passive modalities and medications may be included, these should not be a mainstay of treatment. Active modalities as described earlier and activity modification based on sound ergonomic principles should be emphasized. With lumbar radiculopathy, limiting prolonged sitting is frequently required. With cervical radiculopathy, limiting

Figure 31-6 Root (segmental) distribution. Note that motion in each joint is controlled by four nerve roots running in sequence: hip—flexion, L2 and L3 and extension, L4 and L5; knee—extension (and knee jerk), L3 and L4 and flexion, L5 and S1; ankle—dorsiflexion, L4 and L5 and plantarflexion (and ankle jerk), S1 and S2. (Inversion involves L4 and eversion L5 and S1.) A useful mnemonic for the low limb dermatomes is that “we kneel on L3, stand on S1, and sit on S3.” (Redrawn from McRae R, Kinninman AWG. *Orthopedics and trauma*. New York: Churchill Livingstone; 1997:26.)

Figure 31-7 Volar and dorsal dermatome patterns of the forearm and hand. Pain and paresthesias may radiate into these areas when the affected nerve root is compressed. Note that extremity symptoms as a result of disc disease are almost always unilateral. (Redrawn from Mercier R. *Practical orthopedics*. 5th ed. St. Louis: Mosby; 2000:29.)

static postures such as prolonged computer use or limiting overhead and repetitive upper extremity work can avoid further exacerbation of a painful disorder (Figure 31-12).

Considerations regarding return to play and return to work follow parallel guidelines. The general exertion categories to consider with return to work are listed in Table 31-7. Return to play criteria include the following general principles: resolution of any neurologic deficit, full ROM, and little or no pain, and the athlete is able to perform adequately in practice. In addition, the athlete should have the proper protective equipment, have the confidence to play, and should not be at significant risk of injury by participating (Cole and Herring, 2003).

Spinal Stenosis

Key Points

- Spinal stenosis is a multifactorial process that is most commonly an end result of the degenerative cascade.
- Spinal stenosis most often presents as neurogenic claudication in older adults.
- Clinical findings need to be confirmed with imaging to make a definitive diagnosis, but imaging will not change management in mild symptoms.

Spinal stenosis is a clinical syndrome of buttock or lower extremity pain associated with diminished space available for neural and vascular structures within the spinal canal (Doorly et al., 2010). An understanding of spinal stenosis is important in primary care because it is a common cause of pain, disability, and back surgery in the elderly population. It is also a common source of confusion among clinicians because *spinal stenosis* is both a clinical and radiologic term that must be correlated to determine its clinical significance.

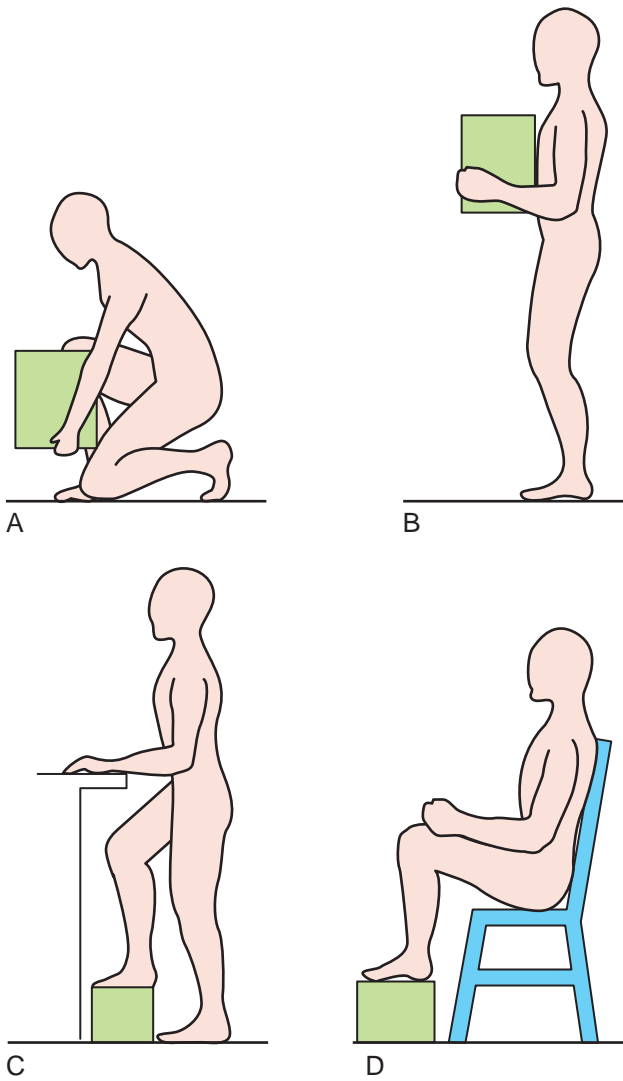

Figure 31-12 General postural instructions. **A**, Bend the knees and hips and keep the back straight when lifting. **B**, Hold objects close to the body when carrying. **C**, Place one foot on a stool when standing. **D**, Keep the knees higher than the hips when sitting and keep the back straight when standing by tucking in the abdomen and tightening the buttocks to decrease swayback. In addition, patients should avoid high-heeled shoes and sleeping on the abdomen, activities that increase lordosis. (Redrawn from Mercier L. *Practical orthopedics*. 5th ed. St. Louis: Mosby; 2000:125.)

Table 31-7 Components of a Return to Work Form

	Occasional Lift Limit (lb)	Frequent Lift Limit (lb)
Sedentary	10	5
Light	20	10
Light to medium	35	20
Medium	50	25
Heavy	75	30-40

Also comment on:

- Number of hours per day and days per week
- Sitting, standing, walking, and driving times
- Ability to do overhead work
- Ability to use the feet and hands for repetitive activity

CLINICAL FEATURES

Most commonly, spinal stenosis occurs because of degenerative changes in the spinal canal. This process is multifactorial and originates from a combination of disc bulging, hypertrophy of arthritic facet joints, and hypertrophy of the ligamentum flavum (Suri et al., 2010). The clinical syndrome that results is variable, but patients can have both lower back pain and lower extremity symptoms. The classic presentation is that of neurogenic claudication in older adults. The lower extremity pain and weakness can be unilateral or bilateral, worsens with walking, and is relieved with sitting (Backstrom et al., 2011). It is a slow, progressive disorder and typically does not present until after age 60 years. Additional findings in the history suggestive of the diagnosis are improvement of symptoms with flexion and worsening with extension. This correlates with the common scenario of symptoms improving when leaning on a shopping cart in the supermarket. Overall, improvement in symptoms with forward bending and absence of pain while seated are the most useful historical findings suggestive of spinal stenosis (Suri et al., 2010). Physical examination tests are not as reliable as symptoms in making the diagnosis, but the presence of a wide-based gait and an abnormal Romberg test result make lumbar spinal stenosis more likely (Suri et al., 2010). The Romberg test is part of the neurologic examination that tests balance and proprioception by having a patient stand with the feet together and the eyes closed. In a positive test result, the patient will not be able to maintain balance with the eyes closed.

An important consideration in the differential diagnosis is evaluating for peripheral vascular disease (PVD). The presentation of neurogenic claudication could certainly be confused with vascular claudication. Differing characteristics include postural changes, which should improve pain in spinal stenosis but not PVD. Also, the discomfort of vascular claudication may be more consistently reproducible with ambulation than neurogenic claudication in terms of walking time and distance (Suri et al., 2010). If concern for vascular disease persists, ankle-brachial index (ABI) studies should be obtained. The ABI compares blood pressures from the ankle and arm both at rest and after exercise. A decreased ABI indicates that blood pressures are lower in the ankle compared with the arm and is suggestive of underlying PVD.

DIAGNOSIS

A history and examination are usually enough to make a presumptive diagnosis of spinal stenosis. To confirm the diagnosis, an MRI is the imaging test of choice (Kreiner et al., 2013). It is not necessary to initially obtain imaging in most cases. For patients with mild or moderate symptoms, imaging will not change the initial management. Furthermore, it is important to recognize that isolated radiographic findings of spinal stenosis without appropriate symptoms do not make the diagnosis of the clinical syndrome of lumbar spinal stenosis. Clinical symptoms that correlate with the radiologic findings must be present to make the diagnosis. Clinicians should be aware of the tendency to use the term *stenosis* in a more general sense to

avoid confusion when evaluating or discussing patients (Suri et al., 2010).

TREATMENT

The treatment approach is based on symptom severity. The overall treatment goals are to relieve pain and improve function. Importantly, the symptoms, not radiologic findings, should direct the treatment approach. On the other hand, classification of stenosis as mild, moderate, or severe is based on radiologic measurements. Radiographically, an anteroposterior (AP) diameter of less than 10 mm in the spinal canal is considered severe stenosis. Although there are objective measures to determine the severity of spinal canal narrowing, the degree of severity has not been shown to correlate to any clinical measure. Specifically, there is poor correlation between MRI assessment of stenosis and walking distance, degree of disability, patient-reported pain, and physician clinical impression (North American Spine Society, 2011). In the absence of reliable objective evidence, physicians must clinically assess the severity of the clinical symptoms in the context of comorbid conditions to determine the most appropriate treatment approach.

Treatment options are generally divided into conservative and surgical approaches. In patients with mild to moderate symptoms, conservative care is effective 70% of the time at 6 months, decreasing to 57% at 4 years (North American Spine Society, 2011). In patients with severe symptoms, conservative care is effective approximately 33% of the time, in contrast to 80% effectiveness of surgical decompression (North American Spine Society, 2011). Conservative care options include physical therapy, analgesic medications, lumbosacral braces, manual therapy, and weight loss. Choosing among the nonsurgical options is challenging because treatments have been poorly investigated in clinical trials (Doorly et al., 2010). Although there is currently no standard of care for conservative treatments, current guidelines state that physical therapy and exercise may be effective in improving outcomes as part of a comprehensive treatment strategy (Kreiner et al., 2013). Regarding pharmacologic treatments, recommendations have been adapted from other more general pain recommendations and have limited evidence when specifically applied to spinal stenosis (Doorly et al., 2010). As with other causes of spinal pain, acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs) are typical first-line pharmacologic agents despite the lack of data specific to spinal stenosis. There is insufficient evidence to support other agents such as skeletal muscle relaxants or calcitonin (North American Spine Society, 2011). Gabapentin warrants specific mention in this discussion because its use is common given the neurogenic origin of symptoms. However, the evidence supporting its use in spinal stenosis is limited to one study of 55 patients with several limitations (North American Spine Society, 2011).

Interventional treatments include epidural steroid injections and spinal surgery. Current recommendations support the use of epidural injections for short term relief of neurogenic claudication symptoms, but evidence is not as strong for long-term benefit (North American Spine Society, 2011). Spinal decompression surgery is recommended for patients with moderate to severe radicular symptoms, especially

when not benefiting from conservative care. Patients with primarily axial back pain as opposed to radicular pain do not typically get as much benefit from surgery. Of note, patients older than 75 years of age undergoing decompression surgery have outcomes similar to younger patients and should be considered for debilitating symptoms (Doorly et al., 2010).

KEY TREATMENT

- Patients with mild to moderate symptoms should be offered conservative treatment options, including analgesia, physical therapy, lumbar braces, and weight loss (Kreiner et al., 2013). (SOR: C).
- Patients with severe symptoms should be considered for surgical evaluation. This recommendation includes patients older than the age of 75 years because outcomes are similar to those in younger patients (North American Spine Society, 2011) (SOR: B).

Spondylolisthesis

Key Points

- Spondylolisthesis is defined as a forward slippage of one vertebral body relative to the one below.
- The most common underlying causes are a bilateral pars interarticularis defect in the younger population and degenerative changes in older adults.

BACKGROUND

Spondylolisthesis is a condition commonly seen by family physicians in both the pediatric and adult population. It is also an important condition to consider relative to the previous section on spinal stenosis because spondylolisthesis can be a cause of spinal stenosis. First, it is important to define terms used in discussing this topic. *Spondylolysis* is a defect of the pars interarticularis of a lumbar vertebra. *Spondylolisthesis* is the forward slippage of a vertebral body relative to the one below. There are five underlying causes of spondylolisthesis (Table 31-8). Types I and II are more common in the pediatric population, and type III is more commonly seen in older adults. This discussion focuses on the two most common types, which are types II and III.

In spondylolisthesis caused by pars defects, it is generally agreed that genetic predisposition plays a role, but

Table 31-8 Types of Spondylolisthesis

Type	Description
I	Congenital abnormality
II	Defect of the pars interarticularis
III	Degenerative
IV	Traumatic
V	Pathologic

otherwise the exact etiology is unclear. The overall incidence is quite high, with quoted rates of 6% by age 14 years. Clinical significance varies significantly based on the individual, but a slippage greater than 25% tends to correlate with the presence of pain (Tallarico et al., 2008).

Degenerative spondylolisthesis is a major cause of spinal stenosis. It is thought to be a multifactorial problem similar to other causes of spinal stenosis, stemming from arthritis of facet joints, ligamentous laxity, and poor muscular stabilization (Kalichman and Hunter, 2008). Degenerative spondylolisthesis occurs mostly at L4 to L5, as opposed to spondylolysis, which occurs at L5 to S1 in approximately 90% of cases (Tallarico et al., 2008).

DIAGNOSIS

The most common complaint is low back pain. This can be exacerbated by activities that stress extension of the spine such as gymnastics or football. In degenerative cases presentation is similar to that of spinal stenosis.

Anteroposterior and lateral plain radiographs are the standard views taken. Oblique views can be added if a pars interarticularis defect is suspected. MRI can be considered for those with persistent symptoms or concerning findings on a neurologic examination. An MRI or bone scan may be useful if there is a need to determine the acuity of a pars fracture. Grading of spondylolisthesis can be done in two ways but is most commonly expressed as a percentage of the AP diameter of the top of the lower vertebrae. Of note, there is some subjectivity in this assessment, so caution is advised when assessing for progression (Kalichman and Hunter, 2008). Low-grade slips are defined as less than 50%, and high-grade slips are greater than 50% (Tallarico et al., 2008).

TREATMENT

The prognosis is excellent in patients with spondylolisthesis caused by a pars defect. Treatment recommendations are variable in this group but depend on age, acuity of the pars defect, level of activity, and degree of impairment. Treatment is based on relative rest from sports with progressive rehabilitation as symptoms decrease. Lumbosacral bracing can be used, especially in the setting of acute pars fractures in younger patients (Tallarico et al., 2008). Bracing is less often done in adult patients but can be used if there are significant symptoms. Surgical treatment is generally reserved for those who have failed conservative care for 6 months. One notable exception is in skeletally immature patients with high-grade vertebral slippage. It is often recommended that these patients undergo fusion because of the risk of further slippage (Tallarico et al., 2008). Return to activity in spondylolysis and spondylolisthesis caused by pars defects is based on improvement of symptoms rather than radiologic improvement. Follow-up is based on age. Whereas patients who are skeletally immature may benefit from serial imaging every 6 months to monitor for progression, those who are near skeletal maturity do not require routine follow-up (Tallarico et al., 2008).

Degenerative spondylolisthesis also has a favorable prognosis, but this often depends on the degree of neurologic symptoms present because of spinal stenosis. Having

neurologic symptoms at baseline is predictive of a poorer prognosis when treated non-surgically (Kalichman and Hunter, 2008). Nonoperative treatment of degenerative spondylolisthesis is similar to that for spinal stenosis and includes progressive aerobic exercise, weight reduction, and analgesic medications. Specific physical therapy modalities that can be of benefit include lumbar bracing, strengthening of back flexor and extensor muscle groups, and back stabilization training (Kalichman and Hunter, 2008). Surgical indications are persistent pain or neurologic deficit that affects quality of life, resistant to conservative care, progressive neurologic deficit, or bowel and bladder symptoms. Of note, progression of slippage does not correlate well to clinical symptoms and is typically not used to guide treatment as much as the clinical presentation (Kalichman and Hunter, 2008).

Vertebral Compression Fractures

Key Points

- Vertebral compression fractures (VCFs) are often identified incidentally and are most commonly asymptomatic.
- They are most commonly caused by osteoporosis but can also be caused by underlying systemic pathology.
- Plain radiographs are the test of choice when a compression fracture is suspected.

Vertebral compression fractures are a common cause of pain and disability, especially in the elderly population. Family physicians play an important role not only in the treatment of recognized fractures but also in prevention of future fractures.

A useful concept when considering the pathophysiology of VCF is the three-column spine theory proposed by Francis Denis in 1983 (Denis, 1983). This concept separates the spine into anterior, middle, and posterior columns by conceptually dividing the vertebral body in half. The anterior column comprises the anterior longitudinal ligament and the anterior half of the vertebral body. The middle column consists of the posterior half of the vertebral body and the posterior longitudinal ligament. The posterior column consists of the pedicles, the facet joints, and the supraspinous ligaments. This concept is significant when assessing the stability of a spinal fracture. If two of the three columns are involved, then the fracture is more likely to be unstable. Most compression fractures are stable because they involve a wedge deformity of the anterior column alone. The middle column remains intact to prevent compression of neural elements (Denis, 1983).

CLINICAL FEATURES

The presentation of VCF is highly variable: most are asymptomatic and identified incidentally (Patel and Shah, 2011). It is estimated that just one third of vertebral fractures are symptomatic (Longo et al., 2012). When they do cause symptoms, there may be a history of minor trauma

preceding the pain, but the event may be as minor as a cough or sneeze. The physical examination may reveal decreased ROM typical of many etiologies of back pain and localized vertebral tenderness but otherwise is not usually helpful in making the diagnosis. An increased kyphosis may also be present, caused by several factors associated with aging. These include a decline in bone mass; weakness of vertebral end plates; and reduction in axial muscle strength, mostly with spinal extension (Sinaki, 2012). These changes can occur with or without vertebral fractures and thus are not helpful in making a diagnosis. The neurologic examination should be normal in an uncomplicated vertebral fracture.

The most common site for fractures is at the thoracolumbar junction. Fractures superior to T7 and those occurring in patients without osteoporosis should prompt further workup to look for potential underlying systemic disease (Patel and Shah, 2011). Possible etiologies include malignancy, hyperparathyroidism, osteomalacia, and tuberculosis.

DIAGNOSIS

As noted, a vertebral fracture should be considered a potential source of back pain in individuals with risk factors for osteoporosis, a prior diagnosis of osteoporosis, or red flags for systemic disease predisposing the patient to vertebral fractures. Given that most patients present without significant trauma, it is appropriate to obtain imaging to make the diagnosis when concern for vertebral fracture exists. If there is concern for a cause other than osteoporosis, a laboratory workup is also appropriate. This can include a complete blood count, erythrocyte sedimentation rate, C-reactive protein, serum calcium, parathyroid hormone, and a vitamin D level. In addition, tuberculosis screening may be indicated.

Plain radiographs are appropriate initial tests when VCF is suspected (Alexandru and So, 2012). Radiographic characteristics of compression fractures include anterior wedging of one or more vertebrae with vertebral collapse, demineralization, and vertebral end-plate irregularity (Patel and Shah, 2011). VCF is defined by a decrease in vertebral height by 20% or at least 4 mm compared with baseline (Longo et al., 2012). Imaging findings that indicate an unstable fracture include loss of greater than 50% of vertebral body height and multiple adjacent compression fractures or failure of two of the three columns. MRI or computed tomograph is appropriate if there is a neurologic abnormality on examination or if there is suspicion for a malignancy-associated vertebral fracture. A bone scan may also be useful if there is concern for malignancy (Longo et al., 2012).

TREATMENT

The overall goals of management include pain control and prevention of further fractures and disability. Treatment options include both conservative measures and interventional methods. Management of acute compression fractures is still controversial, but recent research suggests that an initial trial of conservative treatment is likely most appropriate (Kallmes and Comstock, 2012; Longo et al.,

2012). Common conservative therapies include analgesic medications, bed rest, back braces, and physical therapy.

As with most causes of pain, nonopioid analgesic medications should be used initially. Risks associated with opioids that are especially relevant to the osteoporotic population include falls and constipation. Nasal calcitonin can be used as an adjunct to analgesic medications. It may take up to 2 weeks for optimal pain control but has nearly no side effects or drug interactions (Silverman and Azria, 2002). Physical therapy–based approaches center around rehabilitation of the back extensors (Figure 31-9). This has a role even in the management of acute fractures because isometric exercises of the extensor muscle groups can decrease pain (Sinaki, 2012). For pain that persists beyond 6 weeks despite conservative care, consideration can be given to interventional treatment. Balloon kyphoplasty and vertebroplasty are options for refractory symptoms, but the indications of these procedures are currently not clear. Some studies have shown quicker pain relief with both procedures compared with conservative care, but others have found no improvement in pain and functional measures at 6 months (Anselmetti et al., 2013). Surgical intervention is normally reserved for unstable fractures.

In addition to acute management of vertebral fractures, it is essential for family physicians to address underlying osteoporosis to prevent future fractures. A comprehensive approach to osteoporosis includes regular exercise, adequate calcium and vitamin D intake, smoking cessation, and bisphosphonate medications. Exercise should be considered a standard part of osteoporosis management to improve axial stability. Spinal extensor exercises can decrease the risk of future vertebral fractures even without an increase in bone mass (Sinaki, 2012). In addition, back extensor strength has been correlated to better quality of life in patients with osteoporosis (Sinaki, 2012).

KEY TREATMENT

- Conservative treatments are the appropriate initial approach for the majority of compression fractures and include rest, physical therapy, analgesic medications, and back braces (Kallmes and Comstock, 2012) (SOR: C).
- Nasal calcitonin can be used as a safe adjunctive treatment for pain associated with compression fractures (Silverman and Azria, 2002) (SOR: C).
- Treatment of compression fractures should include a comprehensive treatment of underlying osteoporosis (Wells et al., 2008) (SOR: A).

Myofascial Pain

Myofascial pain is considered a regional pain syndrome caused by myofascial trigger points. Trigger points are discrete, focal, hyperirritable spots located in a taut band of skeletal muscle (Travell and Simons, 1992). The spots are painful on compression and can produce referred pain (Travell and Simons, 1992). Frequently, this is a diagnosis of exclusion, and other pathology, including bone abnormalities, nerve deficits, and inflammatory disorders, should be investigated. Comorbidities should be considered,

including but not limited to depression, anxiety, and central sensitization from a previous or coexisting injury (Travell and Simons, 1992).

Treatment is focused on eliminating factors perpetuating muscular overuse, physical modalities, judicious use of analgesic medicines, and encouraging activity (Alvarez and Rockwell, 2002). Acetaminophen and NSAIDs are good medication choices for periodic use. Symptomatic trigger points can be treated with several modalities such as manual therapies, dry needling, or trigger point injections (Alvarez and Rockwell, 2002). In addition, more integrative approaches should address lifestyle issues such as sleep disturbance, mood disorders, dietary intake, and stress reduction. As with any musculoskeletal disorder, emphasis should be placed on aerobic and specific exercises along with biomechanical approaches to limit exacerbations. This is especially important with chronic pain conditions, defined as pain that lasts more than 3 to 6 months. The ill effects of long-term immobilization and lack of exercise with resultant deconditioning can result in a state that is worse than the original myofascial pain problem.

Chronic Low Back Pain

Key Points

- There are multiple potential pain generators in chronic low back pain, contributing to the difficulty of making a specific diagnosis.
- Chronic back pain is often grouped into mechanical back pain, radicular pain, and pathologic back pain.
- Evaluating for common red flag symptoms helps clinicians efficiently rule out urgent conditions.
- Imaging modalities are not indicated before 6 weeks of back pain symptoms unless red flag symptoms are present.

Chronic low back pain is a very common and costly problem, as well as a source of frustration for both patients and providers. Back pain is by nature a complex problem because of the multiple potential sources of pain, and this complexity is magnified when pain becomes chronic. Having an understanding of this complexity can help guide therapies and provide better patient counseling. Primary care clinicians need to have an approach to caring for patients with chronic back pain. This section expands on the physiologic basis for low back pain, discusses a diagnostic and therapeutic approach, and discusses thoughts on how to use office visits to improve patient care and provider satisfaction.

PHYSIOLOGY

Acute pain is based on nociceptive receptors peripherally at an anatomic site. There are multiple potential pain generators, including the discs, facet joints, sacroiliac joints, ligaments, muscles, and fascia (Salzberg, 2012). In chronic low back pain, there is often increased motion, decreased cushioning, abnormal bone formation, and weakening of

muscles and ligaments, all of which can cause pain to innervated structures. Pain processing occurs in the spinal cord at the dorsal root ganglia and dorsal horn and in the brain at the limbic system, thalamus, and cerebral cortex (Salzberg, 2012).

Chronic pain results in changes to the nervous system such as neuron hyperexcitability, changes in gene expression, and signal amplification to the thalamus. In addition, emotional and psychological changes that take place also color the pain experience (Salzberg, 2012). Taken together, these changes can result in continued pain signals even when there is no further tissue damage. This knowledge is useful clinically because pharmacologic and physical treatments can be focused at different target sites. Possible targets include the peripheral site of pain, the spinal cord, or sites of pain modulation in the brain. In addition, it is important to address the psychological and emotional components because they directly impact pain perception.

DIAGNOSTIC APPROACH

The diagnostic approach to low back pain differs from many other symptoms in that an exact diagnosis is not the end result of most evaluations. Only 15% of patients have a specific identifiable cause of back pain (Manusov, 2012). This has led to multiple classifications systems in attempt to find efficient ways to identify immediate red flag concerns and categorize others with the goal of initiating treatment. There is no evidence that one classification system should be used over another (Manusov, 2012). A commonly used approach is one that was recommended in 2007 by a joint statement from the American College of Physicians and the American Pain Society. It uses the following three categories: nonspecific back pain, radicular pain, and red flag-associated symptoms (see Table 31-2). This and other guidelines have the approach of ruling out tumor, infection, organic causes, and surgical emergencies first and then proceeding with management of mechanical-type back pain.

Early imaging is not indicated unless red flags are present. Advanced imaging, most commonly MRI, may be considered when more invasive treatments are likely but does have downsides. MRI may lead to more surgery without improving outcomes and the “labeling” of a condition that may not in fact fully explain symptoms (Vanwye, 2010).

TREATMENT APPROACH IN PRIMARY CARE

After establishing a working diagnosis of nonspecific or mechanical back pain, developing a therapeutic approach remains challenging. There is a long list of potential therapies from which to choose (see Table 31-6), and symptomatic improvement often does not happen quickly. Physicians need to be comfortable following patients with back pain over the long term, assisting patients with necessary changes, monitoring progress, and dealing with setbacks.

A good place to start is determining the treatment goals. In chronic pain of any type, “curing the pain” is often not a reasonable goal. Consider both patient and provider goals in this process and attempt to agree upon using these goals to judge outcomes because this may improve the therapeutic alliance (Yelland and Schluter, 2006). If a patient is having difficulty with this process, a question to shed light

Table 31-9 Stages of Change

Precontemplation	Not seeing a problem behavior or considering change
Contemplation	Acknowledging a problem but not yet acting to make changes
Preparation	Taking the steps to get ready for change
Action	Making the change
Maintenance	Maintaining the behavior change

on patient values can be, “What do you want your health for?” This may help reframe the discussion, focusing appropriate treatment and outcome goals on what truly matters to the patient.

It may also be helpful at this point to determine how willing a patient is to change any potentially destructive lifestyle habits. Central to the treatment approach is helping the patient become more active and functional, and this often requires changes to existing lifestyle habits, such as increasing physical activity and losing weight. A tool that can be helpful in this assessment is the stages of change model (Table 31-9). This model can help clinicians individualize counseling approaches depending on the patient’s readiness to make necessary lifestyle changes.

After establishing some baseline goals, consider patient preferences in treatment options. A patient-centered approach has become the standard of care and is included in guidelines on management of back pain (National Institute of Health and Clinical Excellence [NICE], 2009). The United Kingdom’s NICE established evidence-based guidelines for treatment of chronic back pain in 2009. The recommended treatment approach is to offer information about self-care in addition to a therapeutic course of physical therapy, manual therapy, or acupuncture. These modalities were judged to have evidence of both clinical and cost effectiveness (NICE, 2009).

The self-care information should include instruction on how to remain active. This likely reduces pain and disability while lowering the number of visits and cost (Vanwyke, 2010). Recommendations should include both rehabilitation exercises specific to the spine and aerobic exercise recommendations. Rehabilitation exercises should progress from passive to more active therapies as the pain moves from acute to more chronic or as the patient progresses and regains function. Aerobic exercise directly impacts a person’s functional status in addition to improving mood and possibly pain perception. Several guidelines may be considered when making aerobic recommendations to patients. One is from the American College of Sports Medicine, which recommends 150 minutes of moderate-intensity exercise per week (Haskell et al., 2007). For patients who are not at this level of exercise, this goal can become part of the treatment plan.

Medication options for nonspecific back pain start with acetaminophen as a first-line recommendation. NSAIDs and weak opioids (such as codeine) are second-line choices. NSAIDs should be cautiously used in elderly patients because of an increased risk of heart disease and renal

Table 31-10 Follow-up Visits for Patients Taking Opioid Medications: Monitoring the Five As

Analgesia

failure (American Geriatrics Society 2012 Beers Criteria Update Expert Panel, 2012). For insufficient pain relief, consider a tricyclic antidepressant (NICE, 2009). Muscle relaxant medications may be useful for the short term but have not been shown helpful in chronic management of low back pain. Anticonvulsant medications such as gabapentin may be indicated for neuropathic pain but do not have evidence of effectiveness in more general musculoskeletal pain (Turk et al., 2011).

Starting opioid medications is a common source of tension for primary care physicians. In general, opioids can be considered as a backup plan when other modalities and medications have failed to give adequate pain relief and pain is still having an impact on function. Risks of opioids include nausea, constipation, sedation, hyperalgesia, misuse, and addiction. Opioids have been shown to improve pain but have not been shown to improve function more than other analgesics (Turk et al., 2011). Because of this lack of functional improvement and several risks associated with its use, the chronic use of opioids remains controversial. It is best to use opioids with defined functional goals in mind, which again should be made mutually with patients. When considering opioid therapies, several tools are available to clinicians to help determine the future risk of medication abuse. Among the most popular are the diagnosis, intractability, risk, and efficacy (DIRE) and the screener and opioid assessment for patients with pain (SOAPP) screening tools. The SOAPP may be more accurate in predicting risk of abuse. If the decision is made to start opioid medications, this can be viewed as a “trial of therapy.” If functional goals are not being achieved, side effects are limiting, or there is evidence of aberrant use, the trial of therapy should be stopped (Table 31-10).

Goals of office visits include monitoring ongoing treatments, monitoring medications for side effects, and helping the patient stay engaged as an active participant in his or her care. One tool that can be useful in this process is the SMART goals (Table 31-11). Helping patients develop attainable goals can assist in behavior changes that are part of their treatment plans and allow for focused discussion in subsequent office visits.

For patients who are worsening or not progressing in terms of function, the first step is reevaluating the diagnosis and making sure no new red flag symptoms are present. Then consideration should be given to a change in therapy, additional workup, or specialist consultation. Reasons for consultation include complex cases with questions about the diagnosis, questions regarding appropriate

Table 31-11 SMART Goals (Using the Example of Wanting to Increase Exercise)

Specific	Walk 15 minutes every day before breakfast (avoid generic goals such as “exercise more”)
Measurable	On a kitchen calendar, track time spent walking for the next month
Attainable	“I currently am able to walk 15 minutes but do so sporadically. Physically, I am able to do this, and it is realistic to wake up 15 minutes earlier.”
Relevant	“Increasing exercise is a vital part of my pain treatment plan.”
Time sensitive	“I will find my tennis shoes today and start walking tomorrow.”

management after a failed treatment course, or when a specific diagnostic or therapeutic procedure is indicated. In addition, consider a psychology referral if a patient has completed one treatment course and still has significant disability or high levels of psychological stress (NICE, 2009).

KEY TREATMENT

- An initial treatment approach should include information on self-care in addition to a course of physical therapy, manual therapy, or acupuncture (Haskell et al., 2008) (SOR: A).

- Self-care information should include instructions on how to best remain active (Haskell et al., 2008) (SOR: A).
- Acetaminophen is the first-line medication choice with NSAIDs and weak opioids being second line. Consider a tricyclic antidepressant for patients with persistent or refractory pain (Haskell et al., 2008) (SOR: A).
- Opioid medications have been shown to improve pain but have not been shown to improve functional measures more than other analgesics (Turk et al., 2011) (SOR: C).

Rheumatic Diseases, 706
Rheumatic Disease in Children, 737
Rheumatology Information on the Internet, 739

Arthritis is the most common health complaint in the United States and a common reason for office visits to family physicians despite the numerous over-the-counter treatments for joint pain and other musculoskeletal problems. In a Centers for Disease Control and Prevention (CDC) National Ambulatory Medical Care Survey, 49 million American adults reported physician-diagnosed arthritis, 21 million of whom reported chronic joint symptoms (Hootman and Helmick, 2006). The 30-year projection rate of patients age 65 and older will increase from 21.4 million to 41.4 million. These statistics lead to 75,000 hospitalizations and 36 million outpatient visits annually.

The term *arthritis* actually applies to more than 180 different disorders, all with pain in or around one or more joints, some with an inflammatory component. Although patients and physicians refer to this collection of diseases as arthritis or “rheumatism,” family physicians must attempt to identify the disease process more precisely because of the many treatments available. Musculoskeletal symptoms might be harbingers of other, serious diseases affecting other organs. Patients should know their prognosis, whether their symptoms will most likely be self-limited, chronic, or progressive.

Rheumatic diseases greatly impact the U.S. health care system and society. Approximately 1% of the U.S. gross national product is spent each year on rheumatic diseases alone. Work absences, lost wages, and long-term disability also impact the quality of life of patient and family. Family physicians must be knowledgeable about new treatment options in the evaluation, assessment, and treatment of these conditions.

Evaluation of Joint and Other Musculoskeletal Symptoms

Precise anatomic localization of pain is the first task of the physician caring for a patient presenting with joint pain while also evaluating stiffness, redness, warmth, or swelling in the absence of trauma. It is important to distinguish pain that is truly articular from *periarticular* pain. Causes of *localized* periarticular pain include bursitis, tendonitis, and

carpal tunnel syndrome; fibromyalgia, polymyalgia rheumatica (PMR), and polymyositis all can cause *diffuse* periarticular pain.

The number of involved joints and presence or absence of symmetry are criteria for further diagnosis of articular pain (Figures 32-1 and 32-2). Monoarticular (one joint) or *oligoarticular* (several joints) arthritides can be caused by conditions such as *osteoarthritis* (OA), gout, pseudogout, or septic arthritis. Asymmetric polyarthritis occurs in ankylosing spondylitis (AS), psoriatic arthritis, Reiter disease, and spondyloarthropathies. *Symmetric* arthritis, meaning that the same joint is affected on the contralateral side but not necessarily to the same degree, is characteristic of *rheumatoid arthritis* (RA), *systemic lupus erythematosus* (SLE), Sjögren syndrome (SS), polymyositis, and scleroderma. Fibromyalgia, reflex sympathetic dystrophy, and predominantly psychological factors must be considered when pain is diffuse, not relatable to specific anatomic structures, or described in vague terms.

Other differentiating criteria include the correlation with activity or rest and the character of the pain. Mechanical causes tend to be more directly related to the joint’s activity than inflammatory conditions. Whereas neuropathies tend to cause burning or prickling sensations, arthritides often cause an aching pain. The presence of joint stiffness after a period of inactivity might also aid in diagnosis; whereas RA is characterized by morning stiffness lasting 30 to 60 minutes or longer, OA-related morning stiffness lasts a shorter period, typically less than 30 minutes, but stiffness might also occur during the day. In neurologic conditions such as Parkinson disease, stiffness might be relatively constant. Vascular pain, such as intermittent claudication, is felt with activity, relieved quickly by rest, and described as a “deep, aching” sensation.

Constitutional symptoms such as fatigue, weakness, malaise, and weight changes are common chief complaints heard in a primary care office practice and often associated symptoms of specific rheumatic diseases. The patient’s functional ability, occupational history, and activities requiring repetitive joint movement, as well as the ergonomics of such activities, should also be considered routinely in initial and serial evaluations. How are the symptoms affecting the patient’s ability to perform self-care

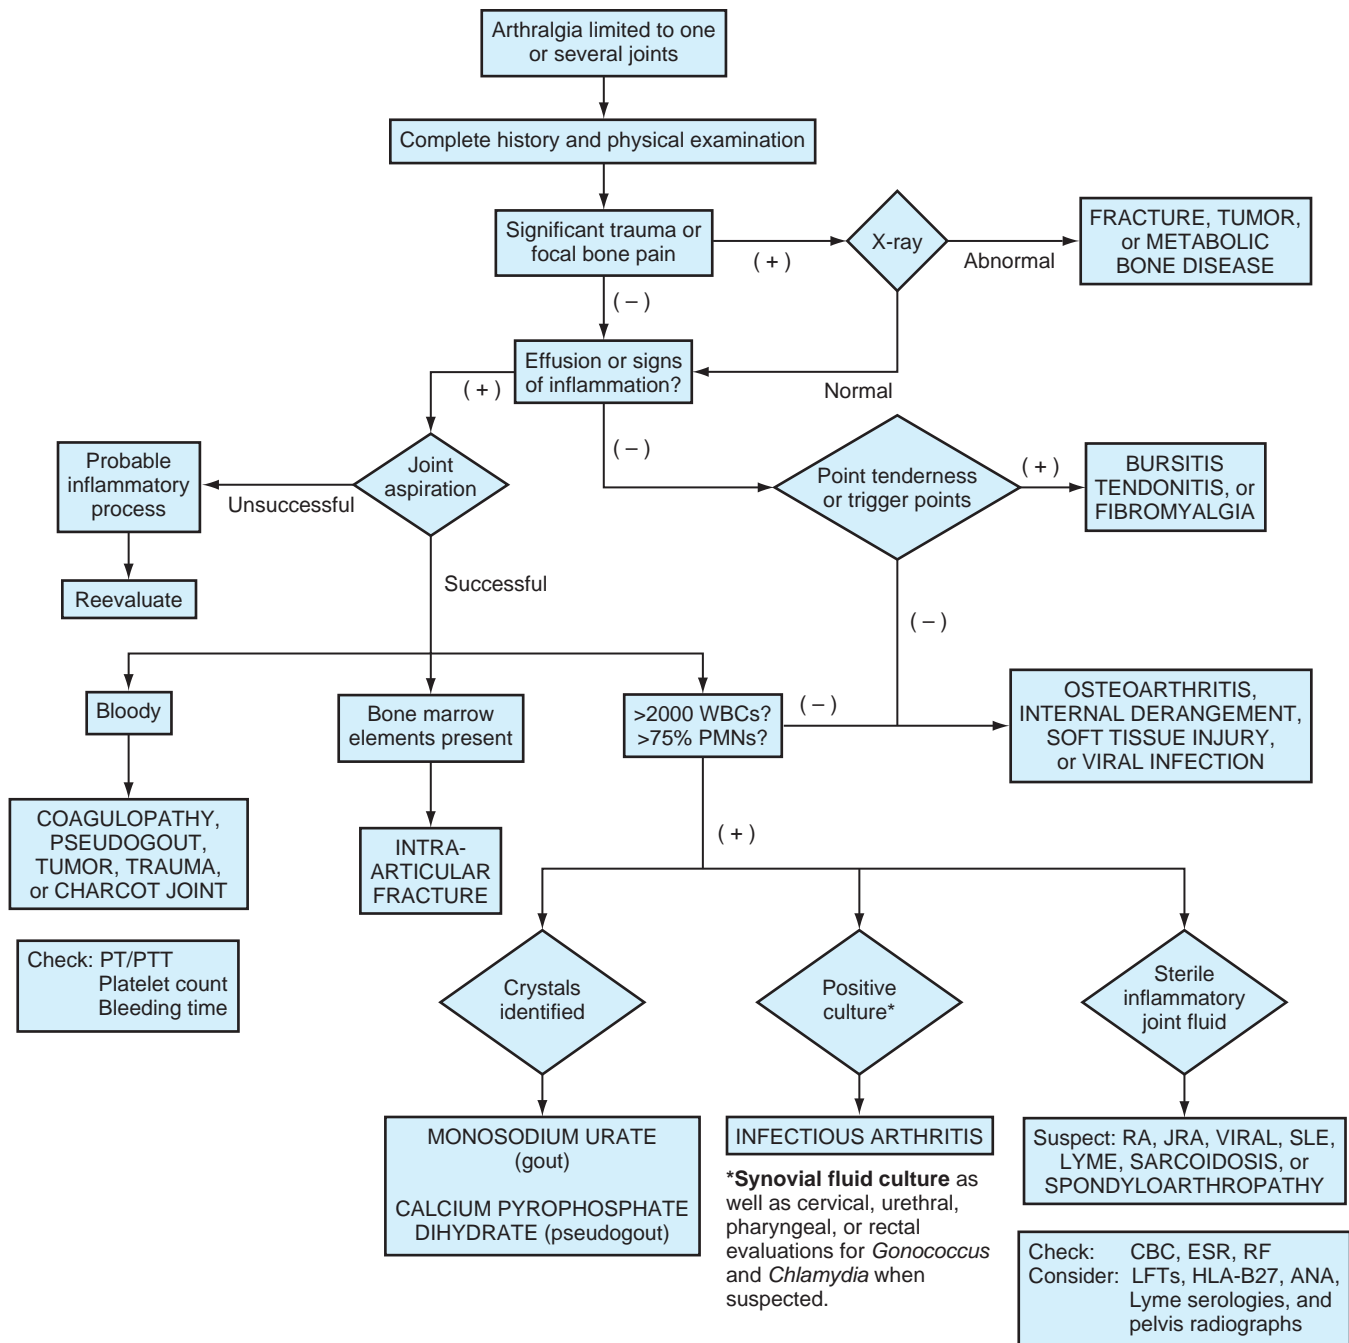

Figure 32-1 Evaluation of monoarticular or pauciarticular symptoms. ANA, Antinuclear antibody; CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; JRA, juvenile rheumatoid arthritis; LFT, liver function test; PMN, polymorphonuclear (leukocyte) neutrophil; PT, prothrombin time; PTT, partial thromboplastin time; RA, rheumatoid arthritis; RF, rheumatoid factor; SLE, systemic lupus erythematosus; WBCs, white blood cells. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum.* 1996;39:1.)

activities of daily living (ADLs) such as bathing, dressing, and eating? Is the patient able to do instrumental activities of daily living (IADLs) such as buying groceries, cooking, using the telephone, and opening jars? Rheumatic disease can have a devastating effect on quality of life for both the patient and the family, with serious psychosocial and economic consequences. Therefore, the physician should address effects on occupational, recreational, and sexual activities in the context of family and other support systems.

PHYSICAL EXAMINATION

A thorough physical examination should be performed on all patients presenting with joint pain, including examination of asymptomatic joints and other organ systems that might be involved. Joints should be examined for swelling, tenderness, deformity, instability, and limitation of motion. Comparisons with the patient's contralateral side can be made in all these parameters, as well as with the physician's

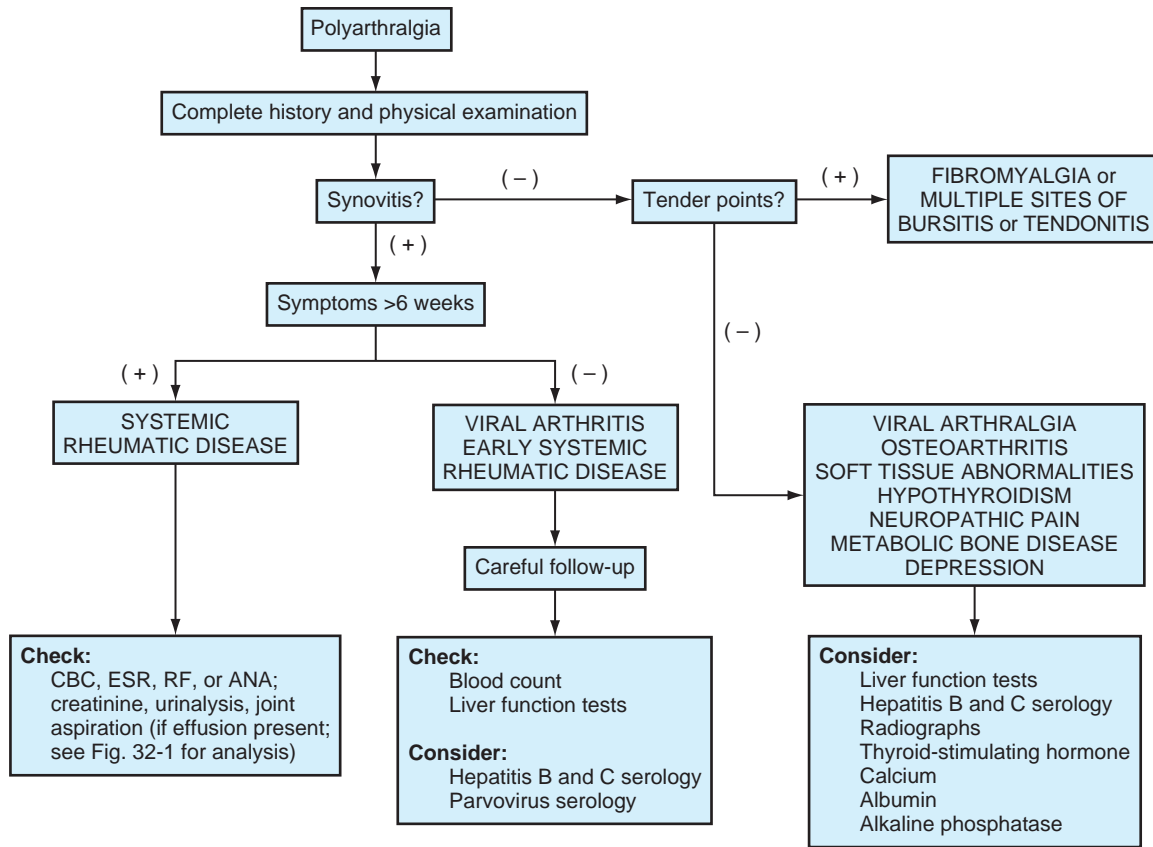

Figure 32-2 Evaluation of polyarthral symptoms. ANA, Antinuclear antibody; CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines: Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum.* 1996;39:1.)

joints as a control. Instability can be tested by moving adjacent bones in the direction opposite to normal movement and observing for greater-than-normal motion. Serial grip strength measurements can be made by asking the patient to squeeze a blood pressure (BP) cuff inflated to 20 mm Hg and recording the maximal grip force in millimeters of mercury. Signs of systemic disease include fever; weight loss; oral or nasal ulcerations; liver, spleen, or lymph node enlargement; neurologic abnormalities; rashes; subcutaneous nodules; eye iritis; conjunctivitis or scleritis; and pericardial or pulmonary rubs. Because of circadian changes in patients with RA, serial comparisons of the physical examination are more accurate if the time of day is also recorded. Using skeleton diagrams of joint involvement facilitates the recording of a comprehensive joint examination (Figure 32-3).

Myalgias can be caused by localized trauma or overuse, systemic infection, metabolic disorder, or primary muscle disease. Multiple tender sites in an otherwise healthy patient suggest fibromyalgia. An elevated creatine kinase (CK) level with proximal weakness may be caused by an inflammatory myopathy such as polymyositis or dermatomyositis.

Rheumatic and other musculoskeletal problems are properly diagnosed by careful history and physical examination rather than by just ordering many laboratory tests, the results of which might actually confuse the diagnosis. Laboratory tests and radiologic imaging help confirm a

Figure 32-3 Skeleton diagram for recording joint examination findings. (From Polley HF, Hunder GG. *Rheumatologic interviewing and physical examination of the joints*. 2nd ed. Philadelphia: Saunders; 1978.)

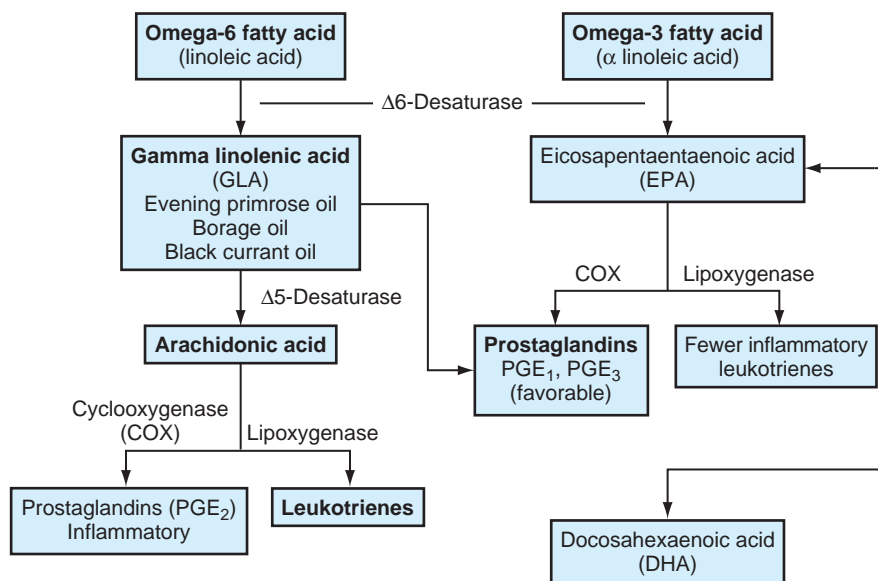

Figure 32-4 Influence of omega-6 fatty acids and omega-3 fatty acids on inflammation. (From Rakel R. *Integrative medicine*. Philadelphia: Saunders-Elsevier; 2007.)

presumptive clinical diagnosis made from a careful history and physical examination.

Pathogenesis of Rheumatic and Other Musculoskeletal Diseases

As with most disease, research into the causes of rheumatologic and musculoskeletal diseases shows that the cause of each disease is actually multifactorial. Further identification of these factors will help the family physician and rheumatologist modify the course of disease and eventually perhaps even prevent them.

Genetic factors have been identified for several arthritides. The presence of the human leukocyte antigen (HLA) system's HLA-DR4 antigen is associated with an increased incidence and severity of RA. The HLA-B27 antigen is found in a higher percentage in patients with AS and other spondyloarthropathies than in the general population. Other factors are apparently involved, however, because its presence or absence neither guarantees nor excludes development of arthritis. Testing for these antigens is not routinely performed. A National Institutes of Health (NIH) study found that genetic factors contributed 39% to 65% of OA variance. About 80% of patients with chondrodysplasia were found to have a type II collagen gene mutation likely linking these findings to OA (Prockop, 1998).

Inborn errors of metabolism are well known to cause diseases such as gout, in which uric acid is overproduced or underexcreted by the kidneys. Poorly controlled metabolic diseases such as diabetes or hemochromatosis might lead to arthropathies. Mechanical or traumatic factors cause OA in soccer players but not in long-distance runners, indicating that the type and direction of joint stress might be more important than the stress itself. Obesity is also an identified factor in OA of the knee, possibly because of metabolic influences as well as mechanical forces (Eaton, 2004).

Infectious agents such as parvovirus B19, human immunodeficiency virus (HIV), *Neisseria gonorrhoeae*, *Borrelia burgdorferi* (Lyme disease), and streptococci (rheumatic fever) are all well-known causes of arthritides. Some speculate that dietary factors might contribute to autoimmune syndromes, and fasting or a vegan diet (or both) can lead to improvement in RA (Kjeldsen-Kragh et al., 1991; McDougall et al., 2002; Smedslund et al., 2010). More specifically, a gluten-free vegan diet can induce changes that are atheroprotective and antiinflammatory in patients with RA (Elkan et al., 2008). The imbalance of omega-6 and omega-3 fatty acids in the standard American diet (a ratio of 30:1, as opposed to the ratio of 1:2 that is thought to have been present in Paleolithic diets) is also postulated to contribute to a more inflammatory state. Whereas omega-6 fatty acids are preferentially converted to more inflammatory prostaglandins such as arachidonic acid, omega-3 fatty acids can be converted into eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which contribute to antiinflammatory series-3 prostaglandin production (Figure 32-4). Omega-3 fatty acids are useful in RA, showing a decrease in use of nonsteroidal antiinflammatory drugs (NSAIDs) and decreased levels of pain (Oh, 2005).

Other medical systems, such as traditional Chinese medicine, may have completely different explanations for the changes seen in rheumatologic conditions. Although a conventional practitioner may not be aware of these, it is helpful to know about complementary modalities that may be beneficial (e.g., acupuncture helping patients with OA and fibromyalgia). See Chapter 12, *Integrative Medicine*.

Laboratory Studies

A complete blood cell count (CBC) with differential, urinalysis, and renal and liver function tests (LFTs) should be performed if asymptomatic rheumatic disease is suspected. Importantly, the frequency of abnormal laboratory results

increases with increasing age in the normal population, even in the absence of disease, including common tests such as erythrocyte sedimentation rate (ESR), uric acid, antinuclear antibodies (ANAs), and rheumatoid factor (RF). Thus, arthritis panels can confuse the situation and should not be performed routinely. For example, only 80% of patients with RA have a positive RF. RF is a serum autoantibody against immunoglobulin G (IgG). Up to 4% of the healthy population has a positive RF, which is also frequently positive in patients with *chronic obstructive pulmonary disease*, viral hepatitis, and sarcoidosis and can also be positive in malignancy and primary biliary cirrhosis and other autoimmune diseases. The higher the RF titer, however, the more likely it is caused by RA. ANA test results are positive in 95% of patients with lupus, and the test is often used to screen for SLE, but the result is also positive in 5% of the normal population. Drug use, age, and other factors might also cause a positive ANA test result. ANA titer also does not correlate exactly with changes in disease activity, so it should not be ordered in the absence of systemic symptoms. A patient with a positive ANA without clinical features is unlikely to have SLE. However, higher titers of ANA make it more likely that the result is related to lupus or another rheumatologic disorder.

Laboratory studies can be helpful in monitoring disease activity and drug toxicity as well as in establishing a diagnosis. CBC can detect anemia secondary to the chronic disease of RA or from NSAID-induced gastrointestinal (GI) blood loss. Patients with SLE can have hemolytic anemia, thrombocytopenia, or lymphopenia. Urinalysis can detect renal disease secondary to SLE, NSAIDs, or disease-modifying antirheumatic drugs (DMARDs) being used to treat RA. An elevated uric acid level can suggest gout. Acute-phase reactants such as ESR and C-reactive protein (CRP) can be useful to monitor disease activity but are non-specific; they can also be negative in the presence of active disease. Patients with temporal arteritis and PMR almost always have a greatly elevated ESR. As a rule of thumb, for men, the upper limit of the normal ESR is age divided by 2; for women, it is age plus 10 divided by 2.

With weakness or muscle pain, CK level should be measured and arthralgias with abnormal liver enzyme levels followed up with hepatitis viral serologies.

Other tests, such as HLA-B27, antineutrophil cytoplasmic antibody, Lyme or parvovirus serologies, myositis-specific antibodies (anti-Jo-1), and antiphospholipid antibodies, are useful only when the clinical suspicion is high for spondyloarthropathies, Wegener granulomatosis, Lyme or parvovirus infection, inflammatory myositis, or antiphospholipid antibody syndrome, respectively ([American College of Rheumatology \[ACR\], 1996](#)).

SYNOVIAL FLUID ANALYSIS

Synovial fluid analysis can be helpful in evaluating a febrile patient with an acute joint to rule out septic arthritis or acute monoarthritis. Synovial fluid should be analyzed for white blood cell (WBC) count differential, cultured, and tested with polarized light microscopy for crystals. Purulent synovial fluid with greater than 90% polymorphonuclear leukocytes (PMNs), low viscosity, and turbid clarity can be caused by infection or crystal arthropathy

Table 32-1 Interpretation of Synovial Fluid Cell Count

Leukocyte Count (WBCs/mm ³)	Interpretation
<200	Normal synovial fluid
<2000	Noninflammatory fluid
>2000	Inflammatory fluid
2000-20,000	Mild inflammation (e.g., SLE)
20,000-50,000	Moderate inflammation (e.g., RA, reactive arthritis)
50,000	Severe inflammation (e.g., sepsis, gout)
>100,000	Sepsis, until proved otherwise

RA, Rheumatoid arthritis; SLE, systemic lupus erythematosus; WBC, white blood cell.

From Towheed TE, Hochberg MC. Acute monoarthritis: a practical approach to assessment and treatment. *Am Fam Physician* 1996;54:2239.

(gout or pseudogout). Urate crystals are needle-shaped and negatively birefringent; calcium pyrophosphate dihydrate crystals are rhomboidal and weakly positively birefringent. Noninflammatory fluids generally have a clear appearance, normal viscosity, fewer than 2000 WBCs/mm³, and less than 75% PMNs ([Table 32-1](#)).

Synovial fluid analysis should always be performed on freshly obtained fluid. A simple bedside test is to attempt to read newsprint through the synovial fluid; newsprint can be read through noninflammatory fluid ([Figure 32-5](#)). Traditional tests on synovial fluid that are of limited or no value include measurement of glucose, lactate, and protein levels; subjective determination of viscosity; mucin clot test (examining the friability of the precipitate formed by mixing synovial fluid with dilute acetic acid); and immunologic tests. When looking for crystals and infection, direct examination, Gram stain, culture, and WBC count with differential are the only tests worth performing on synovial fluid. Inflammatory synovial fluid must be considered secondary to infection until proved otherwise by culture. The presence of crystals in the joint does not exclude the possibility of joint infection.

Synovial biopsy can facilitate a diagnosis in some settings. Arthroscopy has greatly simplified the acquisition of synovial tissue. This might be helpful in the diagnosis of granulomatous disease or infiltrative processes such as lymphoma, metastatic disease, or amyloidosis ([Klippel, 2001](#)).

IMAGING STUDIES

Plain radiographs are still the most common imaging studies done for evaluation and management of rheumatic diseases. Techniques such as magnetic resonance imaging (MRI) and radionuclide scintigraphy (bone scan) are being used more often, but they are costly and often unnecessary. Many arthritides have characteristic radiographic findings, but these techniques are not indicated for most patients with acute and new symptoms of SLE, gout, mechanical lower back pain, or RA because radiographs are usually normal early in the course of the disease. Normal radiographs also do not rule out OA. In established RA, the physician might see periarticular osteoporosis, soft tissue

Figure 32-5 Synovial effusions. **A**, Normal or edema fluid is clear, pale yellow, or colorless. Print is easily read through the tube. **B**, Fluid from noninflammatory joint disease is yellow and clear. **C**, An inflammatory effusion is cloudy and yellow. Print may be blurred or completely obliterated, depending on the number of leukocytes. The effusion is translucent. **D**, A purulent effusion from septic arthritis contains a dense clump that does not even allow light through the many leukocytes. **E**, Hemorrhagic fluid is red. The supernatant may be darker yellow-brown (xanthochromic). A traumatic tap is less uniform and often has blood streaks. (From Schumacher HR. Synovial fluid analysis and synovial biopsy. In Kelley WN, Harris ED, Ruddy S, et al, eds. *Textbook of rheumatology*. 5th ed, vol 1. Philadelphia: Saunders; 1997:609-625.)

swelling, and marginal erosions. Gouty erosions cause characteristic overhanging edges because of reparative changes. (See later in this chapter.)

The severity of radiographic changes in association with severe symptoms can help guide the aggressiveness of treatment. Overreliance on radiographs, however, can lead to undertreatment or overtreatment of disease. Treatment of RA with a DMARD should usually be initiated long before severe radiographic abnormalities are present. The near-ubiquitous presence of osteophytes on the lumbar vertebrae should not be used to justify aggressive surgical treatment for low back pain; on the other hand, many patients with chronic lower back pain have normal lumbar radiographs. Radiographs for acute joint symptoms might be helpful to rule out fractures, metastases, or infection, especially in older patients. If symptoms persist for more than 10 days, the physician should consider repeat radiography, looking for callus formation.

Besides rotator cuff injuries, MRI studies are particularly useful for possible cruciate ligament, complete lateral collateral ligament, and meniscal tears in the knee for potential surgical candidates. Although expensive, MRI shows soft tissue destruction long before plain radiographs. Bone scans also are costly and are nonspecific but demonstrate RA changes before radiographs.

FUNCTIONAL ASSESSMENT

A functional assessment screen is a practical tool for the family physician and takes only minutes (see [eTable 32-1](#) online). Focusing on disease impact on the patient as well as on the patient's joints can be an important contribution by the family physician. Functional assessment helps the primary care physician determine the role of other team physicians (rheumatologist, orthopedic surgeon, physical therapist, occupational therapist, mental health professional). Assessment of function can also lead to a

discussion of disease impact on the family and help them deal with this chronic, possibly progressive condition.

Arthrocentesis

Arthrocentesis is most helpful in diagnosing crystal-induced and septic arthritis. Synovial fluid analysis can also be helpful in ruling out the coexistence of two or more types of arthritis in a single patient and even in a single joint. RA might coexist with a septic joint, secondary OA, hemarthrosis, or calcium pyrophosphate dihydrate (CPPD) disease. Hemarthrosis and bacterial infections usually occur in joints already damaged by arthritis. Arthrocentesis is a simple office procedure that can rule out bacterial infection in an acutely inflamed joint. Untreated or delayed treatment of infectious arthritis can cause rapid joint destruction, necessitating prompt diagnosis. A second line of treatment for RA should generally not be started until crystal arthropathy first has been ruled out. A physician is much more likely to harm a patient by not obtaining synovial fluid analysis when needed to make an accurate diagnosis. This is more common than the relatively rare occurrence of iatrogenic infection (particularly if proper sterile technique is used) or hemarthrosis (usually seen in patients with coagulopathies). The iatrogenic infection rate is generally estimated at one in 10,000, much less common than missed diagnosis of a septic joint. Anticoagulation therapy is not an absolute contraindication in the setting of acute arthritis.

The preferred route of entry for arthrocentesis traverses the shortest distance through tissue and avoids major vessels, tendons, and nerves. The knee, ankle, wrist, and elbow are the easiest joints to aspirate, and aspiration can be performed with only a moderate amount of trauma. Other joints normally require more extensive experience. Sterile technique normally does not require draping, but the same needle should not be used to aspirate the joint and to transfer the aspirated fluid to collection bottles.

eTable 32-1 Functional Assessment Screen

Joint Region	Functional Assessment Maneuver
Upper extremity function	Able to comb hair, feed self, cut meat, button clothes, perform toilet hygiene
Hand	Able to grasp plastic tube 6 to 8 cm in diameter, bend fingers 2 through 5 around a pencil, manage round pincer grip with thumb and index finger, oppose thumb tip to base of fifth finger
Wrist	Flexion and extension, +90 to -80 degrees
Elbow	With elbow at side, can pronate and supinate hand so that thumb rests on table; able to extend extension forearm fully, flex to touch mouth with fingers
Shoulder	Able to grasp hand behind head and behind low back; can identify discrepancy between active and passive ROM to differentiate glenohumeral joint and rotator cuff disorders
Lower extremity function	Able to arise from chair without using arms, ascend and descend stairs without handrail, cross intersection during green light
Hip	Able to cross legs while sitting
Knee	In full extension, able to place heel on opposite knee while seated; with care, able to differentiate effusion, painful inflamed synovium from tissue contractures
Ankles and feet	Able to walk on heels and toes

ROM, Range of motion.

Modified from Klippel JH, ed. *Primer on the rheumatic diseases*. 12th ed. Atlanta: Arthritis Foundation; 2004:117-124. For more information, please call the Arthritis Foundation's information line at 800-283-7800 or log on to www.arthritis.org.

The knee is the easiest joint to aspirate, best done with a medial or lateral approach at the superior third of the patella between it and the femur. Ankle arthrocentesis entry is midline, equidistant from the medial and lateral malleoli. A lateral entry between the olecranon process and the lateral epicondyle is best for the elbow. The shoulder can be approached posteriorly below the posterolateral aspect of the acromion process or anteriorly just lateral to the coracoid process.

A local anesthetic can be used but might distort landmarks; ethyl chloride spray immediately before needle insertion is usually sufficient. An 18-gauge needle is used for the knee and a 20-gauge needle for other joints; only 1 to 5 mL of synovial fluid is needed for diagnostic purposes. Fluid aspiration by itself is often therapeutic because it reduces articular pressure. Cartilage puncture should be avoided, if possible, by inserting the needle only as deeply as needed to obtain fluid, obtaining as much fluid as possible without risking unnecessary trauma by trying to aspirate every last drop, and avoiding side-to-side needle movement.

Therapeutic Corticosteroid Injection. Arthrocentesis can also be a therapeutic technique to deliver local corticosteroid to a joint that has not responded to systemic therapy and after infection has been excluded. Synovial fluid is first aspirated to ensure proper positioning in the joint space followed by 1 to 2 mL of corticosteroid to large joints (knees, hips, shoulders); 0.5 to 1 mL to wrists, elbows, and ankles; and 0.25 to 0.5 mL to small joints and soft tissue sites. A 1:2 dilution with lidocaine can be used to provide instant relief, although many believe lidocaine adds to the risk of infection (e.g., requiring a more complex procedure, changing needles) with limited benefit and therefore do not use it. After injection, the joint should be moved through its passive range of motion (ROM) followed by at least 24 hours of rest. Steroid injections should be limited to no more than three to four times per joint per year because of concerns about possible cartilage and ligamentous damage from repeated injections.

Nonsteroidal Antiinflammatory Drugs. The NSAIDs are among the most frequently prescribed drugs and are used by family physicians for almost all rheumatic and musculoskeletal pain conditions. By suppressing the synthesis of prostaglandins, NSAIDs reduce inflammation and therefore pain but do not prevent tissue injury or joint damage. Cyclooxygenase-2 (COX-2) inhibitors are used for rheumatologic and musculoskeletal pain because of decreased GI side effects. The Vioxx Gastrointestinal Outcomes Research (VIGOR) (Bombardier et al., 2000) and Celecoxib Long-term Arthritis Safety (CLASS) (Silverstein et al., 2000) studies for rofecoxib and celecoxib, respectively, showed that the decreased GI effects outweighed any cardiovascular risk. The Adenomatous Polyp Prevention on Vioxx (APPROVe) study linked rofecoxib (Vioxx) to an increased risk of cardiovascular disease (Bresalier et al., 2005). The Alzheimer's Disease Anti-Inflammatory Prevention Trial (ADAPT) study compared celecoxib (Celebrex) and naproxen (Naprosyn, Aleve) in Alzheimer disease prevention and was stopped secondary to a 50% increase in cardiovascular events in subjects not taking placebo (NIH, 2004). Overall, COX-2 inhibitors have produced minimal decrease in GI bleeding and thus should be used cautiously for

rheumatologic and musculoskeletal pain because the cardiovascular risk outweighs the GI benefit. Currently, celecoxib has a "black box" warning; rofecoxib was removed from the market.

Patients respond to different classes of NSAIDs for unknown reasons, and no NSAID appears superior to others in efficacy. Treatment is largely empiric. Most clinicians start with a low dose and titrate upward if needed. An adequate trial of an NSAID requires that the patient take a maximum dose for 3 weeks before changing to a different NSAID, although many patients will expect a change in medication before this. It is usually best to switch to an NSAID from a different class. There is no benefit to combining nonsalicylate NSAIDs. All COX-1 NSAIDs can cause dyspepsia and GI toxicity, interfere with platelet function, and prolong bleeding times. Other common side effects include renal toxicity; hypertension; and central nervous system (CNS) symptoms such as drowsiness, dizziness, and confusion. A 2004 Cochrane review of NSAIDs for lower back pain concluded that the various types of NSAIDs (e.g., COX-2 inhibitors) are equally effective, and selection of an NSAID for OA should be based on relative safety and patient acceptability.

Combining NSAIDs with misoprostol (Cytotec), 100 to 200 mg four times daily with meals, or omeprazole (Prilosec), 20 mg/day (Hawkey et al., 1998) has been shown to decrease the incidence of gastric and duodenal ulcers. But combining with proton pump inhibitors (PPIs) for prolonged periods of time can interfere with absorption of other nutrients, including B vitamins, iron, magnesium, and calcium, which can lead to neuropathy, anemia, arrhythmia, and fracture (Wilhelm et al., 2013). A meta-analysis of 112 randomized controlled trials (RCTs) found no evidence supporting the effectiveness of H₂ receptor antagonists, while the risk of symptomatic ulcers was significantly reduced by PPIs, misoprostol, and COX-2 inhibitors (Koch et al., 1996). Omeprazole and other PPIs are better tolerated than misoprostol and famotidine (Hawkey et al., 1998). The physician should monitor for decreased renal function, interaction with antihypertensives, and transaminase (alanine aminotransferase [ALT], aspartate transaminase [AST]) elevations when starting NSAID therapy or increasing dosage or when the patient's condition changes.

A common issue for the family physician is whether a patient prescribed aspirin for cardiac prophylaxis needs to stop the aspirin when prescribed a traditional NSAID. Patients taking both do not appear to be at significantly increased risk of GI toxicity. However, the aspirin might not yield any additional cardioprotective benefit because these patients already benefit from the traditional nonselective NSAID antiplatelet effect. If taking both aspirin and NSAID, it is best to take the aspirin at least 4 hours before the NSAID for its full protective effect.

ARTHRITIS OF SYSTEMIC DISEASE

Arthritis can be a component of many systemic diseases, including metabolic disorders; infections; malignancies; and various endocrine, hematologic, and GI diseases. Parvovirus B19 is responsible for erythema infectiosum and can also cause polyarthritis, especially in the hands, knees, and ankles. HIV infection sometimes causes symmetric polyarthritis, spondylitis, or acute oligoarthritis. Hepatitis B

and C can cause acute symmetric polyarthritis in large and small joints. Inflammation in a few large joints and back pain are among the earliest symptoms of infective endocarditis in about 25% of patients with this disorder (Totemchokchyakarn and Ball, 1996).

Lyme arthritis caused by *B. burgdorferi* can cause migratory monoarthritis or oligoarthritis in the knees or shoulders weeks to months after the rash of erythema chronicum migrans has developed. Poorly controlled *diabetes* (affecting foot, ankle, and knee), *hyperthyroidism* (affecting fingers and toes), *hypothyroidism* (causing noninflammatory effusions in knees, wrists, and hands), and *parathyroid disease* (causing chondrocalcinosis) are all endocrine disorders that can cause arthritis.

Metabolic disorders can cause degenerative arthritis. *Hemochromatosis* (caused by iron deposition) typically affects the second and third metacarpophalangeal (MCP) joints, wrists, knees, hips, and shoulders. *Wilson disease* (caused by copper deposition) can cause premature OA in wrists and knees. Sick cell disease can be complicated by knee arthritis; arthritis is also often seen in patients with hemophilia and leukemia. Arthritis is associated with inflammatory bowel disease (IBD) and primary biliary cirrhosis. Reactive carcinoma synovitis can be the presenting symptom of an underlying malignancy, particularly of the breast or the prostate.

REFERRAL TO THE RHEUMATOLOGIST

As for all types of disease conditions, referral to the subspecialist largely depends on the family physician's knowledge, interest level, and logistical ability to provide state-of-the-art care to a given patient for a given disease entity at a given time in the disease course. Patients with specific conditions, such as suspected septic arthritis, acute myelopathy or mononeuritis multiplex, suspected acute tendon or muscle rupture, or acute internal derangement, should probably be referred. In addition, referral should be considered for patients without a specific diagnosis after 6 weeks; those with difficulty in symptom control, systemic symptoms in pregnancy, or severe symptoms; patients requiring steroid, immunosuppressive, or other drugs unfamiliar to the primary care physician; and those with end-stage joint disease. The often nonspecific nature and psychosocial impact of rheumatic symptoms require continued active involvement of the family physician in the patient's care, regardless of referral.

Rheumatic Diseases

OSTEOARTHRITIS

Key Points

- OA affects 20% of the U.S. population; 44% of OA patients are not active.
- Primary and secondary OA must be differentiated.
- NSAIDs, not COX-2 inhibitors, are still the pharmacologic treatment of choice for OA.

Osteoarthritis, also known as “degenerative joint disease,” is the most common form of arthritis and causes more work disability in the United States (17%) than any other disease. Arthritis affects 20% of the U.S. population, about half of whom primarily have OA. In 2005, it was estimated that 27 million Americans had OA (Lawrence et al., 2008). Long thought to result from “wear and tear,” OA is now known to have genetic, traumatic, metabolic, and developmental causes, which complicate prevention and treatment. OA is found radiographically in almost all 75-year-old patients, most of whom are asymptomatic. OA occurs about equally in men and women ages 45 to 55 years, but after 55 years is more common in women (CDC, 2005). Most patients with OA are not seriously affected and are asymptomatic. Others, however, require joint replacement surgery because of its severity.

Although OA is considered a noninflammatory type of arthritis affecting primarily the cartilage, it actually involves active biochemical disease processes as well as mechanical forces that affect the entire synovial joint. An OA variant affecting primarily the hands runs in families and is inflammatory. Women are more prone to this inflammatory variant of OA of the hands that causes Heberden nodes (in distal interphalangeal [DIP] joints) and Bouchard nodes (in proximal interphalangeal [PIP] joints). The articular cartilage may not even be involved, with the disease process centered more on subchondral bone turnover (Peterson et al., 1998). Quadriceps muscle weakness might precede the onset of knee OA, indicating the importance of biomechanical factors (Slemenda et al., 1997).

Osteoarthritis can be separated into primary (idiopathic), hereditary (resulting from collagen gene defects), and secondary. Secondary OA results from previous cartilage damage. Occupations causing repetitive joint trauma predispose a patient to OA. Episodic trauma, congenital anatomic abnormalities (slipped capital femoral epiphyses, congenital hip dysplasias), neuropathies, and endocrine-metabolic causes (obesity, hemochromatosis, Wilson disease, CPPD disease, Paget disease, acromegaly) all might lead to OA. Inflammatory arthritides such as RA, infections, or gout damage cartilage and are often followed by the development of OA.

Occupational kneelers (e.g., shipyard workers, miners, carpet or floor layers) have a significantly higher incidence of knee OA than control groups of clerical workers (Maetzel et al., 1997). However, repetitive sports activities such as long-distance running are unlikely to cause OA in the absence of joint injury or antecedent joint abnormality (Panush and Lane, 1994). More than 44% of patients with diagnosed OA are inactive (Gordon et al., 1998). Low-impact activity in normal joints is not associated with OA, but high-intensity and high-impact activity resulting in injury is associated with OA. Mechanical risk factors might affect the initiation more than the progression of OA. Most mild OA does not progress to severe joint damage. Mild OA might be a different disease than severe OA, which depends on processes other than early OA.

Clinical Findings

Most OA is asymptomatic, an incidental finding on radiographs performed for other reasons. No treatment or further evaluation is indicated for asymptomatic OA. Early

symptomatic OA is characterized by local pain of gradual onset exacerbated by using the involved joint. Pain typically worsens as the day progresses and is relieved by rest. There is less than 30 minutes of localized morning stiffness and no constitutional or systemic symptoms, and the gel phenomenon (stiffness after periods of rest and inactivity) resolves within several minutes of activity. Damp, cool, rainy weather often exacerbates symptoms because of changes in intraarticular pressure associated with changes in barometric pressure. Patients with OA of the knees might complain of buckling or instability, especially when descending stairs. OA of the hip can manifest as pain radiating from the groin and down the anterior thigh. OA of the neck might be felt in the neck, back, or upper extremities, causing pain, weakness, or numbness. As OA progresses, pain can become continuous, including at night.

Primary OA can be divided into three classifications: generalized OA, large-joint OA, and erosive OA. *Generalized* OA involves five or more joints, most often the DIP joints of the hand (Herberden nodes), the PIP joints of the hand (Bouchard nodes), the first carpometacarpal joint, the first MTP joint of the feet, and the knee, hip, and spine. There is a significant familial component. *Large-joint* OA of the knees and hips might occur as part of generalized OA or alone. OA of the knees often occurs in the medial and patellofemoral compartments. OA of the hips can be characterized in two subsets, central and superior poles. Central or medial involvement of the hip joint space occurs in the setting of generalized OA, is usually bilateral, and is seen in women more than men. Most hip OA is superior pole, usually unilateral, seen more in men, and occurs without other joint involvement. As many as 40% to 90% of cases of adult hip OA might arise from subtle developmental abnormalities of the hip, including acetabular dysplasia, developmental (formerly “congenital”) hip dislocation, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis (Brandt and Slemenda, 2004).

A rare form of primary OA known as *erosive OA* involves the hand’s PIP and DIP joints equally, with significant inflammation. Other joints are often not involved, although 15% of erosive OA cases might subsequently evolve into seropositive RA (Kujala et al., 1995).

Physical Findings

Physical findings of OA typically include joint swelling, tenderness, crepitus, and enlargements at joint margins, causing deformity. The location of pain should be precisely localized as to whether it is truly articular or periarticular; if pain is located in the joint, an inflammatory or infectious cause should be ruled out first. Patients might have reduced ROM or, in severe cases, joint instability, resulting in excess motion or locking because of loose cartilage fragments. Warmth and soft tissue swelling because of joint effusion might be present, but a markedly swollen, hot, erythematous joint suggests a septic or microcrystalline disease rather than OA.

Laboratory Studies

Clinical study criteria for OA classification are helpful as a means to standardize the diagnosis (see eTables 32-2 and 32-3 online). Although the diagnosis of OA can almost always be made by history and physical examination,

Table 32-2 Criteria for Classification of Idiopathic Osteoarthritis of the Knee

Clinical and Laboratory	Clinical and Radiographic	Clinical*
Knee pain <i>plus</i> at least five of nine: Age >50 yr Stiffness <30 min Crepitus Bony tenderness Bony enlargement No palpable warmth ESR <40 mm/hr RF <1:40 SFOA	Knee pain <i>plus</i> at least one of three: Age >50 yr Stiffness <30 min Crepitus <i>plus</i> Osteophytes	Knee pain <i>plus</i> at least three of six: Age >50 yr Stiffness <30 min Crepitus Bony tenderness Bony enlargement No palpable warmth
92% sensitive 75% specific	91% sensitive 86% specific	95% sensitive 69% specific

ESR, Erythrocyte sedimentation rate (Westergren); RF, rheumatoid factor; SFOA, synovial fluid signs of OA (clear, viscous, or white blood cell count <2000/mm³).

*Alternative for the clinical category would be four of six, which is 84% sensitive and 89% specific.

From Altman R, Asch E, Bloch G, et al. Development of criteria for the classification and reporting of osteoarthritis: classification of osteoarthritis of the knee. *Arthritis Rheum.* 1986;29:1039-1049, with permission of the American College of Rheumatology.

definitive diagnosis can be helped by synovial fluid analysis; radiography; and normal ESR, ANA, and RF during symptomatic periods. Synovial fluid analysis of large-joint effusions can be used to exclude other processes. Joint effusions in OA typically show leukocyte counts lower than 1000 WBCs/mm³, predominantly lymphocytes (Table 32-2). Serum tests might be misleading because ESR rises with age, and 20% of healthy older adults have positive RF levels. A greatly elevated ESR suggests a process other than OA. Although many have been identified, biochemical markers of OA are not generally useful to practicing clinicians at this time.

Imaging Studies

Radiographs are generally the first-line confirmation of the presence of OA. Treatment should not be based solely on radiographic abnormalities, however, given the frequency of asymptomatic joints demonstrating radiographic OA changes. OA changes include osteophyte formation, asymmetric joint space narrowing (defined as <3 mm on a weight-bearing knee), and subchondral bone sclerosis (Figures 32-6 and 32-7). Later in the disease process, subchondral cysts with sclerotic walls might develop. Periarticular osteoporosis and marginal erosions suggest RA or some other inflammatory arthritis rather than OA. Patients with OA involving atypical joints (MCP joints, wrists, elbows, shoulders, or ankles) should be evaluated for an underlying disorder such as CPPD or hemochromatosis.

Treatment

Treatment of OA includes pharmacologic therapy, non-pharmacologic therapy, and surgery. Before initiating treatment, a definitive diagnosis of OA must be made by careful history and physical examination. No currently available treatment has been shown to alter the natural history of

the disease. Therefore, the goal of management of OA is primarily to relieve pain, stiffness, and swelling. The physician seeks to reduce limitation of motion and disability without causing iatrogenic side effects. Patients and their families must also be educated about the disease and their treatment options (Table 32-3).

Nonpharmacologic therapy includes rest during pain episodes, exercise, weight control, avoidance of trauma, patient and family education, and assistive devices. The

Figure 32-6 Osteoarthritis in the hand. (From Resnick D, Yu JS, Sartoris D. Imaging. In Kelley WN Harris ED, Ruddy S, et al, eds. *Textbook of rheumatology*. 5th ed, vol 1. Philadelphia: Saunders; 1997:626-686.)

patient's ability to perform both self-care ADLs and IADLs requiring higher functioning (e.g., shopping, driving, writing) should be assessed. Physical and occupational therapists can provide great benefit by offering an exercise program and assistive devices to maintain independence and minimize symptoms (Fransen et al., 2001). Patients benefit from the use of canes, walkers, bathtub and toilet wall bars, and dressing sticks for socks and from the other methods of joint protection and symptom relief, such as heat massage. Rest is important for patients with acute pain. Otherwise, helpful exercise programs include swimming, other aerobic conditioning, and walking (van Baar et al., 1999). Weight control and weight reduction have also been shown to improve symptoms (Messier et al., 2004).

Table 32-3 Options in the Management of Patients with Osteoarthritis

Nonpharmacologic therapy	<ul style="list-style-type: none"> • Patient education and self-management programs • Social support through telephone contact • Physical and occupational therapy • ROM and strengthening exercises • Aerobic conditioning • Weight loss • Assistive devices for ambulation and activities of daily living
Pharmacologic therapy	<ul style="list-style-type: none"> • Oral nonopioid analgesics (e.g., acetaminophen) • Topical analgesics (e.g., capsaicin cream) • NSAIDs • Intraarticular steroid injections • Opioid analgesics
Surgical therapy	<ul style="list-style-type: none"> • Closed tidal joint lavage • Arthroscopic debridement and joint lavage • Osteotomy • Total joint arthroplasty

(From Resnick D, Yu JS, Sartoris D. Imaging. In Kelley WN Harris ED, Ruddy S, et al, eds. *Textbook of rheumatology*. 5th ed, vol 1. Philadelphia: Saunders; 1997:626-686.)

First-line pharmacologic therapies for symptom control include acetaminophen, up to 1000 mg four times daily in the absence of liver disease, and traditional NSAIDs, beginning with ibuprofen. Because few RCTs studied differences in efficacy of NSAIDs, the initial choice is empiric. Therefore, relative safety, patient adherence, and cost should determine selection. Risk factors for upper GI bleeding with NSAIDs include age older than 65 years, history of peptic ulcer disease or upper GI bleeding, concurrent use of oral corticosteroids and anticoagulants, and possibly smoking and alcohol consumption. Evidence suggests that NSAIDs are superior to acetaminophen for improving knee and hip pain from OA. No significant difference in overall safety was found, although patients taking NSAIDs were more likely to experience an adverse GI event (Towhead et al., 2006). Particular care must be taken with use among geriatric patients because several studies have shown increased hospital admissions caused by NSAID-related complications in this population (Liantonio and Simmons, 2013). Capsaicin (Zostrix) topical cream four times daily, formerly a first-line agent, now has been shown to have minimal benefit, especially when considering side effects that impair compliance (Mason et al., 2004). Combination therapy (NSAIDs with analgesics) may also be helpful. The addition of tramadol (Ultram, 200 mg/day) in patients responding to 1000 mg/day of naproxen has been shown to allow a significant reduction (by half) in the naproxen dose needed without compromising pain relief (Schnitzer et al., 1999).

Currently, NSAIDs plus a PPI such as omeprazole remain the treatment of choice for prevention of NSAID-induced gastric ulcers. Opioid analgesics and limited intraarticular corticosteroid injections (up to 4 injections per joint per year) are the remaining traditional choices. Opiates should generally be avoided for long-term use but might be helpful for acute exacerbations.

Intraarticular glucocorticoids are often used and are particularly useful in patients with contraindications or continued pain despite NSAIDs. This modality is postulated to work by decreasing cartilage catabolism and osteophyte formation. A meta-analysis found that patients receiving intraarticular steroid injections for OA of the knee were twice as likely to have short-term improvement as control participants (Arroll et al., 2004). Data on injection of the hip and knee joint show the most promise, but efficacy at other sites is less certain. Aseptic technique should be used to prevent iatrogenic complications of infection. Patients should be counseled on postinjection complications such as bleeding, infection, skin hypopigmentation, fat necrosis, and steroid flare.

Because OA is a common incurable disease that causes pain, many other treatments, including dietary supplements and other alternative therapies, have been tried for centuries. Balanced hormone therapy, copper bracelets, bee venom, vitamins, herbs, homeopathic remedies, and certain types of foods are promoted as effective treatments or cures for OA. Family physicians should be aware of proven and unproven remedies used by their patients. One therapy shown to be efficacious is glucosamine sulfate.

Glucosamine and chondroitin sulfates both stimulate the production of proteoglycan in cartilage and inhibit its breakdown. Over-the-counter formulations vary in the amount of glucosamine (made from crab shells) and

chondroitin (processed from cow cartilage). Research has shown that patients have moderately benefited from glucosamine and chondroitin supplements over 3 years with less knee joint space narrowing on radiography, significant reduction of symptoms, and no adverse effects (Richy et al., 2003; Sherman et al., 2012). The major studies of glucosamine used two different formulations of the supplement, which yielded different results: the sulfate and HCL formulations. A 2005 Cochrane review found that whereas the glucosamine HCL preparation failed to show benefit in pain and function, the glucosamine sulfate preparation showed that glucosamine was superior to placebo in the treatment of pain and functional impairment resulting from symptomatic OA. Studies for chondroitin are less convincing, with no consistent improvement in pain or functional status (Ebell, 2006) except for possibly hand OA (Erickson and Messer, 2013; Reginster, 2012), although a more recent study comparing glucosamine sulfate to HCL found no difference between the two formulations (Provenza et al., 2014). The safest daily intake is 1500 mg/day of glucosamine sulfate and 1200 mg/day of chondroitin. Most capsules containing both minerals are also formulated with manganese, theorized to assist in proteoglycan metabolism but not studied (Richy et al., 2003).

A meta-analysis of 11 studies found that S-adenosylmethionine (SAME) was as effective as NSAIDs at reducing pain and functional limitations, with a somewhat better adverse effect profile (Soeken et al., 2002). This is a stimulating supplement and should not be used at bedtime due to potential insomnia.

A Cochrane review of herbal therapies for OA found two studies demonstrating that avocado-soybean unsaponifiables showed beneficial effects on function, pain, intake of NSAIDs, and global evaluation (Little et al., 2000). Another beneficial intervention is transcutaneous electrical nerve stimulation (TENS) for OA of the knee; electrical stimulation has been shown to improve knee OA moderately by 25% and cervical OA by 12% (Osiri et al., 2004).

Studies comparing acupuncture with a sham control found greater improvement in those receiving the actual treatment (Berman et al., 2004; Ezzo et al., 2001; Vas et al., 2004). A meta-analysis found that acupuncture was more effective than placebo in pain reduction in peripheral OA (Kwon et al., 2006). Two studies found that therapeutic touch, an energy modality, showed benefit in OA (Gordon et al., 1998). Although previously cited as beneficial for OA secondary to antioxidants, the literature reports an increased risk of cardiovascular disease with vitamins C and E (Alkhenizan and Palda, 2003).

Other, less traditional therapies have received much media attention but have not shown effectiveness. Cycles of three or more weekly intra-articular injections of hyaluronic acid (viscous substance in synovial fluid that lubricates and protects joints) have been used, with partial success (Abramowicz, 1998a). Hyaluronate sodium (Hyalgan) and hylan G-F 20 (Synvisc) are approved by the Food and Drug Administration (FDA) for OA of the knee. Onset of pain relief can take several weeks and can last for 6 months or longer. Meta-analyses of hyaluronic acid have shown minimal effectiveness versus placebo. The cost-to-benefit ratio favors therapies other than joint injection (Lo et al., 2003).

KEY TREATMENT

- Treatment of OA begins with nonpharmacologic modalities, including weight loss (Messier et al., 2004), physical therapy (Fransen et al., 2001), exercise (van Baar et al., 1999), and orthotics if needed (SOR: A).
- Acetaminophen and NSAIDs are both first-line pharmacotherapy for pain associated with OA, although NSAIDs appear to be more effective (Towhead et al., 2006) (SOR: A).
- Intraarticular glucocorticoids show short-term improvement in pain associated with OA of the hip and knee (Arroll et al., 2004) (SOR: B).
- Treatments such as Synvisc (Lo et al., 2003), glucosamine (Richy et al., 2003), and acupuncture (Kwon et al., 2006) are often used for OA relief before surgical measures (SOR: B).

RHEUMATOID ARTHRITIS**Key Points**

- RA affects women 3 : 1 more than men, with 70% having an insidious onset.
- Symmetric synovitis with morning stiffness longer than 1 hour is the hallmark of RA.
- Constitutional symptoms are common in patients with RA.

Rheumatoid arthritis is a chronic inflammatory systemic disease in which cellular and autoimmune mechanisms result in destruction of tissues, primarily the synovium. A genetic predisposition appears to be important, but a specific inciting infectious agent or other cause has still not been found. RA manifestations vary from very mild, self-limited disease to multiorgan destruction and early death. Increasing knowledge of the modulating factors in disease progression is transforming the treatment of RA. Without treatment, the normally fluctuating disease course results in progressive joint destruction. Patients with active, polyarticular, RF-positive RA have more than a 70% chance of developing joint damage or erosion within 2 years (Fuchs et al., 1989). Because RA is relatively uncommon compared with OA and is now treated quite differently, the family physician must be able to make the correct diagnosis and initiate disease-modifying therapy early, before joint destruction.

Epidemiology

Rheumatoid arthritis affects women more frequently than men ($\approx 3 : 1$ ratio) and occurs in all age groups but has a peak incidence between 20 and 50 years. The prevalence is 1% to 2% of adults, ranging from 0.3% of the population younger than age 35 years to about 10% of those older than age 65 years. There is a higher concordance of RA in monozygotic twins than in dizygotic twins because of gender differences and differences in major histocompatibility complex (MHC) class II gene products (HLA-DR). Combinations of different genes most likely predispose patients to the disease. The HLA-DR antigen appears to be

triggered by many stimuli. After this inciting event, the synovial lining cells and subsynovial vessels proliferate, forming a pannus. Leukocytes invade, followed by a further inflammatory cascade involving proteases and cytokines. RF produces autoantibodies to IgG Fc fragment, influenced by HLA-DR polymorphism and associated with more severe, extraarticular disease. Again, RF is not specific to RA and can be detected in normal persons.

Diagnosis

Rheumatoid arthritis is a clinical diagnosis made by careful history and physical examination. Laboratory testing can be confirmatory but is also misleading if not interpreted in context. Radiographic evidence of erosions appears only several months to 1 year after disease onset. The ACR published useful criteria in 1987 for the diagnosis of RA (Table 32-4). Symptoms must be present for at least 6 weeks for the initial diagnosis.

Symmetric synovitis is the hallmark of RA and can be suggested by joint aspiration of synovial fluid, yielding more than 2000 WBCs/mm³ without crystal or by radiographic evidence of erosions. Because the cause of synovitis cannot be differentiated clinically, extraarticular manifestations can help distinguish RA from other inflammatory conditions.

Table 32-4 American College of Rheumatology Revised Criteria for Classification of Rheumatoid Arthritis (Traditional Format)

Criterion*	Definition
1. Morning stiffness	Morning stiffness in and around the joints lasting at least 1 hour before maximal improvement
2. Arthritis of three or more joint areas	At least three joint areas with simultaneous soft tissue swelling or fluid (not bony overgrowth alone) observed by physician. The 14 possible joint areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints.
3. Arthritis of hand joints	At least one joint area swollen as above in a wrist, MCP, or PIP joint
4. Symmetric arthritis	Simultaneous involvement of the same joint areas on both sides of the body; bilateral involvement of PIP, MCP, or MTP joints is acceptable without absolute symmetry.
5. Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces or juxtaarticular nodules regions, observed by physician
6. Serum rheumatoid factor	Demonstration of abnormal amounts of serum RF by any method that has been positive in fewer than 5% of normal control participants
7. Radiologic changes	Radiologic changes typical of RA on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized to, or most marked adjacent to, the involved joints (osteoarthritis changes alone do not qualify)

*Four or more criteria are needed for the diagnosis of rheumatoid arthritis (RA). Criteria 1 through 4 must be present for 6 weeks or longer. The presence of criteria is not conclusive evidence for the diagnosis of RA. The absence of criteria is not conclusively negative.

MCP, Metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; RF, rheumatoid factor.

From Arnett FC. Revised criteria for the classification of rheumatoid arthritis. *Bull Rheum Dis*. 1989;38:1. Used with permission.

History

Approximately 70% of patients with RA experience an insidious onset over weeks to months, 10% have an acute abrupt onset, and 20% have an intermediate onset, with increasing symptoms for days to weeks. Morning stiffness occurring for more than 1 hour is suggestive of RA. Morning stiffness results from joint immobilization during sleep and is not related to the time of day. As opposed to patients with OA, patients with RA have constitutional symptoms such as fatigue, malaise, weight loss, low-grade fever, and anemia. Small joints in the hands and feet (PIP, MCP) are typically involved first, with larger joints involved later. The joints themselves might be warm to the touch but are usually not erythematous. A pannus of inflamed synovium palpable as a rubbery mass of tissue strongly suggests RA.

The presentation of exacerbations of chronic rheumatoid synovitis might differ from those of early acute synovitis. Chronic inflammation causing fibrosis decreases synovial vascularity, reducing the amount of swelling from previous episodes. Although the frank swelling of burned-out RA appears less severe, the amount of pain, morning stiffness, constitutional symptoms (fatigue, malaise), and joint destruction on radiography shows this physical finding to be misleading. These episodes in patients with chronic, long-term RA should therefore not be considered improvement over more visible, earlier episodes of synovitis.

Less common presentations of RA include acute onset (which has the best prognosis) and palindromic RA, which is characterized by brief episodes of swelling of a large joint such as a knee, wrist, or ankle. Palindromic RA can therefore be easily misdiagnosed as gout.

Approximately 20% of patients with RA have intermittent symptoms. The rest have progressive disease of varying severity from slow to rapid progressive. In addition to morning stiffness, synovitis, and structural damage, RA exhibits classic manifestations in specific joints. Whereas cervical spine involvement is common, thoracic and lumbar spine involvement is rare. Early symptoms are neck stiffness and decreased motion, which can lead to neurologic complications from C1 to C2 instability resulting from tenosynovitis of the transverse ligament of the first cervical vertebra (C1, which stabilizes odontoid process of C2), as well as disease of the apophyseal joints.

Neck pain without neurologic features tends to be self-limited and usually improves, but neck pain and neurologic symptoms often do not correlate well. A neurologic examination, even in the absence of neck pain, is therefore prudent in patients with RA. Radiographs of the cervical spine in flexion and extension might be needed to detect C1 to C2 involvement, which necessitates caution during surgical procedures requiring intubation.

Physical Examination

Upper Extremity. Shoulder RA usually manifests as decreased ROM. Elbow RA is more accessible than shoulder RA for physical examination and joint aspiration. Elbow involvement can manifest with elbow pain and swelling; ulnar compression syndrome (paresthesia and weakness of fourth and fifth digits) can develop from the synovitis. The wrists are affected in most RA patients, in contrast to OA patients; carpal tunnel syndrome is seen frequently. RA

usually involves the MCP and PIP joints rather than the DIP joints. Classic late changes such as swan neck and boutonnière deformities and ulnar deviation of the MCP joints caused by ligamentous laxity might occur. The swan neck deformity is characterized by flexion of the DIP and MCP joints and hyperextension of the PIP joint, probably resulting from shortening of the interosseous muscles and tendons and shortening of the dorsal tendon sheath. The boutonnière deformity results from avulsion of the extensor hood of the PIP because of chronic inflammation. This causes the PIP to pop up in flexion while the DIP stays in hyperextension.

Lower Extremity. Hip involvement in RA might be difficult to detect on physical examination and might manifest as only a small decrease in ROM. If pain develops, it can be felt in the buttock, lower back, groin, thigh, or medial aspect of the knee. RA of the knee is usually easily apparent on examination. A *Baker cyst* (posterior herniation of the joint capsule to the popliteal area) might occur and can be diagnosed by ultrasound. Rupture of a Baker cyst into the posterior leg might mimic thrombophlebitis. RA might involve the MTP, talonavicular, and ankle joints, causing gait problems. The tarsal tunnel containing the posterior tibial nerve can be compressed by synovitis, causing burning paresthesias on the sole of the foot made worse by weight bearing.

Joint Deformities. The synovitis of RA has many effects on cartilage, bone, muscles, tendons, and ligaments. Cartilage and bone erode, and muscles and tendons shorten in response to chronic inflammation. Ligaments are weakened by collagenases released by inflamed synovium and pannus. Upper extremity joints (shoulder, wrist, elbow) are prone to more severe deformities, as previously noted, than knees and ankles because splinting (avoiding joint motion to minimize pain) is easier in these lower extremity joints. The decreased use of these joints leads to more destruction by tendon shortening and contraction of the articular capsule.

Extraarticular Manifestations. Systemic constitutional symptoms such as fatigue, malaise, anorexia, weight loss, and fever occur in addition to joint inflammation and destruction in RA. Significant inflammation of almost all organ systems occurs. Patients have an increased incidence of renal, cardiac, pulmonary, and neurologic disorders; serious infections; and hematologic malignancies such as non-Hodgkin lymphoma. Subcutaneous rheumatoid nodules occur frequently in RA patients, usually in areas subject to pressure such as the elbows and sacrum. Their onset can be abrupt or gradual, and they might also resolve spontaneously. Biopsies are sometimes required to differentiate these from a gouty tophus or xanthoma. Rheumatoid nodules can also occur throughout the body, including (rarely) organs such as the lungs and heart.

Pulmonary involvement can include pleural effusions, interstitial fibrosis, solitary or multiple nodular lung disease, and pleurisy. Asymptomatic pericarditis diagnosed by echocardiography during RA exacerbations is relatively common but rarely results in cardiac-related sequelae. Nodules can occur rarely in the myocardium, heart valves, and aorta. Renal and GI complications are generally secondary to the treatment of RA rather than arising from the disease itself.

Eye dryness from keratoconjunctivitis sicca, episcleritis, or scleritis is associated with RA. Hematologic complications of RA include a hypochromic microcytic anemia with a low serum ferritin level and low or normal iron-binding capacity. Because many RA patients are taking NSAIDs, it can be difficult to distinguish anemia associated with their RA from NSAID-induced GI blood loss. *Felty syndrome* (RA, splenomegaly, leukopenia, leg ulcers, lymphadenopathy, thrombocytopenia, HLA-DR4 haplotype) is most common in patients with severe, nodule-forming RA.

Laboratory Studies

Arthritis panels should not be routinely performed and might only confuse the diagnosis. RF, ESR, uric acid level, ANA, and radiographic abnormalities all increase with age in the general population, even in the absence of disease. Therefore, laboratory studies should be reviewed as confirmatory of the clinical diagnosis made by careful history and physical examination.

Rheumatoid factor, ANA, and ESR are normally the most helpful tests to diagnose RA. RF is present in 80% to 90% of patients with RA. Therefore, 10% to 20% of patients with RA never have a positive RF. Also, up to 4% of normal young persons have low levels of RF. Moreover, RF titers are not helpful in following disease progression; when a patient is discovered to have a positive RF, repeating the test is of no value. Repeating a RF 6 to 12 months later for patients with initially negative RF results may be useful when RA is still being strongly considered. RF can be increased in other diseases, mainly chronic infections (Lyme disease, subacute bacterial endocarditis, tuberculosis, syphilis), viral infections (infectious mononucleosis, cytomegalovirus, influenza), parasitic infections, and other chronic inflammatory diseases such as sarcoidosis, pulmonary interstitial disease, and noninfectious hepatitis.

Anti-cyclic citrullinated peptide (anti-CCP) antibody is another laboratory test useful in the diagnosis of RA when the diagnosis is in question or the RF result is negative. Anti-CCP is more specific than RF for RA with 95% specificity and 69% sensitivity. Positive anti-CCP serology has also been linked with more severe radiologic progression of joint erosions from RA (Nishimura et al., 2007). Anti-CCP results can also be positive in patients with active tuberculosis or other autoimmune diseases.

Other serum tests include ANA titers, complement, ESR, and CBC. Abnormal ANA titers indicate SLE, SS, and scleroderma, but up to 30% of RA patients also have abnormal ANAs. Complements (CH50, C3, and C4) are decreased in SLE but are normal or increased in RA. The ESR, a nonspecific marker of inflammation, might help differentiate RA from other noninflammatory diseases. CRP, an acute-phase reactant, is also nonspecific but increases more rapidly than the ESR in early inflammation. A CBC showing a mild normochromic, normocytic anemia and a normal WBC count suggests RA. Thrombocytosis might also mimic disease activity as another acute-phase reactant, and eosinophilia might be seen.

Synovial fluid analysis in RA shows a yellow-white and turbid but sterile fluid without crystals. WBC counts of synovial fluid in RA are typically 10,000 to 20,000 cells/mm³ but are at least higher than 2000/mm³, with more than 75% PMNs. Synovial CH50 is lower than serum

Figure 32-8 Rheumatoid arthritis marginal erosions and joint space narrowing. (From Resnick D, Yu JS, Sartoris D. Imaging. In Kelley WN Harris ED, Ruddy S, et al, eds. *Textbook of rheumatology*. 5th ed, vol 1. Philadelphia: Saunders; 1997:626-686.)

levels, and the serum and synovial glucose difference is usually higher than 30 mg/dL.

Imaging Studies

Radiography is indicated early when infection or fracture must be ruled out, the patient has a history of malignancy, the physical examination fails to localize the source of pain, or pain persists despite conservative treatment. Early RA might show only soft tissue swelling. Advanced destruction on radiographs should not be required to initiate disease-modifying therapy if a diagnosis of RA is strongly suspected clinically. In late-stage disease, radiographs might show marginal bony erosions, periarticular osteoporosis, and joint space narrowing, especially in the hands and feet (Figures 32-8 and 32-9).

Course

Almost 90% of joints ultimately affected in a given patient are involved during the first year of the disease, allowing the family physician to alert the patient with chronic RA about which joints will ultimately be affected (Anderson, 2004). The rate of spontaneous remission is extremely low, usually occurring within 2 years of disease onset. The presence of RF, nodules, extraarticular manifestations, and HLA-DR4 haplotype is associated with a more severe course. Mortality rates for patients with severe RA are higher secondary to infections; cardiovascular, pulmonary, and renal disease; GI bleeding; and excess malignancy. The strongest predictors of survival appear to be extraarticular manifestations of the disease and comorbidities (Gabriel et al., 2003).

Figure 32-9 Classic forefoot deformities of rheumatoid arthritis. (From Resnick D, Niwayama G. *Diagnosis of bone and joint disorders*. Philadelphia: Saunders; 1988.)

Treatment

Initiation of early aggressive treatment of RA is essential to achieve the best prognosis in an individual patient. An integrated approach using up-to-date pharmacotherapy, patient education, physical and occupational therapy, and surgery is optimal. The family physician's role in early diagnosis of RA and subsequent initiation of DMARDs gives patients the best chance for minimizing joint destruction. The early aggressive treatment of RA begins with initial sign and symptom onset through the first 1 to 2 years of the disease. Considering symptomatology such as the patient's overall function, fatigue, inflammation and erosion of joints, and extraarticular symptoms can lead to an early diagnosis.

Although long used as the mainstay of pharmacologic therapy, NSAIDs provide only symptomatic relief without improving the prognosis. Therefore, almost all patients should start taking a DMARD as soon as the diagnosis of RA has been made (Figure 32-10). Many DMARDs are no more toxic than high-dose NSAIDs. Treatment options include DMARDs (hydroxychloroquine, sulfasalazine, and methotrexate) and minocycline. After 1 to 2 years of this therapy, the disease will have progressed to established RA. For moderate signs and symptoms, single and combination therapy is applicable, with options such as methotrexate, anti-TNF (tumor necrosis factor), anti-K-1, leflunomide, azathioprine, gold, cyclosporine, and other medications for mild RA (Osiri et al., 2003; Wells et al., 2000). The disease progresses to severe RA if the treatment options for established RA have failed. Therapy such as cyclophosphamide (Cytoxan), a different DMARD selection, pulse steroids, and Prosurba Column (protein A) could then be considered. Along with prescribing the DMARD, the family physician must educate the patient and family about the importance of DMARD compliance. Physical and occupational therapy are important for joint protection during exacerbations, as

is exercise to improve function and ROM. Early consultation with a rheumatologist is generally recommended.

Disease-Modifying Antirheumatic Drugs. Although traditional first-line therapy has included aspirin and NSAIDs, DMARDs are now used more frequently in early RA (Table 32-5). Because of the potential for toxicity, it is important to differentiate RA from other causes of synovitis as well as from OA. The 2008 ACR recommendations identified four adverse prognostic factors that would encourage use of DMARDs: functional limitation, extraarticular disease, RF positivity or presence of anti-CCP antibodies, and bony erosions documented on radiographs. Hydroxychloroquine appears to be the least toxic of the DMARDs followed (in order) by sulfasalazine (Azulfidine), methotrexate (Rheumatrex), intramuscular (IM) gold sodium thiomalate (Myochrysin), and aurothioglucose (Solganal). Hydroxychloroquine is dosed at 200 mg orally once or twice daily; however, patients need ophthalmologic follow-up in 6 months (Carmichael et al., 2002; Wassenberg and Rau, 2003). Hydroxychloroquine is generally only used for patients with milder RA symptoms. Significant improvement was seen in patients with mild RA taking hydroxychloroquine compared with those taking placebo (Davis et al., 1991).

Sulfasalazine is given at 2 to 3 g/day in two divided doses (Suarez-Almazor et al., 2000a). Before prescribing sulfasalazine, a sulfa drug, the physician must be aware of potential allergy and check CBC and LFTs weekly for 1 month and then every 4 to 6 weeks. Using sulfasalazine as the sole DMARD for treatment should be limited to patients lacking the poor prognostic factors noted earlier or those with contraindications to methotrexate. A meta-analysis of 15 trials showed that sulfasalazine was effective for treatment of RA (Weinblatt et al., 1999b). Oral gold, or auranofin (Ridaura), is not as effective as IM preparations and should be used only for early mild RA or in combination with other DMARDs (Suarez-Almazor et al., 2000c). Gold is given as 3 mg twice daily, and a CBC must be done every 4 to 6 weeks. Diarrhea is a frequent side effect. The onset of action of most DMARDs is at least several months, so adequate pain control with analgesics should be given and the patient counseled about realistic expectations.

Methotrexate. Many rheumatologists consider methotrexate to be the DMARD of first choice; it is the most frequently used DMARD in the United States. Methotrexate inhibits folic acid synthesis and is the primary choice for moderate to severe RA, showing significant short-term benefit but adverse effects on abrupt withdrawal (Ortiz et al., 2000; Suarez-Almazor et al., 2000a). Folic acid (1 mg/day) reduces methotrexate-induced mouth sores without decreasing the drug's efficacy. Patients cannot drink alcohol and must have LFTs every 4 to 6 weeks. Increasing the dose up to 25 mg/week and using the subcutaneous or IM route might enhance efficacy. Liver biopsies are no longer recommended during therapy unless abnormal alanine transaminase (ALT) or albumin levels persist (Kremer et al., 1994). Methotrexate toxicities include hepatotoxicity, bone marrow suppression, rare development of B-cell non-Hodgkin lymphoma, subcutaneous nodules (treated with colchicine), opportunistic infections,

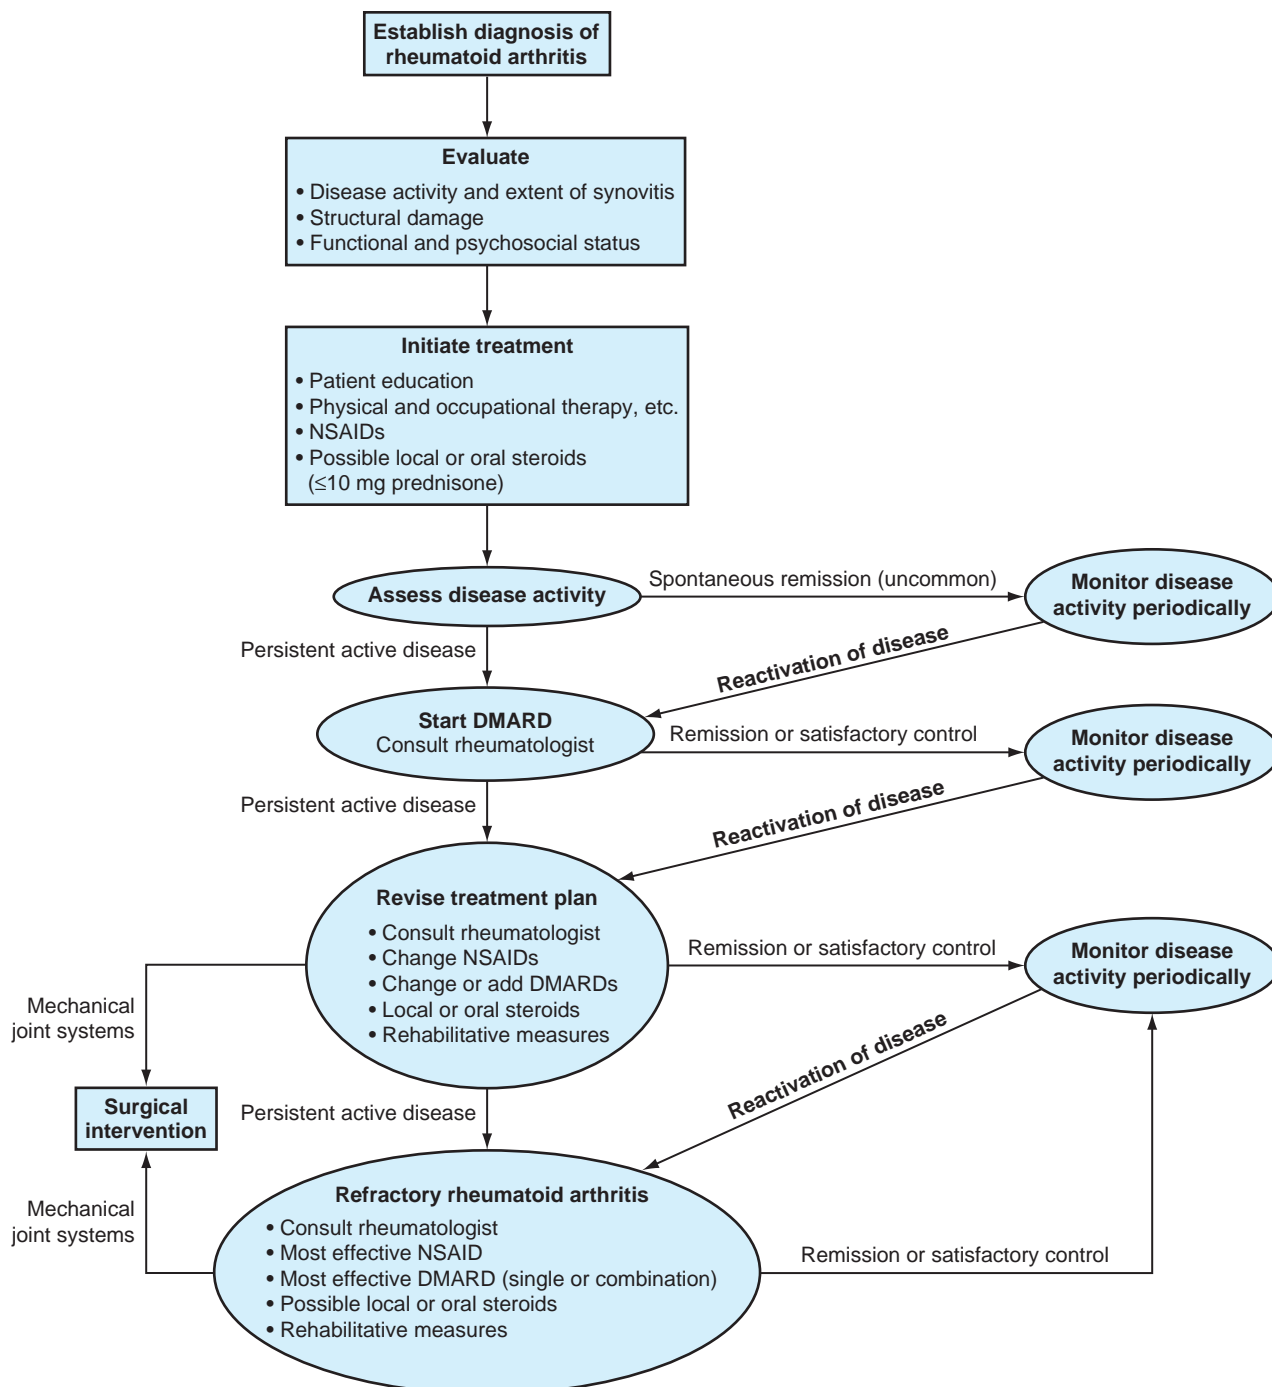

Figure 32-10 Algorithm for management of rheumatoid arthritis. *DMARD*, Disease-modifying antirheumatic drug; *NSAID*, nonsteroidal antiinflammatory drug. (From American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for the initial evaluation of the adult patient with acute musculoskeletal symptoms. *Arthritis Rheum.* 1996;39:1.)

and hypersensitivity pneumonitis (treated with corticosteroids). It can be difficult to withdraw methotrexate after it has been started without causing a disease flare.

Other Disease-Modifying Antirheumatic Drugs. Azathioprine (Imuran) is used for moderate and severe RA as a second- or third-line drug after methotrexate, sulfasalazine, gold, and hydroxychloroquine have been tried. It suppresses bone marrow and can lead to infection. After the initial DMARD therapy, azathioprine can be tried for a 2- to 6-week course. No evidence has demonstrated increased

effectiveness over other DMARDs (Suarez-Almazor et al., 2000d).

Cyclosporine (Sandimmune, Neoral) is used in combination with methotrexate and is given as a 2.5-mg/kg dose to prevent hypertension and renal disease. It has shown modest efficacy in short-term treatment with progressive RA (Wells et al., 2000). D-Penicillamine (Depen, Cuprimine) has unpredictable toxicity, making it a less attractive choice. The alkylating agents cyclophosphamide and chlorambucil, as well as cyclosporine, are effective but are reserved for refractory severe cases because of their toxicities. All

Table 32-5 Selected Disease-Modifying Antirheumatic Drugs

Class/Drug (Brand)	Recommended Dosage	Toxic Effects	Recommended Monitoring
GOLD COMPOUNDS			
Gold sodium thiomalate (Myochrysin)	IM: 10 mg followed by 25 mg 1 wk later; then 25-50 mg weekly until there is toxicity, major clinical improvement, or cumulative dose of 1 g; if effective, interval between doses is increased	Pruritus, dermatitis (frequent in one third of patients), stomatitis, nephrotoxicity, blood dyscrasias, "nitritoid" reaction: flushing, weakness, nausea, dizziness 30 min after injection	CBC, platelet count before every other injection U/A before each dose
Auranofin (Ridaura)	PO: 3 mg BID or 6 mg QD; may increase to 3 mg TID after 6 mo	Loose stools, diarrhea ($\leq 50\%$), dermatitis	Baseline CBC, platelet count, U/A, renal, liver function at onset; then CBC with platelet count, U/A at 9 mo
ANTIMALARIALS			
Hydroxychloroquine (Plaquenil)	PO: 400-600 mg QD for 4-12 wk; then 200-400 mg QD	Retinopathy, dermatitis, muscle weakness, hypoactive DTRs, CNS	Ophthalmologic examination every 3 mo (visual acuity, slit-lamp fundoscopic, visual field tests); neuromuscular examination
Penicillamine (Cuprimine)	PO: 125-250 mg QD; then increasing doses by 125-250 mg at monthly intervals to a maximum of 750-1000 mg	Pruritus, rash, or mouth ulcers; bone marrow depression; proteinuria; hematuria; hypogeusia myasthenia; myositis; GI distress; pulmonary toxicity; teratogenic	CBC every 2 wk until dose stable; then every month U/A weekly until dose stable; then every 9 mo hCG as needed
Methotrexate (Rheumatrex)	PO: 7.5-20 mg weekly	Pulmonary toxicity, ulcerative stomatitis, leukopenia, thrombocytopenia, GI distress, malaise, fatigue, chills, fever, CNS, elevated LFTs or liver disease, lymphoma, infection	CBC with platelet count LFTs weekly for 6 wk; then monthly U/A periodically hCG as needed
Azathioprine (Imuran)	PO: 50-100 mg QD, increase at 4-wk intervals by 0.5 mg/kg/day, up to 2.5 mg/kg/day	Leukopenia, thrombocytopenia, GI, neoplastic if previous therapy with alkylating agents	CBC with platelet count, weekly for 1 mo, twice monthly for 2 mo, then monthly hCG as needed
Sulfasalazine (Azulfidine)	PO: 500 mg/day; then increase, up to 3 g daily	GI, skin rash, pruritus, blood dyscrasias, oligospermia	CBC, U/A every 2 wk for 3 mo; then monthly for 9 mo; then every 6 mo
ALKYLATING AGENTS			
Cyclophosphamide (Cytoxan)	PO: 50-100 mg/day, up to 2.5 mg/kg/day	Leukopenia, thrombocytopenia, hematuria, GI, alopecia, rash, bladder cancer, non-Hodgkin lymphoma, infection	CBC with platelet count, regularly hCG as needed
Chlorambucil (Leukeran)	PO: 0.1-0.2 mg/kg/day	Bone marrow suppression, GI, CNS, infection	CBC with platelet count every wk WBC count 3-4 days after each CBC during first 3-6 wk at therapy hCG as needed
Cyclosporine (Sandimmune)	PO: 2.5-5 mg/kg/day	Nephrotoxicity, tremor, hirsutism, hypertension, gum hyperplasia	Renal function, liver function
PYRIMIDINE SYNTHESIS INHIBITOR			
Leflunomide (Arava)	Loading dose: 100 mg/day for 3 days Maintenance therapy: 20 mg/day; if not tolerated, 10 mg/day	Hepatotoxicity, carcinogenesis Immunosuppression, long half-life	LFTs every month, drug levels after discontinuation (after 1-mo therapy, remains in blood for 2 yr without cholestyramine)
TUMOR NECROSIS FACTOR INHIBITORS			
Etanercept (Enbrel)	2-5 mg SC twice weekly or 50 mg SC weekly	Sepsis, opportunistic infections, congestive heart failure, injection site pain	PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo
Infliximab (Remicade)	5 mg/kg IV on weeks 0, 2, 6; then biweekly	Sepsis, opportunistic infections, reactivation of hepatitis B and TB, pancytopenia	PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo
Adalimumab (Humira)	40 mg SC every 2 wk	Sepsis, opportunistic infections, reactivation of TB	PPD, CBC, ALT at baseline monthly until dose is stable; then every 2-3 mo
EXTRACORPOREAL*			
Staphylococcal protein A immunoadsorption	IV weekly for 12 wk	Hypotension (especially with ACE inhibitor), injection site infection, anemia, flulike symptoms, joint pain	CBC routinely

*Use only in patients whose disease is refractory to disease-modifying antirheumatic drugs (DMARDs).

ACE, Angiotensin-converting enzyme; ALT, alanine transaminase; BID, twice daily; CBC, complete blood count; CNS, central nervous system; DTR, deep tendon reflex; GI, gastrointestinal; hCG, human chorionic gonadotropin; IM, intramuscular; IV, intravenous; LFT, liver function test; PO, oral; PPD, purified protein derivative; QD, once daily; SC, subcutaneously; TB, tuberculosis; TID, three times daily; U/A, urinalysis; WBC, white blood cell.

second-line drugs are teratogenic, so a family physician must help the patient establish an effective means of birth control. The risk of toxic effects is an important factor in choice of these agents, and selection is generally best handled in consultation with the rheumatologist.

Leflunomide (Arava) inhibits pyrimidine synthesis, is given orally, and is considered a possible alternative to methotrexate for decreasing erosion and controlling inflammation, but it provides no apparent benefit over methotrexate and is expensive. Leflunomide has been shown not only to reduce symptoms but also to slow disease progression. The routine dosage is 100 mg/day for 3 days followed by a maintenance dosage of 10 to 20 mg/day. LFTs must be ordered, and as with methotrexate, leflunomide is better for short-term therapy (Suarez-Almazor et al., 2000a). Research continues into combining DMARDs to lower drug resistance. DMARD combination therapy in early RA has shown minimal benefit (Mottonen et al., 1999).

Anticytokine Therapy. Cytokines such as interleukin-1 (IL-1), TNF- α , granulocyte-macrophage colony-stimulating factor, IL-6, and chemoattractant cytokines (known as chemokines) are derived from macrophages and fibroblasts and appear to be the most important cytokines involved in RA treatment (Kavanaugh, 2006). TNF- α is produced by synovial macrophages and causes many destructive inflammatory actions in the rheumatoid joint. Synovial macrophages proliferate; synoviocytes (fibroblast-like cells lining the joint) produce prostaglandins and cytokines, continuing the inflammatory process. Administering monoclonal antibodies such as infliximab (Remicade) to bind TNF- α and block its activity and giving TNF- α receptors such as etanercept (Enbrel) are two approaches to decrease TNF activity. Patients with a suboptimal response to methotrexate at 25 mg/wk (maximum dose) are the best candidates for etanercept or infliximab. Before starting any anticytokine therapy, CBC and tuberculin test (purified protein derivative [PPD]) are required.

Etanercept, a recombinant p75 TNF- α receptor-Fc fusion protein, is given subcutaneously once to twice weekly. It decreases binding of TNF- α to cellular receptors and avoids downstream inflammation. It is well tolerated and is indicated for use alone or with methotrexate for methotrexate-refractory disease (Blumenauer et al., 2003; Weinblatt et al., 1999a). The most common side effect is injection site erythema, which must be carefully watched in RA patients with diabetes mellitus. Etanercept has significantly reduced disease activity in a dose-related manner over 6 months, with no laboratory abnormalities noted (Moreland et al., 1999).

Infliximab, an anti-TNF- α monoclonal antibody, is given intravenously for refractory disease every 4 to 8 weeks. It is 75% human and 25% mouse antibody to TNF- α . The primary mechanism is halting joint space narrowing, with subsequent decreased erosion. It is FDA approved only in combination with methotrexate. Again, caution is warranted in patients with diabetes for skin ulcers. If the patient has a positive PPD, isoniazid and vitamin B₆ therapy must be given for 9 months with the treatment. Fewer appropriate trials exist for infliximab than etanercept; however, the benefit in refractory disease has been demonstrated (Blumenauer et al., 2002).

Adalimumab (Humira), 40 mg subcutaneously every other week, has a greater therapeutic potential when used with methotrexate (OnMedica, 2005). It is a full human anti-TNF- α . Fewer studies exist on its long-term efficacy, but short-term studies show a greater effect than infliximab or etanercept. Risk factors with this regimen include skin infection, malignancy, and demyelination.

Nonsteroidal Antiinflammatory Drugs. The NSAIDs improve inflammation and pain but do not alter disease progression. Therefore, most patients with RA should take a DMARD. NSAIDs are used for analgesia and to help control symptoms. DMARDs generally have a slow onset of action, necessitating use of other agents to help keep the patient comfortable while awaiting onset of the DMARD's action. NSAID-associated GI bleeding is a widespread problem; one in three RA patients will be hospitalized or will die from a GI bleed at some point. Selection of NSAID is largely empiric (Table 32-6). The least toxic NSAIDs are coated or buffered aspirin, salsalate (Disalcid, Mono-Gesic, Salflex), ibuprofen (Advil, Motrin, Nuprin, Rufen), and naproxen sodium (Aleve). The most toxic are indomethacin (Indocin), tolmetin sodium (Tolectin), meclizemate sodium (Meclomen), and ketoprofen (Orudis, Oruvail). High-toxicity NSAIDs provide no more clinical benefit than lower-toxicity drugs (Fries et al., 1991).

Patients receiving long-term nonselective NSAIDs should be monitored several times annually for hematocrit abnormalities and should undergo stool guaiac testing and have renal and liver function evaluated. There is no benefit to combining different NSAIDs.

Aspirin and Salicylates. High-dose aspirin (900-1050 mg four times daily) is as effective as much more expensive NSAIDs but is often less well tolerated and less convenient to take.

Glucocorticoids. Glucocorticoid articular injections are often used for temporary localized suppression of RA but are not recommended for use more than three times per joint per year. Common drugs for injection (used with lidocaine to minimize patient discomfort) include hydrocortisone, triamcinolone (Kenalog, Aristocort), methylprednisolone (Depo-Medrol), dexamethasone (Decadron-LA), and betamethasone (Celestone Soluspan), in ascending order of duration of action.

Systemic corticosteroids are used primarily as bridge therapy for several months when initiating DMARDs and awaiting their onset. Prednisone might be especially useful for constitutional symptoms such as fatigue and malaise. Low-dose prednisone (<7.5 mg/day) in a single morning dose might particularly be useful in older adult patients when other drugs have more potential for toxicity.

Surgery

Surgery is useful in RA patients with more severe disease who, despite optimal medical treatment, develop joint erosions and severe destruction resulting in pain and limitation of function. Surgical procedures range from carpal tunnel release to synovectomy, joint fusion, and arthroplasty. About 90% of older adult patients with severe incapacitating rheumatoid joint disease can expect

Table 32-6 Selected NSAIDs Used in Rheumatoid Arthritis and Osteoarthritis

Class/Drug (Brand)	Usual Dosage Range for Arthritis
I. ARYL CARBOXYLIC ACIDS	
A. Salicylic Acids	
1. <i>Acetylated</i> Aspirin, extended release	1600 mg BID
Aspirin, enteric coated	1000 mg QID
2. <i>Nonacetylated</i> Diflunisal (Dolobid)	250-500 mg BID; maximum, 1500 mg/day
Choline-magnesium salicylate	3 g/day in 1-3 doses
Salsalate (Disalcid, Salflex)	3-4 g/day in 2-3 doses
B. Anthranilic Acid	
1. <i>Meclofenamate Sodium</i>	200-400 mg/day in 3-4 doses
II. ARYLALKANOIC ACIDS	
A. Arylacetic Acid	
1. <i>Diclofenac (Voltaren)</i>	150-225 mg/day in 3-4 divided doses
2. <i>Naproxen (Naprosyn)</i>	250-500 mg BID-TID
3. <i>Naproxen sodium (Anaprox)</i>	275-550 mg BID
B. Arylpropionic Acids	
1. <i>Ibuprofen (Advil, Motrin)</i>	300-800 mg/TID-QID
2. <i>Ketoprofen (Oruvail)</i>	100-200 mg/day
3. <i>Fenoprofen (Nalfon)</i>	300-600 mg TID-QID
C. Oxazolepropionic Acid	
1. <i>Oxaprozin (Daypro)</i>	600-1800 mg/day in 1-2 doses
D. Heteroarylacetic Acid	
1. <i>Tolmetin</i>	600-1800 mg/day in 3-4 doses
E. Indoleacetic and Indeneacetic Acids	
1. <i>Indomethacin (Indocin, Indocin SR)</i>	25-50 mg TID-QID 75 mg QD-BID
2. <i>Sulindac (Clinoril)</i>	150-200 mg BID
F. Pyranocarboxylic Acid	
1. <i>Etodolac (Lodine)</i>	300-500 mg BID
III. ENOLIC ACIDS—OXICAM	
A. Piroxicam (Feldene)	
	20 mg/day
IV. NONACIDIC AGENT	
A. Nabumetone (Relafen)	
	1000-2000 mg divided QD-BID
B. Meloxicam (Mobic)	
	7.5-15 mg QD
V. CYCLOOXYGENASE (COX-2) INHIBITOR	
A. Celecoxib (Celebrex)	
	100-200 mg BID

BID, Twice daily; NSAID, nonsteroidal antiinflammatory drug; QD, once daily; QID, four times daily; TID, three times daily.

excellent pain relief and increased ROM after total hip or knee replacement (Harris and Sledge, 1990).

Other Therapies

Antimicrobial Therapy. On the basis of the theory that persistent mycoplasma infection might cause RA, tetracyclines such as minocycline (Minocin) have been used by

some physicians for years. Minocycline, 100 mg orally twice daily, has shown modest efficacy but can lead to dizziness and dosing sensitivity in early RA (O'Dell et al., 2001). A small study showed that use of minocycline (100 mg twice daily) in early RA (first 3 months after diagnosis) resulted in more frequent remissions, and the need for DMARD therapy was reduced after follow-up for 4 years (O'Dell et al., 1999). These antibiotics result in mild improvement in RA patients, and other actions may include inhibition of collagenase activity, direct antiinflammatory effect, and interference with leukocyte function.

Mind–Body Therapy. Stress management, cognitive-behavioral pain management techniques, relaxation training, biofeedback, and family-oriented behavior therapy have all been shown to improve daily functioning, pain reports, and disease activity in RA patients (Parker et al., 1995). A small RCT showed a 28% decrease in mean disease severity at 4 months using writing therapy (Smyth et al., 1999). Another study showed that 20% of the disability of RA was related to psychosocial factors (Escalante and del Rincon, 1999). Educating patients about methods to cope with their disease can significantly improve quality of life. Interventions shown to improve outcomes include tai chi (Han et al., 2004) and journaling (Smyth et al., 1999). A meta-analysis of psychological interventions (e.g., biofeedback, relaxation, cognitive-behavioral therapy) found significant effects on pain, disability, functional status, and coping, although these might be more effective for patients with RA of shorter duration (Astin et al., 2002).

Nutrition. Nutritional changes are hypothesized to decrease RA signs and symptoms. A Cochrane review of herbs found that γ -linolenic acid (GLA) resulted in some improvement in clinical outcomes (Little and Parsons, 2000; Zurier et al., 1996), consistent with other findings on essential fatty acids. Fish oil, high in omega-3 fatty acids, significantly improved the number of tender joints and morning stiffness (Fortin et al., 1995; Volker et al., 2000); the recommended dose would be 3 g/day, and symptom relief might not be evident until 12 weeks of use. Changes in the total diet have been studied as well. Fasting has anecdotal evidence for inducing remission of symptoms. A 7- to 10-day fast followed by a gluten-free vegan diet was found to sustain improvements (Kjeldsen-Kragh et al., 1991; McDougall et al., 2002). Proceeding immediately to a vegan gluten-free diet resulted in RA symptom improvement (Hafstrom et al., 2001). Symptoms were exacerbated with challenges of foods that patients had reacted to on skin-prick test (Karatay et al., 2004). Therefore, a trial of such a diet or an elimination diet would be reasonable options (Table 32-7). In general, a plant-based Mediterranean diet appears to be a healthy option for patients with RA (Sales et al., 2009).

Monitoring Arthritic Activity

Because RA is a chronic disease with significant psychosocial impact, the continuity that the family physician provides is crucial. The frequency of visits depends on disease activity, need for drug toxicity monitoring, and psychosocial functioning of the patient (see eTable 32-4 online). Periodic ESR and CRP levels, radiography, and functional status

eTable 32-4 Monitoring Rheumatoid Arthritis Activity

Each visit	Evaluate for subjective and objective evidence of active disease: Degree of joint pain Duration of AM stiffness Severity of fatigue Presence of actively inflamed joints on examination Limitation of function
Periodically	Evaluate for disease activity or progression: Evidence of disease progression on physical examination (loss of motion, instability, malalignment, deformity) Erythrocyte sedimentation rate or CRP elevation Progression of radiographic damage of involved joints
Other parameters	For assessing response to treatment (outcomes): Physician global assessment of disease activity Patient global assessment of disease activity Tender and swollen joint count Pain assessment Functional status assessment

CRP, C-reactive protein.

Modified from American College of Rheumatology Ad Hoc Committee on Clinical Guidelines. Guidelines for the management of rheumatoid arthritis. *Arthritis Rheum.* 1996;39:713.

Table 32-7 Elimination Diet: Patient Handout

Special diets called *elimination diets* are sometimes used to discover whether food allergies or sensitivities are related to symptoms you might be having. The goal of an elimination diet is to identify problem foods. The diet is temporary and must be followed very carefully so that a permanent diet to help you feel better can be planned. The steps in an elimination diet follow:

1. Decide which foods might be causing problems. This step involves describing your diet for your doctor and sharing your ideas about what foods might be causing problems. Sometimes food allergy tests are used to help with the decision.
2. Avoid the foods completely for 2 to 4 weeks. This is the actual elimination step. This step involves the greatest restrictions in your diet.
 - The foods need to be avoided completely for symptoms to be noticeable when the foods are added back.
 - Foods should be avoided both in their whole form and as ingredients in food.
 - Keeping track of how you feel during this step is important. It is useful to keep a written record. You may feel worse before you feel better, but that should last only 1 or 2 days. If you feel worse for longer, please call your doctor.
3. Add the foods back one at a time. This is called the *challenge step*. It allows you to learn which foods, if any, are causing symptoms.
 - Decide with your doctor which food to add back first.
 - Keep track of how you feel throughout this step with a written record.
 - On the day a food is added, eat that food twice. For the next 2 days, do not eat that food again but continue to follow the elimination diet. You can have a reaction up to 3 days after a food is eaten.
 - Add a new food every 3 days because you can have a reaction up to 3 days after the challenge food is eaten.
 - If the food does not cause a reaction, that food “passes” and can be added back to your diet when the entire process is over. Do not eat the foods you have added back, even if they “passed,” until you have tested all the foods.
 - After following the elimination diet carefully, you and your doctor will have a better picture of which foods, if any, are causing your problems. Remember that problems with foods can be intermittent, and it is sometimes difficult to tell exactly whether foods are a problem.

From Rakel D. *Integrative medicine*. Philadelphia: Saunders; 2002.

assessment are important in addition to serial joint examination. A team approach using the expertise of a rheumatologist and physical and occupational therapists is generally indicated. Patients' ability to perform their jobs must be considered, and using modified work profiles or absences may be necessary. Osteoporosis resulting from RA should be monitored and prevented. The patient should also be monitored for infection, pulmonary disease, renal disease, or GI bleeding, taking a general health maintenance approach to this systemic disease.

KEY TREATMENT

- NSAIDs are the preferred treatment for pain in RA (SOR: C).
- Treatment of RA with DMARDs should be started as soon as possible (SOR: C).

- Methotrexate has substantial benefit in the treatment of RA and is generally the first-line DMARD (Suarez-Almazor et al., 2000a) (SOR: A).
- Sulfasalazine has proven benefits on RA disease activity (Weinblatt et al., 1999b) (SOR: A). However, it should be used as the sole therapy only in patients with minor symptoms and no poor prognostic signs of RA.
- Hydroxychloroquine has been shown to be effective in the treatment of RA (Davis et al., 1991). However, it is generally used with another DMARD or methotrexate in refractory cases when initial treatment fails (SOR: B).
- Biologic agents such as etanercept and infliximab reduce RA disease activity and are important treatment options in patients with moderate to severe RA who have failed treatment with methotrexate or combination therapy (Blumenauer et al., 2003; Weinblatt et al., 1999a) (SOR: A).

CRYSTAL ARTHROPATHIES

Gout and pseudogout are conditions caused by deposition of crystals of urate and calcium pyrophosphate dihydrate, respectively, with a resulting inflammatory response. These conditions can be distinguished from each other and from other causes of an acutely swollen joint or joints by synovial fluid examination, looking for crystals using polarized light microscopy.

Gout

Key Points

- Hyperuricemia is present (usually >8 mg/dL) in patients with gout.
- Gout affects more men than women.
- Negative birefringent crystals are seen on fluid analysis in gout.

Gout primarily affects middle-aged men (40-60 years) and postmenopausal women. It typically manifests as an acutely painful monoarticular arthritis, possibly becoming chronic after years of progressively more severe and frequent episodes, interspersed with variable symptom-free periods. *Hyperuricemia* is a marker for gout, but each can exist without the other. Asymptomatic hyperuricemia is not a disease. The risk of gout, however, is proportional to the degree and duration of hyperuricemia. Multiple genetic and environmental factors affect uric acid concentration. Uric acid is derived from ingestion of a diet rich in purines (e.g., typical American diet), as well as from endogenous production of purines. Inborn errors of metabolism, either reduced excretion (90% of patients) or increased production (10%) of uric acid, cause primary hyperuricemia. Secondary hyperuricemia results from diseases or drug therapies that raise uric acid levels.

In addition to attempting to prevent acute flares, the family physician's goal in treating patients predisposed to gout is to minimize the risk of developing other sequelae. These include interstitial nephropathy with renal function impairment; accumulation of urate crystal deposits in

joints, soft tissue, cartilage, and bone, called *tophi*; and uric acid calculi in the genitourinary (GU) tract.

Clinical Presentation. The first MTP joint (great toe) is involved in 50% of initial acute gouty attacks (podagra) and is eventually affected in 75% to 90% of patients with gout. This joint sustains more microtrauma and is relatively cool compared with the rest of the body. The heel, ankle, knee, midtarsal joints, and olecranon bursa can all be initially involved but are so less frequently than the first MTP joint. Gout severity ranges from vague aches and pains to severe pain, swelling, redness, and exquisite tenderness. Acute attacks resolve within several days to weeks, even in untreated gout.

In contrast to the typical middle-aged male presentation, gout in women and in older adult patients tends to be polyarticular. Because gout in these patient subgroups tends to involve more than one joint, it can often be misdiagnosed as RA (tophi are mistaken for rheumatoid nodules) or septic joint cellulitis, especially if low-grade fever, leukocytosis, redness, or desquamation is present. Synovial fluid analysis is necessary for definitive diagnosis.

Synovial Fluid Examination. A presumptive diagnosis of gout can be made by clinical signs and symptoms, a negative joint culture, response to NSAIDs or colchicine, and hyperuricemia. However, definitive diagnosis can be made only by finding needle-shaped, negatively birefringent urate crystals on synovial fluid examination or in tophi.

Clinical Stages of Primary Gout. Hyperuricemia is defined as two standard deviations above the individual laboratory's mean based on gender, usually 8 mg/dL in men and 7 mg/dL in women. Hyperuricemia is present in 5% of men, only 5% to 10% of whom develop acute gout. It normally takes at least 20 years of hyperuricemia before a patient has a first episode of gouty arthritis. Lowering the serum uric acid level does not decrease the risk of gouty nephropathy; chronic renal disease is almost always caused by concurrent diseases such as diabetes or hypertension. Because of expense and potential drug toxicity, treatment of asymptomatic hyperuricemia is generally not recommended.

The two most important factors in the development of acute gouty arthritis are obesity and alcohol (Choi et al., 2005). Ethanol metabolism blocks renal excretion of uric acid, leading to gouty attacks. Studies have shown a 2.5-fold increase in the risk of gout in men who drink 2 or more beers per day. This risk was similar but slightly lower in men who drank the same amount of distilled alcohols. In contrast, drinking two 4-oz glasses of wine or more per day was not associated with an increased risk of gout (Choi et al., 2004). Other factors include rapid decrease or increase in serum urate level (thus a possible attack at start of allopurinol treatment), emotional stress, infection, and surgery. Dietary excesses of purine-rich foods (e.g., sweetbreads, sardines, anchovies, kidney, liver) have traditionally been mentioned but are in reality rarely responsible for acute gouty attacks. Diuretics, both hydrochlorothiazide and loop, have been associated with increased serum uric acid. Risks, benefits, and cost must be evaluated before deciding to change or stop these medications for hypertension.

After an initial gouty attack, more than half of patients will have a recurrent attack. The timing is highly variable, however, and the recurrent attack can be weeks or years later. As time passes, gouty attacks tend to become more frequent, more severe, and less responsive to therapy and to involve more joints. Between acute attacks, urate crystals can still be aspirated from asymptomatic joints, demonstrating that this so-called intercritical or interval gout represents a progression of disease. Chronic tophaceous gout occurs at least 10 years into the disease and is now seen infrequently because of more aggressive treatment of gout and hyperuricemia. Tophi can occur anywhere but tend to occur in the helix of the ear, on the proximal ulnar surface of the forearm, on the olecranon, on the Achilles tendon, on the prepatellar bursa, or near active joints. Tophi are not seen on plain radiographs unless they are calcified. The classic radiographic finding of chronic gout is sharply marginated erosions proximal to the joint space, with an overlying rim of cortical bone (Figure 32-11).

Secondary gout is caused by drugs or disease processes affecting uric acid metabolism or excretion. Myeloproliferative and lymphoproliferative diseases, hemolytic anemia, multiple myeloma, and other malignancies result in overproduction. Renal disease, diuretics, salicylates, alcohol, nicotinic acid, and chronic lead intoxication (saturnine gout) all cause underexcretion. Chemotherapy for

Figure 32-11 Advanced gout in the feet. **A**, Calcified tophi (arrow) of gout seen on a radiograph. **B**, Osteophyte formation in knee (arrow). (From Visual Aids, Subcommittee of the Professional Education Committee of the Arthritis Foundation. *Clinical slide collection on the rheumatic diseases*. New York: Arthritis Foundation; 1972:82.)

hematologic or myeloproliferative disorders can result in gouty nephropathy unless adequate hydration and possibly allopurinol prophylaxis are initiated before therapy.

Treatment of Gouty Arthritis. The NSAIDs are generally used first because of their efficacy and relative lack of toxicity. Indomethacin (Indocin) has been used for years for gouty arthritis attacks, but any NSAID can probably be used with similar efficacy as long as an initial maximal dose is given. After 2 days of therapy at the maximal dose, the NSAID can be tapered over the next several weeks.

Colchicine decreases inflammation associated with lactic acid production and phagocytosis of urate; it terminates most gouty attacks within 6 to 12 hours but is limited by GI side effects (nausea, vomiting, abdominal cramps, diarrhea). Two 0.5- or 0.6-mg tablets are taken initially and then 1 tablet every hour until clinical response has been achieved, GI side effects cause discontinuation, or a total of 6 mg has been given (Cox, 2004). Colchicine at 0.5 to 1 mg every 6 hours intravenously, up to 4 mg total, can also be given for a single attack, but the parenteral route is associated with increased bone marrow suppression, renal and hepatic toxicity, and myopathy. No additional colchicine should be given for at least 1 week if the patient is given the full 4-mg total dose.

When NSAIDs and colchicine are ineffective or contraindicated, corticosteroids might be used. Treatment options include oral corticosteroids using prednisone, 0.5 mg/kg, followed by tapering the dose by 5 mg/day. An intraarticular injection can be given using triamcinolone hexacetonide (Aristospan), triamcinolone acetonide, or methylprednisolone (Medrol); typical doses are 10 to 40 mg in large joints and 5 to 20 mg in small joints. Intraarticular injection is preferred for monoarticular episodes. Finally, adrenocorticotropic hormone, 40 to 80 mg intravenously or intramuscularly every 8 to 12 hours, has been successful when all other therapies fail, but it is quite expensive.

Prophylaxis of Recurrent Gout. Asymptomatic hyperuricemia need not be treated, but after one episode of acute gouty arthritis or acute nephrolithiasis, patients should be offered the option of prophylaxis. Some choose not to take a daily drug, particularly if their gouty attacks are not severe or are infrequent. For patients with recurrent gouty attacks, renal damage, nephrolithiasis, or uric acid levels higher than 12 mg/dL or those undergoing cancer chemotherapy, uric acid-lowering therapy should be initiated. Prophylaxis may be discontinued when uric acid levels are brought down to normal levels for 2 months. Patients should be instructed to avoid alcohol, aspirin, diuretics, prolonged fasting, and high-purine foods. Several days before initiating uric acid-lowering therapy, it is prudent to start colchicine, 0.5 mg twice daily, to avoid precipitating an acute attack. This therapy can continue for up to 6 months after the desired uric acid levels have been obtained.

Allopurinol (Zyloprim) is a xanthine oxidase inhibitor that decreases uric acid production but also produces a more soluble metabolite. Allopurinol is therefore effective regardless of the cause of the hyperuricemia. Allopurinol therapy should never be initiated until an acute attack has subsided. Allopurinol is started at 100 mg/day with food and then increased at weekly intervals by 100 mg/day

until the serum uric acid level is lower than 6 mg/dL. The usual effective dose is 200 to 300 mg/day, although some patients require up to 600 mg/day (Perez-Ruiz et al., 1998). Patients should ensure adequate fluid intake to produce more than 2 L of urine output daily. The dose needs to be adjusted for decreased creatinine clearance. If an acute attack occurs when the patient is taking allopurinol, the dose should be maintained and the attack treated as usual (NSAIDs, colchicine, corticosteroids). Allopurinol can cause rash, liver transaminase level elevations, and renal toxicity if used with thiazide diuretics. It might also potentiate the effect of anticoagulants and cause a rash if used with amoxicillin.

The uricosuric drugs probenecid and sulfinpyrazone (Anturane) block renal tubular reabsorption of uric acid. Probenecid is started at 250 mg twice daily for 1 week; increased to 500 mg twice daily; and then increased by 500 mg/week, up to 3 g/day, until the urate level is normal. Sulfinpyrazone is started at 100 mg twice daily, increasing to 400 mg twice daily. These drugs should also never be started during an acute attack but should be maintained if the patient is already taking them. Urate stone formation risk can be minimized by a high fluid intake and alkalinization of the urine. A 24-hour urine sample for determination of creatinine clearance and uric acid level should be obtained before starting these drugs, because the glomerular filtration rate must be higher than 50 mL/min and uric acid excretion less than 800 mg/24 hr.

KEY TREATMENT

- Patients with gout who are overweight should be instructed on weight loss (Choi et al., 2005) (SOR: B).
- Patients with gout should limit their intake of beer and distilled alcohol (Choi et al., 2005) (SOR: B).
- Colchicine is an effective treatment for acute gout but should be used as second-line therapy when NSAIDs or corticosteroids are ineffective (SOR: C).
- Allopurinol should be started for prophylaxis in patients with frequent severe attacks, nephrolithiasis, or gouty tophi (Perez-Ruiz et al., 1998) (SOR: B).
- Antihyperuricemic therapy should be titrated to a dose that results in a serum urate level less than 6 mg/dL (slowly, <0.6 mg/dL/mo) (SOR: C).
- Before starting allopurinol, colchicine prophylaxis can be used for up to 6 months after desired uric acid level is reached to prevent acute attacks (SOR: C).

Pseudogout

Key Points

- The knees are the most common sources of pain in pseudogout (CPDD).
- Genetic factors are present in calcium pyrophosphate deposition disease (CPDD).
- Positive birefringent crystals are seen on fluid analysis in CPPD disease.
- Radiographic appearance of CPDD is punctate or linear densities in cartilage.

Figure 32-12 Chondrocalcinosis in calcium pyrophosphate deposition disease. **A**, Anteroposterior (AP) radiograph of the knee. **B**, Lateral radiograph of the knee. **C**, AP radiograph of the wrist. **D**, Radiograph of the pelvis. (From Reginato AJ, Reginato AM. Diseases associated with deposition of calcium pyrophosphate or hydroxyapatite. In Kelley WN Harris ED, Ruddy S, et al, eds. *Textbook of rheumatology*. 5th ed, vol 2. Philadelphia: Saunders; 1997:1352-1367.)

Calcium pyrophosphate deposition disease is known as pseudogout because of the acute goutlike attacks that CPPD crystals can cause. *Chondrocalcinosis* refers to radiographically detectable densities in cartilage and joint inflammation caused by these calcium-containing crystals. Calcium pyrophosphate (CP) crystals can be deposited not only on articular cartilage but also in ligaments, tendons, soft tissues, and synovium.

This arthritis is caused by genetic factors (autosomal dominant inheritance pattern) secondary to trauma and various metabolic diseases or is sporadic or idiopathic. CPDD is most often associated with aging, and about 4% of the adult U.S. population has articular CP crystal deposits at death (Agudelo and Wise, 2000). CPPD disease can be associated with hyperparathyroidism, hypothyroidism, hypomagnesemia, hypophosphatemia, hemochromatosis, and amyloidosis. Therefore, newly diagnosed CPDD should be followed up with serum measurements of calcium, magnesium, phosphorus, thyroid-stimulating hormone, ferritin, transferrin, serum iron, and alkaline phosphatase (ALP) levels.

The most common site is the knee, although the first MTP joint is also often affected, resulting in difficulty differentiating CPDD from gout. Any joint can be affected, however. Synovial fluid examination for rhomboid or rod-shaped, weakly positively birefringent crystals is diagnostic. Analysis needs to be done promptly after aspiration because identification of crystals diminishes over time. The crystals are also smaller and more difficult to detect, so careful preparation of the slide to avoid false-positive results must be taken. Pseudogout can also cause pseudo-RA. CPDD can be

misdiagnosed as RA because of its often multiple joint involvement with symmetric distribution, morning stiffness, and elevated ESR and because 10% of CPDD patients have positive RF test results. CPDD might also be confused with OA because of its knee and hip involvement, but it also often affects the wrists, MCP joints, elbows, and shoulders. An acute attack of CPDD can cause low-grade fever, leukocytosis (12,000-15,000/mm³), and elevated ESR. The typical radiographic appearance of CPDD is punctate or linear densities in cartilage (chondrocalcinosis) (Figure 32-12). Definitive diagnosis relies on either the typical radiographic signs or synovial fluid confirmation.

Treatment of acute pseudogout consists of removal of the crystals through joint aspiration, use of NSAIDs or colchicine during the acute inflammatory period; intraarticular joint injection with a glucocorticoid when possible; and a limited period of joint immobilization. No solid data support removal of crystals and prevention of crystal deposition, which are done only for diagnostic purposes and pain relief. If only one or two joints are involved, intraarticular injections may give the most symptomatic relief; if more joints are involved, an NSAID or colchicine is a better option. Because of severe pain associated with acute events, limited weight bearing may be needed for a short period while symptoms improve.

For patients with recurrent episodes of pseudogout, prophylaxis with colchicine, 0.6 mg twice daily, should be considered. In 10 patients with recurrent attacks, colchicine was associated with a marked decrease in the number of episodes (10) in 1 year compared with the previous year (32 episodes) (Alvarellos and Spilberg, 1986).

KEY TREATMENT

- Aspiration of the knee joint is done for symptomatic relief and diagnosis of pseudogout (CPDD) (SOR: C).
- A patient with CPDD receives intraarticular injection of glucocorticoid if septic joint has been ruled out and fewer than two joints are involved (SOR: C).
- An NSAID or colchicine is prescribed for acute pain of pseudogout (SOR: C).
- For recurrent pseudogout attacks, colchicine can be used for prophylaxis to decrease number of episodes ([Alvarellos and Spilberg, 1986](#)) (SOR: B).

SPONDYLOARTHROPATHIES

The spondyloarthropathies are a group of multisystem inflammatory disorders that affect predominantly the spine but also other joints and extraarticular tissues. Most are linked to the HLA-B27 gene, but HLA-B27 by itself does not explain the development of these diseases; the pathogenesis of these conditions is still unknown. They include AS, reactive arthritis (Reiter syndrome), psoriatic arthropathy, enteropathic arthropathy, juvenile-onset arthropathy, and undifferentiated spondyloarthropathy. Both genetic and environmental factors probably contribute to the onset and progression of these diseases. Most people with HLA-B27 do not develop these diseases, and these diseases occur in the absence of HLA-B27.

Ankylosing Spondylitis**Key Points**

- Back pain and progressive stiffness are primary symptoms of this chronic inflammatory disease of axial skeleton.
- The male predominance for AS is 5 : 1.
- Clinical history, physical examination, and radiologic findings are key to the diagnosis of AS.

Primary or uncomplicated AS is a systemic inflammatory disorder predominantly affecting the sacroiliac joints and the spine. Patients with secondary AS have IBD, psoriasis, or Reiter syndrome in addition to their arthropathy. Hip and shoulder joints may also be involved in AS. Inflammation occurs at the intervertebral disk's annulus fibrosus-vertebral bone margin. This area is replaced by fibrocartilage and then ossified. Progression of this process results in the classic vertebral fusion known as *bamboo spine*; this ankylosis is a very late finding. Inflammation also occurs at the sites of ligament and tendon attachments (enthesitis) in the spine and pelvis, which become ossified.

Ankylosing spondylitis usually affects men (male : female ratio, 5 : 1) in their 20s and 30s. It often manifests as vague, somewhat diffuse low back pain, felt generally in the buttocks or sacroiliac area but often in the lumbar area. Pain becomes more persistent and bilateral. Back stiffness after inactivity, such as on awakening, becomes more predominant and is relieved by activity or a hot shower. AS can also

disturb sleep, leading to complaints of fatigue, and can be associated with systemic symptoms such as malaise, low-grade fever, and weight loss. Symptoms can be subtle, but AS should be considered if back stiffness or discomfort persists, is relieved by exercise, and occurs in a man younger than 40 years. In juvenile-onset AS, hip and shoulder symptoms might predominate first, but in adult AS, the back is usually the first affected area. Disease progression is highly variable and can be mild and self-limited or can cause disability.

The two most common techniques to detect AS are palpation of the sacroiliac joints and assessment for spinal mobility. Decreased mobility early on is usually caused by pain and muscle spasm rather than by ankylosis. Flexion, hyperextension, axial rotation, and forward flexion should be assessed. Over time, the spine becomes increasingly stiff at an unpredictable rate, and stiffness might or might not eventually involve the entire spine.

Other extraarticular manifestations of AS include acute uveitis (iritis), aortitis, and neurologic complications resulting from cervical spine fractures from even minor trauma. Diaphragmatic breathing and limited chest excursion can be seen as a result of costovertebral involvement. The earliest radiographic abnormality can usually be seen in the sacroiliac joints, with sacroiliitis progressing to bony erosions and sclerosis ([Figures 32-13 and 32-14](#)). These changes might also be seen at the sites of ligamentous attachments to bones. Bone scans, computed tomography (CT), and MRI should be used only if plain radiography does not confirm clinical suspicion of AS.

Seventy percent to 80% of AS patients report substantial relief of their symptoms with NSAIDs, the mainstay of AS therapy ([Song et al., 2008](#)). Continuous NSAID use may decrease radiographic progression of the disease ([Ward, 2005](#)). However, the benefits must be weighed against the risks associated with prolonged NSAID use. Corticosteroids have not been shown to be helpful. Physical therapy focusing on strengthening of back extensor muscles might improve functional status and, at the very least, help maintain an erect position if spinal ossification occurs ([Dagfinrud et al., 2004](#)). Patients should be encouraged to walk erect and to keep the spine erect as much as possible, sleep on a firm mattress with the spine extended, and swim for exercise. Splints and braces do not help.

A home exercise program is better than no intervention for AS patients, and supervised group exercise is better than home exercise. Combined inpatient spa treatment and exercise (group physical exercises, walking, correction therapy, hydrotherapy, sports, sauna) followed by supervised outpatient weekly group physiotherapy is better than weekly physiotherapy alone ([Dagfinrud et al., 2004](#)).

Second-line drug therapies include etanercept, sulfasalazine, and methotrexate, as well as topical or oral steroids for associated uveitis, in consultation with an ophthalmologist. Second-line drugs, however, have shown no clear effect on the progression of decreased spinal mobility ([Dagfinrud et al., 2004](#)). A meta-analysis indicated that all three of the anti-TNF agents were similar in efficacy for patients with AS and that 80% of patients responded to treatment, with improved global, pain, and functional assessment and reduced inflammation, based on morning stiffness ([MacLeod et al., 2007](#)). Sulfasalazine in general is only used for

peripheral AS. Methotrexate, sulfasalazine, and leflunomide are ineffective for axial disease of AS.

KEY TREATMENT

- NSAIDs are the recommended initial therapy for AS (Song et al., 2008) (SOR: A).
- Patients with AS should initiate an exercise program (Dagfinrud et al., 2004) (SOR: B).
- Systemic glucocorticoids are not recommended for AS therapy (SOR: C).
- For AS patients with axial disease who do not respond to NSAIDs, anti-TNF therapy is recommended (MacLeod et al., 2007) (SOR: A).

Reactive Arthritis (Reiter Syndrome)

Key Points

- Signs and symptoms of reactive arthritis develop within 1 month after a GU or GI infection.
- Chlamydia infection or common enteric bacterial infections are the primary cause of Reiter syndrome.
- Only one third of patients with reactive arthritis will present with the classic triad of urethritis, conjunctivitis, and arthritis.

Reactive arthritis, or Reiter syndrome, is characterized by asymmetric oligoarticular arthritis with other extraarticular manifestations within 1 month of GU or GI tract (and possibly pulmonary) infection. The arthritis often occurs after the urethritis, uveitis, or gastroenteritis has resolved.

The classic triad of nongonococcal urethritis, conjunctivitis, and arthritis is fully present clinically in only one third of patients.

Reactive arthritis occurs secondary to *Chlamydia trachomatis* and possibly *Ureaplasma urealyticum* urethritis. Urethritis is sometimes asymptomatic or, in male patients, might manifest not with a mucopurulent discharge but rather with gross hematuria secondary to a hemorrhagic cystitis. *Neisseria gonorrhoeae* infection does not cause reactive arthritis, but a septic joint, including that from gonococcal infection, must be ruled out. GI infections caused by *Shigella*, *Salmonella*, *Campylobacter*, *Klebsiella*, *Clostridium*, or *Yersinia* spp. can all lead to reactive arthritis. By the time the gastroenteritis has resolved and arthritis has developed, the inciting bacterial agent cannot be cultured from the stool. Pulmonary infections with *Chlamydia pneumoniae* might also cause the disease (Braun et al., 1994). Conjunctivitis occurs at the same time or several days after the arthritis, if it occurs at all. The relationship between Reiter syndrome and HIV infection is most likely caused by HIV's association with *Chlamydia* and enteric bacterial infections rather than by HIV itself. Two thirds of patients with reactive arthritis are HLA-B27 positive, indicating genetic factors as well as infectious causes.

Reactive arthritis usually affects several joints, most often in the lower extremity (knees, ankles, feet). Common sites are entheses (where ligaments attach to bones), in particular the Achilles tendon attachment, which causes heel pain. Extraarticular manifestations of reactive arthritis include oral ulcers, aortitis, keratoderma blennorrhagicum (a papulosquamous skin rash occurring most commonly on the palms and soles), and balanitis circinata.

Reactive arthritis usually resolves within 1 year. Although there is no cure, the underlying illness should be treated. When *Chlamydia* is suspected, patients might be given doxycycline or an analogue for up to 3 months, but the optimal duration of therapy is unknown (Mandell et al., 2010). Antibiotics might limit recurrences as well as shorten the course after an episode of urethritis; however, antibiotic use after enteric infections has not been shown to affect the course of reactive arthritis. Reactive arthritis is treated with NSAIDs or intraarticular corticosteroid injections acutely and subsequently with sulfasalazine, 1 g two or three times daily, or methotrexate, 7.5 to 25 mg weekly. No specific studies using anti-TNF therapy have been done, but antidotal research indicates it may be helpful. Long-term disability is uncommon but is usually caused by chronic foot or heel pain or vision problems.

KEY TREATMENT

- NSAIDs are the mainstay of treatment for symptomatic reactive arthritis but do not alter or shorten its course (SOR: C).
- Intraarticular injections can be helpful and are not contraindicated in Reiter syndrome (SOR: C).
- When there is unsatisfactory response to NSAIDs or steroid injections, a trial of sulfasalazine is suggested for patients with reactive arthritis (SOR: C).
- For patients with contraindications or intolerance to sulfasalazine, a trial of etanercept can be attempted (SOR: C).

Psoriatic Arthritis

Key Points

- Psoriatic arthritis affects 5% to 7% of patients with psoriasis.
- Arthritis can occur before or after psoriatic lesions.
- Obtaining family history for psoriasis is important in those without current diagnosis and active psoriatic lesions.

Psoriatic arthritis is seen in approximately 5% to 7% of psoriasis patients, but it might affect up to 40% of hospitalized patients with extensive psoriatic lesions (Cuellar et al., 1994). The associated inflammatory peripheral arthritis might be monoarticular, asymmetric oligoarticular, or symmetric polyarticular, resembling RA. RF is usually absent. Psoriatic arthritis is associated with multiple HLA genes; environmental factors such as infections and physical trauma likely are also involved.

Psoriatic skin lesions predate arthritis in 70% of patients, occur with arthritis in 15%, and follow arthritis in 15%. Family history of psoriasis is therefore important for diagnosis in patients with an arthritis similar to psoriatic but without a known history. Psoriatic arthritis often manifests initially as an asymmetric monoarticular or oligoarticular arthritis of a large joint, such as a knee, evolving into asymmetric polyarticular arthritis. The distribution of involvement of psoriatic arthritis might resemble RA but involves the DIP joints more often, as well as causing enthesitis. Psoriatic arthritis might also cause spondylitis, sacroiliitis, chest wall pain from enthesitis, arthritis mutilans (destruction of phalanges and metacarpals, causing telescoping of fingers), conjunctivitis, and Achilles tendon and plantar fascia involvement. Radiographic abnormalities include marginal erosions at DIP and PIP joints, with new bone formation.

In addition to treating the psoriatic skin lesions, the arthritis is treated first with NSAIDs followed by DMARDs for widespread disease and corticosteroid injections if only one or two joints are involved (Cuellar et al., 1994). A Cochrane analysis showed that high-dose methotrexate and sulfasalazine have efficacy in psoriatic arthritis (Jones et al., 2000). Azathioprine, etretinate, low-dose methotrexate, and colchicines all had some effectiveness versus placebo, but more studies are necessary. Anti-TNF medications are also used if patients continue to have symptoms despite DMARD treatment or if axial disease is present and NSAIDs have not worked. A meta-analysis of RCTs showed that anti-TNF drugs are effective against psoriatic arthritis (Saad et al., 2008). When contemplating a local steroid joint injection, the physician should keep in mind that bacterial colonization of psoriatic skin lesions with streptococcus or staphylococcus is common. Injecting through skin lesions should therefore be avoided.

KEY TREATMENT

- NSAIDs are the first line of treatment for psoriatic arthritis (Cuellar et al., 1994) (SOR: B).
- Methotrexate and sulfasalazine have proven efficacy in the treatment of psoriatic arthritis (Jones et al., 2000)

(SOR: B) used as second-line agents if inadequate response to NSAIDs.

- Patients with axial disease or who have peripheral disease without improvement to DMARD treatments are candidates for anti-TNF medications, which have proven efficacy (Saad et al., 2008) (SOR: A).

Enteropathic Arthropathy

There seems to be a connection between the gut and spondyloarthropathies. Of patients with IBD (ulcerative colitis and Crohn disease), 10% to 20% have a peripheral arthritis different from other defined arthritides. Migratory arthralgias, especially of the knees, ankles, and feet, often coincide with periods of GI disease flares. Other joints, including the spine and sacroiliac joints, might be involved but are seemingly less coincident with bowel exacerbations. HLA-B27 is found in 50% of patients with IBD-associated spondylitis but is not found in a higher percentage than in the general population for this type of spondylitis. RF and ANA are negative. NSAIDs are normally used but must be taken with caution given the patient's underlying GI disease. As noted earlier, dietary factors might increase the patient's baseline inflammatory state, so a trial of dietary manipulation or the addition of omega-3 fatty acids is reasonable.

INFECTIOUS ARTHRITIS

Septic Arthritis

Key Points

- The knees are the most common sources of infectious arthritic pain.
- Septic arthritis is a surgical emergency.
- *Staphylococcus aureus* and *Neisseria gonorrhoeae* are the two most common causes.

Acute bacterial arthritis is one of the few rheumatologic emergencies. Failure by the primary care physician to diagnose this entity and to initiate prompt antibiotic therapy results in significant morbidity (functional disability, joint destruction) and at least 5% mortality. Even in patients with known rheumatologic disease, a bacterial infection may cause an acutely inflamed joint. The three mechanisms of a septic joint are (1) hematogenous spread from a distant location, such as a urinary tract infection (UTI) or pneumonia; (2) contiguous spread from a wound infection, abscess, or osteomyelitis; and (3) direct introduction of bacteria through trauma, surgery, or arthrocentesis. Concern about the third mechanism should not prevent the family physician from ruling out bacterial infection by performing synovial fluid analysis in an inflamed joint if the diagnosis is unclear. As for lumbar puncture, if the physician thinks it should, arthrocentesis probably should be done.

From 80% to 90% of acute bacterial articular infections are monoarticular. In adults with nongonococcal bacterial arthritis, the most common sites are the knee (50%), hip (20%), shoulders (8%), ankles (7%), wrists (7%), elbow (6%), other (5%), and more than one joint (usually two; 12%) (Brusch, 2005). In children, the most common sites

are the knee (40%), hip (28%), ankle (14%), shoulder (4%), wrist (3%), elbow (11%), other (3%), and more than one joint (7%) (Baker and Schumacher, 1993). About 20% of patients are afebrile. Septic joints are normally painful, swollen, red, and warm. Diabetes mellitus, malignancy, chronic liver disease, and other rheumatic diseases (e.g., RA, SLE) increase the risk of a septic joint and probably its severity. Other risk factors for a septic joint include advanced age, intravenous (IV) drug abuse, HIV infection, and having a prosthetic joint. Almost half of adults with septic arthritis are older than 60 years, and the condition usually affects an arthritic hip, knee, or shoulder. Septic arthritis in older adults causes a fever in only 10% of patients and a marked leukocytosis in only one third, although ESR elevation is usually marked. Joint and blood culture results are usually positive.

Most polyarticular disease is seen in immunosuppressed patients or those with underlying rheumatic disease. The causative organism is usually *Staphylococcus aureus*. The mortality rate in patients with polyarticular septic joints approaches 40% (Youssef and York, 1994).

Most cases of septic arthritis are secondary to hematogenous spread of infection. In drug abusers, the causative organism is usually *S. aureus* or gram-negative organisms and affects predominantly the joints of the axial skeleton (hip, shoulder, vertebrae, symphysis pubis, costochondral, sternoclavicular, sacroiliac). Iatrogenic septic arthritis is usually caused by *S. aureus*, *Staphylococcus epidermidis*, and gram-negative organisms. This complication might be difficult to recognize because the joint is already symptomatic (which prompted the arthroscopy or arthrocentesis) before infection. Bacterial infection after arthroscopy is 0.04% to 4% and after arthrocentesis is 0.01%. Septic arthritis complicating RA is polyarticular in 50% of patients, usually caused by *S. aureus*, and arises from pulmonary or UTIs, infected rheumatoid nodules, or foot infections. Prosthetic infections are from direct inoculation or hematogenous spread; the prosthesis often must be removed.

Septic arthritis in children normally involves the lower extremities (knee, hip, and ankle). An infant or child with a septic joint often presents with not moving the infected joint and being generally irritable. Septic arthritis can complicate otitis media, an umbilical catheter, meningitis, or osteomyelitis. *S. aureus* and group B streptococci are the most common organisms in infants and children, except ages 6 months to 2 years, when *Haemophilus influenzae* and *Kingella kingae* organisms predominate. *H. influenzae* septic arthritis is seen especially in partially immunized children.

The most common form of acute bacterial arthritis is disseminated gonococcal infection, which causes a migratory polyarthritides and tenosynovitis, affecting predominantly the small joints of the hands, wrists, elbow, ankles, and knees. Papules and vesicles are often apparent on the trunk and extremities, including the palms and soles. Patients usually do not have symptoms of urethritis, cervicitis, or pharyngitis. If gonococcal arthritis is suspected, empiric treatment should be initiated immediately while culture results are pending. *Neisseria meningitidis* can cause a similar arthritis and rash syndrome after an illness, ranging from a mild upper respiratory infection to frank meningitis. In contrast to gonococcal infections, the

meningococcus might cause oral mucosal lesions as well as skin lesions.

Acute gonococcal arthritis can be confirmed by Gram stain in only 25% of patients and by culture in 50%; nongonococcal bacterial arthritis can be confirmed in 50% and 90% of patients, respectively. It is therefore important to make a clinical diagnosis rather than rely solely on laboratory studies. Fever is often absent or of low grade. Blood cultures are also positive only approximately half the time but might be positive when synovial fluid cultures fail to identify an organism. Synovial fluid analysis usually shows WBC count over 50,000/mm³, with more than 90% PMNs. Crystals can coexist with bacterial infections, and their presence should not rule out bacterial infection. Plain radiography might detect an osteomyelitis and should be done as a baseline study because destruction can be seen on radiographs 10 to 14 days later. Air in the joint suggests an anaerobic infection, which accounts for 1% of septic joints.

The duration of appropriate IV antibiotic treatment depends on the presumptive or culture-identified causative organism. Initial therapy depends on the Gram stain result from synovial fluid. If gram-positive cocci are seen, IV vancomycin should be started empirically. If gram-negative bacilli are seen, a third-generation IV cephalosporin should be initiated. If the Gram stain result is negative, IV vancomycin should be considered. When sensitivity data return, antibiotic therapy can be narrowed appropriately. The duration varies, but often the patient will receive 2 weeks of IV therapy followed by 2 weeks of oral therapy. Intraarticular antibiotic injections are unnecessary. A joint might need repeated needle aspirations or tidal lavage with arthroscopy to sterilize the joint space (Klippel, 2001).

KEY TREATMENT

- Empiric treatment of infectious arthritis with appropriate IV antibiotics is based on Gram stain results; joint and blood culture sensitivities narrow the antibiotic regimen (SOR: C).
- Joints may need drainage in patients with septic arthritis (SOR: C).

Viral Arthritis

See [eAppendix 32-1](#) online.

Lyme Arthritis

Key Points

- *B. burgdorferi* is the most common source of Lyme disease.
- Lyme titer is diagnostic but might have a high false-negative ratio.
- False-positive titers can be caused by RA or lupus.
- About 80% of Lyme disease patients have classic erythema migrans (EM) rash.

Lyme disease is caused by the *Ixodes* tick-borne spirochete *B. burgdorferi* and was first described in 1975 after an apparent outbreak of juvenile RA in Lyme, Connecticut. The

characteristic target rash of EM develops within 1 month (mean 1 week) of a tick bite and can be complicated by CNS disease (meningitis, neuritis), cardiac disease (atrioventricular conduction blocks), and arthritis. It occurs most often in northeastern states (New York, Connecticut, Massachusetts, New Jersey, Rhode Island, Pennsylvania) and upper Midwestern states (Wisconsin, Minnesota). As with other rheumatologic diseases, Lyme disease is a clinical diagnosis, with laboratory tests used only to clarify the diagnosis.

Although most patients with Lyme disease do not recall an actual tick bite, most (80%) manifest the EM rash, which might be confluent or have central clearing or darkening. This rash may enlarge quickly and may be accompanied by arthralgia, myalgia, fatigue, fever, and chills. Weeks to months after the EM rash, neurologic involvement can occur. A facial nerve palsy is common, although most facial nerve palsies are not caused by Lyme disease, even in endemic areas. As with neurologic signs, carditis might be the first presenting symptom, often manifesting as a first-, second-, or third-degree atrioventricular block or bundle branch block. Cardiac symptoms normally do not occur for 1 to 2 months after onset of symptoms.

Arthritis can occur in approximately half of untreated patients with Lyme disease but is rare in treated patients. Rheumatic symptoms occurring late in the clinical course include polyarthralgias, a migratory polyarthritis, or an oligoarticular arthritis with few systemic symptoms. In untreated patients developing an arthritis, some develop a chronic arthritis resistant to antibiotics.

Laboratory Studies

The current recommended approach is a two-tier strategy using a sensitive enzyme-linked immunosorbent assay (ELISA) and, if the result is positive, Western blot. ELISA is associated with a high false-positive rate, so all positive results must be confirmed with a positive Western blot. Western blot can test for both immunoglobulin M (IgM) and IgG antibodies to *B. burgdorferi*. IgM antibodies typically appear within 1 to 2 weeks and IgG in 2 to 6 weeks after onset of EM rash. Only one third of patients with a single lesion of EM are seropositive at diagnosis (Verdon and Sigal, 1997). The presence of EM is itself enough to make the clinical diagnosis, and testing is not required. Negative serology in a suspected case should be followed by acute- and convalescent-phase samples (2-4 weeks after initial sample). False-positive ELISA test results can occur in RA, juvenile rheumatoid arthritis (JRA), SLE, and infectious mononucleosis. Serologic testing after treatment is not helpful because seroreactivity persists long after successful treatment.

Treatment

Treatment of early Lyme disease in adults includes doxycycline, 100 mg twice daily, or amoxicillin, 500 mg three times daily, for 21 days. Amoxicillin is first-line therapy in children younger than 8 years old; cefuroxime axetil or erythromycin is used in cases of doxycycline or amoxicillin allergy (Worsmer et al., 2006). Oral therapy is as effective as IV therapy for patients with either early Lyme disease or Lyme arthritis and is less costly (Eckman et al., 1997). Concern about the risk of late neurologic sequelae should

32-1 *Viral Arthritis*

Many viruses cause acute arthritis. The most significant are parvovirus B19 (the cause of fifth disease or erythema infectiosum in children), HIV, hepatitis viruses, and rubella.

Fifth disease, characterized by a slapped cheek–type facial rash, causes mild self-limited arthralgias in 10% of children but in 80% of adults. The arthralgias in adults have a rheumatoid arthritis–like distribution, affecting the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints, knees, wrists, and ankle joints. In most adults, these arthralgias last no more than 2 weeks, but 10% can have persistent symptoms that are low grade with intermittent flares. Nonsteroidal antiinflammatory drugs (NSAIDs) constitute the standard treatment.

Initial HIV infection often manifests as an influenza-like illness with arthralgias. Whether HIV itself causes a reactive arthritis is controversial because many believe that co-infection with other agents, rather than HIV itself, is the cause. HIV infection can cause several distinct pain syndromes. A few patients have described an acute symmetric polyarthritis of the hands and wrists, with periosteal new

bone formation around involved joints. Others have developed a subacute oligoarticular arthritis that might cause severe disability but is transient, lasting 1 to 6 weeks. This primarily affects the knees and ankles; it does respond to NSAIDs. Up to 10% of HIV-infected patients experience painful articular syndrome—severe, intermittent pain of the shoulders, elbows, and knees lasting less than 1 day. Also, fibromyalgia has been reported in up to 29% of HIV patients (Klippel, 2001).

A symmetric migratory arthritis predominantly affecting the hands and knees can be caused by hepatitis B virus–initiated immune complexes. Patients with chronic active hepatitis B can have recurrent arthritis. Hepatitis A is not known to cause arthritis. Hepatitis C causes cryoglobulinemia, arthritis, and palpable purpura.

Postvaccination arthritis and arthralgias can occur from rubella vaccine, as well as live rubella virus–induced migratory polyarthralgia affecting the PIP and MCP joints, knees, wrists, ankles, and elbows. Rubella-associated arthritis generally lasts up to 2 weeks.

not lead to more aggressive treatment with IV antibiotics for these patients (Wormser et al., 2000). Early treatment prevents recurrent arthritis as well as neurologic and cardiac sequelae. IV therapy with ceftriaxone (Rocephin), cefotaxime (Claforan), or penicillin G is used for early disseminated and late Lyme disease. IV antibiotic therapy is preferable for patients with neurologic symptoms, with the possible exception of those with facial palsy alone (Steere, 1989). Most patients are symptomatically better with 20 days of treatment. Continued symptomatology in patients with treated infection does not respond to further antibiotics (Klippel, 2001). Antibiotic treatment failures can occur but are rare and usually associated with poor absorption. Antibiotic resistance to typically used agents has not been shown.

For preventive measures against Lyme disease, see [Appendix 32-2](#) online.

KEY TREATMENT

- Adults and children 8 years and older should be treated with oral doxycycline for 21 days for early Lyme disease (Wormser et al., 2006) (SOR: A).
- Pregnant women and children younger than 8 years should be treated with oral amoxicillin or cefuroxime (SOR: C).
- Patients with neurologic (excluding isolated facial nerve palsy) or cardiac manifestation are treated with IV antibiotic therapy for Lyme disease (Wormser et al., 2000) (SOR: B).

Other Infectious Arthritides

Although mycobacteria, parasites, and fungi rarely cause arthritis, the incidence has increased with increasing numbers of HIV/AIDS and other immunosuppressed patients. *Mycobacterium tuberculosis* arthritis occurs by hematogenous spread from the lung and is diagnosed by synovial fluid culture. The classic tuberculosis infection involves the spine and is known as Pott disease. Thoracic vertebrae are most often involved, but a monoarticular arthritis can also occur in large, weight-bearing joints. Mild arthritides might also be caused by *Giardia lamblia* infection, histoplasmosis, cryptococcosis, blastomycosis, sporotrichosis, coccidioidomycosis, actinomycetes, and atypical mycobacteria.

RHEUMATIC FEVER

Key Points

- Rheumatic fever is seen 2 to 4 weeks after β -hemolytic streptococcal pharyngitis.
- Antibiotic treatment for streptococcal infection can help prevent development of rheumatic fever.
- The Jones criteria and ASO titers are helpful in diagnosis of rheumatic fever.

Rheumatic fever is a systemic inflammatory process initiated by group A β -hemolytic streptococcal pharyngitis. Often, younger children in particular do not recall

Table 32-8 Revised Jones Criteria for Diagnosis of Acute Rheumatic Fever*

Major manifestations	Carditis Polyarthritis Chorea Erythema marginatum Subcutaneous nodules
Minor manifestations	<i>Clinical:</i> Arthralgia, fever <i>Laboratory:</i> Elevated acute-phase reactants (ESR, CRP) Prolonged PR interval
Plus:	Supporting evidence of antecedent group A streptococcal infection Positive throat culture or rapid streptococcal antigen test Elevated or rising streptococcal antibody titer

*If supported by evidence of preceding group A streptococcal infection, the presence of two major manifestations or of one major and two minor manifestations indicates a high probability of acute rheumatic fever.

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

From Gibofsky A, Zabriskie JB. Rheumatic fever. In Klippel JH, ed. *Primer on the rheumatic diseases*. 12th ed. Atlanta: Arthritis Foundation; 2001:282.

antecedent pharyngitis, which usually occurs 2 to 4 weeks before symptom onset. Rheumatic fever appears to be linked only to pharyngitis; group A streptococcal (GAS) impetigo does not seem to be associated with rheumatic fever. Rheumatic fever most often affects children 4 to 9 years of age, and the onset is usually characterized by an acute febrile illness that can cause large-joint migratory arthritis, CNS involvement (Sydenham chorea), characteristic rash, and carditis with inflammation of heart valves and subsequent damage. Antibiotic treatment of GAS pharyngitis greatly reduces the development of rheumatic fever. The 1992 revised Jones criteria are useful in the diagnosis of acute rheumatic fever (Table 32-8).

Rheumatic fever–related arthritis is often preceded by arthralgias out of proportion to frank swelling, lasting approximately 1 week. Arthralgias usually migrate to lower extremity joints and then to the upper extremities. Children experience this arthritis less frequently than adolescents and adults. The arthritis then resolves spontaneously. Carditis involving the valves, particularly the mitral valve, is the most severe sequela. Rheumatic heart disease is the most common serious sequela and usually occurs 10 to 20 years after the original attack. Patients might also have erythema marginatum, a rash with open or closed ring lesions with sharp outer edges or macular rings with pale centers, or both. The rash spreads centrifugally from the trunk to the extremities with lesions that come and go.

The antistreptolysin O (ASO) titer is the most useful laboratory test because pharyngeal culture results are often negative by the time rheumatic fever develops. The ASO titer rises 4 to 5 weeks after the onset of GAS pharyngitis or 2 to 3 weeks after development of rheumatic fever. Because only 80% of patients with rheumatic fever develop an increase in ASO titer, clinically suspicious rheumatic fever with a negative ASO titer should be followed up by testing for antistreptococcal antibody, such as anti-DNase, anti-DNase B, and antihyaluronidase antibody tests.

Aspirin is the drug of choice for acute rheumatic fever and usually results in a dramatic response. The usual dosage is 80 to 100 mg/kg/day for children and 4 to 8 g/day for

32-2 *Prevention of Lyme Disease*

Lyme disease is best prevented by avoiding tick bites. Frequent checks for ticks and prompt removal can prevent the disease; transmission of infection is more likely with prolonged tick attachment. Infection occurs in only 1% of cases after tick attachment for less than 72 hours compared with 20% after 72 hours ([Sood et al., 1997](#)). Other effective measures include light clothing (to increase tick visibility), cuffs tucked into socks, and diethyltoluamide (DEET) repellent. Lipoprotein OspA (LYMErix) vaccine given in three

doses at 0, 1, and 12 months (the third dose is ideally in March because tick season begins in April), although widely marketed to the general public, should be limited to those at highest risk. The long-term safety and effectiveness of the vaccine have been mixed in studies; the vaccine is expensive; and antibiotics for early disease are effective in preventing complications ([Advisory Committee on Immunization Practices, 1999](#)).

adults. Penicillin should also be given for a 10-day course whether or not pharyngitis is present, and family members and other close contacts should be cultured and treated if necessary. IM penicillin is more effective than oral penicillin in clinical trials. No benefit has been shown from IV immune globulin (IVIG) or corticosteroids for rheumatic fever, but studies continue (Manyemba and Mightosi, 2004).

Patients who have had documented rheumatic fever and who develop subsequent GAS pharyngitis are at high risk for a recurrent rheumatic episode and thus at increased risk for worsening rheumatic heart disease. For this reason, prevention of recurrent episodes requires continuous antimicrobial prophylaxis (Gerber et al., 2009). Before prophylaxis initiation, a full treatment course for GAS pharyngitis should be completed. In the United States, typical prophylactic therapy is with long-acting IM benzathine penicillin G every 4 weeks until early adulthood (\approx 18 years of age).

KEY TREATMENT

- Patients with acute GAS pharyngitis should receive antibiotic therapy to help prevent the complication of acute rheumatic fever (Denny et al., 1950) (SOR: B).
- Patients with acute rheumatic fever should receive appropriate antibiotic therapy to eradicate the GAS infection, regardless of whether pharyngitis is present at diagnosis (SOR: C).
- Use of aspirin is the treatment of choice for the acute symptoms of acute rheumatic fever (SOR: C).
- Prevention of recurrent acute rheumatic fever requires prophylactic treatment for GAS pharyngitis with antibiotics (Gerber et al., 2009) (SOR: A).

SYSTEMIC LUPUS ERYTHEMATOSUS

Key Points

- The 5-year survival rate of SLE patients is 90%.
- The female:male ratio is 2:1 before and 4:1 after puberty.
- Four of 11 criteria are needed for SLE diagnosis.

Systemic lupus erythematosus is a generalized autoimmune disease of unknown cause characterized by the production of antibodies to numerous antigens. The most common antibodies found in SLE are those directed against the cell nucleus (ANAs). These antibodies bind DNA, RNA, nuclear proteins, and protein–DNA or protein–RNA complexes. Antibodies to double-stranded DNA and an RNA–protein complex called Sm are found almost exclusively in SLE. Immune complex deposition results in inflammation and vasculitis, causing multiorgan pathology.

Systemic LE is most common in women of reproductive age (15–40 years), and the female:male ratio is approximately 2:1 before puberty and 4:1 after puberty. However, SLE can be seen in all ages, including infants and older adults; in these two subpopulations, the female:male ratio is only 2:1. SLE affects approximately one in 1000 to 2500

in the general population, but the disease incidence in African American and Latino women is much higher (up to one in 250 in African American women ages 18–65 years). The 5-year survival rate after diagnosis is 90%.

Systemic LE also shows a strong familial tendency. An association with MHC genes *DR2*, *DR3*, *DR4*, and *DR5* has been found. As with other rheumatologic diseases, SLE appears to result from a genetic abnormality that can be triggered by environmental factors. Some of these hypothesized factors include infections, stress (neuroendocrine changes), exposure to sunlight, diet, and toxins, including drugs. In addition to autoantibody production, SLE involves immune cell (B, T, monocyte) abnormalities. Because of the wide variety of presentations, the ACR created a classification system to standardize the diagnosis of SLE (Table 32-9). To confirm a diagnosis of SLE, patients must have at least 4 of 11 criteria present either serially or simultaneously.

Clinical Features

Constitutional symptoms found in patients with SLE include fatigue, malaise, fever, and weight loss. The family physician therefore has an important role to play in the diagnosis of this multisystem disease, which must be differentiated from infections such as HIV (which often is false positive in SLE) and subacute bacterial endocarditis; other connective tissue diseases such as vasculitis, RA, and mixed connective tissue disease; and malignancies such as lymphomas. SLE is characterized by specific organ system abnormalities. The disease most often affects the skin, joints, kidneys, CNS, GI tract, and lungs, with a spectrum of disease severity and an unpredictable course. SLE is truly systemic; other asymptomatic organ involvement must be searched for during active periods of disease, regardless of the presenting sign or symptom.

Mucocutaneous Manifestations. More than 90% of SLE patients eventually have a mucocutaneous manifestation. The classic malar butterfly rash gave lupus its name because it was thought to resemble the bite of a wolf. This rash is present in only one third of patients; when it occurs, it is often after sunlight exposure. One third to two thirds of SLE patients are extremely photosensitive. Sun exposure not only can cause a maculopapular, erythematous rash but also can induce a flare of systemic symptoms. Other lesions can occur, such as bullae or generalized erythema.

Subacute cutaneous lupus erythematosus (SCLE) occurs in sun-exposed areas of the skin, particularly on the upper torso, in two forms—annular or papulosquamous lesions. The former variant might be confused with erythema annulare and the latter with psoriasis or lichen planus. About 70% of patients with photosensitivity have anti-Ro antibodies (Boumpas et al., 1995). SCLE lesions do not result in scarring. Discoid lupus lesions are raised plaques that often occur in the absence of any other systemic manifestations, most often on the face, neck, scalp, and external ears. Unlike SCLE lesions, these erythematous plaques with heavy scales can cause scarring, with a hypopigmented, atrophic central area. Other mucocutaneous manifestations of SLE include alopecia, which resolves when the acute SLE exacerbation ends, unless the alopecia is secondary to discoid scarring. Oral, nasal, and vaginal ulcerations as well as palpable purpura also occur.

Table 32-9 Criteria for Classification of Systemic Lupus Erythematosus*

1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or b. Pericarditis—documented by electrocardiogram or rub or evidence of pericardial effusion
7. Renal disorder	a. Persistent proteinuria higher than 0.5 g/day or higher than 3+ if quantitation not performed or b. Cellular casts: may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	a. Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance) or b. Psychosis: in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, electrolyte imbalance)
9. Hematologic disorder	a. Hemolytic anemia—with reticulocytosis or b. Leukopenia—less than 4000/mm ³ total on two or more occasions or c. Lymphopenia—less than 1500/mm ³ on two or more occasions or d. Thrombocytopenia—less than 100,000/mm ³ in the absence of offending drugs
10. Immunologic disorder	a. Positive lupus erythematosus cell preparation or b. Anti-DNA: antibody to native DNA in abnormal titer or c. Anti-Sm: presence of antibody to Sm nuclear antigen or d. False-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with “drug-induced lupus” syndrome

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person is said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus (SLE). *Arthritis Rheum.* 1982;25:1271-1277, with permission of the American College of Rheumatology.

Latent lupus refers to the condition of those patients who do not meet the ACR criteria for diagnosis of SLE but have many features consistent with lupus. This form is mild and is treated symptomatically. Many of these patients never develop classic SLE; there are no identifiable prognostic indicators of propensity for progression to frank lupus.

Drug-induced lupus occurs when a patient taking a drug develops clinical and serologically consistent lupus, which then resolves (clinically and then serologically) on discontinuation of the drug. Drugs known or suspected to cause lupus include *antituberculous* drugs (e.g., isoniazid, streptomycin), *antibiotics* (e.g., penicillin, tetracycline, sulfa, griseofulvin), *anticonvulsants* (e.g., phenytoin [Dilantin], ethosuximide [Zarontin], carbamazepine [Tegretol]), *phenothiazines* (e.g., perphenazine [Trilafon], promethazine [Phenergan], thioridazine [Mellaril]), and *antihypertensives* (e.g., hydralazine, methyldopa, reserpine), as well as oral contraceptives, lithium, propylthiouracil, and procainamide. Symptoms are usually mild and do not involve the CNS or kidneys.

Musculoskeletal Manifestations. Arthralgias and arthritis are the most common initial symptoms of SLE. The typical pattern is symmetric involvement of the hands, wrists, or knees, either migratory or persisting in an involved joint. There may be subcutaneous nodules similar to those of RA, but SLE usually does not cause RA-like erosions. Subluxations causing swan neck deformities and other deformities in the hands are known as *Jaccoud arthropathy*, which is characterized by deformity without erosion of bone and cartilage. Patients with SLE sometimes

experience myalgias but usually not to the degree seen in dermatomyositis.

Musculoskeletal complications of SLE also include osteoporosis and avascular necrosis of bone (osteonecrosis), especially in corticosteroid-treated children with SLE. In one study, 65% of premenopausal women with SLE had abnormal bone mineral density (Petri, 1995). Screening for osteoporosis, even in premenopausal women, and treatment, if indicated, are therefore prudent measures, as is minimizing the use of corticosteroids. Late SLE can cause osteonecrosis, particularly of the hip, independent of active SLE episodes. Major risk factors for osteonecrosis include a prednisone dosage higher than 20 mg/day for 1 month or longer and the presence of Raynaud disease or vasculitis. Avascular necrosis of the hip is diagnosed early by MRI.

Renal Disease. Called *lupus nephritis*, SLE-induced renal disease is typically asymptomatic until relatively late. More than 50% of all patients and 75% of African American patients with SLE have renal involvement. Immune complex deposition along the glomerular basement membrane leads to the nephrotic syndrome or renal failure, which can be the presenting sign. An elevated serum creatinine level can be found, as well as proteinuria, hematuria, pyuria, and casts in the absence of infection. Definitively diagnosed by renal biopsy, lupus nephritis constitutes a spectrum of severity from mild to more severe that involves mesangial, focal proliferative, diffuse proliferative, and advanced sclerosing forms of glomerulonephritis (Petri, 1998). Patients with SLE should have an annual urinalysis and renal function test to rule out proteinuria. An elevated creatinine level

(>2 mg/dL) is the best predictor of prognosis. Patients with SLE have had successful renal transplants, although lupus nephritis can recur.

Neuropsychiatric Disease. Neuropsychiatric symptoms are common when SLE is active but can occur in isolation. Manifestations include headache, generalized seizures (20% of SLE patients), stroke, cranial and peripheral neuropathies, psychosis, severe depression (40%), cognitive abnormalities, and organic brain syndrome. Cranial neuropathies may manifest as visual defects, tinnitus, vertigo, nystagmus, ptosis, or facial palsies. A migraine-type headache is common and can be intractable. *Neuropsychiatric lupus* is a diagnosis of exclusion after other causes of the patient's symptoms have been ruled out. Electroencephalographic findings are often abnormal but nonspecific. MRI of the head can show diffuse, small focal areas of increased signal density on the cerebral white matter and cortical gray matter that clear with corticosteroid treatment. Cerebrospinal fluid (CSF) studies are important to rule out infectious causes. Even in long-term mild disease, neurocognitive abnormalities affecting memory or causing speech abnormalities often persist. Antiribosomal P antibody presence correlates with cognitive impairment in SLE (Hirohata and Nakanishi, 2001).

Cardiovascular Manifestations. Patients with SLE have an increased risk of premature atherosclerosis from the disease itself as well as from its treatment; up to 40% of SLE patients have been found to have this complication in screening studies. Corticosteroids increase cardiac risk factors such as weight, BP, cholesterol, and homocysteine levels, which the family physician must keep in mind. Primary coronary disease prevention monitoring and patient education plans for the SLE patient are important because the mortality rate from myocardial infarction is approximately 10 times that in an age- and gender-matched population (Klippel, 2001). Myocarditis and endocarditis are rare, but pericarditis can occur in up to 45% of patients with SLE (25% in most series). Symptoms might be mild or severe, but constrictive pericarditis and cardiac tamponade are rare.

Thrombosis is a major cause of morbidity and mortality in lupus patients. Between 30% and 50% of SLE patients make antiphospholipid autoantibodies to the phospholipid part of the normal cell membrane, although most people with these antibodies do not have lupus. Types of antiphospholipid antibodies include anticardiolipin antibody, β 2-GP-I antibody and lupus anticoagulant. Lupus anticoagulant antibodies might result in prolonged partial thromboplastin time (PTT) and prothrombin time (PT) but paradoxically result in an increased risk of thrombotic events for these patients. This might be caused by an antibody-induced vasculopathy. Anticardiolipin and β 2-GP-I antibodies can be detected using ELISA, but there is no direct testing for the lupus anticoagulant. If the lupus anticoagulant is clinically suspected but activated PTT is normal, more sensitive coagulation tests should be done, including kaolin clotting time (KCT), modified Russell viper venom time (RVVT), and platelet neutralization procedure (PNP) (Petri, 1994).

Antiphospholipid antibody syndrome is defined as the presence of lupus anticoagulant, β 2-GP-I antibody or

anticardiolipin antibody with one of these four entities: arterial thrombosis, venous thrombosis, recurrent first-trimester or one late (second- or third-trimester) spontaneous abortion, or thrombocytopenia. This acquired autoimmune hypercoagulability is more common in patients with SLE than in the general population.

The incidence of spontaneous abortion, intrauterine death, and prematurity is also increased in women with SLE alone. Studies differ, but currently pregnancy is not thought to exacerbate SLE, as formerly thought. It is recommended that women be flare-free for 6 months and do not have serious comorbidities such as renal disease before deciding to become pregnant. Fertility is not affected by SLE. Women with either recurrent first-trimester or late pregnancy loss can reduce their risk of pregnancy loss with heparin and low-dose aspirin therapy.

Other Manifestations. Serositis that causes pericarditis, pleurisy, and peritonitis is common in SLE. Bilateral pleural effusions are usually small and are seen most often in drug-induced lupus patients and in older adult patients. Pleurisy is clinically more common than pericarditis, which rarely becomes severe enough to be constrictive.

Systemic LE can cause multiple GI symptoms such as nausea, vomiting, anorexia, and abdominal pain, often as a result of peritoneal inflammation. Mesenteric vasculitis can cause lower abdominal pain and rectal bleeding. Hepatomegaly with increases in liver enzyme levels and pancreatitis with amylase level elevations can occur with SLE. In addition to hepatomegaly, splenomegaly and lymphadenopathy can occur with lupus exacerbations.

Lung involvement can include pulmonary hemorrhage, pulmonary hypertension, and pneumonitis. *Lupus pneumonitis* often manifests as a diffuse interstitial disease. *Shrinking lung syndrome*, seen in late SLE, is a restrictive condition with decreased lung volumes resulting from abnormal musculoskeletal respiratory function.

Laboratory Abnormalities

There are no specific tests for lupus. The lupus erythematosus cell, formed when complexes of nuclei and antibodies are phagocytosed by PMNs, is highly specific but of low sensitivity. ANA, anti-double-stranded DNA, and antiphospholipid antibody are all markers for SLE, but antibody test results are misleading if not considered in the clinical context. From 2% to 5% of patients with SLE are ANA negative, but 5% of the normal population and up to 20% of healthy young women are ANA positive (Fritzler et al., 1985). Antibodies to an RNA-protein complex called Sm (anti-Smith antibody) and to double-stranded DNA (dsDNA) are almost unique for SLE, both being 95% specific. Whereas ESR is normally increased, CRP is normal (Linares et al., 1986).

Autoantibodies in SLE include ANA and anticytoplasmic antibodies (including lipoproteins), antibodies against blood cells, antibodies against various organs and structures (e.g., gastric mucosa, neurons, muscle sarcolemma, thyroglobulin), and antibodies against collagen. Different antibodies against different parts of the cell nucleus appear as the four patterns of ANA staining. These include membranous antibodies against single-stranded DNA, speckled antibodies against extractable ribonucleoproteins, dsDNA

antibodies against native dsDNA, nucleolar antibodies against nucleolar antigens and sometimes associated with scleroderma, and homogeneous antibodies against deoxyribonucleoproteins.

In active SLE, serum complement (C3, C4, and often CH50) levels are depressed. ESR is often elevated during active disease but is not a precise indicator of disease activity. DNA autoantibodies also do not correlate well with periods of active disease. A normochromic normocytic anemia, leukopenia (2500-4000 WBCs/mm³), and thrombocytopenia are common because of bone marrow suppression or the autoimmune process, although other causes must be ruled out first. SLE can manifest as immune thrombocytic purpura years before the patient develops other symptoms of lupus.

The confirming tests for lupus (e.g., ANA, anti-DNA titers) are generally not helpful in follow-up. Monitoring for disease or treatment sequelae often involves serial CBC; renal function testing (creatinine); urinalysis; C3 and C4; and laboratory tests monitoring specific drug toxicities, including homocysteine and cholesterol levels for patients taking corticosteroids.

Treatment

The major goal of treatment is to treat the active disease without causing iatrogenic long-term complications and to be supportive of the patient and family. The family physician has a vital role in educating patients with SLE about signs and symptoms of disease flares. Continued monitoring, even when the disease appears inactive, is also important. General advice includes avoiding sun exposure or using potent sunscreens, early evaluation of unexplained fevers, annual influenza vaccine, adequate rest and exercise, and weight control. Other specific information tailored to the patient's needs is also important, such as SLE and its effect on pregnancy.

Vigilance for severe infections, particularly when corticosteroids are being used, should be continual. Proper monitoring for drug toxicities must include ophthalmologic examination with antimalarials and monitoring for corticosteroid-induced side effects. Treatment approaches for SLE emphasize using a drug combination to minimize corticosteroid use. Corticosteroids increase cardiovascular risk factors, including weight, BP, and cholesterol and homocysteine levels. Too-rapid steroid tapering should also be avoided. Immunosuppressive drugs are also being used more often, requiring careful monitoring.

The NSAIDs are still the drugs of choice for musculoskeletal manifestations, especially mild symptoms. The potential renal and GI toxicity of these drugs being used for a disease that in itself causes renal and GI damage must be kept in mind and monitored. Gastroduodenal cytoprotective therapy should be strongly considered for patients taking NSAIDs.

For minor polyarthritic disease activity, prednisone at 0.5 mg/kg/day in a single dose can be given, but many recommend other agents if the daily maintenance prednisone dose is 10 mg or more. Antimalarials such as hydroxychloroquine (Plaquenil) are often used for lupus arthritis but require ophthalmologic monitoring every 6 to 12 months. For severe arthritis or flare-ups, prednisone at 1.0 mg/kg/day; intraarticular injection with triamcinolone

hexacetonide; or IV methylprednisolone sodium succinate (Solu-Medrol), 1000 mg over 90 minutes daily for 3 days, can be used, followed by oral prednisone. Methotrexate, 7.5 mg orally once weekly, along with folic acid supplementation or azathioprine, can also be used to minimize prednisone dosage, although methotrexate cannot be used during pregnancy.

Cutaneous lupus is treated with sunscreen and sun avoidance, topical or intralesional corticosteroids, topical cryotherapy with liquid nitrogen (less often), and antimalarials. The most common antimalarials are hydroxychloroquine, chloroquine (Aralen), and quinacrine. For patients who cannot take antimalarials, dapsone and retinoids such as etretinate (Tegison) or isotretinoin (Accutane) might be used with appropriate precautions. Fluocinonide cream has greater effect than hydrocortisone for discoid lupus (Jessop et al., 2001). Dapsone should not be used in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, and retinoids should be avoided in pregnant patients. Severe cutaneous lupus can be treated with high-dose corticosteroids, but if the daily dose of prednisone exceeds 10 mg, methotrexate or azathioprine should be considered. Finally, thalidomide is effective for discoid lupus, but its use is limited by concerns about neuropathy and teratogenicity.

Lupus nephritis, once diagnosed by renal biopsy, can be treated with high-dose corticosteroids alone or with steroid-sparing drugs such as methotrexate or azathioprine. Cyclophosphamide for rapidly progressive or severe nephritis is effective but has substantial toxicities and is generally best left for the rheumatologist to prescribe. Toxicity can be minimized somewhat with prehydration and a mesna (Mesnex) injection, a cyclophosphamide metabolite binder, to avoid hemorrhagic cystitis. Later development of hematologic malignancies (rare) and premature ovarian failure (common) can result from cyclophosphamide use. If cyclophosphamide is indicated in a young woman, her family physician should raise options such as egg harvesting to preserve fertility.

Patients with SLE and antiphospholipid antibody syndrome who consequently have venous or arterial thrombosis can be treated with warfarin (Coumadin) to keep the international normalized ratio between 2 and 3. Although somewhat controversial, therapy should continue for at least 3 to 6 months, and often, lifelong anticoagulation is recommended based on high risk for subsequent events. Severe hemolytic anemia responds to IV methylprednisolone. Leukopenia rarely requires treatment. Severe thrombocytopenia with platelet counts below 50,000/mm³ can be treated with methylprednisolone, danazol (Danocrine), immunosuppressive drugs, and possibly splenectomy.

Arthritis, serositis, and constitutional signs usually respond to 0.5 mg/kg/day of prednisone; nephritis and CNS disease usually require doses of 1 mg/kg/day. Patients who do not respond to high-dose steroids after 7 weeks should be considered for immunosuppressive drugs.

Rarely, plasma exchange is necessary for severe thrombotic thrombocytopenic purpura and pulmonary hemorrhage. Plasmapheresis has not shown long-term benefit for lupus nephritis. End-stage lupus nephropathy is treated with dialysis or kidney transplantation. Other experimental therapies for SLE include immunotherapy with anti-CD4, anti-TNF- α , and interferon- α .

Treatment of SLE has been successful in decreasing morbidity and mortality in what used to be considered a universally progressive, terminal disease. More than 90% of treated patients survive at least 15 years. SLE evolves over time with new manifestations and sometimes vague symptomatology arising unpredictably. Therefore, good communication in an ongoing physician–patient relationship and teamwork between the family physician and the rheumatologist are necessary for optimal care.

KEY TREATMENT

- Cutaneous lupus should initially be treated with topical corticosteroids (Jessop et al., 2001) (SOR: B) and avoidance of precipitating factors such as sun exposure (SOR: C).
- Patients with persistent cutaneous lesions should be considered for treatment with antimalarials such as hydroxychloroquine (SOR: C).
- NSAIDs are the initial treatment for SLE-associated myositis, serositis, and arthritis. Refractory cases can be treated with 0.5 to 1 mg/kg/day of prednisone (SOR: C).

SJÖGREN SYNDROME

Sjögren syndrome is an autoimmune disorder caused most likely by T cell–mediated exocrine gland destruction characterized by dry eyes (keratoconjunctivitis sicca) and dry mouth (xerostomia). Patients with secondary SS have these symptoms in association with other autoimmune diseases such as RA, SLE, polymyositis, systemic sclerosis, or biliary cirrhosis.

A diagnosis of definite SS requires a minor salivary gland biopsy; a probable SS diagnosis can be based on demonstrating decreased salivary function. Exclusions to the diagnosis based on the San Diego Criteria include patients with HIV, primary fibromyalgia, sarcoidosis, preexisting lymphoma, keratitis sicca, hepatitis B or C, or salivary gland enlargement (Table 32-10). Objective evidence of ocular dryness can be obtained by the Schirmer II test, which involves stimulating the nasolacrimal reflex by inserting a cotton swab into the nostril; the increase in tear flow is then measured for both eyes (Tsubota, 1991). Rose bengal staining of the corneal or conjunctiva epithelial layer is another objective test. Serologic evidence of SS includes an elevated RF (>1:320), elevated ANA (>1:320), or presence of anti-SS-A (Ro) or anti-SS-B (La) antibodies.

Salivary secretions can be quantified by asking the patient to suck on a sugarless piece of candy for 3 minutes and then expectorate. If there is very little or no expectorant, a probable diagnosis of SS can be made; a follow-up minor salivary gland biopsy is definitively diagnostic. Patients not fitting these objective criteria can be reassured that their dry eyes or mouth are most likely not caused by an autoimmune disorder. Other manifestations of SS include constitutional symptoms such as fatigue, dry skin, vaginal dryness, upper respiratory tract dryness, and difficulty swallowing (caused by decreased saliva). SS is not the only entity that can cause enlarged lacrimal and salivary glands and glandular dysfunction. SS needs to be differentiated from infiltrative processes (lymphoma, sarcoidosis, fatty

Table 32-10 San Diego Criteria for Sjögren Syndrome

I. Primary Sjögren syndrome*	<p>A. Symptoms and objective signs of ocular dryness</p> <ol style="list-style-type: none"> 1. Schirmer test <8 mm wetting per 5 minutes <i>and</i> 2. Positive rose bengal staining of cornea or conjunctiva to demonstrate keratoconjunctivitis sicca <p>B. Symptoms and objective signs of dry mouth</p> <ol style="list-style-type: none"> 1. Decreased parotid flow rate using a Lashley cup or other method <i>and</i> 2. Abnormal findings from biopsy of minor salivary gland (focus score of ≥ 1 based on average of four evaluable lobules) <p>C. Serologic evidence of a systemic autoimmunity</p> <ol style="list-style-type: none"> 1. Elevated rheumatoid factor >1:320 <i>or</i> 2. Elevated antinuclear antibody <1:320 <i>or</i> 3. Presence of anti-SS-A(Ro) or anti-SS-B(La) antibodies
II. Secondary Sjögren syndrome	Characteristic signs and symptoms of Sjögren syndrome (described above) plus clinical features sufficient to allow a diagnosis of rheumatoid arthritis, SLE, polymyositis, scleroderma, or biliary cirrhosis
III. Exclusions	Sarcoidosis, preexisting lymphoma; HIV infection; hepatitis virus B or C infection; primary fibromyalgia; and other known causes of autonomic neuropathy, keratitis sicca, or salivary gland enlargement

*Definite Sjögren syndrome requires objective evidence of dryness of eyes and mouth and autoimmunity, including a characteristic minor salivary gland biopsy (criteria IA, IB, and IC). Probable Sjögren syndrome does not require a minor salivary gland biopsy but can be diagnosed by demonstrating decreased salivary function (criteria IA, IB-1, and IC).

SLE, Systemic lupus erythematosus.

From Fox RI, Saito I. Criteria for diagnosis of Sjögren syndrome. *Rheum Dis Clin North Am.* 1994;20:391.

infiltrates, hemochromatosis), infectious diseases (blepharitis, HIV, hepatitis B and C, tuberculosis, syphilis), neuro-pathic dysfunction of the glands caused by multiple sclerosis or Bell palsy, autonomic neuropathy, and drug side effects.

Treatment of keratoconjunctivitis sicca consists of the use of artificial tears while monitoring for blepharitis caused by preservatives used in these preparations. Punctal plugs can be used to increase eye moisture, with either collagen plugs that dissolve after 2 days or silicone plugs, which are more durable but can be removed if excessive tearing occurs. If this is helpful, permanent punctal occlusion surgery might be considered. Humidifiers may also be helpful. Cyclosporine ophthalmic preparations are FDA approved for treatment of keratoconjunctivitis sicca, with objective and subjective improvement in dry eyes (Sall et al., 2000).

Dry mouth can be relieved by sugarless mints or gum. Frequent sips of water are also helpful. Those with continued symptoms may be candidates to try artificial saliva solutions (Salivart, Mouth Kote). Meticulous dental care should be encouraged because caries can occur more frequently with reduced salivary flow. Secretagogues such as pilocarpine or cevimeline can be used, but adverse effects such as flushing, increased perspiration, and increased bowel or bladder motility might outweigh their benefits. Topical antifungal troches are useful for low-grade oral infections.

Systemic treatment of SS is similar to that of SLE. NSAIDs and antimalarials, in particular, are useful for concomitant

arthralgias and other systemic symptoms, but corticosteroids and immunosuppressants might be needed for refractory severe systemic disease.

KEY TREATMENT

- Simple treatments such as the use of humidifiers, artificial tears, sugarless gums, and frequent sips of water are adequate in most patients with keratoconjunctivitis sicca and xerostomia of SS (SOR: C).

VASCULITIC SYNDROMES

Vasculitis refers to a broad spectrum of conditions involving inflammation of blood vessels. Although many classification schemes have focused on the size of the vessels involved, this might not be very useful clinically because of the significant amount of overlap between these disorders. Many vasculitides characteristically affect certain age groups for unknown reasons: Kawasaki disease in children, temporal arteritis in elderly adults, and Henoch-Schönlein purpura with a bimodal distribution. Most vasculitic syndromes are of unknown cause. Pathologic findings are usually not diagnostic for a specific syndrome; the diagnosis is still made primarily on clinical grounds. Most vasculitides tend to cause sporadic involvement of vessels with skip lesions. That is, they involve only part of the vessel wall for only part of the segmental length of the vessel and do not occur uniformly in other vessels of the same size.

Giant Cell Arteritis

Also known as *temporal arteritis*, giant cell arteritis (GCA) usually occurs in patients older than 50 years. It is most common in Caucasians, particularly in people of northern European ancestry. Giant multinucleated cells are found in vessel walls, most frequently in the temporal arteries but sometimes in the vertebral or carotid arteries. The disease usually begins gradually, with constitutional symptoms, such as fatigue, malaise, fever, weight loss, and PMR (a separate entity characterized by proximal muscle pain and stiffness, elevated ESR, and constitutional symptoms), occurring for weeks or even months. Specific symptoms then develop, such as jaw claudication (masticatory muscle discomfort with chewing); new-type or new-onset headache; scalp tenderness, particularly overlying the temporal arteries; diplopia; and visual loss secondary to retinal ischemia. Patients might also have loss of taste or hearing. About 30% of patients have neurologic symptoms such as peripheral neuropathies and transient ischemic attacks. About 10% of patients have respiratory tract symptoms such as a sore throat, cough, and hoarseness.

On physical examination, the temporal arteries might be tender, thickened, and erythematous. New carotid artery bruits should also raise suspicion. The aortic arch or its branches might be involved, manifested by reduced BP in one or both arms or arm claudication. Temporal artery biopsies confirm the diagnosis before initiating treatment, although the skip lesion nature of involvement means that a negative temporal artery biopsy does not rule out the diagnosis. The ESR tends to be high in GCA, usually 80 to 100 mm/hr, although in one small study, 25% of all patients

with GCA on temporal artery biopsy had a normal ESR (Weyand et al., 2000). ALP and AST levels are mildly elevated in one third of patients. Serum IL-6 levels parallel inflammatory activity, and CRP may also be used to follow inflammation. The family physician should consider the diagnosis of GCA for any patient older than 50 years presenting with new-onset or new-type headache, elevated ESR, abrupt loss of vision, PMR, and prolonged fever.

The treatment for temporal arteritis or clinically suspected temporal arteritis with a negative biopsy result is prednisone, 40 to 60 mg/day for 2 to 4 weeks. One should not wait for the biopsy results if clinical suspicion is high; treatment should start immediately. If symptoms and laboratory values suggest that the disease is under control, the dose is decreased 10 mg every 2 weeks for 1 month and then by 10% of the daily dose every 2 weeks (serum ESR and CRP levels are measured before decreasing the dose). Full courses often last 9 to 12 months. Prednisone often eliminates symptoms within 12 to 48 hours. GCA is usually self-limited, up to 2 years, at which time prednisone can be discontinued in most patients, although some still require small doses of corticosteroids for years to control symptoms. Because thoracic aortic aneurysms and renal artery stenosis are relatively common sequelae, the patient should be evaluated for these.

KEY TREATMENT

- Prednisone is the treatment of choice in temporal arteritis (SOR: C).

Polymyalgia Rheumatica

As with GCA, PMR usually occurs in Caucasians older than 50 years, especially those of northern European ancestry. Constitutional symptoms such as fever, fatigue, malaise, and weight loss occur early on followed by neck and proximal upper extremity muscle aches. PMR is sometimes misdiagnosed as a frozen shoulder because of this. PMR later involves the lower extremity proximal muscles of the hips and thighs. Morning stiffness of large joints can make it difficult for the patient to perform ADLs, such as getting out of bed or combing the hair. The only typical physical finding is muscle tenderness but without other objective signs. A transient mild synovitis of the knees, wrists, and sternoclavicular joints might occur. The diagnosis is made clinically by noting the combination of proximal extremity and truncal muscle pain and stiffness, increased ESR, and response to steroids.

Both PMR and GCA (temporal arteritis) are often seen together. PMR can precede, appear simultaneously with, or follow the onset of GCA symptoms. These two conditions might represent different manifestations of the same pathologic process. The best treatment for PMR is corticosteroids, with the dose determined by patient characteristics as well as by whether GCA is present. The typical dose is 15 to 30 mg/day of prednisolone; the daily dose is reduced by 5 mg/week until the dose is 15 mg/day, at which point the dosage is decreased by 2.5 mg/month.

Treatment can be stopped after 6 to 12 months if the ESR remains normal and the patient remains asymptomatic at a daily dose of 2.5 mg. Serial ESRs should be performed

every 2 to 3 weeks, although following the patient's symptoms closely is more important than simply following laboratory values. For recurrences, 15 mg of prednisolone is restarted and gradually tapered. NSAIDs might help relieve symptoms but do not protect against vasculitis.

KEY TREATMENT

- Prednisone is the treatment of choice in PMR (SOR: C).

Other Vasculitic Conditions

See [eAppendix 32-3](#) online for discussions on:

- Takayasu arteritis
- Polyarteritis nodosa
- Churg-Strauss syndrome
- Wegener granulomatosis
- Cryoglobulinemia
- Hypersensitivity vasculitis
- Behçet disease

Inflammatory Myopathies

This heterogeneous group of diseases causes inflammation of skeletal muscle, increases in levels of enzymes derived from muscle, and proximal muscle weakness or myopathy. The two most common myopathies are dermatomyositis and polymyositis. Inflammatory myopathies are classified by patient age at onset or by coexisting diseases, such as myositis associated with neoplasia or myositis associated with collagen vascular diseases (e.g., systemic sclerosis, SLE, SS). They have a bimodal distribution and are seen most often between age 10 to 15 and 45 to 60 years. Myositis is most common after age 50 years. The cause of inflammatory myopathies is unknown, but evidence suggests a genetic predisposition (associated with certain HLA markers) combined with an environmental insult, such as viruses, thereby initiating an autoimmune process.

Patients usually experience progressive, symmetric, proximal muscle weakness with fatigue, malaise, and morning stiffness. Muscles often affected are those of the shoulder, neck, and pelvic girdle. Pulmonary (interstitial pneumonitis or fibrosis), cardiac (cardiomyopathy, congestive heart failure, arrhythmias), pharyngeal (dysphagia), and musculoskeletal (myalgias, arthralgias) symptoms might occur, although most patients do not experience synovitis. CK as well as ALT, AST, and lactate dehydrogenase (LDH) levels might be elevated, although ESR is elevated only half the time. Muscle biopsy can also be helpful in diagnosis. *Dermatomyositis* is characterized by all of these manifestations plus a scaly, erythematous, or violaceous rash on the face and neck, upper back (shawl sign), and upper anterior chest and neck (V sign). Other signs include dystrophic cuticles, mechanic's hands (darkened or dirty-appearing horizontal lines across palmar aspect of fingers), and Gottron's papules seen on dorsal aspects of the PIP, DIP, or MCP joints, elbows, patellae, and medial malleoli ([Olsen and Wortmann, 2004](#)). Disease in patients with skin changes but without muscle inflammation is termed *amyopathic dermatomyositis*.

Inflammatory myopathies can result from malignancies. Screening for malignancies common for the patient's gender

and age should be undertaken, but further exploration is not indicated. However, ovarian cancer appears to be associated with dermatomyositis, so the family physician should consider evaluation for this.

Before treatment, a thorough motor neurologic examination is done, with muscle enzyme levels (CK, aldolase, ALT, AST, LDH) and cancer screening tests appropriate for patient age and gender. Prednisone, 1 mg/kg/day for up to several months, is the drug of choice; the earlier it is started in the disease process, the more effective it normally is. If prednisone is not sufficient, methotrexate, azathioprine, or another immunosuppressant is added.

Systemic Sclerosis

Key Points

- CREST syndrome and diffuse cutaneous systemic sclerosis are the primary manifestations of systemic sclerosis.
- The female:male predominance is 8:1 for sclerosis.
- The major ACR criterion for systemic sclerosis is skin thickening proximal to the MCP and MTP joints.

"Scleroderma," or hardening of the skin, is now recognized to be a disorder involving almost every organ system in the body and is therefore more appropriately referred to as *systemic sclerosis*. Systemic sclerosis is characterized by a progressive fibrosis of the skin, blood vessels, lungs, kidneys, heart, and GI tract. The degree of skin involvement (diffuse or limited) is useful for prognosis. *Diffuse cutaneous systemic sclerosis* (DCSS) involves almost the entire body, including the trunk, face, neck, and extremities. Cardiopulmonary disease is the leading cause of death in DCSS. Limited cutaneous systemic sclerosis has a more benign course and involves the face, neck, and distal extremities below the knee and elbow. CREST syndrome (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) is one of the limited forms of systemic sclerosis, characterized by cutaneous thickening of the distal limbs only. Skin biopsy showing subcutaneous fibrosis is helpful if the diagnosis is in doubt.

Systemic sclerosis affects women up to eight times more often than men; the peak incidence is in the 40s and 50s. There is no significant familial connection, but systemic sclerosis patients typically have a family history of autoimmune disease. Many chemicals and toxins have been implicated, most clearly silica exposure in coal miners.

The major ACR classification criterion for systemic sclerosis is skin thickening proximal to the MCP or MTP joints. The three minor ACR criteria are involvement distal to the MCP joints (sclerodactyly), fingertip-pitting scars or loss of subcutaneous tissue, and chronic pulmonary interstitial changes. Patients with the major criterion or two of the three minor criteria are considered to have systemic sclerosis; however, many patients with clear-cut systemic sclerosis do not meet these criteria because their disease might be early or undifferentiated or in an overlap category with other connective tissue diseases. Ninety-five percent of patients have a positive ANA test result, most often nucleolar staining. Various serologic tests, including anti-RNA

32-3 Other Vasculitic Conditions

Takayasu Arteritis

Takayasu arteritis is a rare vasculitis affecting the aorta and its branches, seen most often in Asian women younger than 40 years. Constitutional symptoms (fatigue, malaise, fever) progress to decreased or absent pulses, bruits, and visual symptoms. Hypertension is common. An elevated erythrocyte sedimentation rate and thrombocytosis are present when the disease is active. An electrocardiogram might show ischemia; definitive diagnosis is made by an aortogram showing narrowing, vessel occlusion, or aneurysm. Takayasu arteritis is usually chronic. Treatment is with 1 mg/kg/day of prednisone until clinical remission followed by a tapering dose. Low-dose aspirin or other antiplatelet agents can complement steroid therapy, and weekly methotrexate might allow steroid doses to be decreased.

Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a systemic vasculitis of medium-sized and small arteries. Patients might have weight loss, fatigue, myalgias, and arthralgias. Skin, peripheral nerves, kidneys, and the gastrointestinal (GI) tract are affected most frequently, but any organ except the lungs can be involved. PAN occurs in all age groups but is most common in middle age and in men more than women.

Palpable purpura, livedo reticularis, and skin infarctions suggest PAN. Multiple mononeuropathies manifested by pain or paresthesias lead to muscle weakness supplied by the involved nerve. Renovascular hypertension from renal vasculitis and glomerulonephritis, coronary arteritis, and GI arteritis resulting in GI bleeding might occur. The disease is associated with hepatitis B and hepatitis C infections as well as with mixed cryoglobulinemia. However, hepatic function does not parallel disease activity.

The diagnosis is made by biopsy of an affected organ and finding a necrotizing vasculitis. Arteriograms show narrowing or multiple small aneurysms. Before the use of high-dose corticosteroids, the 5-year survival of PAN patients was less than 15%; survival is now higher than 60% (Lhote and Guillevin, 1995). Antiviral therapy such as lamivudine has improved the treatment of hepatitis B virus-associated PAN, and chemotherapeutic agents are now being used for severe refractory cases with success.

Churg-Strauss Syndrome

Churg-Strauss syndrome is a rare systemic vasculitis involving the lungs, skin, peripheral nerves, GI tract, and kidneys. It is seen in patients with asthma and allergies, most often in middle age, and in men. Asthma and allergy symptoms become exacerbated followed by a peripheral eosinophilia and vasculitis. Urinalysis shows red blood cell casts and

proteinuria; chest radiographs show diffuse interstitial disease or multiple nodules. Biopsy of an involved site reveals eosinophilic infiltrates and microgranulomas. High-dose prednisone is the treatment of choice.

Wegener Granulomatosis

Wegener granulomatosis is a small-vessel, necrotizing, granulomatous vasculitis involving the upper and lower respiratory tracts and the kidneys. These three locations are not always involved, however, and other areas, such as skin (purpura, nodules, ulcers) and eyes (uveitis, episcleritis), might be affected. Wegener granulomatosis can occur at any age but most often occurs between ages 30 and 50 years. Patients might present with epistaxis, sinus pain, nasal or oral ulcers, and nasal septal perforation. Lower respiratory tract involvement can manifest as dyspnea, hemoptysis, and chest pain; cavitary lesions can be seen on radiographs. Musculoskeletal pain out of proportion to signs of inflammation is also common.

Urinalysis can show red blood cell casts, proteinuria, and hematuria. About 80% of patients with active multisystem disease have serum antineutrophil cytoplasmic autoantibodies (ANCA), which are present in only a minority of patients with other vasculitides (Jennette and Falk, 1992). However, changes in ANCA titers cannot be used to monitor response to therapy.

Combined high-dose prednisone and cyclophosphamide have improved survival for patients with severe disease, whereas prednisone alone can be used for milder disease. Methotrexate has also been used because of cyclophosphamide's toxicity. Studies using trimethoprim-sulfamethoxazole (TMP-SMX) therapy show conflicting assessment of efficacy. Superinfections can occur, particularly with immunosuppressive therapy. *Pneumocystis jiroveci* pneumonia prophylaxis is therefore recommended.

Cryoglobulinemia

Cryoglobulins (CGs) are immunoglobulins that reversibly precipitate at lower temperatures. Type I CGs are monoclonal and are often seen with multiple myeloma and other malignancies. These precipitate in cooler regions of the body, causing plugging of small vessels and leading to necrosis; however, this type of vasculitis is rare. Type II cryoglobulinemia can be primary (also known as *essential*) or secondary to rheumatologic or infectious diseases. Rheumatologic diseases that can cause types II and III cryoglobulinemia include rheumatoid arthritis, systemic lupus erythematosus, polyarteritis nodosa, systemic sclerosis, and Sjögren syndrome. Many infections can be associated with cryoglobulins, but hepatitis C accounts for more than 80% of vasculitides associated with mixed CGs.

Types II and III CGs are mixed in that they contain both IgM and IgG. IgG antibodies form an immune complex with an antigen, inducing production of IgM antiglobulins. CGs manifest clinically as palpable purpura, ulcers, and urticaria; enlargement of the reticuloendothelial system (hepatosplenomegaly, lymphadenopathy); and most often, glomerulonephritis. To detect CGs, serum is allowed to clot, precipitate is separated out, and the serum is incubated in cold temperatures for 2 to 3 days. Immunoelectrophoresis of the precipitate is then performed.

Treatment of secondary cryoglobulinemia is directed at the underlying malignancy or infection. Interferon- α alone or with ribavirin can be used for mild disease, but severe manifestations might require corticosteroids and cyclophosphamide.

Hypersensitivity Vasculitis

Drug reactions are the most common cause of hypersensitivity vasculitis. Palpable purpura, ulcerations, and arthralgias are the most frequent symptoms. It usually occurs abruptly and is diagnosed by biopsy. There is normally limited underlying organ involvement. Other diagnoses must be ruled out, however, because underlying organ damage is associated with other conditions, such as Wegener granulomatosis, Churg-Strauss syndrome, and cryoglobulinemia. Treatment of hypersensitivity vasculitis is simply to discontinue the offending agent and use corticosteroids, if necessary.

Behçet Disease

Behçet disease is a systemic inflammatory condition characterized by oral and genital ulcerations; it often includes a concomitant vasculitis. The diagnosis can be difficult and is a clinical one. Multiple oral aphthous ulcers are often the first sign of Behçet disease. Genital ulcers involving the scrotum, penis, vulva, and cervix occur either concurrently with the oral ulcers or later, independent of the oral lesions. Uveitis might occur several years after the oral lesions and, if severe, might progress to blindness; patients complain of seeing spots early in the disease course.

Patients with Behçet disease might also develop papulopustular skin lesions; synovitis in the large joints; and, less commonly, septic meningitis and ischemic vasculitis in the brainstem that cause sudden focal neurologic deficits. Vasculitic aneurysms in the pulmonary circulation can lead to a pulmonary arteriobronchial fistula, with subsequent hemorrhage and severe hemoptysis. Abdominal pain, bleeding, or perforation is also seen. Differentiating Behçet disease from Crohn disease can be difficult because patients with Crohn disease might also have aphthous ulceration, skin lesions, and uveitis. Topical corticosteroids and colchicine are each used for treating mucocutaneous symptoms of Behçet disease; retinal manifestations and central nervous system disease respond to oral glucocorticoids and azathioprine. The primary goal of the family physician is to recognize the disease and refer to an ophthalmologist as soon as possible.

polymerase, anticentromere antibody, and antifibrillar, can provide prognostic information.

The vast majority (>90%) of patients with systemic sclerosis have *Raynaud phenomenon*, which is the initial complaint in most patients, although some might complain first of puffy hands and fingers and of arthralgias. Patients with Raynaud phenomenon experience cold hands and feet, usually triggered by cold temperature or emotional stress. Vasospasm of the digital arteries and arterioles causes skin pallor followed by cyanosis. With rewarming, the digits have a hyperemic or red color, thus completing this white, blue, and red phenomenon.

Scleroderma's skin changes result from inflammation and subsequent collagen deposition. The skin feels (and is) thickened, with decreased flexibility. As the skin becomes more fibrotic and thickened, it becomes very dry, causing pruritus. Late-stage skin changes include atrophy. Arthralgias and myalgias progress to muscle atrophy and weakness.

Patients with scleroderma can develop two different pulmonary diseases: pulmonary hypertension and pulmonary fibrosis. Pulmonary hypertension (which can occur independently of fibrosis) is associated with a poor prognosis. GI symptoms include dysphagia with heartburn, dry mucosal membranes, esophageal reflux, and dysmotility. Cardiac manifestations are usually late and caused by coronary vasospasm, myocardial fibrosis, and pericardial effusions.

Scleroderma renal crisis is characterized by accelerated hypertension, rapidly progressive renal failure, or both (Steen, 1994). Depression is present in more than 50% of patients with systemic sclerosis and is often amenable to antidepressants. Thyroid fibrosis might lead to hypothyroidism; sicca syndrome can be treated with artificial tears and good dental care.

Treatment. Treatment for systemic sclerosis is difficult. Penicillamine, immunosuppressive drugs, and other agents have been used to treat scleroderma, but none has yielded dramatic results. Localized sclerosis can soften with ultraviolet-A (UVA) light therapy, with dramatic improvement in symptoms seen in two small non-RCTs (Kreuter et al., 2004; Stege et al., 1997). Other options include high-dose topical corticosteroids and methotrexate. Treatments for calcinosis, including probenecid, colchicine, and warfarin, have not shown improvement. A five-patient study showed that the calcium channel blocker (CCB) diltiazem caused significant regression in calcinosis and clinical improvement (Palmieri et al., 1995); more studies are needed. Raynaud phenomenon is treated by cold avoidance for the entire body (not only hands), tobacco avoidance, and biofeedback or other stress reduction techniques; pharmacologic therapy includes CCBs, topical nitroglycerin, and prazosin (Pope et al., 2000). A meta-analysis concluded that CCBs are efficacious for reduction in frequency and severity of attacks (Thompson et al., 2005). Skin care consists of avoiding excessive bathing and using moisturizers.

The NSAIDs are used first for musculoskeletal symptoms of systemic sclerosis, but low-dose corticosteroids or narcotic analgesics might be needed. No studies have been performed, but in general, acid-reducing medications such as PPIs or H₂ blockers are used to prevent the development of possible esophageal strictures, given the high rates of

esophageal dysmotility in the systemic sclerosis. Delayed small intestinal tract transit time may lead to bacterial overgrowth, causing GI symptoms; antibiotics might be effective. Angiotensin-converting enzyme inhibitors are useful in the treatment of renal crisis manifested by hypertension and renal failure.

For scleroderma-like disorders, see [eAppendix 32-4](#) online.

KEY TREATMENT

- Systemic sclerosis is difficult to treat. UVA therapy is the most effective treatment for localized skin sclerosis (Kreuter et al., 2004; Stege et al., 1997) (SOR: B).
- Pharmacologic therapy with calcium channel blockers is effective at decreasing the frequency and severity of Raynaud's phenomenon (Thompson et al., 2005) (SOR: B).

Diffuse Fasciitis with Eosinophilia

See [eAppendix 32-5](#) online.

FIBROMYALGIA SYNDROME

Key Points

- Fibromyalgia syndrome (FMS) accounts for 20% of visits to rheumatologists.
- The diagnosis is confirmed by 3 months of widespread pain with associated fatigue, cognitive dysfunction, and unrefreshed sleep.
- The female:male predominance is 9:1 for FMS.

Fibromyalgia syndrome is one of the most common rheumatic diseases, affecting up to 20% of patients seen in rheumatology practices (Keefe and Caldwell, 1997). The diagnosis of FM was modified in 2010 from counting trigger points to the evaluation of widespread pain persisting for 3 months. Pain is considered widespread when it affects all four quadrants of the body, meaning it must be felt on both the left and right sides of the body as well as above and below the waist. The traditional areas of discomfort can be seen in [Figure 32-15](#). The widespread pain along with associated symptoms, including fatigue, awaking unrefreshed, and difficulty with cognition, help make the diagnosis (Wolfe et al., 2010).

The diagnostic criteria require a subjective assessment by the clinician. The most important ingredient is widespread pain for three months. To solidify the diagnosis, then ask, "Are you having problems with fatigue? Waking up tired? Thinking or remembering things?" Then the clinician should follow up with more detailed inquiries about other somatic conditions such as irritable bowel syndrome, headache, dry mouth, or bladder spasms. Three months of pain accompanied by these other symptoms suggest the diagnosis.

Psychological factors and comorbid conditions might aggravate symptoms. FMS is more common than RA and causes a comparable degree of disability and loss of family income. About 90% of FMS patients are women, and there

32-4 *Scleroderma-Like Disorders*

Localized scleroderma (involving the skin only) is classified into two groups, morphea and linear scleroderma. Localized scleroderma often starts as an ivory-colored fibrotic-centered skin lesion surrounded by a hyperpigmented area up to 30 cm in diameter. *Morphea* is one or more plaques,

usually on the trunk and thighs. *Linear* scleroderma is more often seen on the lower extremities as a fibrotic band. Effective treatment is as difficult for localized scleroderma as it is for systemic sclerosis.

32-5 *Diffuse Fasciitis with Eosinophilia*

Diffuse fasciitis with eosinophilia (DFE), also known as eosinophilic fasciitis or Shulman syndrome, is a relatively rare disorder that involves the trunk and limbs but spares the hands and face. There is no organ involvement or Raynaud phenomenon associated with DFE. The diagnosis is made by deep biopsy involving muscle, subcutaneous tissue, and skin. DFE can be associated with hematologic

malignancies. Monitoring for these is therefore prudent if the cause is unknown. The disease course can be benign, with no change or even with regression over years. Corticosteroids, penicillamine, antimalarials, and methotrexate have been used with success. Physical therapy can also be helpful.

Figure 32-15 Location of the specific tender points in fibromyalgia. (From Freundlich B, Leventhal L. Diffuse pain syndromes. In Klippel JH, ed. *Primer on the rheumatic diseases*. 11th ed. Atlanta: Arthritis Foundation; 1997:123-127.)

is evidence of familial aggregation. Fibromyalgia might also be present in patients with autoimmune disorders such as SLE, RA, and AS, and should be suspected when symptoms are unresponsive to antiinflammatory therapies.

Fibromyalgia syndrome is probably caused by central pain mechanism dysfunction, possibly in neurotransmitters. Several studies have found that FMS patients have up to three times higher levels of substance P in CSF than normal control participants (Russell et al., 1994). FMS can be initially triggered by trauma or peripheral inflammatory arthritis, but peripheral, ongoing inflammation is not present in this syndrome. Important secondary factors contributing to the patient's pain include nonrestorative sleep, muscle deconditioning secondary to pain, and psychological factors. Pain is most common in the neck, back, shoulders, pelvic girdle areas, and hands. Paresthesias in the extremities are also common, as are tension-type headaches, irritable bowel syndrome, primary dysmenorrhea, chronic fatigue syndrome, restless legs syndrome, temporomandibular joint (TMJ) dysfunction, and regional fibromyalgia (myofascial pain syndrome). Although some patients with FMS have depression, most do not. Physical examination reveals tenderness with moderate pressure in the traditional defined points seen in Figure 32-15. Care must be taken on examination not to palpate too softly or too firmly. The proper amount of palpation pressure is about the amount of pressure required to blanch the nail of the examining finger when it is pressed against the patient's forehead (Yunus, 1996).

No laboratory tests are available to diagnose FMS. CBC results; tests for ESR, muscle enzyme, electrolyte, and ANA levels; and radiography are all normal in the absence of comorbid disease. Sleep electroencephalograms are often

abnormal and should be considered if a history of particular sleep disturbances is suspected (see eTable 32-5 online). Because FMS is often seen in association with other rheumatic diseases, the diagnosis is often missed because FMS symptoms might be mistaken for the comorbid disease. Conversely, patients presenting with FMS should be evaluated for an underlying condition.

The cause of fibromyalgia is unknown. Muscle biopsies reveal no apparent abnormalities. There is great overlap with chronic fatigue syndrome, but there is no evidence that an infection such as chronic Epstein-Barr virus (EBV) is associated with fibromyalgia. About 80% of fibromyalgia patients have sleep disturbances, particularly disrupted non-rapid eye movement (non-REM) sleep (stages 3 and 4, which is deep, restorative sleep). Non-REM sleep deprivation studies have reproduced the signs and symptoms of FMS, which make the sleep disturbance possibly an integral part on the pathogenesis and continuation of fibromyalgia. Patients with RA and other rheumatic diseases have disrupted sleep with nocturnal awakening and arousals to a lighter stage of sleep throughout the night. Sleep studies reveal that patients often cannot recall these episodes on awakening the next day but do feel fatigued or describe themselves as light sleepers.

Treatment

It is important to educate patients with FMS and to reassure them that FMS is a common disease, that it is not psychiatric, and that there are treatments available.

Tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin-norepinephrine reuptake inhibitors (SNRIs) help relieve pain associated with fibromyalgia. A meta-analysis (18 RCTs with a variety

eTable 32-5 Conditions Associated with Sleep Disturbance and Fibromyalgia

Symptoms	Diagnoses to Consider
Headaches, rhinitis	Sinusitis
Nocturia	Diabetes mellitus, diuretic use, interstitial cystitis
Dry mouth	Sjögren syndrome, anticholinergic signs, medications
Snoring, daytime naps	Sleep apnea
Morning leg pain	Nocturnal myoclonus, restless leg syndrome
Morning facial pain	Bruxism, temporomandibular disorder
Joint pain, swelling	Rheumatologic conditions
Shortness of breath	Asthma, coronary heart failure
Awakening for unknown reasons	Spouse snores, pet in room, noises, lights, dry air

From Freundlich B, Leventhal L. Diffuse pain syndromes. In Klippel JH, ed. *Primer on the rheumatic diseases*. 12th ed. Atlanta: Arthritis Foundation; 2001:188.

of antidepressants) concluded there was strong evidence of efficacy for antidepressants for relief of pain, fatigue, mood, sleep disturbance, and health-related quality of life (Hauser et al., 2009). The effect size for pain reduction was large for TCAs and small for the SSRIs and SNRIs, although newer studies of SNRIs were not included. Studies of the SNRIs milnacipran (Savella) and duloxetine (Cymbalta) have shown significant reductions in pain, and both have been FDA approved for the treatment of fibromyalgia. Amitriptyline doses are typically 25 to 50 mg at night, much lower than the doses used for the treatment of depression. The addition of amitriptyline to SSRIs or SNRIs showed a trend toward improvement versus medication alone, but results were not statistically significant (Goldenberg et al., 1996).

Cyclobenzaprine has a chemical structure similar to TCAs, and various dosing regimens have been studied in the treatment of fibromyalgia. A meta-analysis found that pain was significantly decreased in patients receiving cyclobenzaprine over placebo at 4 weeks but not statistically significant at 8 or 12 weeks. Overall, patients treated with cyclobenzaprine were three times more likely to report subjective improvement, and five patients would need to be treated for one patient to experience symptom improvement (Tofferi et al., 2004).

Pregabalin (Lyrica), a second-generation anticonvulsant, was the first medication to be FDA approved for the treatment of fibromyalgia. As with gabapentin, pregabalin has effects on cellular calcium channels and may exert its analgesic effects by blocking various neurotransmitters. Multiple large studies have shown its efficacy for the treatment of pain, fatigue, and improvement in sleep (Mease et al., 2008). Gabapentin has not been FDA approved for this use but is efficacious for reducing pain in fibromyalgia (Arnold et al., 2007).

The NSAIDs and corticosteroids are usually not helpful because no evidence indicates FMS is an inflammatory disease, and NSAIDs are no better than placebo in the treatment of pain. Combination analgesic therapy with acetaminophen and tramadol was found to decrease pain significantly in these patients (Bennett et al., 2003). However, the long-term use of tramadol needs to be carefully considered, and this approach is best used after other therapies (e.g., antidepressants) have failed.

At least two thirds of FMS patients use some type of complementary method, such as herbal supplements or acupuncture. A meta-analysis of acupuncture suggested benefit, but study quality was generally poor (Berman et al., 1999). Local anesthesia injected into tender points can sometimes relieve pain, and topical capsaicin (Zostrix) cream has helped some patients. Treatment of underlying depression is also important.

Daily exercise programs, particularly aerobic exercise, and physical therapy might also help FMS patients; it is important that exercise regimens begin at a low intensity and build up slowly. A review of controlled trials for aerobic exercise for fibromyalgia found beneficial effects in overall global function, physical function, and possibly in reduction of pain and tender points (Busch et al., 2008).

Cognitive-behavioral treatment (CBT) is promising for FMS patients, although there have been few controlled studies. There might be even more benefit if CBT is

combined with physical exercise. Patients are often resistant to starting exercise programs such as walking or bicycling because they fear exacerbation of pain. CBT programs can overcome negative self-statements that prevent the initiation of exercise or limit the amount of exercise that can be done. An emphatic ongoing relationship with a caring physician is particularly important treatment for patients with FMS. Although musculoskeletal rehabilitation has no effect by itself, physical therapy can help subacute low back pain and other comorbidities. Subacute aerobic exercise is also effective in decreasing symptoms but might need to begin at very low levels (Busch et al., 2002; Busch et al., 2008).

KEY TREATMENT

- Aerobic exercise programs have positive effects for overall global function, physical function, and pain (Busch et al., 2008) (SOR: A).
- Antidepressant therapy is effective for fibromyalgia patients; TCAs show the greatest improvements (Hauser et al., 2009) (SOR: A).
- Pregabalin improves pain, fatigue, and sleep in patients with fibromyalgia (Arnold et al., 2007; Mease et al., 2008) (SOR: A).
- Acetaminophen and tramadol significantly reduce pain associated with fibromyalgia (Bennett et al., 2003) (SOR: B), but prolonged use of tramadol should be considered only after inadequate response to antidepressant therapy (SOR: C).

TEMPOROMANDIBULAR JOINT SYNDROME

See [eAppendix 32-6](#) online.

Rheumatic Disease in Children

JUVENILE RHEUMATOID ARTHRITIS

Juvenile rheumatoid arthritis, formerly known as Still disease, is a heterogeneous group of diseases clinically distinct from adult RA. Although much less common than RA, JRA is four times more common than sickle cell anemia or cystic fibrosis and 10 times more common than other pediatric diseases, such as hemophilia, muscular dystrophy, acute lymphocytic leukemia, and chronic renal failure (Gortmaker, 1984). Fortunately, most children with JRA have long remissions without loss of function or significant residual deformity.

There are no specific laboratory tests to diagnose JRA. Other causes for arthritis must be excluded, including reactive arthritis from extraarticular infection, septic arthritis, neoplastic disorders, endocrine disorders (thyroid disease, type 1 diabetes mellitus), degenerative or mechanical disorders, and idiopathic pediatric joint pain. The diagnosis of JRA requires true arthritis (signs of inflammation rather than simply arthralgias) persisting for more than 6 weeks, with onset at or before age 16 years.

The three major subtypes of JRA are pauciarticular (40%-50%), polyarticular (30%), and systemic (5%-10%), all with different clinical presentations and courses; their

32-6 Temporomandibular Joint Syndrome*

The term *temporomandibular joint (TMJ) syndrome* is used to describe the presence of pain in and around the TMJs; tenderness or spasm of the head and neck muscles, particularly the muscles of mastication; joint noises; and, in late, severe cases, limited mandibular movement. Prolonged muscle dysfunction can lead to intraarticular dysfunction. Malfunction of the joint is more common than pathology of the joint. Risk factors include fatigue and spasm of the head, neck, and masticatory muscles caused by emotional stress, bruxism, teeth clenching and excessive gum chewing, teeth malocclusion, maxillary or mandibular malalignment, and excessive and prolonged opening of the mouth. Other causes of TMJ dysfunction include inflammatory arthritis such as rheumatoid arthritis, infectious arthritis, and osteoarthritis.

Pain is increased with jaw movement and might radiate to the ear, eye, head, face, and head and neck muscles. The differential diagnosis includes sinusitis, arthritis, tumors, neuromuscular disorders, and tooth pain.

Treatment of TMJ syndrome consists of a mechanically softer diet, local heat application, and nonsteroidal antiinflammatory drugs. Cyclobenzaprine given at night and behavioral modification of jaw relaxation are also recommended. Isometric jaw exercises, including jaw opening, with lateral jaw deviated, and jaw thrusting, can also be taught to patients. Occlusal adjustment and splints have been shown to improve TMJ syndrome and can be used up to 6 months. Insufficient evidence exists on using hyaluronate to treat TMJ disorders (Koh and Robinson, 2003). Oral surgery might be helpful if these measures are not effective and symptoms are severe.

*Based on the Centers for Disease Control and Prevention case definition. From Gibofsky A, Zabriskie JB. Rheumatic fever. In Klippel JH, ed. *Primer on the rheumatic diseases*. 12th ed. Atlanta: Arthritis Foundation; 2001:282.

differentiation determines treatment. *Pauciarticular* JRA involves four or fewer joints, usually large joints asymmetrically. Early-onset pauciarticular JRA affects mostly girls younger than 4 years and has a 30% risk of chronic iridocyclitis and a 10% risk of ocular damage. Late-onset pauciarticular JRA affects mostly boys older than 8 years, many of whom later develop spondyloarthropathies; 10% develop iridocyclitis. Slit-lamp ophthalmic examinations are recommended. *Polyarticular* JRA is defined as arthritis in five or more joints; patients are RF positive or negative. RF-positive patients usually are girls age 8 years or older, have symmetric small-joint arthritis, and have a worse functional prognosis than RF-negative patients. *Systemic-onset* JRA is characterized by high intermittent fevers ($>38.8^{\circ}\text{C}$; 102°F), rash, hepatosplenomegaly, lymphadenopathy, arthralgias, pericarditis, pleuritis, and growth delay. Anemia, leukocytosis, and thrombocytosis are common laboratory findings. Extraarticular symptoms are usually mild and self-limited. Boys and girls are equally affected. The severity of the arthritis is a harbinger of prognosis.

The NSAIDs are the first-line treatment for JRA, but patience is necessary because clinical improvement might not be seen for up to 1 month. Approximately two thirds of patients need another agent in addition to NSAIDs; methotrexate is often used, particularly for systemic and polyarticular JRA. Corticosteroids are used orally for severe, life-threatening, systemic JRA and intraarticularly for pauciarticular JRA. Eye inflammation is best treated by an ophthalmologist.

Juvenile RA is an excellent example of a disease that significantly affects the entire family. JRA can actually have a greater negative psychological impact on siblings than on the patient (White and Shear, 1992). Most children with JRA require extensive physical as well as psychological support. Encourage families to receive support from social programs and JRA advocacy and support groups. The consulting rheumatologist and physical and occupational therapists are vital, but patients and families also benefit greatly from a continuous, supportive relationship with the family physician. Physical and occupational therapy are important because children often stop using painful joints, adding to disability.

SPONDYLOARTHROPATHIES

Four spondyloarthropathies are seen in children: juvenile AS, psoriatic arthritis, Reiter syndrome (reactive arthritis), and IBD-associated arthritis. Definitive diagnoses of these conditions are often delayed. Patients with JAS must have their lumbar spine motion monitored. Plain radiographs often do not show the changes characteristic of adult AS. NSAIDs are used for treatment. Significant arthritis can be seen in 7% to 20% of IBD patients.

SYSTEMIC LUPUS ERYTHEMATOSUS IN CHILDHOOD

Systemic lupus erythematosus primarily affects adolescent girls, many of whom do not have the typical malar rash. The small joints of the hands or feet and the kidneys are typically affected; the patient should be monitored for proteinuria and hematuria. Because of steroid side effects, immunosuppressant drugs are often used for severe cases.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is a small-vessel vasculitis seen mostly in children. Immune complexes are deposited, causing petechiae, nephropathy, or renal disease (40%) and GI bleeding. The purpura is usually in dependent areas such as the buttocks and lower extremities. Affected children often present with abdominal pain after an upper respiratory infection. Symptoms typically resolve spontaneously without treatment within 2 weeks, but serious GI and renal involvement can occur, requiring steroids. NSAIDs might be helpful for arthralgias.

KAWASAKI SYNDROME

Kawasaki syndrome (KS), also known as Kawasaki's disease, is the leading cause of acquired heart disease in children. Prolonged high fever (up to 40°C [104°F]), with an urticaria-like rash and injection of mucous membranes, including a strawberry tongue, is followed by erythema of the palms and soles and desquamation of the fingertips. Most patients have cervical lymphadenopathy. A myocarditis is present in more than 50% of patients and is manifested by a tachycardia. Many other symptoms might also occur, such as respiratory, neurologic, and GI symptoms (Table 32-11). Because KS symptoms resolve spontaneously, cardiac manifestations might not be diagnosed. A coronary arteritis and even aneurysms might develop, with significant morbidity and mortality. Laboratory studies are not helpful. Serial electrocardiograms are recommended at diagnosis, 2 to 3 weeks into the illness, and 1 month after that.

Although KS's seasonal variation (winter and spring) and epidemics suggest an infectious cause, none has yet been identified. IV fluids, aspirin, and IVIG have been used most frequently for KS. Antibiotics are of no use unless there is a concomitant bacterial infection. Steroids might actually increase the incidence of aneurysms and should be avoided, if possible.

Table 32-11 Diagnostic Guidelines for Kawasaki Syndrome*

Fever lasting >5 days <i>plus</i> four of the following five criteria:
1. Polymorphous rash
2. Bilateral conjunctival infection
3. One or more of the following mucous membrane changes: <ul style="list-style-type: none"> • Diffuse infection of oral and pharyngeal mucosa • Erythema or fissuring of the lips • Strawberry tongue
4. Acute, nonpurulent cervical lymphadenopathy (one lymph node must be >1.5 cm)
5. One or more of the following extremity changes: <ul style="list-style-type: none"> • Erythema of palms, soles, or both • Indurative edema of hands, feet, or both • Membranous desquamation of the fingertips
Other illnesses with similar clinical signs must be excluded.

*Based on the Centers for Disease Control and Prevention case definition. From Freundlich B, Leventhal L. Diffuse pain syndromes. In Klippel JH, ed. *Primer on the rheumatic diseases*. 12th ed. Atlanta: Arthritis Foundation; 2001:409.

NONARTICULAR RHEUMATISM

Any pain and stiffness without true inflammation in the joint and with normal laboratory results in children is termed *nonarticular rheumatism*, or “growing pains.” These usually occur at night, last several hours, and often resolve spontaneously or are helped by massage or analgesics. Pain is sometimes felt behind the knees. No further evaluation is indicated unless pain occurs during the day. Overuse or hypermobile joints are two possible explanations; nonarticular rheumatism does not normally cause any reduction in activity.

Rheumatology Information on the Internet

A great deal of information on rheumatic diseases for both physicians and patients can be found on the Internet. This can be a valuable tool for family physicians in this era of active research and new treatment modalities in rheumatology. Patients might receive online support from numerous advocacy and support groups for these conditions, although the Internet can also be a source of misinformation, with charlatans touting arthritis cures. Websites of the ACR, Arthritis Foundation, and Medline Plus are particularly good sources of information (see [Web Resources](#)).

Dermatology

RICHARD P. USATINE and JENNIFER KREJCI-MANWARING

CHAPTER OUTLINE

Principles of Diagnosis, 740
General Management, 741
Skin Problems Beginning in Childhood, 742
Inflammatory Dermatologic Diseases, 747
Infectious Skin Diseases, 756

Infestations, 767
Hypersensitivity Reactions and Other Eruptions, 769
Skin Signs of Systemic Disease, 771
Benign Growths, 773
Premalignant and Malignant Skin Lesions, 775

Principles of Diagnosis

Dermatologic diagnoses often begin with *pattern recognition*. Experts can look at most lesions and make an immediate and accurate diagnosis through pattern recognition. The basic terms used to describe lesion morphology and patterns provide the vocabulary to describe what is seen. The physician then combines keen observation of the lesions (including type and distribution) with a careful history to create an informed differential diagnosis. If the diagnosis is still not known, the physician can consult a dermatology atlas (online or print), textbook, or expert to complete the diagnosis. In some cases, further testing (scraping, culture, biopsy) may be needed.

INITIAL EVALUATION

Although medical school teaches students to perform the history before doing the physical examination, this is not the most efficient way to approach the diagnosis of a skin condition. When the patient has a skin complaint, immediately look at the skin while asking your questions. Look carefully at the lesions and determine the lesion morphology. **Table 33-1** provides definitions for the terms used to describe primary and secondary morphology. A magnifying glass and good lighting help to distinguish the morphology of many skin conditions. Next, touch the lesions, with gloves when appropriate. For some lesions, such as actinic keratosis (AK) with scaling or the sandpaper rash of scarlet fever, lightly feeling the skin provides much information. For deeper lesions, such as nodules and cysts, deep palpation is needed. Observe the distribution of the lesions. Try to determine if the primary lesions are arranged in groups, rings, lines, or merely scattered over the skin.

Determine which parts of the skin are affected and which are spared. Be sure to look at the remainder of the skin, nails, hair, and mucous membranes. Patients often show only one small area and appear reluctant to expose the rest of their skin, especially their feet. With many skin conditions, it is essential to look beyond the most affected area because other areas may provide important clues (e.g., nail pitting when considering psoriasis). Patients may have

lesions on their back or feet that they have not observed. For example, a patient may have a papular eruption on the hands or arms that represents an autosensitization reaction (*id reaction*) to a fungal infection on the feet; not looking for the fungus on the feet will lead to a missed diagnosis (**Figures 33-1** and **33-2**). Some skin diseases have manifestations in the mouth; finding white patches on the buccal mucosa may lead to the correct diagnosis of lichen planus (**Figure 33-3**).

When the physician starts to look at the skin, the patient history will be more focused, directed toward finding the correct diagnosis. The following information assists in making a dermatologic diagnosis and planning treatment:

- Onset and duration of skin lesions: continuous or intermittent?
- Pattern of eruption: Where did it start? How has it changed?
- Any known precipitants, such as exposure to medication (prescription, over the counter [OTC]), foods, plants, sun, topical agents, chemicals (occupation, hobbies)?
- Skin symptoms: itching, pain, paresthesia
- Systemic symptoms: fever, chills, night sweats, fatigue, weakness, weight loss
- Underlying illnesses: diabetes, thyroid disease, human immunodeficiency virus (HIV)
- Family history: acne, atopic dermatitis (AD), psoriasis, skin cancers, dysplastic nevi

The most important in-office examinations of the skin are the following:

Microscopy. To diagnose a fungal infection, scrape some of the scale onto a microscope slide, add 10% potassium hydroxide (KOH) (best with dimethyl sulfoxide [DMSO] and fungal stain), and look for the hyphae of dermatophytes or the pseudohyphae of *Candida* or *Pityrosporum* species.

Wood's light examination. This is helpful in diagnosing tinea capitis and erythrasma. Tinea capitis caused by *Microsporum* spp. produces green fluorescence, but *Trichophyton* spp. do not fluoresce. Erythrasma has a coral-red fluorescence. A Wood's lamp also helps distinguish lesions of vitiligo in patients with fair skin.

Table 33-1 Primary and Secondary Skin Lesions

Lesions	Description
PRIMARY (BASIC) LESIONS	
Macule	Circumscribed flat discoloration (≤ 5 mm)
Patch	Flat nonpalpable discoloration (> 5 mm)
Papule	Elevated solid lesion (≤ 5 mm)
Plaque	Elevated solid lesion (> 5 mm) (often a confluence of papules)
Nodule	Palpable solid (round) lesion, deeper than a papule
Wheal (hive)	Pink edematous plaque (round or flat), topped and transient
Pustule	Elevated collection of pus
Vesicle	Circumscribed elevated collection of fluid (≤ 5 mm in diameter)
Bulla	Circumscribed elevated collection of fluid (> 5 mm in diameter)
SECONDARY (SEQUENTIAL) LESIONS	
Scale (desquamation)	Excess dead epidermal cells
Crusts	Collection of dried serum, blood, or pus
Erosion	Superficial loss of epidermis
Ulcer	Focal loss of epidermis and dermis
Fissure	Linear loss of epidermis and dermis
Atrophy	Depression in skin from thinning of epidermis or dermis
Excoriation	Erosion caused by scratching
Lichenification	Thickened epidermis with prominent skin lines

**Figure 33-1** Vesicular tinea pedis leading to an autosensitization reaction. (© Richard P. Usatine.)

Surgical biopsy. The biopsy can be used as a diagnostic and treatment tool. Having a reasonable differential diagnosis will help the physician choose shave, punch, or elliptic biopsy. Similarly, when submitting your specimen to pathology, always include background information and the differential to aid the pathologist.

General Management

TOPICAL CORTICOSTEROIDS

The choice of a topical steroid involves maximizing benefit and minimizing adverse effects. Many skin conditions

**Figure 33-2** Autosensitization reaction secondary to vesicular tinea pedis (id reaction). (© Richard P. Usatine.)**Figure 33-3** Oral lichen planus showing Wickham striae. (© Richard P. Usatine.)

benefit greatly from topical steroids. However, local adverse effects of topical steroids are common with regular use over weeks to months. The most common adverse effect of topical steroids is skin *atrophy*, in which the epidermis becomes thin and the superficial capillaries dilate. Epidermal atrophy can be accompanied by hypopigmentation and telangiectasias. If atrophy involves the dermis, striae may occur. Although the epidermal atrophy may be reversible in months, striae are irreversible. When steroids are continuously applied to the face, perioral dermatitis, acne or rosacea-like eruptions can occur.

Systemic adverse effects are rare and occur when large amounts of topical steroids are absorbed systemically. The risk of such absorption increases with stronger steroids, thinner skin, younger patients, longer duration of therapy, and the use of occlusion in therapy. Prescribing the minimum strength needed for the shortest duration required helps prevent adverse effects. In choosing the best topical steroid, consider the following factors:

1. **Skin disorder.** As the severity of the disorder increases, the need for higher-potency steroids increases. Also,

Table 33-2 Potency of Topical Corticosteroids

Potency	Generic Drugs	Brand Names
“Superpotent” (class 1)	Clobetasol, betamethasone dipropionate, halobetasol, fluocinonide	Clobex, Diprolene, Olux, Psorcon, Temovate, Ultravate, Vanos
High potency (classes 2 and 3)	Betamethasone dipropionate, mometasone, halcinonide, fluocinonide, desoximetasone, triamcinolone 0.1%, fluticasone, amcinonide	Diprolene, Elocon, Halog, Lidex, Psorcon, Topicort, Aristocort, Cutivate, Cyclocort
Midpotency (classes 4 and 5)	Prednicarbate, mometasone, betamethasone valerate, hydrocortisone probutate, fluocinolone, desoximetasone, hydrocortisone valerate, triamcinolone 0.025%	Dermatop, Elocon, Luxiq, Pandel, Synalar, Topicort, Westcort, Cordran, Cutivate, Locoid
Low potency (classes 6 and 7)	Alclometasone, desonide, fluocinolone, hydrocortisone	Aclovate, DesOwen, Synalar, Hytone, Desonate

thicker lesions (e.g., psoriatic plaques, lichen planus) need higher-potency steroids.

- Site.** Use only the weakest-potency steroids on the face, genitals, and intertriginous areas, where skin is thin or moist and skin atrophy and striae occur most rapidly. There are exceptions, however, as when clobetasol is needed to treat certain vulvar disorders such as lichen sclerosis. The skin on the palms and soles is so thick that the most potent steroids are often needed.
- Age.** Avoid the use of high-potency topical steroids in infants and children because they have greater surface area per body mass than adults and have greater risk and consequences of systemic absorption.
- Steroid potency** (strength and concentration). There are more than 50 types and brands of steroids; family physicians should know at least one steroid from each of four basic strengths (Table 33-2). Generic agents can be used from all the potency groups to save on costs.
- Vehicle.** The vehicle is the substance in which the steroid is dispersed. The most common vehicles are ointments, creams, gels, solutions, lotions, and foams. The choice of vehicle is determined by the characteristics of the lesion (dry or moist), the site involved, and patient preference. Furthermore, the vehicle affects the potency of the steroid because it determines the rate at which the steroid is absorbed through the skin.

Most skin preparations can be applied twice a day, conveniently in the morning and evening. Try to estimate and prescribe an appropriate amount; many topical products are supplied in 15-g, 30-g, 60-g, and 80-g sizes; 80 g is about the size of a tube of toothpaste. Based on common practice, it is accepted that 2 g of cream is required to cover the face or one hand, 3 g for an arm, 4 g for a leg, and 12 to 30 g for an entire body. Therefore, if you calculate that out to 1 month's worth of medication, you would need a 30- to 60-g tube for the face but up to 900 g or almost 2 lb for the whole body. To avoid adverse effects of steroid overuse, do not prescribe large quantities for small lesions and specify the duration of use. On the other end of the spectrum, prescribing only 15 g of steroid for a large area of involvement will be frustrating to the patient when the steroid is depleted before completing the prescribed treatment. Generic triamcinolone comes in 1-lb tubs (454 g), which is extremely helpful for patients with inflammatory conditions covering much of the body. It is therefore important to specify the quantity you want on the prescription; otherwise, the pharmacist may choose whatever size is in stock.

The duration of therapy is usually the time required for resolution of symptoms or lesions. To avoid adverse effects, the highest potency steroids should not be used for longer than 2 to 4 weeks continuously. However, these can be used intermittently for chronic conditions such as psoriasis in a pulse-therapy mode (e.g., apply every weekend, with steroid-sparing medication on weekdays). For conditions with dry skin, liberal use of emollients between steroid applications can minimize steroid exposure while maximizing the benefits of therapy.

MANAGEMENT OF PRURITIS

Often, patients present because of the pruritus associated with a skin condition rather than the skin condition itself. Itching associated with visible lesions often responds to relatively nonspecific antipruritic treatments. If the itching is generalized, patients may obtain temporary relief from cool or tepid baths with the addition of colloidal oatmeal (Aveeno). Soap should be avoided. Oral antihistamines can be given every 6 to 8 hours, especially at bedtime to promote sleep. Diphenhydramine (Benadryl) and hydroxyzine (Atarax, Vistaril) are first-generation antihistamines that are relatively safe and effective, although caution should be used in older adult patients. Second-generation antihistamines are similarly effective for reducing pruritus in the daytime and are less sedating for some patients. These include fexofenadine (Allegra), loratadine (Claritin), desloratadine (Clarinex), cetirizine (Zyrtec), and levocetirizine (Xyzal). Usually, second-generation antihistamines are given once daily.

Skin Problems Beginning in Childhood

ATOPIC DERMATITIS (ECZEMA)

Key Points

- AD is a common inherited childhood disorder that may occur with other atopic conditions such as allergic rhinitis and asthma.
- Topical steroids and emollients are the mainstays of treatment for AD.
- Topical and systemic antibiotics are used for AD secondarily infected with bacteria.

Figure 33-4 Atopic dermatitis. (© Richard P. Usatine.)

Figure 33-5 Atopic dermatitis in the antecubital fossa. (© Richard P. Usatine.)

Atopic dermatitis is a potentially debilitating condition that can compromise quality of life. Its most frequent symptom is pruritus. Pruritus leads to scratching, resulting in secondary skin changes such as excoriation, crusting, and lichenification. Consequently, AD has been referred to as “the itch that rashes.”

Atopic dermatitis is a common problem affecting up to 15% of all children. In most cases, AD occurs before 5 years of age, frequently on the face or extensor surfaces in the first year of life (Figure 33-4). As children grow, the antecubital and popliteal fossae (flexural surfaces) are often involved (Figure 33-5). The disease may occur intermittently between periods of complete remission. By adulthood, the incidence becomes less than 1%. Treatment should be directed at limiting itching, repairing the skin, and decreasing inflammation. Lubricants and topical corticosteroids are the mainstays of therapy. Topical pimecrolimus and tacrolimus are considered steroid-sparing agents and are effective for short-term use or in cases unresponsive to topical corticosteroids. These agents are only approved for second-line treatment in patients older than 2 years of

Figure 33-6 Impetiginized atopic dermatitis. (© Richard P. Usatine.)

age. When required for rare severe cases, oral corticosteroids can be used.

Always look for signs of bacterial superinfection, such as weeping of fluid and crusts (Figure 33-6). Superinfection with *Staphylococcus aureus* may lead to worsening of AD because the bacteria functions as a super antigen. *S. aureus* superinfections are usually sensitive to methicillin, so oral cephalexin is frequently a good choice for treatment. Bleach baths are helpful to cut down on colonization. (Add $\frac{1}{4}$ - $\frac{1}{2}$ cup regular bleach per full tub of lukewarm water and soak for 5 to 10 minutes before washing off the bleach water.) Apply emollients or topical medications (or both) immediately after the bath.

KEY TREATMENT

- Topical steroids and emollients are the mainstay of treatment for AD (Hanifin et al., 2004) (SOR: A).
- Topical and systemic antibiotics are used for AD with secondary bacterial infection; weeping fluid and crusting during an exacerbation should prompt consideration of antibiotic use (Hanifin et al., 2004) (SOR: A).
- Topical calcineurin inhibitors (immunomodulators such as pimecrolimus and tacrolimus) reduce the rash severity and symptoms of AD in children and adults (Hanifin et al., 2004) (SOR: A).
- Dietary restriction is useful only for infants with proven egg and cow's milk protein allergies (Hanifin et al., 2004; Lifschitz & Szajewska, 2014) (SOR: B).
- The value of antihistamines in AD is controversial; if used, the sedating agents are most effective and can be given at night (Hanifin et al., 2004) (SOR: B).

PITYRIASIS ALBA

Pityriasis alba is a common hypopigmented dermatitis that may affect nearly one third of school-age children in the United States. The condition is more common in patients with a history of AD. Patients present with numerous hypopigmented macules ranging from 1 to 4 cm in size on the face, neck, and shoulders (Figure 33-7). The macules

Figure 33-7 Pityriasis alba. (© Richard P. Usatine.)

are poorly defined and may have fine scales. Occasionally, erythema and pruritus occur before the lesions. Sun exposure can cause more contrast of the lesions as the surrounding normal skin tans. Generally, pityriasis alba is self-limited and asymptomatic, so therapy is typically unnecessary. Lesions usually fade by adulthood. Topical steroids, emollients, and phototherapy have limited efficacy. Hydrocortisone 1% cream or ointment may provide some benefit, and if used for no more than 2 weeks, the patients should be relatively safe from adverse effects.

KERATOSIS PILARIS

Keratosis pilaris is very common and presents as tiny (<1 mm) keratotic follicular papules found on extensor arms and thighs and occasionally the cheeks. The numerous papules give the skin a rough feeling. Often there is a ring of erythema around the follicle. The incidence of keratosis pilaris is increased in patients with AD. Treatment consists of emollients combined with keratolytic agents; common preparations are 5% or 12% ammonium lactate (AmLactin, Laclotion, Lac-Hydrin) and urea-based creams or lotions. Microdermabrasion has also been used to treat keratosis pilaris. Patient education should stress that keratosis pilaris is genetic and cannot be cured. Any smoothing with topical or mechanical agents is temporary and will return if the treatment is stopped.

MELANOCYTIC NEVI

Nevi (moles) are benign lesions composed of collections of nevus cells of neuroectodermal origin. They appear in childhood, tend to increase in number throughout the adult

Figure 33-8 Intradermal nevus. (© Richard P. Usatine.)

Figure 33-9 Compound nevus. (© Richard P. Usatine.)

years, and then resolve with age. *Pigmented* nevi can be flat, raised, or pedunculated and have impressive variations in size, color, and surface characteristics. Histologically, *junctional* nevi are located in the epidermis, *intradermal* nevi in the dermis, and *compound* nevi in the epidermis and dermis. Junctional nevi are flat and pigmented, intradermal nevi are raised and skin colored, and compound nevi are raised and pigmented (Figures 33-8 and 33-9).

Unless they become suspicious for melanoma, nevi need not be removed except for cosmetic reasons or because of chronic irritation based on their location. Nevi should be examined frequently, however, for changes in color, shape, or size. These changes may herald the onset of a melanoma

Figure 33-10 Dysplastic nevus. (© Richard P. Usatine.)

in a previously benign nevus and warrant excision with pathologic evaluation of the tissue.

Nevi that are present at birth and are visible shortly thereafter are considered *congenital* nevi. Although these nevi may have a slightly higher risk of developing melanoma than acquired nevi, it is not cost effective or sensible to recommend the removal of all congenital nevi. It is even controversial with regard to removal of large, “bathing suit” nevi, which have the highest risk of melanoma. Children born with these nevi are at risk for developing melanoma in the central nervous system (CNS) as well as subcutaneous melanoma, which is not visible as a color or surface change and requires palpation to detect it on routine skin examination.

Dysplastic nevi (atypical moles) are markers for an increased risk of melanoma. These nevi have more atypical features but are not at high risk of converting to melanoma (Figure 33-10). Therefore, removing dysplastic nevi does not provide a survival benefit for patients. The presence of five or more dysplastic nevi should alert the patient and physician to this higher risk of melanoma, and therefore regular skin examinations should be performed along with sun protection and avoidance.

INFANTILE HEMANGIOMA

A hemangioma is an extremely common type of benign tumor that occurs most frequently in infants and children. It is composed of newly formed blood vessels that result from malformation of angioblastic tissue during fetal life. The two main types are capillary (superficial) and cavernous (deep) hemangiomas (Figures 33-11 and 33-12).

Hemangiomas undergo a growth phase before resolving spontaneously. Although some regression begins by the end of the first year of life, many hemangiomas do not completely resolve until the child is 10 to 12 years old, and some may leave permanent textural or color changes. Although typically benign, rapidly proliferating hemangiomas can ulcerate. Those on the face may obscure vision and can cause blindness. Those on the anterior neck can compress the upper respiratory track during proliferation and can be life threatening. Hemangiomas of the genital region are

Figure 33-11 Strawberry hemangioma. (© Richard P. Usatine.)

Figure 33-12 Cavernous hemangioma. (© Richard P. Usatine.)

also problematic and may indicate other internal malformations. Persistent or obstructive hemangiomas have been successfully treated with propranolol, lasers, excision, systemic corticosteroids, interferon, imiquimod, and cryosurgery.

ACNE VULGARIS

Acne is a disorder of the pilosebaceous follicles on the face, chest, and back. Follicular obstruction leads to comedones, and inflammation results in papules, pustules, and nodules. The four most important steps in acne pathogenesis are (1) sebum overproduction related to androgenic hormones and genetics, (2) abnormal desquamation of follicular epithelium (keratin plugging), (3) *Propionibacterium acnes*

Figure 33-13 Acne fulminans. (© Richard P. Usatine.)

proliferation, and (4) neutrophil chemotaxis, which leads to inflammation. These steps are stimulated by androgens, and strong genetic factors determine a person's likelihood of developing acne. Although common, acne can cause physical pain, psychosocial suffering, and scarring. Acne may be associated with fever, arthritis, and other systemic symptoms in acne fulminans (Figure 33-13).

Topical treatments include retinoids, antibiotics, benzoyl peroxide (BPO), azelaic acid, and α - or β -hydroxyl acid products. Topical retinoids are comedolytic and antiinflammatory; normalize follicular hyperproliferation and hyperkeratinization; and reduce the numbers of microcomedones, comedones, and inflammatory lesions. The most frequently prescribed topical retinoids include tretinoin (Retin-A), adapalene (Differin), and tazarotene (Tazorac). Topical retinoids frequently cause skin irritation, peeling, and redness. Mild cleansers and noncomedogenic moisturizers can reduce the inflammation, as does less frequent dosing of the retinoids (every other day or twice weekly). Glycolic acid (α -hydroxy acid) and salicylic acid (β -hydroxy acid) come in various products, are used in chemical peels, and are also effective for hyperkeratinization.

Topical antibiotics are effective against *P. acnes* and act as antiinflammatories. Erythromycin and clindamycin are frequently used once or twice daily. Topical dapsone (Aczone) was approved in 2008 for acne treatment. Benzoyl peroxide is also effective against *P. acnes* and is available OTC in various preparations. Combination products with antibiotics, retinoids, or BPO are convenient methods of delivering synergistic medications in one preparation. If two separate products are to be used instead of a combination product, it is best that they are applied at different times to avoid one product inactivating the other.

Oral medications used in acne treatment include antibiotics, hormone therapies, and isotretinoin. Isotretinoin is a known teratogen and should not be used in women of childbearing age unless avoidance of pregnancy is ensured. Contraception counseling is mandatory, and two negative pregnancy test results are required before initiation of therapy. The baseline laboratory examination should also include determination of cholesterol, fasting triglycerides, transaminase levels, blood urea nitrogen (BUN) or creatinine, and a complete blood count (CBC). Pregnancy tests must be repeated monthly for women of childbearing

Figure 33-14 Acne conglobata (© Richard P. Usatine.)

potential. Other laboratory examinations should be repeated routinely during treatment.

KEY TREATMENT

- Topical benzoyl peroxide (gel, cream, lotion, wash) has an antimicrobial effect in acne treatment. Higher percentage products (10%) cause more irritation and are not more effective (Agency for Healthcare Research and Quality [AHRQ], 2001) (SOR: A).
- Topical antibiotics such as clindamycin and erythromycin are beneficial treatments (AHRQ, 2001) (SOR: A).
- Combination products with antibiotics and BPO deliver synergistic medications in one preparation (AHRQ, 2001) (SOR: B).
- Topical retinoids (tretinoin, adapalene, tazarotene) are excellent to treat all types of acne and the primary treatment in comedonal acne (AHRQ, 2001) (SOR: A).
- Azelaic acid is useful to treat postinflammatory hyperpigmentation and acne (AHRQ, 2001) (SOR: B).
- Oral antibiotics with proven benefit in acne include tetracycline, doxycycline, minocycline, and erythromycin and are particularly useful for inflammatory acne and trunk acne (AHRQ, 2001; Strauss et al., 2007) (SOR: A).
- Isotretinoin is the most powerful treatment for cystic and scarring acne that has not responded to other therapies (Figure 33-14) (Strauss et al., 2007) (SOR: A).
- Prolonged use of tetracycline antibiotics, particularly doxycycline, may be associated with an increased risk of inflammatory bowel disease, particularly Crohn disease (Margolis et al., 2010) (SOR: B).

VIRAL EXANTHEMS

Viral causes of rashes include varicella, rubeola, rubella, roseola, and erythema infectiosum (fifth disease). Treatment is aimed at symptoms using acetaminophen or ibuprofen for fever and diphenhydramine for pruritus.

Varicella

Varicella is now much less common because of universal varicella vaccination of children. Occasionally, a family

Figure 33-15 Chickenpox. (© Richard P. Usatine.)

physician sees a case of breakthrough chickenpox in a vaccinated child. Unvaccinated adults may also present with varicella. Patients with varicella have fever and general malaise as a mild prodrome lasting 1 to 2 days before the rash appears. The rash typically begins on the face, scalp, or trunk and then spreads to the extremities. The lesions appear as erythematous macules and progress to papules with an edematous base. The papules quickly evolve into vesicles, appearing as “dewdrop on a rose petal” (Figure 33-15). The vesicles evolve into pustules, which become umbilicated and subsequently crust over in the ensuing 8 to 12 hours. A defining characteristic of varicella is that lesions may be present in all stages simultaneously.

In children, the most common varicella complication is secondary bacterial infection of excoriated lesions. Other complications include cerebellar ataxia, encephalitis, meningitis, transverse myelitis, and rarely Reye syndrome. Varicella pneumonia and encephalitis can be serious complications in adults. Because of the risk of Reye syndrome, aspirin use should be avoided in patients with varicella. Acyclovir is recommended for adolescents, adults, and children with varicella who are taking steroids or otherwise immunocompromised.

Measles (Rubeola) and Rubella

Rubeola presents as maculopapular (morbilliform) eruption. It starts on the face and spreads centrifugally. It is associated with cough, coryza, conjunctivitis, fever, and Koplik spots (red-white-blue macules in mouth). As with varicella, rubeola is now uncommon because of vaccinations.

The exanthem of rubeola (measles) begins around the fourth febrile day, with discrete lesions that become confluent as they spread from the hairline downward, sparing the palms and soles. The exanthem typically lasts 4 to 6 days. The lesions fade gradually in order of appearance, leaving a residual yellow-tan coloration or faint desquamation. Rubeola is also distinguished by the presence of Koplik spots in the oral mucosa. These are usually small white or bluish macules with a ring of erythema on the buccal mucosa.

Rubella is similar to rubeola and is caused by a togavirus. It causes less severe symptoms, and its exanthem characteristically has a duration of 2 to 3 days. Rubella is

associated with tender cervical lymphadenopathy, most notably in the posterior cervical and occipital areas. Another unique feature is Forchheimer spots, which are pinpoint red macules and petechiae over the soft palate and the uvula.

Hand, Foot, and Mouth Disease

This common childhood illness usually occurs in the summer or early fall and presents as flat-topped vesicles on hands, feet, and mouth, especially on the palms and soles. Every case may not involve all three sites. Hand, foot, and mouth disease is most often caused by coxsackievirus A16.

However, a number of atypical hand-foot-and-mouth disease cases are now being reported with an expanded range of cutaneous findings that are associated with coxsackievirus A6 infection (Lott et al., 2013). In a recent series, two adults and three children with atypical hand, foot, and mouth disease were identified. Four of five patients exhibited widespread cutaneous lesions, and systemic symptoms prompted four of five patients to seek emergency care. In two patients with a history of AD, accentuation in areas of dermatitis was noted. Infection with CV-A6 was confirmed in all patients (Lott et al., 2013).

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is caused by human parvovirus B19 and primarily affects children 3 to 12 years old. The prodrome may consist of fever, anorexia, sore throat, and abdominal pain. After the fever resolves, the classic erythematous facial rash (“slapped cheek”) appears. The exanthem progresses to a diffuse, reticular or “lacy” pattern on the extensor extremities that may wax and wane for several weeks.

Roseola Infantum (Sixth Disease, Exanthem Subitum)

Roseola infantum, or exanthem subitum, is caused by human herpesvirus 6. This disease occurs in children younger than 3 years. As in fifth disease, the rash of sixth disease appears after the resolution of several days of high fever. The diffuse morbilliform eruption often spares the face and is of short duration, typically fading within 3 days.

Inflammatory Dermatologic Diseases

SEBORRHEA

Seborrheic dermatitis is a chronic inflammatory disorder affecting areas of the head (scalp, face) and body where sebaceous glands are prominent. The inflammation is thought to be caused by *Malassezia (Pityrosporum)* spp. All age groups may be affected, and seborrhea can be chronic or intermittent. On the scalp, seborrhea can range from mild dandruff to thick, adherent plaques. Seborrhea on the face and body appears as erythema with greasy or waxy scales. On the face, two common locations are around the eyebrows and nose and around the beard and mustache in men (Figures 33-16 and 33-17). When on the body, it is found on the chest and groin.

Treatments are aimed at the inflammation and the *Malassezia* overgrowth and include shampoos containing

Figure 33-16 Seborrheic dermatitis. (© Richard P. Usatine.)

Figure 33-17 Seborrheic dermatitis around beard and mustache. (© Richard P. Usatine.)

selenium sulfide, ketoconazole, or pyrithione zinc. Topical antifungal lotions and corticosteroid preparations are also effective. Low-potency corticosteroids used intermittently are safe and effective. In infants, seborrheic dermatitis might only involve the scalp (cradle cap) or can be seen in other areas of skin folds such as the diaper area. If not treated prophylactically, seborrheic dermatitis has a tendency to recur.

KEY TREATMENT

- Shampoos containing ketoconazole, selenium sulfide, or zinc pyrithione are effective for moderate to severe seborrhea capitis (Danby et al., 1993; Pierard-Franchimont, 2002) (SOR: A).
- Ketoconazole 2% cream, gel, or emulsion is safe and effective for facial seborrheic dermatitis (Chosidow et al., 2003; Pierard et al., 1991) (SOR: B).
- Oral terbinafine, 250 mg daily for 4 weeks, is effective for moderate to severe seborrhea (Scaparro, 2001; Vena et al., 2005) (SOR: A).

Figure 33-18 Psoriatic plaques. (© Richard P. Usatine.)

- Hydrocortisone 1% cream or lotion can be used twice daily on face, scalp, or other affected area (Firooz et al., 2006) (SOR: B).
- Desonide 0.05% lotion is safe and effective for short-term treatment of seborrheic dermatitis of the face (Freeman, 2002) (SOR: B).
- For moderate to severe seborrhea on the scalp, 0.05% fluocinonide solution once daily is affordably priced and beneficial (SOR: C).

PSORIASIS

Psoriasis is a common skin disorder that most often appears as inflamed plaques covered with a thickened, silvery-white scale. Psoriasis is divided into the following nine categories, although a patient can have more than one type at the same time:

1. *Plaque psoriasis* accounts for 80% to 90% of patients with psoriasis (Figure 33-18).
2. *Scalp psoriasis* causes plaques on the scalp (Figure 33-19).
3. *Guttate psoriasis* appears as small, round plaques that resemble water drops (Figure 33-20).
4. *Inverse psoriasis* causes lesions in the intertriginous areas (skin folds) of the axilla, groin, inframammary, inguinal and intergluteal regions. Inverse psoriasis may not exhibit classic scaly plaques, and the erythema, scaling, or maceration in these areas is often mistaken for fungal infection (Figure 33-21).
5. *Palmar-plantar psoriasis* occurs on the plantar aspects of the hands and feet (palms and soles) (Figure 33-22).
6. *Erythrodermic psoriasis* is widespread erythema and scales.
7. *Pustular psoriasis* can be localized or generalized. In the generalized form, superficial pustules may appear and coalesce to form lakes of pus that dry and desquamate in sheets (Figure 33-23).
8. *Nail psoriasis* causes the nails to develop pits, onycholysis, “oil spots,” or onychauxis (nail thickening).

Figure 33-19 Scalp psoriasis. (© Richard P. Usatine.)

Figure 33-21 Inverse psoriasis under breasts. (© Richard P. Usatine.)

Figure 33-20 Guttate psoriasis after streptococcal throat infection in child. (© Richard P. Usatine.)

Figure 33-22 Palmoplantar psoriasis as a form of localized pustular psoriasis. (© Richard P. Usatine.)

9. *Psoriatic* arthritis commonly affects the joints of the hands, feet, and knees but can involve other joints as well.

One percent to 2% of the U.S. population has plaque psoriasis. Genetic factors are involved: when both parents are affected by psoriasis, the rate of psoriasis may be as high as 50%; with one parent affected, the rate is approximately 16%. Psoriasis can appear at any age, but the two peak age ranges are 16 to 22 years and 57 to 60 years. Guttate psoriasis often occurs after streptococcal pharyngitis or another upper respiratory infection. Pustular psoriasis may

Figure 33-23 Generalized pustular psoriasis presenting as erythroderma. (© Richard P. Usatine.)

be provoked by the withdrawal of systemic steroids in a patient already diagnosed with psoriasis.

The most common areas involved include the elbows, knees, extremities, trunk, scalp, face, ears, hands, feet, genitalia, intertriginous areas, and the nails. In most cases, diagnosis of psoriasis is based on the clinical appearance. The differential diagnosis list is long, but a KOH (potassium hydroxide) preparation or skin biopsy may be needed. A biopsy may also be helpful to establish the diagnosis in less common types of psoriasis (pustular, palmar-plantar, inverse). Psoriasis should not be treated with oral or systemic steroids; this can precipitate a life-threatening case of generalized pustular psoriasis.

A meta-analysis showed that 68% to 89% of patients treated with clobetasol (ultrahigh-potency steroid) had clear improvement or complete healing (Nast et al., 2007). Comparable efficacy was shown for topical calcipotriene (vitamin D analog) and tazarotene (retinoid), with a slight increase in adverse effects for tazarotene (Affi et al., 2005). Combination topical steroids and calcipotriene or tazarotene is the most promising current topical treatment and seems to have increased efficacy and fewer side effects (Affi et al., 2005; Nast et al., 2007). Clinical trials suggest that tacrolimus (0.1%) ointment twice daily produces a good response in a majority of patients with facial and intertriginous (inverse) psoriasis (Brune et al., 2007; Lebwohl et al., 2004; Martin et al., 2006). Methotrexate as a weekly oral dose of 5 to 15 mg can be very effective for widespread psoriasis not responding to topical treatments (Saporito and Menter, 2004). Acitretin (Soriatane) is a potent systemic retinoid used for psoriasis that is widespread or palmar-plantar and not responding to topical treatments (Pearce et al., 2006).

Etanercept (Enbrel) is a subcutaneous biologic agent that is especially valuable in patients with psoriatic arthritis, as well as those with moderate to severe cutaneous psoriasis (Nast et al., 2007). Adalimumab (Humira), a subcutaneous biologic agent, and infliximab (Remicade), an intravenous (IV) biologic agent, are effective for patients with psoriatic arthritis as well as those with moderate to severe cutaneous psoriasis (Bansback et al., 2009). Ustekinumab (Stelara), the most recently approved subcutaneous biologic agent, significantly reduced signs and symptoms of psoriatic arthritis and diminished skin lesions compared with placebo (Gottlieb et al., 2009).

KEY TREATMENT

- Potent topical steroid ointments are a good choice for first-line therapy of psoriasis (Affi et al., 2005) (SOR: A).
- Clobetasol successfully treated 68% to 89% of patients with psoriasis (Nast et al., 2007) (SOR: A).
- Topical calcipotriene and tazarotene show comparable efficacy as clobetasol for psoriasis (Affi et al., 2005) (SOR: A).
- Topical steroids and calcipotriene or tazarotene show increased efficacy in psoriasis and fewer side effects (Affi et al., 2005; Nast et al., 2007) (SOR: A).
- Tacrolimus (0.1% ointment twice a day) helps most patients with facial and inverse psoriasis (Brune et al., 2007; Lebwohl et al., 2004; Martin et al., 2006) (SOR: B).

Figure 33-24 Pityriasis rosea with herald patch on neck. (© Richard P. Usatine.)

- Narrow-band ultraviolet B (UVB) is safer and more effective than broadband UVB for psoriasis (Ibbotson et al., 2004) (SOR: A)
- Methotrexate (5-15 mg/wk) is effective for widespread psoriasis not responding to topical treatments (Saporito and Menter, 2004) (SOR: A). It is also beneficial for psoriatic arthritis.
- Acitretin (Soriatane) is used for unresponsive widespread or palmar-plantar psoriasis (Pearce et al., 2006) (SOR: A).
- Etanercept (Enbrel) and other biologic agents are especially valuable in patients with psoriatic arthritis or cutaneous psoriasis (Ash et al., 2012) (Nast et al., 2007) (SOR: A).

PITYRIASIS ROSEA

Pityriasis rosea is a common acute eruption usually affecting children and young adults; the cause is unknown. It is characterized by the formation of an initial herald patch (Figure 33-24) followed by the development of a diffuse papulosquamous rash. Pityriasis rosea is difficult to identify until the appearance of characteristic, smaller, secondary lesions that follow Langer lines in a “Christmas tree” pattern (Figure 33-25). The rash of pityriasis rosea typically lasts 5 to 8 weeks, with complete resolution in most patients. The rash is usually asymptomatic, but treatment for pruritus may be needed and can include calamine lotion, topical steroids, and oral antihistamines. Systemic steroids are generally not recommended.

Ultraviolet (UV) radiation and erythromycin have been used with varying results. Because no bacterial cause has been associated with the disease, the likely effect of erythromycin is a result of its antiinflammatory properties. Postinflammatory hyperpigmentation may occur with UVB radiation therapy, so some experts recommend against its use. High-dose acyclovir (800 mg four times a day) may help shorten disease, especially if instituted early in the disease course, but studies are limited.

Patients should be reassured about the self-limited nature of pityriasis rosea. Persistence of the rash or pruritus beyond 12 weeks should prompt reconsideration of the

Figure 33-25 Pityriasis rosea with “Christmas tree” pattern on back
(© Richard P. Usatine and E.J. Mayeaux, Jr. *The Color Atlas of Family Medicine.*)

original diagnosis, such as secondary syphilis and consideration of laboratory work or biopsy to confirm the diagnosis, and questioning the patient again about use of medications that may cause a rash similar to that of pityriasis rosea.

ROSACEA

Rosacea, sometimes called “acne rosacea,” is an inflammatory disease with unknown etiology. Various facial manifestations occur, and symptoms differ from patient to patient. The four types of rosacea are erythematotelangiectatic, papulopustular, phymatous, and ocular. Patients may have overlapping features of more than one type. The predominant manifesting complaints of *erythematotelangiectatic* rosacea are intermittent central facial flushing and erythema. Many patients complain of a stinging or burning pain associated with flushing episodes. Common triggers include exposure to the sun, cold weather, sudden emotion (including laughter or embarrassment), hot beverages, spicy foods, and alcohol consumption.

Papulopustular rosacea presents with acnelike papules and sterile pustules and can occur alone or in combination with the erythema and telangiectasias (Figure 33-26). Intermittent or chronic facial edema may also occur in all forms. Some patients develop *rhinophyma*, a coarse hypertrophy of the connective tissue and sebaceous glands of the nose. This can be extremely disfiguring and even cause nasal airway obstruction. Approximately one third of patients with rosacea develop ocular symptoms, including eyes that are itchy, burning, or dry; a gritty or foreign body sensation; and erythema, swelling, or hordeolum of the eyelid. The ocular changes can become chronic. Corneal

Figure 33-26 Rosacea. (© Richard P. Usatine.)

neovascularization and keratitis can occur, leading to corneal scarring and perforation. Episcleritis and iritis have also been reported to occur in patients with rosacea.

First-line treatment is avoidance of triggering or exacerbating factors. Although patients have different trigger(s), almost all patients benefit from strict sun avoidance and protection. Acne-like lesions respond well to long-term topical treatment using metronidazole, azelaic acid, erythromycin, and clindamycin. Oral tetracyclines used in antimicrobial (high) doses or antiinflammatory (low) doses are helpful for moderate to severe rosacea. Topical retinoid therapy may also be effective, but irritation can limit its tolerability. Laser treatment is an option for progressive telangiectasia, erythema, or rhinophyma. Ocular symptoms generally require oral tetracyclines. Consultation may be required for the management of rhinophyma, ocular complications, or severe disease.

KEY TREATMENT

- Best evidence supports the topical use of metronidazole (0.75% or 1%) and azelaic acid (15% or 20%) for rosacea (van [Zuuren et al., 2011](#)) (SOR: A).
- If the skin lesions are more extensive, oral antibiotics, such as doxycycline, are recommended for rosacea (van [Zuuren et al., 2011](#)) (SOR: C).
- Both antiinflammatory (low-dose) doxycycline (40-mg delayed-release Oracea) and 100-mg doxycycline are equally effective once-daily treatments for moderate to severe rosacea; a higher dosage (100 mg) is associated with a higher incidence of adverse effects (mostly gastrointestinal [GI] symptoms) ([Del Rosso et al., 2008](#)) (SOR: B).
- Pulsed-dye laser and intense pulse light result in significant reduction in erythema, telangiectasia, and patient-reported associated symptoms ([Neuhaus et al., 2009](#)) (SOR: B).
- Ocular rosacea may be treated with oral doxycycline. ([Bartholomew et al., 1982](#); [Seal et al., 1995](#)) Cyclosporin 0.05% ophthalmic emulsion is an option for topical treatment of ocular rosacea (van [Zuuren et al., 2011](#)) (SOR: C).

Figure 33-27 Lichen planus with linear papules. (© Richard P. Usatine.)

Figure 33-28 Lichen planus on the lateral ankle. (© Richard P. Usatine.)

LICHEN PLANUS

Lichen planus is a papular pruritic skin eruption characterized by its violaceous color and polygonal shape. Most frequently, flat-topped papules and plaques are found on the flexor surfaces of the upper extremities, on the genitalia, around the ankles, and on the mucous membranes (Figures 33-27 and 33-28). Skin lesions can be intensely pruritic. Lichen planus is most commonly associated with hepatitis C infection and the association is strongest for the oral form of lichen planus.

Patients with lichen planus are usually between 30 and 60 years old, although the disorder may occur at any age. Men and women are equally affected, and there is no racial predisposition. The cutaneous form spontaneously resolves within 6 months in about half of patients, and most forms resolve within 18 months. Mucous membrane lesions may become chronic and persist for years. Most cases can be treated symptomatically with mid- to high-potency topical steroids and oral antihistamines. Topical steroids can be used in the mouth in various vehicles, including gel, ointment, or oral paste. Many drugs cause lichenoid reactions, so a review of the medication history may find a precipitating medication that needs to be stopped. More severe cases or those involving the mucous membranes can be treated with systemic steroids, oral acitretin, or UV light.

Figure 33-29 Lichen simplex chronicus. (© Richard P. Usatine.)

KEY TREATMENT

- Treatment of lichen planus starts with high-potency topical steroids twice daily to the affected areas (Usatine & Tinitigan, 2011) (SOR: C).
- Intralesional triamcinolone (3 mg/mL) is considered for hypertrophic or mucous membrane lichen planus lesions (Usatine & Tinitigan, 2011) (SOR: C).
- Systemic treatment with oral steroids or acitretin can be considered for severe cases of lichen planus that involve mucous membranes (Zakrzewska et al., 2005) (SOR: B).

LICHEN SIMPLEX CHRONICUS

Lichen simplex chronicus (LSC) is a secondary condition that results from repeated mechanical trauma to the skin, usually through rubbing and scratching, which causes lichenification (thickening of epidermis). Skin appears leathery, violaceous to hyperpigmented, and scaly (Figure 33-29). Involved areas are within the patient's easy reach, such as the arms, legs, posterior neck, upper back, buttocks, and scrotum. The cycle of pruritus, which is alleviated by scratching, perpetuates the condition. Pruritus is usually worse during periods of inactivity, usually at bedtime and during the night. Stress also may provoke pruritus, which is relieved by rubbing and scratching and often becomes an unconscious behavior.

Treatment of LSC is aimed at treating existing lesions, reducing pruritus, providing insight into the itch-scratch cycle, and eliciting behavioral changes. Topical steroids decrease inflammation and pruritus and help "thin down" the hyperkeratosis. Because lesions are by nature chronic, long-term treatment should be stressed. Occlusion can be used to increase potency and enhance delivery of the topical steroid and also provides a barrier to scratching. Flurandrenolide tape (Cordran) is very effective and can be cut to fit each lesion of LSC. Anxiolytics and antihistamines such as diphenhydramine and hydroxyzine may be considered as adjunct treatments. Behavior modification is also useful. In severe, debilitating cases, oral doxepin and clonazepam may be considered. For secondary infections, a topical or oral antibiotic is appropriate.

CONTACT DERMATITIS

Key Points

- Contact dermatitis is classified as irritant (ICD) or allergic (ACD).
- Clinical findings of ICD and ACD can be identical, and both entities can be present simultaneously.
- Nickel is the most common cause of ACD.
- Avoidance of irritating substances or environments and allergens is key to therapy. Dry-skin care and topical corticosteroids are also helpful.
- Referral for patch testing can help identify the causative agent in ACD.

Contact dermatitis may be classified by cause into two subgroups, ICD and ACD. ICD occurs when the skin is exposed to an environment or substance in a sufficient frequency, quantity, or duration that it overcomes the barrier function of the skin. Therefore, given adequate exposure, anyone may experience ICD. ACD is a delayed-type hypersensitivity (type 4) reaction to a topical agent and requires initial contact with a substance causing a T helper cell type 2 (Th2)–mediated immune response in a predisposed individual. Only with repeated exposure do the primed T cells cause the clinical response of dermatitis.

Findings of contact dermatitis can include erythema, vesicles, bullae, exudation, crusting, blisters, swelling, and scaling. Common areas affected are the hands, neck, eyelids, face, genitalia, and legs. ICD and ACD can look identical and can present on similar body areas. Both may be intensely pruritic, further complicating the diagnosis. In addition, ACD and ICD can be present simultaneously, as with health care workers allergic to latex who wash their hands repeatedly throughout the day. A careful history and patch testing are often the key to diagnosis.

Each year, millions of patients develop an allergic rash after contact with poison ivy, poison sumac, or poison oak, and contrary to popular belief, the fluid within these vesicles does not cause poison ivy “to spread.” Nickel is the most common nonplant cause of ACD and is historically more common in women because of costume jewelry and ear piercing (Figure 33-30). With the increased popularity of jewelry and body piercing, the prevalence is rising in men.

The top 15 most frequently positive allergens are nickel sulfate (19.5%), Myroxylon Pereira (11.0%), neomycin (10.1%), fragrance mix I (9.4%), quaternium-15 (8.6%), cobalt chloride (8.4%), bacitracin (7.9%), formaldehyde (7.7%), methyl dibromoglutaronitrile/phenoxethanol (5.5%), p-phenylenediamine (5.3%), propolis (4.9%), carba mix (4.5%), potassium dichromate (4.1%), fragrance mix II (3.6%), and methylchloroisothiazolinone/methylisothiazolinone (3.6%) (Fransway et al., 2013).

In the workplace, ACD is very common. For skin conditions, 90% of workers' compensation claims result from contact dermatitis. Common offenders in specific occupations are rubber or latex in health care workers, hair and clothing dyes in hairdressers, chromates in cement workers, and the Rhus family (poison ivy, oak, and sumac) in

Figure 33-30 Contact dermatitis to nickel jewelry in the umbilicus. (© Richard P. Usatine.)

agricultural workers. ICD most often develops in response to excessive exposure to soaps, cleansers, hand sanitizers, and water exposure. Therefore, the primary treatment is avoidance of these irritating substances, application of a barrier ointment such as petrolatum, and protective equipment such as gloves.

For ACD caused by plants, the skin and clothes should be thoroughly washed with soap and water as soon as possible to minimize exposure to the antigen. Cool, wet soaks for 10 to 15 minutes may be soothing. Superpotent topical steroids, such as clobetasol propionate or betamethasone dipropionate applied twice daily for 1 to 2 weeks, are effective for treating small areas of moderate ACD. Systemic steroids are reserved for severe episodes and should be continued for at least 2 weeks to prevent rebound dermatitis. In otherwise healthy persons, a tapering dose of prednisone is not required for short courses of systemic therapy. Severe pruritus may respond to antihistamines such as hydroxyzine, diphenhydramine, or a nonsedating H₂ blocker such as loratadine, cetirizine, or fexofenadine.

If ACD is suspected based on history, consultation for patch testing with a dermatologist can be customized to the patient's occupation or hobbies. After the offending agent is identified, avoidance is crucial. When the offending agent is occupational, a change in jobs may be required. Alternative protective equipment can be sufficient in other cases, such as substituting nitrile gloves for latex. Generalized dry-skin care, topical steroids, or immunomodulators (pimecrolimus, tacrolimus) can help prevent recurrence and treat flares.

Figure 33-31 Dyshidrotic eczema with tapioca vesicles (pompholyx).
(© Richard P. Usatine.)

Figure 33-32 Stasis dermatitis. (© Richard P. Usatine.)

DYSHIDROTIC ECZEMA (POMPHOLYX)

Dyshidrotic eczema is a form of dermatitis characterized by a pruritic vesicular eruption on the fingers, palms, and soles (Figure 33-31). Patients may be affected at any age, with women affected twice as often as men. The condition may be acute, intermittent, or chronic. Eruptions occur with varying severity and can be mild or debilitating. Before the formation of vesicles, patients describe itching or burning of the hands and feet. Small vesicles appear along the lateral aspects of the fingers or feet, palms, and soles. Lesions may persist for weeks and may be accompanied by erythema of the palms and soles.

Treatment of dyshidrotic eczema includes high-potency topical steroids and cold compresses for symptomatic relief of the burning sensation. Greasy emollients are helpful to moisturize, protect, and prevent fissures. If fissures do occur, cyanoacrylate (“superglue”) can be used to seal small cracks in the skin and decrease pain. Short courses of oral steroids may be used for acute flares.

STASIS DERMATITIS

Stasis dermatitis occurs on the lower extremities in patients with chronic venous insufficiency (Figure 33-32). Impaired function of the venous valves permits backflow of the

Figure 33-33 Nummular eczema. (© Richard P. Usatine.)

blood from the deep venous system to the superficial system, causing increased venous hydrostatic pressure and increased permeability of dermal capillaries. The condition typically affects middle-aged and older-adult patients, except for patients with acquired venous insufficiency resulting from surgery, trauma, or thrombosis.

Stasis dermatitis can range from mild to severe. In all stages, reddish brown discoloration is caused by staining from hemosiderin that has leaked out of red blood cells in the overtaxed dermal capillaries. Pedal edema and scaling are also present in various degrees, and one leg can be more affected than the other. ACD is often superimposed on stasis dermatitis and can mislead the physician into suspecting cellulitis because of a sudden reddening, weeping, or induration of the area. Because of the impaired skin barrier and frequent use of OTC products and “home remedies,” neomycin, lanolin, iodine, fragrances, and preservatives are common triggers for ACD in these patients.

Long-term treatment focuses first on reducing pedal edema with compression therapy after assessing the integrity of the arterial circulation to prevent claudication or ischemic necrosis. Compression stockings are best applied early in the morning before the patient rises from bed, when leg edema is at a minimum. For the pruritus and dermatitis, stasis dermatitis is treated in the same manner as other forms of acute eczematous dermatitis. Dry skin care with mild cleansers (Dove, Cetaphil) and bland emollients (petrolatum, Aquaphor, or Absorbase) should be used liberally. Medium-potency topical corticosteroids (e.g., triamcinolone 0.1% ointment) should be used twice daily when inflammation and pruritus are present. If infection is suspected, mupirocin should be used preferentially over other topical antibiotics to avoid ACD to bacitracin or neomycin. For severe cases with exuberant purulent drainage and induration, oral antibiotics with activity against *Staphylococcus* and *Streptococcus* should be used.

NUMMULAR DERMATITIS (NUMMULAR ECZEMA)

Nummular dermatitis consists of well-demarcated, coin-shaped lesions of eczema, typically on the extremities and less often the trunk in adults (Figure 33-33). Nummular

Figure 33-34 Erythroderma secondary to pustular psoriasis. (© Richard P. Usatine.)

dermatitis tends to worsen in dry, cold weather. Lesions may be mildly to severely pruritic and as a result become excoriated or even lichenified with scratching. Nummular dermatitis can be confused with plaques of psoriasis or *tinea corporis*, but skin scrapings will not reveal hyphae on KOH preparation. Also, lesions lack the typical central sparing of *tinea corporis*. If necessary, a biopsy can help differentiate nummular eczema from psoriasis.

As with all eczematous dermatitis, general dry skin care is recommended with mild cleansers and bland emollients. An intermediate to potent topical steroid may be applied two to four times daily to the affected areas. When lesions improve, a lower potency steroid or immunomodulator (tacrolimus, pimecrolimus) should be used to minimize skin atrophy. Pruritus may be treated with an antihistamine if needed.

GENERALIZED EXFOLIATIVE DERMATITIS

Exfoliative dermatitis, also known as *erythroderma*, is an uncommon but serious skin disorder defined as erythema and scale covering over 90% of the body surface area (Figure 33-34). The four most common causes of erythroderma are psoriasis, AD, cutaneous T-cell lymphoma (CTCL), and drug reactions. More than 60 drugs (more often allopurinol, β -lactam antibiotics, antiseizure medications, and sulfa drugs) have been implicated in cases of exfoliative dermatitis. More than half of patients will have a known underlying skin disease, but in up to 25%, an etiology may never be determined and is termed *idiopathic* erythroderma. The majority of patients are adults older than age 40 years.

The long-term prognosis is good in patients with drug-induced exfoliative dermatitis. The course tends to be remitting and relapsing in idiopathic cases. The prognosis of patients with associated malignancy usually depends on the outcome of the malignancy. A skin biopsy can help establish the diagnosis when the underlying skin disease is not known. The approach to treatment should include discontinuation of potentially causative medications and a search for any underlying malignancy. Initial evaluation and treatment usually require hospitalization for fluid and electrolyte replacement, temperature modulation, and prevention and treatment of secondary infection.

ERYTHEMA NODOSUM

Erythema nodosum is an acute inflammatory process involving the fatty tissue layer underlying the skin (panniculitis). The condition is more frequently seen in women, and although it is often idiopathic, many cases are associated with streptococcal infections of the upper respiratory tract, drugs such as estrogens or oral contraceptives, sarcoidosis, and inflammatory bowel disease. Other, less frequent bacterial causes include tuberculosis, brucellosis, mycoplasma, and chlamydia. Fungal infections such as blastomycosis and histoplasmosis may also cause erythema nodosum. Rare causes are Behçet disease, acute myelogenous leukemia, and Hodgkin disease.

Patients present with tender red nodules, most frequently on the pretibial area or lower legs. The nodules may become fluctuant but do not suppurate or ulcerate. New lesions may continue to appear for several weeks. Additional symptoms may include fever, malaise, and arthralgia. Treatment is aimed at determining any underlying cause. Infectious processes should be evaluated and treated appropriately. Discontinuation of any possible offending agents is also advised. Bed rest, leg elevation, and nonsteroidal antiinflammatory drugs (NSAIDs) are the mainstays of therapy. Spontaneous resolution occurs within 4 to 6 weeks in most patients, but residual leg pain and ankle edema can persist for weeks.

GRANULOMA ANNULARE

Granuloma annulare is a benign, self-limited dermatosis characterized by a raised annular distribution (Figure 33-35). The condition may be localized, generalized, perforating, or subcutaneous. Except for subcutaneous granuloma annulare, the subtypes have similar appearances, but each follows a distinct clinical course. *Subcutaneous* granuloma annulare appears differently, with deep dermal or subcutaneous nodules. Patients with *localized* granuloma annulare present with groups of 1- to 2-mm papules in an annular arrangement over the distal extremities, ranging in color from skin tone to erythematous. Lesions most frequently appear on the dorsal surfaces of the hands and feet, fingers, and extensor aspects of the arms and legs. In *generalized* granuloma annulare, patients have a few to thousands of papules and rings that involve many body regions. The rings tend to be distributed symmetrically. Patients with *perforating* granuloma annulare present with up to hundreds of grouped 1- to 4-mm papules that may evolve into pustular lesions that drain and umbilicate, leaving atrophic

Figure 33-35 Granuloma annulare. (© Richard P. Usatine.)

scars. These lesions tend to appear on the extensor surfaces of extremities and the dorsa of the hands and fingers. Granuloma annulare may resolve spontaneously but can take several years. When patients request treatment, steroid injections are most effective.

Infectious Skin Diseases

BACTERIAL INFECTIONS

Key Points

- Most bacterial skin infections are caused by *Streptococcus pyogenes* or *S. aureus*.
- Impetigo is the most superficial bacterial skin infection and often appears with honey-crust lesions.
- Erysipelas is a superficial bacterial skin infection that extends into the cutaneous lymphatics, most often on the face or lower leg.
- Cellulitis is a deeper skin infection that requires oral antibiotics active against *S. pyogenes* and *S. aureus*.
- Abscesses often require incision and drainage to resolve completely.
- Community-acquired methicillin-resistant *S. aureus* is a common cause of abscesses and other bacterial skin infections.

Impetigo

Impetigo is a bacterial infection of the epidermis caused by *S. aureus* and group A β -hemolytic streptococci (GABHS). Both organisms may be present at the same time in the affected site. Community-acquired methicillin-resistant *S. aureus* (CA-MRSA) may cause impetigo. Various types of dermatitis can become secondarily infected with bacteria, and the skin is then called “impetiginized.” About 30% of people are colonized in the anterior nares by *S. aureus*. Impetigo is highly infectious, and the bacteria are readily transmitted from one person to another through direct contact, entering through broken skin created by

Figure 33-36 Impetigo on the back and buttocks of a child showing honey crusts. (© Richard P. Usatine.)

cutaneous diseases, burns, surgery, trauma, radiation therapy, and insect bites.

Impetigo is a common condition that occurs in all age groups and in both genders equally. The incidence in those younger than 6 years is higher than in adults. The peak incidence occurs during the summer and fall. Most patients recover without complications. Individuals with impetigo from streptococcal infections can develop glomerulonephritis as a rare complication. Impetigo is usually diagnosed clinically based on its characteristic appearance of honey crusts and superficial erosions (Figure 33-36). Exudate from beneath the skin crust should be obtained for culture and sensitivity testing if a community outbreak has occurred, MRSA is suspected, or poststreptococcal glomerulonephritis is present.

Mupirocin ointment is the treatment of choice for small areas of impetigo and is as effective as oral antibiotics, including cases caused by MRSA and GABHS. Mupirocin three times daily for 5 days each month is also recommended intranasally for patients found to be chronic nasal carriers. Oral antibiotics are used in patients with extensive impetigo or with refractory infection. A cephalosporin, semisynthetic penicillin, or β -lactam- β -lactamase inhibitor is recommended. If bacterial cultures reveal MRSA, trimethoprim-sulfamethoxazole, doxycycline (older than age 10 years), or clindamycin are appropriate. Gentle debridement of crusts using antibacterial soap and a washcloth is also recommended. Patients should be encouraged to use careful handwashing to prevent further spread of infection.

Erysipelas (St. Anthony's Fire)

Erysipelas is a superficial bacterial skin infection that extends into the cutaneous lymphatics. Usually, this infection is caused by *S. pyogenes* infection and occurs on the face or lower leg. Bacterial inoculation into an area of damaged skin is the initial event in developing erysipelas, although patients may not recall the precipitating event. The source of the bacteria is often from the host's nasopharynx. A history of recent streptococcal pharyngitis is reported in up to one third of patients.

Figure 33-37 Cellulitis on the foot of a child after a break in the skin. (© Richard P. Usatine.)

The most common complaints during the acute infection are pain, fever, chills, and swelling of the skin. Infants, young children, and older adult patients are the groups most often affected, with a peak incidence at age 60 to 80 years. Erysipelas may become a red, indurated, tense, and shiny plaque with sharply demarcated margins. Local inflammatory signs, such as warmth, edema, and tenderness, are universal. Lymphatic involvement is manifested by a peau d'orange look to the skin, with sharp borders and regional lymphadenopathy. More severe infections may include numerous vesicles or bullae, petechiae, and even skin necrosis. Streptococci cause erysipelas in as many as 80% of cases, with two thirds of those caused by group A and 25% by group G streptococci. *S. aureus* has been implicated in cases of recurrent erysipelas secondary to lymphedema. Atypical forms have been caused by *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Yersinia enterocolitica*, and *Moraxella* spp. and should be considered in cases refractory to standard antibiotic therapy.

In cases involving the extremities, elevation and rest of the affected limb are recommended to reduce local swelling and inflammation. Oral or intramuscular penicillin for 10 to 14 days is sufficient for many cases of erysipelas. A macrolide such as erythromycin or azithromycin may be used if the patient is allergic to penicillin. Hospitalization for close monitoring and IV antibiotics are recommended for severe cases and for infants, older adults, and immunocompromised patients. Facial erysipelas should be treated empirically with a penicillinase-resistant antibiotic such as dicloxacillin to cover for possible *S. aureus*. Predisposing skin lesions, such as tinea pedis and stasis ulcers, should be treated aggressively to prevent superinfection.

Cellulitis

Cellulitis is an acute infection of the skin and soft tissues, usually developing after a break in the skin. The condition is characterized by localized pain, swelling, tenderness, erythema, and warmth (Figure 33-37). The vast majority of cases are caused by *S. pyogenes* or *S. aureus*. Other causes include *Vibrio vulnificus* and *Pseudomonas* spp. Cellulitis is generally localized and nonrecurrent when treated appropriately. Death is extremely rare but may occur when the condition is neglected or caused by a highly virulent

Figure 33-38 Folliculitis secondary to methicillin-resistant *Staphylococcus aureus* (MRSA). (Courtesy of Alisha N. Plotner, MD, and Robert T. Brodell, MD, with permission from *J Fam Pract* 2008; 57(4):253-255.)

organism. Patients typically present with a red, hot, swollen, and tender area of skin. Unlike erysipelas, the borders are neither elevated nor sharply demarcated. Lymphangitis and local lymphadenopathy may be present. Fever is common, and patients with severe cases may develop hypotension. Those with mild cellulitis may be treated as outpatients. Oral antibiotics are usually effective for treatment of cellulitis in immunocompetent hosts. Severe cases or patients with comorbid conditions (e.g., cardiac, renal, or hepatic failure, immunosuppression) should be initially treated with IV antibiotics in the hospital setting. Elevation of affected limbs improves resolution of swelling.

Folliculitis

Folliculitis is caused by infection or irritation of individual hair follicles. Patients with folliculitis present with pustules at the bases of hairs, particularly on the scalp, back, legs, buttocks, and arms (Figure 33-38). Folliculitis occurs more often in obese, immunocompromised, or diabetic patients. *S. aureus* is the most common pathogen. A form of folliculitis caused by *Pseudomonas* spp., "hot tub folliculitis," occurs when patients use poorly maintained hot tubs. The condition may be self-limited, requiring only the use of antibacterial soap, or may persist and require topical or systemic antibiotic therapy. If a pseudomonas infection is suspected and lesions persist for more than 5 days without treatment, an oral fluoroquinolone (e.g., ciprofloxacin) should be considered. The hot tub must also be drained and cleaned.

Abscesses: Furuncles and Carbuncles

Furuncles, or "boils," are small abscesses in the skin. Patients present with a painful, often fluctuant swelling in areas of friction such as the axilla, inframammary, buttocks, and inner thigh. A *carbuncle* is a collection of furuncles and usually occurs on the back of the neck in middle-aged and older men. Antibiotic therapy should be considered if the furuncle is not yet fluctuant, there is evidence of surrounding cellulitis or lymphadenitis, or the lesion is on the face. Carbuncles have many interconnecting sinuses and tend to recur despite drainage and antibiotics. Surgical

Figure 33-39 Erythrasma in the groin. (© Richard P. Usatine.)

drainage and resection of the lesions are often necessary. Many abscesses are now caused by MRSA, and if fluctuant, the first-line treatment is incision and drainage.

Erythrasma

Erythrasma is a superficial skin infection caused by *Corynebacterium* spp., a normal inhabitant of the skin. The infection typically occurs in intertriginous spaces, especially in obese, hyperhidrotic, or diabetic patients (Figure 33-39). Moderate itching and discomfort may occur, and the infected skin is often reddish brown and may be slightly raised, with some central clearing. The lesions are largely confluent but may have poorly defined borders. Because of the production of porphyrins by the infecting corynebacteria, Wood's light demonstrates the lesions as a coral red. However, if the patient has recently washed the affected area, the coral-red fluorescence may be absent. Erythrasma is often confused with a fungal infection. Erythrasma may be treated with topical erythromycin or clindamycin. Oral antibiotics are only needed in very extensive involvement.

FUNGAL INFECTIONS

Key Points

- Tinea capitis should be treated with oral antifungal agents.
- Tinea infections may be transmitted from person to person by animals (pets, livestock) and through fomites.
- OTC topical antifungals are often effective for tinea pedis.
- Tinea versicolor is caused by infection with *Malassezia* spp. and can be treated by topical antidandruff shampoos or oral antifungals (ketoconazole, fluconazole).

Dermatophytosis (Tinea)

Mucocutaneous fungal infections are caused by dermatophytes (*Microsporum*, *Epidermophyton*, and *Trichophyton* spp.) and yeasts. About 40 species in the three dermatophyte genera can cause tinea pedis and manus, tinea capitis,

Figure 33-40 Thrush caused by *Candida albicans*. (© Richard P. Usatine.)

tinea corporis, tinea cruris, and onychomycosis. Yeasts of *Candida* spp. can cause diaper dermatitis, balanitis, vulvovaginitis, and thrush (Figure 33-40). The yeastlike organism of *Malassezia* (*Pityrosporum*) spp. causes tinea versicolor and contributes to seborrhea. Although tinea versicolor has the name *tinea* in it, it is not a true dermatophyte.

The most important test for a suspected fungal infection is the KOH prep. Scrape the leading edge of the lesion onto a slide using the side of a #15 scalpel or another slide. Use the coverslip to push the scale into the center of the slide. Add 2 drops of KOH (with or without fungal stain) to the slide and place a coverslip on top. Examine with microscope starting with 10× magnification and low light to look for the cells and hyphae. The fungal stain helps the hyphae to stand out among the epithelial cells. Look for groups of cells that appear to have fungal elements within them; do not be fooled by cell borders that look linear and branching. Switch to 40× magnification to confirm any areas that appear to have fungal elements by looking for true fungal morphology. The fungal stains bring out these characteristics, including cell walls, nuclei, and arthroconidia (Figure 33-41). KOH test characteristics without fungal stain are sensitivity, 77% to 88%, and specificity, 62% to 95% (Thomas, 2003).

Tinea Corporis

Tinea corporis is a superficial dermatophyte infection of the cornified layers of skin on the trunk and extremities. Lesions are typically annular with central clearing and a scaling border and may be pruritic (Figure 33-42). Infection may be transmitted from person to person, by animals such as household pets or farm animals, and through fomites. Because the cornified layer of skin is involved, topical

Figure 33-41 *Trichophyton rubrum* seen after potassium hydroxide (KOH) preparation using fungal stain. (© Richard P. Usatine.)

Figure 33-42 Tinea corporis showing concentric circles. (© Richard P. Usatine.)

therapy is usually sufficient for localized cases. A topical antifungal should be applied to the lesion and proximal surrounding skin twice daily for a minimum of 2 weeks. Various agents have demonstrated effectiveness, including the azoles (miconazole, clotrimazole, ketoconazole, itraconazole) and the allylamines (naftifine, terbinafine). Terbinafine 1% cream (available OTC as Lamisil AF) produced a mycologic cure of 84.2%, versus 23.3% with placebo (Budimulja et al., 2001). In another study, patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks (Voravutininon, 1993). Patients should be instructed to avoid direct contact with others and avoid sharing towels and clothing to prevent spread of the infection. Oral antifungal agents should be considered for first-line therapy for tinea corporis covering large areas of the body (Figure 33-43).

Figure 33-43 Tinea corporis covering half the body. (© Richard P. Usatine.)

KEY TREATMENT

- All topical antifungal agents (not nystatin) may be effective, but evidence supports the greater effectiveness of the allylamines (e.g., terbinafine) over the less expensive azoles (e.g., clotrimazole) for tinea pedis and corporis (Crawford et al., 2000) (SOR: A).
- Terbinafine 1% cream or solution once daily for 7 days is highly effective for tinea corporis or cruris (Budimulja et al., 2001) (SOR: B).
- Oral terbinafine, 250 mg once daily, showed higher cure rates for tinea corporis and cruris than griseofulvin (Voravutininon, 1993) (SOR: B).

Tinea Pedis

Tinea pedis, or “athlete’s foot,” is most often caused by *Trichophyton rubrum*. Typically, patients describe pruritic scaly soles, often with painful fissures between the toes. The most characteristic type of infection is interdigital (Figure 33-44). Erythema, maceration, and fissuring occur between the toes and are accompanied by intense pruritus. Patients may also have chronic hyperkeratotic tinea pedis, characterized by plantar erythema and hyperkeratosis (dry-looking scaly feet) that may be completely asymptomatic or mildly pruritic. This is described as a moccasin distribution (Figure 33-45). Inflammatory tinea pedis causes painful vesicles on the foot (see Figure 33-1).

Tinea pedis is more common in men than in women and rarely occurs in children. Infection can occur through contact with infected scales on bath or pool floors, so wearing protective footwear in shared areas may help

Figure 33-44 Tinea pedis between the toes. (© Richard P. Usatine.)

Figure 33-46 Tinea cruris in a woman. (© Richard P. Usatine.)

Figure 33-45 Tinea pedis in a moccasin distribution. (© Richard P. Usatine.)

decrease the likelihood of infection. Occlusive footwear promotes infection by creating warm, humid, macerating environments; therefore, patients should try to minimize foot moisture by limiting the use of occlusive footwear and frequently changing socks.

The treatment of tinea pedis involves application of an antifungal cream to the web spaces and other infected areas. Topical antifungal agents containing allylamines (naftifine, terbinafine, butenafine) or azoles (clotrimazole, miconazole, econazole) all work to treat tinea pedis. Allylamines cure slightly more infections than azoles but are more expensive. No differences in efficacy were found between individual allylamines or individual azoles (Crawford et al., 2000). Infrequently, systemic therapy is used for refractory infections. Twice-daily application of the allylamine terbinafine has resulted in a higher and more rapid cure rate than twice-daily application of the imidazole clotrimazole (Lotrimin AF).

KEY TREATMENT

- With topical antifungals to treat tinea pedis, allylamines cure slightly more infections than azoles but are more expensive (Crawford et al., 2000) (SOR: A).

- Consider oral antifungals such as terbinafine, 250 mg daily for 2 weeks, when tinea pedis is severe or does not respond to topical agents (Bell-Syer et al., 2004) (SOR: B).
- Oral itraconazole is equal to oral terbinafine in patient outcomes. Itraconazole can be prescribed as two 100-mg tablets daily for 1 week (Bell-Syer et al., 2004; Thomas, 2003) (SOR: B).

Tinea Cruris

Tinea cruris, commonly called “jock itch,” is a dermatophyte infection of the groin. This dermatophytosis is more common in men than women and is frequently associated with tinea pedis. Tinea cruris occurs when ambient temperature and humidity are high. Occlusion from wet or tight-fitting clothing provides an optimal environment for infection. Tinea cruris involves the proximal medial thighs and may extend to the buttocks and lower abdomen (Figure 33-46). The scrotum tends to be spared. Patients with this dermatophytosis frequently complain of burning and pruritus. Care should be taken to evaluate the feet as a source of infection.

Treatment is identical to tinea pedis with topical antifungals. Oral antifungal therapy is needed if the tinea cruris has spread beyond the groin (Figure 33-47). Inverse psoriasis may be mistaken for tinea cruris but will not respond to antifungal treatment (Figure 33-48). The fungicidal allylamines naftifine and terbinafine and the allylamine derivative butenafine are more costly topical tinea treatments but allow for a shorter duration of treatment compared with fungistatic azoles (clotrimazole, econazole, ketoconazole, oxiconazole, miconazole, sulconazole) (Nadalo et al., 2006).

KEY TREATMENT

- Tinea cruris may be treated with a topical allylamine or a topical azole (Nadalo et al., 2006) (SOR: B).
- Fluconazole, 150 mg once weekly for 2 to 4 weeks, appears effective against tinea cruris (Nozickova et al., 1998) (SOR: B).

Figure 33-47 Tinea cruris that has spread up to umbilicus. (© Richard P. Usatine.)

Figure 33-48 Inverse psoriasis that resembles tinea cruris. Note nail pitting of psoriasis. (© Richard P. Usatine.)

Tinea Capitis

Tinea capitis, the most common dermatophytosis in children, is an infection of the scalp and hair follicle. Transmission is fostered by poor hygiene and overcrowding and can occur through contaminated hats, brushes, and pillowcases. After being shed, affected hairs can harbor viable organisms for more than 1 year. Tinea capitis is characterized by irregular or well-demarcated alopecia and scaling (Figure 33-49). Cervical and occipital lymphadenopathy may be prominent. When hairs fracture a few millimeters from the scalp, “black dot” alopecia is produced. Tinea scalp infection also may result in a cell-mediated immune response termed a *kerion*, which is a boggy, sterile, inflammatory scalp mass (Figure 33-50). A kerion does not require antibiotics or incision and drainage. If a kerion does not respond to oral antifungals alone, an oral steroid may be added for a short course.

Figure 33-49 Tinea capitis with prominent cervical lymphadenopathy. (© Richard P. Usatine.)

Oral griseofulvin daily for 6 to 8 weeks is a proven treatment for tinea capitis, even if it requires a somewhat longer course than the other antifungal agents (Fleece et al., 2004). It is available in a liquid form for children. Alternatively, 4 weeks of oral terbinafine daily is as effective as 8 weeks of griseofulvin, but at week 12, the efficacy of griseofulvin decreased to 44%, but the efficacy of terbinafine was 76% (Caceres-Rios et al., 2000). Oral fluconazole is another option because it is available in liquid form and appears to be effective and safe, but fewer clinical trials have been done (Foster et al., 2005).

KEY TREATMENT

- Give oral griseofulvin daily for 6 to 8 weeks to treat tinea capitis (Fleece et al., 2004) (SOR: B).
- Consider 4 weeks of oral terbinafine daily (Caceres-Rios et al., 2000) (SOR: B).
- Consider oral fluconazole (available as liquid) as an option to treat tinea capitis (Foster et al., 2005) (SOR: B).

Onychomycosis

Onychomycosis is a fungal infection that affects the toenails or fingernails. It may involve any component of the nail unit, including the nail matrix, nail bed, or nail plate. Onychomycosis may be unsightly but is often asymptomatic. In the worst cases, it causes enough discomfort and disfigurement to produce physical and occupational limitations. Use of topical agents should be limited to cases involving less than half the distal nail plate and patients unable

Figure 33-50 Kerions secondary to tinea capitis inflammation (A and B). (© Richard P. Usatine.)

Figure 33-51 Tinea versicolor with hypopigmentation (A) and hyperpigmentation (B). (© Richard P. Usatine.)

to tolerate systemic treatment. Agents include ciclopirox 8% (Penlac), azoles, and allylamines. Topical treatments are poorly effective because of inadequate nail plate penetration. Oral antifungal agents such as terbinafine and itraconazole have replaced older therapies in the treatment of onychomycosis. Oral antifungals offer shorter treatment regimens, higher cure rates, and fewer adverse effects.

KEY TREATMENT

- Terbinafine is more effective than griseofulvin, and terbinafine and itraconazole are more effective than no treatment (Cochrane review; Bell-Syer et al., 2004) (SOR: A).

- Two clinical trials of nail infections found no evidence of benefit for topical treatments (did not include ciclopirox) compared with placebo (Cochrane review; Crawford et al., 2000) (SOR: A).

Tinea Versicolor

Versicolor means varied colors and tinea versicolor presents with hypopigmented, pink, or brown macules and patches with fine scale (Figure 33-51). Tinea versicolor is also called *pityriasis versicolor* as pityriasis stems from a Greek word meaning “bran,” indicating flaking or scaly skin. Tinea versicolor is found on the back, chest, abdomen, and upper arms, often in a capelike distribution. Tinea versicolor is caused by *Malassezia furfur* (*Pityrosporum*), a lipophilic

Figure 33-52 “Spaghetti and meatballs” pattern of tinea versicolor on microscopy (blue fungal stain, 40×). (© Richard P. Usatine.)

yeast that can be normal human cutaneous flora. *Pityrosporum* is also associated with seborrhea, and thus antidandruff shampoos are effective in treating this tinea. *Pityrosporum* spp. thrive on sebum and moisture and tend to grow on the skin in areas where sebaceous follicles secrete sebum. Topical and oral treatments are effective, but tinea versicolor tends to recur, especially during the warmer months. The diagnosis can usually be made with the clinical examination, and if there is any doubt, a KOH prep can be examined for the typical “spaghetti and meatballs” pattern (Figure 33-52). The spaghetti or “ziti” is the short mycelial form, and the meatballs are the round yeast of *Pityrosporum ovale*.

Patients may apply selenium sulfide 2.5% lotion or shampoo to the involved areas daily for 1 week. A double-blind study found that selenium sulfide (2.5%) lotion applied daily for 10 minutes for 7 consecutive days was effective in the treatment of tinea versicolor (Sanchez and Torres, 1984). A single oral dose of 400 mg of oral fluconazole or ketoconazole can also be used to treat tinea versicolor. Fluconazole provided the best clinical as well as mycologic cure rate, with no relapse during 12 months of follow-up (Bhagal et al., 2001). Oral itraconazole, 200 mg twice daily for 1 day a month, has been shown to be safe and effective as a prophylactic treatment for tinea versicolor (Faergemann et al., 2002).

KEY TREATMENT

- Selenium sulfide 2.5% lotion (or shampoo) daily for 1 week is effective treatment of tinea versicolor (Sanchez and Torres, 1984) (SOR: B).
- Ketoconazole 2% shampoo (Nizoral) may be applied daily for 3 days to treat tinea versicolor (Lange et al., 1998) (SOR: B).
- Oral fluconazole or ketoconazole (400 mg) also treats tinea versicolor (Bhagal et al., 2001) (SOR: B).
- Oral itraconazole (200 mg twice a day, 1 day a month) is effective prophylactic treatment for tinea versicolor (Faergemann et al., 2002) (SOR: B).

VIRAL INFECTIONS

Key Points

- Herpes simplex virus type 1 (HSV-1) is the most common cause of oral herpes infection (80%). HSV-2 is the primary pathogen in genital herpes (70%-90%). Both can cause oral or genital lesions.
- HSV-1 and HSV-2 are characterized by a primary infection, latent periods, asymptomatic shedding, and reactivation.
- Approximately 10% to 20% of the U.S. population develop zoster, but rates are likely to decrease with varicella-zoster virus (VZV) vaccine for children.
- Corneal involvement should be suspected when herpes zoster involves the tip of the nose and is an ophthalmologic emergency because it can lead to blindness.
- For herpes zoster, antiviral therapy (acyclovir, valacyclovir, famciclovir) should be started within 3 days of onset of symptoms to reduce disease severity and incidence of postherpetic neuralgia.
- Human papillomavirus (HPV) types 6 and 11 are associated with condylomata acuminata (genital warts); HPV types 16 and 18 are associated with carcinoma. The quadrivalent HPV vaccine (Gardasil) is active against HPV types 6, 11, 16, and 18 and is approved for both genders ages 9 to 26 years. The bivalent vaccine (Cervarix) is active against HPV types 16 and 18 and is approved only for girls and women ages 9 to 25 years.
- Molluscum contagiosum is a common, self-limited viral infection most often affecting children. It is considered sexually transmitted in adults.
- Lesions of molluscum usually resolve spontaneously over months to years; with or without treatment, lesions can leave pitted scars.

Herpes Simplex

Herpes simplex virus types 1 and 2 are very common pathogens that cause orolabial and genital blisters and erosions. Seroprevalence of HSV-1 is estimated at 80% to 90% worldwide and is the most common cause of oral herpes infection (80%). HSV-2 is the primary pathogen in genital herpes (70%-90%) and is one of the most common sexually transmitted infections (STIs). Approximately 50 million Americans have genital herpes, and an estimated 1 million new cases occur each year.

Herpes simplex infection can be characterized by an initial infection, episodes of latency, asymptomatic viral shedding, and recurrent activation. Spread of HSV-1 is primarily through direct contact with contaminated saliva or other secretions. Symptoms of primary orolabial herpes usually occur 3 to 7 days after exposure and include a prodrome of fever, sore throat, and lymphadenopathy. Localized pain, tingling, tenderness, or burning can occur before the eruption of the vesicles, which are usually grouped on a background of erythema and edema (Figure 33-53). The lesions coalesce, ulcerate, and heal within 2 to 3 weeks.

Herpes simplex type 2 is usually transmitted through genital contact and must involve mucous membranes or open or damaged skin. Primary HSV-2 occurs up to 3 weeks after exposure to the virus and has more severe clinical

Figure 33-53 Oral herpes gingivostomatitis as primary infection in 2-year-old child. (© Richard P. Usatine.)

Figure 33-54 Herpes simplex type 2 recurrence on the penis with a cluster of vesicles. (Courtesy Jack Rezneck, Sr., and *The Color Atlas of Family Medicine*.)

manifestations. Systemic symptoms include fever, malaise, edema, inguinal lymphadenopathy, dysuria, and vaginal or penile discharge. These are more common in women. In men, painful vesicles and erosions usually occur on the penis but can also appear on the buttocks or perineum (Figure 33-54). In women, lesions occur primarily on the labia but may also appear on the cervix, buttocks, or perineum. Symptoms of the primary episode typically last 2 to 3 weeks. Risk factors for genital herpes include age 15 to 30 years (the ages of greatest sexually activity), increased

number of sexual partners, black or Hispanic race, lower income levels and education, female gender, homosexuality, and HIV.

In both serotypes, HSV may be latent for months to years after the primary infection. During latency, the virus resides in the sensory nerve root ganglia. Recurrent outbreaks are often preceded by a prodrome of pain, itching, tingling, burning, or paresthesias and are usually less severe than the primary outbreak.

The diagnosis of herpes simplex is conveniently done with a direct fluorescent antibody (DFA) test, and results may be obtained within hours. A viral culture can be performed, but results take 2 to 5 days. Serologic testing is also available that can establish serostatus, but this is not helpful for acute disease.

The treatment of HSV depends on whether the infection is a first episode or a recurrence. Many different dosing schedules are available with oral antivirals, including acyclovir (Zovirax), valacyclovir (Valtrex), and famciclovir (Famvir). Suppressive therapy may be considered in patients with recurrent genital herpes. Women who are pregnant or contemplating pregnancy should receive information regarding neonatal transmission and possible cesarean delivery if active lesions are present at the onset of labor. The risk of transmission is highest for women with a primary infection during the third trimester of pregnancy. Neonatal herpes infection can cause long-term CNS morbidity, such as mental retardation, chorioretinitis, seizures, and even death.

Herpes Zoster (Shingles)

Zoster is caused by the reactivation of the VZV (human herpesvirus 3 [HHV-3], chickenpox). After the primary infection, VZV lies dormant in the dorsal root ganglia. The time between the onset of primary chickenpox and reactivation can be any time, but usually is decades later. Approximately 10% to 20% of the U.S. population eventually develop one or more cases of zoster in their lifetime. The incidence is much higher in immunocompromised patients and older adults. These rates are likely to decrease over time now that a VZV vaccine is given as part of the routine immunization schedule in children.

Patients typically experience pain and paresthesias followed by the appearance of small groups of vesicles on an erythematous base in a dermatomal distribution (Figure 33-55). The rash rarely crosses the midline of the body and is usually confined to a single dermatome. The eruption may be accompanied by a fever, headache, and malaise. Lesions usually resolve in 2 to 3 weeks. Pain can be severe and may persist long after skin lesions heal in a condition known as *postherpetic neuralgia*. Corneal involvement should be suspected when lesions appear on the tip of the nose or in the distribution of cranial nerve V1 (ophthalmic branch of trigeminal nerve) and should prompt an emergency ophthalmology consultation because this can cause permanent blindness (Figure 33-56).

Antiviral therapy such as acyclovir, valacyclovir, and famciclovir should be started within the first 3 days of onset of symptoms to reduce the severity and duration of symptoms and skin lesions. Early treatment may also reduce the incidence and severity of postherpetic neuralgia. However, benefits can be seen even if started up to 7 days after onset

Figure 33-55 Herpes zoster in a dermatomal pattern. (© Richard P. Usatine.)

Figure 33-56 Herpes zoster on the face with herpes ophthalmicus. (© Richard P. Usatine.)

of symptoms. Analgesics such as acetaminophen and even narcotics are sometimes required to control the pain caused by zoster. Cool compresses may also help soothe during the acute phase. Postherpetic neuralgia occurs in up to 40% of adult patients older than age 60 years but in less than 10% of patients younger than 60 years. In 2006, the Food and Drug Administration (FDA) approved a live, attenuated vaccine (Zostavax) for adults older than 60 years who are

Figure 33-57 Kissing warts on the fingers. (© Richard P. Usatine.)

immunocompetent and have not already had zoster. The vaccine decreased the burden of illness by 61% and decreased the incidence of postherpetic neuralgia by 67% in large clinical trials (Oxman et al., 2005).

Verruca (Warts)

Warts are common growths of skin and mucosa caused by the HPV. Currently, more than 100 types of HPV have been identified. Specific HPV types often correlate to the lesion location, morphology, or oncogenic potential. Although most are benign, warts can be disfiguring or can cause significant psychological distress, and some cause cancer.

Verruca vulgaris (common warts) are dome-shaped keratotic papules that usually develop on the dorsal hands, fingers, or other sites on the extremities (Figure 33-57). *Palmoplantar* warts are on the palms or soles and are surrounded by hyperkeratotic callus-like skin. These can be painful when occurring on weight-bearing surfaces. Multiple plantar warts may combine to become a large mosaic wart. Both common warts and palmoplantar warts have characteristic punctuate black dots, mistakenly leading to the common term “seed warts,” but these black dots actually represent thrombosed capillaries. *Filiform* warts have fingerlike projections and often appear on the face. *Verruca plana* (flat warts) are smooth, small (1-4 mm) flesh-colored papules, often occurring on the face or legs and often spread by scratching or shaving (Figure 33-58). Although inconspicuous at first, flat warts propagate rapidly, often into the hundreds.

Condylomata acuminata (genital warts) occur on the external genitalia, perineum, perianal, or adjacent intertriginous regions but can also be found on the oral mucosa. These lesions are generally considered sexually transmitted, but it is usually impossible to determine when the inoculation occurred. The lesions begin as small papules, which often become whitish with maceration and take on a cauliflower-like appearance as they grow (Figure 33-59). Condylomata are associated with cervical carcinoma and penile cancer. Among the many subtypes of HPV, types 6 and 11 are most often associated with condylomata, but types 16 and 18 are most often associated with the development of carcinoma.

There is no standard treatment for warts. Most warts spontaneously regress over many months to years. Local

treatments include cryotherapy, salicylic acid, imiquimod, podophyllin, 5-fluorouracil (5-FU), cantharidin, and duct tape. For physician-applied treatments such as cryotherapy or podophyllotoxin, patients should be seen every 3 to 4 weeks for repeat treatment as needed. For home treatments with salicylic acid, podofilox (Condylox), or imiquimod (Aldara), most are applied daily, and patients should be advised that treatment can take months of extreme persistence for resolution. Office and home treatment modalities can also be combined to hasten resolution, but studies are lacking.

Women with condylomata should have annual Papanicolaou tests to evaluate for cervical neoplasia. For both men and women, it is advisable to refrain from sexual activity while genital lesions are present, to prevent transmission. In 2006, the FDA approved an HPV vaccine (Gardasil),

recommended for girls and women age 11 to 26 years regardless of abnormal Pap history, positive HPV status, or genital warts. It is active against HPV types 6, 11, 16, and 18. In clinical trials, Gardasil decreased the incidence of cervical intraepithelial neoplasia, cervical cancer, and anogenital warts by 90% (Villa et al., 2006). Since it was first released, the indications have now been expanded to include both genders ages 9 to 26 years.

Molluscum Contagiosum

Molluscum contagiosum is a common, self-limited viral infection seen most frequently in children and can occur anywhere on the body, most often on the trunk, face, and extremities. In adults, mollusca are considered sexually transmitted and occur in the genital region or lower abdomen. Infection occurs through direct skin-to-skin contact or indirect contact with fomites. The typical molluscum lesion is a pink to flesh-colored, firm, smooth, dome-shaped papule with central umbilication (Figure 33-60). A white material can sometimes be visualized in the umbilication and can be easily expressed. This caseous material is teeming with viral particles. Lesions are usually 2 to 5 mm in diameter and number less than 30 but can number in the hundreds. Particularly in immunocompromised patients, the infection may be much more extensive, may fail to resolve spontaneously, and may be resistant to treatment. Over months to years, lesions of molluscum normally resolve spontaneously.

Some patients or parents desire treatment, and cryotherapy, cantharidin, trichloroacetic acid, tretinoin (Retin-A), or imiquimod may be effective. Cantharidin is most easily given to young children because its application is painless. Cryotherapy is another good option, but many young children will not willingly submit to this therapy, which is painful. Often it is best to reassure parents that molluscum is not harmful and will eventually resolve, although with or without treatment, lesions can leave pitted scars.

Infestations

Key Points

- Scabies is a pruritic rash involving interdigital spaces, wrists, ankles, waist, groin, and axillae.
- The three types of human lice infest the scalp hair, the body, or the pubic hair.

SCABIES

Scabies is caused by the mite *Sarcoptes scabiei*, an obligate human parasite. Patients present with a pruritic rash that is often worse in the night. Skin findings include papules, nodules, burrows, and vesiculopustules (Figure 33-61). The distribution includes the interdigital spaces, wrists, ankles, waist, groin, and axillae. Pruritic nodules around the axillae, umbilicus, or on the penis and scrotum are highly suggestive of scabies. In children, the head can also be involved. Look for burrows because these are pathognomonic of scabies and will be the best site to find mites.

For the most part, scabies is a clinical diagnosis based on the typical rash and the history. It is often helpful if other family members have pruritus and a similar rash. In cases in which the diagnosis is in question or there appears to be multiple recurrences, the scraping is worthwhile to confirm the clinical impression. A dermatoscope or magnifying lens can be used to look for the small arrowhead-appearing mite at the end of a burrow. Scraping of active lesions can yield the identification of mites, eggs, or feces under the microscope (KOH or mineral oil can be used on the slide) (Figure 33-62).

Crusted (Norwegian) scabies is a highly contagious form with a propensity for older adults and immunocompromised or physically debilitated patients (Figure 33-63). Widespread, crusted lesions appear with thick, hyperkeratotic scales over the elbows, knees, palms, and soles. Infections may occur with thousands of mites at a time and can be especially problematic in nursing homes or assisted-living environments. Ivermectin is an oral treatment for

Figure 33-61 Scabies with a visible burrow (arrow). (© Richard P. Usatine.)

Figure 33-62 Scabies mite (40 \times). (© Richard P. Usatine.)

resistant or crusted scabies with demonstrated safety and efficacy. Most studies used a single dose of ivermectin at 200 $\mu\text{g}/\text{kg}$ (Strong and Johnstone, 2007).

Permethrin cream is applied from the neck down (including the head when involved) and rinsed off 8 to 14 hours later. Usually this is done overnight. Repeating the treatment in 1 to 2 weeks increases the cure rate. Unfortunately, scabies resistance to permethrin is increasing. Antihistamines and midpotency steroid creams can be used for symptomatic relief of itching. It is important to note that pruritus may persist for weeks or months after successful treatment because the dead mites and eggs still have antigenic qualities that may cause persistent inflammation. Environmental decontamination is a standard component of all therapies. Clothing, bed linens, and towels should be machine-washed in hot water. Clothing or other items (e.g., stuffed animals) that cannot be washed may be

Figure 33-63 Crusted scabies on the hands of a 2-year-old child. (© Richard P. Usatine.)

dry cleaned, heated in hot dryer for 15 minutes, or stored in sealed bags for 1 month. All household or family members living in the infested home should be treated. Failure to treat all involved individuals often results in recurrences within the family.

KEY TREATMENT

- Begin treatment of scabies with permethrin 5% cream (Strong and Johnstone, 2007) (SOR: A).
- Oral ivermectin (200 µg/kg) is used to treat resistant or crusted scabies. (Strong and Johnstone, 2007) (SOR: A).
- Antihistamines and steroid creams can be used for symptomatic relief of itching (SOR: C).
- Environmental decontamination is a standard component of all scabies therapy (SOR: C).
- All those living in the infested home should be treated to prevent recurrences (SOR: C).

PEDICULOSIS CAPITIS (HEAD LICE)

Lice are obligate human parasites transmitted by person-to-person contact. Infestations are increasing in frequency because of the development of resistance to current treatments. The infestation is usually detected because of intense itching and the presence of eggs or nits adherent to the hair shaft (Figure 33-64). After the nit is attached to the hair shaft, the head louse develops over 3 to 4 days. Within 12 days of hatching, the nymph becomes a sexually mature adult capable of reproducing. After a single fertilization, each female lays up to 10 eggs a day during her 30-day life span. Typically, infestation occurs over a 2-week period, resulting in an allergic reaction to the louse saliva, causing the pruritus. Without frequent blood meals from the host, lice survive only 15 to 20 hours.

Detection of a single live louse is sufficient for diagnosis of infestation. Nits should be examined for viable embryo, which will show some movement under magnification. Because of the route of transmission, outbreaks are often seen in daycare centers, classrooms, and homeless shelters.

Figure 33-64 Pearly nits of head lice. (© Richard P. Usatine.)

Effective eradication of pediculosis often requires two treatments given 7 to 10 days apart. Several OTC preparations are available, including 4% piperonyl butoxide with 0.33% pyrethrins (RID, Pronto, A-200) and permethrin (Nix). Malathion is available by prescription for treatment of resistant strains but should not be used in infants or children younger than 6 years. Instructions for use must be followed carefully, including treatment of all household contacts. Removal of all nits is not necessary after eradication but can be done with a fine-toothed comb if desired. Schools often require no visible nits before permitting children to return to classes. Use of a 50% vinegar and water rinse after shampooing may help reduce adherence of nits to the hair shaft.

Bedding and clothing should be washed in the hottest water possible or dry cleaned. Combs, barrettes, and hair ornaments may be soaked in hot water for 10 minutes. Items that cannot be otherwise cleaned, such as stuffed animals and decorative pillows, can be sealed in plastic bags for 2 weeks.

KEY TREATMENT

- Pediculicides effective in the treatment of head lice include 1% permethrin cream rinse, pyrethrins with piperonyl butoxide shampoo, and malathion cream; no evidence shows one is better than another (Cochrane review; Dodd, 2006) (SOR: A).

PEDICULOSIS CORPORIS (BODY LICE)

Body lice are most frequently seen in patients who live in environments that prevent regular changing of clothing and bedding, such as homeless people. Diagnosis should be suspected in patients with generalized itching and excoriations and poor hygiene. Body lice are more likely to be found in the seams of clothing than on the patient (Figure 33-65).

Initial treatment of body lice entails washing the entire body surface and wearing clean clothing. In severe infestations, topical use of permethrin, pyrethrin, or malathion may be indicated. Again, clothing and bedding should be washed in hot water or dry cleaned. As an alternative to topical treatment, ivermectin may be given orally.

PHTHIRUS PUBIS (PUBIC LICE, CRAB LICE)

Pubic lice are sexually transmitted and may be transmitted through clothing and towels. Treatment is the same as for head lice and should include any sexual contacts. Additionally, the presence of pubic lice should prompt consideration of other STIs.

Hypersensitivity Reactions and Other Eruptions

Key Points

- Morbilliform drug reactions occur 1 to 2 weeks after initial exposure but occur much quicker (1-3 days) on repeat exposure.
- Urticaria can be acute or chronic and is triggered by drugs, infections, arthropods, autoimmune disease, food, and even emotional stress.
- The mainstay of therapy for urticaria is avoidance of known triggers and antihistamines.
- Oral corticosteroids for urticaria should be limited to short-term therapy of severe episodes.
- Erythema multiforme (EM) is a reaction pattern secondary to a variety of etiologic agents and characterized by distinctive target lesions.
- Half of EM cases are caused by HSV; drugs and other infections are also common causes.
- Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) typically occur 7 to 21 days after starting NSAIDs, antibiotics, or antiepileptics.

“MORBILLIFORM” (MACULOPAPULAR, EXANTHEM-LIKE) REACTION

Morbilliform eruption is by far the most common type of drug eruption, reported in response to almost every drug. Small pink to red papules and macules usually start on the face or upper chest and can extend to limbs, resembling measles (Figure 33-66). The rash may be relatively asymptomatic or extremely pruritic. The typical course begins 7 to 14 days after drug initiation if the first exposure. On reexposure to the same medicine, the eruption will occur much more quickly, within 1 to 3 days. A maculopapular

Figure 33-66 A, Amoxicillin drug eruption in a young woman with mononucleosis. B, Amoxicillin rash in a child with otitis media. (© Richard P. Usatine.)

Figure 33-67 Urticarial drug eruption secondary to trimethoprim-sulfamethoxazole therapy. (© Richard P. Usatine.)

reaction is not generally life threatening and does not proceed to anaphylaxis; therefore, when no alternative drug is available, the offending agent can be continued. The eruption can be treated symptomatically with antihistamines and midpotency topical corticosteroids.

URTICARIA

Urticaria, commonly known as “hives,” can be acute or chronic, and the numerous triggers include drugs, food, infections, arthropods, autoimmune disease, and stress. The wheals consist of circumscribed areas of raised erythematous plaques that are often annular and very pruritic (Figure 33-67). These wheals can occur on any skin area and are transient and migratory. The acute form of urticaria lasts less than 4 to 6 weeks, and the chronic form lasts more than 6 weeks. When there is an obvious new drug causing the eruption, the causation is easy to determine.

For patients taking multiple medications who have no evidence of infection or illness, the diagnosis can be very difficult. Skin prick testing or radioallergosorbent assay testing (RAST), typically done through an allergy specialist, may help determine the cause but may be elusive. Patients with chronic urticaria unresponsive to antihistamines require an extensive workup. In more than 50% of cases of chronic urticaria, no etiology is found, and it is considered idiopathic or chronic “autoimmune” urticaria.

The mainstay of therapy for urticaria is avoidance of known triggering agents and antihistamines. Classic antihistamines are effective (diphenhydramine, hydroxyzine, doxepin), but sedation limits their use to primarily nighttime dosing. Second- and third-generation antihistamines

Figure 33-68 Erythema multiforme secondary to recurrent genital herpes simplex. (© Richard P. Usatine.)

are helpful for daytime use, and dose escalation up to four times the normal daily dose may be necessary (cetirizine, loratadine, fexofenadine, desloratadine, levocetirizine). Oral corticosteroids are useful but should be limited to short-term therapy of severe acute urticaria. H₂-receptor antagonists (cimetidine, ranitidine, famotidine) and leukotriene antagonists are sometimes helpful as adjunctive therapy.

ERYTHEMA MULTIFORME

Erythema multiforme is a reaction pattern secondary to a variety of etiologic agents characterized by distinctive target lesions. About 50% of cases of EM are caused by infections, most often HSV and *Mycoplasma pneumoniae* (Figure 33-68). The other 50% are caused by drugs, most often NSAIDs, sulfonamides or other antibiotics, antiepileptics, and barbiturates. A small number of cases are due to foods and other allergens, immunologic or connective tissue disease, malignancy, and hormones.

Lesions begin as dull-red macules or urticarial plaques on the palms, soles, or extensor surfaces of the extremities and tend to expand in size. A small papule, vesicle, or bulla develops in the center with concentric rings forming around the blister. The center of the lesion becomes dusky or violaceous from necrosis of the epidermis. Most EM cases spontaneously subside within 3 weeks without sequelae.

Identification of the cause should be made, if possible. Patient should be queried for prescription and OTC medications and history of HSV. A thorough examination should be performed, looking for oral or genital ulcers with Tzanck prep or DFA test for HSV. Cultures of the skin, nose, throat, and conjunctiva are indicated to evaluate for infections and treated appropriately.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS

Both SJS and TEN are rare, severe, life-threatening reactions that are almost always drug related. The most common offending medications are NSAIDs, antibiotics, and anti-seizure medications. SJS or TEN typically occurs 7 to 21 days after the start of the medication.

Stevens-Johnson syndrome often presents with a prodrome of fever, painful swallowing, stinging eyes, and painful skin. Two or more mucosal surfaces eventually become involved (conjunctiva, oral mucosa, genitalia) with vesicles, bullae, erosions, or hemorrhagic crusts. Skin lesions usually begin as dusky purpuric macules that progress to bullae or erosions on the trunk and spread centrifugally. *Targetoid lesions*, similar to EM, may also be present. By definition, less than 10% body surface area (BSA) is involved in SJS. A similar presentation occurs in TEN, but the bullae and erosions involve greater than 30% BSA. Also, the skin that initially appears normal may easily slide off with gentle tangential pressure (the Nikolsky sign), leaving more denuded skin. When skin and mucosal involvement is 10% to 30% BSA, it is considered a SJS–TEN overlap.

Both SJS and TEN can be fatal; the mortality rate is 1% to 5% for SJS and 25% to 35% for TEN, but it may be even higher in elderly patients or those with comorbidities. Above all, removal of the offending agent is paramount. Most patients are treated in a burn unit because the skin is necrotic and no longer functioning as a barrier. Care is supportive and aimed at regulation of fluids, electrolytes, protein, temperature, and prevention of infection. Neither systemic steroids nor intravenous immune globulin demonstrate consistent clinical efficacy in clinical studies, which are limited because of the rarity of SJS and TEN.

Skin Signs of Systemic Disease

LUPUS ERYTHEMATOSUS

Key Points

- Lupus erythematosus (LE) is an autoimmune disease of connective tissue that may be limited to the skin (cutaneous lupus), or the skin findings may indicate systemic disease.
- All LE variants are photosensitive, and primary treatment should include education in sun protection and avoidance.

Lupus erythematosus is an autoimmune disease of connective tissue that has frequent dermatologic manifestations. LE may be limited to the skin, or the skin findings may indicate systemic disease. For dermatologic purposes, there are three main variants:

1. *Acute cutaneous* (ACLE): exemplified by the malar rash, usually associated with systemic disease and positive antinuclear antibodies (Figure 33-69)
2. *Subacute cutaneous* (SCLE): characteristic photosensitive papulosquamous annular lesions of the trunk and arms, associated with anti-Ro antibodies (70%); up to 25% will have systemic involvement (Figure 33-70)
3. *Discoid* (DLE): inflammation involves deeper adnexal structures, with predilection for head and neck; results in scarring; fewer than 10% have systemic involvement (Figure 33-71)

Acute cutaneous LE presents as the classic “butterfly rash” and tends to follow sun exposure. Erythema and

Figure 33-69 Systemic lupus erythematosus and with malar rash. (© Richard P. Usatine.)

Figure 33-70 Subacute cutaneous lupus erythematosus in sun-exposed areas. (© Richard P. Usatine.)

edema may be mild to severe. The presence of *poikiloderma* (patches of hypopigmentation, hyperpigmentation, telangiectasias, and epidermal atrophy) may help to differentiate the malar rash of lupus from other skin diseases of the midface, such as rosacea or seborrheic dermatitis, which are not poikilodermatous. There is sparing of the nasolabial folds and the skin under the nose and upper lip, areas that are shaded from the sun.

Lesions of SCLE are very photosensitive and appear as annular, scaly, erythematous patches or papulosquamous rings with central clearing. These usually affect the lateral face (instead of central face), upper chest, arms, and shoulders, areas that are sun exposed. Discoid lesions are

Figure 33-71 Discoid lupus with hyperpigmentation atrophy and scarring. (© Richard P. Usatine.)

somewhat photosensitive but also found on nonexposed skin and mucosal surfaces. Most often these present on the ears, face, and neck and appear as scaly, brightly erythematous to violaceous plaques. Because of the deeper involvement of inflammation, as DLE lesions resolve, they often leave behind hyper- or hypopigmentation, even depigmentation. Severe scarring, alopecia, and disfigurement may also occur. ACLE, or systemic lupus erythematosus (SLE), is more common in women, especially of childbearing age (female:male ratio, 6-10:1), suggesting a hormonal factor in susceptibility. The female:male ratio for patients with only cutaneous forms of lupus is much lower (3-4:1 for SCLE; 2:1 for DLE). The prevalence of ACLE and SLE is also fourfold higher in African American women than white American women, and DLE is slightly more common in African Americans. However, SCLE is more prominent in whites (80%).

Occasionally, drugs can induce ACLE or SCLE. Whereas procainamide, hydralazine, isoniazid, quinidine, and phenytoin are most frequently reported for ACLE, hydrochlorothiazide, calcium channel blockers (diltiazem), angiotensin-converting enzyme inhibitors, terbinafine, NSAIDs, griseofulvin, and tumor necrosis factor antagonists are most frequently reported for SCLE. Drug-induced ACLE usually fades after the drug is discontinued but may take many months. Drug-induced SCLE may or may not clear with cessation of the drug.

For skin lesions of lupus, sun protection and sun avoidance are crucial because all types are photosensitive. Although discoid lesions are not as photosensitive as the other variants, some patients with ACLE, SLE, or SCLE can even be triggered by indoor light. Topical corticosteroids

Figure 33-72 Heliotrope rash of dermatomyositis. (© Richard P. Usatine.)

and calcineurin inhibitors (pimecrolimus, tacrolimus) are the mainstay in treatment of skin lesions. If oral medications are required to control skin disease, antimalarials (most often hydroxychloroquine) are first-line therapy.

DERMATOMYOSITIS

Key Points

- Dermatomyositis is an autoimmune disease of unclear etiology but sometimes triggered by malignancy, drugs, or infection.
- High-dose corticosteroids with a slow taper over 2 to 4 years are the primary treatment, and muscle disease usually responds more rapidly than skin disease.

Dermatomyositis is presumably an autoimmune disease that is triggered by an outside factor. Antinuclear antibodies or anticytoplasmic antibodies (antisynthetase) are found in up to 95% of patients. Clinically, dermatomyositis is characterized by a symmetric proximal inflammatory myopathy and distinct skin lesions. Proximal muscle weakness may precede the skin findings, may follow them, or may be absent (“dermatomyositis sine myositis”). Classic cutaneous lesions include the *heliotrope rash*, pink to lilac, poikilodermatous or edematous patches of the periocular skin (Figure 33-72). The *shawl sign* consists of poikiloderma of the upper chest, shoulders, and upper back. Gottron papules are erythematous, scaly or lichenified papules or plaques over the knuckles. Similar plaques may be seen on the elbows, mimicking psoriasis. Other common cutaneous findings are periungual telangiectasias (visible dilated capillary loops) and ragged cuticles (cuticular dystrophy).

Although the etiology of dermatomyositis is unknown, triggers may include malignancy, drugs, and infection. In adults with dermatomyositis, studies report a wide range of association with internal malignancy (10%-50%). Common malignancies include genitourinary, ovarian, colon, breast, lung, pancreatic, and lymphoma. The same association is not found in juvenile cases of dermatomyositis. Therefore,

any adult with a new diagnosis of dermatomyositis should be screened with a chest, abdominal, and pelvic computed tomography with close surveillance for 2 to 3 years.

Double-blind, placebo-controlled trials are lacking for this rare disease, but the mainstay of treatment for dermatomyositis is high-dose corticosteroids with slow taper over 2 to 4 years. Other immunosuppressants used include methotrexate, azathioprine, cyclophosphamide, and cyclosporine. In general, the myopathy responds more rapidly and easily than the skin lesions, and severe pruritus can persist long after muscle disease is controlled. For skin lesions, sun protections, topical corticosteroids, or antimalarials may help.

SARCOIDOSIS

Sarcoidosis is a systemic granulomatous disease of unknown etiology that most often involves the lungs (90%). The skin is involved in about one third of patients with systemic sarcoidosis. In the United States, women and African Americans are more frequently affected. As with syphilis, sarcoidosis is considered a “great imitator” because it has widely variable presentations and may involve almost any organ system.

Classic skin lesions of sarcoidosis are red-brown, non-scaly papules and plaques appearing on the face, especially around the nose or mouth (Figure 33-73). The color can vary significantly from yellow to red to brown, and lesions also occur on the trunk or extremities and tend to be symmetric. Lesions on the alar rim of the nose, also known as *lupus pernio*, are highly associated with granulomatous infiltration of the upper airway. Patients with cutaneous sarcoidosis should have a complete evaluation for systemic

Figure 33-73 Cutaneous sarcoidosis. (© Richard P. Usatine.)

disease, including history and physical examination, renal and hepatic function testing, chest radiography, pulmonary function tests, electrocardiography, and ophthalmologic evaluation.

Lesions of cutaneous sarcoidosis are difficult to treat and tend to recur. The most effective therapy is intralesional injection of corticosteroids repeated at 2- to 4-week intervals. Topical corticosteroids are often ineffective because they do not penetrate the skin lesions adequately. Systemic corticosteroids are effective in treating lesions that are widespread or impairing function. In especially difficult cases, agents such as hydroxychloroquine or methotrexate may be used.

Benign Growths

Key Points

- The most important reason to be able to recognize benign skin growths is to differentiate them from skin cancers.
- Seborrheic keratoses (SKs), epidermal cysts, and dermatofibromas can be surgically excised if they are suspicious for cancer or causing symptoms.
- Pyogenic granulomas bleed easily and should be excised and sent for pathology to rule out amelanotic melanoma.
- SKs and dermatofibromas have characteristic patterns with dermoscopy that can help guide the need for a biopsy.

SEBORRHEIC KERATOSIS

Seborrheic keratoses are hyperkeratotic lesions of the epidermis that often appear to be stuck on the surface of the skin (Figure 33-74). SKs usually have a discrete border and vary in color from pink or tan to brown, gray, or even black. Most lesions have a rough surface and usually range from 2 mm to 3 cm in diameter but can be larger. SK may start as a hyperpigmented macule and progress to the characteristic plaque. The trunk is the most common site, but the lesions can be found on the extremities, face, and scalp.

The incidence of SK increases with age in men and women. *Stucco keratoses*, a variant of SK, are many skin-colored or white, dry scaly lesions often seen on the arms and legs. *Dermatosis papulosa nigra* is another type of SK consisting of many small, brown or black papules on the faces of patients with highly pigmented skin.

Differentiating between SK and melanomas can be a challenge, especially in patients with numerous lesions. Both have varying dark colors, the potential for large size, and irregularity. SKs have a rough surface, and the keratin can have horn cysts or look cerebriform. The best way to differentiate a SK from a melanoma is with a dermatoscope. This special magnifying light can distinguish specific characteristics of the keratosis with higher specificity than with the naked eye. These characteristics are comedo-like openings and milia-like cysts (see Figure 33-74).

Some patients want their SKs treated for cosmetic reasons or to decrease irritation from abrasion on clothing.

Figure 33-74 Seborrheic keratosis with horn cysts (comedo-like openings). (© Richard P. Usatine.)

Figure 33-75 Pyogenic granuloma. (© Richard P. Usatine.)

Cryosurgery, curettage, and shave excision are the most frequently used methods of removal. Cryotherapy with liquid nitrogen is effective for most SKs, except for extremely thick lesions. Repeat treatments may be necessary. Curettage can be performed with or without electrocautery after administration of local anesthesia. Excisional biopsy should be used to remove lesions suspicious for melanoma.

PYOGENIC GRANULOMA

Pyogenic granulomas (lobulated capillary hemangiomas) are benign vascular lesions that occur most often in young adults and children (Figure 33-75). These rapidly growing hemangiomas may start at sites of trauma. Treatment is surgical removal. Pyogenic granulomas do not have malignant potential, but it is important to send the tissue for pathology to rule out an amelanotic melanoma. Lesions

Figure 33-76 Dermatofibroma on the leg with a hyperpigmented halo. (© Richard P. Usatine.)

most commonly occur on areas of trauma or friction such as the fingers, head, neck, and extremities and on mucous membranes. Pyogenic granulomas frequently occur on the gingiva during pregnancy and regress spontaneously after childbirth. Patients usually are acutely concerned that the lesion has grown quickly and bleeds easily with little or no trauma.

Removal can be accomplished with shave excision and then curettage and electrodesiccation of the base to reduce chances of recurrence. Alternatively, the whole lesion can be cut out down to subcutaneous fat. Pyogenic granulomas will recur if any residual tissue remains after excision.

EPIDERMAL INCLUSION CYSTS

Epidermal inclusion cysts, also known as *sebaceous cysts*, are filled with keratin and lined with stratified squamous epithelium. Epidermal cysts usually occur on the back, face, and chest and open to the skin through a small, central punctum or keratin-filled plug. The cysts may remain small for years or may grow rapidly. Rupture of the cyst wall into the dermis initiates an inflammatory response.

Acutely inflamed, fluctuant cysts should be incised and drained. However, unless the cyst wall is removed or destroyed, there is a high risk of cyst recurrence. Alternately, the cyst may be removed intact by excision and blunt dissection. Complete drainage is enhanced with gauze packing, which is changed frequently during wound healing. The use of antibiotics is unnecessary unless a concurrent cellulitis exists. If a patient requests removal of an epidermal cyst before an acute inflammatory event, the cyst wall can be more easily shelled out, minimizing the risk of recurrence.

DERMATOFIBROMA

Dermatofibromas (benign fibrous histiocytomas) are most likely fibrous reactions to minor trauma, insect bites, viral infections, ruptured cysts, or folliculitis. The nodules can be found anywhere on the body but most often appear on the legs and arms. Dermatofibromas are firm, raised papules, plaques, or nodules that vary from 3 to 10 mm in diameter (Figure 33-76). Dermatofibromas have a central fibrous

Figure 33-77 Dermatofibroma undergoing pinch test in which the lesion dimples downward. (© Richard P. Usatine.)

scar and often have a hyperpigmented or pink halo around the central hypopigmented area. This has a characteristic pattern on dermoscopy.

Dermatofibromas dimple downward when compressed laterally (Figure 33-77). Dermatofibromas are usually asymptomatic but may be tender or pruritic. Dermatofibromas can be confused with melanomas, and if growing rapidly, it could be a malignancy called a *dermatofibrosarcoma protuberans*. An incisional or excisional biopsy can be used to determine the diagnosis. Because of the dermal location of the nodules, excision is superior to shave biopsy to ensure clear histology and complete removal. A punch biopsy can be used for smaller lesions. Dermatofibromas that are stable in size and asymptomatic can be left alone without treatment.

Premalignant and Malignant Skin Lesions

Key Points

- AK is a scaly macule on sun-damaged skin and often easier to feel than to see.
- Topical 5-FU therapy is used for patients with multiple AKs rather than treating each lesion with cryotherapy.
- Bowen disease (BD) (squamous cell carcinoma [SCC] in situ) and superficial BCC look more like patches of dermatitis than tumors.
- The typical nodular basal cell carcinoma presents as a pearly colored papule with overlying telangiectasias and a central depression or ulcer.
- Left untreated, local destruction from BCC can be extensive.

Figure 33-78 Extensive actinic keratoses on the forearms and dorsum of the hands. (© Richard P. Usatine.)

- Most SCCs arise from AKs, radiation dermatitis, leukoplakia or erythroplakia, and burn scars or chronic ulcers.
- Organ transplant recipients have a 5% to 10% greater risk of developing BCC and a 40 to 250 times greater risk of developing SCC.
- Risk factors for melanoma include fair skin, red or blond hair, no tan or easily burns, freckles, excessive childhood sun exposure, blistering childhood sunburns (more than three), moles (nevi) or dysplastic nevi, family or personal history of melanoma, immunosuppression, and older age.
- One third of melanomas arise in a preexisting nevus.
- Depth of tumor invasion (Breslow depth) is the most important prognostic indicator for melanoma; most patients with thin tumors (<1 mm) have more than a 90% 10-year survival.

ACTINIC KERATOSIS

Actinic keratoses are also known as “solar keratoses” because of their relationship to chronic sun exposure. These lesions are most common on the dorsal surfaces of the hands and arms, neck, ears, bald scalp, and face, areas that are not covered by clothing on a daily basis (Figure 33-78). AKs are usually scaly, pink to flesh-colored macules or papules and are often easier to feel than see. They have a rough texture as a bare finger slides over the skin. The lesions have malignant potential and can transform into SCC at a rate of about 0.1% per lesion per year. Lesions that appear like AKs but are indurated and large should be biopsied because they could already have become SCC in situ or SCC.

Cryotherapy with liquid nitrogen is a rapid and practical method for treating AKs when a limited number of lesions are present. However, a recent Cochrane review found that photodynamic therapy appears more effective and has a better cosmetic outcome than cryotherapy for individual lesions (Gupta et al., 2012). For field-directed treatments, diclofenac, 5-FU, imiquimod, and ingenol mebutate had similar efficacy (Gupta et al., 2012).

The medication available for field directed treatments include topical 5-FU (Efudex 5%, Carac 0.5%), diclofenac (Solaraze), imiquimod 5% and 3.75% (Aldara, Zyclara), ingenol mebutate 0.015% and 0.05% (Picato). These treatments can be temporarily disfiguring with erythema, crusting, or ulcerations, but if the skin is kept lubricated with petroleum jelly during treatment, the process usually looks worse than it feels. Both 5-FU and diclofenac are applied daily for 4 weeks. Patients often will not tolerate the 4-week duration, but if erythema or crusting is achieved in 2 to 3 weeks, treatment may still be successful. Lesions will take another 2 to 4 weeks to heal. Treatment with imiquimod 5% is once daily for 3 to 5 days of the week (depending on irritation) and is continued for 12 to 16 weeks. Imiquimod 3.75% is applied daily for 2 weeks followed by 2 weeks of no treatment then application is repeated daily for another 2 weeks. Imiquimod is supplied in small, expensive packets, so it is less practical for treating larger surface areas, although imiquimod 3.75% is approved for larger areas, and the 5% cream is approved for only 25 cm². Ingenol mebutate 0.015% and 0.05% are also approved to treat only 25 cm². The 0.015% cream is applied daily for 3 days to the face or scalp while the 0.05% cream is applied daily for 2 days to nonfacial body areas.

Photodynamic therapy is performed with aminolevulinic acid (Levulan) in combination with either red or blue light. The photosensitizing acid is applied to the skin, allowed to penetrate for 1 to 3 hours, and then exposed to the light source for approximately 16 minutes. This is performed in the office, and the patient must avoid all natural light for the next 48 hours.

Treating AKs with liquid nitrogen using a 1-mm halo freeze demonstrated complete response of 39% for freeze times less than 5 seconds, 69% for times more than 5 seconds, and 83% for times more than 20 seconds (Thai et al., 2004). More hypopigmentation is caused by 20 seconds of freeze time. The physician should base duration of freeze time on the size and thickness of the lesion, using sufficient time for clearance while attempting to avoid hypopigmentation and scarring.

All patients with AK or skin cancer should be educated on daily sun protection and sun avoidance. This includes sunscreen with a sun protection factor (SPF) of 30 or greater, wide-brimmed hats, long sleeves and pants, and avoiding peak hours of sunlight (10 AM to 4 PM).

KEY TREATMENT

- Sunscreen twice daily for 7 months may protect against development of actinic dermatoses (de Berker et al., 2007) (SOR: A).
- Treating AKs with liquid nitrogen showed complete response of up to 83% for freeze times longer than 20 seconds (Thai et al., 2004) (SOR: A).
- Treat multiple AKs of the face, scalp, forearms, and hands topically with 5-FU, imiquimod, ingenol mebutate, diclofenac, or photodynamic therapy (de Berker et al., 2007) (Gupta et al., 2012) (SOR: A).
- Average complete clearance of AKs using 5-FU was 52% (±18%) and for imiquimod, 70% (±12%) (Gupta et al., 2005) (SOR: A).

Figure 33-79 Bowen disease (squamous cell carcinoma in situ) on the arm. (© Richard P. Usatine.)

BOWEN DISEASE AND ERYTHROPLASIA OF QUEYRAT

Bowen disease is SCC in situ most often caused by chronic solar damage. Therefore, lesions are found most often on the dorsal hands and forearms, neck, ears, bald scalp, and face. HPV also has been documented as a cause of BD, especially HPV-16. Inorganic arsenic ingestion, radiation dermatitis (x-ray damage), immunosuppression or HIV, burn scars, and chronic ulcers are also associated with BD.

Bowen disease often presents with an asymptomatic, slowly enlarging, erythematous, scaly patch on the skin that mimics an eczematous dermatitis (Figure 33-79). The head and neck are most frequently affected followed by the extremities. As they enlarge, lesions may become hyperkeratotic, crusted, fissured, or eroded. When BD occurs on mucous membranes, it is a white, red, or erosive patch. SCC in situ on the penis is referred to as *penile intraepithelial neoplasia* (erythroplasia of Queyrat).

Treatment of BD depends on the location, size, number of lesions, clinician's expertise, patient factors (age, immune status, concomitant medication, comorbidities, compliance), cosmetic outcome, and patient preference. For the trunk or extremities, electrodesiccation and curettage (ED&C) is practical. Cryotherapy is also an option but often results in poorer wound healing. One prospective study suggests a superiority of ED&C over cryotherapy in treating BD, especially for lesions on the lower leg. Curettage was associated with a significantly shorter healing time, less pain, fewer complications, and a lower recurrence rate (Ahmed et al., 2000). For larger or poorly defined lesions, topical therapy with 5-FU or imiquimod can be used, working best when the patient can see and reach the lesion. In a randomized, double-blind, placebo-controlled trial of imiquimod daily for 16 weeks, nine of 12 patients (75%) in the imiquimod group and none in the placebo group had complete clearance of BD, with no recurrence in the 9-month follow-up (Patel et al., 2006). Lesions can also be excised with 4-mm margins or referred for Mohs micrographic surgery (MMS) when tissue sparing is crucial. Mohs surgery is recommended for BD at sites such as digits or penis, where

it is important to limit removal of unaffected skin. It is also useful for poorly defined or recurrent head and neck BD (Cox et al., 2007). Excision should be an effective treatment with low recurrence rates, but the limited evidence cannot address specific lesion sites (Cox et al., 2007).

The overall risk of progression of BD to invasive cancer is about 3% to 5%. However, the risk is greater for patients with oral and genital lesions ($\approx 10\%$), as well as those with a history of arsenic exposure or lesions located in a chronic scar or ulcer.

KEY TREATMENT

- Curettage and electrodesiccation may be superior to cryotherapy in treating BD, especially for lesions on the lower leg (Ahmed et al., 2000) (SOR: A).
- Use of 5-FU is more practical than surgery for large BD lesions, especially at potentially poor healing sites (Cox et al., 2007) (SOR: B).
- Imiquimod effectively clears BD lesions in most patients (Patel et al., 2006) (SOR: B).
- Mohs surgery is recommended for BD at the digits or penis and is useful for poorly defined or recurrent head and neck BD (Cox et al., 2007) (SOR: B).

BASAL CELL CARCINOMA

Basal cell carcinoma is the most common human malignancy. In the United States, BCC affects almost 3 million people per year, and this estimate is likely low because no national registry exists for nonmelanoma skin cancers. BCC typically appears in areas of sun-exposed skin, is usually slow growing, and rarely metastasizes. The prognosis is excellent with proper therapy, but BCC can cause significant local destruction and disfigurement if neglected. The estimated lifetime risk in whites is approximately one in five, but it increases to one in three in those older than age 65 years living in southern latitudes. The incidence is extremely low in those with highly pigmented skin. Organ transplant recipients have a five to 10 times greater risk of BCC.

Patients often present with a nonhealing sore on the face, ears, scalp, neck, or upper trunk. The most common type of BCC is *nodular*, which is usually a pink papule or nodule, with a central depression or ulceration and pearly, rolled borders with overlying telangiectasias (Figure 33-80). *Superficial* BCC is the second most common type (Figure 33-81). *Sclerosing* (morpheaform, infiltrating) BCC is the least common (Figure 33-82). It is not unusual to see pigment in a nodular BCC (Figure 33-83). A shave biopsy is usually adequate to confirm the diagnosis.

Superficial BCC can be treated with ED&C or topically with 5-FU or imiquimod. Imiquimod 5% cream once daily five times weekly for 6 weeks for superficial BBC produced an initial clearance rate of 90%, with 80% of subjects clinically clear at 2 years (Gollnick et al., 2005). In another study, superficial BCC lesions on the trunk or limbs were treated with 5-FU cream twice daily for up to 12 weeks. The histologic cure rate was 90%, and the mean time to clinical cure was 10.5 weeks. 5-FU was generally well tolerated, with a good cosmetic outcome; most patients

Figure 33-80 Nodular basal cell carcinoma on nasal ala. (© Richard P. Usatine.)

Figure 33-81 Superficial basal cell carcinoma on back. (© Richard P. Usatine.)

had no pain or scarring and only mild erythema (Gross et al., 2007).

Nodular BCC can be excised with 3- to 5-mm margins or treated with ED&C, depending on location and patient comorbidities and preference. Cryotherapy is another option but is infrequently performed because of poor wound healing. Tumors that are more aggressive by histologic pattern (morpheaform, micronodular, or infiltrating) or

Figure 33-82 Sclerosing basal cell carcinoma. (© Richard P. Usatine and the Skin Cancer Foundation.)

Figure 33-83 Pigmented nodular basal cell carcinoma. (© Richard P. Usatine.)

those occurring near vital or cosmetically sensitive structures are best treated with MMS. This tissue-sparing method also allows for examination of almost 100% of the tissue margins. MMS is the removal of tumor by scalpel in sequential layers, in which each tissue sample is frozen, stained, and microscopically examined. This is repeated until all the margins are clear. MMS is the treatment of choice for BCCs greater than 2 cm, with poorly defined margins, aggressive histology, involving areas of cosmetic or functional importance (mouth, ears, nose, eyelids), or recurrent lesions (Thissen et al., 1999).

Patients diagnosed with BCC have an approximately 30% higher risk than the general population of being diagnosed with another BCC unrelated to the previous lesion. Because BCC can recur, patients should have frequent full-body skin examinations at least twice yearly for the first 2 years and then yearly if no new lesions occur. As with all sun-related

Figure 33-84 Squamous cell carcinoma under ear. (© Richard P. Usatine.)

malignancies and precancerous lesions, patients must be instructed on sun protection and sun avoidance.

KEY TREATMENT

- Mohs surgery (three studies; $n = 2660$) is the “gold standard” but is not needed for all BCCs. The recurrence rate was 0.8 to 1.1. Systematic review also showed the following (Thissen et al., 1999) (SOR: A):
 - Surgical excision (three studies; $n = 1303$): the recurrence rate was 2 to 8. The mean cumulative 5-year rate was 5.3. Recommended margins are 4 to 5 mm.
 - Curettage and desiccation (six studies; $n = 4212$): the recurrence rate was 4.3 to 18.1. The cumulative 5-year rate was 5.7 to 18.8. Three cycles of curettage and desiccation can produce higher cure rates than one cycle.
 - Cryosurgery (4 studies; $n = 796$): the recurrence rate was 3.0 to 4.3. The cumulative 5-year rate (3 studies) was 0 to 16.5.
- Superficial BCC is effectively treated with imiquimod 5% cream (Gollnick et al., 2005) or 5-FU cream (Gross et al., 2007) (SOR: B).

SQUAMOUS CELL CARCINOMA

Cutaneous SCC is the second most common form of skin cancer, also arising primarily on sun-exposed skin of middle-aged and older adults. Most SCCs arise from sun-induced precancerous lesions (AKs). As in BD, there is a higher risk of SCC in patients with radiation dermatitis (x-ray damage), leukoplakia or erythroplakia (in oral or

Figure 33-85 Squamous cell carcinoma on lip. (© Richard P. Usatine.)

genital mucosa), burn scars, and chronic skin ulcers. It is important to note that organ transplant recipients have a 40 to 250 times greater risk of developing SCC, purportedly from interaction of HPV and immunosuppression.

Lesions are typically pink to flesh-colored papules or nodules, often with crusting or ulceration (Figure 33-84). They may also be keratotic or may develop a cutaneous horn. The most common locations include the face, scalp, lips, ears, neck, dorsal arms and hands, and genitalia (Figure 33-85). Although many SCCs are asymptomatic, symptoms such as bleeding, pain, and tenderness may be noted. SCC has an overall *metastasis* rate of 2% to 3%, but it is highly variable based on location, size, depth, invasion, and immunosuppression; rates can be as high as 30% to 40%. High-risk areas for metastasis include the ear, lip, genitalia, and areas of chronic inflammation (burns, scars, ulcers). A biopsy is required for diagnosis, which can be done with the shave or punch technique. Treatment of superficial SCC is covered under BD.

Many SCCs can be excised with 4- to 5-mm margins. Smaller lesions may be amenable to ED&C. Several series report excellent cure rates with ED&C, and experience suggests that small (<1 cm), well-differentiated, primary slow-growing tumors arising on sun-exposed sites can be removed by experienced physicians with curettage (Motley et al., 2003). As with BCC, tumors of SCC that are large, invasive, recurrent or near vital or cosmetically sensitive structures are best treated with Mohs surgery. Surgical resection with 4-mm margins should be adequate for well-defined low-risk tumors less than 2 cm in diameter. Such margins are expected to remove the primary tumor mass completely in 95% of cases. MMS should therefore be considered as first-line treatment of high-risk SCC, particularly at sites where wide surgical margins may be difficult to achieve without functional impairment (Motley et al., 2003). In a prospective, multicenter case series of 1263 patients with SCC who underwent MMS, recurrence after MMS was diagnosed in 15 of the 381 patients (3.9%) who completed the 5-year follow-up: 2.6% in patients with primary SCC, and 5.9% in patients with previously recurrent SCC (Leibovitch et al., 2005).

Table 33-3 Mnemonic for Signs and Symptoms of Melanoma

ABCDE	Description
Asymmetry	Half the mole does not match the other half
Border irregularity	Edges of mole are ragged, blurred, or notched
Color	Color over mole is not homogeneous; may be varying shades of tan, brown, or black; patches of red, blue, or white in some cases
Diameter	Mole is >6 mm
Evolution	Previously stable mole that is changing (evolving) in color, size, or other signs or symptoms

KEY TREATMENT

- Surgical resection with 4-mm margins should remove small cell carcinoma (low risk, <2 cm) completely in 95% of patients (Motley et al., 2003) (SOR: A).
- MMS is considered first-line treatment of high-risk SCC (Motley et al., 2003) (SOR: B).

MELANOMA

Melanoma is the most lethal of the cutaneous malignancies, causing more than 77% of skin cancer deaths. In the United States, more than 68,000 new cases of invasive melanoma and almost 57,000 new cases of melanoma in situ were diagnosed in 2010. Melanoma arises from the pigment-producing cells (melanocytes) located predominantly in the skin, but it also found in the eyes, ears, GI tract, leptomeninges, and oral and genital mucous membranes. Early detection and treatment of melanoma are the best means of reducing mortality.

The development of melanoma is not completely understood and is not as directly linked to chronic sun exposure as is BCC or SCC. Risk factors include a fair complexion, red or blond hair, inability to tan or predisposition to burn, freckles, excessive childhood sun exposure, more than three blistering childhood sunburns, an increased number of moles (nevi) or dysplastic nevi, a family history of melanoma, a personal history of melanoma, immunosuppression, and older age.

One third of melanomas arise in a preexisting nevus. A changing or newly acquired nevus in a person older than age 20 years is the most common warning sign for melanoma. An increase in size, change in color, asymmetry of borders, and variegated pigmentation are signs that warrant a biopsy. The mnemonic ABCDE (asymmetry, border irregularity, color, diameter, evolving) is helpful to assess lesions that may be melanocytic (Table 33-3). Symptoms such as bleeding, itching, ulceration, and pain in a pigmented lesion are less common but also warrant further evaluation.

The subtypes of melanoma include superficial spreading melanoma (60%-70%), nodular melanoma (15%-30%), lentigo malignant melanoma (5%-15%), and acral lentiginous melanoma (5%-10%). These are essentially histologic subtypes but do tend to favor certain areas or populations. Superficial spreading, the most common type, usually

Figure 33-86 Superficial spreading melanoma on back. (© Richard P. Usatine.)

Figure 33-87 Lentigo maligna melanoma on the face. (© The Skin Cancer Foundation.)

occurs on the trunk or legs (Figure 33-86). Lentigo maligna melanoma is a superficial variant and usually found on the face in elderly persons (Figure 33-87). Nodular melanomas often have a solid-black color, and their thickness predicts a worse prognosis (Figure 33-88). Acral lentiginous melanoma is most often found on the great toe or thumb and is the most common type to occur in African Americans (Figure 33-89).

Excisional biopsy, including 1 to 2 mm of normal skin surrounding the pigmented lesion, is optimal to provide accurate diagnosis and histologic staging. Referral for biopsy may be appropriate based on the location and size of the lesion. “Scoop shave” biopsies can be performed as long

Figure 33-88 Nodular melanoma with 22-mm Breslow depth. (© Richard P. Usatine.)

Figure 33-89 Acral lentiginous melanoma on heel of African American woman. (© Richard P. Usatine.)

as the depth of the specimen obtained is greater than 1 to 2 mm. This is important because the depth of tumor invasion (Breslow depth) is the most important prognostic indicator and used in staging. Melanomas are also staged based on the presence of ulceration (histologically), lymph node involvement, and location of metastasis. Diagnosing melanoma early is critical to a good prognosis. Most thin tumors (Breslow depth <1 mm) have a greater than 90% 10-year survival rate.

Treatment for melanoma is primarily surgical and depends on the depth of the tumor. Lesions with Breslow thicknesses less than 1 mm can be excised with 1-cm margins. Lesions with Breslow thicknesses of 1 mm or greater should be referred for sentinel lymph node biopsy to provide accurate staging. There is limited adjuvant therapy for melanoma that has spread to the lymph nodes other than interferon- α . However, two new medications have been approved for metastatic melanoma. Ipilimumab (Yervoy) is a CTLA-4 inhibitor (found on T-cells) and dosed

intravenously every 3 weeks for a total of four doses. Vemurafenib (Zelboraf) is a kinase inhibitor for BRAF-positive patients only and is dosed 1 tablet twice daily (Culos et al., 2013; Heakal et al., 2011). Ipilimumab is slow to take effect, and only about one in four patients respond, but responses can be very long lasting. Vemurafenib, on the other hand, usually demonstrates a fast antitumor response, but it does not last and is often followed by treatment resistance. Vemurafenib can only be used for patients who have the *BRAF* mutation, which accounts for just half of all patients with metastatic melanoma. Patients who do not have the mutation should not take vemurafenib because data show that it could accelerate their disease (Heakal et al., 2011).

For 2 to 3 years after any diagnosis of melanoma, patients should be seen every 3 to 6 months because most metastases occur in the first few years. If no new tumors are found, annual full-body skin examinations should be performed for life because of the higher risk of subsequent primary melanomas. Strict sun protection and sun avoidance should also be followed.

KEY TREATMENT

- World Health Organization recommendations for excision margins are 5 mm for melanoma in situ lesions, 1 cm for lesions less than 1 mm, and 2 cm for melanomas 2 to 4 mm in thickness (Lens et al., 2002) (SOR: A).
- Sentinel lymph node biopsies are recommended for melanomas 1 mm or greater in depth for staging purposes but do not improve survival (Tanis et al., 2008) (SOR: B).
- Interferon- α may offer some benefit in recurrence-free and overall survival of melanoma patients (Garbe and Eigentler, 2007) (SOR: B).
- Ipilimumab (Yervoy) is a new biologic agent that may extend survival in cases of metastatic melanoma and can be used in any patient (Culos et al., 2013) (SOR: B).
- Vemurafenib (Zelboraf) is an oral therapy for metastatic melanoma but is only effective for cases that are BRAF positive.

Long-Term Complications of Diabetes, 811
Five Things Patients Must Do to Become Successful Diabetes Self-Managers, 815

Introduction

Diabetes mellitus is a heterogeneous group of disorders with distinct genetic, etiologic, immunologic, and pathophysiologic mechanisms that result in glucose intolerance and hyperglycemia. Patients with diabetes develop insulin deficiency, impaired peripheral insulin action, or both. Chronic exposure to hyperglycemia, glycemic variability, and resultant oxidative stress in genetically prone individuals can result in both acute (diabetic ketoacidosis [DKA] and hypoglycemia) and long-term (micro- and macrovascular) complications.

Diabetes is currently classified into four major types on the basis of etiology and clinical presentation:

1. **Type 1 diabetes (T1DM):** characterized by a gradual loss of insulin-producing pancreatic β -cells secondary to autoimmune destruction
2. **Type 2 diabetes (T2DM):** genetically predisposed individuals develop a chronic progressive disease characterized by insulin resistance and subsequent β -cell failure
3. **Gestational diabetes mellitus (GDM):** defined as hyperglycemia with onset or first recognition during pregnancy
4. **Other specific types,** including monogenetic forms of diabetes (i.e., neonatal diabetes and maturity onset diabetes of the young), diabetes attributable to diseases of the exocrine pancreas (i.e., cystic fibrosis), other endocrinopathies, and drug-induced diabetes (e.g., steroids) ([American Diabetes Association \[ADA\], 2011a](#))

The prevalence of diabetes is increasing throughout the Western world. The World Health Organization estimates that more than 347 million people worldwide currently have diabetes, and 90% of all cases involve T2DM ([ADA, 2011a](#); [World Health Organization, 2013](#)). This number is projected to grow to 439 million individuals worldwide (7.7% of the population) by 2030 ([Shaw et al., 2010](#)).

HISTORICAL OVERVIEW

In 1920, diabetes was a terminal disease with a life expectancy of 6 to 12 months ([Bliss, 1982](#)). Its treatment consisted of restricting caloric intake to less than 500 calories per day. Individuals who breached that nutrition threshold in an attempt to appease their hunger would develop DKA

and die within hours to days. Life for patients with diabetes in the early 1900s was, in a word, miserable. Patients suffered from malnutrition, cataracts, blindness, gangrene, impotence, and immune-resistant infections (e.g., pneumonia, tuberculosis, boils, and carbuncles). Surgeons recognized the futility of operating on gangrenous, rotting legs; patients were equally likely to die from surgical complications as from the underlying infection. Women who were able to conceive were unable to carry their macrosomic babies to term. The “sickish sweet smell of rotten apples” breeched the halls of hospital wards as dehydrated patients with DKA lay hopelessly waiting to die ([Bliss, 1982](#)). All too often, death from diabetes would be considered a blessing by those who long suffered the consequences of chronic hyperglycemia.

The first human injection of insulin (derived from extracts obtained from dog pancreases) was given to a 14-year-old patient named Leonard Thompson in Toronto, Canada, on January 11, 1922. Weighing only 64 lb on admission, this “hopeless charity case” who was near death from DKA received a 7.5-cc injection of “thick black muck” in each hip ([Bliss, 1982](#)). The dose was calculated by Dr. Frederick Banting, who discovered insulin, and his medical student Charles Best based on their work with pancreatectomized dogs. Thompson nearly died from boils and sepsis because the “iletin” extract was impure and unsterile. Yet, to the amazement of all in attendance, his blood glucose level declined from 420 mg/dL to 330 mg/dL. Shortly after the pancreatic extract was purified, Thompson received additional injections. He was eventually discharged from the hospital and later died at 27 years of age secondary to complications from pneumonia.

In October 1922, another patient, Elsie Needham, became the first individual to ever have DKA reversed with the use of insulin. Although insulin was in short supply, physicians such as Eliot Joslin used the drug successfully to treat patients who were starving or dying of acute diabetes complications. Although the insulin extract had an immediate effect on reducing mortality, Joslin professed that lifestyle intervention remained the foundation of care for all individuals with diabetes.

Thus, less than a century ago, the discovery of insulin saved the lives of millions of people with diabetes while changing the process through which medicine is studied and practiced to this day. In short order, drug purification

methods were developed and perfected. The field of endocrinology was born. Other hormones were discovered and purified. Pharmaceutical companies began to fund clinical trials, allowing clinicians and scientists the opportunity to evaluate the safety and efficacy of new compounds.

Before 1920, clinicians relied on their own marketing skills to sell their homemade snake oil products from horse-drawn buggies. Various folkloric remedies, which rarely worked, were available to anyone and promoted to “cure whatever ails you.” People were becoming skeptical about the practice of medicine, as well as about those who claimed to be experts at curing diseases such as diabetes, tuberculosis, senility, and sexually transmitted diseases. Doctors had not yet gained the public’s trust in them as healers. After all, what could these men actually heal?

After the discovery of insulin was solidified, Banting refused to take the traditional approach of proclaiming his findings to the news media. Instead, he took the then-unprecedented route of publishing his data in a reputable medical journal ([Banting and Best, 1922](#)). People slowly began to trust physicians, not merely as quasi-mystical healers but as practitioners who could identify and cure disease through scientific discovery. Importantly, however, as Eliot Joslin noted in 1923, “Insulin is not a cure for diabetes” ([Bliss, 1982](#)).

By 1945, the lifespan of patients with diabetes had increased by nearly 45 years. Starvation and DKA gave way to long-term micro- and macrovascular complications as the primary causes of death in patients with diabetes. In 1955, sulfonylureas became the first oral medications developed and marketed for the treatment of diabetes. However, testing urine for the presence of sugar was still used as a crude means by which therapeutic decisions could be rationalized. The Ames glucometer, introduced in 1970, provided patients with the first tool for performing self-monitoring of blood glucose (SMBG), which has since become an important component of diabetes management. Metformin was approved by the U.S. Food and Drug Administration (FDA) in 1995. In 2010, more than 48 million prescriptions for generic metformin were filled in the United States alone ([IMS Institute for Healthcare Informatics, 2011](#)).

In 1993, the Diabetes Control and Complications Trial (DCCT) demonstrated that intensive glycemic control (i.e., keeping blood glucose levels as close as possible to the normal range) reduces the incidence and progression of microvascular complications (e.g., retinopathy, nephropathy, and neuropathy) in T1DM ([DCCT Research Group, 1993](#)). Whether the same held true in T2DM remained uncertain until 1998, when the U.K. Prospective Diabetes Study (UKPDS) established that intensively lowering blood glucose levels reduces microvascular complications in T2DM as well ([UKPDS Study Group, 1998](#)). However, these and other landmark long-term, randomized controlled trials (RCTs) have consistently demonstrated that individuals whose diabetes is intensively managed have a higher risk of hypoglycemia; weight gain; and, in some cases, all-cause mortality than their peers who are treated to a more relaxed or conventional glycemic target ([Action to Control Cardiovascular Risk in Diabetes \[ACCORD\] Study Group, 2008](#), [The Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation](#)

[[ADVANCE](#)] Collaborative Group, 2008, [DCCT Research Group, 1993](#); [Duckworth et al., 2009](#); [UKPDS Study Group, 1998](#)).

Based on the findings of the DCCT and UKPDS, the ADA recommends an A1C target of 6.5% to 7% for most healthy patients in the United States ([ADA, 2013b](#)). However, rather than focusing on a specific glycemic target, care should be customized based on factors such as the patient’s age, disease duration, hypoglycemia risk, presence or absence of significant comorbidities, expected longevity, and capability for and attitudes regarding diabetes self-management ([Ismail-Beigi et al., 2011](#)). Metabolic targets for lipids and blood pressure should also be customized. Following a healthy lifestyle, including a healthy eating plan, adequate physical activity, modest weight reduction (8-10 lb), and smoking cessation, is crucial for reducing the risk of long-term complications. Finally, SMBG should be incorporated into every patient’s daily routine as a means of identifying glycemic variability, predicting hypoglycemia, and evaluating immediate responses to therapeutic interventions.

The recent guideline modifications regarding individualizing metabolic targets notwithstanding, American medicine is achieving a historic level of success in treating this chronic progressive illness. Ninety percent of all patients with diabetes are managed in the primary care setting ([Unger, 2012c](#)). Some critics argue that practitioners are failing to treat patients successfully to their metabolic targets; apparently, these naysayers do not understand the importance of positive trending. Recently published data from the National Health and Nutrition Examination Survey (NHANES) suggested that, in 2010, 18.8% of all patients with diabetes successfully achieved an A1C of less than 7%, a blood pressure less than 130/80 mm Hg, and a low-density lipoprotein (LDL) cholesterol level less than 100 mg/dL compared with only 1.7% of surveyed individuals with diabetes from 1988 to 1994 ([Stark Casagrande, et al., 2013](#)).

American medicine is changing. Our treatments for diabetes, hypertension, and hyperlipidemia have improved. These improvements in the management of diabetes and related disorders may be attributed in large part to the primary care providers who care for the increasingly high numbers of patients exposed to prolonged glycemic burden, as well as to patients’ desire to become more active participants in their own diabetes care. The renewed emphasis on individualized, patient-centered diabetes care may further expand our success in this area in the near future.

Prediabetes: A Treatable Precursor of Type 2 Diabetes

Diabetes affects 25.8 million Americans (18.8 million have been diagnosed with diabetes, and an estimated 7 million remain undiagnosed). Based on NHANES data obtained between 2005 and 2008, 35% of U.S. adults 20 years of age or older and 50% of individuals 65 years of age and older meet the diagnostic criteria for prediabetes. In 2010, 79 million Americans were estimated to have prediabetes. In 2011, an estimated 280 million people were estimated to have *prediabetes* worldwide ([ADA, 2011b](#)). By 2030, the

Table 34-1 Diagnosing Prediabetes and Diabetes

Parameter	Euglycemia	Prediabetes	Diabetes
Fasting glucose (mg/dL)	<100	100-125 (impaired fasting glucose)	>126
2-hour postprandial glucose (mg/dL)	<140	140-199 (impaired glucose tolerance)	>200
A1C (%)	<5.7	5.7-6.4	>6.5

Data from American Diabetes Association. Diagnosis and classification of diabetes mellitus. *Diabetes Care*. 36(suppl 1):S67-S74, 2013.

International Diabetes Federation predicts that this number will increase to 400 million as westernization and obesity push into Asia, Africa, and South America (Unger and Moriarty, 2008).

The costs of caring for patients with diabetes will continue to rise. Annual health care costs in the United States for a person without diabetes are \$5615. Diabetes inflicts a 2.3-fold increase in annual costs of care, raising this figure to \$12,195. In 2012, diabetes cost \$245 billion in health care expenditures, an increase of 41% since 2007. Astonishingly, diabetes care now accounts for nearly 30% of the total Medicare budget. Thus, screening and implementing preventive strategies for prediabetes warrant political, medical, and bioethical consideration (ADA, 2013a).

Diabetes is a chronic, progressive disorder that, over the course of time, exposes patients to a prolonged, excessive glycemic burden, which activates pathways favoring oxidative stress and endothelial cell dysfunction. Complication pathways are propagated, resulting in micro- and macrovascular disease. Given the physical, emotional, and financial consequences associated with diabetes, screening high-risk patients could identify those with an intermediate form of dysglycemia who are likely to progress to clinical diabetes. The diagnostic criteria for prediabetes and diabetes are shown in Table 34-1.

Between 6% and 10% of patients with impaired glucose tolerance (IGT) progress to clinical diabetes each year, but up to 65% of individuals with both impaired fasting glucose (IFG) and IGT progress to clinical diabetes annually (Garber et al., 2008). Progression rates of IFG or IGT to diabetes vary according to degrees of initial hyperglycemia, racial and ethnic backgrounds, and environmental influences. The higher the glucose values, the greater the risk of progression to diabetes and diabetes complications. Primary care physicians are trained not only in managing patients within effective chronic disease-state models but also in identifying patients who are likely to develop diseases such as hypertension, diabetes, obesity, and cancer. High-risk individuals, after they have been identified (Table 34-2), should be screened for prediabetes and diabetes.

A1C has also been shown in prospective studies to predict progression to clinical diabetes. Zhang et al. (2010) noted that whereas individuals with a screening A1C at baseline of between 5.5% and 6% had a 5-year progression rate of 9% to 25%, those with an A1C of 6% to 6.5% progressed over 5 years at a rate of 25% to 50%.

Diagnostic tests for prediabetes and diabetes should be repeated to rule out laboratory error unless the diagnosis is unequivocal. A screened symptomatic patient with an A1C of 7.9% and a random blood glucose of 265 mg/dL can simply be treated for diabetes. However, a patient with a screening A1C of 6.2% with a euglycemic 2-hour

Table 34-2 Screening Patients at High Risk for Developing Prediabetes

Patients at Risk for Developing Prediabetes	Patients to Target for Prediabetes Screening
History of PCOS	Family history positive for diabetes
History of GDM	History of cardiovascular disease
Children of parents with T2DM	Obesity
Patients with abdominal obesity	Sedentary lifestyle
	Nonwhite ancestry
	Previous history of IGT or IFG
	History of hypertension
	History of elevated triglycerides, low HDL cholesterol, or both
	History of GDM
	History of PCOS
	Delivery of a baby weighing >9 lb
	Patients with schizophrenia or bipolar disorder

GDM, Gestational diabetes mellitus; HDL, high-density lipoprotein;

IFG, impaired fasting glucose; IGT, impaired glucose tolerance;

PCOS, polycystic ovary syndrome; T2DM, type 2 diabetes mellitus.

Data from Garber AJ, Handelsman Y, Einhorn D, et al. Diagnosis and management of prediabetes in the continuum of hyperglycemia: when do the risk of diabetes begin? A consensus statement from the American College of Endocrinology and the American Association of Clinical Endocrinologists. *Endocr Pract*. 14:933-945, 2008.

post-glucose challenge value should be rescreened. Preferably, the same test should be repeated for confirmation. If the initial A1C is 6.4% with a secondary measurement performed 2 months later of 6.3%, the diagnosis of prediabetes is confirmed. One can also make the diagnosis of prediabetes if the results of two different tests such as the A1C and the 2-hour post-glucose challenge are higher than diagnostic thresholds.

A1C can be useful as a screening tool for patients who present to the emergency department for management of an acute illness. An A1C greater than 5.7% performed in the acute-care setting has a sensitivity of 54.8% and a specificity of 71.3% for detecting prediabetes. An A1C of 6% has a sensitivity of 76.9% and a specificity of 87.3% for diagnosing diabetes in the acute-care setting (Silverman et al., 2011).

To prevent progression to clinical diabetes, the ADA recommends moderate exercise, weight loss (7%-10% of baseline weight in obese individuals), consideration of metformin (in patients with a body mass index [BMI] >35 kg/m²; age younger than 60 years; or, in women, a history of GDM) (ADA, 2013b). Modifiable cardiovascular disease (CVD) risk factors must also be addressed, including smoking cessation, targeting blood pressure to less than 140/90 mm Hg, and targeting LDL cholesterol to less than 100 mg/dL. A recent study suggested that a single period of moderate

exercise expending 350 kcal of energy can improve insulin sensitivity for obese patients into the following day (Newsom et al., 2013). In the Nurses' Health Study, whereas each 2-hour increment spent watching television daily was associated with a 14% increased risk of developing T2DM, a similar increment spent standing or walking was associated with a 12% risk reduction (Hu et al., 2011).

The relationship among environmental factors, the increased risk of obesity, and a reduction in desire to increase physical activity is well established. Unfortunately, the acute medical models fail to address meaningful and effective strategies that may prevent or reverse the diabetes epidemic. Proactive public health initiatives designed to educate parents and children about the importance of healthy lifestyle choices may be our best hope for minimizing the nuclear burden of the looming health care costs associated with chronic hyperglycemia.

Zhang et al. (2003) suggested that screening obese patients for prediabetes is cost effective. Screening studies cost less than \$200 per case. Patients who screen positive for prediabetes can initiate low-cost lifestyle interventions and metformin, if necessary. These noninvasive therapies will result in a savings of greater than \$8000 per quality-adjusted life year gained for screened individuals.

Weight reduction and physical activity can improve insulin-mediated glucose disposal, reduce postprandial hyperglycemia, delay pancreatic β -cell death, and slow the progression of glucose intolerance to clinical T2DM.

The Diabetes Prevention Program (DPP) was the most comprehensive clinical trial to date evaluating the importance of lifestyle modification as a deterrent to diabetes in high-risk patients (Knowler et al., 2002). A total of 3234 overweight subjects with prediabetes were randomized to one of three cohorts. The intensive lifestyle intervention (ILI) group received intensive instruction in diet, physical activity, and behavioral modification. The patients assigned to this group were counseled to reduce their fat and calorie consumption and to exercise for 150 minutes per week and were targeted to lose 7% of their baseline weight. Subjects in the ILI group reduced their risk of progression to diabetes by 58% over 4 years. The second group used metformin, 850 mg twice daily, and received information regarding lifestyle intervention but no intensive counseling. Their risk of progression to clinical diabetes was reduced by 31%. The control group was given a placebo in place of metformin and attended classes related to lifestyle intervention. About 5% of the lifestyle intervention group developed diabetes each year during the study period compared with 11% of those in the placebo group. A follow-up to the DPP showed that preservation of β -cell function and delay of progression to diabetes in high-risk individuals can persist for at least 10 years with lifestyle intervention or metformin (DPP Research Group, 2009).

The FDA has not approved any pharmacotherapeutic agents for the treatment of prediabetes. However, several therapies have proven to be effective at delaying or preventing the progression of prediabetes to diabetes. Compared with placebo, acarbose has been shown to reduce progression of prediabetes to T2DM by 25% over a 3.3-year period regardless of age, sex, or BMI (Chiasson et al., 2003).

Pioglitazone reduced the risk of conversion to diabetes in patients with isolated IGT or with combined IFG and IGT in

both men and women, as well as in all age and weight groups compared with placebo (DeFronzo et al., 2011). Unfortunately, the mean weight gain in pioglitazone-treated patients was 3.6 kg. Thus, one might argue that pioglitazone may be a strong candidate as a pharmacologic intervention for prediabetes. However, use of pioglitazone in this patient population will likely result in weight gain.

The ORIGIN Trial (Outcome Reduction with Initial Glargine Intervention) was a 6-year RCT designed to assess the effects of treatment with insulin glargine compared with standard care on cardiovascular outcomes in more than 12,500 subjects worldwide. Study participants had either prediabetes or early T2DM, as well as a high cardiovascular risk profile. A total of 6264 patients were randomized to receive glargine titrated to achieve fasting normoglycemia. Glargine achieved the targeted long-term glycemic control (median fasting glucose of 93.6 mg/dL and A1C of 6.2%) over 6.2 years without increasing the overall incidence of cancer or heart disease. In addition, glargine delayed the progression from prediabetes to T2DM by 28%. However, patients randomized to the glargine group experienced nearly three times the frequency of hypoglycemia events compared with those in the standard cohort and gained on average 3.5 lb over the course of the study (Gerstein et al., 2012).

Recommended treatment strategies for managing prediabetes vary depending on the particular published guidelines consulted and are summarized in Table 34-3.

In summary, patients who are at high risk for diabetes should be screened for prediabetes and clinical diabetes using a fasting blood glucose, 2-hour post-glucose challenge, or A1C test (assuming patients are not pregnant). Unless a patient has symptoms strongly suggestive of diabetes (e.g., thirst, weight loss, blurred vision, paresthesias, and fatigue) in association with significantly abnormal screening laboratory values, a diagnosis of abnormal glucose tolerance should be confirmed with repeat testing.

For individuals who are diagnosed with prediabetes (IFG or IGT), adoption of healthy lifestyle choices with the goal of restoring normal glucose regulation becomes the key to preventing disease progression to T2DM. Every 1 kg of weight lost is associated with a 16% reduction in the risk of progression to diabetes. Physical activity improves peripheral insulin resistance and enhances weight loss.

Patients also should be instructed to monitor their blood glucose levels. One common recommendation is to perform 7-point SMBG (before and after each meal and at bedtime) for 3 successive days before each clinic appointment. This will allow the clinician to gauge changes in fasting and postabsorptive glucose values that require attentive intervention.

The American Association of Clinical Endocrinologists (AACE) recommends initiating off-label use of metformin in patients likely to progress to clinical diabetes whose A1C level is greater than 6.0% (Garber et al., 2008). The pharmacologic goal of prediabetes management should be directed toward pancreatic β -cell preservation. Patients who have prediabetes have lost 80% of their β -cell function and are considered to be maximally insulin resistant (Gastaldelli et al., 2004).

Ambitious screening of high-risk patients and encouragement of healthy lifestyle principles by primary care

Table 34-3 Management and Prevention of Type 2 Diabetes Mellitus in High-Risk Individuals

Published Guidelines	Clinical Recommendations for the Management of Prediabetes
American Diabetes Association	Refer to effective ongoing support program targeting a weight loss of 7% from baseline At least 150 min/wk of moderate physical activity such as walking Consider metformin if A1C increases above the threshold of 6% despite lifestyle intervention Monitor annually for progression to clinical diabetes
American Association of Clinical Endocrinologists	Lifestyle intervention strategies, including weight reduction of 5% to 10% from baseline with long-term maintenance Moderate-intensity exercise program for 30 to 60 min/day at least 5 days/wk Dietary recommendations: lower sodium intake, avoidance of excessive alcohol, caloric restriction, increased fiber intake, possible limitation on carbohydrate intake Initiation of metformin or acarbose for “low-risk” patients or pioglitazone for “high-risk” patients or for those in whom lower-risk therapies have not succeeded Incretin therapies may also prove effective in β -cell preservation No targeted A1C is recommended Use statins to achieve an LDL cholesterol level <100 mg/dL, non-HDL cholesterol <130 mg/dL, and/or apolipoprotein B \leq 90 mg/dL Target blood pressure of <130/80 mm Hg Antiplatelet therapy (low-dose aspirin) for all patients with prediabetes for whom there is no identified excess risk for GI, intracranial, or other hemorrhagic condition

GI, Gastrointestinal; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

physicians will reduce the number of individuals who ultimately progress to clinical diabetes and suffer the consequences of a chronic hyperglycemia burden.

Type 2 Diabetes Mellitus

PATHOGENESIS

The Genome-Wide Association study has detected 18 polymorphisms (genetic variations) that may increase a person's likelihood of developing T2DM (Hamman, 1992). Over time and under the influence of environmental triggers, the activation of these alleles distorts the homeostatic control of normal glycemia (Unger, 2012d). Several of the recently described activators of prediabetes and T2DM pathogenesis that may be of particular interest to family physicians are discussed in Table 34-4. Other environmental triggers include low levels of vitamin D; obesity; high-fat diets; lack of physical activity; concurrent illnesses; and use of certain prescription medications, which may induce treatment-emergent diabetes.

Genetically susceptible individuals may possess polymorphisms (alterations in the normal DNA sequencing that form a typical allele) that favor reduction in satiety, increased appetite, reduced energy expenditure, and increased intraabdominal fat accumulation. These individuals will become obese, which will induce physiological stress and overproduction of insulin by their pancreatic β cells. Over time, genetic coding will begin the process of programmed β -cell death (apoptosis). The San Antonio Metabolism Study demonstrated that patients with prediabetes who have 2-hour postprandial glucose levels of 140 to 180 mg/dL have effectively lost 80% of their β -cell function and are maximally insulin resistant. Additionally, 18% of patients with prediabetes are already diagnosed with diabetic retinopathy (Gastaldelli et al., 2004). Thus, the dreaded long-term microvascular (i.e., retinopathy, neuropathy, and nephropathy) and macrovascular (i.e., coronary heart disease, peripheral vascular disease, and stroke)

complications are already in the progressive stages long before these patients progress to T2DM.

MAINTENANCE OF NORMAL GLUCOSE HOMEOSTASIS AND DIABETES PATHOGENESIS

Glucose homeostasis is rigidly maintained within the range of 85 to 140 mg/dL via the interaction of multiple hormones (i.e., insulin, glucagon, amylin, leptin, resistin, glucagon-like peptide 1 [GLP-1], glucose-dependent insulinotropic polypeptide [GIP], adiponectin, growth hormone, cortisol, and somatostatin). Insulin modulates the metabolism of fat and protein while regulating intracellular transport of glucose. Insulin also regulates hepatic glucose production and peripheral glucose uptake and disposal by skeletal muscles and limits lipolysis. The body stores approximately 450 g of glucose, which is used as an energy source for the brain, skeletal muscles, and cellular metabolism. The brain requires 125 g of glucose daily. Another 125 g of glucose is used by the rest of the body. Daily intake of 180 g of dietary glucose and 70 g of glucose from gluconeogenesis (via the kidneys and liver) replenishes the body's glucose stores (Unger, 2012a).

A decrement in plasma glucose of as little as 20 mg/dL (i.e., from 90 to 70 mg/dL) will suppress β -cell insulin release while triggering the release of counterregulatory hormones (i.e., glucagon, catecholamines, cortisol, and growth hormone) (Gerich, 1988). Likewise, a 10-mg/dL increase in plasma glucose will stimulate insulin secretion and mitigate glucagon release by the pancreatic α cells (Shrayef and Gerich, 2010).

Postabsorptive endogenous glucose release is maintained by hepatic glycogenolysis (the breakdown of glycogen, accounting for 50% of the total basal glucose) and hepatic gluconeogenesis (the formation of glucose from noncarbohydrate molecules such as amino acids and lactic acidosis, accounting for 30% of the body's basal glucose). Renal gluconeogenesis provides an additional 20% of the body's total endogenous energy stores. This “basal glucose” prevents hypoglycemia while supplying sufficient energy

Table 34-4 Environmental Activators of Type 2 Diabetes Mellitus

Environmental Activator	Suspected Mechanism Leading to Induction of Type 2 Diabetes Mellitus
Advanced age	Aging-related alterations of DNA methylation can affect cell signaling and gene transcription. This may upregulate a state of chronic inflammation in older individuals.
Late-morning rising and large caloric intake at dinner (late chronotype)	Late bedtimes and late-morning rising are associated with skipping breakfast and shifting more calories consumed to later in the day. This increases the risk of obesity and diabetes.
Sleep disorders (e.g., obstructive sleep apnea, defective REM sleep, shift work–related, insomnia, and restless leg syndrome)	Circadian misalignment affects sleep architecture as well as glucose–insulin metabolism, substrate oxidation, homeostasis model assessment of insulin resistance index, leptin concentrations, and hypothalamic–pituitary–adrenal axis activity. Depression is common in people with sleep disorders and can also increase diabetes risk.
Mental illness	Patients with major depression, bipolar disorder, or schizophrenia tend to smoke, be physically inactive and overweight, and have increased levels of C-reactive protein (favoring an inflammatory state). Low levels of tissue plasminogen activator in patients with schizophrenia may affect signaling within dopamine neurotransmitters, affecting insulin resistance and promoting diabetes.
Exposure to second-hand smoke	Women exposed to second-hand smoke from at least one parent have been found to have an 18% higher rate of diabetes than nonexposed women. Smoking causes adipocyte hypertrophy, insulin resistance, leptin resistance, and chronic pancreatic inflammation.
History of physical or sexual abuse	Results of the Nurses' Health Study II indicate the following associations: Physical abuse: <ul style="list-style-type: none"> ■ Moderate: 26% higher diabetes risk in adults ■ Severe: 54% higher diabetes risk in adults Forced sexual activity before adulthood: <ul style="list-style-type: none"> ■ 1 occasion: 34% higher diabetes risk in adults ■ >1 occasion: 69% higher diabetes risk in adults
Chemical exposure	In patients with a genetic predisposition to the development of diabetes, 10 chemicals have been determined to activate alleles that, in turn, favor the onset of β -cell apoptosis. Chemicals that have the greatest propensity toward β -cell destruction include arsenic, dioxin (a contaminant chemical in Agent Orange), hexachlorobenzene (a banned fungal chemical for agriculture), and perfluorooctanoic acid (a chemical found in Teflon, which is known to be toxic in animals and is found in the blood of 98% of the U.S. population).
Early menarche	Menarche occurring between the ages of 8 and 11 years may increase T2DM risk by up to 70%. Early menarche is associated with obesity and insulin resistance.

REM, Rapid eye movement; T2DM, type 2 diabetes mellitus.

References: Audouze et al., 2013; Elks et al., 2013; Gonnissen et al., 2013; Hoirisch-Clapauch and Nardi, 2013; Johansson et al., 2013; Lajous M et al., 2013; López-Otin et al., 2013; Pouwer et al., 2013; Reutrakul et al., 2013; and Rich-Edwards et al., 2010.

sources for the brain in the fasting state (Gerich et al., 2001). As noted earlier, ingested carbohydrates provide an exogenous source of glucose for the body's energy needs.

Intracellular transport of glucose occurs within skeletal muscles and adipose tissue as endogenous insulin binds to membrane-bound receptors. Glucose transporter type 4 (GLUT4) actively transports glucose intracellularly for storage as glycogen or in adipose tissue as fat.

The gastrointestinal (GI) tract participates in glucose homeostasis by permitting glucose entry to the body during digestion. Approximately 60% of the insulin response to an oral glucose load is prompted by the potentiating effect of two gut-derived incretin hormones. GLP-1, secreted by L cells, helps regulate the rate of glucose appearance by inhibiting glucagon secretion and hepatic glucose production, regulating gastric emptying, and reducing food intake by postulated centrally mediated mechanisms. GIP is secreted by the K cells of the proximal duodenum in response to glucose stimulation enhanced by fat and promotes triglyceride storage in adipose cells.

The levels of both GLP-1 and GIP increase within minutes of eating, probably as a result of a combination of endocrine and neural signals that stimulate incretin release before digested food comes into contact with the L cells of the small bowel and colon. Plasma levels of GLP-1 are low (5–10 pmol/L) in the fasting state and increase rapidly after eating, reaching 15 to 50 pmol/L. Circulating levels of both

GLP-1 and GIP decrease rapidly because of enzymatic inactivation via dipeptidyl peptidase-4 (DPP-4) and renal clearance. Approximately two thirds of the insulin response to an oral glucose load results from the potentiating effect of gut-derived incretin hormones.

The pancreas regulates glucose homeostasis by secreting insulin from centrally positioned β cells and glucagon from α cells located on the periphery of the pancreatic islet. Insulin is secreted in response to high plasma glucose levels and GLP-1 stimulation after nutrient intake.

Insulin is normally secreted into the portal circulation in two phases. In the fasting state, basal insulin is secreted at the approximate rate of 1 unit/hr to minimize hepatic glucose production (Kruszynska et al., 1987). Basal insulin also limits lipolysis and excess flux of free fatty acids (FFAs) to the liver, which can result in a state of postabsorptive insulin resistance. The circulating glucose levels are maintained at a level that allows for the extraction of this energy source by obligate glucose consumers such as the central nervous system. Basal insulinopenia (in T1DM) stimulates hormone-sensitive lipase and FFA release from fat stores, which, in turn, triggers hepatic production and release of ketone bodies, leading to ketogenesis and DKA.

The second-phase postprandial glucose peak occurs between 1 and 2 hours after a meal, with a mean peak time of 75 minutes (Slama et al., 2006). Eating prompts a five- to 10-fold increase in prandial insulin release from pancreatic

β cells in euglycemic individuals. The meal-stimulated insulin response is triggered by a rise in plasma glucose and FFA concentrations, as well as neuroendocrine-augmented release of incretin hormones GIP and GLP-1. At basal insulin levels of 5 to 10 microunits/mL, hepatic glucose production and lipolysis (FFA release) are suppressed, which effectively counteracts the hyperglycemic effects of glucagon. Proximal uptake of glucose within skeletal muscles is not effective. As postabsorptive insulin levels exceed 40 to 50 microunits/mL, hepatic glucose suppression becomes optimally suppressed (Shrayyef and Gerich, 2010). This postabsorptive state may last between 4 and 6 hours and is dependent on the food content of each meal. High-fat meals such as pizza prolong the postabsorptive state (Sheard et al., 2004).

The liver performs two different functions, depending on the level of circulating insulin. In the presence of low levels of insulin (≤ 25 mU/mL; e.g., in the fasting state), glucose is derived from glycogenolysis and gluconeogenesis to maintain euglycemia (Consoli, 1987). As circulating insulin levels rise, glucose is stored in the liver as glycogen and released into the plasma in response to hypoglycemia. After an overnight fast, the liver of a euglycemic individual produces glucose at a rate of approximately 2 mg/kg/min. Interestingly, in T2DM, despite a threefold increase in circulating plasma insulin levels, the liver will secrete an additional 25 to 30 g of glucose nightly into the plasma. Thus, the primary defect in T2DM appears to be related to peripheral glucose disposal caused by defective skeletal muscle transport rather than excessive hepatic glucose production (Unger, 2012A).

Amylin is a peptide hormone that is co-secreted from pancreatic β cells with insulin and is thus deficient in patients with diabetes. Amylin inhibits glucagon secretion, delays gastric emptying, and acts to increase satiety. Amylin also suppresses postprandial triglyceride concentrations and is known to reduce markers of oxidative stress and endothelial cell dysfunction (Unger, 2008b).

Although FFAs are the primary fuel for most organs, glucose is the obligate energy source of the brain under most physiological conditions. Glucose transport across the blood-brain barrier is more efficient than FFA absorption. During a prolonged fast, FFAs and ketone bodies supply the brain with its metabolic requirements (Shrayyef and Gerich, 2010). Lipolysis increases plasma levels of FFAs, which augment insulin resistance at multiple levels. The rise in FFAs impairs both the first- and second-phase insulin response in genetically predisposed individuals (DeFronzo, 2009). This portends to glucotoxicity occurring with each meal. Chronic exposure to elevated plasma glucose favors β -cell apoptosis (cell death). Hepatic glucose production is also accelerated by a rise in FFAs. Additionally, FFAs competitively bind to insulin receptors on myocytes, after which the GLUT4 transport mechanism is blocked from carrying glucose as an energy source from plasma into cells (DeFronzo, 2009).

Intracellular signaling occurs between the β and α cells such that glucose levels are tightly regulated, minimizing the likelihood of postprandial hypoglycemia. In the presence of decreasing plasma glucose levels, the α cells will signal the β cells to cease insulin production and secretion as glucagon levels rise. The secretion of glucagon results in

Table 34-5 Regulators of Normal Glucose Homeostasis

Regulating Component	Glucose Production	Glucose Disposal	Lipolysis

hepatic gluconeogenesis and a return to euglycemia. As β cell function and mass deteriorates, the neurologic pathways of communication between the α and β cells are disrupted, resulting in excess glucagon production. Clinically, patients experience elevations in fasting and postabsorptive glucose levels.

The role of the kidneys in maintaining normoglycemia through the filtration and reabsorption of glucose and gluconeogenesis is well established. Each day, 180 L of plasma filters through the kidneys, translating into a filtration load of approximately 180 g of glucose. Ninety percent of renal glucose reabsorption occurs within the proximal glomeruli tubules, where sodium-glucose co-transporter 2 (SGLT2) is present. Ten percent of circulating glucose is reabsorbed in the distal tubules via sodium-glucose co-transporter 1 (SGLT1). SGLT1 is also expressed in the gut and is responsible for absorption of both dietary glucose and galactose. The glucose transport mechanism becomes saturated when plasma glucose levels exceed 180 to 190 mmol/L. Beyond the point of transporter saturation, any additional glucose is detected as glycosuria (DeFronzo et al., 2012). The key hormonal and metabolic regulators of normal glucose homeostasis are shown in Table 34-5.

Insulin acts as a growth factor in the brain and supports neuronal repair, dendritic sprouting and synaptogenesis, and protection from oxidative stress. The increased risk of Alzheimer disease, Parkinson disease, and stroke in people with T2DM suggests that shared mechanisms or pathways of cell death, possibly related to insulin dysregulation, may underlie all of these disorders. Although the disease anatomy varies with each disorder, a wide range of genetic and environmental factors triggers activation of similar biochemical pathways in all of them, suggesting a complex network of biochemical events that feed into a final common path toward cellular dysfunction and death (Rasool et al., 2013).

Patients with T2DM exhibit multiple abnormalities in glucose homeostasis, including impaired first- and second-phase insulin secretion; inappropriately timed and excessive glucagon secretion; increased hepatic glucose production despite elevations in endogenous plasma insulin levels; reduced peripheral uptake of glucose within skeletal muscle cells; loss of central neural protection promoting alterations in satiety and weight gain; an overexpression of SGLT2 within the renal proximal tubules, subsequently increasing plasma reabsorption of glucose and promoting insulin resistance; amplified lipolysis, resulting in β cell apoptosis; and loss of the meal-triggered insulin response, which may

Table 34-6 Summary of Pathological Deficits Associated with Type 2 Diabetes Mellitus

Target Organ/Tissue	Physiological Defects	Glycemic Effects
Pancreatic β cells	Loss of first-phase insulin secretion Delayed second-phase insulin secretion Loss of amylin secretion	Glucose toxicity results in β -cell apoptosis.
Pancreatic α cells	α -Cell hypertrophy Loss of α - and β -cell signaling results in loss of appropriate and timely counterregulation; patients are more likely to develop hypoglycemia awareness autonomic failure over time. Exaggerated, paradoxical, and untimely secretion of glucagon during both the fasting and postprandial states	Hyperglucagonemia results in glucose toxicity, β -cell destruction, and excessive hepatic glucose production. Patients experience an increase in fasting and postprandial glucose levels; this increases their A1C. Insulin resistance is exacerbated.
Hepatocytes	Excessive hepatic glucose production despite initial elevations in circulating plasma insulin levels The liver excretes >25 g/day of extra glucose into the plasma	Increases insulin resistance Increases gluconeogenesis and glycogenolysis
Myocytes	Impaired uptake and intracellular utilization of glucose	Increases peripheral insulin resistance Increases fasting and postabsorptive glucose levels Marked deficiency in peripheral glucose utilization is the most significant defect observed in insulin resistance.
Gut	Reduction in secretion of GLP-1 and GIP by the intestines in response to oral glucose stimulation When GLP-1 is secreted, \approx 80% of the gut hormone is immediately deactivated by DPP-4; reduced levels of GLP-1 result in proportionally lower amounts of GLP-1 being expressed at pancreatic β -cell receptors. GLP-1 resistance at target tissue site Amylin levels are reduced within pancreatic islets; amylin and insulin are co-secreted in a glucose-dependent manner.	Alters gastric emptying Causes weight gain Increases fasting and postprandial glucose levels Reduces sense of satiety Causes loss of neuroprotection against Alzheimer disease and Parkinson disease Reduction in amylin accelerates gastric emptying and impairs satiety. The overall effect is a rise in postprandial glucose values.
Adipose tissue	Increased lipolysis in response to a reduction in circulating endogenous insulin	β -cell destruction Increases FFAs Increases hepatic glucose production because the liver is unable to store glycogen Impairs GLUT4 transport of glucose into muscle, exacerbating peripheral insulin resistance
Brain	Loss of neuroprotection	Increases appetite Favors obesity Increases oxidative stress Insulin resistance appears to be associated with Alzheimer disease and Parkinson disease.
Kidneys	Increased expression of SGLT2 in the proximal glomerular tubules Daily renal filtered glucose threshold increases from 180 to 240 g/day.	90% of filtered glucose is absorbed via SGLT2 in the proximal tubules, and 10% is absorbed by SGLT1 in the distal tubules. SGLT1 is also expressed in the gut, where daily dietary glucose absorption of 180 g occurs. If the renal glucose threshold of the SGLT2 transport mechanism is surpassed, glycosuria occurs. In T2DM, the threshold is increased from 180 to 240 g/day, which results in an increased renal absorption of glucose regardless of the patient's state of chronic hyperglycemia. Excessive reabsorption of glucose from the kidneys exacerbates insulin resistance.

DPP-4, Dipeptidyl peptidase-4; FFA, free fatty acid; GIP, glucose-dependent insulintropic polypeptide; GLP-1, glucagon-like peptide 1; GLUT4, glucose transporter type 4; SGLT2, sodium-glucose co-transporter 2; T2DM, type 2 diabetes mellitus.

Data from DeFronzo RA. From the triumvirate to the ominous octet: a new paradigm for the treatment of type 2 diabetes mellitus. *Diabetes*. 58:773-795, 2009.

maintain weight and euglycemia for years. [Table 34-6](#) summarizes the common pathogenic pathways related to T2DM.

The pathogenesis of T2DM is multifactorial. Genetically or environmentally challenged individuals begin the transformation from euglycemia to clinically apparent T2DM as their skeletal muscles and hepatocytes exhibit early evidence of insulin resistance. Initially, pancreatic β cells attempt to compensate for IGT by overproducing insulin. Obesity plays a major role in the progression of prediabetes to T2DM. Compared with lean individuals, overweight euglycemic subjects appear to require a longer time to achieve satiety, and the magnitude of their appetite suppression also reduced ([Matsuda, 1999](#)). Thus, obesity tends to

become self-promoting. As meal portions increase, so does the secretion of GLP-1, resulting in β -cell hypertrophy.

Few individuals can maintain hypersecretion of insulin for a prolonged period of time. Patients who have primary relatives with T2DM will lose their acute, first-phase insulin response to a glucose stimulus and experience a delay in the initiation of their second-phase response. IGT will now become apparent as patients progress into a state of prediabetes. Over time, other metabolic defects appear, which tend to aggravate the existing state of hyperglycemia. As endogenous insulin levels decline, lipolysis is accelerated because insulin action normally stabilizes fat cells. Lipolysis further aggravates the first-phase insulin response, promotes

Table 34-7 Factors Promoting Patients' Adherence to Their Diabetes Management Regimen

Higher socioeconomic status and level of education
 Resolution of comorbid mental illness symptomatology
 Spousal, familial, and communal support
 Satisfaction with doctor–patient relationship
 Availability of and support from a diabetes health care team
 Appointment reminder cards, reminder phone calls regarding upcoming appointments, minimal clinic waiting room delays, and emphasis on the positive aspects of patient's diabetes self-management efforts rather than on patient's failures or oversights
 Simplified treatment regimens
 Particular aspect of the regimen; patient adherence to medication regimens surpasses their adherence to lifestyle or behavioral recommendations
 Co-management of “complex” patients with a mental health professional

glycogen breakdown by hepatocytes, and prevents the peripheral uptake of glucose by skeletal muscle cells.

The complex pathogenesis of diabetes underscores the importance of combining rational polypharmacy designed to target specific metabolic defects with ILIs when managing patients with T2DM.

LIFESTYLE INTERVENTIONS FOR TYPE 2 DIABETES MELLITUS

Lifestyle interventions focusing on both diet and physical activity are clearly beneficial for patients with diabetes. Reducing caloric intake to 1100 kcal/day has been shown to decrease fasting blood glucose levels in obese patients with T2DM and in those with normal glucose tolerance in as few as 4 days (Markovic et al., 1998).

Behavior changes are almost always necessary for patients to adopt and maintain a healthy lifestyle, reduce their long-term risks, and perform daily self-care tasks essential to attaining adequate glycemic control. By some estimates, fewer than 50% of patients with diabetes adhere to recommended lifestyle and behavioral guidelines (Peyrot et al., 2005). Furthermore, adherence is a multidimensional concept in that some patients may comply with their medication regimens while ignoring dietary or physical activity recommendations. Others, who say they “feel just fine,” may try to exercise for 2 to 3 hours per day in an attempt to avoid starting medications that are needed to manage their hyperglycemia, hypertension, and hyperlipidemia. In addition, a study of NHANES data collected from patients with T2DM found that 29% of insulin-treated patients, 65% of those taking oral medications, and 80% of those whose diabetes was managed by diet and exercise alone either never performed SMBG—a key component of diabetes self-management—or did so less than once a month (Harris, 2001). Factors that promote patient adherence to their diabetes management regimen are listed in noted in Table 34-7.

New ADA nutrition guidelines published in 2013 focus on overall nutrition and patient preferences rather than any particular dietary prescription (Evert et al., 2013). The “diabetic diet” has been officially replaced with concepts such as “healthful eating patterns” and “individualized

Table 34-8 Medical Nutrition Therapy Recommendations for Patients with Diabetes

Patients with diabetes should receive customized MNT recommendations from a registered dietitian who is familiar with the components of diabetes nutritional interventions. Portion control and healthy food choices are suitable options for patients with literacy and numeracy concerns. Older adults may also benefit from this simplified approach to meal planning. Reducing food intake and increasing energy expenditure is recommended to promote weight loss in obese adult patients with T2DM. Modest weight loss may result in improvement in glycemia, blood pressure, and lipids, especially when initiated soon after patients are diagnosed with diabetes. Intensive lifestyle education and management is recommended for newly diagnosed patients with diabetes. The optimal mix of macronutrients (i.e., carbohydrates, fats, and proteins) in the daily diet should be individualized. Patients' personal preferences regarding foods and metabolic goals should be considered when discussing eating patterns and meal planning. Substituting low-glycemic index foods for higher-glycemic index foods may modestly improve glycemic control. People with diabetes should consume fiber and whole grains in a manner similar to what is recommended to the general public. People with diabetes should minimize their consumption of sugar-containing beverages.

MNT, Medical nutrition therapy; T2DM, type 2 diabetes mellitus. Data from Evert AB, Boucher JL, Cypress M, et al. Nutrition therapy recommendations for the management of adults with diabetes. *Diabetes Care*. 36:3821-3842, 2013.

eating plans.” Clinicians should emphasize personal characteristics and preferences (e.g., patients' tradition, culture, religion, health beliefs, health goals, and financial circumstances) when providing nutrition counseling. In addition, clinicians should refer newly diagnosed patients with diabetes to a registered dietitian to ensure that they receive timely and appropriate medical nutrition therapy (MNT). Highlights of the ADA nutrition recommendations are listed in Table 34-8.

The Look AHEAD study was a 4-year RCT comparing ILI with standard diabetes education and support in 4503 adult patients with T2DM and BMIs of 25 kg/m² or greater. The study sought to determine the frequency of remission from T2DM to prediabetes or normoglycemia between the two groups of subjects. Partial or complete remission of diabetes was defined as transition from meeting the criteria for a diagnosis of diabetes to having prediabetic or nondiabetic levels of glycemia (fasting plasma glucose <126 mg/dL and A1C <6.5% with no antihyperglycemic medication). Partial or complete remission was observed in 11.5% (95% confidence interval, 10.1%–12.8%) of the ILI group at 4 years compared with 1.5% to 2.7% of the conventionally managed individuals (*P* <0.001), thus supporting the importance of early lifestyle intervention after patients are diagnosed with diabetes (Gregg et al., 2012).

Intensive lifestyle intervention also has been considered as a means by which cardiovascular risk may be reduced. Although the Look AHEAD study successfully improved T2DM remission rates when ILI was initiated soon after diagnosis, weight loss and exercise did not translate into a reduction in cardiovascular risk. Weight loss was greater in the intervention group than in the control cohort throughout the study (8.6% vs. 0.7% at 1 year and 6.0% vs. 3.5%

at study end after 9.6 years). The ILI group also demonstrated greater reductions in A1C and greater initial improvements in fitness and cardiovascular risk factors. However, cardiovascular end points occurred in 403 patients in the intervention group and in 418 patients in the control group ($P = 0.51$). Thus, ILI focusing on weight loss did not appear to reduce the rate of cardiovascular events in overweight or obese adults with T2DM (Look AHEAD Research Group, 2013).

Obesity prevalence rates began to increase sharply 30 years ago, and obesity has since emerged as a global public health hazard. Thirty-five percent of the U.S. adult population is obese (BMI ≥ 30 kg/m²), and another 35% is classified as overweight (BMI, 25-29.9 kg/m²) (Flegal et al., 2012). Obesity is associated with disorders such as metabolic syndrome, prediabetes, T2DM, and CVD. Indeed, 80% of patients with T2DM are overweight or obese (National Diabetes Information Clearinghouse, 2013). The third report of the U.S. National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults classified T2DM as a coronary heart disease risk equivalent (NCEP Expert Panel, 2002). This classification was based in part on the observation that people with T2DM and no prior myocardial infarction (MI) (mean age, 58 years) were at the same risk as people without diabetes who had a prior MI (mean age, 56 years) for MI (20% and 19%, respectively) and coronary mortality (15% and 16%, respectively) (Haffner et al., 1998).

Therapy for obesity includes lifestyle modification, pharmacologic interventions, and bariatric surgery. The presence and severity of obesity-related complications should be assessed before initiating therapy for overweight patients. Complications related to insulin resistance include hypertension, hyperlipidemia, treatment-resistant diabetes, obstructive sleep apnea, proteinuria, and fatty liver disease. Patients also may have complications related to mechanical or functional disorders, including gastroesophageal reflux, stress incontinence, immobility, and joint pain.

Weight loss medications (i.e., phentermine/topiramate ER, lorcaserin) should be considered for overweight or obese patients with T2DM who fail to achieve moderate weight loss (i.e., $\approx 10\%$ of their baseline weight) through lifestyle modification (Garvey, 2013). Weight loss drugs can also be used in conjunction with certain oral agents for diabetes (e.g., metformin, SGLT2 inhibitors, and GLP-1 receptor agonists), which are discussed in greater detail in the Long-Term Complications of Diabetes section of this chapter. Patients who fail to improve their metabolic profiles while using FDA-approved weight loss agents may be candidates for bariatric surgery (also known as “metabolic surgery”).

Bariatric surgery consists of several well-defined procedures. Restrictive surgeries such as laparoscopic adjustable gastric banding (LAGB) and vertical banded gastroplasty (VBG) reduce the volume of the stomach by 85% to decrease food intake and induce early satiety. VBG is also known as sleeve gastrectomy. LAGB is considered a minimally invasive intervention through which a restrictive band is placed around the upper stomach to partition a small proximal pouch. Initially, these bands were designed for open surgical placement and were not adjustable. However, further refinement has now enabled surgeons to place the adjustable

Table 34-9 Preoperative Factors Positively Predicting Diabetes Resolution after Bariatric Surgery in Severely Obese Patients with Type 2 Diabetes Mellitus

Baseline A1C of 6.5% to 7.9% (77% remission rate vs. 50% remission rate for those having a baseline A1C $>10\%$)
Duration of diabetes of ≤ 5.5 years
Baseline C-peptide >3 ng/mL (suggestive of severe insulin resistance)
Baseline BMI >45 kg/m ²
Significantly elevated basal and 2-hour postprandial insulin levels

BMI, Body mass index.

Data from Scherthaner G, Brix JM, Kopp HP, et al. Cure of type 2 diabetes by metabolic surgery? A critical analysis of the evidence in 2010. *Diabetes Care*. 34(suppl 2):S355-S360, 2011.

Table 34-10 Benefits of Bariatric Surgery in Severely Obese Patients with Type 2 Diabetes Mellitus

Average 1.72 life-years gained in patients with a history of diabetes for <5 years before surgery
Patients with a BMI of 30-34 kg/m ² have the most cost-effective outcomes over time
Cost-effectiveness ratio of \$7,000 to \$12,000 per quality-adjusted life year gained
Cost savings greatest in patients 65 to 74 years of age who have had diabetes for <5 years
Bariatric surgery resulted in a remission rate of $\approx 40\%$ to 80% (After bariatric surgery, the likelihood of diabetes relapse is 8% annually.)
Systolic blood pressure reduced 11.25% during the first 2 years followed by an additional 1.4% reduction until year 10; no further improvement in blood pressure observed thereafter
Total cholesterol reduced 16.1% during the first 2 years followed by a 1.2% reduction each year thereafter until year 10
HDL cholesterol improves 10% during the first 2 years and then decreases by 0.05% through year 10

BMI, Body mass index; HDL, high-density lipoprotein.

Data from Hoerger TJ, Zhang P, Segel JE, et al. Cost-effectiveness of metabolic surgery for severely obese adults with diabetes. *Diabetes Care*. 33:1933-1939, 2010.

appliance laparoscopically. Malabsorptive procedures such as biliopancreatic diversion (BPD) shorten the small intestine to decrease nutrient absorption. Combined procedures such as the roux-en-Y gastric bypass (RYGB) incorporate both restrictive and malabsorptive elements. RYGB surgery is considered the gold-standard treatment for severe obesity. Both BPD and RYGB alter the secretion of gut hormones that affect satiety. Factors that predict the resolution of T2DM after bariatric surgery are listed in Table 34-9. Table 34-10 lists the benefits of bariatric surgery for patients with T2DM.

Patients who are considering bariatric surgery should be counseled about the risks and benefits of the different types of available procedures. Specific contraindications to bariatric surgery are few and include mental or cognitive impairment that limits patients' ability to understand the procedure and thus precludes informed consent. Very severe coexisting medical conditions such as unstable coronary artery disease or advanced liver disease with portal hypertension may, in some instances, render the risks of surgery unacceptably high. On average, bariatric surgery is associated with a mortality risk in the range of 0.3%. Significant or major complications occur in just over 4% of patients (Flum et al., 2009).

Physical activity and weight loss lower the risk of developing T2DM by 58% in high-risk individuals ([American College of Sports Medicine and ADA, 2010](#)). Physical activity decreases peripheral insulin resistance by improving glucose uptake by skeletal muscle cells. During muscle activity, glucose is transported into myocytes and used to replenish muscle glycogen stores. Glycogen is metabolized during exercise in a process known as glycogenolysis. Moderate exercise consisting of the use of 350 kcal of energy will result in improvement of peripheral insulin sensitivity over the course of 24 hours ([Newsom et al., 2013](#)). In T2DM, GLUT4 is impaired at rest but enhanced by the muscle contractions that occur during physical activity. Thus, insulin resistance at the periphery improves with exercise ([Wang Y et al., 2009](#)) Recommendations for T2DM physical activity prescribing are shown in [Table 34-11](#).

Self-monitoring of blood glucose allows patients to evaluate their individual responses to lifestyle and pharmacologic interventions and to assess whether they are achieving their short-term glycemic targets. SBGM can also be used to detect extreme changes in blood glucose levels, including hypoglycemia, hyperglycemia, and DKA. Patients who successfully use SBGM can learn to adjust insulin doses, alter activity levels, and better understand the correlation between food intake and pharmacologic therapy.

Structured glucose testing is useful for recognizing specific problematic glycemic patterns such as hypoglycemia, fasting hyperglycemia, and postprandial hyperglycemia. Identifying the most likely cause of these patterns can assist patients in altering behaviors or changing medications or dosages to improve overall glycemic control ([Polonsky et al., 2009](#)). Structured testing can be performed before and after meals to determine the effect of food intake on glycemic excursions. Patients who perform SMBG before and after exercise will learn how insulin resistance at peripheral muscle sites appears to improve with mild to moderate activity performed 5 days per week. In addition, by testing pre- and postprandial blood glucose at breakfast for 2 or 3 days before initiating exercise, they can better determine at what time of day exercise will have the greatest glucose-lowering effect. When a patient begins an exercise program, this paired testing pattern is simply repeated, and exercise-related reductions in blood glucose can be identified. The same SMBG testing pattern can be repeated for each meal but should be individualized based on patients' eating, working, exercise, and sleeping habits.

The difference between premeal and 2-hour postprandial blood glucose levels is known as the Δ (or delta, a math symbol indicating the difference between two values). A physiological response to a meal should result in a positive Δ value of 0 to 50 mg/dL. For example, an insulin-requiring patient with T2DM checks his blood glucose before lunch and notes the blood glucose level as 100 mg/dL. He anticipates that he will require 8 units of rapid-acting insulin to cover the carbohydrates consumed for that meal. Two hours after eating, his postmeal glucose is 134, and his Δ is +34. This means that he administered the correct amount of insulin for that meal. The interpretation of Δ values resulting from structured SMBG around meals is explained in more detail in [Table 34-12](#). Note that any negative Δ values 2 hours postprandially would indicate that the patient is at risk for developing postabsorptive hypoglycemia. Thus,

Table 34-11 Summary of Physical Activity Recommendations for Patients with Type 2 Diabetes Mellitus

- Perform at least 150 minutes of moderately intense physical activity (50%-70% of maximum heart rate) over at least 3 days/wk with no more than 2 consecutive days void of exercise.
- Indications for exercise stress testing:
 - Age >40 years with or without cardiovascular risk factors in addition to diabetes
 - Age >30 years plus:
 - T1DM or T2DM of a disease duration >10 years
 - Hypertension
 - Current cigarette smoker
 - Dyslipidemia
 - Proliferative or preproliferative retinopathy
 - Chronic kidney disease, including microalbuminuria
 - Known history of stroke, coronary artery disease, or peripheral vascular disease
 - Autonomic neuropathy
 - End-stage renal disease
- Unless contraindicated, patients should be encouraged to participate in resistance training (2 to 4 sets of 8 to 10 repetitions each) twice weekly.
 - Adults should train each major muscle group 2 or 3 days/wk using a variety of exercises and equipment.
 - Very light or light intensity is best for older people or previously sedentary adults starting exercise.
 - Two to four sets of each exercise will help adults improve strength and power.
 - For each exercise, 8 to 12 repetitions will improve strength and power, 10 to 15 repetitions will improve strength in middle-aged and older people starting exercise, and 15 to 20 repetitions will improve muscular endurance.
 - Adults should wait at least 48 hours between resistance training sessions.
 - Contraindications for resistance training include poor left ventricular function, unstable angina, proliferative diabetic retinopathy, cardiac autonomic neuropathy, a history of exercise-induced ventricular dysthymias, vertigo, and vestibular dysfunction.
- Monitor blood glucose before and after exercise. Proactively treat for hypoglycemia:
 - If pre-exercise blood glucose level is <100 mg/dL, patients using secretagogues or insulin should consume 15 g of carbohydrates before initiating physical activity.
 - Consuming 5 to 30 g of carbohydrates may be necessary to minimize hypoglycemia risk during intense or prolonged physical activity lasting more than 30 minutes.
- Patients requiring supervised cardiovascular rehabilitation programs include:
 - Those with cardiac autonomic neuropathy, coronary artery disease, peripheral vascular disease, stroke, proliferative retinopathy, macular edema, autonomic neuropathy (loss of sweating capacity), or peripheral neuropathy (increased risk of falls and foot ulcerations)

T1DM, Type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus. American College of Sports Medicine and American Diabetes Association, 2010; Bjarnason-Wehrens et al., 2004; Garber CE et al., 2011.

patients with negative Δ values should continue monitoring their blood glucose 3 and 4 hours after the meal to ensure that they do not experience a rapid decline in blood glucose.

In summary, lifestyle intervention provides the foundation of care for all patients with diabetes. Patients at high risk for developing diabetes should be encouraged to increase their physical activity and to adopt a healthier meal plan in an attempt to reduce both their weight and their cardio-metabolic risk. ILI appears to have a greater effect on inducing diabetes remission if it is initiated soon after patients

Table 34-12 Interpretation of Structured Self-Monitoring of Blood Glucose Δ Values*

Δ (mg/dL)	Interpretation	Intervention
0-50	Correct insulin was given for amount of carbohydrates consumed Correct lag time procedure was followed	None
51-100	Insulin-to-carbohydrate undercalculation Incorrect lag time Possible snacking between end of meal and 2-hour test	Increase prandial insulin dose by 1 to 2 units next time this type of food is eaten Make sure to inject insulin at least 15 minutes before meals
100-200	Patient possibly had elevated blood glucose before the meal and did not take a correction dose of insulin Insulin-to-carbohydrate mismatch Insulin may have been omitted Possible error in SMBG technique	Teach patient how to use a premeal insulin sensitivity factor (see discussion of physiological insulin replacement) If a patient omitted insulin, the Δ value illustrates the effect of this decision If postmeal Δ is consistently elevated, increase prescribed baseline insulin dose by 1 unit/day until Δ is 0-50 or 2-hour postprandial glucose is <140 mg/dL Educate patient on proper SMBG technique; touching fruit, cake, or ice cream after a meal may leave sugar deposits on the fingertips and result in falsely high SMBG results
Any negative value (e.g., -25)	Miscalculation of insulin-to-carbohydrate ratio; too much insulin bolused for amount of carbohydrates eaten; patient is likely to become hypoglycemic in the next 1 to 2 hours	Educate patient regarding insulin absorption principles: 1 hour after administering bolus, 90% of rapid-acting insulin analog remains in depot; 2 hours after bolusing, 60% of insulin remains in depot. Thus, if 10 units of insulin are given at 8:00 AM, 6 units remain to be absorbed at 10:00 AM. A premeal glucose value of 120 mg/dL and a 2-hour postprandial value of 90 mg/dL yield a Δ of -30 mg/dL. The patient still has 6 units remaining to be absorbed and is likely to become hypoglycemic. Appropriate surveillance and intervention should be initiated.

*The Δ value is calculated by determining the difference between the premeal and 2-hour postprandial glucose values. A physiological rise in 2-hour postprandial glucose levels from baseline in euglycemic individuals is ≤ 50 mg/dL.

SMBG, Self-monitoring of blood glucose.

Adapted with permission from Unger J. *Diabetes management in primary care*. 2nd ed. Philadelphia: Lippincott, Williams and Wilkins; 2012.

are diagnosed with impaired glycemic control. Patients should be referred to a registered dietitian soon after being diagnosed to receive their customized MNT and meal program.

The ADA and the American College of Sports Medicine encourage the prescribing of cardiovascular and resistance training for nearly all patients with diabetes. Before initiating any form of intensive physical activity, patients with a disease duration of longer than 10 years should undergo a stress test. Patients with advanced disease should exercise in a supervised environment.

Obese or overweight patients with T2DM may be considered candidates for antiobesity pharmacotherapeutic interventions, especially if they are at high risk for CVD. Patients who are unable to modify their weight should be referred to a bariatric surgeon.

The use of structured SMBG will allow patients to determine patterns of glycemic control in relation to the use of their medications, meals, and exercise habits. In addition, structured SMBG may be useful in predicting the onset of hypoglycemia.

MEDICAL MANAGEMENT OF PATIENTS WITH TYPE 2 DIABETES MELLITUS

The goals of therapeutic intervention in patients with T2DM are to (1) encourage the adoption of healthy lifestyle choices (i.e., cease alcohol, nicotine, and substance abuse; follow a healthful eating plan; and increase physical activity); (2) encourage modest weight reduction (5%-10% from baseline); and 3) introduce safe, effective, and rational pharmacologic interventions in a timely manner that will allow patients to achieve their customized metabolic targets.

Primary care physicians are actively involved in screening, diagnosing, and managing patients with diabetes; 90% of all patients with diabetes are managed in the primary care setting. Diabetes is a multifactorial disease state that is chronic and progressive. As such, its management requires frequent reassessment and adjustment.

ENCOURAGING PATIENT SELF-CARE

Clinicians should be viewed as “coaches” who direct diabetes care, although patients are ultimately responsible for carrying out the complex daily self-management regimen. Unlike with other chronic diseases such as cancer, patients with diabetes are required to make multiple decisions each day that may affect their glycemic control. Glucose levels may vary based on physical activity, sleep duration, timing and dosing of antihyperglycemic therapies, food consumption, macronutrient intake, renal and hepatic status, concomitant prescribed medications, recent history of hypoglycemia, and accuracy of SMBG technique. Therefore, patients must take an active role to achieve their metabolic targets and successfully manage their diabetes.

Diabetes self-management can become all-encompassing and distressful. Patients with diabetes have to make choices and decisions throughout each day in hopes of keeping their blood glucose levels within the physiological range of 90 to 130 mg/dL. Patients should never be blamed for failing to achieve their fasting blood glucose, postprandial glucose, or A1C targets. Instead, clinicians must work with patients to provide the tools they need to become successful at diabetes self-management.

When euglycemic individuals eat, their glucose levels are maintained within a narrow range (85-126 mg/dL). This

occurs because the normally functioning pancreas is provided with neuroendocrine signals, allowing its α and β cells to coordinate the perfect level of insulin secretion to cover the carbohydrates consumed in each meal. Patients with diabetes have multiple physiological deficits. Over time, their β -cell function deteriorates to the point at which insulin must be used to maintain adequate control of plasma glucose levels. When insulinopenic patients eat, exogenous insulin must be given based on a dose calculation they determine before each meal. Dose determinations are not always simple, and by no means are they always correct. Patients have to substitute their brain for their pancreas to control their glycemia and self-manage their disease. Therefore, criticism of patients with diabetes should be tempered at all times, and patients should be encouraged to attain the best level of glycemic control of which they are capable.

INDIVIDUALIZED METABOLIC TARGETS

Randomized controlled trials such as the DCCT in patients with T1DM (DCCT Research Group, 1993) and the UKPDS (U.K. Prospective Diabetes Study Group, 1998) and Kumamoto Study (Ohkubo et al., 1995) in those with T2DM established glycemic therapeutic goals that minimize the risk of long-term complications. Neither the DCCT nor the UKPDS was successful at maintaining A1C levels below 7% in their intensively treated cohorts.

More recently, published RCTs have attempted to intensify patients' glycemic control to a target A1C below 6.5% using a variety of interventions. The primary objective of the ACCORD study (ACCORD Study Group, 2008) was to decrease CVD in high-risk patients. More than 10,000 patients either with or at risk for developing CVD were randomized either to an intensive intervention targeting an A1C level of less than 6.0% or to an intervention with a more conservative A1C target of less than 7.9%. The intensively treated cohort demonstrated a 22% higher rate of cardiovascular mortality than the more conservatively managed patients. Based on ACCORD data, the ADA now recommends that clinicians consider patients' disease duration, severity of comorbidities, hypoglycemia history, and life expectancy when setting individualized metabolic targets. Patients deemed to be at high risk should have an A1C target of 7.5% to 8%, but most healthy patients should be treated to an A1C target of 6.5% or less to 7% (ADA, 2013b; Ismail-Beigi et al., 2011).

Some have speculated that the excess mortality rate in ACCORD may have been related to hypoglycemia. Interestingly, however, severe hypoglycemia was associated with an increased risk of death in the more conservative treatment cohort more so than in the intensively managed cohort (Bonds et al., 2012). Additionally, severe hypoglycemia events were more prevalent in patients having a higher baseline A1C; those with A1C levels closer to the 7% target had more frequent, but less severe, hypoglycemia episodes. Hypoglycemia results in the release of counterregulatory hormones, including cortisol, norepinephrine, and epinephrine. Hypoglycemia may also increase the risk of QTc prolongation (Beom et al., 2013). Patients who experience QTc prolongation during an episode of severe hypoglycemia would be subject to potentially fatal arrhythmias (i.e.,

torsades de pointes ventricular tachycardia) induced by the release of catecholamines (Figure 34-1).

Could repeated episodes of hypoglycemia be protective against sudden death, as observed in ACCORD patients who were closer to the prescribed A1C target? A single episode of hypoglycemia will result in defective counterregulation and a blunted adrenergic response to future events. Additionally, patients who become hypoglycemic lose their ability to recognize the symptoms of low blood glucose. Thus, hypoglycemia awareness/autonomic failure (also called "hypoglycemia unawareness") may result in a form of hypoglycemia preconditioning that protects against the development of a fatal arrhythmia.

Patients with suboptimal glycemic control who are ambitiously treated to a fasting glucose or A1C level based on politically motivated incentive payment programs may be at risk for developing fatal arrhythmias. Clinicians must consider all aspects of patients' medical, behavioral, and social history before determining their optimal individualized glycemic targets.

Metrics other than A1C are also important to evaluate to identify and mitigate each patient's long-term risk for complications. Hirsch and Brownlee have suggested that A1C and duration of diabetes (glycemic exposure) accounted for only 11% of the total risk in the retinopathy cohort of T1DM patients in the DCCT (Hirsch and Brownlee, 2010). The remaining 89% of a patient's likelihood for developing microvascular complications may be derived from genetics, environmental factors, poorly controlled lipids, and hypertension. Although targeting glycemic control patients is a noble goal, clinicians must never forget the complex metabolic nature of T2DM. Normalization of lipids, blood pressure, and renal function cannot be overshadowed by the struggle to become a "glycemic perfectionist."

The ADA and AACE have each published statements providing a framework for initiating and titrating pharmacologic therapies for patients with T2DM in the primary care setting (ADA, 2013b; Garber et al., 2013). A summary of the highlights for the AACE comprehensive diabetes management algorithm is offered in Table 34-13. Both the ADA and AACE statements include recommended metabolic treatment targets, which are summarized in Table 34-14. Clinicians should remember that managing patients with diabetes entails customizing targets for blood pressure, weight, and lipids, in addition to glycemia.

The American Academy of Family Physicians has yet to publish any guidelines on diabetes management. Patients are unique entities with individual concerns, fears, and abilities to address their given disease state. Primary care physicians must never lose sight of the importance of directing individualized care toward what is safe and efficacious for each patient.

PHARMACOLOGIC MANAGEMENT OF TYPE 2 DIABETES MELLITUS

After pharmacotherapy is initiated, patients must become even more active participants in their diabetes self-management. Performing SMBG, adhering to MNT and physical activity recommendations, and undergoing professional surveillance to determine whether metabolic targets

Figure 34-1 Torsades de pointes is a distinctive form of polymorphic ventricular tachycardia characterized by a gradual change in the amplitude and twisting of the QRS complexes around the isoelectric line. Torsades de pointes is associated with a prolonged QTc interval, which may be congenital or acquired. The arrhythmia usually terminates spontaneously but may reoccur and degenerate into a fatal form of ventricular fibrillation.

Table 34-13 Summary of the American Association of Clinical Endocrinologists 2013 Treatment Algorithm for Diabetes

- Lifestyle intervention remains the foundation of diabetes care across all A1C levels.
- If a patient's A1C is $\geq 9\%$, initiate and titrate basal insulin.
- Patients with an A1C $< 7.5\%$ may be treated with monotherapy, as follows:
 - Metformin is considered first-line therapy.
 - Second-line therapies include GLP-1 receptor agonists, DPP-4 inhibitors, and α -glucosidase inhibitors.
 - If A1C is $> 6.5\%$ after 3 months of therapy, add a second agent.
- Consider dual or triple combination therapy in patients with A1C levels $\geq 7.5\%$ and $\leq 9\%$, as follows:
 - GLP-1 receptor agonists and DPP-4 inhibitors are the preferred agents.
 - Basal insulin may also be used.
 - SGLT2 inhibitors are acceptable drugs for combination therapy (ADA guidelines do not mention SGLT2 inhibitors).
 - If A1C is not at goal after 3 months, add a third agent.
- For patients who are symptomatic with an A1C of 8.5%, initiate basal insulin.
- Practical strategies to consider when customizing pharmacologic intervention include:
 - Prescribe medications that are less likely to result in hypoglycemia.
 - Medications that minimize weight gain should be preferred.
 - A1C testing should be repeated every 3 months until patients achieve their individualized goals.
 - Lifestyle intervention should be emphasized at each visit.
 - Smoking is unacceptable; encourage patients to stop nicotine use. Patients may be referred to 800-QUIT-NOW for free smoking cessation assistance.
 - Combination therapy using agents with complementary mechanisms of action is often required to help patients to achieve their prescribed glycemic targets.
 - When using insulin, DPP-4 inhibitors, SGLT2 inhibitors, metformin, GLP-1 receptor agonists, and bromocriptine may be continued. Sulfonylureas and thiazolidinediones should be discontinued because of increased risks of weight gain and hypoglycemia.
- Cost is important, but safety trumps cost.

ADA, American Diabetes Association; DPP-4, Dipeptidyl peptidase-4; GLP-1, glucagon-like peptide 1; SGLT2, sodium-glucose co-transporter 2.

Table 34-14 Metabolic Treatment Targets for Most Patients with Diabetes

Metabolic Target	AACE Guidelines	ADA Guidelines
A1C (%)	≤6.5	≤7.0
Fasting or premeal blood glucose (mg/dL)	<110	70-130
2-hour postprandial blood glucose (mg/dL)	<140	<180
Blood pressure (mm Hg)	<130/80	<140/80
LDL cholesterol (mg/dL)	<100 (<70 for high-risk patients with CVD)	<100
HDL cholesterol (mg/dL)	>40 for men; >50 for women	>50
Triglycerides (mg/dL)	<150	<150

AACE, American Association of Clinical Endocrinologists; ADA, American Diabetes Association; CVD, cardiovascular disease; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

are being achieved are all necessary to lessen the impact of diabetes-related complications.

Patients should be aware of the potential risks and clinical benefits of the different types of oral agents. Some medications may increase weight or induce hypoglycemia; others must be held before undergoing certain diagnostic procedures. The continued use of oral agents during acute inpatient care may be detrimental. Insulin is the preferred drug for patients with diabetes who are admitted to the hospital for acute illness. Insulin also may be necessary in certain situations that complicate T2DM management, including concomitant use of corticosteroids, surgery, restricted oral nutrient intake, and pregnancy. Table 34-15 lists the noninsulin medications currently approved for patients with T2DM, as well as their mechanisms of action and safety concerns. Information on dosing adjustments required for incretin agents based on renal status is provided in Table 34-16.

In summary, clinicians should individualize metabolic targets for patients with diabetes. Lifestyle intervention remains the foundation of care for all patients with diabetes. Patients whose glycemic control deteriorates over time should be ambitiously managed initially with metformin or a combination of medications designed to address their particular pathophysiological defects. Treatment-naive patients will likely have some remaining β -cell function at the time of diagnosis and should respond to oral agents or incretins. Over time, β -cell function and mass will deteriorate, necessitating the use of insulin to control fasting and postprandial glucose excursions. Pharmacotherapy agents that have a low risk for potentiating hypoglycemia and weight gain should be preferred. Specific agents should be selected based on their likely effectiveness in reducing blood glucose levels to patients' individualized target range while taking into consideration patients' unique characteristics and preferences.

INSULIN INITIATION FOR PATIENTS WITH TYPE 2 DIABETES MELLITUS

Insulin is the most powerful tool in the diabetes pharmacologic armamentarium. Timely initiation of exogenous insulin appears to reduce insulin resistance and induce β -cell rest and does not increase cardiovascular or cancer risk over time (Gerstein et al., 2012). Thus, insulin initiation should be considered for symptomatic patients who have an A1C higher than 8.5% or for any patients who have an A1C higher than 9.0%. Basal insulin is simple to initiate and may be used safely in combination with several oral agents and with GLP-1 receptor agonists.

Type 2 diabetes mellitus is a progressive disease. Therefore, its effective treatment requires early initiation of appropriate therapies, frequent monitoring, and reassessment to make certain that therapeutic goals are attained.

Exposure to chronic hyperglycemia can cause micro- and macrovascular complications, many of which may already be apparent at the time of diabetes diagnosis. Multiple defective metabolic pathways work to overcome the body's defensive mechanisms, resulting in loss of β -cell function and mass. Ultimately, genetically prone individuals whose β cells become exposed to a progressively antagonistic metabolic environment will demonstrate apoptosis. As endogenous insulin levels are unable to prevent lipolysis, plasma FFA concentrations increase, further promoting apoptosis. FFAs also impair the body's first-phase insulin response and amplify hepatic glucose production. FFAs potentiate peripheral insulin resistance by blocking the ability of GLUT4 to transport glucose from the plasma into the myocytes. Patients exposed to chronic hyperglycemia may or may not experience symptoms similar to those with poorly controlled T1DM (i.e., fatigue, thirst, weight loss, hunger, frequent urination, and dry skin secondary to dehydration).

Intensified and individualized therapy targeting glycemic control is crucial for reducing the incidence of microvascular complications in patients with T2DM. Evidence supports efforts that appear to induce "metabolic memory," a theoretical protective mechanism through which early reversal and avoidance of hyperglycemia appear likely to minimize the risk of developing long-term complications (DCCT/EDIC Research Group, 2005). The fact that early initiation of intensive insulin therapy reduces insulin resistance and appears to induce β -cell rest suggests that such a regimen should be initiated sooner rather than later in treatment-naive patients with T2DM (Weng et al., 2008).

Recent RCTs have demonstrated that insulin interventions can be readily initiated and successfully titrated in the primary care setting (Gerstein et al., 2006; Meneghini et al., 2007). Additionally, with few exceptions, "needle phobia" often is less of an issue for patients than for clinicians. Most patients are willing to intensify their diabetes management according to the best guidance provided by their physicians. Clinicians are encouraged to develop several basal and prandial insulin protocols (perhaps using insulin pens or even disposable insulin patch pump devices) that can be introduced easily to patients (Figure 34-2).

Before initiating an insulin regimen, clinicians must consider patients' eating, sleeping, and exercise patterns and their ability to carry out diabetes self-management tasks. Perhaps most important, patients will need education

Table 34-15 Food and Drug Administration–Approved Noninsulin Pharmacologic Agents for Type 2 Diabetes Mellitus Treatment

Agents (Trade Name[s])	Mode of Action	Safety Concerns, Within-Class Distinctions, and Other Important Considerations
SULFONYLUREAS		
Glyburide (Micronase, Diabeta) Glipizide (Glucotrol) Glipizide-GITS (Glucotrol XL) Glyburide, micronized (Glynase) Glimepiride (Amaryl)	Insulin secretagogue	Increase the risk of hypoglycemia, especially in elderly adults and those with renal insufficiency or weight gain Meta-analysis suggests that sulfonylureas may increase stroke risk (Monami et al., 2013b) Short effective durability of drug except in patients with monogenetic T2DM (i.e., maturity-onset diabetes of the young) Glimepiride lowers fasting and postprandial glucose and has the best safety profile; avoid glyburide in elderly patients and those with CVD
BIGUANIDES		
Metformin (Glucophage) Metformin XL (Fortamet) Metformin XR (Glucophage XR, Glumetza) Metformin oral suspension	Decrease hepatic glucose production and glucose absorption from the GI tract and increase peripheral utilization of glucose	Must take with food to avoid gastritis and GI side effects Caution required for use in elderly patients and those with an estimated GFR rate <45 mL/min Withhold before contrast studies are performed; metformin may be restarted after serum creatinine is repeated and determined to be within a safe targeted range ≤10% of patients may be intolerant to side effect profile May reduce cancer risk in some patients with diabetes May improve fertility in patients with PCOS Some diabetologists prefer a dosing protocol involving rapid titration from 500 mg/day extended release with food to 2 g/day over 2 weeks
α-GLUCOSIDASE INHIBITORS		
Acarbose (Precose) Miglitol (Glyset)	Slow gut absorption of carbohydrates by inhibiting α-glucosidase enzymes	Contraindicated in inflammatory bowel disease, malabsorption syndromes, and partial bowel obstructions May induce hypoglycemia when used in combination therapy; oral glucose (dextrose), whose absorption is not inhibited by α-glucosidase inhibitors, should be used instead of sucrose (cane sugar) for hypoglycemia treatment; hypoglycemia will also respond to glucagon injection Glycemic efficacy of acarbose has been noted to be equal to that of metformin in treatment naive Chinese patients (Yang et al., 2014)
THIAZOLIDINEDIONE		
Pioglitazone (Actos)	Enhances tissue sensitivity to insulin in skeletal muscles by activating intracellular peroxisome proliferator-activated receptors	May cause resumption of ovulation in anovulatory premenopausal women Cases average weight gain of 0.9-2.6 kg Contraindicated in any patient with advanced heart failure (NYHA class III or class IV) or a history of bladder cancer Liver function testing required at baseline and every 2 months for the first year and then periodically thereafter Increases fracture risk in women
GLITINIDES		
Repaglinide (Prandin) Nateglinide (Starlix)	Rapid-acting insulin secretagogue with short (1- to 2-hour) duration of action; same mechanism of action as sulfonylureas but with a different binding site to pancreatic β cells	More effective than metformin, sulfonylureas, and thiazolidinediones at lowering postprandial blood glucose Less risk of hypoglycemia than sulfonylureas because of more rapid kinetics Must be taken 15 minutes before meals Approximately 1 month of therapy is required before fasting blood glucose decreases May either be weight neutral or result in slight weight increase
D2-DOPAMINE AGONIST		
Bromocriptine (Cycoset)	Resets dopaminergic and sympathetic tone within the central nervous system	Reduces glucose, triglycerides, and insulin resistance in patients with T2DM Can be used with all other oral agents and insulin Should be taken daily within 2 hours of rising Consider for use in patients who are shift workers; improving dopaminergic and sympathetic tone within the SCN may reduce insulin resistance; shift workers have disruption in their SCN pacemaker
BILE ACID SEQUESTRANT		
Colesevelam (Welchol)	Uncertain mode of action; may affect secretion of GLP-1	Not indicated as monotherapy in T2DM; may be used with metformin or metformin + sulfonylurea May be considered for off-label use in patients with prediabetes to reduce LDL cholesterol to <100 mg/dL and preserve β-cell function May be considered for use in T2DM patients who have elevated LDL cholesterol

Continued on following page

Table 34-15 Food and Drug Administration–Approved Noninsulin Pharmacologic Agents for Type 2 Diabetes Mellitus Treatment (Continued)

Agents (Trade Name[s])	Mode of Action	Safety Concerns, Within-Class Distinctions, and Other Important Considerations
DPP-4 INHIBITORS		
Sitagliptin (Januvia) Sitagliptin + metformin/sitagliptin + metformin, extended release (Janumet/Janumet XR) Saxagliptin (Onglyza) Saxagliptin + metformin, extended release (Kombiglyze XR) Linagliptin (Tradjenta) Linagliptin + metformin (Jentadueto) Alogliptin (Nesina) Alogliptin + metformin (Kazano) Alogliptin + pioglitazone (Oseni)	Block the action of DPP-4 enzymes, resulting in a two- to threefold increase in plasma levels of endogenous GLP-1	Most common side effects are rash and rhinitis Doses of all DPP-4 inhibitors, with the exception of linagliptin, must be adjusted based on renal status (see Table 34-15) As a class, DPP-4 inhibitors do not appear to increase the risk of CAD, HF, or hospitalizations for CHF; they also do not mitigate cardiovascular risk (Monami et al., 2013a) Oseni is contraindicated in patients with established NYHA class III or class IV HF and is not recommended in patients with symptomatic HF
GLP-1 RECEPTOR AGONISTS		
Exenatide (Byetta) Liraglutide (Victoza) Exenatide QW (Bydureon)	Enhance nutrient-stimulated insulin secretion via activation of GLP-1 receptors on β cells; inhibit glucagon secretion; delay gastric emptying; reduce appetite	Associated with weight loss Favorable effect on cardiovascular biomarkers Low rates of hypoglycemia Favor preservation of β -cell function GLP-1 infusion studies demonstrate favorable effects on endothelial cell function in humans Direct link to acute pancreatitis has not been demonstrated Contraindicated in patients with personal or family history of medullary thyroid carcinoma or MEN II (medullary thyroid cancer + pheochromocytoma) Most common adverse effect is nausea, which can be avoided if patients do not eat beyond the point of satiety When used with insulin secretagogue or insulin, reduce dose of secretagogue or insulin to minimize the likelihood of inducing hypoglycemia Exenatide is injected twice daily within 1 hr of eating; liraglutide is injected once daily without regard to meals; exenatide QW is injected once weekly Contraindicated in patients with a history of pancreatitis. Pancreatitis has been observed in patients taking GLP-1 receptor agonists or DPP-4 inhibitors. However, no direct signal has been noted that would implicate the incretin class as inducers of pancreatitis or pancreatic cancer in patients with diabetes Discontinue use in patients suspected of having pancreatitis Exenatide QW may cause injection nodules
SYNTHETIC AMYLIN ANALOG		
Pramlintide (Symlin)	Exogenous replacement of amylin, which is deficit in proportion with insulin deficiency in diabetes	Adjunct treatment in patients with T1DM or T2DM who use mealtime insulin therapy and have not achieved desired glucose control despite optimal insulin therapy May be used with or without sulfonylurea or metformin in T2DM Injected before meals Adverse effects include nausea and severe hypoglycemia Should be used only in patients who do not have hypoglycemia awareness autonomic failure (i.e., hypoglycemia unawareness) Can result in weight loss and satiety Challenging to titrate
SGLT2 INHIBITOR		
Canagliflozin (Invokana)	Reduces the renal threshold of glucose absorption from 180 g/day to approximately 70 g/day by blocking the SGLT2 co-transporter in the distal tubules of the glomeruli. Because glucose is not absorbed in the plasma, insulin resistance improves in a glucose-dependent manner, and patients experience a reduction in fasting and postprandial glucose levels, A1C, weight, and BP.	Side effects include increased frequency of urination, glycosuria, UTIs, mycotic infections, and diarrhea. Elderly patients should be carefully observed for treatment-induced orthostatic hypotension. Contraindicated in patients with renal insufficiency and a GFR <45 mL/min/1.73 m ² Canagliflozin dose should be 100 mg/day taken in the morning if the estimated GFR is 45-60 mL/min/1.73 m ² ; can be titrated to 300 mg if the GFR is >60 mL/min/1.73 m ² Co-administration with nonselective inducers of UGT enzymes (Rifampin, phenytoin, phenobarbital, ritonavir) will decrease the efficacy of canagliflozin

Table 34-15 Food and Drug Administration–Approved Noninsulin Pharmacologic Agents for Type 2 Diabetes Mellitus Treatment (Continued)

Agents (Trade Name[s])	Mode of Action	Safety Concerns, Within-Class Distinctions, and Other Important Considerations
Dapagliflozin (Farxiga)	Starting dose is 5 mg daily. Can increase to 10 mg daily for patients requiring additional glycemic control As with other agents in this class, SGLT2 inhibitors interfere with 1,5-anhydroglucitol assays	Should not be initiated in patients with an eGFR <60 mL/min/1.73 m ² Results in approximately 70 g of glucose excretion in urine weekly
Empagliflozin (Jardiance)	Doses are 10 and 25 mg daily	Do not initiate in patients with eGFR <45 mL/min/1.73 m ² and discontinue if eGFR is persistently <45 mL/min/1.73 m ²

about how to prevent, predict, and effectively manage hypoglycemia.

Optimal insulin replacement regimens replicate physiological insulin secretion in the fasting and postabsorptive states. Euglycemic individuals produce sufficient insulin to maintain plasma glucose levels in the range of 85 to 140 mg/dL. Exogenous basal insulin replacement is prescribed to reduce the magnitude of excessive hepatic glucose production in the fasting state. The two available basal insulin analogs are glargine and detemir. Both are characterized by a relatively flat time-action profile with an onset of action within 1 to 4 hours. A double-blind, randomized,

Figure 34-2 Patient displaying a V-Go disposable insulin patch pump (Valeritas, Bridgewater, NJ). Designed for use in patients with type 2 diabetes mellitus and available in three sizes (V-Go 20, V-Go 30, and V-Go 40), these devices deliver rapid-acting lispro or aspart insulin at a single specific basal rate of 0.83, 1.25, or 1.67 units/hr. An additional 36 units of prandial (bolus) insulin may be delivered by the patient before meals or for correction dose if glucose levels are elevated. Patients must remove and replace the pump after 24 hours. The advantages of the pump include improvement in A1C, adherence to mealtime bolus insulin prescribing, no visual association with needle therapy, and a reduction in total daily Insulin dose (Rosenfeld and Grunberger, 2013). Most patients can learn to use the V-Go system in 5 to 10 minutes.

crossover, investigator-initiated study of once-daily dosing demonstrated that the pharmacokinetics (i.e., absorption, metabolism, distribution, and excretion) and pharmacodynamics (i.e., variability of absorption from injection site, time to peak effect, and duration of action) of these insulin analogs were equivalent (King, 2009).

Table 34-17 Simple Basal Insulin Protocols That May Be Effectively and Efficiently Initiated in the Primary Care Setting

Protocol	Initial Dose of Basal Insulin	Titration Schedule	Comments	Reference(s)
Canadian INSIGHT Trial	10 units at 9:00 PM	Increase dose by 1 unit at 9:00 PM daily until fasting glucose is ≤ 110 mg/dL.	Very simple titration schedule Can also increase dose by 5 units every Monday instead of adjusting daily	Gerstein et al., 2006.
PREDICTIVE 303 Protocol TITRATE Protocol	10 units at 9:00 PM	Perform SMBG every morning and base insulin dose on 3-day average of glucose values. The target fasting glucose is 80-110 mg/dL. Adjust 9:00 PM dose based on the average fasting glucose level over 3 days as follows: <80 mg/dL = -3 units 80-110 mg/dL = no adjustment >110 mg/dL = +3 units	Treatment goals can be modified. TITRATE study targets were set at 70-90 mg/dL. PREDICTIVE 303 Protocol should be considered perpetual; patients should not stop adjusting doses unless instructed by their clinicians.	Meneghini et al., 2007; Blonde et al., 2009
Insulin-Resistant Weight Protocol	0.4 units/kg of body weight at 9:00 PM	For patients who are obese, treatment-naive, and have symptomatic hyperglycemia who require a more rapid method of insulin initiation and titration; can increase the dose by 5 units each Monday up to a maximum of 60 units. After a patient has reached the 60-unit dose of basal insulin, add prandial insulin targeting a specific meal ("basal-plus" regimen) or reduce the basal dose by 20% and initiate either exenatide or liraglutide.	Can use in combination with a GLP-1 receptor agonist, SGLT2 inhibitor, DPP-4 inhibitor, or prandial insulin Continue metformin unless patient is metformin intolerant.	Unger, 2011

DPP-4, Dipeptidyl peptidase-4; GLP-1, glucagon-like peptide 1; SMBG, self-monitoring of blood glucose; T2DM, type 2 diabetes mellitus.

Approximately 60% of patients with T2DM are able to achieve an A1C of 7% or less using basal insulin replacement in combination with oral agents or a GLP-1 receptor agonist. Patients who are still unable to achieve their target fasting, postprandial, or A1C goals should be transitioned to a basal-plus (basal insulin plus one prandial injection at the largest meal) or basal-bolus (basal insulin plus prandial injections for all meals) insulin regimen that provides long-acting insulin for basal needs and rapid-acting insulin (i.e., lispro, aspart, or glulisine) to minimize the peak rise in glucose levels after carbohydrate ingestion.

Table 34-17 lists several practical regimens that may be used to initiate patients on basal insulin. Successful initiation of basal insulin requires patients to understand their individualized glycemic targets and to know how to safely achieve these objectives. In clinical trials, patients who are provided with a specific algorithm are almost always able to safely and effectively lower their A1C to their prescribed target. Thus, allowing patients to self-titrate should be the rule rather than the exception.

Table 34-18 lists the appropriate time to consider adding prandial insulin to one's basal regimen. Physiological insulin regimens should be individualized and titrated based on the factors shown in Table 34-19. Rapid-acting insulin analogs exhibit a peak onset of pharmacodynamics (blood glucose-lowering capacity) 60 minutes after injection. Peak carbohydrate absorption after a meal occurs 75 to 90 minutes after eating. Thus, to synchronize the peak activity of insulin with the expected risk in postprandial glucose, the analog should be injected 15 minutes before meals unless premeal blood glucose is less than 80 mg/dL (Unger, 2011). The delay between the time of injection and the start of the meal is known as the "lag time." Patients who inject just before eating may experience postprandial hypoglycemia within 1 hour of starting the meal only to develop postprandial hyperglycemia 2 to 3 hours later.

Table 34-18 Practical Considerations for Initiating Prandial Insulin

Consider adding prandial insulin:

- For patients who have not attained the recommended A1C of $\leq 7\%$ despite successful basal insulin dose titration and the achievement of fasting glucose levels of < 100 mg/dL (An alternative to starting prandial insulin is to add an incretin-based therapy to basal insulin, which will reduce postprandial and fasting glucose levels; however, exenatide QW is not approved for use with insulin.)
- When basal insulin dose titration has resulted in repeated episodes of nocturnal hypoglycemia
- When the basal insulin dose has exceeded 60 units/day
- For patients who have not met their A1C goal within 1 year of initiating basal insulin
- If the "BeAM factor" is > 55 mg/dL
 - BeAM factor: the difference between bedtime and morning ("AM") blood glucose levels
 - Patients titrating basal insulin to a fasting glucose target of ≤ 100 mg/dL who have a BeAM factor > 55 mg/dL are less likely to achieve an A1C $\leq 7\%$ without experiencing nocturnal hypoglycemia; therefore, these patients should initiate prandial insulin
 - A BeAM factor > 55 mg/dL is associated with an increased risk of nocturnal hypoglycemia, but not overall hypoglycemia

Holman RR, Farmer AJ, Davies MJ, et al. Three-year efficacy of complex insulin regimens in type 2 diabetes. *N Engl J Med.* 361:1736-1747, 2009; Zisman A, Aleksandra V, Zhou R. The BeAM factor: an easy-to-determine, objective, clinical indicator for when to add prandial insulin vs. continued basal insulin titration. Presented at the American Diabetes Association 71st Scientific Sessions (Abstract 1121-P), San Diego, CA, June 2011.

For a basal-plus regimen (basal insulin plus one prandial dose per day), identifying the meal to target for intervention might be simplified with the use of structured SMBG, as described in the Type 1 Diabetes Mellitus section of this chapter. SMBG should be performed before and 2 hours after each meal for 3 days. The meal with the highest Δ (difference between premeal and 2-hour postprandial

Table 34-19 Factors to Be Considered When Prescribing Physiological Insulin Replacement Therapy

Factor	Comment
Meal consumption	Does patient skip meals?
	Are meals consumed on a scheduled basis?
	What are the approximate sizes and carbohydrate contents of meals?
	Has patient received meal planning education from a registered dietitian or certified diabetes educator?
Work schedule	Does patient have an eating disorder?
	Does patient work irregular shifts?
	Does an irregular work schedule affect sleep?
Adherence history	Does patient frequently travel?
	Does travel schedule require flexible meal and insulin injection scheduling?
	Does patient have a history of omitting insulin doses?
	Is patient willing to perform frequent SMBG?
Physical activity	Does patient understand how to properly perform SMBG and interpret glucose values, patterns, and averages?
	Does patient exercise?
	What type of exercise does patient do?
	What time of day does exercise occur?
	Does exercise time vary?
	Is patient a professional athlete?
Hypoglycemia history	Is patient planning to initiate an exercise program for the first time?
	What are patient's glucose targets before, during, and after exercise?
	Does patient know how to predict and treat hypoglycemia?
	Does patient have a history of hypoglycemia unawareness?
	Does patient live alone?
	Does patient know how to predict and treat hypoglycemia?
	Are there comorbidities (e.g., heart disease, chronic kidney disease, seizures, hypoglycemia unawareness) that could preclude patient from being intensively managed and thereby increasing their risk of hypoglycemia?
Does patient have access to and wear a CGM device?	
Comorbidities of concern	Does patient know to perform SMBG before driving?
	What is patient's target A1C?
	Coronary artery disease or cardiac arrhythmias
	Preconception planning or pregnancy
	Cancer
Learning skill deficiencies	End-stage renal disease
	Mental illness
	Diabetic neuropathy
Learning skill deficiencies	Diabetic retinopathy
	Advanced age
	Does patient have deficient reading, writing, or math (numeracy) skills?
Learning skill deficiencies	Is there a language barrier that may affect patient's ability to learn how to administer and self-titrate insulin?

CGM, Continuous glucose monitoring; SMBG, self-monitoring of blood glucose.

Figure 34-3 Insulin disappearance curve. This graph demonstrates the amount of insulin remaining in the subcutaneous depot over time after a subcutaneous injection (insulin on board). After 2 hours (circle), 64% of the original dose remains in the depot waiting to act. Thus, if 10 units of insulin are given at 10:00 AM, 6 units remain as active drug at noon. The glucose-lowering effects of rapid-acting analogs persist for up to 6 hours after a subcutaneous injection. If a patient gives a correction dose of insulin before the insulin from the previous injection is completely absorbed (a practice known as “insulin stacking”), hypoglycemia is likely to occur. For example, if the blood glucose level is 200 mg/dL at noon and the patient injects an additional 6 units for lunchtime, the subcutaneous depot has now been increased to 12 units. Patients should always calculate insulin on board from the previous injection before injecting supplemental insulin. Insulin stacking is a major cause of hypoglycemia and can easily be avoided. (Adapted with permission from Unger J. *Diabetes management in primary care*. 2nd ed. Philadelphia: Lippincott, Williams and Wilkins; 2012.)

glucose levels) becomes the initial point of intercession. The goal is to achieve a physiological Δ (0-50 mg/dL) for the meal. For example, if the pre-breakfast glucose is 100 mg/dL and the 2-hour postprandial glucose after breakfast is 142 mg/dL, the breakfast $\Delta = 142 - 100$, or 42 mg/dL. Patients with A1C levels above 12% may require immediate initiation of a basal-bolus regimen to reduce postprandial hyperglycemia after all meals.

Structured SMBG also allows patients to identify impending hypoglycemia. Any negative Δ (difference between premeal and 2-hour postprandial glucose resulting in a negative value) would predict a high risk of impending hypoglycemia. For example, if a patient has a premeal glucose level of 187 mg/dL and a 2-hour postprandial glucose level of 100 mg/dL after taking 10 units of insulin, one could predict impending hypoglycemia based on the Δ of -87 mg/dL. If the patient received two 10 units of insulin 2 hours before eating, he or she would be at risk for impending hypoglycemia (Figure 34-3). Calculating Δ values from structured SMBG can also help patients adjust their baseline doses of prandial insulin based on glycemic patterns that become apparent over several days. Table 34-12 lists the causes of low and elevated Δ values.

After a basal-plus or basal-bolus insulin regimen is initiated, a repeat A1C should be obtained to determine if the patient is beginning to trend toward the prescribed glycemic target. Insulin therapy may be intensified based on the patient's A1C level and structured SMBG results.

The initial dose of any prandial rapid-acting insulin can be approximated as 0.1 unit/kg of body weight per meal. Thus, a 100-kg person would require 10 units of rapid-acting insulin, which would be injected 15 minutes before eating. If the 2-hour postprandial glucose is 0 to 50 mg/dL, the correct amount of insulin was given to cover the

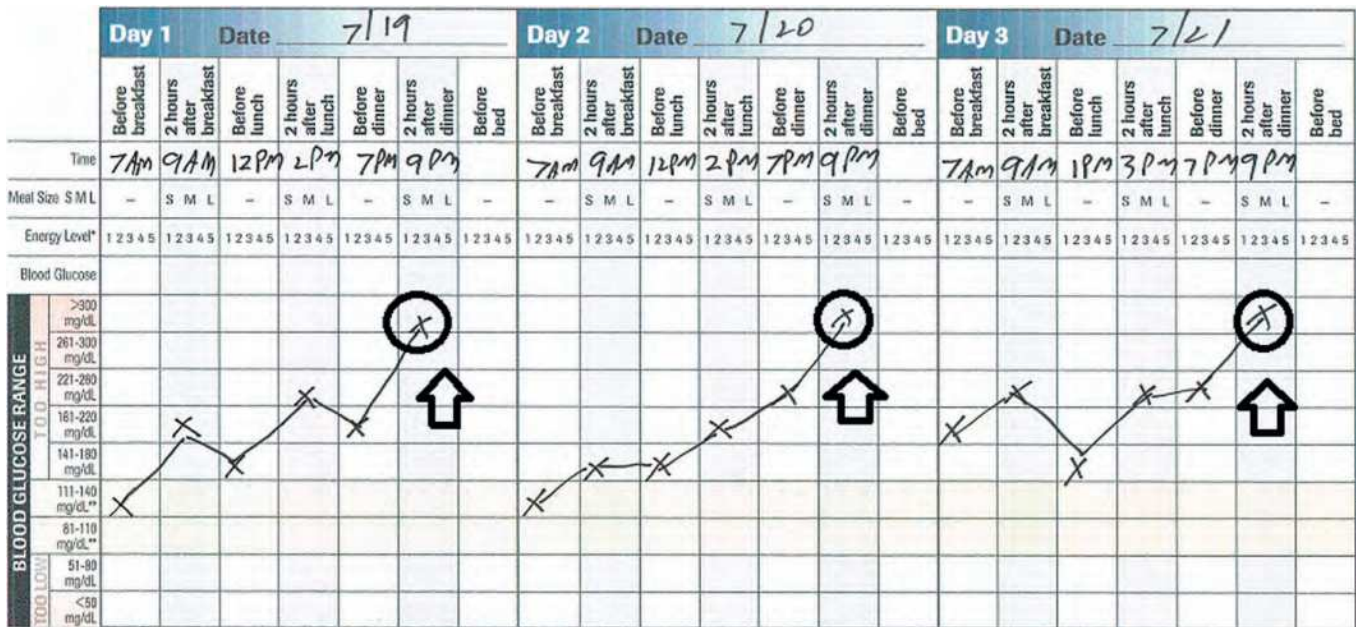

Figure 34-4 Insulin initiation and intensification for patients with advanced type 2 diabetes mellitus (T2DM). *Although any meal may be targeted for rapid-acting insulin intensification, structured self-monitoring of blood glucose should be performed before and 2 hours after each meal for 3 days before a scheduled office visit. The meal that shows the greatest 2-hour postprandial glucose increase (the greatest Δ value) should be targeted for intensification. Note: “Advanced T2DM” refers to patients who have had diabetes for more than 5 years, those whose A1C is greater than 9%, and those who are no longer able to control their glucose with triple combination drug therapy. In this example using the Accu-Check 360 blood glucose analysis system, the patient and his physician were able to determine that the greatest rise in prandial glucose values occurred consistently with dinner. Therefore, basal-plus insulin therapy was initiated, targeting the postprandial excursions at dinner.

carbohydrate content of that meal. However, if the 2-hour postprandial glucose level is consistently above 50 mg/dL, the patient can adjust the mealtime dose of insulin by 1 unit/day until the Δ target is achieved. Figure 34-4 summarizes a popular approach to initiating basal-bolus therapy in the primary care setting. The keys to successful initiation of insulin are summarized in Table 34-20.

PREMIXED INSULIN FORMULATIONS

Premixed preparations combine rapid-acting (prandial) and long-duration (basal) insulins in a single vial or pen injector. Using these fixed-dose insulins can reduce dosing errors that may occur when patients attempt to mix neutral protamine Hagedorn (NPH) and regular insulin in the same syringe. Such formulations are also helpful in other situations. For example, when combining NPH with a rapid-acting analog, the injection must be made immediately to avoid alteration in the glucose-lowering effects of the analog. Patients with visual impairments may have a family member preload their rapid- and intermediate-acting insulin into syringes for use later in the day. However, this may result in absorption variability and hypoglycemia. By contrast, using premixed insulin preparations is simple, user friendly, and more physiological than NPH-plus-regular-insulin injections.

The human premixed insulins (Humulin 50/50, Humulin 70/30, and Novolin 70/30) combine regular and NPH insulin in a single dose. Thirty units of 50/50 insulin would consist of 15 units of regular plus 15 units of NPH. The 70/30 preparations consist of 70% NPH and 30% regular

insulin. When used, these insulins must be injected at least 30 minutes before a meal.

Analog premixed insulins (lispro mix 75/25, lispro mix 50/50, and biaspart mix 70/30), unlike human mixed insulins, consist of a set percentage of rapid-acting insulin (either lispro or aspart) plus the rapid-acting insulin combined with protamine, which delays the absorption of that insulin component. By prolonging the duration of action of a percentage of the aspart or lispro within the mixed formulation, protamine improves the glucodynamic effect of the insulin. Patients using a mixed insulin would receive the benefits of a basal and a bolus insulin in a single injection. Thus, a 20-unit dose of lispro 75/25 would contain 5 units of lispro plus 15 units of lispro plus protamine. The analog premixed insulins should be injected 15 minutes before eating to minimize postprandial glycemic excursions.

Although less expensive than the analog premixed formulations, human premixed insulins are less effective at minimizing postprandial glycemic excursions. Using premixed analogs can result in hypoglycemia; however, the incidence of severe hypoglycemia appears to be slightly higher for individuals using human premixed formulations (2%-14% of patients) versus those using premixed analogs (2%-8% of patients).

Premixed insulin analogs might be useful for patients who have a baseline A1C between 8.5% and 10%. Other candidates who might be successful users of premixed analogs include those who eat three meals daily and adhere to a regular schedule for work and physical activity. Another advantage of premixed analogs is that patients receive two insulins for a single insurance copayment.

Table 34-20 Keys to Successful Insulin Initiation in Patients with Type 2 Diabetes Mellitus

Suggest that insulin will help patients achieve their individualized fasting, postprandial, and A1C targets in a timely, safe, and efficient manner.

Provide each patient with a written, individualized treatment plan for insulin intensification.

Use insulin pens or disposable pumps rather than syringes and vials; this may improve dosing accuracy and adherence.

Teach patients how to proactively identify impending hypoglycemia using structured SMBG.

Patients should always be allowed to titrate their basal and prandial insulin doses with prescribed guidance and tutorials from their clinician.

Use insulin analogs; regular human insulin increases the risk of hypoglycemia.

Explain the differences between “basal” and “bolus” insulin to patients to minimize dosing errors.

When adding a GLP-1 receptor agonist to basal insulin, consider reducing the dose of the basal insulin by 20%.

Patients with renal insufficiency should reduce their insulin doses by 10% and monitor their glucose levels carefully because insulin is secreted in the urine. Renal insufficiency may increase circulating insulin levels and increase the risk for hypoglycemia.

To reduce weight gain when insulin is initiated, consider discontinuing any thiazolidinedione, sulfonylurea, or glitnides. Agents that may be continued safely after initiating insulin include metformin, bromocriptine, SGLT2 inhibitors, α -glucosidase inhibitors, DPP-4 inhibitors, and GLP-1 receptor agonists.

Some patients may be able to discontinue insulin if their doses are relatively low (<20 units/day), and they attain an A1C <7.5%. Thus, initiating insulin does not always mean that the patient will be on insulin forever.

Patients must be instructed about how to inject insulin properly. Also, be sure to discuss the proper timing of basal and prandial insulin administration with each patient.

Patients who are shift workers should consider using an insulin pump (continuous subcutaneous insulin infusion) to improve their glucose levels.

Patients with high A1C levels (>10%) do not feel well after eating. This is because their postprandial glucose levels go from bad to worse. After initiating insulin, their symptoms of fatigue and sluggishness should improve dramatically, motivating them to intensify their insulin therapy, if necessary.

DPP-4, Dipeptidyl peptidase-4; GLP-1, glucagon-like peptide 1; SGLT2, sodium–glucose co-transporter 2; SMBG, self-monitoring of blood glucose.

The initiation and titration of premixed insulins has proven successful in allowing patients to achieve their glycemic targets. In a 48-week, multicenter, open-label trial, patients with T2DM and who were not achieving targets on oral agents with or without once-daily basal insulin were placed on premixed biaspart (70/30) in three phases. In phase 1, patients initiated treatment with the premixed formulation once before supper. The dosing frequency was increased to twice daily in phase 2 and to three times daily in phase 3 at 16 and 32 weeks, respectively, if patients did not achieve an A1C of less than 6.5%. Patients reached the end of their participation in the study when they achieved an A1C of 6.5% or less or at 48 weeks, whichever came first. At the end of the trial, 77% of patients had achieved A1C levels of less than 7.0%, and 60% of patients attained an A1C level of 6.5% or less through dosing once, twice, or three times with premixed biaspart (Garber et al., 2006).

Whether treatment-naïve patients should begin treatment with basal insulin or a premixed insulin analog was

the primary study question of the Initiating insulin therapy in type 2 diabetes: a comparison of biphasic and basal insulin analogs [INITIATE] trial (Raskin et al., 2004). A total of 233 patients with poorly controlled diabetes on oral agents who had a baseline A1C greater than 8% were randomized to take either insulin glargine or premixed biaspart (70/30) for 28 weeks. At the conclusion of the study, 66% of patients taking premixed biaspart reached the recommended ADA target A1C of less than 7% compared with 40% of those taking glargine. As expected, postprandial glycemic excursions for the biaspart group were approximately 25% lower than for patients using glargine. Minor hypoglycemia occurred more commonly in patients taking the premixed insulin, but no episodes of severe hypoglycemia were recorded during the trial.

Treatment of patients with T2DM should no longer be protocol driven. The ACCORD trial demonstrated that intensive therapy can be used successfully to reduce A1C to less than 6.5% in patients with T2DM. Unfortunately, the all-cause mortality rate in ACCORD was 22% in intensively managed patients (ACCORD Study Group, 2008). Not all patients are at risk if ambitiously treated, however. In fact, the patients who were able to lower their A1C to below 6.5% within 4 months of randomization did not demonstrate an increase in all-cause mortality. Those who were unable to achieve their targeted goal by intensification appeared to have elevated postprandial glucose levels that were more refractory to treatment. These individuals also had longer disease durations and were at higher risk of experiencing fatal arrhythmias caused by severe hypoglycemia (Riddle et al., 2010).

Thus, metabolic targets for diabetes must be individualized based on the patient’s age, disease duration, number and severity of comorbidities, history of hypoglycemia awareness autonomic failure, ability to participate in self-diabetes management, and life expectancy. Most newly diagnosed patients with diabetes should attempt to lower their A1C to 6.5% or less. Pharmacotherapy choices should be selected based on their ability to correct and reverse the metabolic defects associated with T2DM and insulin resistance. Simply attempting to target a given glycemic parameter is no longer a safe or acceptable practice when managing patients with either T1DM or T2DM.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus accounts for 5% to 10% of all individuals diagnosed with diabetes and results from a cellular-mediated autoimmune destruction of the pancreatic β cells. Markers of immune destruction of β cells include islet cell autoantibodies (ICAs), autoantibodies to insulin (IAs), autoantibodies to glutamic acid decarboxylase (GAD65), antibodies to an insulinoma-associated antigen-2 (ICA512), and autoantibodies to the tyrosine phosphatases (IA-2 and IA-2 β) (ADA, 2012). One or more of the autoantibodies are present in 85% to 90% of individuals who initially experience fasting hyperglycemia.

The rate of β -cell destruction in T1DM varies. Whereas infants and children tend to demonstrate rapid β -cell death, adults typically present with a lengthy prodromal phase leading to latent autoimmune diabetes of adulthood (LADA)

Figure 34-5 Structure of human insulin. The precursor of insulin, proinsulin, is produced within the endoplasmic reticulum of the pancreatic β cells. Proinsulin is then transported to the Golgi apparatus and packaged into secretory vesicles. The C-peptide chain is released from the center of the proinsulin sequence while the two disulfide bonds remain intact. One C-peptide molecule is formed with each insulin molecule. Therefore, C-peptide levels can serve as an accurate measure of endogenous insulin production. C-peptide levels in euglycemic individuals range from 0.5 to 2.0 ng/mL. Patients with type 1 diabetes mellitus are deficient in C-peptide. (Adapted with permission from Unger J. *Diabetes management in primary care*. 2nd ed. Philadelphia: Lippincott, Williams and Wilkins; 2012.)

(Unger, 2008a). Some children and adolescents may present with DKA as the first manifestation of the disease. Others have modest fasting hyperglycemia that can rapidly change to severe hyperglycemia or DKA in the presence of infection or other stress. Adults may retain residual β -cell function (remaining C-peptide positive; Figure 34-5) that is sufficient to prevent DKA for many years. Residual β -cell function detected 3 to 6 years after the onset of T1DM has also been associated with a lower risk of hypoglycemia, reduced exogenous insulin requirement, and improved glycemic control (Sorensen et al., 2013).

Patients with near-complete insulin deficiency who remain antibody negative are classified as having “type 1B diabetes” (Notkins and Lernmark, 2001). Most patients with type 1B diabetes are of African or Asian ancestry.

Patients with T1DM are prone to other autoimmune disorders such as autoimmune thyroid disease (15%-30%), celiac disease (4%-9%), and Addison disease (0.5%) (Unger, 2012e). Assays for thyroid peroxidase autoantibodies (for autoimmune thyroid disease), tissue transglutaminase autoantibodies (for celiac disease), and 21-hydroxylase autoantibodies (for Addison disease) may be used to screen asymptomatic patients to identify those at high risk for

clinical progression to these conditions. Thirty-three percent of patients with T1DM screen positive for at least one additional organ-specific autoantibody when initially diagnosed with diabetes, and 19% have evidence of clinical disease. Given the high preponderance of these antibodies at the onset of T1DM, screening for coexisting autoimmune disorders appears to be warranted (Triolo et al., 2011).

To date, no intervention has been developed that can unequivocally prevent the development of T1DM or arrest the progression of immune system destruction of β cells after diagnosis. Although some promising studies in the area of diabetes prevention and reversal have given the field much encouragement, most of these efforts are unfolding at large academic or research-focused medical centers. Nonetheless, family physicians play a vital role in working with patients who are at high risk for developing T1DM. In families with established T1DM, all first-degree relatives, including the parents of the patient (if they are younger than 45 years of age), are at increased risk for T1DM and should be counseled about this risk. Identical twins are at the greatest risk. Second- and third-degree relatives of patients with T1DM are also at heightened risk if they are younger than 21 years of age.

Table 34-21 Features of Type 1 Diabetes Mellitus, Type 2 Diabetes Mellitus, and Latent Autoimmune Diabetes of Adulthood

Condition	Features					
	DKA	Cardiovascular Complications	Microvascular Complications*	Pathophysiology	Autoantibodies	Insulin Requirements
T1DM	Develops rapidly unless patient receives insulin therapy	Increased risk of cardiovascular morbidity and mortality related to stroke, acute coronary event, or coronary revascularization; high incidence of cardiovascular complications compared with euglycemic people, especially in women	Increased risk	Autoimmune destruction of pancreatic β cells	Patients typically test positive for ≥ 2 autoantibodies	Insulin required at diagnosis
LADA	Absent at diagnosis but may develop with severe insulinopenia	Risk is two to four times higher than in euglycemic people	Increased risk	Latent autoimmune destruction of pancreatic β cells	Glutamic acid decarboxylase autoantibodies most common; islet cell antibodies less common Patients typically test positive for only one autoantibody	Insulin therapy is ultimately necessary; may be considered if autoantibodies are identified
T2DM	Usually absent	Risk is two to four times higher than in euglycemic people	Increased risk	Peripheral insulin resistance; reduced pancreatic β -cell mass and function; reduced insulin	Usually absent	Usually needed late in the disease course when the remaining β -cell mass and function can no longer support acceptable glycemic control with oral agents or incretin mimetics

*Retinopathy, nephropathy, and neuropathy

LADA, Latent autoimmune diabetes of adulthood; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Unger J. Diagnosing and managing latent autoimmune diabetes in adults. *Pract Diabetol.* 21:32-37, 2008.

After being apprised of their diabetes risk, such individuals should be made aware of T1DM screening and intervention studies such as the National Institutes of Health's T1DM TrialNet (<http://www.diabetestrialnet.org>). The advantages of screening for T1DM risk through such research-oriented programs include state-of-the-art antibody determinations in specialized research laboratories, a superb follow-up and support network of T1DM specialists, protection of laboratory data from insurance carriers, and the opportunity to participate in further clinical research studies aimed at diabetes prevention. Participating in a research study incurs no cost to patients or their insurance companies.

Early vitamin D supplementation may protect against T1DM progression, although the exact mechanism is uncertain. Vitamin D is a potent modulator of the immune system and is involved in regulating cell proliferation and differentiation (Zella and DeLuca, 2003). A meta-analysis of data from five observational studies recently indicated that children supplemented with vitamin D had a 29% reduction in T1DM risk compared with their unsupplemented peers (Zipitis and Akobeng, 2008).

LATENT AUTOIMMUNE DIABETES IN ADULTS

Latent autoimmune diabetes in adults is a slowly progressive form of autoimmune diabetes characterized by older age at diagnosis, the presence of pancreatic autoantibodies, and the lack of an absolute insulin requirement at diagnosis. Although patients with LADA present with more preserved β -cell function than those with classic T1DM, they tend to have a rapid and progressive loss of β -cell function necessitating intensive insulin intervention. Approximately 10% of all patients diagnosed with T2DM actually have LADA (Isomaa et al., 1999). Table 34-21 compares the characteristics of T1DM, T2DM, and LADA.

Although the exact pathogenesis of LADA is unclear, the underlying immune-mediated destruction of β cells in patients with this form of the disease leads to insulin dependency more rapidly than in patients with T2DM. Protective alleles appear to delay absolute exogenous insulin dependency in people with LADA compared with those with T1DM.

Suspicion of LADA should be heightened in patients with coexisting autoimmune disorders such as hypothyroidism,

who are not excessively overweight, and who have deteriorating glycemic control despite intensification of oral therapies and the use of incretin mimetics. Physicians may consider GAD65 testing to determine whether LADA is present.

Because of the ambiguous pathophysiology and clinical characteristics of LADA, no specific guidelines have been established for its treatment. Nevertheless, theoretical advantages of intensive insulin therapy exist. Eighteen years after the DCCT, a follow-up study showed that early control of diabetes over 6.5 years seems to provide continued protection against micro- and macrovascular complications (DCCT Research Group, 1993; DCCT/EDIC Research Group, 2005). This result occurred despite the fact that patients in the DCCT who received intensive treatment had deteriorating A1C levels over time, but those in the conventional treatment group showed improvement upon completion of this landmark study. Early stabilization of glycemic control in patients with T1DM is postulated to establish “metabolic memory,” which theoretically protects against long-term complications.

PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes mellitus occurs in individuals in whom genetic susceptibility outweighs genetic protection. Distinctive environmental triggers play a supporting role in provoking a cellular-mediated autoimmune process directed to one or more β -cell proteins (autoantigens). As islet cell destruction occurs, autoantibodies are delivered into the pancreatic lymph nodes, where destructive T-effector cells are produced and outnumber the stabilizing T-regulatory cells. Initially, the decline in β -cell function and loss of β -cell mass present clinically as loss of first-phase insulin response to an intravenous glucose challenge. Over time, patients progress through stages of “dysglycemia” (glucose values >200 mg/dL at 30, 60, or 90 minutes during an oral glucose tolerance test). Ultimately, the clinical syndrome of T1DM becomes evident when the majority of β -cell function has been lost and most β cells have been destroyed. At this juncture, frank hyperglycemia supervenes. To date, no intervention has been developed that can unequivocally prevent the development of T1DM or arrest the progression of immune system destruction of β cells after diagnosis, although some promising studies have given the field much encouragement (Unger, 2012e).

OUTPATIENT MANAGEMENT OF ADULTS WITH TYPE 1 DIABETES MELLITUS

The ultimate goal of insulin replacement therapy is to mimic the normal insulin response to hyperglycemia in both the fasting and postprandial states. Physiological insulin replacement regimens include the use of basal-bolus insulin preparations administered in a multiple daily injection (MDI) regimen or through continuous subcutaneous insulin infusion (CSII; insulin pump therapy). Nonphysiologic regimens include NPH insulin with or without a rapid-acting insulin, premixed insulin analogs, or analog basal insulin therapy alone given once or twice daily. Such regimens fail to mimic the normal glucose-stimulated insulin response of pancreatic β cells. Physiological insulin

therapies require individualization and titration based on the factors shown in Table 34-19.

Insulin Analog Formulations

Basal Insulin Analogs. The two available basal analogs include glargine and detemir. Glargine provides glycemic control that is at least comparable with NPH in adults, adolescents, and children. However, the risks of mild and severe episodes of hypoglycemia are significantly reduced with glargine compared with NPH use in adults. Combining glargine with a rapid-acting insulin analog as part of an MDI regimen provides benefits over the use of NPH plus regular human insulin (Garg et al., 2011).

The absence of clear peaks in the time-action profiles of glargine and detemir contributes to the lower risk of hypoglycemia with these analogs compared with NPH. In addition, the analogs demonstrate less variability in absorption compared with NPH, suggesting that the analog formulations have a more predictable glucose-lowering effect than NPH in T1DM (Heise et al., 2004).

Rapid-Acting Insulin Analogs. Rapid-acting insulin analogs begin to exhibit their glucose-lowering effects within 10 to 15 minutes after an injection compared with the 30- to 60-minute onset of action of regular human insulin. The three available rapid-acting insulin analogs are lispro, aspart, and glulisine. Aspart and glulisine have also been approved for injection immediately after a meal. Postprandial administration can be useful for patients who forget to take their insulin before eating. Pediatric and elderly patients whose food consumption and mealtimes are unpredictable may also bolus after eating.

Table 34-22 lists the pharmacologic characteristics of commercially available insulin preparations, as well as an investigational long-acting basal insulin (degludec), which is now in phase 3 clinical trials.

INITIATING AND INTENSIFYING PHYSIOLOGICAL INSULIN THERAPY IN PATIENTS WITH TYPE 1 DIABETES MELLITUS

Findings from large RCTS clearly demonstrate that early and aggressive management of glycemia significantly decreases the development and progression of both micro- and macrovascular complications of diabetes (DCCT Research Group, 1993; DCCT/EDIC Research Group, 2005). Unfortunately, intensification of therapy and improved glycemic control are often associated with an increased frequency of severe hypoglycemia (DCCT Research Group, 1993). Thus, the rate-limiting step to diabetes intensification remains fear on the part of patients or providers of inducing iatrogenic hypoglycemia. Patients must receive education about how to avoid, recognize, and treat hypoglycemia. If necessary, clinicians should consider the use of a continuous glucose monitoring (CGM) devices, which have alarms to help patients avoid hypoglycemia. Table 34-23 lists self-management goals for patients who are prescribed basal-bolus insulin therapy.

Patients with T1DM must make many therapeutic decisions, most often without physician guidance, on a daily basis. Amazingly, most patients become quite adept at adjusting their insulin doses according to their specific and

Table 34-22 Pharmacologic Characteristics of Commercially Available Insulin Preparations

Insulin Preparations	Onset of Action	Peak Action (hr)	Duration of Action (hr)
HUMAN INSULINS			
Prandial			
Regular	30-60 min	2-4	6-8
Intermediate Acting			
NPH	1-4 hours	6-10	10-16
Premixed			
70/30 (70% NPH, 30% regular)	0.5-1.0 hr	First peak 2-3 hr; second peak several hours later	10-16
50/50 (50% NPH, 50% regular)	0.5-1.0 hr	First peak 2-3 hours; second peak several hours later	10-16
INSULIN ANALOGS			
Basal			
Glargine	1-4 hr	No pronounced peak	24 (terminal half-life = 12.5 hr)
Detemir	1-4 hr	No pronounced peak	20-24
Degludec*	—	No peak	>24 hr (terminal half-life = 25 hr)
IDegAsp* (degludec + aspart)	10 min [†]	No peak	>24 hr (equal to degludec)
PRANDIAL			
Lispro/aspart/glulisine	5-15 min	1-2	3-4
Premixed			
Lispro mix 75/25 (75% protamine lispro/25% lispro)	15 min	0.5-1.2	10-16
BiAsp 70/30 (70% protamine aspart/30% aspart)	15 min	0.5-1.2	10-16
Lispro mix 50/50	15 min	0.5-1.2	10-16

*These insulins are in phase 3b clinical trials and have been submitted for review to the Food and Drug Administration.

[†]Degludec has a flat profile under steady-state conditions. There is no peak. Therefore, "time to peak action" and onset of action become irrelevant. Steady state for degludec is achieved on the third day of treatment. The effect of the previous injection will cover the time between injection and onset of action of the subsequent injection. The duration of action is dose dependent. Higher doses increase the duration of action for any insulin. The terminal half-life of insulin degludec is 25 hours compared with 12.5 hours for insulin glargine. There are no published data regarding the duration of action of insulin degludec. However, the end of action (end of action is defined as blood glucose levels >150 mg/dL) was not reached by 42 hours after the conclusion of glucose clamping for subjects receiving either 0.6 or 0.8 units/kg. The duration of action of IDegAsp is determined by the degludec component. The onset of action of IDegAsp is based on the aspart component. BiAsp has an onset of action of 10 minutes and a duration of action of 1 to 3 hours.

NPH, Neutral protamine Hagedorn.

Table 34-23 Self-Management Goals for Patients Using Basal-Bolus Insulin Therapy

Prescribe a protocol that will allow patients to successfully and safely achieve the ADA's fasting blood glucose target of 90-130 mg/dL. Target 2-hour postprandial blood glucose levels <180 mg/dL. Minimize the rise in postprandial blood glucose levels from premeal baseline levels of ≤ 50 mg/dL. Minimize the risk of developing hypoglycemia by instructing patients about appropriate pattern glucose testing and means by which hypoglycemia may be predicted and treated proactively. Allow patients to self-titrate their basal and prandial insulin doses based on specified treatment targets (fasting and postprandial glucose excursions). Encourage use of certified diabetes educators and registered dietitians to assist patients in learning and appropriately incorporating their treatment regimens into their active lifestyles. Individualize insulin regimens to include considerations for exercise, travel, and sleep. Recognize and effectively manage patients with mental illness and eating disorders. Individualize treatment based on cultural, religious, and personal preferences. Periodically review injection and SMBG technique to ensure that these basic skills are being performed properly.

ADA, American Diabetes Association; SMBG, self-monitoring of blood glucose.

immediate metabolic requirements. On occasion, patients may bolus inappropriate doses of insulin. In such cases, clinicians should never rebuke patients for missing their fasting or postprandial glucose targets. After all, they are doing the best they can with the insulin dosing resources provided by their health care providers.

The following steps may be used to safely and effectively initiate and titrate basal-bolus insulin for insulin-requiring patients (Unger, 2007):

Step 1. Determine the total daily dose (TDD) of insulin. The TDD is equal to the weight in kg \times 0.7. For example, a 70-kg patient would require a total of $70 \times 0.7 = 49$ units of insulin daily.

Step 2. Determine the starting dose of basal insulin analog (glargine or detemir) and rapid-acting insulin (aspart, lispro, or glulisine).

$$\text{Basal insulin dose/24 hours} = 50\% \text{ of TDD}$$

$$\text{Bolus insulin dose/24 hours} = 50\% \text{ of TDD}$$

Basal insulin minimizes the effects of hepatic glucose production, thus keeping blood glucose levels regulated in the fasting state. The basal insulin requirement is equal to 50% of the TDD. Thus, a patient requiring 50 units/day of insulin would require approximately 25 units of

basal insulin. The remaining 50% would be dedicated to bolus insulin.

These percentages may vary from patient to patient. Some individuals may require a 40/60 split favoring bolus insulin. Basal insulin should be injected at a consistent time each day or night because its maximum duration of action is 24 hours. After it is initiated, the basal insulin can be titrated by increasing the dose by 1 unit/day until fasting blood glucose is less than 100 mg/dL (Harris et al., 2008).

Step 3. Establish a prandial dosing regimen.

A. Determine baseline prandial insulin dosage:

Dose of prandial insulin = 0.1 units/kg/meal (e.g., a 70-kg patient would require 70×0.1 units = 7 units of rapid-acting insulin per meal)

B. Establish the lag time for insulin injection:

Insulin should be injected 15 minutes before a meal unless the blood glucose level before eating is less than 80 mg/dL, in which case insulin should be injected at the onset of the meal.

C. Allow the patient to adjust the insulin dose based on the size of the meal (Table 34-24). For example, a patient with a baseline prescribed prandial insulin dose of 7 units plans to eat a Thanksgiving-sized feast. The dose of insulin would be $7 + 3 = 10$ units injected 15 minutes before eating. The baseline prandial insulin dose can be further adjusted based on structured glucose testing (Table 34-25).

D. Adjust the patient's initial baseline dose of insulin periodically based on the results of structured SMBG. Step 4: Fine tune basal-bolus doses of insulin based on structured SMBG.

- Perform SMBG before eating and 2 hours after each meal.
- If 2-hour postprandial glucose is consistently more than 50 mg/dL above baseline for a given meal, increase insulin dose by 1 to 2 units. The target 2-hour postprandial Δ is 0 to 50 mg/dL (see Table 34-12).
- Any negative Δ (e.g., -25 mg/dL from baseline) predicts hypoglycemia. Blood glucose levels must be rechecked in 1 hour to monitor for hypoglycemia.
- A pattern of negative Δ values for a given meal suggests a mismatch between insulin dosing and carbohydrate intake for that meal. Reduce insulin dose by 1 to 2 units.

Table 34-25 shows examples of how structured glucose testing may be used to fine tune prandial insulin regimens.

Step 5: Establish an insulin sensitivity factor to determine correction doses for premeal hyperglycemia.

- Correction doses may be used to correct an elevated blood glucose value before eating.
- Patients can safely correct if their premeal glucose level is greater than 180 mg/dL.
- Postcorrection blood glucose target should always be 150 mg/dL (to avoid overshooting that conservative goal and inducing hypoglycemia).
- Insulin sensitivity factor is the number of mg/dL that 1 unit of insulin is expected to lower blood glucose and is based on the "rule of 1800."

$1800/TDD =$ Expected drop in blood glucose from 1 unit of insulin. Example: If TDD is 70 units, the insulin sensitivity factor would be:

$$1800/70 = 25.7 \text{ (Round off to 25.)}$$

Thus, if the premeal blood glucose is 200 mg/dL and the target blood glucose is 150 mg/dL, the patient would give

Table 34-24 Prandial Dose Adjustments of Rapid-Acting Insulin

Meal Size	Prandial Insulin Dose Adjustment
Standard meal	No change
Very large meal with dessert	+3 units from baseline dose
Large meal without dessert	+1 to 2 units from baseline dose
Smaller than usual meal	-1 to 2 units from baseline dose

Table 34-25 Example of Structured Self-Monitoring of Blood Glucose for Patients with Type 1 Diabetes Mellitus

Date	Pre-Lunch Glucose (mg/dL)	2-Hour Post-Lunch Glucose (mg/dL)	Δ (Difference between Baseline Glucose and 2-Hour Postmeal Glucose)	Reasons for Δ Being <0 (a "Negative Δ ") (Could Indicate Impending Hypoglycemia; List Actions Taken for Hypoglycemia)	Reasons for Δ Being >50 mg/dL (List Corrective Actions)
2/13	125	225	+100	—	Bolus given at meal time rather than 15 minute before eating Mismatch of insulin to carbohydrate (ate dessert); will give 2 units for dessert next time
2/14	110	154	44 (at target)	—	—
2/15	227	117	-110	Overcorrected on premeal insulin dose; became hypoglycemic 3 hours after eating but consumed 15 g of carbohydrate	
2/16	153	169	+16	Perfect	No need for adjustments for this type of food
3/17	125	200	+75	Stopped daily afternoon workouts; caring for ailing mother-in-law	Advised to increase baseline lunchtime prandial insulin dose by 2 units
3/18	100	190	+90		
3/19	135	235	+100		

a correction dose of 2 units (to correct for 50 mg/dL above target) in addition to the baseline prandial insulin dose at that particular meal. A patient who normally boluses 7 units before eating and has a 200 mg/dL premeal glucose value would add 2 units to the prandial dose for a total bolus dose of $7 + 2 = 9$ units before eating.

- Patients who plan to eat a large meal may adjust their mealtime dose further according to the options mentioned in [Table 34-24](#).
- SMBG should be performed 2 hours after eating to ensure that the correction dose did not cause glucose levels to trend toward hypoglycemia as a result of overcorrection.

Multiple daily injections should be initiated and maintained with the use of insulin pens rather than syringes and vials. Insulin pens allow for accuracy, portability, flexibility, and ease of use. Insulin pens typically do not need refrigeration, which may provide for additional patient adherence to therapy over vial-and-syringe insulin delivery. Patients must be familiar with the nuances of using each type of pen delivery device. Most important, errors in insulin delivery can be avoided if patients make certain that they are giving the appropriate formulation of insulin for basal or prandial coverage.

Patients whose A1C levels rise despite being provided adequate dosing protocols for a basal-bolus regimen may be nonadherent to their prescribed insulin regimen. One study found that 64% of T1DM patients were incorrectly assessing their prandial insulin requirements ([Ahola et al., 2010](#)). Barriers to insulin intensification in T1DM include fear of hypoglycemia, weight gain, inconvenient dosing protocols, and confusion about appropriate dosing of mealtime insulin ([Cavan et al., 2012](#)). [Table 34-26](#) lists the advantages of insulin pens over syringes and vials ([Asamoah, 2008](#)).

Table 34-26 Advantages of Insulin Pen Delivery Systems versus Syringes and Vials

<p>Clinicians can teach pen use to patients in <3 min on average. There is no need to inconvenience patients by having them learn the technique of insulin injection offsite.</p> <p>Use of 30- or 31-gauge short needles with pens has significantly reduced the needle phobia that patients have about taking injections. Also, needles are less painful when they do not have to be inserted through the rubber stopper of a vial, which destroys the fine tip needle coating and thus increases injection pain.</p> <p>Pens are easier than vials and syringes to carry in a pocket or purse. Pen devices have been shown to be more accurate than syringes for delivering insulin doses ≤ 5 units, so they may benefit children and adolescents, who usually require smaller doses (Gnanalingham et al, 1998).</p> <p>Older patients with diabetes who have comorbidities or disabilities (e.g., visual impairments, tremors, or impaired motor skills) that may exacerbate the difficulties of self-injection and increase the risk of dosing errors often find that pen devices can help to overcome such limitations.</p> <p>Numerous patient surveys have demonstrated that patients prefer pens over vials and syringes (Asamoah, 2008).</p>

Gnanalingham MG, Newland P, Smith CP. An evaluation of NovoPen, BD-Pen, and syringe devices at small doses of insulin [Abstract P118]. Insulin pen: the "iPod" for insulin delivery: why pen wins over syringe. *J Diabetes Sci Technol.* 2:292-296, 2008.

INSULIN PUMP THERAPY AND CONTINUOUS GLUCOSE SENSORS

Continuous subcutaneous insulin infusion, also known as insulin pump therapy, allows patients with diabetes to achieve improved glycemic control while using less daily insulin, reducing the likelihood of weight gain and hypoglycemia, and limiting diurnal glycemic variability compared with insulin delivery via vials and syringes or insulin pen devices ([Weissberg-Benchell et al., 2003](#)). Because of the lifestyle flexibility that insulin pump users enjoy, quality-of-life assessment scores consistently favor CSII over MDI regimens. Switching from an MDI regimen to CSII will limit the number of short-term complications such as hypoglycemia and DKA, as well as reduce the risk for long-term microvascular complications ([Weissberg-Benchell et al., 2003](#)).

Although CSII is certainly the most sophisticated and precise insulin-delivery method currently available, patients who initiate pump therapy must be solidly committed to diabetes self-management. SMBG must be performed six to eight times daily unless patients use concomitant CGM devices. Patients must understand insulin pharmacokinetics, become adept at appropriate dosing and timing of prandial insulin, and be knowledgeable about exercise physiology. Pumps are machines that may fail, malfunction, or even be lost. Therefore, pump users must be trained to fall back to an emergency protocol such as pen or syringe insulin delivery to allow them to control hyperglycemia and minimize the risk of DKA if their pump malfunctions.

Fortunately, the vast majority of insulin pump users are skilled diabetes self-managers who often put clinicians to shame with their disease state knowledge. Because pump users are both challenging and intelligent members of the diabetes community, primary care physicians should learn the basics of pump therapy. Clinicians who feel comfortable intensively managing patients with MDI regimens are also capable of initiating and titrating insulin pump regimens ([Unger, 2012b](#)).

Ideally, insulin replacement should mimic the normal glucose and endogenous insulin response to the fasting and prandial states. However, prandial injection therapy, whether given by a syringe or a pen device, cannot provide an exact physiological dose to replicate first- and second-phase insulin secretion. A pen- or syringe-delivered dose of insulin mimics only first-phase (acute) insulin secretion. The bolus dose may not be sufficient to cover a delayed rise in glucose that may occur if the consumed meal is high in fat. Thus, patients may experience an insulin-to-carbohydrate mismatch, resulting in early postabsorptive hypoglycemia followed by an increase in plasma glucose as the rapid-acting insulin analog absorption is mitigated. To address this problem, insulin pumps allow patients to provide a bolus of insulin in percentages over time. For example, 20% of the insulin dose may be bolused immediately, and the remainder can be released as an "extended bolus" over several hours.

A similar problem exists regarding basal insulin delivered via pen or syringe. Giving one dose via pen or syringe assumes that basal insulin requirements will not change during the 24-hour period after the dose is given. However, patients who exercise will have reduced basal insulin requirements. Before patients arise in the morning, their

Table 34-27 Candidates for Continuous Subcutaneous Insulin Infusion Therapy

CSII should be considered for patients who:

- Have frequent hypoglycemia or hypoglycemia unawareness
- Fail to reach goal A1C with MDI insulin regimen
- Exercise regularly
- Experience the dawn phenomenon, which cannot be controlled with a single daily injection of basal insulin
- Travel frequently or are employed in shift work
- Are pregnant or planning for pregnancy
- Are children or adolescents
- Have gastroparesis
- Have a history of frequent DKA
- Experience severe insulin resistance (requiring >250 units of insulin daily)
- Would prefer to use an insulin pump rather than following an MDI regimen
- Are undergoing chemotherapy; glycemic variability may increase cancer-related mortality
- Have multiple micro- and macrovascular complications; hypoglycemia increases mortality in these patients
- Have ESRD
- Are athletes at any level of competition

CSII, Continuous subcutaneous insulin infusion; DKA, diabetic ketoacidosis; ESRD, end-stage renal failure; MDI, multiple daily injection.

basal insulin requirements increase in response to physiological insulin resistance caused by increased production of cortisol and growth hormone (a circumstance known as the “dawn phenomenon”). In the afternoon hours, insulin requirements are typically lower than during the morning and evening hours. Unfortunately, after a pen or syringe injection of basal insulin is given, the drug’s influence on basal insulin levels cannot be altered; one cannot turn up or turn down the level of basal insulin injected the evening before in response to exercise or varying degrees of insulin resistance occurring in the 24-hour period after the injection. Insulin pumps address this issue by allowing patients to program multiple basal insulin delivery rates to match their individualized sleep patterns, physical activity, menstrual schedule, medications, and travel plans. (Such a feature is ideal for steroid-dependent patients who experience postprandial hyperglycemia and normal fasting glucose values.)

Thus, CSII allows patients with T1DM or insulin-requiring T2DM to enjoy a flexible lifestyle while avoiding hypoglycemia. By programming changes to both basal and bolus insulin delivery rates, pump users adjust their regimen to closely simulate normal endogenous β -cell insulin secretion.

Insulin pumps have been available since the 1980s, and more than 400,000 pump devices are sold annually worldwide (Unger, 2012b). Table 34-27 lists some of the indications for considering CSII in insulin-requiring patients with diabetes.

Patients may also integrate their CSII regimen with CGM. CGM systems operate by measuring glucose levels in interstitial fluid. The devices consist of three components: a disposable sensor that measures glucose levels, a transmitter that is attached to the sensor, and a receiver that displays and stores glucose information. The information stored in the receiver is then converted into estimated mean values of glucose standardized to capillary blood glucose levels

measured during calibration. Using an applicator or self-insertion device, patients insert a thin plastic sensor just under the skin of the abdomen or upper arm. These devices can display real-time glucose values and trends, and some can help patients avoid hyper- and hypoglycemia by sounding an alarm or vibrating when glucose levels rise above or fall below preprogrammed upper and lower thresholds. The receiver can store information for later use, and long-term data can be downloaded to a computer. Real-time trend graphs can be downloaded to a computer or displayed on the pump screen, which can be useful in identifying glycaemic trends in response to physical activity, meals, insulin doses, menstruation, illness, or other factors.

The Medtronic MiniMed 530G system integrates CGM with CSII in one device that uses sensor-augmented pump technology. The CGM communicates with the pump and will automatically suspend insulin delivery when glucose values reach a pre-programmed low threshold.

EXERCISE AND TYPE 1 DIABETES MELLITUS MANAGEMENT

During the transition from rest to exercise, skeletal muscles shift from using predominantly FFAs released from adipose tissue to a mixture of muscle triglycerides, muscle glycogen, and glucose derived from glycogenolysis. During the initial stages of moderate exercise, muscle glycogen is the primary energy source. However, as exercise becomes more prolonged, glycogen stores become depleted, requiring the body to rely on circulating FFAs and plasma glucose as fuel sources. During heavy exercise (30-60 minutes at 80% of maximal oxygen uptake), peripheral glucose utilization may be as high as 1 to 1.5 g/min (Wasserman et al., 2002). This source of energy must be continuously replaced at an equal rate to prevent the onset of exercise-induced hypoglycemia.

In euglycemic individuals, plasma glucose levels are sustained during exercise because pancreatic insulin secretion decreases while levels of glucagon, growth hormone, cortisol, and catecholamines increase. Patients with T1DM lack the ability to regulate both endogenous insulin secretion and counterregulatory hormones in response to exercise, making maintenance of physiological fuel regulation nearly impossible. Thus, patients must adjust their carbohydrate consumption and insulin doses, as well as their exercise intensity, mode, and duration, to minimize the risk of hypoglycemia and exercise-induced DKA.

Intensive management of T1DM increases the risk of exercise-induced hypoglycemia. Exercise acutely increases peripheral glucose utilization within skeletal muscles, thus making circulating exogenous insulin “turbo-charged.”

Patients with poorly controlled T1DM are at risk for exercise-emergent DKA (Riddell and Perkins, 2006). Prolonged exercise triggers hepatic glucose production. Insulinopenic patients with a baseline plasma glucose level greater than 240 mg/dL experience a rise in plasma glucose levels as exercise intensifies. Low circulating insulin levels cannot suppress hepatic glucose production during exercise. Dehydration combined with an exercise-induced increase in catecholamines will likely hasten the onset of DKA in these individuals (Marliss and Vranik, 2002). Table 34-28 lists suggested practical guidelines to minimize blood

Table 34-28 Suggestions for Minimizing Blood Glucose Excursions before, during, and after Exercise for Patients with Type 1 Diabetes Mellitus

Time Period	Recommendations
Before exercise	<p>Determine the timing, mode (aerobic vs. resistance training), and intensity of exercise to be performed.</p> <p>Perform SMBG before exercising.</p> <p>A safe target blood glucose before moderate exercise is 120-180 mg/dL.</p> <p>If blood glucose is <120 mg/dL, consume 15 g of carbohydrates to provide an energy source during exercise.</p> <p>Do not exercise if blood glucose is ≥ 250 mg/dL and ketosis is present or if glucose is ≥ 300 mg/dL and no ketones are present.</p> <p>If activity is moderate or strenuous, lasts <90 min, and begins within 90 min of a meal, a reduction in prandial doses of lispro, aspart, or glulisine is warranted.</p> <p>Insulin doses may need to be increased and monitored more frequently during periods of prolonged resistance training or when training occurs in a warm environment.</p> <p>Consume 250 mL of fluids 20 min before exercise to maintain hydration.</p>
During exercise	<p>Monitor blood glucose level every 30 min.</p> <p>Continue fluid intake of 250 mL every 20 min during vigorous exercise.</p> <p>If blood glucose drops to <100 mg/dL during periods of moderate or intense exercise, consume 15 g of carbohydrates every 20-30 min.</p> <p>Consider using a CGM device, which will indicate the directional trend in blood glucose during exercise.</p>
After exercise	<p>Perform SMBG overnight if exercise is atypical.</p> <p>Consider consuming additional slow-acting carbohydrates to protect against exercise-induced nocturnal hypoglycemia.</p> <p>Patients with hypoglycemia awareness should wear a CGM device, which will alert them to impending nocturnal hypoglycemia.</p>

CGM, Continuous glucose monitoring; SMBG, self-monitoring of blood glucose.

glucose excursions before, during, and after exercise for patients with T1DM.

Each year, 13,000 Americans are diagnosed with T1DM. Early intervention using an MDI or CSII insulin regimen is likely to minimize patients' long-term risks of micro- and macrovascular complications. Modern insulin formulations and delivery systems allow more patients to achieve their target glycemic and metabolic goals. T1DM is no longer an acute disease with a "death sentence" of 6 months as it was before the discovery of insulin. As our understanding of T1DM pathogenesis expands and our treatment armamentarium becomes more accessible, patients with diabetes are now able to live full and productive lives.

As clinicians, we must give our patients credit for making multiple decisions each day that will ultimately determine their ability to physiologically control glucose levels against incredible odds. We should never chastise our patients or imply that they are "noncompliant" because their glucose levels are poorly controlled. As family doctors, our role is to coordinate care for our patients and to make sure all patients are treated toward success rather than failure. T1DM is a challenging chronic disease. No specialty is better equipped to manage all aspects of diabetes than family medicine.

Long-Term Complications of Diabetes

Prolonged exposure to hyperglycemia, glycemic variability, genetic predisposition, oxidative stress, obesity, environmental factors, duration of disease, and timing of intensive management initiation are important determinants in the development of long-term diabetes-related complications. Microvascular disease resulting in small vessel injury can lead to disorders affecting the peripheral, sensory, and autonomic nerves; kidneys; and eyes. Macrovascular

complications damage large vessels, resulting in coronary artery disease, MI, angina, peripheral arterial disease, and stroke. The link between glycemic burden and induction of disease-specific complication pathways has been established to involve four independent biochemical abnormalities: increased polyol pathway flux, increased formation of advanced glycation end products, activation of protein kinase C, and increased hexosamine pathway flux. These seemingly unrelated pathways have an underlying common denominator, which is an increase in oxidative stress caused by the overproduction of superoxide by the mitochondrial electron transport chain (Figure 34-6). Hyperglycemia, whether acute (postprandial) or chronic, has tissue-damaging effects on cell types such as capillary endothelial cells of the retina, mesangial cells in the renal glomerulus, and peripheral neurons. Cells that can effectively assimilate glucose as an energy source before transporting nonessential glucose out of the cell are less prone to complications. Cells such as neurons and nephrons, which are inefficient interstitial transporters of glucose, undergo oxidative stress, which induces endothelial dysfunction, vascular inflammation, and activation of pathways that trigger complications. Other cells, such as those in the GI tract, are more efficient at transporting excessive glucose out of the cell, thereby minimizing the risk of oxidative stress.

Vascular endothelial cells form physical and biological barriers between vessel walls and circulating blood cells, with the endothelium playing an important role in the maintenance of vascular homeostasis. Central to this role is the endothelial production of nitric oxide (NO), which is synthesized by the constitutively expressed endothelial isoform of NO synthase. Vascular diseases, including hypertension, diabetes, and atherosclerosis, are characterized by impaired endothelium-derived NO bioactivity that may contribute to clinical cardiovascular events. Endothelial cells exposed to oxidative stress generate high levels of reactive oxygen species via their mitochondrial electron-transport chain. Susceptible cells activate biochemical pathways

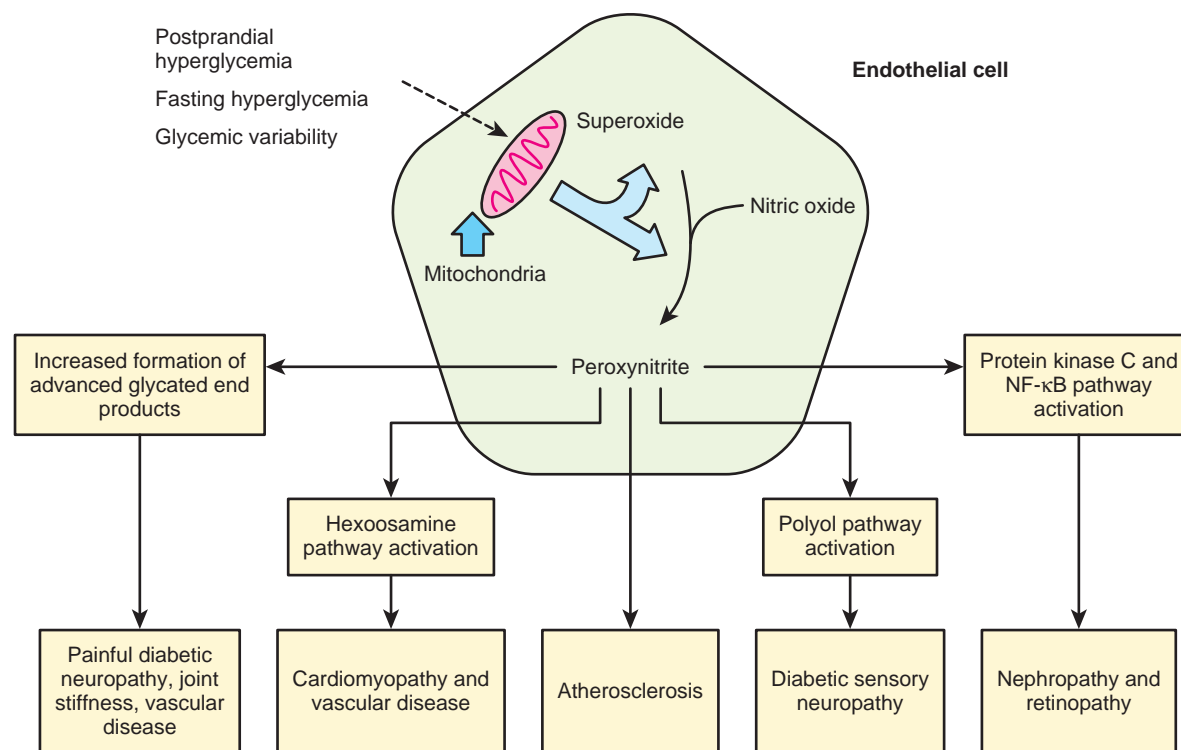

Figure 34-6 Downstream effects of oxidative stress–induced diabetes complication pathways. Postprandial and fasting hyperglycemia, as well as glycemic variability, result in the production of superoxide within the mitochondria of endothelial cells. Nitric oxide regulates vascular tone and minimizes adhesion molecule penetration of the vascular walls. When superoxide interacts with peroxynitrate, the endothelial cell's mitochondrial electron transport system becomes impaired, resulting in endothelial dysfunction. Transcription of endothelial-derived cytokines induce pathways known to activate microvascular complications. Peroxynitrate also favors lipid oxidation leading to atherosclerosis and macrovascular disease. Activation of the protein kinase C and nuclear factor κ B pathways favors induction of nephropathy and retinopathy. Neuropathic induction is activated through the polyol pathway. Excessive advanced glycation results in painful diabetic neuropathy. *NF- κ B*, Nuclear factor- κ B. (Adapted with permission from Unger J. *Diabetes management in primary care*. 2nd ed. Philadelphia: Lippincott, Williams and Wilkins; 2012.)

likely to progress to long-term micro- and macrovascular complications unless metabolic stability is restored.

Brownlee (2001) determined that patients with both acute and chronic hyperglycemia live in a constant state of oxidative stress favoring end-stage complications. Exposure to blood glucose levels greater than 180 mg/dL results in prolonged endothelial cell dysfunction and vascular inflammation that persist for 7 days even after the acute episode of hyperglycemia is reversed. Clinically, patients who record a fasting blood glucose level greater than 180 mg/dL have likely been exposed to oxidative stress that has persisted throughout their resting hours. Failure to recognize and correct the chronic hyperglycemic state will place patients at risk for all-cause mortality and long-term complications.

Tables 34-29 and 34-30 list practical pointers related to each of the major long-term micro- and macrovascular complications observed in patients with diabetes. Table 34-31 summarizes the ADA's recommendations for use of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in patients with diabetic nephropathy.

Primary care physicians should play a proactive role in screening patients for micro- and macrovascular complications. All patients with diabetes should be provided with written, individualized glycemic targets for fasting glucose,

postprandial glucose, and A1C. Glycemic targets should be determined based on patients' duration of disease, presence or absence of significant comorbidities (especially macrovascular disorders), ability to safely and effectively perform SMBG, history of hypoglycemia unawareness, and psychosocial support mechanisms. Patients with renal insufficiency are at risk for treatment-emergent hypoglycemia and should have their prescription and herbal medications reviewed at each visit. Patients with chronic liver disease should discontinue use of sulfonylureas and consider lowering insulin doses. Chronic liver disease appears to increase β -cell sensitivity to sulfonylureas and reduce hepatic clearance of insulin, both of which can lead to a higher risk of hypoglycemia.

Undoubtedly, diabetes is a very complex disorder that requires a comprehensive treatment plan for most patients. Primary care physicians should not hesitate to communicate with consulting physicians who are co-managing their diabetes patients. Primary care physicians need to develop better means for monitoring their patients for compliance related to their specialty care visits. In addition, clinicians must communicate their concerns about patients' poor metabolic control to co-managing specialists to ensure that patients receive timely and appropriate screening and management of their long-term complications.

Table 34-29 Diabetes-Related Microvascular Complications: Practical Pointers

Complication	Statistics of Interest	Clinical Presentation	Treatment Strategies	Prevention or Reversal
Neuropathy	<p>50% of patients with clinical neuropathy may be asymptomatic</p> <p>Affects 25%-30% of all patients with diabetes</p> <p>Cardiac autonomic neuropathy associated with a threefold increased risk of mortality</p>	<p>Pain derived from small nerve fibers may be sharp, burning, and lancinating</p> <p>Patients describe pain as "bee stings through socks" or "walking on hot coals"</p> <p>Pain typically worse at rest and improves with activity</p> <p>Negatively affects sleep, quality of life, and balance; may lead to anxiety and depressive symptoms</p> <p>Autonomic symptoms include loss of sweating on forehead and feet; abdominal distention; nocturnal diarrhea and constipation; erectile dysfunction and vaginal dryness; orthostatic hypotension; cardiac autonomic dysfunction; and hypoglycemia awareness</p> <p>autonomic dysfunction</p>	<p>FDA-approved drugs include duloxetine and pregabalin</p> <p>Avoid tricyclic antidepressants in patients >65 years of age because of adverse side effects</p> <p>For refractory pain, consider gabapentin + methadone</p>	<p>Smoking cessation</p> <p>Weight reduction</p> <p>Improvement in triglycerides</p> <p>Consider use of vitamin D₃, 4000 IU, and magnesium oxide, 250 mg, at bedtime</p> <p>For autonomic dysfunction, glycemic variability must be minimized and A1C should be brought as closely and safely as possible to the range of 7%-7.5%</p>
Nephropathy	<p>30% of patients with T1DM and 10%-40% of patients with T2DM will eventually develop ESRD</p> <p>Diabetes accounts for 38% of all ESRD in the United States</p> <p>The mean A1C of patients initiating treatment for ESRD is 7.6%, suggesting that risk factors such as genetics, BP, smoking, obesity, and hyperlipidemia may be influential in determining both disease progression and outcomes</p> <p>Diabetes-related ESRD declined in all age groups by 3.9% per year from 1996 to 2006 as physicians became more aware of the importance of intensive metabolic management of glucose, BP, and hyperlipidemia</p> <p>The highest mortality rates are observed with macroalbuminuria (albumin-to-creatinine ratio >300 mg/g) and a GFR <60 mL/min/1.73 m²</p>	<p>CKD is defined as having an estimated GFR <60 mL/min/1.73 m² over 6 months</p> <p>CKD stages are based on the estimated GFR (mL/min/1.73 m²) as follows:</p> <ul style="list-style-type: none"> ■ Normal: >90 ■ Stage 1: >90 with kidney damage ■ Stage 2: 60-89 with kidney damage ■ Stage 3: 30-59 ■ Stage 3A: 45-59 ■ Stage 3B: 30-44 ■ Stage 4: 15-29 ■ Stage 5: <15 	<p>Discontinue nicotine and alcohol</p> <p>Screen high-risk patients for sleep apnea, vitamin D deficiency, and secondary hyperparathyroidism</p> <p>DCCT: intensively managing T1DM reduces the incidence of microalbuminuria by 39%</p> <p>ADVANCE: 21% reduction in the risk of new or worsening nephropathy noted in patients as systolic BP was reduced to 110 mm Hg</p> <p>ACE inhibitors and ARBs decrease the risk of progression to macroalbuminuria by as much as 60%-70%</p> <p>A moderately low-protein diet (0.9 g/kg/day) used in patients with T1DM and progressive diabetic nephropathy reduced the risk of ESRD and death by 76% without affecting the decline in GFR</p> <p>Drugs that require dosage adjustments in patients with nephropathy include metformin, sulfonamides, α-glucosidase inhibitors, glitazides, and insulin. The incretin-based therapies exenatide, sitagliptin, saxagliptin, and alogliptin require dosage reductions in people with a creatinine clearance of <50 mL/min; liraglutide and linagliptin require no adjustments. SGLT2 inhibitors are ineffective at estimated GFR <45 mL/min/1.73 m²</p> <p>Screen and treat patients for anemia to reduce the risk of heart failure and CKD progression; maintain hemoglobin levels ≥12 g/dL</p> <p>Use aspirin to prevent CVD; higher doses are needed because patients with CKD are aspirin resistant</p> <p>Lowering LDL cholesterol to <100 mg/dL may minimize CVD risk but not CKD progression</p>	<p>Yearly measurements of creatinine, urinary albumin excretion, and potassium</p>

Table 34-29 Diabetes-Related Microvascular Complications: Practical Pointers (Continued)

Complication	Statistics of Interest	Clinical Presentation	Treatment Strategies	Prevention or Reversal
Retinopathy	Prevalence of diabetic macular edema in the United States is 28% Only 63% of diabetes patients have had screening eye examinations	<p>"Mild" refers to the presence of microaneurysms only.</p> <p>"Moderate" NPDR is defined as the presence of microaneurysms and either hard exudates or blot hemorrhages caused by the deposition of lipoproteins and the exudation of red blood cells from retinal microaneurysms.</p> <p>"Severe" NPDR is characterized by a large number of retinal hemorrhages or the presence of cotton-wool exudates (microinfarcts within the nerve fiber layer of the retina) and the development of intraretinal microvascular abnormalities (collateral vessels) in the resulting ischemic areas of the retina.</p> <p>PDR is associated with the development of abnormal new retinal blood vessels that may bleed into the vitreous cavity and become fibrotic; the resulting traction on the macula leads to visual loss.</p> <p>Diabetic macular edema results in thickening of the retina and decreased central visual activity.</p>	<p>Minimize glycemic variability</p> <p>DCC1: intensive diabetes management reduced risk of proliferative retinopathy by 47%</p> <p>UKPDS: intensive BP control resulted in a 47% risk reduction in vision loss for patients treated to a target of <150/85 mm Hg vs. those treated to 180/95 mm Hg</p>	<p>Screen T1DM patients 3-5 years after initial diagnosis; repeat annually if no retinopathy observed</p> <p>Screen T2DM patients at time of diagnosis; repeat annually if no retinopathy observed</p> <p>Screen before conception and during the first trimester of pregnancy; reevaluate every 1 to 3 months if retinopathy is present</p> <p>Optical coherence tomography can demonstrate intraretinal edema affecting the macula</p> <p>Digital retinal photography allows for rapid acquisition of high-quality retinal images without requiring pupillary dilatation; these cameras can be used by primary care physicians with interpretation by trained ophthalmologists</p>

Table 34-30 Diabetes-Related Macrovascular Complications: Practical Pointers

Complication	Statistics of Interest	Clinical Presentation	Treatment Strategies	Prevention or Reversal
Coronary heart disease, stroke, and peripheral arterial disease	The mortality rate at the time of acute MI is essentially doubled in patients with diabetes compared with those without diabetes. For MI survivors, follow-up mortality in patients with diabetes is essentially doubled compared with those without diabetes. 80% of diabetes-related deaths are attributable to coronary heart disease, stroke, and peripheral arterial disease.	Chest pain, shortness of breath, anxiety (in women), orthostatic hypotension, loss of beat-to-beat variability, abnormalities in QT interval (QT prolongation), depression, erectile dysfunction, low testosterone levels in men, fatigue, peripheral edema, congestive heart failure, and sudden death For peripheral arterial disease: <ul style="list-style-type: none"> ■ Some patients are asymptomatic ■ Pain with ambulation; subsides with rest ■ Hair loss ■ Brittle nails ■ Dry, scaly, atrophic skin ■ Dependent rubor ■ Pallor with leg elevation after 1 minute at 60 degrees (normal color should return in 10-15 seconds; >40 seconds indicates severe ischemia) ■ Ischemic tissue ulceration (punched-out, painful, with little bleeding), gangrene ■ Absent or diminished femoral or pedal pulses ■ Arterial bruits 	Low-dose aspirin Lower LDL cholesterol to <100 mg/dL Lower BP to <130/80 mm Hg Target A1C to lowest and safest level using rational pharmacology to minimize risk of hypoglycemia, especially in patients with T2DM and preexisting coronary artery disease	Screen for and manage risk factors related to unhealthy lifestyle choices: inactivity, obesity, smoking, alcohol, and inactivity. Reduce and slow progression of microalbuminuria and CKD. Recommendations for ABI screening to detect peripheral arterial disease in patients with diabetes: <ul style="list-style-type: none"> ■ A resting ABI should be used to establish diagnosis of peripheral arterial disease in high-risk patients. ■ Index is calculated as the ratio of systolic BP at the ankle to that at the arm. ■ High-risk patients include those with exertional claudication, nonhealing wounds, and age ≥65 years or age ≥50 years with a history of smoking or diabetes. ■ Normal values defined as 1.00 to 1.40; borderline 0.91 to 0.99. ■ Abnormal values are ≤0.90.

ABI, Ankle-brachial index; CKD, chronic kidney disease; MI, myocardial infarction; LDL, low-density lipoprotein; T2DM, type 2 diabetes mellitus.
 Rooke TW, Hirsch AT, Misra S, et al. 2011 ACCF/AHA focused update of the guideline for the management of patients with peripheral artery disease (updating the 2005 guideline): a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 124:2020-2045, 2011; Fowler MJ. Table 34-31 Treatment for Diabetic Nephropathy

Category	Recommended Treatment
T1DM or T2DM with micro- or macroalbuminuria	ACE inhibitors or ARBs
T1DM with hypertension and albuminuria	ACE inhibitors delay progression of nephropathy
T2DM with hypertension and microalbuminuria	ACE inhibitors or ARBs delay the progression to macroalbuminuria
T2DM with hypertension, macroalbuminuria, and renal insufficiency (serum creatinine >1.5 mg/dL)	ARBs delay the progression of nephropathy
T1DM or T2DM with microalbuminuria and normal BP	ACE inhibitors or ARBs

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus.

Table 34-32 Five Key Behaviors to Help Patients Become Successful Diabetes Self-Managers

1. Know your metabolic targets (A1C, BP, and lipids).
2. Know how to achieve your metabolic targets.
 - a. Increase physical activity.
 - b. Consume a healthy diet.
 - c. Perform SMBG in a timely manner.
3. Stop smoking and alcohol use.
4. Take your prescribed medications.
5. Be certain your health care providers understand how to successfully and intensively manage diabetes.

BP, Blood pressure; SMBG, self-monitoring of blood glucose.

Five Things Patients Must Do to Become Successful Diabetes Self-Managers

A diagnosis of diabetes presents numerous challenges for patients, their families, and the clinicians who direct their care. At times, the burden of having diabetes may seem overwhelming. Unfortunately, diabetes is a chronic disease requiring daily adjustments in care and, in most cases, adoption of intensive lifestyle alterations. Rather than increase their concern about the future risk of long-term complications, newly diagnosed patients with diabetes should be reassured that their lives can be long, productive, and healthy if they adopt the five specific behaviors listed in [Table 34-32](#). Of primary importance is reassuring patients

that the number 1 complication of *well-controlled* diabetes is ... nothing!

CHAPTER OUTLINE

Hypothalamic–Pituitary Axis, 817
Approach to Pituitary Disease, 818
Pineal Gland, 828
Thyroid Disorders, 828

Adrenal Glands, 839
Ovarian and Testicular Disorders, 847
Disturbances in Calcium and Phosphate, 861

Key Points

- The hypothalamic–pituitary axis (HPA) orchestrates the hormonal secretions of the other endocrine glands.
- The pituitary is composed of the adenohypophysis, or anterior lobe, and the neurohypophysis, or posterior lobe.
- The hormonal secretions of the anterior pituitary are regulated by a number of hypothalamic-releasing hormones and inhibitory molecules.
- The posterior lobe of the pituitary is where nerve endings, originating in the paraventricular and supraoptic nuclei, project as the supraopticohypophyseal tract.

Hypothalamic–Pituitary Axis

The hypothalamus affects several nonendocrine functions, including appetite, sleep, body temperature, and activity of the autonomic nervous system. In addition, the hypothalamus modulates the pituitary hormone secretions. The other half of the HPA, the pituitary gland, is often referred to as the “master gland” in recognition of its role in orchestrating the hormonal secretions of the other endocrine glands (Mooradian and Korenman, 2007; Mooradian and Morley, 1988).

The pituitary gland is located in the anterior fossa, in the sella turcica, in close proximity to the optic chiasm. The pituitary is composed of the adenohypophysis, or anterior lobe, and the neurohypophysis, or posterior lobe, and is connected to the hypothalamus by the pituitary stalk.

See [Table 35-1](#) for a listing of hormones from each lobe of the pituitary.

Control of pituitary hormones is a complex process involving the hypothalamus, both lobes of the pituitary, and hormones endogenously produced by the various organs of the endocrine system.

Hormones secreted from the anterior pituitary lobe are regulated by a number of hypothalamic-releasing hormones and inhibitory molecules. These factors reach the pituitary through the portal circulation and, upon interaction with specific receptors, either stimulate or inhibit the secretion of the anterior pituitary hormones.

The main releasing hormones produced in the hypothalamus include thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), corticotropin-releasing hormone (CRH), and growth hormone–releasing hormone (GHRH). There are two major inhibitory factors: dopamine, which principally inhibits prolactin release, and somatostatin, a potent inhibitor of growth hormone (GH) and, to a lesser extent, thyrotropin or thyroid-stimulating hormone (TSH).

A number of other factors have been identified and shown to have important regulatory effects on anterior pituitary function. The kisspeptin hormones are a family of peptides encoded by the *KiSS-1* gene and are thought to play a critical role in reproduction. Kisspeptin receptors stimulate GnRH release and activation of the mammalian reproductive axis. Mutations in kisspeptin receptor GPR-54 cause idiopathic hypogonadotropic hypogonadism (HH) characterized by delayed or absent puberty (Jayasena and Dhillon, 2009).

There is a short-loop regulatory system within the HPA, which, via the portal circulation, allows pituitary hormones to flow in a retrograde direction back to the hypothalamus to feedback on their own releasing hormones. In addition, there is a long-loop negative feedback on the pituitary, mediated by hormones secreted by endocrine glands in the periphery (Mooradian and Korenman, 2007; Mooradian and Morley, 1988). It is the interplay between the effects of the hypothalamic-releasing hormones, the short-loop regulatory system and the long-loop negative feedback that controls pituitary hormonal secretions. For example, a rise in plasma thyroid hormone level feeds back and suppresses pituitary TSH and hypothalamic TRH secretion.

As we achieve better understanding of the intricacies of these processes and feedback controls, new therapeutic modalities are postulated. Secretion of GH is regulated by two hypothalamic hormones, GHRH and somatostatin. New data suggest that γ -aminobutyric acid (GABA) may also play a role in GH secretion. Although research in this area is relatively new, it does suggest a possible alternative approach to growth retardation caused by insufficient GH secretion or gigantism caused by GH excess (Powers, 2012).

The posterior pituitary lobe is essentially an extension of the hypothalamus, where the nerve endings, originating in the paraventricular and supraoptic nuclei, project as the supraopticohypophyseal tract. The posterior pituitary

Table 35-1 Pituitary Hormones

Hormones of the adenohypophysis or anterior pituitary lobe	Thyroid-stimulating hormone (TSH or thyrotropin)
	Follicle-stimulating hormone (FSH)
	Luteinizing hormone (LH)
	Prolactin (PRL)
	Growth hormone (GH or somatotropin)
	Adrenocorticotropic hormone (ACTH)
Hormones of the neurohypophysis (pars nervosa) or posterior pituitary lobe	α -Melanocyte-stimulating hormone (α -MSH)
	Antidiuretic hormone (ADH or vasopressin)
	Oxytocin

hormones are directly controlled by neural impulses and are released into the inferior hypophyseal veins and then into the systemic circulation (Mooradian and Morley, 1988).

Approach to Pituitary Disease

Key Points

- Pituitary disease may manifest with pituitary hormone excess or deficiency or symptoms of mass expansion, including headaches and visual disturbances.
- Pituitary adenoma is the most common cause of pituitary dysfunction in adults.
- HPA function should be assessed whenever a mass is discovered in the sella turcica.
- Evaluation of pituitary function (deficiency or excess) involves imaging and serum measurements of prolactin, GH, insulin-like growth factor type 1 (IGF-1), free thyroxine (FT₄), TSH, adrenocorticotropic hormone (ACTH), cortisol, luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone (in men), and estradiol (in women). Twenty-four-hour urinary free cortisol and dexamethasone suppression tests (DSTs) are used for evaluating cortisol excess.

The most common cause of pituitary disease is the development of benign tumors (adenomas). These tumors can cause symptoms because of excessive production of hormones such as prolactin, GH, or ACTH or can cause pituitary hormone insufficiency secondary to tissue destruction. The pituitary hormones that can be lost early from gradual destruction of pituitary tissue include GH and GnRH followed by TSH and ACTH (Mooradian and Korenman, 2007; Mooradian and Morley, 1988). However, occasionally, the autoimmune destruction of the pituitary can be cell specific and cause selective pituitary hormone deficiency.

Pituitary tumors can expand into surrounding tissue such as the optic chiasm and hypothalamus and cause visual field defects and symptoms of hypothalamic disease, respectively. Early manifestations of optic chiasm impingement can be subtle and include seeing images that float apart or seeing half of a face higher than the other half (the

Picasso effect or hemifield slide phenomenon). These symptoms emerge when the patient is tired or anxious and are the result of failure to fuse the images from both eyes because of the lack of nasal fields (Mooradian and Morley, 1988). Expansion of tumors into the hypothalamus can cause disturbances in sleep, appetite, temperature regulation, sweating, water balance, and memory (Mooradian and Morley, 1988).

In children, pituitary adenomas are less common, and hypothalamic pituitary dysfunction is usually the result of hypothalamic tumors, notably craniopharyngiomas.

When microadenoma (<10 mm) is discovered incidentally, the initial evaluation should seek hormone hypersecretion by measuring levels of serum prolactin, IGF-1, TSH, and FT₄, as well as 24-hour urine free-cortisol or a 1-mg overnight DST (Mooradian and Korenman, 2007; Mooradian and Morley, 1988). More extensive workup is required for pituitary masses larger than 10 mm (macroadenoma) regardless of symptoms.

The overall workup and management of pituitary disease should include identifying and treating hormonal deficiency or excess as well as diagnosing and managing mass effects of the tumors.

HYPOPITUITARISM

Key Points

- Hypopituitarism refers to total or partial deficiency of one or more pituitary hormones.
- Hypopituitarism could be the result of a genetic cause; a deficiency in hypothalamic releasing factor; or, more commonly, the result of pituitary tissue destruction secondary to mass expansion, infiltrative process, autoimmune or infectious disease, vascular accidents, radiation injury, or trauma.
- Pituitary apoplexy may result in life-threatening hypocortisolism.
- Lymphocytic hypophysitis is a rare autoimmune disease of the pituitary occurring in women during late pregnancy or in the postpartum period. This disease may mimic pituitary tumor but does not require resection.
- Kallmann syndrome is characterized by an isolated defect in GnRH secretion.
- Approximately 10% of patients with empty sella syndrome have clinically apparent hypopituitarism, and some may have pituitary adenomas.
- Systemic disease, including end-stage liver disease or chronic renal failure, is associated with variable degrees of hypopituitarism without significant histopathologic changes in the pituitary.

Hypopituitarism refers to total or partial deficiency of one or more pituitary hormones resulting in end-organ changes or reduced hormonal secretion of target endocrine glands (Toogood and Stewart, 2008). The deficiencies could be the result of primary disease of the pituitary or secondary to failure of hypothalamic hormone synthesis or transport. There are no good estimates of the incidence of hypopituitarism because the disease is often subclinical.

Causes

Hypopituitarism could be the result of a genetic cause; a deficiency in hypothalamic releasing factor; or, more commonly, the result of pituitary tissue destruction secondary to mass expansion, infiltrative process, autoimmune or infectious disease, vascular accidents, radiation injury, or trauma (Toogood and Stewart, 2008). Sometimes the etiology of hypopituitarism cannot be identified and is considered idiopathic. Most of these cases are sporadic, although there are well described familial causes of hypopituitarism.

The most common cause of hypopituitarism in the adult population is *intrasellar pituitary tumors*. Occasionally, hypopituitarism is resolved with surgical or medical treatment of the pituitary mass. Parasellar masses that cause hypopituitarism include craniopharyngiomas, meningiomas, optic nerve gliomas, teratomas, germinomas, chordomas, metastatic cancer, and lymphomas.

The second most common cause of hypopituitarism in adults is *postpartum pituitary necrosis* (Sheehan syndrome). The portal system of the anterior pituitary vascular supply, increased oxygen demand of an enlarged pituitary gland during pregnancy, excessive blood loss, and possibly increased intravascular coagulation converge to cause ischemic injury of the pituitary. Other ischemic causes of pituitary necrosis can occur in systemic vascular diseases such as diabetes mellitus, temporal arteritis, and sickle cell disease. These diseases can also result in hemorrhagic infarction (*apoplexy*) of the pituitary with acute onset of severe headache, visual impairment, altered mental status, and hypopituitarism. The sudden decline in ACTH, and thus hypocortisolism, may be the most life-threatening consequence of hypopituitarism, requiring emergency treatment with corticosteroids. Although pituitary adenomas are the most common cause of pituitary apoplexy, often it may be related to complications of diabetes, radiotherapy, or open heart surgery (Toogood and Stewart, 2008).

Rarely, infectious diseases can lead to hypopituitarism. Examples include meningitis, intracranial abscess, septic shock, fungal infections of the central nervous system (CNS), tuberculosis (TB), malaria, and syphilis.

Infiltrative diseases of the pituitary, and more commonly of the hypothalamus, can cause hypopituitarism. Sarcoidosis can present with hypopituitarism along with polydipsia and polyuria. Histiocytosis X may present as a suprasellar tumor. Lipid storage diseases and hemochromatosis can cause hypopituitarism often with hypogonadotropin deficiency.

Lymphocytic hypophysitis is a rare autoimmune disease of the pituitary occurring in women during late pregnancy or in the postpartum period. Lymphocytes and plasma cells infiltrate the pituitary gland, which results in the destruction of anterior pituitary cells (Toogood and Stewart, 2008). Lymphocytic hypophysitis cannot be distinguished from tumor except by biopsy. The diagnosis is suspected in women who develop hypopituitarism during or immediately after pregnancy in the absence of a history of hemorrhage during delivery or previous history of infertility or menstrual disorders.

Mutations in the *PROP-1* gene are the most common causes of congenital hypopituitarism and present as

deficiencies of GH, prolactin, TSH, LH, and FSH. Older adults with *PROP-1* gene mutations may manifest with ACTH deficiency (Wu et al., 1998). Mutations of genes that code for specific anterior pituitary hormones have also been described, the most common of which is isolated genetic deficiencies of GH, which manifests with short stature and begins in infancy or childhood. *Kallmann syndrome* is characterized by an isolated defect in GnRH secretion. Young men develop a eunuchoid appearance and testosterone deficiency, and women manifest with amenorrhea or oligomenorrhea. The syndrome may also be associated with hyposmia or anosmia (Oliveira et al., 2001). Iatrogenic causes of hypopituitarism include surgical ablation and radiotherapy. Hypothalamic and pituitary deficiency may occur after several years, with GH and gonadotropin deficiencies the most common. Prolactin level may be mildly elevated.

Approximately 10% of patients with *empty sella syndrome* have clinically apparent hypopituitarism and some may have pituitary adenomas (Mooradian and Morley, 1988). The empty sella syndrome occurs when a defect in the sellar diaphragm allows the subarachnoid space to herniate into the pituitary fossa. It is a relatively common disorder found in 5% to 8% of autopsies. Systemic disease, including end-stage liver disease or chronic renal failure, is associated with variable degrees of hypopituitarism without significant histopathologic changes in the pituitary (Mooradian, 2001; Nowak and Mooradian, 2007).

Clinical Manifestations

Key Points

- Progressive loss of hormones occurs in pituitary injury with loss of GH and gonadotropin followed by TSH and ACTH deficiency.
- ACTH deficiency results in cortisol deficiency, leading to hypotension, shock, and cardiovascular collapse.
- TSH deficiency results in signs and symptoms of hypothyroidism.
- Gonadotropin deficiency results in signs and symptoms of hypogonadism.
- GH deficiency causes short stature in children and may be asymptomatic in adults.

The clinical manifestations of hypopituitarism are highly variable and depend on the age and sex of the patient as well as on the etiology of the pituitary disease (Toogood and Stewart, 2008). Patients can be completely asymptomatic for many years or present with dramatic symptoms of nausea, vomiting, headache, and vascular collapse. The latter is more common in pituitary apoplexy when the sudden withdrawal of ACTH and ensuing adrenal insufficiency cause hemodynamic instability. It is believed that at least 75% of the glandular tissue must be destroyed before an individual becomes clinically symptomatic. If the etiology is a space-occupying lesion, such as an expanding adenoma or carotid aneurysm, the clinical manifestations will include headache and visual field defects, which are classically bitemporal hemianopsia (loss of peripheral vision). Other subtle changes in vision include changes in color perception, patchy scotomas, and difficulty in passing a thread through the eye of a needle (Mooradian and Morley, 1988).

Failure to lactate may be the first clinical sign of Sheehan syndrome. Lethargy, anorexia, weight loss, failure to resume normal menstrual periods, and loss of pubic hair may also be present later in the postpartum period. On the other hand, symptoms and signs of pituitary infarction may be subtle and not recognized for years.

Patients with *panhypopituitarism* (Simmonds syndrome) are usually pale and lethargic; have dry skin and low blood pressure (BP); and, rarely, may look cachectic (Mooradian and Morley, 1988; Toogood and Stewart, 2008). These patients have lost all the anterior pituitary hormones, and the clinical manifestations are the result of a mixture of hypogonadism, hypothyroidism, adrenal insufficiency, and GH deficiency. The clinical manifestations depend on whether the deficiency is partial or complete. Individual signs and symptoms are reflections of the biologic actions of various hormones secreted by the pituitary.

Growth hormone deficiency manifests as growth retardation in children. The body proportion and primary teeth are normal, but secondary tooth eruption is delayed. In up to 10% of children with GH deficiency, symptomatic hypoglycemia may occur. In adults, GH deficiency may be asymptomatic. Subtle changes may occur in insulin sensitivity, manifested by reduced insulin requirements in patients with diabetes, decreased muscle and bone mass with increased adiposity, delayed wound healing, and fasting hypoglycemia, and may contribute to anemia of hypopituitarism. Additional adverse effects associated with GH deficiency in adults include an increase in low-density lipoprotein (LDL) and a decrease in high-density lipoprotein (HDL) cholesterol, decreased cardiovascular function, increased risk of cardiovascular events, and a diminished sense of well-being. Life expectancy is reduced in these patients compared with age-matched control participants (Svensson et al., 2004).

Gonadotropin deficiency results in HH or secondary hypogonadism (Toogood and Stewart, 2008). In prepubertal children, HH manifests as failure to achieve pubertal changes along with a lack of a pubertal growth spurt. Girls have primary amenorrhea and lack breast development and widening of the pelvis. In boys, the testicular size remains small; the scrotal skin does not thicken; and penile growth, muscle development, and hoarseness of voice do not appear. In adults, HH presents as infertility, loss of libido, decreased facial hair, and muscle mass in men and amenorrhea, decreased breast size, and atrophic vaginal mucosa in women. If left untreated, men and women with hypogonadism develop osteoporosis. A deficiency in TSH causes secondary hypothyroidism unless the patient has concomitant Graves disease or an autonomously functioning thyroid nodule. The classical clinical manifestations of hypothyroidism include lethargy, easy fatigability, dry skin, cold intolerance, constipation, fine silky hair, slow mentation, and slow relaxation phase of deep tendon reflexes. Other features include anemia and hyponatremia secondary to increased antidiuretic hormone (ADH) secretion. In general, these symptoms are less severe in patients with TSH deficiency compared with patients with primary thyroid failure, and other findings, such as hypercholesterolemia, hypercarotenemia, myxedema, and effusions in body cavities, may occur less frequently (Toogood and Stewart, 2008).

A deficiency in ACTH results in deficiency of cortisol secretion and is referred to as *secondary adrenal insufficiency*. The clinical features resemble primary adrenal disease such as Addison disease. In both entities, anorexia, lethargy, nausea, vomiting, abdominal pain, postural hypotension, and vascular collapse may occur. Whereas hyponatremia is more common in ACTH deficiency, hyperkalemia is seen only in primary adrenal insufficiency and loss of aldosterone secretion, primarily regulated by the renin–angiotensin system (RAS) and serum potassium and sodium concentrations. Hyperpigmentation of the skin and vitiligo are features of primary adrenal insufficiency, and patients with ACTH deficiency have difficulty tanning upon exposure to sunlight. Mild ACTH deficiency may be asymptomatic and go undiagnosed for a long time.

Diagnosis

Key Points

- If one pituitary hormone insufficiency is documented, the other pituitary hormones should be tested.
- An 8 AM plasma cortisol level below 3 µg/dL strongly suggests hypocortisolism. A level 18 µg/dL or greater excludes ACTH deficiency.
- Serum FT₄ must be used with serum TSH concentration in assessing thyroid function.
- A normal or subnormal LH level in menopausal or amenorrheic women, in the presence of a low estradiol level, indicates secondary hypogonadism (in men, a low testosterone level).
- The diagnosis of GH deficiency requires provocative testing.

Because the presenting complaints of hypopituitarism can be subtle, clinicians need a high index of suspicion to arrive at the correct diagnosis (Toogood and Stewart, 2008). If the clinical manifestations fit hypogonadism, hypothyroidism, or adrenal insufficiency, those hormonal tests should be ordered to confirm the diagnosis. After one pituitary hormone insufficiency is documented, every attempt should be made to test the status of the other pituitary hormones as well. The underlying etiology of the disease should be determined by computed tomography (CT) or magnetic resonance imaging (MRI) of the hypothalamic–pituitary area. Occasionally, angiography is needed when carotid artery aneurysm is suspected or to define the blood supply of the tumor. Formal ophthalmologic examination, with visual field evaluation, should be ordered if the patient is symptomatic or harbors a pituitary mass lesion.

Pituitary hormone secretion is episodic, and in general, dynamic testing is more valuable than single baseline hormone measurements. For practical reasons, however, screening can be done with pituitary hormone and target hormone measurements simultaneously. For evaluating suspected hypopituitarism, tests include thyroid function, LH, serum testosterone in men and estradiol in women, IGF-1 (because GH has a short half-life in blood), prolactin, and morning cortisol. Provocative testing for GH and ACTH reserves may be required as well. Patients with known pituitary disease and deficiencies of ACTH, TSH, or

gonadotropins have a 95% chance of subnormal provocative stimulus for GH. Also, patients with known pituitary disease and a serum IGF-1 concentration lower than normal can be presumed to have GH deficiency (Gharib et al., 2003). Provocative tests for GH are either physiologic (sleep or exercise) or pharmacologic, such as insulin-induced hypoglycemia, GHRH with arginine test, and levodopa with arginine test (Billir et al., 2002; Gharib et al., 2003). GH deficiency is diagnosed when GH does not rise above 5 ng/mL in response to two or more stimuli.

A plasma cortisol level below 3 µg/dL at 8 AM on two occasions in a patient with a disorder known to cause hypopituitarism strongly suggests hypocortisolism, and in the presence of normal or low serum ACTH concentration, it establishes the diagnosis of secondary adrenal insufficiency. Conversely, a cortisol level of 18 µg/dL or greater virtually excludes the diagnosis of ACTH deficiency.

To evaluate ACTH reserve, an insulin hypoglycemia test (0.1-0.15 U/kg IV) should be done. A normal cortisol response to adequate hypoglycemic stimulus (blood glucose <50 mg/dL) is either an incremental level of 6 to 10 µg/dL or an absolute level greater than 20 µg/dL. The test allows for concomitant evaluation of GH reserve; however, it is contraindicated in elderly adults and those with coronary artery disease (CAD) or epilepsy (Nowak and Mooradian, 2007).

An alternative is the metyrapone test, 750 mg orally every 4 hours for 6 doses, which assesses the sensitivity of the pituitary to negative inhibition of cortisol. Metyrapone blocks 11β-hydroxylase, an enzyme that catalyzes the final step in cortisol biosynthesis, which inhibits cortisol production. The decrease in cortisol secretion after metyrapone is given should result in a compensatory increase in the ACTH level. The level of the precursor steroid 11-deoxycortisol should also increase. A normal response is an increase in serum 11-deoxycortisol level greater than 10 µg/dL, when serum cortisol level is reduced to less than 8 µg/dL, indicating adequate suppression of glucocorticoid synthesis. In the more convenient overnight test, metyrapone 30 mg/kg orally, is administered at midnight. An increase in the 8 AM serum 11-deoxycortisol level to greater than 7 µg/dL is found in healthy persons. If symptomatic postural hypotension occurs after metyrapone administration, hydrocortisone should be administered exogenously.

Cosyntropin (synthetic ACTH), 250 µg administered intramuscularly or intravenously should result in an increase in the serum cortisol level to 18 µg/dL or greater at 60 minutes in normal subjects. The test may not reliably determine the ACTH reserve, especially in those with recent ACTH deficiency and in patients whose adrenal glands may not be atrophied enough. There is some controversy whether the 1-µg cosyntropin stimulation test (intravenous [IV] only) may be more sensitive for the diagnosis of subtle secondary adrenal insufficiency.

Thyrotropin (TSH) deficiency is diagnosed when low baseline FT₄ and low or normal TSH is documented on more than one measurement. Gonadotropin deficiency in men is tested with measurements of baseline LH, FSH, and total testosterone. Serum samples are drawn between 8 AM and 10 AM, and low concentrations should be confirmed with a second serum sample. The 8 AM to 10 AM serum testosterone concentration generally should be 300 to 1000 ng/dL.

A low testosterone value (< 200 ng/dL) with low or normal LH is indicative of HH (Mooradian and Korenman, 2006). For serum total testosterone levels between 200 and 400 ng/dL, free testosterone level should also be ordered (Mooradian and Korenman, 2006).

The presence of amenorrhea in premenopausal women, along with a low estrogen level (<30 pg/mL), establishes the diagnosis of HH. In menopausal women, the absence of elevated FSH and LH is sufficient for the diagnosis.

Elevated serum prolactin levels in a hypogonadal individual suggest a pituitary adenoma. Prolactin deficiency often indicates severe intrinsic pituitary disease and is uncommon without concomitant deficiencies of other anterior pituitary hormones.

Conditions known to mimic hypopituitarism should be excluded when evaluating patients, including anorexia nervosa, protein-calorie malnutrition, systemic illness, chronic renal failure, and liver cirrhosis.

Treatment

Key Points

- Hydrocortisone is given to ACTH-deficient adults at 20 to 30 mg/day and increased twofold to threefold during times of illness and other stresses.
- Serum IGF-1 concentration and growth rate in children are used for monitoring the effectiveness of GH replacement.

The treatment of hypopituitarism depends on the etiology and the particular hormonal deficiency (Mooradian and Morley, 1988; Toogood and Stewart, 2008). Surgical and medical interventions may be necessary for treatment of pituitary masses, infiltrative diseases, and carotid aneurysms.

Growth hormone deficiency is treated with recombinant human GH (somatotropin) preparations (Gharib et al., 2003). The recommended GH dose in children with GH deficiency is 0.04 mg/kg/day. In adults, recombinant human GH is administered subcutaneously at 0.001 to 0.008 mg/kg/day. The usual starting dose is 0.1 to 0.3 mg/day for a 70-kg man with a typical maintenance dose of 0.3 to 0.6 mg/day (Gharib et al., 2003). In general, women require higher doses than men because estrogen increases GH resistance. Serum IGF-1 concentration should be monitored to maintain it at the midnormal range. Side effects that should be monitored include edema, carpal tunnel syndrome, arrhythmias, paresthesias, and glucose intolerance.

Growth hormone can also be used in other causes of growth retardations such as chronic renal disease, Turner syndrome, and Prader Willi syndrome. Mortality caused by hypopituitarism is a significant issue; however, this may not translate when GH is used alone. For a pediatric patient who has one of these other nonpituitary causes of growth retardation, this might be a clinically appropriate option to consider. Early referral to a pediatric endocrinologist bears consideration (Sherlock and Stewart, 2013).

Treatment of secondary hypogonadism depends on the gender of the individual and whether fertility is desired.

Estradiol and progesterone replacement is the treatment of choice for secondary hypogonadism in premenopausal women who have intact uteri and do not desire fertility. These hormones can be given cyclically or daily in fixed-dose combinations. In individuals who have undergone hysterectomy, estrogen replacement alone is sufficient to maintain vulvar and vaginal lubrication, relieve symptoms of vasomotor instability, and reduce bone loss.

HYPERFUNCTIONING PITUITARY ADENOMAS

Key Points

- Pituitary adenomas may present with visual impairment, headache, or hormonal abnormalities.
- Prolactinomas are the most common type of functioning pituitary adenoma. These adenomas manifest with galactorrhea and hypogonadism.
- Nonpathologic causes of hyperprolactinemia are sought, and primary hypothyroidism is excluded.
- MRI is the imaging modality of choice for the anatomic evaluation of the hypothalamus and pituitary gland.
- Prolactin level greater than 150 ng/mL and pituitary adenoma not identified on imaging studies suggest macroprolactinemia.
- A dopamine agonist (bromocriptine or cabergoline) is the first-line treatment of prolactinomas.

Pituitary adenomas can arise from any cell type and can be either functioning or nonfunctioning. The precise pathogenesis of these adenomas is not known, but mutations found in several genes can play a role in the development of many adenomas.

With prolactinomas the most common type, other functioning pituitary adenomas include gonadotropic, thyrotropic, somatotropic, and corticotropic adenomas.

Hyperprolactinemia and Prolactinomas

Diagnosis. Prolactin is a polypeptide secreted from the lactotrophs of the anterior pituitary (Leung and Pacaud, 2004; Mancini et al., 2008). Its main function is the development of breast tissue in preparation for milk production and the maintenance of lactation during the postpartum period. Unlike the other pituitary hormones, the regulation of prolactin release is predominantly under inhibitory control. Whereas dopamine is the principal inhibitor, prolactin stimulators, such as TRH and estrogen, have minor roles.

Hypersecretion of prolactin may be physiologic or pathologic in origin (Leung and Pacaud, 2004; Mancini et al., 2008). Physiologic stimulators include exercise, pain, breast stimulation, sexual intercourse, general anesthesia, and pregnancy. Pathologic causes of hyperprolactinemia include prolactinomas, decreased dopaminergic inhibition of prolactin secretion through pharmacologic agents, and decreased clearance of prolactin.

Early manifestation of prolactin hypersecretion is galactorrhea and menstrual irregularities, notably amenorrhea in women and erectile dysfunction or loss of libido in men. Rarely, galactorrhea with gynecomastia can occur in men.

These patients are at risk of developing osteoporosis secondary to hypogonadism as well as a result of the direct inhibitory effect of prolactin on bone formation. Galactorrhea is rarely found in postmenopausal women with hyperprolactinemia and mass effect of prolactinomas, such as headache or visual disturbance, cause the principal presenting symptoms (Mancini et al., 2008). Similarly, the diagnosis of prolactinomas in men is often delayed because the clinical signs and symptoms of hyperprolactinemia are less obvious.

Clinical evaluation of patients suspected to have prolactinomas should include a thorough evaluation of medication history and the presence of comorbidities. Many drugs are known to cause hyperprolactinemia, including phenothiazines, haloperidol, metoclopramide, H₂ antagonists, imipramines, selective serotonin reuptake inhibitors (SSRIs), calcium channel blockers, and hormones (Leung and Pacaud, 2004; Mancini et al., 2008). The physical examination may reveal galactorrhea and visual field defects. Women may have mild hirsutism, and men may have decreased facial hair growth.

Laboratory tests include serum prolactin and thyroid function. Primary hypothyroidism is associated with hyperprolactinemia secondary to elevated levels of TRH that induces prolactin secretion. Laboratory testing should also seek systemic illnesses, such as liver or renal failure. MRI is the imaging modality of choice for the anatomic evaluation of the hypothalamus and pituitary gland. Complete pituitary hormone evaluation should be performed when an adenomatous mass is noted in the region of the pituitary.

Features to distinguish hyperprolactinemia associated with pituitary tumors include (1) prolactin levels greater than 150 ng/mL, (2) loss of normal sleep-associated increases in prolactin levels, and (3) failure of prolactin levels to rise in response to exogenous TRH. None of these tests are absolute, and the diagnosis of prolactinoma depends on radiologic studies.

Clinicians should be aware of two prolactin assay-related conditions that may cause diagnostic confusion. In *macroprolactinemia*, large-molecular-weight prolactin aggregates with globulins, which are then recorded in the assay as elevated levels of prolactin in the absence of any physiologic or pathologic cause of hyperprolactinemia (Mancini et al., 2008). This condition is suspected when the patient is found to have very high prolactin level without galactorrhea or any tumor demonstrated on pituitary MRI. The second area of confusion occurs when very high concentrations of serum prolactin overwhelm the assay reagents such that the measurements underestimate the true concentration of prolactin. This is referred to as the “hook” effect.

The gold standard for differentiating hyperprolactinemia from macroprolactinemia is via gel filtration chromatography (GFC). But if available, a simple, inexpensive, and suitable alternative to GFC that should be considered is polyethylene glycol (PEG) precipitation. Because macroprolactinemia is a benign condition, early laboratory testing, such as PEG, which can definitively determine the presence of macroprolactin molecules, eliminating the need for further hormonal or imaging investigation or surgery (Kasum et al., 2012).

Treatment. The treatment of hyperprolactinemia depends on the etiology, presence or absence of mass effects, (e.g.,

visual changes), presence of bothersome galactorrhea or associated pituitary hormone deficiencies, and whether fertility is desired (Leung and Pacaud, 2004; Mancini et al., 2008). If possible, drugs known to cause prolactin elevation should be discontinued, and the serum prolactin concentration should be measured again. Persistent hyperprolactinemia requires imaging of the pituitary and hypothalamus.

Treatment of prolactinomas includes dopamine agonists as first-line therapy. In select subgroups, surgical excision is recommended, usually through the transsphenoidal approach. In rare cases, with large residual tumor mass postsurgery, nonresponsive to medical therapy, radiation therapy may be offered. Associated hormone deficiency should also be targeted. Often, as the prolactin levels are normalized, symptoms of hypogonadism can be reversed.

Bromocriptine and cabergoline are U.S. Food and Drug Administration (FDA)–approved dopamine agonists for treatment of hyperprolactinemia. Cabergoline has greater tolerability than bromocriptine and is more effective in achieving normalization of prolactin levels in 90% of individuals with prolactinomas. Because of long-standing experience, however, bromocriptine is the preferred agent in women who wish to become pregnant. Bromocriptine should be discontinued after pregnancy has been confirmed even though the risk of teratogenicity is small. Pregnant women with prolactinomas should be warned to report any visual disturbances or headaches because up to 10% of microprolactinomas and 30% of macroprolactinomas increase in size sufficient to cause symptoms. During pregnancy, prolactin levels should be monitored periodically, but interpretation of the results may be difficult. Pregnant women with macroadenomas should receive similar advice and have serial visual field testing. Pergolide is an alternative to bromocriptine and cabergoline, but it is not FDA-approved for this use. Caution should be exercised with all of these ergot derivatives because of rare case reports of valvular heart damage in patients taking the drug at very high doses for prolonged periods.

The dosage of dopamine agonist may be reduced when prolactin levels have been normalized for 1 year and tumor size has been significantly reduced. Medication withdrawal may be considered after 2 years in those with normal prolactin levels and an MRI scan showing no tumor or tumor reduction more than 50% and more than 5 mm from the optic chiasm with no invasion of the cavernous sinus. Withdrawal of therapeutic drug may lead to recurrent prolactin hypersecretion and adenoma growth, although in some patients, microadenomas have resolved after a few years of treatment. MRI of the pituitary and serum prolactin levels should be monitored closely thereafter.

Indications for transsphenoidal surgery in patients with prolactinomas include medical treatment failure or medication intolerance, very large tumors threatening visual pathways, or hemorrhagic infarcts (apoplexy). Approximately 30% of macroadenomas can be successfully removed surgically.

ACROMEGALY AND GIGANTISM

See [eAppendix 35-1](#) online.

CUSHING DISEASE

Key Points

- Cushing syndrome is categorized into ACTH-dependent and ACTH-independent cases. Pituitary ACTH-dependent Cushing syndrome is Cushing disease.
- The diagnosis is established when the clinical findings of Cushing syndrome are associated with laboratory documentation of excess cortisol production.
- Measurement of 24-hour urinary free cortisol excretion is a good screening tool.
- Comparison of serum ACTH concentration with serum cortisol level can help determine the cause of hypercortisolism.
- Treatment of Cushing syndrome is directed at the cause of hypercortisolism. The treatment of choice for Cushing disease is selective transsphenoidal resection.

Hypercortisolemia, (also hypercortisolism, hyperadrenocorticism) caused by either exogenous administration of cortisol or other synthetic glucocorticoids or endogenous overproduction of cortisol leads to a constellation of clinical and biochemical findings referred to as Cushing syndrome (Arnaldi et al., 2003; Biller et al., 2008; Findling and Raff, 2005). The multiple causes include pituitary adenomas, excess production of CRH leading to hyperplasia of corticotropes in the pituitary, ectopic production of ACTH and CRH, and adrenal cortical adenomas and carcinomas. The term *Cushing disease* specifically refers to pituitary-dependent cortisol hypersecretion (Biller et al., 2008).

Whereas pituitary, ACTH-dependent Cushing disease accounts for at least 70% of endogenous cases, the most common cause of ACTH-independent Cushing syndrome is prolonged glucocorticoid therapy.

Patients who have undergone bilateral adrenalectomy for hypothalamic pituitary–dependent Cushing syndrome may develop pituitary tumors associated with marked skin pigmentation. This condition is referred to as *Nelson syndrome*. The skin hyperpigmentation occurs because of excess production of melanocyte-stimulating hormone (MSH), which is a product of the gene that also encodes ACTH and β -endorphin.

Diagnosis

A high index of suspicion is required to make the diagnosis of Cushing syndrome as manifestations of the disease are insidious and develop over months (Arnaldi et al., 2003; Findling and Raff, 2005). The clinical features include weight gain with centralized obesity distributed in the face, neck, trunk, and abdomen with facial rounding and plethora. The thinning of the skin and loss of subcutaneous tissue results in easy bruising and emergence of violaceous abdominal striae (Arnaldi et al., 2003; Findling and Raff, 2005).

In cases of ectopic ACTH-dependent Cushing syndrome, extreme elevations of ACTH levels cause rapid hyperpigmentation and are more likely to demonstrate features of mineralocorticoid excess, such as hypokalemia and metabolic alkalosis (Findling and Raff, 2005).

35-1 Acromegaly and Gigantism

Key Points

- Excess growth hormone (GH) secretion in children before the fusion of epiphyses results in gigantism. In adults, bones grow wider and thicker along with overgrowth of soft tissues, resulting in acromegaly.
- The vast majority of patients with acromegaly have a pituitary tumor.
- Elevated serum concentration levels of age and gender-matched serum insulin-like growth factor type 1 (IGF-1) provides the best single test to screen for acromegaly. The diagnosis of acromegaly is confirmed when GH is not suppressed 1 to 2 hours after ingestion of 75 g of glucose.
- Transsphenoidal surgery to remove the pituitary adenoma is usually the treatment of choice in individuals with acromegaly.
- Octreotide (Sandostatin) is a somatostatin analogue that is often effective in normalizing growth hormone and IGF-1 levels. Pegvisomant is a GH receptor antagonist also approved for the treatment of acromegaly.

Acromegaly is a rare disease with approximately 400 new cases per year in the United States. Excess GH secretion in children before the fusion of epiphyses results in gigantism. In adults, bones grow wider and thicker along with overgrowth of soft tissues, resulting in acromegaly (Ben-Shlomo and Melmed, 2008; Clemmons et al., 2003; Melmed et al., 2009).

The vast majority of patients with acromegaly have a pituitary tumor. In rare cases, acromegaly can be the result of ectopic production of GH or GH-like peptides or growth hormone-releasing hormone by nonpituitary tumors such as carcinoid or islet cell tumors.

The clinical manifestations of the disease result from local expansion of the pituitary mass, associated pituitary hormone deficiency, and the effects of excess GH.

Acromegaly has an insidious course, and a burn-out phase may emerge after years of ailment when changes in physical appearance may become static or slow down. In these patients, GH levels remain elevated, and the metabolic complications persist. Rarely, the tumor may undergo autoinfarction with the resolution of GH oversecretion.

Patients with acromegaly have a twofold increase in risk of dying, mostly because of cardiovascular events. Cardiovascular complications include hypertension and cardiomyopathy, with diastolic dysfunction and arrhythmias. It is also associated with an increased incidence of colon polyps and possibly an increased risk of colon cancer. Visceromegaly occurs in acromegaly with involvement of the thyroid, heart, liver, and prostate. Uterine leiomyomata are also more common in women with the syndrome of acromegaly (Ben-Shlomo and Melmed, 2008).

Diagnosis

When acromegaly is suspected, based on finding of the classic clinical characteristics, the diagnostic approach includes (1) documentation of GH excess, (2) evidence of activity, (3) tumor localization, (4) evidence of other pituitary hormonal excess or deficiencies, and (5) exclusion of multiple endocrine neoplasia (MEN) type 1 (Ben-Shlomo and Melmed, 2008; Melmed et al., 2009). GH excess is documented when elevated serum levels of IGF-1 and GH are not suppressed 1 to 2 hours after ingestion of 75 g of glucose. This glucose load in healthy individuals should result in the suppression of the GH level to 1 ng/mL or lower within 1 to 2 hours of administration. In contrast, a paradoxical rise in GH level is often found in patients with acromegaly. Administration of thyrotropin-releasing hormone or L-DOPA (levodopa) also paradoxically raises serum GH levels (Ben-Shlomo and Melmed, 2008; Clemmons et al., 2003; Katznelson et al., 2011; Melmed et al., 2009).

Evidence of GH activity is demonstrated with elevated IGF-1; an impaired glucose tolerance test result; and increased phosphate, alkaline phosphatase, and urinary hydroxyproline levels. Postprandial plasma glucose levels may reveal impaired glucose tolerance in as many as 50% of those with acromegaly. Prolactin levels should be measured because hyperprolactinemia is associated with acromegaly in 25% to 30% of cases. Prolactin levels may be higher than 200 ng/mL when a somatomammotropic adenoma is present. Thyroid function tests should be obtained to work up hypopituitarism. Workup for other hormonal dysfunction can be postponed until after therapy because these may change. Patients should be routinely given stress doses of steroids during surgery and all other invasive procedures.

Tumor localization should start with magnetic resonance imaging (MRI) of the pituitary. If pituitary imaging results are normal, an extrapituitary ectopic source should be considered and MRI of the chest, abdomen, and pelvis obtained.

Finally, to exclude MEN type 1, serum calcium should be measured and other hormonal parameters tested if appropriate.

Treatment

The objectives of treatment are to arrest the deleterious effects of growth hormone excess on bone and soft tissue growth and on metabolic parameters as well as prevent or reverse the pressure effects of the tumor. Transsphenoidal surgery to remove the pituitary adenoma is the initial treatment of choice (Ben-Shlomo and Melmed, 2008; Clemmons et al., 2003; Melmed et al., 2009). The success rate of

surgery is variable and depends on the size of the adenoma and the surgical skills of the surgeon. Many adenomas originally thought to be cured with surgery have very high relapse rates. Pharmacologic treatment recently was proposed as first-line therapy of choice for select individuals such as those who decline after surgery and in those who have an unacceptable surgical risk (Clemmons et al., 2003; Melmed et al., 2009).

In general, pharmacologic treatment is used as an adjuvant when surgery has not reduced GH and IGF-1 levels to normal. Octreotide (Sandostatin) is a somatostatin analogue often effective in normalizing GH and IGF-1 levels (Freda, 2002). It can also reduce tumor size in some patients. Clinical manifestations of acromegaly may

improve more significantly than normalization of GH and IGF-1 levels (Freda, 2002). Side effects include gastrointestinal symptoms and an increased incidence of gallstones. The depot forms of octreotide can be given intramuscularly once monthly.

Pegvisomant is a GH receptor antagonist approved for the treatment of acromegaly (Clemmons et al., 2003). It is given as a daily subcutaneous injection. Less effective therapies include dopamine agonists. These tend to be more effective when there is concomitant hyperprolactinemia, suggesting a somatolactotropin origin of tumor.

Radiotherapy may be required for patients in whom surgery and medical therapy fail to control GH excess and its clinical manifestations.

Gonadal dysfunction is associated with decreased testosterone levels in men; in women, it is associated with decreased serum estradiol levels and menstrual disorders, notably amenorrhea. Virilization and androgen excess are more common in cases of Cushing syndrome caused by adrenal carcinomas. Glucocorticoid excess also interferes with calcium and bone metabolism and leads to osteoporosis. Catabolic effects of excess glucocorticoid on muscles cause proximal muscle weakness. Glucose intolerance is found in 30% to 60% of those with hypercortisolism.

Other complications of hypercortisolism include risk of opportunistic infections, including *Pneumocystis jirovecii* (formerly *carinii*) pneumonia, and hypercoagulable state with thromboembolic events secondary to increased plasma concentration of several clotting factors and neuropsychiatric changes (Arnaldi et al., 2003; Findling and Raff, 2005).

Establishing the Cause

The diagnosis is established when the clinical findings of Cushing disease are associated with laboratory documentation of excess cortisol production, loss of diurnal variation of plasma cortisol level, and more than 50% suppression of plasma and urine cortisol after the administration of 2 mg of dexamethasone every 6 hours (high-dose DST). Measurement of 24-hour urinary free cortisol excretion is a good screening tool (Arnaldi et al., 2003; Findling and Raff, 2005). Late night salivary cortisol is another good screening tool (Nieman et al., 2008). Alternatively, impaired suppression of cortisol, after an overnight 1-mg DST, can be used as a screening tool in nonobese individuals. A plasma ACTH concentration less than 5 pg/mL and a serum cortisol concentration greater than 15 µg/dL suggest an ACTH-independent cause. Plasma ACTH concentration greater than 15 pg/mL in a patient with hypercortisolism suggests ACTH-dependent hypercortisolism (Arnaldi et al., 2003; Findling and Raff, 2005).

Suppression of urinary cortisol excretion after administration of high-dose dexamethasone is consistent with the diagnosis of Cushing disease, but urinary cortisol excretion in cases of ectopic ACTH syndrome is usually not suppressible. When the high-dose DST fails to differentiate an ectopic source from a pituitary source of ACTH and radiographic imaging is not conclusive, further CRH testing and petrosal sinus sampling of ACTH are indicated to localize the tumor to the pituitary.

The vast majority of patients with ACTH-dependent Cushing syndrome have a pituitary adenoma as the cause. The few who have an ectopic source of ACTH must be identified with high-resolution CT scanning of the chest, abdomen, and pelvis.

Treatment

The treatment of choice for Cushing disease is selective transsphenoidal resection of the pituitary adenoma. The cure rate for this procedure, at experienced centers, is 70% to 80% for microadenomas. In some patients, total hypophysectomy is considered when the disease recurs after transsphenoidal resection. Many postsurgical patients require low-dose cortisol replacement for up to 12 months until their endogenous adrenal function recovers.

Bilateral adrenalectomy with or without pituitary irradiation is offered to patients who have recurrence of hypercortisolemia or have severe disease. For those who are poor surgical candidates, adjunctive medical therapy is offered and includes metyrapone (a blocker of 11-β-hydroxylase), mitotane, and cyproheptadine. These treatment options have variable efficacy (Biller et al., 2008; Nieman et al., 2008).

CRANIOPHARYNGIOMAS, THYROTROPIN-SECRETING PITUITARY ADENOMAS, GONADOTROPIC ADENOMAS, AND OTHER ADENOMAS

See eAppendix 35-2 online.

POSTERIOR PITUITARY DISORDERS

Arginine vasopressin (AVP) and oxytocin are the principal hormones secreted from the posterior pituitary (Mooradian and Korenman, 2007; Mooradian and Morley, 1988). The two major stimuli of oxytocin secretion are suckling during lactation and dilation of the cervix during labor. Oxytocin is not essential for initiation of labor but can be used pharmacologically to initiate labor or to control postpartum hemorrhage and uterine atony. Rarely, it has been used to induce milk ejection. The physiologic role of this hormone in males is not known (Mooradian and Morley, 1988).

Arginine vasopressin differs from oxytocin by only one amino acid. AVP is found in all mammals except pigs and related species in which lysine vasopressin replaces AVP. In humans and many mammals, AVP and oxytocin are associated with two neurophysins (Mooradian and Morley, 1988). The exact roles of the latter are not known except that they are carrier proteins involved in storage and transport of posterior pituitary hormones.

Antidiuretic hormone is synthesized in the hypothalamus and migrates down into the posterior lobe of the pituitary to be stored and later secreted. Some ADH is secreted directly into the cerebrospinal fluid (CSF) rather than the posterior pituitary. Thus, pathologic lesions affecting the hypothalamus below the median eminence may preserve some functional ADH that migrates from the CSF into the systemic circulation.

The half-life of AVP in circulation is only 20 minutes because of its susceptibility to peptidases. Loss of the terminal amino group in position 1 makes this peptide resistant to degradation; substitution of the *levo* analogue of arginine for dextro-arginine in position 8 reduces presser effect without altering its antidiuretic properties (Mooradian and Morley, 1988). The resultant peptide deamino-8-D-arginine vasopressin (DDAVP; desmopressin) is currently the treatment of choice for central diabetes insipidus (DI).

The biologic effects of AVP are initiated at two receptors referred to as V1 and V2. The V1 receptors are located in the vascular system, and their stimulation results in vasoconstriction. V2 receptors are located in the kidneys, and stimulation of these receptors results in free water reabsorption (Korbonits and Carlsen, 2009).

Plasma osmolality, blood volume, and BP are the most important physiologic stimuli of AVP secretion. Other

Craniopharyngiomas, Thyrotropin-Secreting Pituitary Adenomas, Gonadotropic Adenomas, and Other Adenomas

Craniopharyngiomas

Key Points

- Also known as Rathke pouch tumors, craniopharyngiomas are histologically benign but act similar to low-grade malignancies.
- Individuals with craniopharyngioma may present with hypopituitarism, headache, and visual disturbance.
- Central diabetes insipidus is the most common endocrine dysfunction associated with craniopharyngiomas.

Craniopharyngiomas, also known as Rathke pouch tumors, are rare and generally benign tumors (Karavitaki and Wass, 2008). Although craniopharyngiomas are histologically benign, they act similar to low-grade malignancies. The 20-year survival rate for children with craniopharyngioma is 60%; in those with tumor recurrence, this rate decreases to 25% (Biller et al., 2008). They are usually diagnosed in infants and children and in adults between the ages of 55 and 65 years (Bunin et al., 1998). The clinical presentation includes headache; visual disturbances; and features of hypopituitarism, notably growth failure in children and hypogonadism in adults. Hypothyroidism is found in 40% and adrenal insufficiency in 25% of patients (Biller et al., 2008).

Central diabetes insipidus is the most common endocrine dysfunction associated with craniopharyngiomas. A variation of this tumor is a “Rathke” cleft cyst. As with craniopharyngioma, it is benign, but because of its location in the posterior portion of the anterior pituitary gland, it has a similar symptom complex (i.e., visual disturbance, pituitary dysfunction, and headaches). Most are asymptomatic, although not uncommon, occurring in 2% to 26% of autopsies, with a female-to-male ratio of 2 : 1. Symptomatic Rathke cleft cysts are extremely rare with only approximately 150 reported cases (Naik and Thakore, 2013).

DIAGNOSIS

These tumors are identified with magnetic resonance imaging (MRI) or computed tomography of the head. Key

radiologic features that differentiate a craniopharyngioma from other tumors include calcification noted in the suprasellar region and the presence of at least one cyst in the tumor. The diagnostic workup should include visual field testing and evaluation of pituitary hormone function (Karavitaki and Wass, 2008).

TREATMENT

Treatment may consist of surgery, radiation, or a combination of both. Surgical resection may be technically difficult, and the operative mortality rate can be as high as 20%; recurrence rates of 25% to 50% have been reported. Radiotherapy is used as an adjuvant. Pituitary hormone deficiencies should be identified and corrected.

Thyrotropin-Secreting Pituitary Adenomas

Key Points

- Thyroid-stimulating hormone (TSH)-secreting adenomas should be considered in hyperthyroid patients with diffuse thyroid enlargement and normal to high serum TSH levels.
- The differential diagnosis includes syndrome of thyroid hormone resistance.
- Transsphenoidal resection of the TSH-secreting pituitary adenoma is the treatment of choice.

Pituitary TSH-secreting tumors are very rare. The mean age at presentation is 41 years, with a slightly higher percentage of cases occurring in women. A number of these tumors have been identified in patients with long-standing untreated hypothyroidism. However, in most cases, the etiology is unknown and may cause hyperthyroidism due to excess production of TSH and thyroid hormones.

Thyroid-stimulating hormone adenomas may be responsible for concomitant secretion of other pituitary hormones, such as growth hormone; prolactin; and, rarely, gonadotropin.

DIAGNOSIS

Most patients present with classical symptoms of hyperthyroidism. Because of variable biologic activity of TSH secreted by the adenoma, some patients may have mild or no symptoms of hyperthyroidism (Beck-Peccoz et al., 1996; Losa et al., 2008). Other clinical features include a diffuse goiter, visual field disturbance, other pituitary hormone excess or deficiencies commonly presenting with menstrual dysfunction, and galactorrhea (Beck-Peccoz et al., 1996).

Laboratory tests reveal normal to high serum TSH and high serum free thyroxine (FT₄) and free triiodothyronine (FT₃) levels. The nocturnal surge in TSH levels seen in normal subjects is not seen in those with TSH-secreting adenomas. Other biochemical abnormalities include elevations of the α -subunit of glycoprotein hormones. In a handful of patients, TSH hypersecretion occurs in the absence of a pituitary tumor, and the cause is attributed to a disturbance in the TSH secretory set point or thyroid hormone resistance. The disproportionate elevation of serum α -subunit relative to TSH distinguishes patients with TSH-secreting tumors from those who do not have tumors.

Hyperthyroid patients with normal or elevated serum TSH values should have MRI scanning to evaluate the contents of the sella turcica (Beck-Peccoz et al., 1996; Losa et al., 2008).

TREATMENT

Transsphenoidal resection of a TSH-secreting pituitary adenoma is the treatment of choice (Beck-Peccoz et al., 1996; Losa et al., 2008). β -Blockers may be useful in ameliorating symptoms of hyperthyroidism. Adjuvant medical therapy, in those with concomitant hyperprolactinemia, includes bromocriptine and cabergoline. The use of the somatostatin analogue octreotide may result in normalization of serum TSH and T₄ and T₃ concentrations in a significant percentage of patients. Tumor size may also be reduced with the use of octreotide and is currently used postoperatively in unsuccessful surgical cases and before surgery for 6 to 12 months in those with large macroadenomas (Beck-Peccoz et al., 1996; Losa et al., 2008).

Medications that inhibit thyroid hormone synthesis are not indicated because they may result in pituitary tumor growth.

Gonadotropic and Other Adenomas

(LH) concentration or serum free α -subunit concentration is elevated while concentrations of intact FSH and LH are normal.

Many adenomas, previously misdiagnosed as nonsecretory, are found to secrete gonadotropins or their subunit fragments. Currently, gonadotropic adenomas are considered to be the most common pituitary adenoma (Korbonits and Carlsen, 2009).

DIAGNOSIS

Hormonal secretions from a gonadotropic adenoma do not usually result in a clinical syndrome. Therefore, the diagnosis of these adenomas is often delayed and presents with manifestations related to tumor expansion such as visual impairment or headaches. Some adenomas are discovered incidentally when head imaging is performed for nonrelated symptoms.

In occasional patients, ovarian hyperstimulation and an elevated serum testosterone level may cause clinically appreciable changes in women, including menstrual irregularities. In prepubertal girls and boys, premature puberty may occur. Occasionally, large adenomas may interfere with the normal gonadotropin secretions and result in hypogonadism (Korbonits and Carlsen, 2009).

Magnetic resonance imaging of the brain will detect a microadenoma and should prompt pituitary hormone evaluation. A gonadotropic adenoma is suspected when (1) the serum prolactin concentration is less than 100 ng/mL, (2) insulin-like growth factor type 1 levels are not elevated, (3) the patient does not have high TSH-driven hyperthyroidism, and (4) the patient is not acromegalic and does not have Cushing syndrome. A supranormal FSH level and free α -subunit of glycoprotein hormones in a male patient often indicates a gonadotropic adenoma. Using gonadotropin assays to differentiate a gonadotropic adenoma from natural menopause is not possible. A supranormal FSH level in the presence of subnormal LH concentration is unusual in menopause. A supranormal serum free α -subunit concentration and normal concentrations of intact FSH and LH also suggest a gonadotropic adenoma. In some cases, a thyrotropin-releasing hormone (TRH) stimulation test may be helpful. Although exogenous TRH given to a patient with a gonadotropic adenoma will raise the serum levels of FSH, LH, and α -subunit, it does not stimulate gonadotrophs in primary hypogonadism.

TREATMENT

Adenomas that are not causing neurologic or hormonal dysfunction may be conservatively managed with observation and monitoring. For large or symptomatic cases, transsphenoidal surgery is the treatment of choice to reduce tumor size, reduce hormonal hypersecretion, and relieve pressure-related symptoms and signs. Comparing pre- and postoperative measurements of FSH or free α -subunit levels may assist with the determination of residual tumor.

Radiation therapy may be used as an adjuvant when residual tumor is present. Drug therapy has not been found to be consistently effective in people with these adenomas.

Key Points

- Many adenomas, previously misdiagnosed as nonsecretory, are found to secrete gonadotropins or their subunit fragments.
- Because hormonal secretions from a gonadotropic adenoma do not usually result in a clinical syndrome, the diagnosis is often delayed, and patients present with manifestations related to tumor expansion.
- Gonadotropic adenomas are suspected when the follicle-stimulating hormone (FSH) level is supranormal in the presence of a subnormal luteinizing hormone

factors that modulate AVP secretion include pain, stress, nausea, hypoglycemia, hypercapnia, angiotensin II, atrial natriuretic hormone, and a host of drugs. Many stimuli of AVP release also promote thirst. Thirst is less sensitive for AVP release than these other stimuli and therefore thirst is a second-line defense against dehydration.

Central Diabetes Insipidus

Key Points

- DI is characterized by excessive dilute urine with thirst and polydipsia and results from decreased ADH secretion.
- The differential diagnosis of hypotonic polyuria includes neurogenic DI (vasopressin sensitive), nephrogenic DI (vasopressin resistant), and primary polydipsia.
- The water restriction test assists in the diagnosis.
- DDAVP is the primary treatment for central DI.

Clinical Features. The disease is characterized by the production of excessive dilute urine with secondary thirst and polydipsia. *Polyuria* is defined as 3 L/day or greater in adults and 2 L/day or greater in children. Central DI can be familial or sporadic and can be caused by head trauma, neurosurgery, neoplasms, granulomas, infections, inflammation, chemical toxins, vascular disorders, congenital malformations, and genetic causes. Other causes include hypoxic encephalopathy; infiltrative disorders, notably *histiocytosis X* (Hand-Schuller-Christian disease); anorexia nervosa; acute fatty liver of pregnancy; and Wolfram syndrome (central DI, diabetes mellitus, optic atrophy, and deafness) (Reddy and Mooradian, 2009). An autoimmune process is probably the cause of idiopathic DI and accounts for 30% to 50% of cases of central DI (De Bellis et al., 1999).

Thickening or enlargement of the posterior pituitary seen on MRI may represent lymphocytic infiltration and inflammation. Classically, DI after head trauma or neurosurgical procedures goes through three phases. Polyuria appears in the first 1 to 2 days after surgery followed by a period of oliguria for 3 to 4 days, which culminates in a polyuric phase. These phases are a reflection of the early paralysis of vasopressin-producing cells followed by neuronal degeneration and massive release of vasopressin with subsequent permanent loss of vasopressin production.

Vasopressin-resistant DI is usually a familial disorder, although sporadic causes are recognized in chronic medullary kidney disease associated with sickle cell disease, multiple myeloma, amyloidosis, Sjögren syndrome, and renal medullary cystic disease. In addition, prolonged primary polydipsia can wash out the normal medullary concentration gradient and may mimic vasopressin-resistant nephrogenic DI.

Diagnosis. Although a variety of diseases may present as polyuria and polydipsia, thorough history and routine laboratory evaluation can narrow the differential diagnosis of hypotonic polyuria to three possibilities: neurogenic DI (vasopressin sensitive), nephrogenic DI (vasopressin

resistant), or primary polydipsia (Mooradian and Morley, 1988).

Serum sodium concentrations less than 137 mEq/L and polyuria are usually manifestations of primary polydipsia. For patients with serum sodium concentrations less than 143 mEq/L, a water deprivation test should be carried out after an overnight fast, with hourly measurement of body weight, urine volume, and osmolality. In severe cases, the dehydration test can be started at 6 AM. When the urine osmolality remains constant during three consecutive measurements or if the patient loses more than 5% total body weight, then plasma osmolality, vasopressin, and sodium concentrations should be determined, and aqueous vasopressin (0.1 unit/kg subcutaneously) or 10 µg of nasal desmopressin should be administered and the response evaluated. An increase in urine osmolality of 150 mOsm/kg above baseline will exclude nephrogenic DI.

In central DI, administration of 10 µg of nasal desmopressin will result in increases in urine osmolality of as much as 800%. The response to desmopressin in partial central DI may result in urine osmolality increases of 15% to 50%.

Patients with nephrogenic DI continue to have urine osmolality levels that remain below isosmotic. Patients with primary polydipsia respond to the water deprivation test with urine concentrating to 500 mOsmol/kg, or higher. In comparison, urine osmolality in normal subjects undergoing the water deprivation test will increase to 800 mOsmol/kg or higher. Administration of exogenous vasopressin produces no further concentration in cases of primary polydipsia.

When the water suppression test yields equivocal results, the serum AVP concentration at baseline and following the water restriction test should be measured. However, the results of these tests may still be misleading because primary polydipsia results in submaximal secretion of AVP, mimicking the pattern of AVP secretion in partial central DI.

Treatment. The treatment of choice for central DI is DDAVP. DDAVP can be administered intravenously, subcutaneously, nasally, or orally. An initial nasal inhalation of 5 µg at bedtime is given. The dose is increased by 5-µg increments until nocturia has been resolved. After nocturia is successfully treated, a morning dose is given. The total daily dosage of nasally administered desmopressin is 5 to 20 µg/day (Loh and Verbalis, 2008). Desmopressin given by mouth should be given on an empty stomach. Absorption can be reduced by up to 50% when desmopressin is taken with food. A 0.1-mg tablet is equivalent to 2.5 to 5.0 µg of nasal inhalation spray (Loh and Verbalis, 2008).

Patients with partial DI will benefit from oral agents that potentiate AVP action or stimulate the release of AVP. These agents include chlorpropamide, carbamazepine, or clofibrate. In such cases, desmopressin requirements may be lower than available preparations can provide. Patients with nephrogenic DI benefit from thiazide diuretics or indomethacin.

Patients with DI should wear a medical ID bracelet. When the ability to drink fluids is impaired, IV hydration will be required to avoid dehydration and hypernatremia.

Syndrome of Inappropriate Antidiuretic Hormone Secretion

Key Points

- Laboratory evaluation of plasma osmolality, urine osmolality, and urine sodium concentration assist in determining the cause of hyponatremia.
- Water restriction and salt replacement are the most important treatment modalities in hyponatremia. The underlying cause should be identified and treated when possible.
- Vasopressin antagonists are currently indicated for the treatment of euvoletic and hypervolemic hyponatremia.

The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is associated with plasma ADH concentrations that are inappropriately high for the plasma osmolality. Laboratory and clinical features of SIADH include (1) euvoletic hyponatremia; (2) decreased measured plasma osmolality (< 275 mOsm/kg); (3) urine osmolality greater than 100 mOsm/kg; (4) urine sodium usually greater than 40 mEq/L; (5) normal acid–base and potassium balance; (6) blood urea nitrogen (BUN) less than 10 mg/dL; (7) hypouricemia less than 4 mg/dL; (8) normal thyroid and adrenal function; and (9) absence of advanced cardiac, renal, or liver disease (Reddy and Mooradian, 2009).

Conditions or factors associated with SIADH include CNS trauma and infections, tumors, drugs, major surgery, pulmonary disease (e.g., TB), hormone administration, human immunodeficiency virus (HIV) infection, hereditary SIADH, idiopathic causes, and cerebral salt wasting. In some cases, it is difficult to differentiate SIADH from mild to moderate depletion hyponatremia (Reddy and Mooradian, 2009) (Table 35-2).

The response of urinary and plasma sodium concentration to an infusion of 1 to 2 L of 0.9% (isotonic) saline may help in the differential diagnosis. In a patient with SIADH who is at equilibrium, the administered saline will be excreted; therefore, there will be an increase in urinary sodium while plasma sodium concentration will either not change or decrease slightly. If the patient has depletion hyponatremia from renal losses, sodium from the administered saline is retained, and the excess water is excreted. Urinary sodium decreases, and plasma sodium concentration increases (Reddy and Mooradian, 2009).

A *reset osmostat* may be suspected when mild hyponatremia persists despite changes in fluid and salt intake. A reset osmostat may be confirmed by having the patient receive a fluid bolus of 10 to 15 mL/kg. Normal patients, or those with a reset osmostat, should excrete 80% of this bolus in 4 hours, which does not occur with SIADH (Reddy and Mooradian, 2009).

Cerebral salt wasting induces SIADH-like symptoms. Salt wasting followed by volume depletion occurs in some cases of cerebral disease. This leads to a secondary rise in ADH levels. The mechanism underlying cerebral salt wasting is unclear (Reddy and Mooradian, 2009).

Treatment. Management of SIADH should begin with water restriction and treatment or elimination of the underlying etiology. In all patients with hyponatremia, free water intake from all sources should be restricted to less than 1 to 1.5 L/d. In patients with mild symptoms, the rate of urinary solute excretion, which is the main determinant of urine output, can be increased by a high-salt, high-protein diet or supplementation with urea (30–60 g/day) or salt tablets (200 mEq/day) (Reddy and Mooradian, 2009). However, salt therapy is generally contraindicated in patients with hypertension and edema because it leads to exacerbation of both conditions. In addition, water restriction is contraindicated in patients with subarachnoid hemorrhage with hypovolemia, in whom water restriction may result in hypotension, creating a risk for cerebral infarction. This risk is more pronounced if the patient has cerebral salt wasting, which must be treated first with isotonic or hypertonic saline solution until adequate volume status has been demonstrated.

In general, plasma sodium concentration should be corrected at a rate of 1 mEq/L/hr until the reversal of neurologic symptoms (Reddy and Mooradian, 2009). Then the correction rate is reduced to 0.5 mEq/L/hr until the plasma sodium has reached a level of 120 to 125 mEq/L. This approach effectively prevents the devastating neurologic consequences of acute hyponatremia and is associated with reduced risk of osmotic demyelination of pontine and extrapontine neurons.

The most specific treatment for SIADH is to block the V2 receptors in the kidney that mediate the diuretic effect of ADH. Vasopressin antagonists are currently indicated for the treatment of euvoletic and hypervolemic hyponatremia (Loh and Verbalis, 2008; Reddy and Mooradian, 2009).

For hospitalized patients, conivaptan is given as an IV loading dose of 20 mg delivered over 30 minutes and then as 20 mg continuously over 24 hours. Subsequent infusions may be administered every 1 to 3 days at 20 to 40 mg/day by continuous infusion (Reddy and Mooradian, 2009). More recently, an orally active vasopressin receptor antagonist, tolvaptan, became available. Rapid correction of hyponatremia has been reported in patients receiving these agents; therefore, frequent checks of plasma sodium are needed.

Chronic SIADH can occur in patients with ectopic ADH-producing tumors and in patients in whom antipsychotic drugs cannot be discontinued. If water restriction and salt tablet therapy are ineffective, the following drug therapy could be attempted: (1) administration of loop diuretic along with salt tablets, (2) demeclocycline, (3) lithium carbonate, and (4) orally active vasopressin antagonists such as tolvaptan. (Cost and increased liver enzymes limit tolvaptan's utility. In addition, tolvaptan should not be used for longer than 30 days and should not be used in patients with liver disease.) Demeclocycline is nephrotoxic in patients with cirrhosis and is contraindicated in children because of interference with bone development and teeth discoloration. (It also has a cost consideration.) Lithium carbonate may induce interstitial nephritis and renal failure; therefore, lithium should be considered for use only in patients in whom demeclocycline is contraindicated (Reddy and Mooradian, 2009).

Table 35-2 Select Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion

Nonosmotic stimuli	Nausea, pain, stress Human immunodeficiency virus (HIV) Acute psychosis Surgery Pregnancy (physiologic) Hypokalemia Congestive heart failure exacerbation
CNS lesions	Tumors (neuroblastoma) Cerebrovascular accident (stroke) Meningitis, encephalitis Abscess Guillain-Barré syndrome Hydrocephalus Pituitary stalk lesion Delirium tremens Demyelinating disease Acute porphyria
Malignancies	Lymphoma, leukemia, Hodgkin disease Carcinoma of the uterus Ureteral, prostate, and bladder carcinoma Carcinoma of the duodenum and pancreas Ectopic production of vasopressin by tumors (small cell lung carcinoma, carcinoids) Cancers of the head and neck and nasopharynx Renal cell carcinoma Osteosarcoma
Increased intrathoracic pressure	Mediastinal tumors (thymoma, sarcoma) Positive-pressure ventilation Infections (pneumonia, TB, aspergillosis, lung abscess) Bronchogenic carcinoma, mesothelioma Bronchiectasis, empyema COPD Pneumothorax
DRUG INDUCED	
Antipsychotics	Phenothiazines Haloperidol
Antidepressants	SSRIs, TCAs, MAOIs Bupropion
Anticonvulsants	Carbamazepine, oxcarbazepine Sodium valproate
Analgesics and recreational drugs	Morphine (high doses) Tramadol MDMA ("ecstasy")
Nonsteroidal antiinflammatory drugs	Colchicine, venlafaxine Duloxetine (Cymbalta)
Cardiac drugs	Thiazides, clonidine ACE inhibitors, aldosterone antagonists Amiloride, loop diuretics Methyldopa, amlodipine Amiodarone, lorcinide Propafenone, theophylline, terlipressin Unfractionated heparin (aldosterone antagonist)
Antidiabetic drugs	Chlorpropamide Tolbutamide, glipizide
Lipid-lowering agent	Clofibrate
Antineoplastic agents	Cyclophosphamide Vincristine, vinblastine Cisplatin, hydroxyurea Melphalan
Immunosuppressives	Tacrolimus, methotrexate Interferon- α and - γ , levamisole Monoclonal antibodies
Antibiotics	Azithromycin, ciprofloxacin Trimethoprim-sulfamethoxazole Cefoperazone-sulbactam, rifabutin

ACE, Angiotensin-converting enzyme; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; MAOI, monoamine oxidase inhibitor; MDMA, 3,4-methylenedioxyamphetamine; SSRI, selective serotonin reuptake inhibitor; TB, tuberculosis; TCA, tricyclic antidepressant.

Modified from Reddy P, Mooradian AD. Diagnosis and management of hyponatremia in hospitalized patients. *Int J Clin Pract.* 2009;63:1494-1508.

KEY TREATMENT

- Hydrocortisone is given to ACTH-deficient adults at 20 to 30 mg/day, increased twofold to threefold during times of illness and other stresses (Toogood and Stewart, 2008) (SOR: A).
- The goal of thyroid replacement should be to achieve a normal serum free thyroxin concentration and clinical euthyroidism (Oiknine and Mooradian, 2006) (SOR: A)
- A dopamine agonist is first-line treatment of prolactinomas (Mancini et al., 2008) (SOR: A).
- Transsphenoidal surgery to remove the pituitary adenoma is usually the treatment of choice in individuals with acromegaly (Melmed et al., 2009) (SOR: A).
- Octreotide (Sandostatin) is often effective in normalizing GH and IGF-1 levels. Pegvisomant is a GH receptor antagonist also approved for the treatment of acromegaly (Melmed et al., 2009) (SOR: A).
- Treatment of Cushing syndrome should be directed at the cause of hypercortisolism. The treatment of choice for Cushing disease is selective transsphenoidal resection (Biller et al., 2008) (SOR: A).
- Desmopressin is the primary treatment for central DI (Loh and Verbalis, 2008; Reddy and Mooradian, 2009) (SOR: A).
- Water restriction and salt replacement are the most important treatment modalities in hyponatremia. The underlying cause should be identified and treated when possible (Reddy and Mooradian, 2009) (SOR: A).
- Vasopressin antagonists are currently indicated for the treatment of euvolemic and hypervolemic hyponatremia (Loh and Verbalis, 2008; Reddy and Mooradian, 2009) (SOR: A).

Pineal Gland

The pineal gland, in general, is rarely thought of and especially not as part of the endocrine system, which is not surprising because there are rare (if any) diseases directly attributed to the pineal gland. The one area where there does seem to be consensus is the role the pineal gland appears to play in our orientation to day and night. It is also widely accepted that this is probably a teleologic holdover from more primitive parts of the human brain. There appears to be an interrelationship between some of our neurohormones, sleep, and what is generally referred to as the circadian rhythm (or sleep cycle). Sleep appears to have a significant effect on some hormones (GH) but little effect on others (MSH). One area where this occurs, of which most physicians are aware, is the normal cortisol surge that occurs in early morning and that seems to be absent or dulled when sleep deprived.

The deleterious effect of sleep deprivation is well known, anecdotally, in long-haul truckers and airline transport pilots. Over the past 15+ years, there have been significant changes in work hours for medical and surgical residents in an effort to eliminate, or at least ameliorate, sleep deprivation-induced iatrogenic errors. The negative physiologic effects of sleep deprivation have long been documented. Animal studies have definitively shown that when sleep deprived long enough (total sleep deprivation), the

animal dies (Rechtschaffen et al., 1989). New data suggests that during sleep, the brain clears “toxins,” specifically β -amyloid, which is associated with Alzheimer disease (Spira et al., 2013; Xie et al., 2013).

Thyroid Disorders

Key Points

- Primary thyroid disorder is caused by abnormal function of the thyroid gland.
- Secondary thyroid disorder is the result of abnormalities at the level of the pituitary.
- Tertiary thyroid disorder is caused by malfunction at the level of the hypothalamus.

Thyroid disorders can be categorized into processes that affect function (physiology) as well as structure (anatomy). The etiology of some of these are extraglandular, including metastatic neoplasia, pituitary disorders, dietary issues, autoimmune diseases, infections, and genetic or familial diseases (multiple endocrine neoplasia [MEN] IIA and familial medullary thyroid carcinoma [FMTC]). Other causes are intrinsic to the thyroid and include cysts, nodules, goiter, and primary neoplasia.

Irrespective of the disease process, all thyroid diseases exist in one of three functional states: euthyroid, hyperthyroid, or hypothyroid, each defined by the level of total bound and free circulating thyroid hormone. The presence of any one of these states in an individual can be transient, static, or progressing. Laboratory abnormalities of circulating thyroid hormone, at any point in time, do not prove disease and do not depend on the etiology of thyroid dysfunction. All three states may exist at different times during the course of an illness, and each state can exist with or without disease or clinical findings. In addition, the various thyroid structures can reflect disease independent of endocrinologic function.

Accurate assessment of thyroid function, with determination of presence or absence of disease, requires data in addition to levels of circulating thyroid hormones. These data include serum free thyroid hormone levels; thyrotropin (TSH) levels; and in some cases, antithyroid antibody titers. This battery of tests provides diagnosis in the majority of common thyroid disorders. When imaging studies and fine-needle aspiration are added, 90% to 95% of patients with thyroid disease who present in the primary care setting can be diagnosed and appropriately managed (Figure 35-1).

Thyroid disorders affect 60 to 80/1000 adults worldwide and up to 8.9% of the adult U.S. population (Bagchi et al., 1990; Vanderpump et al., 1995). Because most thyroid disorders have an insidious onset or closely mimic other, more common disorders, they are easily missed and, although rarely fatal, can cause significant morbidity. Early recognition is critical to minimizing that morbidity. With the exception of conditions such as simple goiter or visible nodule, patients who ultimately are diagnosed with thyroid disease rarely present to family physicians with complaints suggesting thyroid disorder.

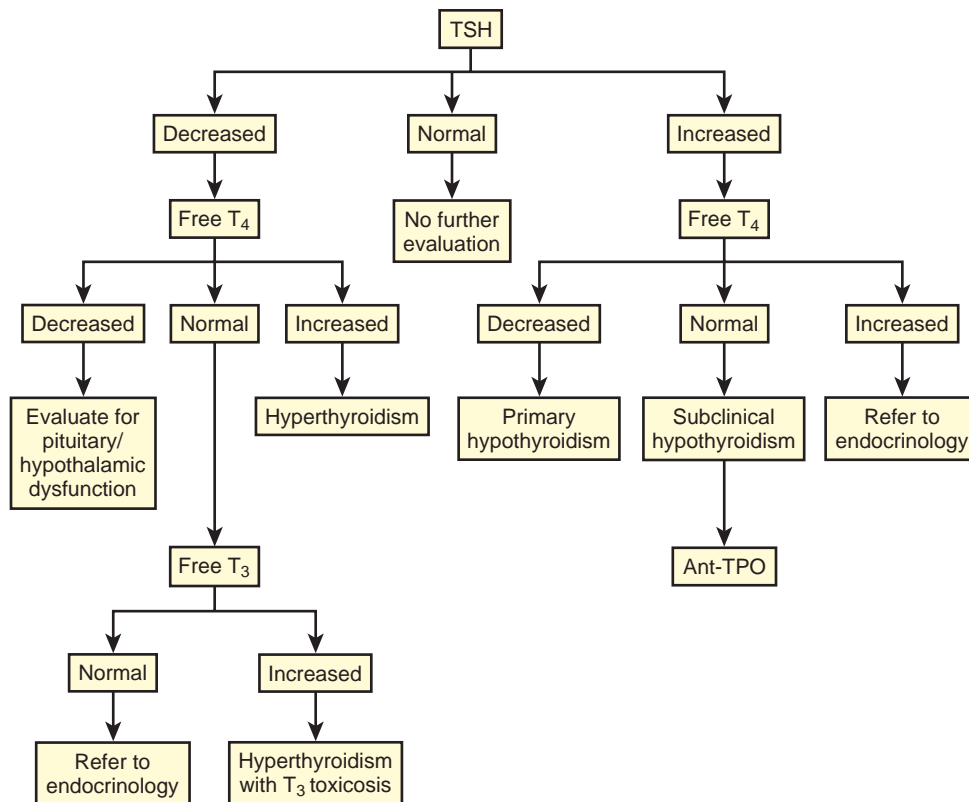

Figure 35-1 Algorithm for the diagnosis of thyroid dysfunction, beginning with an abnormal serum thyrotropin level. *anti-TPO*, Anti-thyroid antibodies; T_3 , triiodothyronine; T_4 , thyroxine; *TSH*, thyroid-stimulating hormone.

ANATOMY AND PHYSIOLOGY

Key Points

- Thyroxine (T_4) is the major product of the thyroid gland.
- Triiodothyronine (T_3) is the active hormone at the cellular level.
- The majority of circulating T_3 is formed in the peripheral circulation by deiodination of T_4 .
- T_4 serves as a reservoir (prohormone) for T_3 .
- Serum thyrotropin (sTSH) is required in all evaluations of dementia and depression.

Histologically, the thyroid gland consists of five primary elements: follicular cells, colloid, interstitial tissue, “C” cells, and lymphoid cells. The most prominent element is the follicular cell, which produces colloid. The thyroid follicle is the functional unit of the gland and the site where colloid is stored. It is within the follicle where thyroid hormone (thyroxine or T_4) synthesis occurs. The remaining cellular elements are “C” cells, which are few in number, and lymphoid cells. The few “C” cells are located in the intrafollicular space and produce calcitonin. Lymphoid cells are found scattered throughout the gland stroma in small, isolated clusters.

Circulating Thyroid Hormones

Biosynthesis of thyroid hormone is unique among endocrine glands because final assembly occurs extracellularly

in the follicular lumen. The source of thyroid hormones (T_4 and triiodothyronine [T_3]) is *thyroglobulin* (Tg), an iodoprotein, produced by the follicular cells. Thyroglobulin is the major portion of intraluminal colloid and is the most important protein of the thyroid gland (Kopp, 2005). Thyroglobulin provides a matrix for the synthesis of thyroid hormones and a vehicle for subsequent storage. Stored thyroglobulin is oxidized by thyroid peroxidase (TPO), adding an iodine molecule to tyrosine to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). MIT and DIT are then assembled into the final products, tetraiodothyronine (T_4) and triiodothyronine (T_3), which are stored in the follicular colloid for future use. When stimulated by serum thyrotropin (sTSH), thyroglobulin within the colloidal space is internalized by thyroid cells and enzymatically degraded to release T_4 and T_3 into the peripheral circulation. Approximately one third to half of T_4 released into the peripheral circulation is deiodinated to form T_3 .

In the peripheral circulation, T_4 and T_3 are bound to thyroid-binding globulin (TBG). Thyroxine is bound to TBG in concentrations 10 to 20 times greater than T_3 , and neither bound T_4 nor bound T_3 is directly available to tissues. Only unbound or “free” portions of T_4 and T_3 are metabolically available at the cellular level. The free portion of T_4 represents 0.02% to 0.05% of total serum T_4 , and the free portion of T_3 represents 0.1% to 0.3% of total serum T_3 (Benvenga, 2005; Meier and Burger, 2005; Toft and Beckett, 2005). Most T_3 (>99.5%) is bound to TBG, but T_3 is not as tightly bound as T_4 , allowing easier release into the free-state.

Table 35-3 Laboratory Tests for Evaluation of Thyroid Function

	Screening	Hyper	Hypo	Graves	CAT	Nodule	Thyroiditis	Other
TSH	Yes	Yes	Yes	Yes	Yes	Yes	Yes	No
T ₄	No	No	No	No	No	No	No	No
T ₃	No	Yes	No	Yes	No	No	No	No
FT ₄	No	Yes	Yes	Yes	No	Yes	Yes	No
FT ₃	No	No	No	No	No	No	No	No
Thyroglobulin	No	No	No	No	No	No	No	Yes
TSH-RS Abs	No	Yes	No	Yes	No	No	No	No
TPO Abs	No	No	No	No	Yes	No	No	No
Tg Abs	No	No	No	No	±	No	No	No
Thyroid microsomal Abs	No	No	No	No	No	No	Yes	±

CAT, Chronic autoimmune thyroiditis; FT₃, free triiodothyronine; FT₄, free thyroxine; T₃, triiodothyronine; T₄, thyroxine; Tg Abs, thyroglobulin antibodies; TPO Abs, thyroid antiperoxidase antibodies; TSH, thyroid-stimulating hormone (thyrotropin); TSH-RS Abs, TSH receptor-stimulator antibodies.

Thyroid hormones exert their effect by binding to thyroid receptors (TRs) within cells. At the cellular level, T₃ is roughly twice as biologically active as T₄. This is, in part, because T₃ binds more strongly to TR than T₄ does, thus, it easily displaces T₄ from binding sites (Yen, 2005). T₃ is the biologically active form of thyroid hormone. Thyroxine's role in this process appears to be that of a prohormone, providing a readily accessible reservoir for conversion to T₃. What other purpose(s) or role(s) T₄ plays is unknown (Bianco and Larsen, 2005).

Thyroid hormones (T₄ and T₃) regulate growth, development, and metabolism by affecting oxygen consumption and protein, carbohydrate, and vitamin metabolism. Around puberty, the effect on growth and development begin to wane, and in adults, thyroid hormones essentially affect only metabolism (Yen, 2005).

Normal thyroid function, in terms of circulating levels of T₄, T₃, FT₄, and free T₃ (FT₃) and the thyrotropin feedback system, appears to remain stable throughout life. Without intrinsic disease of the hypothalamic–pituitary–thyroid axis, age does not appear to have an adverse effect on the function of the thyroid gland or its component parts in terms of serum concentration of T₄ and T₃ (Hassani and Hershman, 2006; Oiknine and Mooradian, 2006). Although changes in measurable levels of total serum T₄ and T₃ do occur as a result of changes in transport protein concentrations, FT₄ and FT₃ levels remain mostly constant (Hassani and Hershman, 2006).

LABORATORY TESTING

Tests for thyroid disorders include laboratory studies, imaging, and biopsy. Before imaging or biopsy is undertaken, it is important to determine the functional state of the thyroid gland even when the initial presentation is a thyroid mass or thyromegaly. This is accomplished via laboratory testing of a peripheral blood sample. These simple and readily available tests provide direction for further workup. Initial laboratory tests, regardless of presenting complaint or finding, include sTSH and FT₄. The results of these initial studies help determine the functional state of the gland (hyperthyroid, euthyroid, or hypothyroid) and

thus suggest which additional tests are required (Garber et al., 2012) (Table 35-3).

Second-tier laboratory tests include thyroid antibodies and FT₃ if T₃ toxicosis is suspected. As noted previously, aging and comorbidities that affect circulating levels of thyroid transport protein can result in T₄ levels that appear to be abnormally low, suggesting a hypothyroid state. However, FT₄ and FT₃ will be normal, as will sTSH. Thyroid antibodies are useful in evaluating several disease states, primarily Graves disease and chronic autoimmune thyroiditis (CAT or Hashimoto thyroiditis). In Graves disease, the primary antibody culprit is TSH receptor-stimulator antibody (TSH-RS Abs). In CAT, the primary antibodies are thyroid anti-peroxidase antibodies (TPO Abs) and thyroglobulin antibodies (Tg Abs). Patients with hypothyroidism occasionally exhibit TSH receptor-blocker antibodies (TSH-RB Abs), but the role this plays in the disease course is unclear. Thyroid microsomal antibodies (TPO Abs, Tg Abs) are occasionally seen in the self-limited processes of postpartum thyroiditis and silent thyroiditis. Figure 35-1 provides an algorithm for diagnosing thyroid dysfunction.

Imaging

Thyroid ultrasonography is the first-line study a primary care physician should obtain for a palpable thyroid mass. The goal is to determine whether the mass is cystic, solid, or mixed. It is also used as a presumptive screen for malignancy in the hands of an experienced radiologist because malignant thyroid nodules have unique ultrasonographic characteristics. If the patient is hyperthyroid, with suppressed sTSH, ultrasonography is done in conjunction with radioisotope scan.

Nuclear imaging uses iodine 123 (¹²³I) to evaluate gland activity. Patients with normal gland function show homogeneity throughout the gland, with the exception of areas where cysts or nonfunctioning nodules are located. Patients with autonomously functioning nodules or multinodular goiter show uptake of ¹²³I in nodular areas, with the remainder of the gland, under the control of sTSH, being hypoactive or inactive.

CT and MRI are not useful in diagnosis and treatment of nonmalignant diseases of the thyroid and thus are not

recommended as initial studies. For biopsy-proven malignancy, CT and MRI can be useful preoperatively to define the area of involvement and for postoperative follow-up. CT and MRI should be reserved for the surgeon and oncologist.

Biopsy

Ultrasound-guided fine-needle aspiration (FNA) biopsy is a well-defined procedure for evaluating thyroid masses. It is safe and virtually painless in the hands of an experienced interventional radiologist, endocrinologist, or pathologist. When a definitive diagnosis cannot be made and there is concern for possible malignancy, surgical referral is required. This usually results in a lobectomy or subtotal thyroidectomy.

HYPERTHYROIDISM

Key Points

- Hyperthyroidism is diagnosed with a suppressed sTSH and increased FT₄.
- Graves disease is caused by an abnormal response to circulating antithyroid antibodies.
- Serum TSH in Graves disease is usually less than 0.01 mIU/L and may be unmeasurable. TSH-RS Abs are often present.
- Diagnosis of Graves disease in a patient without goiter and ophthalmic abnormality should be suspect.

Hyperthyroidism is a biochemical process represented by an increase in thyroid hormone biosynthesis and secretion (Bahn et al., 2011; Toft, 2001). The diagnosis of hyperthyroidism is based on sTSH level less than 0.1 mIU/L and elevated FT₄ and FT₃ and is often associated with symptoms consistent with a hypermetabolic state (Table 35-4). Determining the exact etiology requires further testing, including laboratory studies and imaging (Table 35-5).

Table 35-4 Symptoms Consistent with a Hypermetabolic State

Tachycardia, wide pulse pressure
Systolic hypertension
Fever, tremor
Warm moist skin
Anxiety, hyperactivity
Diarrhea, weight loss

Modified from Braverman LE, Utiger RD. Introduction to thyrotoxicosis. In Braverman LE, Utiger RD, eds. *The thyroid: a fundamental and clinical text*. 9th ed. Philadelphia: Lippincott, Williams & Wilkins; 2005.

Table 35-5 Common Causes of Hyperthyroidism

Autonomous functioning (toxic) nodule
Toxic multinodular goiter (TMNG, Plummer disease)
Factitious disorder (Munchausen disease)
Iatrogenic disease
TSH receptor-stimulator antibody production (Graves disease)
Acute thyroiditis
TSH-producing pituitary tumor (adenoma)

TMNG, Toxic multinodular goiter; TSH, thyroid-stimulating hormone (thyrotropin).

Graves Disease

Graves disease is the most common cause of hyperthyroidism and results from the development of TSH-RS Abs. These antibodies attach to TSH receptors in the thyroid gland and “mimic” the action of TSH, stimulating production and release of T₄. Because of excess circulating T₄, the pituitary feedback loop for TSH production is suppressed, resulting in sTSH levels significantly below 0.01 mIU/L. Serum TSH levels greater than 0.05 mIU/L, although not impossible with Graves disease, should make the diagnosis suspect.

Graves disease can present at the family physician’s office as thyrotoxicosis or thyroid storm but more often presents with hypermetabolic symptoms or goiter. How it is treated initially is determined by the patient’s age, comorbidities, and acuity of symptoms. The primary symptomatic treatment is directed toward the cardiovascular responses of tachycardia, systolic hypertension, and volume depletion. Concurrent with this is the administration of antithyroid medication (propylthiouracil [PTU] or methimazole [MMI]). After the patient’s symptoms have been controlled and there is evidence the hyperthyroid state is resolving, planning for long-term treatment can ensue.

Three courses of action can be followed for long-term treatment of patients with Graves disease. The goal is to maintain a euthyroid state. This can be accomplished with continued use of antithyroid medication, adjusting the dose to maintain sTSH in a normal range. A second option is ablation of the thyroid gland using ¹³¹I or total thyroidectomy (Bahn et al., 2011). Either is appropriate, and in either case, the patient must take some medication on a permanent basis. As a third option, an occasional patient will undergo spontaneous remission, so a trial of antithyroid medication for 6 months to 1 year may be worthwhile. When this approach is tried, it requires close follow-up in case the patient rebounds. The majority of patients with Graves disease elect radioactive ablation and long-term treatment with thyroxine replacement.

Intervention to treat the symptoms of hyperthyroidism begins with a β-adrenergic receptor blocker as a temporizing agent to control sympathetically mediated symptoms. Specific therapy is deferred pending confirmation of the cause. For Graves disease, autonomously functioning nodule, or toxic multinodular goiter (TMNG), specific intervention includes PTU or MMI to control thyroxine synthesis and, with PTU, to reduce conversion of T₄ to T₃ in the peripheral circulation. Cases of serious liver injury have been associated with PTU use; thus, some experts suggest that MMI be used in every patient who chooses antithyroid medications as treatment for Graves disease with the exception of the women in the first trimester of pregnancy, in whom PTU is preferred (Bahn et al., 2011). After the patient is converted to a euthyroid state, specific treatment, based on cause, can be instituted.

With treatment of Graves disease, the goiter, which is found in more than 90% of these patients, may shrink. However, large goiters often require surgery for a satisfactory cosmetic appearance.

Thyroxine-Producing Nodules

Autonomously functioning thyroid nodules are found occasionally during workup for a hypermetabolic state

or palpation of a thyroid mass. Autonomous nodules have a much higher incidence of occurring in iodine deficient areas, accounting for approximately 60% of cases of thyrotoxicosis.

Autonomous functioning nodules and TMNG (Plummer disease) produce values for sTSH and FT₄ similar to those found in Graves disease, although sTSH is generally not less than 0.05 mIU/L. In both cases, one would expect the TSH-RS Abs to be negative or, at most, at an extremely low titer. Evaluation includes radioisotope scan with ¹²³I, which will demonstrate the nodule(s). These tumors are rarely malignant, and treatment is surgical after appropriate thyroid suppression. Long-term results are excellent, with no expectation of recurrence.

For patients with TMNG, and those with autonomous nodules who cannot tolerate surgery, ¹³¹I ablation can be used. The ¹³¹I is picked up by the most active portion(s) of the gland, so residual normally functioning thyroid gland often remains. However, iatrogenic hypothyroidism is always possible. After ¹³¹I treatment of an autonomous nodule or TMNG, sTSH levels are required to determine if the gland can provide sufficient T₄ to meet physiologic requirements.

Other Causes of a Hyperthyroid State

Two often overlooked causes of a hyperthyroid state are fictitious and iatrogenic hyperthyroidism caused by excess exogenous T₄. In each case, patients have suppressed sTSH but generally only in the low normal range. From a laboratory perspective, these entities mimic painless, sporadic thyroiditis, with elevated T₄, low sTSH, and negative thyroid antibodies. If one measures FT₄ and FT₃, the relative ratio (FT₄ : FT₃) will be altered from what is normal. To identify fictitious thyrotoxicosis, it may be necessary to obtain an ¹²³I uptake study, which will demonstrate a minimally active thyroid gland. With Graves disease, autonomous functioning nodule, or TMNG, there is marked glandular activity. Elevated sTSH and elevated FT₄ levels are consistent with central hyperthyroidism or thyroid hormone resistance syndrome, and an evaluation of the pituitary for a TSH-producing tumor is required.

Thyrotoxicosis

Thyrotoxicosis is a physiologic process manifesting as hypermetabolism and hyperactivity that is caused by high serum concentrations of T₄, T₃, or both (Braverman and Utiger, 2005). It is not necessarily caused by excess hormone production and therefore may not represent a true hyperthyroid state. Although in the majority of patients the cause of thyrotoxicosis is excess T₄, in 2% to 4% of patients, it is due to elevated T₃ levels, with concomitant upper limit of normal T₄ levels (Meier and Burger, 2005).

Thyrotoxicosis is more common in female patients and in persons of northern European extraction and is rare in blacks. Spontaneous thyrotoxicosis is most often caused by Graves disease, accounting for 60% to 90% of all cases, followed by silent, or postpartum, thyroiditis caused by the sudden spike of circulating T₄, although it is transient and usually not clinically significant. Other less common, but not rare, causes of thyrotoxicosis include TMNG, autonomous functioning adenoma, and ingestion of exogenous thyroid hormone. Acute onset of thyrotoxicosis is almost

always caused by thyroiditis. Thyrotoxicosis associated with Graves disease has a more insidious course, evolving over a more protracted period. If a patient is thyrotoxic and the thyroid gland is not palpable, consider painless thyroiditis, unsuspected Graves disease, or exogenous thyroxine. A thyrotoxic patient with a goiter or ophthalmopathy has Graves disease until proven otherwise. Treatment of hypermetabolic symptoms should not be delayed pending further testing or referral.

Symptoms of hyperthyroidism in younger individuals are usually the result of sympathoadrenal activity, but elderly patients have an age-related desensitization of β-adrenergic receptors, which probably accounts for a blunting of some symptoms usually associated with hyperthyroidism (Hassani and Hershman, 2006; Oiknine and Mooradian, 2006; Trivalle et al., 1996).

In older individuals with altered sympathetic and parasympathetic function, symptoms of thyrotoxicosis tend to include cardiovascular dysfunction, dyspnea, weight loss, and proximal muscle weakness. Cardiovascular symptoms in elderly adults usually consist of resting tachycardia, wide pulse pressure, exercise intolerance, and dyspnea on exertion. Atrial fibrillation is uncommon but occurs more often in older individuals (5%-15%) (Franklyn and Gammage, 2005).

Other cardiovascular effects that affect both young and old individuals are decreased peripheral resistance, decreased cardiac filling times, increased blood volume, and fluid retention. Individuals with preexisting CAD may have ischemic congestive heart failure (CHF) as a result of their hypermetabolic state, but this generally improves with appropriate antithyroid therapy. Atrial flutter, paroxysmal supraventricular tachycardia, premature ventricular beats, and ventricular fibrillation are rare complications of thyrotoxicosis and may represent unsuspected CAD.

Signs and symptoms of CHF are common in both young and old individuals with thyrotoxicosis (Trivalle et al., 1996). Because of decreased effective circulating arterial volume, aldosterone secretion increases, with a concomitant increase in sodium retention that results in dependent edema. After the thyrotoxicosis is effectively treated, all CHF symptoms quickly resolve. When periorbital edema is present, a diagnosis of Graves disease should be considered, and TSH-RS Abs titers should be checked.

Apathetic thyrotoxicosis is an uncommon presentation but represents the most common mental disorder associated with excess thyroid hormone production and release. Symptoms include apathy, lethargy, pseudodementia, weight loss, and depressed mood. It usually occurs in older patients without symptoms of tachycardia, hyperphagia, sweating, warm skin, or goiter (Wagle et al., 1998). This syndrome is easily confused with depression or dementia and, unless specifically sought, is easy to miss. A screening sTSH should be included in every depression or dementia workup.

The treatment of thyrotoxicosis is straightforward with three objectives; ameliorate acute symptoms, suppress synthesis and secretion of thyroid hormones, and treat the primary cause to prevent recurrence (Bahn et al., 2011). Acute symptoms respond readily to β-adrenergic receptor blocking agents, which should be continued until FT₄ levels have returned to the normal range. Calcium channel

blockers can be used in patients who cannot tolerate β -blockers. Inhibition of synthesis of thyroid hormones is achieved with PTU or MML. Adjunct therapies include fluid resuscitation with D5 or D10 normal saline and administration of steroids. Fever generally responds satisfactorily to acetaminophen. The high fevers associated with thyroid storm may require cooling blankets. Nonsteroidal drugs and salicylates should be avoided in the acute phase because of competition for thyroid hormone binding sites on transport proteins. This can cause release of bound thyroid hormone into the peripheral circulation. With aggressive therapy, acute symptoms of thyrotoxicosis should improve within 12 to 24 hours. After acute symptoms are controlled, treatment of the primary cause can be considered. This could include watchful waiting in the case of thyroiditis, surgery for an autonomously functioning adenoma, or ^{131}I in Graves disease.

Thyroid Storm

Key Points

- Unrecognized thyroid storm has a mortality rate as high as 75%.
- Thyroid storm is usually the result of another disorder that unmasks a preexisting, but unidentified, hyperthyroid state.
- Thyroid storm is a clinical diagnosis, not defined by levels of TSH, T_4 , or T_3 .
- Suspicion of thyroid storm is a medical emergency with close monitoring in the intensive care unit and appropriate consultation by an endocrinologist.

Thyroid storm is a severe variant of thyrotoxicosis in which the metabolic state is sufficiently increased such that organ system failure can occur. It represents a rare complication of thyrotoxicosis and has a mortality rate as high as 75%, depending on how quickly it is recognized and treated (Tiegens and Leinung, 1995; Trzepacz et al., 1989; Wartofsky, 2005).

The diagnosis of thyroid storm is based on clinical findings, not measured levels of circulating T_4 or sTSH. Thyroid storm is often precipitated by infection, with associated symptoms that mask a thyrotoxic state. Clinical findings in thyroid storm include hyperpyrexia ($>102^\circ\text{F}$), tachycardia out of proportion to temperature, gastrointestinal (GI) dysfunction (nausea, vomiting, diarrhea, jaundice), and CNS dysfunction (marked hyperirritability, anxiety, confusion, apathy, coma) (Wartofsky, 2005). There is usually pronounced decompensation of one or more organ systems. Any patient presenting with goiter, fever, and marked tachycardia should be considered to be in thyroid storm and treated accordingly. Admission to the medical intensive care unit and consultation with an endocrinologist are appropriate.

Treatment of thyroid storm includes β -blockers, anti-thyroid drugs, corticosteroid therapy, antipyretics, aggressive fluid replacement, and identification and treatment of any precipitating process. For patients with severe symptoms, Lugol solution or supersaturated potassium iodide will help inhibit release of T_4 into the peripheral circulation.

Table 35-6 Causes of Hypothyroidism

Insufficient intake of dietary iodine (uncommon in the United States)
Autoimmune disease (primarily Hashimoto thyroiditis)
Surgery (thyroid surgery)
Radiation exposure (head and neck)
Viral infection
Central disease (primary pituitary failure)

If either is used, it should only be given after loading doses of antithyroid drugs, to block iodine-induced synthesis of T_4 . Lithium also has an antithyroid effect and can be used in severe cases of thyroid storm. Severe thyrotoxic symptoms, unresponsive to all of these regimens, may respond to sodium iodate at 500 mg/day.

HYPOTHYROIDISM

Hypothyroidism is a hypometabolic state resulting from levels of circulating thyroid hormone insufficient to meet body requirements. Serum TSH will be greater than 10 mIU/L and can be significantly increased (>25 mIU/L) in protracted cases. Primary causes are listed in Table 35-6.

Chronic Autoimmune Thyroiditis (Hashimoto Thyroiditis)

Key Points

- Hashimoto thyroiditis is an autoimmune disorder that results in fibrosis of the thyroid gland.
- Hashimoto thyroiditis is the most common cause of hypothyroidism in the United States.
- Diagnosis of Hashimoto thyroiditis is based on an elevated sTSH, low normal to low FT_4 , and TPO Abs.

The most common cause of hypothyroidism worldwide is inadequate dietary intake of iodine. Because of the addition of iodine to table salt, however, this is a rare cause in the United States. In the United States and the rest of the developed world, the most common cause of hypothyroidism is CAT (Hashimoto disease). CAT is caused by the development of antithyroid antibodies that attack the thyroidal struma, causing progressive fibrosis. TPO Abs and Tg abs appear to be responsible, with TPO Abs considered the primary cause (Dayan and Daniels, 1996). Diagnosis is based on elevated sTSH, a low normal or low FT_4 , and the presence of TPO Abs (Garber et al., 2012).

Hashimoto thyroiditis occurs most often in women, with a female-to-male ratio of 10-14:1. CAT is usually diagnosed in the fifth decade of life and is progressive (Vanderpump, 2005). As it progresses, more functioning thyroid gland becomes fibrotic, and less indigenous T_4 is produced. After diagnosis, replacement doses of T_4 should be used. In adults, the average replacement dose of L-thyroxine is 1.6 $\mu\text{g}/\text{kg}/\text{day}$. Serum TSH is followed annually to ensure adequate control.

Other Forms of Hypothyroidism

Central hypothyroidism is caused by pituitary failure and is rare. The diagnosis is suggested with low to nonexistent

sTSH levels in a patient without symptoms of hypermetabolism (thyrotoxicosis) and with low circulating FT₄. Generally, when presented with these data, further evaluation to determine the etiology of the hypothyroidism is not necessary. However, the patient should be evaluated for pituitary failure if this has not already been done (see Approach to Pituitary Diseases).

Depending on the degree of injury, thyroiditis (postpartum, sporadic, or subacute) can result in a transient hypothyroid state, with eventual recovery. Subacute thyroiditis is more likely to undergo this process with insufficient T₄ production for 3 to 6 months. Treatment is usually unnecessary, but low-dose thyroxine replacement can be used on a temporary basis for patients who become symptomatic.

Other causes of hypothyroidism include dietary iodine deficiency, surgery, ¹³¹I radiation therapy, and nonthyroid head and neck cancer treatment.

Hypothyroidism is typically treated with L-thyroxine replacement alone. However, some believe that patients occasionally have T₄-resistant disease and recommend mixed T₄-T₃ replacement. Although true T₄ resistance is controversial, if a patient receiving replacement T₄ has sTSH in the therapeutic range but continues to complain of hypothyroid symptoms, combination T₄-T₃ can be tried to alleviate symptoms. But it is prudent to ensure that the sTSH is maintained above 1.0 mIU/L to guard against unintended consequences of iatrogenic hyperthyroidism (Gencer et al., 2013; Taylor et al., 2013).

Initial dose of L-thyroxine will depend on the patient's age, duration of hypothyroid state, and comorbidities. In a young healthy adult, treatment with L-thyroxine may start with full replacement dosing. For someone older than 50 to 60 years without evidence of CAD, an L-thyroxine dose of 0.05 mg (50 µg) daily is recommended, with increases weekly of 0.025 mg to 0.05 mg, depending on clinical response (Garber et al., 2012). If the patient becomes tachycardic, is tremulous, or sweats, the time interval should be extended between increases in dosage to every 2 to 3 weeks. After the patient is stabilized on 0.1 to 0.125 mg of L-thyroxine daily, further increases are made based on sTSH response. Serum TSH only needs to be checked every 4 to 6 weeks. More frequent testing does not allow a sufficient interval for developing homeostasis and can result in overdosing. When the patient is on a steady dose, further treatment is adjusted so that sTSH remains at 0.5 to 4.5 mIU/L (mean, 2.5 mIU/L). Doses of L-thyroxine resulting in sTSH less than 0.1 mIU/L indicate iatrogenic hyperthyroidism and should be avoided (Gencer et al., 2013).

Thyroiditis

Forms of thyroiditis include tender thyroiditis such as subacute granulomatous thyroiditis (probable viral etiology), infectious thyroiditis (probable bacteria etiology), radiation thyroiditis, and palpation- or trauma-induced thyroiditis. Nontender thyroiditis includes silent thyroiditis, postpartum thyroiditis, drug-induced thyroiditis, fibrous thyroiditis, and CAT (Hashimoto thyroiditis) (Bahn et al., 2011; Farwell, 2005; Lazarus, 2005).

The mechanism of injury to the thyroid gland is disruption of thyroid architecture caused by lymphocytic infiltration, resulting in leakage of colloid-stored thyroxine

into the peripheral circulation. This nonphysiologically triggered leakage of stored T₄ causes a spike in peripheral circulating T₄ and transient hypermetabolic symptoms. Early testing in the disease can demonstrate an elevated FT₄ level, although not necessarily outside the normal range. Depending on the duration of the destructive process and degree of injury, sTSH may be normal, low normal, or low. If the cause of this variability is not appreciated, it could lead to the erroneous initial diagnosis of Graves disease (increased FT₄ and low sTSH). With protracted acute thyroiditis, however, sTSH is not as low as in Graves disease, and TSH-RS Abs titers are low to absent. In addition, patients with acute thyroiditis lack Graves disease optic findings and goiter.

As a general rule, acute thyroiditis is a short-lived process, with T₄ stores being rapidly depleted. This represents a case of thyrotoxicosis (increased circulating T₄) but not hyperthyroidism (increased production of T₄). Follow-up testing over the next few weeks demonstrates progressively lower T₄ levels, which eventually return to normal. As T₄ levels return to normal, the acute hypermetabolic symptoms begin to decline. The duration of T₄ elevation determines how low the sTSH will go and how quickly it will return to normal.

Treatment of Hypothyroid Disease

Synthetic levothyroxine (L-thyroxine) is the drug of choice for the treatment of TSH-deficient hypothyroidism (Oiknine and Mooradian, 2006). A typical replacement dose in adults is approximately 1.6 µg/kg/day. The daily requirements should be individually determined based on clinical and biochemical evaluations. The FT₄ level should be in the middle to upper third of normal range. Attention to other, coexistent diseases is required when replacing thyroid hormone (Garber et al., 2012). Thyroid replacement increases the clearance of cortisol and will uncover a subclinical adrenal insufficiency. This must be considered when replacing thyroxine in a patient with secondary hypothyroidism. The ACTH status should be assessed and, if deficient or the status is uncertain, glucocorticoid replacement is indicated before thyroid hormone is replaced.

Subclinical Thyroid Disease

Key Points

- Subclinical thyroid disease is based on a TSH level that is above the normal reference range in an asymptomatic patient with normal FT₄.
- The American Thyroid Association (ATA) and the American Association of Clinical Endocrinologists (AACE) recommend that screening for hypothyroidism should be considered in all adults over the age of 60 years.
- The decision to treat subclinical hypothyroidism when serum TSH is less than 10 mIU/L should be individualized.
- The ATA and AACE suggest treatment of subclinical hypothyroidism (sTSH <10 mIU/L in patients positive for TPO Abs or a history of atherosclerotic vascular disease or symptoms consistent with hypothyroidism).

Discussion about subclinical thyroid disease has focused on whether it is a real clinical entity. Subclinical thyroid diseases are defined as (1) subclinical hyperthyroidism (or subclinical thyrotoxicosis) with sTSH less than 0.1 mIU/L and normal circulating FT₄ and FT₃ or (2) subclinical hypothyroidism with sTSH greater than 4.5 mIU/L but less than 10.0 mIU/L with normal circulating FT₄. Both entities assume a patient who is asymptomatic or has minimal signs and symptoms.

The primary questions concerning subclinical thyroid disease are whether early intervention is beneficial and whether patients should be screened. The only disease state that has been directly related to subclinical thyroid disease is overt hypothyroidism. Individuals with subclinical hypothyroidism have a higher incidence of progression to overt hypothyroidism than the general population. Annually, 3% to 5% of patients identified with subclinical hypothyroidism progress to overt hypothyroidism with sTSH levels greater than 10.0 mIU/L (Toft and Beckett, 2005). The majority of these represent early CAT. For patients with subclinical hypothyroidism, a TPO Ab measurement should be considered.

Currently, no consensus exists among national organizations as to whether these individuals should start therapy during this phase of their disease. Treating those with symptoms seems appropriate, but there is no evidence to support the premise that early treatment alters the disease course or associated comorbidities (hyperlipidemia, hypertension, CAD).

Studies have demonstrated a two to three times higher incidence of atrial fibrillation in patients with subclinical hyperthyroidism compared with individuals with normal sTSH levels (Ross, 2005a, 2005b). The Framingham data suggest that some individuals with subclinical hyperthyroidism are at increased risk for paroxysmal atrial fibrillation (Oiknine and Mooradian, 2006). In addition, good evidence indicates that osteoporosis is associated with overt hyperthyroidism. New evidence suggests that osteoporosis is also associated with subclinical hyperthyroidism (Gencer et al., 2013).

Although data supporting adverse consequences of subclinical hyperthyroidism continue to accumulate, there still are no outcomes data to show a decrease in mortality or morbidity from early intervention. The AACE, however, does recommend treatment of subclinical hyperthyroidism caused by nodular thyroid disease (AACE, 2002).

New guidelines from the ATA and AACE, published in 2012, have moved from their previous position of not recommending treatment of subclinical hypothyroidism to suggesting that treatment be considered for individuals with a sTSH between 4.5 and 10 mIU/L who are positive for TPO Abs or have a history of atherosclerotic vascular disease and anyone with symptoms suggestive of hypothyroidism (Garber et al., 2012).

A review of the literature on how variation of thyroid function tests affect cardiovascular, bone, metabolic, pregnancy, neurologic, and psychological outcomes, suggests there may be a correlation between these and thyroid test variability (i.e., “normal” range) (Taylor et al., 2013). Evidence synthesis shows that higher sTSH and lower T₄ levels are associated with more cardiovascular risk factors and cardiovascular events and worse metabolic parameters

and pregnancy outcomes. Furthermore, it shows that lower sTSH and higher T₄ levels are associated with reduced bone mineral density (BMD) and increased fracture risk. High-quality data are lacking for neurologic and psychological outcomes. The conclusion suggests that even with thyroid function data within currently accepted normal range (0.1–4.5 mIU/L), there is an association with adverse health outcomes (Taylor et al., 2013). Data from the Thyroid Studies Collaboration support these findings. Specifically, subclinical hypothyroidism is associated with an increased risk of coronary heart disease (CHD) events, increased CHD mortality, and heart failure (HF). Subclinical hyperthyroidism is associated with an overall risk of total mortality, CHD mortality, HF, and atrial fibrillation. Atrial fibrillation is particularly increased in individuals whose sTSH is suppressed below 0.1 mIU/L (Gencer et al., 2013; Rodondi et al., 2005).

By extrapolation from the results of these data, it is reasonable to assume that treatment of subclinical thyroid disease could be beneficial, but definitive outcomes data are lacking. However, it is clear that careful control and follow-up of treatment of overt thyroid disease is essential.

ANATOMIC DISEASES

Anatomic diseases of the thyroid gland include a number of primary and secondary disorders (Table 35-7). The list includes goiter, nodules, primary neoplasia, metastatic neoplasia (rare), and familial disorders.

Goiter

Goiter is the most common anatomic disease, and the major cause of goiter worldwide is iodine deficiency. When simple goiter occurs in areas of adequate iodine intake, there appears to be a strong genetic component to the disease. In the United States, goiter found independent of Graves disease is usually associated with CAT as the disease progresses to a hypothyroid state. Goiter is the result of both hypertrophy and hyperplasia of the thyroid gland. In the case of iodine deficiency, this is caused by excess thyrotropin production, leading to glandular growth and colloid production.

In Graves disease, stimulation of the thyroid by TSH-RS Abs causes excess production of T₄ and T₃, in turn resulting in uncontrolled production of colloid to store the excess production of thyroid hormone. In fact, goiter is the most common clinical finding in Graves disease after thyrotoxicosis, occurring in nearly 100% of patients (Chiovato et al., 2001).

Goiter is one of the five hallmarks of Graves disease. Goiter associated with hypothyroidism often improves after euthyroid doses of thyroxine have been achieved, although

Table 35-7 Anatomic Diseases of Thyroid

Goiter	Simple, toxic, iodine deficiency
Nodule	Adenoma, incidental, toxic
Cyst	Simple, complex
Malignancy	Primary: papillary or follicular, medullary, lymphoma Metastatic: lymphoma, breast, pulmonary, other Familial: multiple endocrine neoplasia type IIA

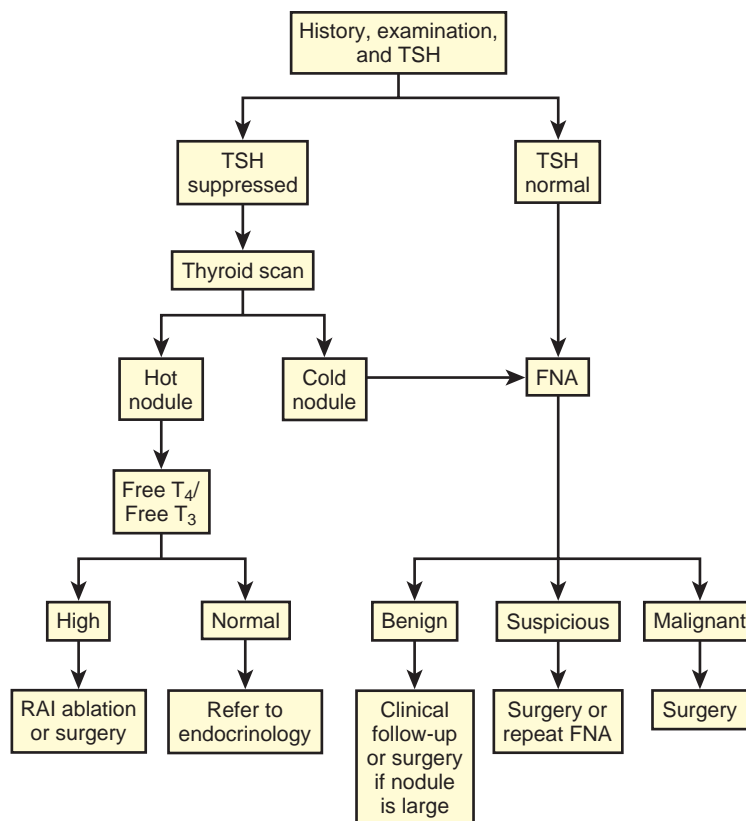

Figure 35-2 Algorithm for the clinical evaluation of thyroid nodule. FNA, Fine-needle aspiration; RAI, radioactive iodine; T_3 , triiodothyronine; T_4 , thyroxine; TSH, thyroid-stimulating hormone.

it may take 6 months to 1 year. If the goiter does not involute with thyroxine replacement, excision may be required. Besides goiter, the other four hallmarks of Graves disease are thyrotoxicosis, ophthalmopathy, local myxedema, and acropachy (clubbing of fingers and toes).

Nodules and Cysts

Thyroid nodules come in a variety of sizes and types. The incidence of malignancy in nodules smaller than 1.0 cm in size, which typically are found incidental to some non-thyroid-related diagnostic procedure (e.g., head and neck ultrasonography), is less than 0.5%. Current recommendations for evaluation of these “incidentalomas” include TSH and FT₄ levels and careful palpation of the thyroid gland (Ross, 2005a) and adjacent cervical nodes (Cooper et al., 2009) (Figure 35-2).

If results of tests and palpation are normal or negative, annual follow-up with palpation by the physician is recommended. As long as growth remains minimal and there were no ultrasonographic hallmarks of malignancy on the initial scan, these nodules can be monitored clinically.

The exception to annual follow-up in nodules smaller than 1.0 cm is when a solitary nodule occurs before 14 years of age because these have a greater than 50% incidence of malignancy. Other reasons to obtain FNA of a nodule smaller than 1.0 cm include high-risk history (nodules >5 mm) or presence of cervical adenopathy (all nodules regardless of size) (Cooper et al., 2009).

A nodule that is palpable on examination or 1.0 cm or larger on ultrasonography requires further evaluation. If

the sTSH is within normal range and a local endocrinologist experienced in FNA is available, referral without imaging is appropriate. However, if ultrasonography is performed and it shows a purely cystic lesion, FNA is not necessary. As long as the cyst remains small or is asymptomatic, no intervention is required. However, if the cyst increases in size or becomes symptomatic, it can be drained via FNA.

If the patient with a palpable nodule has a suppressed sTSH, this would suggest a nodule that is functioning autonomously. Before any intervention (surgical or FNA), a radioisotope ¹²³I scan is indicated. If the lesion is “hot,” suppression is the course of action before FNA or surgery is performed. If “cold,” it could represent a cystic, mixed, or solid mass, thus requiring further evaluation by FNA (first choice) or surgical exploration.

Benign nodules do not require therapeutic intervention unless the nodule’s size is causing symptoms (tracheal compression or pain). These generally do not respond to suppression; thus, surgical excision is the treatment of choice.

Malignancy

Malignancy of the thyroid, both primary and secondary, is rare, accounting for fewer than 2% of all cancers, and generally, tumors are not aggressive. *Papillary carcinoma* is the most common, accounting for approximately 80% of primary thyroid malignancies. Follicular carcinoma, which arises from the same cell type as papillary carcinoma, accounts for about 5% of thyroid neoplasia. Undifferentiated and anaplastic carcinoma makes up fewer than 10% of all thyroid malignancies, and medullary carcinoma of the

thyroid about 5% of thyroid malignancies (Baloch and Livolsi, 2005).

The most common cancers that metastasize to the thyroid are breast, lung, and kidney. Primary lymphoid cancer occurs in the thyroid, but its incidence is unknown because it cannot be distinguished from lymphoma that originates elsewhere in the body. Treatment of thyroid cancers is generally surgical with ^{131}I therapy with subtotal thyroidectomy. As with cancers elsewhere in the body, primary treatment will depend on tissue diagnosis and clinical evaluation. New imaging techniques are being used to evaluate patients who are thyroglobulin positive but whole-body iodine scan negative for differentiated thyroid cancer. This imaging technique uses ^{18}F fluorine-labeled fluorodeoxyglucose positron emission tomography/computed tomography (^{18}F FDG PET/CT), and ATA guidelines from 2009 recommend this screening in select patients with any one of five main indicators. Presently, this level of nuclear scan may only be available in larger metropolitan areas and academic medical centers (Cooper et al., 2009; Palaniswamy and Subramanyam, 2013).

Two familial thyroid malignancies include MEN IIA and FMTc. MEN IIA is an autosomal dominant disorder that can cause “C”-cell hyperplasia and hyperparathyroidism. The diagnosis is often serendipitously found during evaluation for hypercalcemia or renal calculi.

LONG-TERM FOLLOW-UP OF THYROID DISORDERS

For patients receiving long-term thyroid therapy for hypothyroidism, monitoring is done via sTSH unless there is hypothalamic-pituitary disease. It takes 4 weeks after initiating treatment (or changing dose) before clinically significant change occurs in sTSH level. In most patients, checking sTSH once every 4 weeks is sufficient until steady state is reached. After the patient is stabilized, sTSH can be checked at 6 months and then annually unless the patient develops new symptoms (Garber et al., 2012).

Patients determined to have benign nodules after adequate evaluation are followed annually with careful palpation of the thyroid gland. Unless there is a size change or new symptoms, no additional testing is required. Ultrasound imaging of the thyroid is not recommended for follow-up of nodules smaller than 1.0 cm. Repeat ultrasonography is required in patients with an enlarging nodule, evidence of a new thyroid mass, or who complain of pain or pressure. Unless the patient is experiencing symptoms of hyper- or hypothyroid, repeat testing of sTSH or FT₄ is not indicated (Cooper et al., 2009).

SICK EUTHYROID SYNDROME (THYROID HORMONE ADAPTATION SYNDROME)

Thyroid function can appear suppressed during severe illness and may not represent abnormal thyroid function. Serious illness has been shown to affect laboratory tests of thyroid function (sTSH, T₄, thyroglobulin), but there is no clear evidence that this reflects a disease state (Chopra, 1997). Because these changes appear to have no direct adverse effect on the patient’s overall clinical state, this condition is labeled “sick euthyroid syndrome.” In broad terms,

sick euthyroid syndrome is more of academic interest than clinical. Administration of T₄ to a seriously ill individual does not improve the outcome for most patients, but evidence suggests that high doses of T₃ after cardiac surgery may be beneficial (Wiersinga, 2005).

The physician should remember the rare patient whose thyroid disease is uncovered by serious illness. If a seriously ill patient is not responding as expected, (e.g., difficulty in weaning from ventilator support), checking thyroid function may be appropriate, although any interpretation of results should be reviewed by a clinician experienced in interpreting thyroid tests in seriously ill patients before intervention (Garber et al., 2012).

DRUGS AFFECTING THYROID FUNCTION AND TESTING

Key Points

- Therapeutic drugs have a variety of effects on thyroid function, including delayed or suppressed synthesis.
- Therapeutic drugs may block the effect of thyroid hormone at the cellular level.
- Phenothiazines, dopamine, phenytoin, and glucocorticoids block release of TSH from the pituitary.
- Amiodarone can cause both hyperthyroidism and hypothyroidism. Approximately 20% of patients can develop hypothyroidism from fibrosis of the gland.

Many common drugs can affect thyroid function, bioavailability of thyroid hormone, and laboratory testing. Drugs that affect thyroid function fall into several categories: some inhibit synthesis of T₄, some block secretion of T₄, some block TSH release, some affect extrathyroidal conversion of T₄ to T₃, and some influence thyroxine at the tissue or cellular level (Table 35-8). PTU and MMI inhibit thyroid hormone synthesis by interfering with thyroid peroxidase. PTU has the added advantage of inhibiting extrathyroidal conversion of T₄ to T₃. Neither PTU nor MMI inhibits T₄ release (secretion) from the thyroid gland. Amiodarone, lithium, and cytokines can affect synthesis and secretion. In the absence of iodine, amiodarone can precipitate both hyperthyroid and hypothyroid events. In the United States, where dietary iodine is plentiful, patients taking amiodarone tend to develop hypothyroidism from fibrosis of the

thyroid gland. The incidence is approximately 20% (Harjai and Licata, 1997; Roti and Vagenakis, 2005). Patients taking these drugs, especially amiodarone, should be screened regularly with sTSH for developing thyroid dysfunction. Dopamine, glucocorticoids, and phenytoin have been shown to inhibit release of TSH from the anterior pituitary. Salicylates and other NSAIDs, furosemide, heparin, and enoxaparin compete for binding sites on thyroid hormone transport proteins. Use of these drugs in acute thyroid disease can potentially exacerbate thyrotoxic symptoms by releasing thyroid hormone into the peripheral circulation. Serum TSH and FT₄ should be monitored in regular users of these medications (Table 35-9).

Phenytoin, phenobarbital, carbamazepine, and rifampin stimulate hepatic enzymatic activity, thus shortening thyroid hormone clearance times and increasing conversion of T₄ to T₃. Serum TSH levels should be monitored routinely, until stable, when these medications are added or deleted from a patient's regimen. Sucralfate, cholestyramine, calcium carbonate, aluminum hydroxide, soluble fiber, soy products, and ferrous sulfate inhibit absorption of exogenous L-thyroxine from the gut. Oral L-thyroxine should be taken on an empty stomach.

β-Blockers exert their effect on thyroid hormones at the cellular level, and benzodiazepines block uptake of T₃ at the cellular level (Hedley et al., 1989; Tiegens and Leinung, 1995; Wartofsky, 2005). Calcium channel blocking agents inhibit uptake of thyroid hormone by hepatic and muscle cells (Table 35-9).

THYROID DISEASE IN PREGNANCY

Pregnancy can exacerbate an already existing thyroid disorder, thus requiring extra vigilance on the part of the family physician. Careful monitoring and proactive clinical intervention are key. The majority of women with hypothyroidism, who are euthyroid on stable doses of thyroid replacement, require increased doses of thyroxine replacement during their pregnancy. In pregnancy, the normal range for sTSH is trimester specific. If trimester-specific sTSH ranges are not available at the local laboratory, the recommended upper levels for normal are 2.5 mIU/L for the first trimester, 3.0 mIU/L for the second trimester, and 3.5 mIU/L for the third (Garber et al., 2012). Being aware of this need and being prepared to make dosage adjustments in a timely manner are important. Consulting an endocrinologist to help with the care of these patients is advised (Shankar et al., 2001).

Silent or postpartum thyroiditis during pregnancy is essentially a benign, short-term disease and requires only symptomatic treatment. Occasional checks of sTSH and FT₄ levels are justified to monitor recovery. For the rare pregnant patient who requires suppression of T₄ synthesis, judicious use of antithyroid drugs (PTU and MMI) is generally considered to be safe. There is some concern that MMI may cross the placental barrier more readily than PTU, but this has not proven to be of concern in a clinical setting. It is important, however, to remember that prolonged suppression of the thyroid or suppression late in pregnancy can

result in a transient depression of neonatal thyroid function and may induce goiters in the neonate. PTU and MMI can be found in breast milk. This has not proven to be of concern as long as the dose is kept low. PTU (maximum, 150 mg/day) and MMI (maximum, 20 mg/day) caused no problems with a nursing child (Glinoe, 2005). Both PTU and MMI are category D pregnancy risk, and the American Academy of Pediatrics reports no sign or symptom in infants or adverse effects on lactation and supports use of these drugs during breastfeeding. In the United States, PTU has generally been the antithyroid drug of choice in pregnant and nursing women; however, recent reports concerning hepatotoxicity from PTU have limited use of PTU to the preferred agent during the first trimester of pregnancy, and MMI is first-line therapy during the second and third trimesters of pregnancy and nursing.

SCREENING FOR THYROID DISEASE

Screening for asymptomatic thyroid disease is controversial, but screening in specific populations may be beneficial (American Academy of Family Physicians [AAFP], 2009; Bahn et al., 2011; Garber et al., 2012; Helfand, 2004; Ladenson et al., 2000). Women older than the age of 50 years have the highest incidence of spontaneous hypothyroidism compared with all males and mixed younger populations, approaching 5% per year. Thus, screening has a good chance of finding disease early. However, the evidence supporting benefit from early intervention is not strong and probably does not justify the cost. However, the ATA and AACE changed their guidelines in 2012 to say that screening for hypothyroidism should be considered in adults older than 60 years old (Garber et al., 2012). Patients who present with paroxysmal atrial fibrillation should be routinely screened for hyperthyroidism, although the incidence of positive findings is low.

One area where screening is advantageous is patients with newly diagnosed dementia. This is especially true if the clinical course is atypical or accelerated. Both hypothyroidism (myxedema) and hyperthyroidism (apathetic thyrotoxicosis) can present with dementia-like symptoms and, in these patients, timely intervention can completely reverse the signs and symptoms of dementia or depression caused by thyroid dysfunction.

If screening is undertaken, the test of choice is a sTSH. When coupled with FT₄, the vast majority of clinically significant hyperthyroidism and hypothyroidism can be diagnosed. If symptoms are present or there are overt signs of disease, the initial testing should include sTSH, FT₄, and FT₃. Thyroid panels providing T₄, T₃, T₇, FT₄ index, and T₃ uptake are no longer advocated.

KEY TREATMENT

- Thyrotoxicosis is treated initially with β -blockers and antithyroid medication to control symptoms and stop synthesis and release of thyroid hormone into the peripheral circulation (Bahn et al., 2011; Oiknine et al., 2006; Trivalle et al., 1996) (SOR: A).
- Hypothyroid (TSH >10 mIU/L) replacement T₄ dose is approximately 1.6 μ g/kg/day (Oiknine et al., 2006) (SOR: A).

- With the exception of thyroid antibody–positive subclinical hypothyroidism with TSH less than 10 mIU/L, prophylactic treatment has not been shown to have a positive effect on lipids or CAD risk (Bahn et al., 2011; Garber et al., 2012; Helfand, 2004; Ladenson et al., 2000) (SOR: A).
- Treatment of subclinical hyperthyroidism should be considered when TSH is less than 0.1 mIU/L in all patients older than 65 years and in patients younger than 65 years with any of the following comorbidities: heart disease, osteoporosis, menopause, or hyperthyroid symptoms (ATA and AACE, 2011) (SOR: B).

Adrenal Glands

PHYSIOLOGY

The adrenal glands are located at the superomedial aspects of the kidneys. The glands consist of two endocrine tissues of different embryologic origins: the primarily steroid-producing adrenocortical tissue in the cortex and the catecholamine-producing chromaffin cells in the medulla. The adrenal cortex consists of three zones that vary in both their morphologic features and the hormones they produce. The outer, *zona glomerulosa*, is the unique source of the mineralocorticoid aldosterone. The intermediate, *zona fasciculata*, and the inner, *zona reticularis*, produce the glucocorticoids cortisol and corticosterone and the androgens dehydroepiandrosterone (DHEA) and DHEA sulfate (DHEA-S). The chromaffin cells in the adrenal medulla mainly secrete the catecholamines epinephrine and norepinephrine (Table 35-10) (Williams and Dluhy, 2008).

Mineralocorticoids are major regulators of extracellular fluid volume and potassium metabolism. Volume is regulated through a direct effect on the collecting duct of the kidney, where aldosterone causes an increase in sodium retention and in potassium excretion. The release of aldosterone is regulated by the RAS, plasma potassium levels, and ACTH. The RAS maintains the circulating blood volume by regulating aldosterone secretion. Aldosterone-induced sodium retention occurs in volume deficiency states, but aldosterone-dependent sodium retention is reduced when volume is ample. An increase in plasma potassium or a decrease in plasma sodium stimulates aldosterone release. ACTH stimulates mineralocorticoid output, but this effect on aldosterone secretion is transient.

Table 35-10 Adrenal Gland Anatomy and Steroids

Cortex	Zona glomerulosa
	Aldosterone
	Zona fasciculata

	Glucocorticoids
	Cortisol
	Corticosterone
	Dehydroepiandrosterone (DHEA)
	DHEA sulfate (DHEA-S)
	Medulla
Norepinephrine	
Dopamine	

The release of *cortisol*, the main glucocorticoid in humans, is pulsatile and directly stimulated by ACTH or its precursors, such as pro-opiomelanocortin. The release of ACTH from the anterior pituitary is regulated by corticotrophin-releasing hormone (CRH), which is produced by the hypothalamus. High cortisol levels inhibit the biosynthesis and secretion of CRH and ACTH through a negative feedback mechanism. Cortisol release follows a circadian rhythm with its highest level in the morning and is sensitive to light, sleep, stress, and disease. The glucocorticoid effects are multisystemic. They stimulate proteolysis and gluconeogenesis, inhibit muscle protein synthesis, and increase fatty acid mobilization. Gluconeogenesis results in an increase in blood glucose concentrations. At high levels, glucocorticoids are catabolic and result in loss of lean body mass. Glucocorticoids modulate the immune response through their antiinflammatory effects and modulate perception and emotion in the CNS.

The production of the adrenal androgens is controlled by ACTH, not by gonadotropins. Among the adrenal androgens, DHEA is the most abundant circulating hormone in the body and is readily conjugated to its sulfate ester DHEA-S. The adrenal androgens are converted into androstenedione and subsequently into potent androgens (testosterone) or estrogens (estradiol) in the peripheral tissues. Adrenal secretion of DHEA and DHEA-S increases in children around 6 to 8 years of age and peaks between the ages of 20 to 30 years. However, the production of DHEA-S by the adrenal glands is reduced by 70% to 95% during the aging process; by age 70 years, serum DHEA-S levels are approximately 20% of their peak values and continue to decrease with age. Adrenal androgens have minimal effects in men, whose sexual characteristics are predominantly determined by gonadal steroids (testosterone). In women, adrenal-derived testosterone is important in maintaining pubic and axillary hair. Adrenal androgen hypersecretion in men causes no clinical signs but in women manifests with signs of hirsutism and masculinization.

The adrenal medulla secretes epinephrine, norepinephrine, and dopamine. Most catecholamine output in the adrenal vein is epinephrine; norepinephrine also enters the circulation from noradrenergic nerve endings. In emergency situations, the secretion of adrenal catecholamines is increased to prepare the individual for stress ("fight or flight" response). Hypoglycemia and certain drugs are also potent stimuli to catecholamine secretion.

DISORDERS OF CORTICAL HYPOFUNCTION

Primary Adrenal Insufficiency

Key Points

- Primary adrenal insufficiency is defined as the failure of the adrenal cortex to produce glucocorticoids and mineralocorticoids.
- The most frequent cause of primary adrenal insufficiency is autoimmune. In the developing world, however, TB remains the most common cause.
- Symptoms are usually insidious and include fatigue, orthostatic hypotension, weight loss, and hyperpigmentation.

- Acute adrenal insufficiency should be considered in critically ill patients with unexplained hypotension.
- A baseline cortisol and ACTH level followed by an ACTH stimulation test can establish diagnosis.
- Detection of adrenal cortex antibodies or 21-hydroxylase autoantibodies supports the diagnosis of autoimmune adrenalitis. Abdominal CT may be helpful if other causes are suspected.

Primary adrenal insufficiency (AI) is defined as the failure of the adrenal cortex to produce adequate amounts of glucocorticoids and mineralocorticoids (Arlt and Allolio, 2003; Salvatori, 2005). Primary AI can result from processes that damage the adrenal glands or from drugs (e.g., ketoconazole, etomidate) that block the synthesis of cortisol. All causes of primary AI involve the adrenal cortex as a whole and result in a deficiency of cortisol and aldosterone (plus adrenal androgen), although the severity of the deficiencies may vary. An exception is the *syndrome of isolated glucocorticoid deficiency*. The reported prevalence of primary AI (Addison disease) in developed countries is 39 to 60 persons per 1 million population. In adult patients, the mean age at diagnosis is 40 years (range, 17-72 years).

The most frequent cause of primary AI in developed countries is *autoimmune adrenalitis*. However, in the developing world, TB remains the most common cause of adrenal failure. Autoimmune adrenalitis is sometimes accompanied by other autoimmune endocrine deficiencies (autoimmune polyglandular syndromes [APS]). The adult form (type II, Schmidt syndrome) of polyglandular syndrome consists mainly of AI, autoimmune thyroid disease, and insulin-dependent (type 1) diabetes mellitus. Several infectious processes associated with acquired immunodeficiency syndrome (AIDS) such as cytomegalovirus (CMV), *Mycobacterium tuberculosis*, *Cryptococcus neoformans*, *Mycobacterium avium intracellulare*, *Histoplasma capsulatum*, and Kaposi sarcoma may damage the adrenal gland and lead to insufficiency. In young males, adrenoleukodystrophy (or the less severe adrenomyeloneuropathy), an X-linked recessive disorder of metabolism of long-chain fatty acids, can cause spastic paralysis and adrenal insufficiency. AI can precede neurologic symptoms and should prompt the clinician to perform a careful neurologic examination in young males with primary AI. Other causes are listed in Table 35-11.

Chronic (Primary) Adrenal Insufficiency. Most of the symptoms are nonspecific and occur insidiously. Chronic AI manifestations include weakness, chronic fatigue, anorexia, unintentional weight loss, listlessness, joint pain, and orthostatic hypotension. Some patients may initially present with GI symptoms (abdominal pain, nausea, vomiting, diarrhea), but others may present with symptoms that can be attributed to depression or anorexia nervosa. In contrast to secondary AI, primary AI is often associated with lack of aldosterone as well as cortisol. Thus, signs of mineralocorticoid deficiency (salt craving, postural hypotension, electrolyte abnormalities) are usually indicative of primary AI. The most specific sign of primary AI is hyperpigmentation of the skin and mucosal surfaces, which results from the melanocyte-stimulating activity of β -lipotropin that derives from the same precursor as ACTH.

Table 35-11 Causes of Primary Adrenal Insufficiency

Autoimmune	Isolated adrenal insufficiency (Addison disease) Polyglandular autoimmune syndrome types I and II
Infectious	Tuberculosis Fungal Histoplasmosis Paracoccidioidomycosis HIV/AIDS Cytomegalovirus Syphilis African trypanosomiasis
Vascular	Bilateral adrenal hemorrhage Sepsis (Waterhouse-Friderichsen syndrome) Coagulopathy Thrombosis, embolism Infarction
Infiltrative	Metastatic carcinoma (most often lung, breast, stomach, or colon) Lymphoma Sarcoidosis Amyloidosis Hemochromatosis
Congenital	Congenital adrenal hyperplasia 21 α -Hydroxylase deficiency 11 β -Hydroxylase deficiency 3 β -ol-Dehydrogenase deficiency 20,22-Desmolase deficiency Familial adrenocorticotrophic hormone resistance syndromes Familial glucocorticoid deficiency Adrenoleukodystrophy Adrenomyeloneuropathy Adrenal hypoplasia
Iatrogenic	Bilateral adrenalectomy Anticoagulation therapy Drugs Adrenolytic: mitotane, aminoglutethimide, metyrapone, trilostane Other: ketoconazole, rifampin, etomidate, phenytoin, barbiturates, megestrol acetate

Patients with autoimmune adrenalitis present with vitiligo, Hashimoto thyroiditis (70% in APS II), type I diabetes, and pernicious anemia. Thinning or loss of pubic and axillary hair may occur in women as a result of lack of androgen production by the adrenal cortex. Both systolic and diastolic BP are usually reduced (systolic BP <110 mm Hg).

Acute (Primary) Adrenal Insufficiency. In critically ill patients, it is crucial to consider the possibility of adrenal insufficiency. AI should be suspected in the presence of unexplained catecholamine-resistant hypotension, especially if the patient has pallor, hyperpigmentation, vitiligo, scanty axillary and pubic hair, hyponatremia, or hyperkalemia. Furthermore, AI caused by adrenal hemorrhage and adrenal vein thrombosis should be considered in a severely ill patient with abdominal pain or rigidity, vomiting, confusion, and arterial hypotension. In acutely ill patients, a plasma cortisol level greater than 25 μ g/dL rules out adrenal insufficiency, but a level in the normal range does not. Further testing may be required.

Laboratory Evaluation. Patients with adrenal insufficiency present with hyponatremia (frequent), hyperkalemia, acidosis, mild elevation of plasma creatinine

concentrations, hypoglycemia, hypercalcemia (rare), mild normocytic anemia, lymphocytosis, and mild eosinophilia. In addition, hormone levels are useful in diagnosis. A random measurement of serum cortisol level is usually inadequate to assess adrenal function caused by the pulsatile and diurnal variation of cortisol secretion. However, a morning cortisol level (measured between 8 and 9 AM) of 3 μ g/dL or less indicates primary AI and obviates the need for further tests. A level of 19 μ g/dL or greater rules AI out. Patients with levels between 3 and 19 μ g/dL need further testing. If primary AI is suspected, basal ACTH and cortisol levels should be measured followed by a short ACTH stimulation test. For testing, synthetic ACTH (cosyntropin) is given intravenously or intramuscularly at 250 μ g, and the serum cortisol level is measured 60 minutes after injection. A normal response to this test (cortisol \geq 20 μ g/dL) excludes primary AI. In patients with severe secondary AI, plasma cortisol increases little or not at all after the administration of cosyntropin because of adrenocortical atrophy.

Detection of adrenal cortex antibodies or 21-hydroxylase autoantibodies supports the diagnosis of autoimmune adrenalitis. Antibodies against other endocrine glands are common in patients with autoimmune AI, and evaluation might be warranted. However, the incidence of antiadrenal antibodies in serum from patients with normal adrenal function who have other autoimmune endocrine diseases is low (2%), with the exception of those with hypoparathyroidism (16%). Abdominal CT scan may be helpful if infection, hemorrhage, infiltration, or neoplastic disease is suspected.

Treatment. In chronic AI, any underlying cause, such as infection or malignancy, should be treated. Glucocorticoid replacement is usually required for symptomatic patients and is given in two or three daily doses with half to two thirds of the daily dose given in the morning to mimic the physiologic daily pattern of cortisol secretion. Hydrocortisone (15–25 mg) or cortisone acetate (25–37.5 mg) is preferred because of its mineralocorticoid action and shorter biological half-life, which prevents unfavorably high nighttime glucocorticoid activity. The goal is to use the smallest dose that relieves the patient's symptoms to prevent side effects from steroid use, such as weight gain and osteoporosis. Because a reliable marker of glucocorticoid action is lacking, clinical judgment and careful assessment of clinical signs and symptoms guide treatment.

In patients with primary AI, mineralocorticoid replacement is necessary and is attained by fludrocortisone, in a single daily dose of 0.05 to 0.2 mg, as a substitute for aldosterone. The dose can be adjusted based on measurements of BP, serum sodium and potassium, and renin activity (aiming at concentrations within the middle or upper normal range). All patients should carry a card or wear a bracelet or necklace with information on current treatment and recommendations in emergency situations. Patients should be advised to double or triple the dose of hydrocortisone temporarily when they have a febrile illness or injury. In addition, they should be given ampoules of glucocorticoid for self-injection or glucocorticoid suppositories to be used in case of vomiting.

Patients with ACTH deficiency should be treated with glucocorticoids, preferably hydrocortisone (i.e., the

glucocorticoid that the adrenals produce). Hydrocortisone replacement, usually 10 to 12 mg/m², should be given orally as 20 to 30 mg/day divided into two doses with two thirds of the daily dose given in the morning and one third given in the early afternoon or evening (Coursin and Wood, 2002; Toogood and Stewart, 2008). Alternatively, prednisone is given at a total daily dosage of 5 to 7.5 mg/day in one to two doses. Clinical evaluation is the primary modality to assess the adequacy of cortisol replacement. It is important to increase the dose of hydrocortisone two- to threefold in time of illness and other stresses. All patients should carry medical alert tags or cards to identify the need for high-dose glucocorticoids in an emergency. Those with secondary adrenal insufficiency usually do not require mineralocorticoid replacement because ACTH is not essential for aldosterone secretion.

Secondary and Tertiary Adrenal Insufficiency

Key Points

- Secondary adrenal insufficiency results from ACTH deficiency and is often seen in panhypopituitarism or after chronic glucocorticoid excess.
- Lack of production of CRH from the hypothalamus results in tertiary adrenal insufficiency.
- In secondary adrenal insufficiency, mineralocorticoid production is maintained by the RAS. Thus, hyperkalemia is absent, but hyponatremia may occur as a result of loss of glucocorticoid effect on free-water clearance.
- Low ACTH and cortisol levels suggest secondary or tertiary adrenal insufficiency.

Secondary adrenal insufficiency is defined as a deficiency of ACTH. Isolated ACTH deficiency is rare and may be congenital or caused by lymphocytic hypophysitis. Secondary AI more commonly occurs in the setting of panhypopituitarism from underlying causes such as pituitary or metastatic tumors, craniopharyngioma, infections (TB, histoplasmosis), infiltrative disease (sarcoidosis), head trauma, or postpartum pituitary necrosis (Sheehan syndrome). Chronic glucocorticoid excess, either exogenous (glucocorticoid treatment for >4 weeks) or endogenous (Cushing syndrome), causes secondary AI by prolonged suppression of the production of CRH. Tertiary adrenal insufficiency results from the lack of CRH production from the hypothalamus.

Clinical Presentation. Signs and symptoms are similar with those of primary AI, but electrolyte and fluid abnormalities or hypotensive symptoms are absent because the mineralocorticoid production is still maintained by the RAS. Hyperpigmentation is not seen. Menstrual dysfunction, headache and visual symptoms, hypothyroidism, and DI may be present as a result of panhypopituitarism (see Approach to Pituitary Diseases).

Laboratory Evaluation. Plasma cortisol and ACTH levels should be checked initially. Low ACTH (<5 pg/mL) and cortisol levels suggest secondary or tertiary adrenal insufficiency, and pituitary CT or MRI is indicated. The

cosyntropin stimulation test may be helpful in identifying adrenal insufficiency. With an abnormal result, ACTH level may determine primary (high ACTH) versus secondary (normal or low ACTH) disease. However, in secondary AI, the ACTH stimulation test might not be abnormal because sufficient ACTH might be present to prevent adrenal gland atrophy. In these patients, CRH stimulation test can assess ACTH response. Secondary AI shows little or no increase in the ACTH or cortisol level throughout the test but in tertiary AI, the ACTH increases in an exaggerated fashion and remains elevated longer. The insulin tolerance test and the metyrapone test are also available but less commonly used to assess the integrity of the HPA axis by its response to hypoglycemia or inhibited cortisol synthesis, respectively.

Treatment. As described in primary AI, treatment of underlying disorders and glucocorticoid replacement are necessary in secondary and tertiary AI; however, mineralocorticoid replacement is not.

Isolated Aldosterone Deficiency

See eAppendix 35-3 online.

DISORDERS OF CORTICAL HYPERFUNCTION: HYPERCORTISOLISM

Cushing Syndrome

Key Points

- Cushing syndrome results from chronic exposure to excessive levels of glucocorticoids.
- Cushing syndrome may be ACTH dependent (pituitary or ectopic tumors) or ACTH independent (adrenal or exogenous glucocorticoids).
- Reddish purple striae, plethora, proximal muscle weakness, easy bruising, and unexplained osteoporosis are discriminatory symptoms.
- CT or MRI of the adrenal glands may differentiate among the various types of ACTH-independent Cushing syndrome.

Cushing syndrome is a group of signs and symptoms that result from prolonged and inappropriately high exposure of tissue to glucocorticoids (Nieman et al., 2008). Excess cortisol production is the hallmark of endogenous Cushing syndrome and may result from excess ACTH secretion from the pituitary (Cushing disease) or from ectopic tumors secreting ACTH or CRH. ACTH-independent adrenal production of cortisol is caused by adrenocortical tumors or hyperplasias. However, the most common cause of Cushing syndrome is *iatrogenic* from exogenous glucocorticoid administration. Certain psychiatric disorders (anxiety, depression), poorly controlled diabetes, and alcoholism can be associated with mild hypercortisolism and may produce results suggestive of Cushing syndrome.

Clinical Presentation. Although Cushing syndrome might be easy to diagnose when full blown, the diagnosis can be challenging in mild cases. The spectrum of clinical presentation is broad. Some discriminatory symptoms

35-3 *Isolated Aldosterone Deficiency*

Key Points

- Isolated aldosterone deficiency may be congenital or acquired.
- In hyporeninemic hypoaldosteronism, chronic asymptomatic hyperkalemia, normal or low sodium level, and mild to moderate renal insufficiency are usually present.
- Aldosterone secretion does not increase appropriately in response to salt restriction in all forms of hypoaldosteronism.

Background

Aldosterone deficiency disorders may be congenital or acquired. The congenital disorders may be caused by ineffective aldosterone synthesis or pseudohypoaldosteronism (ineffective aldosterone action). However, aldosterone deficiency is most commonly a secondary cause or due to impaired renin release from the kidney (hyporeninemic hypoaldosteronism).

Clinical Presentation

The typical patient with acquired aldosterone deficiency is 50 to 70 years old and usually presents with chronic asymptomatic hyperkalemia with a normal or low sodium level and mild to moderate renal insufficiency. Half of patients

present with hyperchloremic metabolic acidosis caused by renal tubular acidosis type IV, and more than half have diabetes.

Diagnostic Studies

In most cases of isolated hypoaldosteronism, a deficiency in renin production is noted in adults with diabetes mellitus and mild renal failure and in whom hyperkalemia and metabolic acidosis are out of proportion to the degree of renal impairment. The feature common to all forms of hypoaldosteronism is the inability to increase aldosterone secretion appropriately in response to salt restriction. Most patients have unexplained hyperkalemia, which is often exacerbated by restriction of dietary sodium intake. Plasma renin levels fail to increase normally after sodium restriction and postural changes.

Treatment

The treatment is to replace the mineralocorticoid deficiency. Administration of fludrocortisone (0.05-0.15 mg/day orally) should restore the electrolyte imbalance if the salt intake is adequate (e.g., 150-200 mmol/day). Higher doses of mineralocorticoid may be required in patients with hyporeninemic hypoaldosteronism to correct hyperkalemia, which might be problematic in patients with hypertension or congestive heart failure. An alternative approach is to reduce salt intake and administer furosemide, which can ameliorate acidosis and hyperkalemia.

include reddish purple striae, plethora, proximal muscle weakness, bruising without any obvious trauma, and unexplained osteoporosis. More often, patients present with features caused by cortisol excess such as obesity, depression, diabetes, hypertension, or menstrual irregularity. A dorso-cervical fat pad (buffalo hump), facial and supraclavicular fullness, thin skin, peripheral edema, hirsutism or female balding, and poor skin healing are typically seen in Cushing syndrome. Children usually have slow growth, abnormal genital virilization, short stature, and pseudoprecocious or delayed puberty.

Laboratory Evaluation. Before the diagnosis of Cushing syndrome is considered, exogenous intake of glucocorticoids should be excluded. According to the 2008 Endocrine Society Clinical Practice Guidelines (Nieman et al., 2008), tests to be considered for diagnosis include urine free cortisol (UFC); a late-night salivary cortisol, 1-mg overnight DST; or the longer, low-dose DST (2mg/d for 48 h). UFC and salivary cortisol should be obtained at least twice. The diagnosis of Cushing syndrome is made if two test results are unequivocally abnormal. The diagnostic accuracy of other tests previously used, such as random cortisol levels, is too low to recommend them for testing (Figure 35-3).

The UFC provides an integrated assessment of cortisol secretion over 24 hours and measures the cortisol not bound to cortisol-binding globulin (CBG). Unlike serum cortisol, which measures both free and CBG-bound cortisol, UFC is not affected by conditions and medications that alter CBG. A 24-hour urine cortisol secretion or an overnight urine sample (10 PM to 8 AM) can be ordered in conjunction with urine creatinine to assure accuracy of the results. UFC reflects renal filtration, and values are significantly lower in patients with moderate to severe renal impairment. A patient can be assumed to have Cushing syndrome if basal urinary cortisol secretion is more than three times the upper limit of normal and one other test is abnormal. However, UFC may be normal in mild cases of Cushing syndrome, in which case salivary cortisol may be more useful.

Late-night salivary cortisol is usually measured at bedtime or between 11 PM and midnight because the loss of circadian rhythm, with absence of a late-night cortisol nadir, is a consistent biochemical abnormality in those with Cushing syndrome. The active free cortisol in the blood is in equilibrium with cortisol in the saliva, and the concentration of salivary cortisol does not appear to be affected by the rate of saliva production. Overall, in adults, the accuracy of the test is similar to that of UFC.

Various protocols have been used for the DST, but most commonly 1 mg of dexamethasone is given between 11 PM and midnight, and cortisol is measured between 8 AM and 9 AM the following morning. In patients with endogenous Cushing syndrome, a low dose of dexamethasone fails to suppress ACTH and cortisol secretion. A normal response is a serum cortisol of 5 µg/dL or less. To enhance DST sensitivity, experts have advocated requiring a lower cutoff for suppression of the serum cortisol to 1.8 µg/dL or less to achieve sensitivity rates greater than 95%.

Some endocrinologists prefer to use the 48-hour 2-mg/day, low-dose DST (LDDST) as an initial test because of its improved specificity compared with the 1-mg test. The LDDST may be helpful in conditions with overactivation of

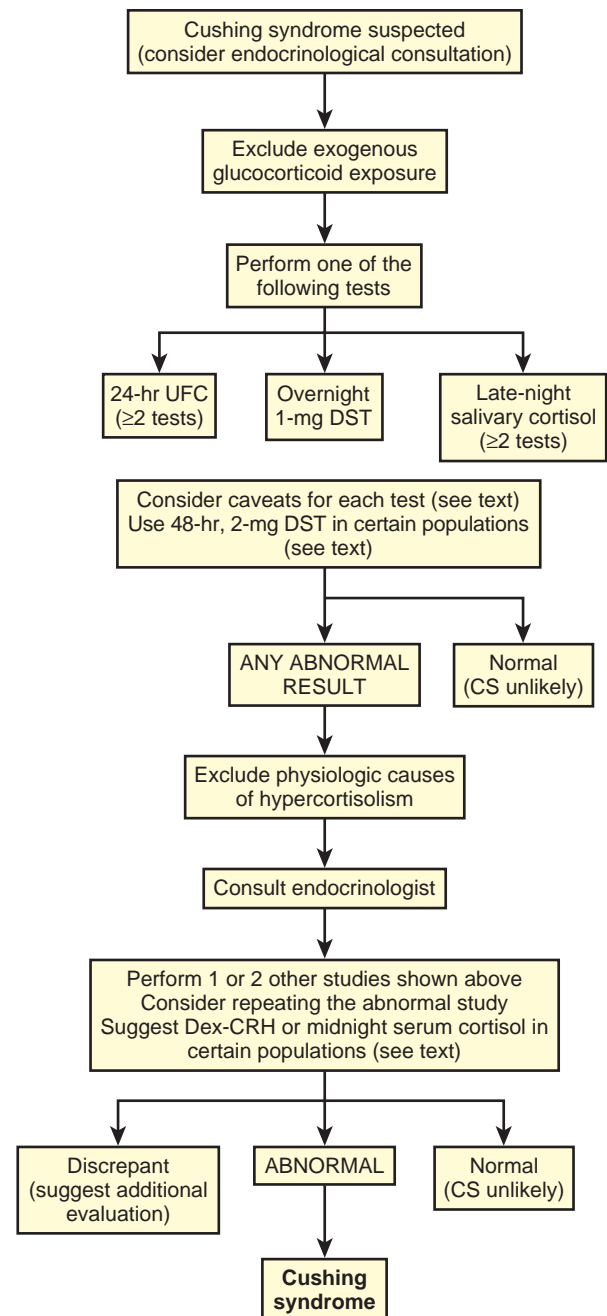

Figure 35-3 Clinical approach to a patient with suspected Cushing syndrome. CS, Cushing syndrome; Dex-CRH, dexamethasone/corticotropin-releasing hormone test; DST, dexamethasone suppression test; UFC, urine free cortisol. (Courtesy The Endocrine Society.)

the HPA axis but without true Cushing syndrome, such as in certain psychiatric disorders, obesity, and alcoholism. Dexamethasone is given in doses of 0.5 mg every 6 hours for 48 hours, beginning at 9 AM on day 1. Serum cortisol is measured at 9 AM on the second day 6 hours after the last dose of dexamethasone (Funder et al., 2008).

New studies have shown a link between baseline levels of ACTH and major depressive disorder. One study published in the *Journal of Affective Disorders* in 2013 using a combined dexamethasone suppression–CRH stimulation test

found higher baseline levels of ACTH in patients with major depressive disorder compared with control participants (Sher et al., 2013). These results implied decreased feedback control of ACTH by circulating cortisol levels. The correlation between these findings is not known but may represent a new area for diagnosing and treating major depression. Additional testing is recommended for patients with initial abnormal or discordant results, such as the dexamethasone–CRH stimulation test or the midnight serum cortisol test. The dexamethasone–CRH stimulation test has been developed to improve the sensitivity of the LDDST. The administration of dexamethasone at a dose of 2 mg/day over 48 hours is followed by administration of CRH (1 µg/kg IV) 2 hours after the last dose of dexamethasone. Cortisol is measured 15 minutes later. ACTH and cortisol should increase after administration of CRH in patients with Cushing disease.

After hypersecretion of cortisol is confirmed, the next step is to determine whether the Cushing syndrome is ACTH dependent or independent. This is accomplished through measurement of the late-afternoon ACTH level when it is normally low. Cushing syndrome is ACTH *dependent* if plasma ACTH is greater than 10 pg/mL and ACTH *independent* if ACTH level is less than 5 pg/mL. For an intermediate ACTH level, further testing with the CRH stimulation test is performed. A rise in cortisol by 20% or in ACTH of at least 50% over baseline after administration of CRH is considered evidence for an ACTH-dependent lesion. In these patients, high-dose dexamethasone suppression test (HDDST), combined with cranial MRI studies, may help in localizing the site of ACTH overproduction. HDDST (2 mg of dexamethasone every 6 hours for 2 days) provides close to 100% specificity if the criterion used is suppression of urinary free cortisol by more than 90% and can differentiate Cushing disease from ectopic ACTH production. If the workup results are still equivocal or suggestive of ectopic ACTH production, inferior petrosal sampling is performed, obtaining ACTH samples from the periphery and petrosal sinuses simultaneously. A ratio of petrosal sinus to peripheral ACTH of 2 to 1 is diagnostic of a pituitary source and can be further used to localize the side of ACTH production from the pituitary gland. For patients with ACTH-independent lesions, abdominal CT or MRI may localize the site of the lesion.

Treatment. The treatment of Cushing syndrome depends on the cause. For endogenous disease, surgical resection of the causative tumor is indicated. The treatment of choice for Cushing disease is transsphenoidal hypophysectomy. Other treatment modalities include various forms of radiation therapy and pharmacologic inhibition of ACTH secretion.

Patients with adrenal adenomas are treated with unilateral adrenalectomy and have an excellent prognosis. These patients require glucocorticoid therapy both during and after surgery until the residual adrenal gland recovers. For patients with biopsy-proven adrenal carcinoma that is not amenable to surgery, mitotane is the treatment of choice. For ectopic ACTH syndrome, ideal treatment is the excision of identified benign tumors. However, for ectopic tumors that are unidentified or unresectable, medications that block steroidogenesis, such as ketoconazole, metyrapone, or aminoglutethimide, may be useful.

Aldosteronism

Key Points

- In primary aldosteronism (PA), secretion of aldosterone is inappropriately high and, when it is the result of an adrenal adenoma, it is relatively autonomous from renin–angiotensin secretion.
- Secondary aldosteronism is generally related to hypertension, and the aldosterone secretion is driven by high plasma renin.
- Patients present with hypokalemia and hypertension that may be resistant to treatment (Conn syndrome).
- The ratio of plasma aldosterone to renin is the most reliable test for screening for PA.
- A ratio of plasma aldosterone to renin of 20 or greater and a plasma aldosterone higher than 15 ng/dL support the diagnosis of primary hyperaldosteronism.

Background. Primary aldosteronism was first described by Jerome Conn in 1955 as a syndrome (Conn syndrome) characterized by hypertension and hypokalemia caused by an adrenal aldosterone-producing adenoma (APA). The secretion of aldosterone from the adrenal *zona glomerulosa* is regulated mainly by the RAS and by potassium anions. PA is now recognized to be the most common form of secondary hypertension. In PA, the secretion of aldosterone is inappropriately high, relatively autonomous from the RAS, and nonsuppressible by volume expansion or sodium loading. In secondary aldosteronism associated with hypertension, the aldosterone secretion is driven by high plasma renin and is suppressed by volume expansion.

Primary aldosteronism is commonly caused by an APA (35% of cases); unilateral or bilateral idiopathic adrenal hyperplasia (IHA) (2% and 60% of cases, respectively); an adrenal carcinoma (rare); or in rare cases, familial hyperaldosteronism (FH), either type I (glucocorticoid-remediable aldosteronism [GRA]) or type II (familial occurrence of APA, IHA, or both). There are two types of aldosteronomas: a corticotrophin-responsive (and renin-unresponsive) type and a renin-responsive type. PA had been previously described in fewer than 1% of patients with hypertension. However, recent studies estimate the prevalence of PA is 5% to 13% among hypertensive patients.

Clinical Presentation. Few symptoms are specific to the syndrome. Patients present with moderate to severe hypertension that may be resistant to usual pharmacologic treatments. Hypokalemia is usually present, and the serum sodium concentration tends to be high-normal or slightly above the upper limit of normal. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, or nocturia (Funder et al., 2008). However, hypokalemia might be absent; thus, any patient with hypertension could be a candidate for this disorder. Patients with PA may be at higher risk than other patients with hypertension for target organ damage of the heart and kidney. A significantly higher rate of cardiovascular events (i.e., stroke, atrial fibrillation, and myocardial infarction [MI]) has been noted in patients with APA or IHA compared with patients matched for age, gender, and hypertension. Patients with APA have more severe hypertension, more frequent hypokalemia, and

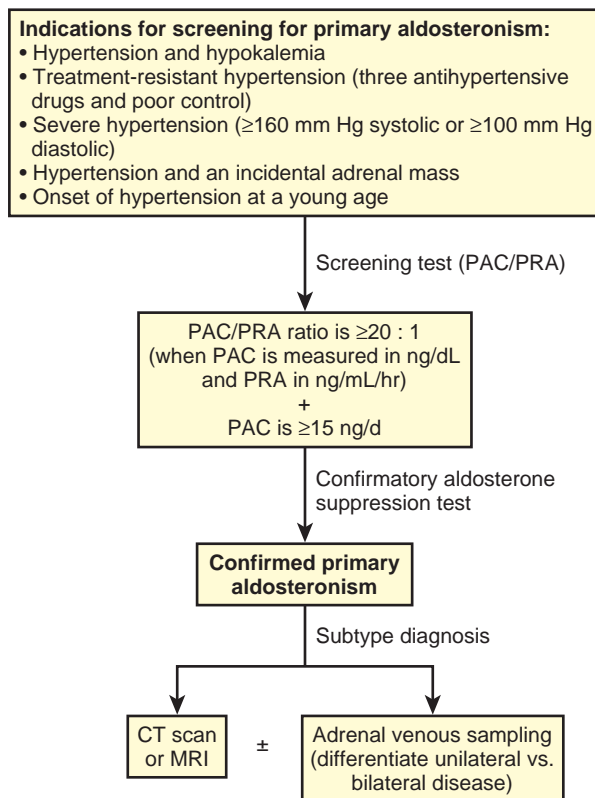

Figure 35-4 Indications for screening for primary aldosteronism and flow chart for clinical assessment. *CT*, computed tomography; *MRI*, magnetic resonance imaging; *PAC*, plasma aldosterone concentration; *PRA*, plasma renin activity.

higher plasma and urinary levels of aldosterone and are younger (<50 years) than those with IHA.

Hypokalemia, when present, strongly suggests associated mineralocorticoid excess. However, most patients with PA have baseline blood levels of potassium in the normal range. Therefore, hypokalemia should not be the criterion used to make the diagnosis of PA. Screening for PA should be considered in patients with hypertension and hypokalemia, treatment-resistant hypertension (three antihypertensive drugs and poor control), severe hypertension (≥ 160 mm Hg systolic or ≥ 100 mm Hg diastolic), hypertension and an incidental adrenal mass, and onset of hypertension at a young age (Figure 35-4). When an evaluation for secondary hypertension is performed, the diagnosis of PA should also be considered. In patients with suspected PA, the screening can be accomplished by measuring a morning ambulatory paired random plasma aldosterone concentration (PAC) and plasma renin activity or concentration (PRA or PRC). This test can be performed while the patient is taking antihypertensive medications (except for spironolactone, eplerenone, and high-dose amiloride) and without posture stimulation. The aldosterone-to-renin ratio (ARR) is currently the most reliable available means of screening for PA. A test result is considered positive when the PAC/PRA ratio is 20:1 or greater (when PAC is measured in nanograms per deciliter and PRA in nanograms per deciliter per hour) and the PAC is higher than 15 ng/dL. All positive results should be followed by a confirmatory aldosterone suppression test to verify autonomous aldosterone production before treatment is initiated.

If the diagnosis of PA is confirmed, lateralization of the source of the excessive aldosterone secretion is critical to guide further management. All patients with PA should undergo an adrenal CT scan as the initial study in subtype testing and to exclude large masses that may represent adrenocortical carcinoma. MRI has no advantage over CT in subtype evaluation of PA. In patients with PA, adrenal venous sampling is the reference standard test to differentiate unilateral from bilateral disease. This is important because unilateral adrenalectomy in patients with APA or primary adrenal hyperplasia results in normalization of hypokalemia and improvement of hypertension in all patients and cure of hypertension in 30% to 60%. Glucocorticoid-remediable aldosteronism is an autosomal dominant disease and may be diagnosed by genetic testing.

Treatment. The treatment approach depends on the cause of PA. Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or unilateral hyperplasia. BP control improves in almost 100% of these patients postoperatively, and the average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 72%. A potassium supplement or a mineralocorticoid receptor antagonist (or both) should be given preoperatively to correct the hypokalemia but should be discontinued postoperatively.

Medical management is recommended for patients with APA who do not undergo surgery and for those with IHA or GRA. Spironolactone has been the drug of choice for PA and is titrated to achieve BP control and normokalemia without the aid of oral potassium supplement. Eplerenone is a competitive and selective aldosterone receptor antagonist and may be used as an alternative agent. Compared with spironolactone, eplerenone has less antiandrogenic and progestational actions but is more expensive. In patients who are intolerant to aldosterone receptor antagonists, amiloride may be an alternative treatment that can reduce BP and normalize potassium levels, but it does not protect against the negative effects of aldosterone excess. Patients with IHA may be resistant to drug therapy caused by hypervolemia and may require a second antihypertensive agent such as a thiazide diuretic in combination with the aldosterone receptor antagonist.

DISORDERS OF HYPERFUNCTION: ADRENAL MEDULLA

Pheochromocytoma

Key Points

- Pheochromocytomas are catecholamine-secreting neuroendocrine tumors that originate in the adrenal medulla (80% to 85% of cases) or in any sympathetic ganglion (paragangliomas).
- Hypertension, tachycardia, pallor, palpitations, diaphoresis, and anxiety are common.
- Paroxysmal hypertension often occurs, even in normotensive persons, and may be severe and result in hypertensive emergencies.
- Plasma and urine catecholamines and metanephrines are measured to diagnose pheochromocytoma.
- CT, MRI, and iodine-123-meta-iodo-benzyl-guanidine (^{123}I -MIBG) may be helpful for tumor localization.

Pheochromocytomas are catecholamine-secreting neuroendocrine tumors arising from chromaffin cells of neural crest origin (Lenders et al., 2005). About 80% to 85% of pheochromocytomas originate in the adrenal medulla, and 15% to 20% are extraadrenal (paragangliomas). Pheochromocytomas are rare tumors with an incidence of one to two per 100,000 adults per year. Sporadic forms of pheochromocytoma are usually diagnosed in individuals age 40 to 50 years, but hereditary forms are diagnosed earlier, most often before age 40 years. The traditional “rule of 10” for pheochromocytomas (10% bilateral, 10% extraadrenal, 10% familial, 10% malignant) is now challenged by advances in diagnosis and genetics. Hereditary pheochromocytomas occur in MEN II, von Hippel-Lindau syndrome, neurofibromatosis type 1, and familial paragangliomas. Pheochromocytoma is rare in children but, when found, is often extraadrenal, multifocal, and associated with hereditary syndromes.

Clinical Presentation. Paroxysmal signs and symptoms due to the episodic secretion of catecholamines provide clues to the diagnosis of pheochromocytoma. The presentation can vary greatly, and therefore the pheochromocytoma is often referred to as the “great mimic.” Anesthesia and tumor manipulation are the most well-known stimuli to elicit a catecholaminergic crisis. Hypertension, tachycardia, pallor, palpitations, diaphoresis, headache, and feelings of panic or anxiety are common. The hypertension is often paroxysmal and may occur in patients with hypertension or in normotensive persons. The hypertensive episodes can be severe, resulting in hypertensive emergencies. Persons with paragangliomas may have normal BP or hypotension. Orthostatic hypotension (a result of hypovolemia), fever, nausea, flushing, leukocytosis, and polycythemia are less common findings. Metabolic abnormalities may be present and include hyperglycemia, lactic acidosis, and weight loss.

Laboratory Evaluation. All patients with suspected pheochromocytoma should undergo biochemical testing. Traditional tests include measurements of urinary and plasma catecholamines, urinary metanephrines (normetanephrine and metanephrine), and urinary vanillylmandelic acid. Measurement of plasma-fractionated metanephrines (normetanephrine and metanephrine) is a newer test. Plasma and urine metanephrine measurements are the most sensitive tests for diagnosis but do not always indicate a pheochromocytoma. Many physiological stimuli (i.e., stress), drugs (e.g., phenoxybenzamine, tricyclic antidepressants), and clinical conditions (i.e., hyperthyroidism, heart failure, stroke) may cause an increase in circulating catecholamines and metabolites and lead to false-positive test results. The use of clonidine or glucagon to suppress catecholamine release from the sympathoadrenal system provides a dynamic pharmacologic test to distinguish increased catecholamine release caused by sympathetic activation from increased release caused by a pheochromocytoma.

If there is biochemical evidence for pheochromocytoma, tumor localization by CT scan of the entire abdomen (and pelvis), with and without contrast, should be performed. MRI with gadolinium has similar diagnostic sensitivity (90%-100%) and specificity (70%-80%) and is usually

the preferred modality, especially for extraadrenal lesions. ¹²³I-MIBG isotope scanning has increased specificity (95%-100%) over CT and MRI and is more appropriate for patients with extraadrenal, metastatic, multifocal, or recurrent disease.

Treatment. Preoperatively, phenoxybenzamine, prazosin, doxazosin, or urapidil can be used for the blockade of the α -adrenoceptors. Phenoxybenzamine is often preferred because it blocks α -adrenoceptors noncompetitively. Alternative drugs for preoperative management are labetalol or calcium channel blockers, either alone or in combination with α -adrenergic receptor blockers. Treatment must be initiated 10 to 14 days before surgery and is titrated until mild orthostasis (systolic BP should not fall below 90 mm Hg in standing position) is present. Blockade of β -adrenoceptors should never be initiated before blockade of α -adrenoceptors. Laparoscopic removal of intra- and extraadrenal pheochromocytomas is the preferred surgical approach. All patients should be followed up every year for at least 10 years after surgery. BP and catecholamines should be monitored indefinitely in patients with extraadrenal or familial pheochromocytoma to detect possible recurrence. For malignant disease, radical surgical removal is recommended, but the 5-year survival rate remains poor (~50%). Treatment with ¹³¹I-MIBG, cytotoxic chemotherapy, and molecularly targeted therapies have shown disappointing results.

MIXED DISORDER: CONGENITAL ADRENAL HYPERPLASIA

See eAppendix 35-4 online.

KEY TREATMENT

- In primary adrenal insufficiency, long-term glucocorticoid and mineralocorticoid replacement is necessary. The baseline steroid dose should be increased two- to threefold during periods of febrile illness or injury (Arlt and Allolio, 2003; Salvatori, 2005) (SOR: A).
- Therapeutic intervention for secondary and tertiary adrenal insufficiency requires treatment of underlying disorders. Glucocorticoid replacement is necessary (Arlt and Allolio, 2003) (SOR: A).
- Oral fludrocortisone (0.05-0.15 mg/day) is the treatment of choice for aldosterone deficiency. In hyporeninemic hypoaldosteronism, furosemide with reduced salt intake can ameliorate acidosis and hyperkalemia (Arlt and Allolio, 2003) (SOR: A).
- Surgical resection is usually the treatment of choice for Cushing disease and ACTH-independent Cushing syndrome (Nieman et al., 2008) (SOR: A).
- Treatment of aldosteronism is directed at the underlying cause. Aldosterone antagonists such as spironolactone are effective therapy (Funder et al., 2008) (SOR: A).
- Laparoscopic removal of intra- and extraadrenal pheochromocytomas after α -adrenoceptor blockade is the preferred treatment (Lenders et al., 2005) (SOR: A).
- Treatment of congenital adrenal hyperplasia with glucocorticoids may result in amelioration of symptoms (New, 2004, 2010) (SOR: A).

35-4 *Mixed Disorder: Congenital Adrenal Hyperplasia*

Key Points

- Congenital adrenal hyperplasia is a family of inherited disorders of adrenal steroidogenesis.
- Whereas female patients may present with symptoms of androgen excess, male patients may be asymptomatic or present with diminished fertility or oligozoospermia.
- Patients can be identified early with hormonal and molecular genetic testing.

Congenital adrenal hyperplasia (CAH) is a family of inherited disorders of adrenal steroidogenesis. These defects result in the absence of or the decreased synthesis of cortisol, which causes oversecretion of adrenocorticotropic hormone via feedback regulation that leads to overstimulation and hyperplasia of the adrenals. The clinical symptoms vary from mild to severe and depend on the particular hormones that are deficient or produced in excess. In the classical form of CAH, there is a severe enzymatic defect owing

to mutations in the CYP21 gene. The affected female may present with genital ambiguity at birth because of virilization of the genitalia prenatally (New, 2004). The late-onset form of CAH does not present with prenatal virilization and is less severe. The milder enzyme deficiency, called non-classical 21-hydroxylase deficiency (NC21OHD), is most frequent in Ashkenazi Jews and is the most common autosomal recessive disorder in humans. Similar to classical CAH, NC21OHD may cause premature development of pubic hair, advanced bone age, accelerated linear growth velocity, and diminished final height in both men and women. Women may present with symptoms of androgen excess, including hirsutism, temporal baldness, and infertility. In women, secondary amenorrhea is a frequent occurrence, and menarche may be normal or delayed. Male patients may be asymptomatic or present with diminished fertility or oligozoospermia, early beard growth, acne, and growth spurt. Patients can be identified early with hormonal and molecular genetic testing and be treated with glucocorticoids, which results in reversal of symptoms within 3 months (New, 2010).

Ovarian and Testicular Disorders

Sexual development in both males and females is driven by the HPA. The normal process is the result of pulsatile release of GnRH from the hypothalamus, which stimulates the pituitary to release FSH and LH (GHRH and GH also play a role). Release of FSH and LH activates the ovaries and testes to produce estrogen and testosterone and is responsible for stimulation of gametogenesis. This process is assisted by conversion of adrenal androgens from the adrenal cortex into androstenedione and subsequently into potent androgens (testosterone) or estrogens (estradiol) in the peripheral tissues (see [Adrenal Glands](#) section). Errors can occur along this complex pathway, resulting in early sexual development (precocity), delayed sexual development (delayed menarche), errors of translation (male feminization syndrome), early loss of reproductive function (premature menopause), and inappropriate response to stimuli (polycystic ovary syndrome [PCOS])

NORMAL SEXUAL DEVELOPMENT

Sexual differentiation in humans is controlled by genetics (presence of Y chromosome determines development of testis and absence determines the development of ovary with additional X chromosome), environment (e.g., nutrition), and hormones ([MacLaughlin and Donahoe, 2004](#)). Congenital conditions associated with aberrations of chromosomal, gonadal, or anatomic sex development are called “disorders of sex development” ([Houk et al., 2006](#)).

In the postgonadal phase, hormones control external genitalia differentiation and secondary sexual development. Puberty refers to a physiological transition phase (>4 years long) between childhood and adulthood during which there is pubertal growth spurt and development of secondary sexual characteristics. Puberty is preceded by adrenarche (6-7 years in girls and 7-8 years in boys), marked by increasing amounts of adrenal androgens (DHEA, DHEA-S, and androstenedione). The growth spurt (a striking increase in growth velocity during puberty) is a complex hormonal phenomenon in which GH, thyroid hormones, and sex steroids play major roles. Gonadarche (the secretion of gonadal sex steroids) follows adrenarche and is initiated by activation of the GnRH pulse generator in the hypothalamus. These GnRH pulses result in increased gonadotropin secretion and subsequent production of sex hormones by the gonads.

Sexual maturation in females starts with breast development (thelarche) at a mean age of 11 years followed by pubic hair development and menses (menarche). In males, it starts with scrotal corrugation and testicular enlargement at a mean age of 11.5 years followed by growth of the penis and pubic hair.

In males, release of LH stimulates testicular Leydig cells to produce testosterone. FSH, in conjunction with testosterone, stimulates spermatogenesis. In females, FSH stimulates development of primary ovarian follicles and increases production of estrogen from ovarian granulosa cells. LH in females stimulates ovarian theca cells to produce androgens and the corpus luteum to synthesize progesterone. LH induces ovulation through the midcycle surge.

Estradiol production in males increases the bone age, BMD, and the rate of epiphyseal fusion. In females, it stimulates the development of the breasts, labia, vagina, and uterus and proliferation of endometrium. In addition, estradiol enhances development of and increase in the ducts of the breast and body fat. Whereas estrogen in low levels enhances linear growth, high levels increase the rate of fusion of epiphyses. Testosterone is responsible for the increase in muscle mass, sebaceous glands, and voice changes seen in pubertal males, and it is a linear growth accelerator. In females, testosterone accelerates linear growth and stimulates pubic and axillary hair development. Progesterone in females is responsible for development of a secretory endometrium and plays a role in breast development. Lineal growth and pubic hair development in both males and females is caused by androgens from the adrenal gland.

[Figures 35-5](#) and [35-6](#) show normal pubertal developmental stages of Marshall and Tanner.

ABNORMAL PUBERTY

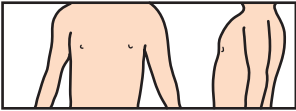

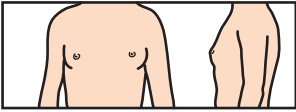

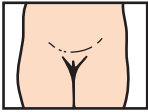

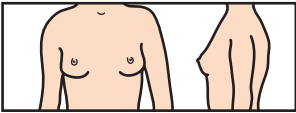

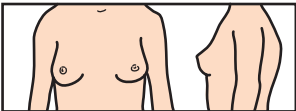

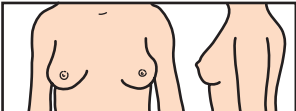

Key Points

- Evaluation should begin if signs of puberty develop in girls younger than 8 years or in boys younger than 9 years.
- Diagnoses of true puberty and pseudopuberty should be differentiated.
- Evaluation includes a comprehensive history and physical examination, growth chart, and wrist radiograph.
- If true puberty is suspected, consider cranial CT or MRI to rule out CNS lesions.

Evaluation of suspected abnormal puberty begins with obtaining a detailed history, including growth and development (timing of physical and developmental milestones), medical conditions, dietary history, social history, ethnicity, and family history. Physical examination should be thorough, including current weight, and a complete examination, with focused examination for development of secondary sexual characteristics and genitalia. A detailed growth chart from birth to the present day should be obtained. A radiograph of the left wrist is needed to estimate bone age ([Blondell et al., 1999](#)).

Precocious Puberty

Precocious puberty (premature onset of puberty) may be defined as the appearance of secondary sexual maturation at an early age. The age of onset of puberty before the age of 8 years in girls and before the age of 9 years in boys is considered precocious puberty. The Lawson Wilkins Pediatric Endocrine Society guidelines recommend that breast development or pubic hair in white girls before age 7 years and in black girls before age 6 years should be evaluated for precocious puberty. Boys of all races should be evaluated for precocious puberty with signs of secondary sexual development at 9 years of age or younger ([Kaplowitz and Oberfield, 1999](#)). These guidelines are under some debate as setting perhaps too early an age for defining

Tanner stage	Breasts*	Standard	Pubic hair*	Standard	Growth	Other
1	Prepubertal, elevation of papilla only		Prepubertal, villus hair only	—	Basal; about 5.0 to 6.0 cm (2.0 to 2.4 in) per year	Adrenarche Ovarian growth
2	Breast buds appear under enlarged areolae (11.2 years)		Sparse growth of slightly pigmented hair along the labia (11.9 years)		Accelerated: about 7.0 to 8.0 cm (2.8 to 3.2 in) per year	Clitoral enlargement Labia pigmentation Uterus enlargement
3	Breast tissue beyond areola without contour separation (12.4 years)		Hair is coarser, curled, and pigmented; spreads across the pubes (12.7 years)		Peak velocity: about 8.0 cm (3.2 in) per year (12.5 years)	Axillary hair (13.1 years) Acne (13.2 years)
4	Projection of areola and papilla forms a secondary mound (13.1 years)		Adult-type hair but no spread to medial thigh (13.4 years)		Deceleration: <7.0 cm (2.8 in) per year	Menarche (13.3 years) Regular menses (13.9 years)
5	Adult breast contour with projection of papilla only (14.5 years)		Adult-type hair with spread to medial thigh but not up linea alba (14.6 years)		Cessation at about 16 years	Adult genitalia

*The Tanner stages of puberty in girls are based on breast size and shape and pubic hair distribution. Mean age of milestone attainment is shown in parentheses for the reference population of Marshall and Tanner. Actual age at milestone attainment may vary among individuals and among different study populations.

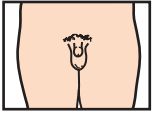

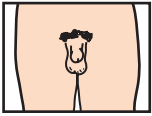

Figure 35-5 Pubertal milestones for girls. (From Blondell RD, Foster MB, Dave KC. Disorders of puberty. *Am Fam Physician*. 1999;60:209, 223.)

precocity. Some child endocrinologists believe that defining precocity as only children with sexual development younger than 7 years will lead to missing some conditions that may respond to early intervention; they prefer the formerly used age of younger than 8 years old in girls to trigger investigation (Carel and Léger, 2008; Midyett et al., 2003; Traggiai and Stanhope, 2003). Children with developmental disabilities have a higher incidence of precocity (Siddiqui et al., 1999). However, the majority of children (>75%) investigated for precocious puberty have benign diagnoses that are considered to be normal variations and do not require any treatment (Kaplowitz, 2004).

Precocious puberty is classified as *central* (GnRH dependent) or *peripheral* (non-GnRH dependent). The peripheral group includes autonomous gonadal activation, gonadal tumors with production of sex steroids, adrenal disorders, and exposure to exogenous agents with properties of sex steroids. Precocious puberty may be differentiated into *progressive* (one stage to next in 3–6 months) or *nonprogressive* (no progression of pubertal signs over time). Other

terminology is based on the pubertal signs in relation to the individual's gender. *Isosexual* refers to precocity in the same gender (e.g., feminization of a female). *Heterosexual* (or *contrasexual*) would be precocious puberty resulting in virilization of a female.

Benign variants of precocious pubertal development (incomplete precocious puberty or variations in pubertal development) include nonprogressive precocious puberty, isolated precocious thelarche, isolated precocious pubarche, isolated menarche, and adolescent (male) gynecomastia. *Isolated thelarche* (unilateral or bilateral breast development) without progression of other signs of puberty generally resolves spontaneously, especially in girls younger than 2 years and requires no treatment. *Isolated precocious pubarche* (pubic hair development) as a result of early adrenarche is usually self-limited. Evaluation beyond a complete history, physical examination, and bone age determination would include an ACTH stimulation test to rule out late-onset congenital adrenal hyperplasia. *Gynecomastia* in adolescent males is common and presents more of a social than a

Tanner stage	Standard	Genitalia*	Pubic hair*	Growth	Other
1		Prepubertal testes: <2.5 cm (1.0 in)	Prepubertal, villus hair only	Basal: about 5.0 to 6.0 cm (2.0 to 2.4 in) per year	Adrenarche
2		Thinning and reddening of scrotum (11.9 years) Testes: 2.5 to 3.2 cm (1.0 to 1.28 in)	Sparse growth of slightly pigmented hair at base of penis (12.3 years)	Basal: about 5.0 to 6.0 cm (2.0 to 2.4 in) per year	Decrease in total body fat
3		Growth of penis, especially length (13.2 years) Testes: 3.3 to 4.0 cm (1.32 to 1.6 in)	Thicker, curlier hair spreads to the mons pubis (13.9 years)	Accelerated: about 7.0 to 8.0 cm (2.8 to 3.2 in) per year	Gynecomastia (13.2 years) Voice breaks (13.5 years) Muscle mass increases
4		Growth of penis and glands, darkening of scrotum (14.3 years) Testes: 4.1 to 4.5 cm (1.64 to 1.8 in)	Adult-type hair but no spread to medial thigh (14.7 years)	Peak velocity: about 10.0 cm (4.0 in) per year (13.8 years)	Axillary hair (14.0 years) Voice change (14.1 years) Acne (14.3 years)
5		Adult genitalia (15.1 years) Testes: >4.5 cm (1.8 in)	Adult-type hair with spread to medial thigh but not up linea alba (15.3 years)	Deceleration and cessation (about 17 years)	Facial hair (14.9 years) Muscle mass continues to increase after stage 5

*The Tanner stages of puberty in boys are based on the development of the genitalia and pubic hair distribution. Mean age of milestone attainment is shown in parentheses for the reference population of Marshall and Tanner. Actual age at milestone attainment may vary among individuals and among different study populations.

Figure 35-6 Pubertal milestones for boys. (From Blondell RD, Foster MB, Dave KC. Disorders of puberty. *Am Fam Physician*. 1999;60:209, 223.)

physical problem. Careful explanation and reassurance for the child and parent that this is a self-limited condition is the best approach.

Accidental precocity occasionally results from unusual dietary habits or inappropriate use of medications (estrogen creams). A careful review for these, early in the evaluation, is helpful.

Central (GnRH-Dependent) Precocious Puberty. Central (or true) precocious puberty is caused by early activation of hypothalamic GnRH secretion. Most patients have no identifiable cause, and the precocity is labeled as “idiopathic.” Initial evaluation begins with history, examination, growth chart, and wrist radiographs. Morning testosterone levels are useful in boys, and GnRH-agonist stimulation tests are helpful in females to identify a central etiology. A wide variety of CNS lesions are known to cause central isosexual precocity, so cranial CT or MRI is indicated to rule out these pathologies. An underlying CNS disorder is not unusual in boys presenting with precocious puberty. Treatment is focused on managing the underlying cause. GnRH analogues that reversibly inhibit gonadotropin secretion can be used to prevent secondary sexual development and early epiphyseal fusion that occurs in children who are

very young at the onset of puberty, especially when it progresses rapidly (Carel et al., 2004). The optimal age to discontinue therapy is 11 years. When therapy is discontinued, puberty commences normally. There is a slowly progressive form of central isosexual precocity in which no height is lost. These patients may be considered for a nontherapeutic approach with careful observation (Palmert et al., 1999) (Table 35-12).

In many studies, the most common causes of precocity are benign and need no treatment. Detailed evaluation with hormonal studies and imaging may be reserved for patients with severe symptoms and signs (Kaplowitz, 2004, 2005; de Vries and Phillip, 2005).

KEY TREATMENT

- Common causes of precocity are benign and require no treatment. Careful nontherapeutic observation may be considered (Carel et al., 2004) (SOR: A).
- Treatment of precocity with GnRH analogues, which reversibly inhibit gonadotropin secretion, can be used to prevent secondary sexual development and early epiphyseal fusion (Carel et al., 2004) (SOR: A).

Table 35-12 Precocious Puberty: Types, Causes, and Treatment

Etiology	Symptoms	Tests and Treatment
CENTRAL PRECOCITY*		
Idiopathic	Development of secondary sexual characteristics	GnRH analogues Discontinue at 11 years
CNS lesions (including congenital defects): hamartomas, tumors, infection, trauma, radiation, after androgen exposure, craniopharyngioma, others	History of trauma Medical history Headache, visual changes possible	FSH, LH, prolactin, sex steroids, TSH MRI of brain Treatment per pathology
Primary hypothyroidism	Signs of hypothyroidism without increase in growth velocity	Thyroid profile Treatment with thyroxine
INCOMPLETE ISOSEXUAL PRECOCITY		
<i>Females:</i> Isolated precocious thelarche	Breast enlargement without other secondary sexual changes	Most cases are benign
<i>Females:</i> Isolated precocious adrenarche	Pubic hair development, adult odor, acne	DHEA may be increased Adrenal steroid hormones and sex hormones: normal ACTH stimulation test to exclude CAH Usually benign; no treatment needed
<i>Females:</i> Isolated precocious menarche	Menarche precedes breast development or appearance of pubic hair	Normal bone age Ultrasonography: normal pelvis with prepubertal uterus Usually benign; check for abuse and ovarian and genital pathology
<i>Females:</i> Estrogen-secreting tumors of ovary or adrenal glands Ovarian cysts	Abdominal symptoms Signs of precocious puberty	CT or MRI in addition to hormonal tests Treat as per pathology
<i>Females and males:</i> McCune-Albright syndrome	Autonomous hyperfunction of gonads; rapid development of precocity Café au lait spots, fibrous dysplasia	Ultrasonography or CT of abdomen: large ovarian masses LFTs, DHEA sulfate, TSH, phosphate, cortisol
<i>Males:</i> Gonadotropin-secreting tumors; excessive androgen production Testicular or adrenal tumors Virilizing CAH Premature Leydig and germinal cell maturation	Excessive virilization Enlargement of testis (unilateral)	CT or MRI of abdomen Ultrasonography Hormonal tests Treat per pathology Surgery may be indicated
<i>Males and females:</i> Iatrogenic	History of using sex steroids and related products	Stop causative agent
CONTRASEXUAL PRECOCITY (ISOLATED VIRILIZATION)		
Isolated Precocious Adrenarche		
<i>Females:</i> Virilizing CAH, androgen-secreting ovarian or adrenal neoplasm, Cushing syndrome, glucocorticoid resistance, arrhenoblastoma	Prepubertal masculinization	Tests for CAH Cortisol Testosterone MRI of abdomen and pelvis Treat per pathology
<i>Males:</i> Estrogen-secreting tumor, chorionepithelioma; increased extraglandular aromatization of adrenal steroids causing increased extraglandular estrogen production and unusual CAH variations	Prepubertal feminization in boys is rare	Tests for CAH Cortisol and estrogen levels Testosterone MRI of abdomen and pelvis Treat per pathology
Iatrogenic	History of using sex steroids and related products	Stop causative agent
Nonprogressive precocious puberty	Stabilization of precocity Normal bone age	Normal bone age Ultrasonography: normal pelvis with prepubertal uterus

*True precocious puberty: gonadotropin dependent.

ACTH, Adrenocorticotropic hormone; CAH, congenital adrenal hyperplasia; CNS, central nervous system; CT, computed tomography; DHEA, dehydroepiandrosterone; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LFT, liver function test; LH, luteinizing hormone; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone.

DELAYED PUBERTY

Key Points

- Lack of thelarche (breast development) by the age of 12 years in girls or lack of testicular enlargement by the age of 14 years in boys indicates delayed puberty.

- Whereas constitutional delay is characterized by delayed but spontaneous onset of puberty, organic delay is caused by gonadal, pituitary, or central dysfunction.

Delayed puberty in girls is defined as lack of thelarche by age 12 years or duration between thelarche and menarche

longer than 5 years (age 17 years). In boys, delayed puberty is defined as no testicular enlargement by age 14 years with more than 5 years between initial and complete development of the genitalia (age 19 years). Delayed puberty in both males and females is classified as *constitutional* (idiopathic) or *organic* (gonadal, pituitary, or central cause). A retrospective study of 232 male and female patients with delayed puberty revealed that the majority (53%) had constitutional delay of growth and maturation, with much higher incidence in males (63%) compared with females (30%). The remaining 47% of the total 232 patients had mixed etiologies; 19% had functional HH, 12% had permanent HH, 13% had permanent hypergonadotropic hypogonadism, and there was no clear etiology for the remaining 3% (Sedlmeyer and Palmert, 2002).

Constitutional delay is characterized by physiologic delay but subsequent spontaneous onset of puberty, and it is a diagnosis of exclusion. The cause is a delay in GnRH pulse generation, with low levels of gonadotropins. Height and weight in these children tend to be below the fifth percentile, but most catch up during adolescence, reaching normal adult height and weight. Family history may reveal similar delays of puberty in one or both parents, which can be reassuring for the child and parent. Values for FSH, LH, DHEA-S, prolactin, testosterone, and estradiol levels will be consistent with prepubertal values until onset of puberty and normal sexual maturation.

The two common causes of delayed puberty from organic etiologies are pituitary dysfunction and HH. Panhypopituitarism in children may present as delayed puberty, but it would occur in conjunction with growth failure, secondary hypothyroidism, and adrenal insufficiency. Differentiation of organic forms of delay from constitutional delay may be difficult to establish in certain patients, requiring a series of observations and testing (no single study or imaging technique will differentiate these). HH presents with low levels of FSH and LH as a result of defective GnRH pulsation. Causes include anorexia nervosa, excessive weight loss, extreme exercise (cross country runners), tumors, head trauma, infiltrative processes, infection, and radiation. *Hypergonadotropic* hypogonadism is usually caused by gonadal failure and presents with high levels of gonadotropins and low levels of sex steroids (Table 35-13).

Evaluation of delayed puberty, as with all evaluations for abnormal sexual development, begins with a detailed history focusing on growth patterns, presence of any secondary sexual development, diet, exercise habits, congenital abnormalities, neurologic symptoms, and family history. Physical examination includes a thorough search for early signs of sexual maturation using Tanner staging. Measurement of arm span in relation to height is helpful in growth assessment. Arm span that exceeds height more than 5 cm is consistent with adult configuration. When this is present in children, it may mean delayed epiphyseal closure caused by hypogonadism. Wrist radiography is useful to determine bone age. Initial laboratory screening should include complete blood cell count, erythrocyte sedimentation rate, and liver function tests. Serum FSH, LH, estradiol, and testosterone levels can distinguish between primary and secondary hypogonadism. In primary hypogonadism (ovarian and testicular failure), serum gonadotropin levels are elevated. In patients with constitutional delay

Table 35-13 Causes of Hypogonadotropic Hypogonadism

CONGENITAL	
Isolated gonadotropin deficiency	Idiopathic HH Kallmann syndrome Non-X-linked Partial HH (fertile eunuch syndrome)
Associated with CNS disorders	Prader-Willi syndrome Laurence-Moon-Biedl syndrome Möbius syndrome Lowe syndrome Noonan syndrome LEOPARD syndrome X-linked ichthyosis Genetic defects GnRH receptor gene mutations <i>FGFR1</i> <i>GPR54</i> Adrenal hypoplasia, congenital Multiple pituitary hormone deficiency
ACQUIRED	
Organic lesions	Tumors Craniopharyngiomas Pituitary adenomas (e.g., prolactinoma, nonfunctioning tumor) Meningioma Pituitary apoplexy Infiltrative disorders Sarcoidosis, hemochromatosis Histiocytosis X Head trauma Leydig cell tumors, choriocarcinoma CNS radiation therapy

CNS, Central nervous system; GnRH, gonadotropin-releasing hormone; HH, hypogonadotropic hypogonadism; HPT, hypothalamic-pituitary-testicular; LEOPARD, lentigines, electrocardiographic defects, optic hypertelorism, pulmonary stenosis, abnormalities of genitalia, retarded growth, deafness.

From Allan CA, McLachlan RI. Androgen deficiency disorders. In DeGroot LJ, Jameson JL, eds. *Endocrinology*. 5th ed, vol 3. Philadelphia: Saunders; 2006.

of puberty and congenital GnRH deficiency, serum gonadotropin levels are low. Prolactin, TSH, adrenal androgens, and karyotype (to rule out Turner, Klinefelter, and Noonan syndromes) should be evaluated if the clinical presentation warrants.

Therapy for delayed puberty is targeted at the underlying disorder, if identified. If the cause is unknown, observation with reassurance and psychosocial support and reevaluation after 4 to 6 months is an option. Hormonal therapy with estrogen (girls older than 12 years) or testosterone (boys older than 14 years) is an option. Short-term use of exogenous hormones does not appear to have long-term sequelae, except for the potential effect on skeletal maturation, which might result in failure to achieve potential adult height. In females taking estrogen replacement therapy, progestins should be added to the regimen after breakthrough bleeding occurs or after 1 year of therapy.

PROBLEMS OF THE TESTICLE AND OTHER MALE ENDOCRINE ISSUES

Male Hypogonadism

Male hypogonadism is defined as “inadequate gonadal function” manifested by deficiency in gametogenesis or secretion of gonadal hormones. Primary hypogonadism is caused by dysfunction in the testes from either chromosomal or acquired disorders (Table 35-13). Secondary hypogonadism is caused by an abnormality of the HPA. Males may present with infertility, decreased testicular size, changes in libido, impotency, gynecomastia, delayed puberty, or a combination of these (Swerdlhoff and Wang, 2004).

Diagnosis. The clinical diagnosis begins with history, including information about sexual developmental milestones, current symptoms, ambiguous genitalia at birth, cryptorchidism, behavioral abnormalities, anosmia, surgeries, sexually transmitted diseases (STDs), and medications. The history should include the presence of acute and chronic medical conditions and neurologic symptoms. The physical examination is directed toward sexual characteristics, body habitus, gynecomastia, and signs of hypogonadism. The testes should be measured for length and width with an orchidometer. Consistency of the testes should be noted and a scrotal examination done for the presence of varicocele. A nonpalpable prostate may imply testosterone deficiency. A low morning (8-10 AM) serum testosterone level is suggestive of hypogonadism. Serum LH and FSH levels are elevated in primary hypogonadism and normal to low in secondary hypogonadism. Semen analysis assesses the capability of spermatogenesis. An increase in sex hormone-binding globulin (SHBG) may imply hyperthyroidism, severe androgen deficiency, liver disease, or estrogen excess. A low level of SHBG may indicate hypothyroidism, PCOS, obesity, or acromegaly. The prolactin level should be measured to identify a prolactinoma followed by CT or MRI if the level is elevated. Other studies, such as BMD; pituitary imaging; genetic studies; and, in some cases, testicular biopsy may be indicated.

Two congenital conditions causing hypogonadism are Klinefelter syndrome and Kallmann syndrome. Klinefelter syndrome is the most common genetic cause of male infertility caused by hypogonadism. It is caused by a chromosomal aberration, most often 47,XXY. Phenotypic males can present with small, firm testicles; infertility; tall height; long legs; gynecomastia; and varying symptoms of androgen deficiency and undervirilization. Kallmann syndrome is an inherited disorder (see Approach to Pituitary Diseases [Hypopituitarism]). The most common form is isolated gonadotropin deficiency caused by defective GnRH secretion from the hypothalamus. Patients with Kallmann syndrome usually come to medical attention because of delayed puberty or incomplete sexual development. Anosmia or hyposmia is present in 80% of patients and establishes the diagnosis of Kallmann syndrome in those with isolated gonadotropin deficiency.

Requests to measure serum testosterone have become common in primary care. The increased interest in this disorder has been brought about by a number of things. First, and perhaps most important, is access to information. For example, if one enters “male hypogonadism” in Google,

there are more than 300,000 results. It is common now for a patient to present with a list of symptoms and Internet data supporting his belief that he has a problem. In addition, there are now a wide variety of pharmacologic options available, including testosterone injections, topical gels, and oral medications. Added to this is the plethora of over-the-counter preparations on the market which are touted to increase testosterone. In addition, there are growing numbers of articles in the scientific literature (albeit perhaps not totally objective) supporting hypogonadism as a disorder causing significant morbidity that requires therapeutic intervention (Dandona and Rosenberg, 2010).

Laboratory Evaluation. To start the discussion of laboratory evaluation, it is important to understand that a low serum testosterone level does not, by itself, provide a diagnosis of hypogonadism. Whether or not a low level represents a pathologic condition or is merely a laboratory phenomenon is not clear cut. An article published in the *American Family Physician* (2006) provides a very good review of this topic, and one of its main points is that in the absence of specific symptoms or physical findings, there is no clearly agreed upon normal testosterone level for defining hypogonadism (Margo and Winn, 2006). Generally accepted normal values for total serum testosterone are 300 to 1000 ng/dL, but when hypogonadism becomes a real physiologic condition is unclear. The level most often used for defining hypogonadism is 200 ng/dL, which is the level set by the AACE in its 2002 guidelines (update). But data clearly defining this level as a pathologic state are lacking (AACE, 2002).

When a low serum total testosterone level is obtained, it is necessary to verify that this does represent a pathologic condition before any consideration of therapeutic intervention can be entertained. Specific testing to evaluate a low testosterone level includes a repeat total serum testosterone and FSH. Some experts recommend that the serum testosterone be checked in the early morning (8-10 AM). Although this does improve reproducibility, it must be remembered that pituitary gonadotrophs are released in surges so limiting collection of serum testosterone to a specific time of day is not a guarantee that the results represent actual 24-hour circulating levels.

If the second testosterone level is low and the FSH level is normal or elevated, a free testosterone level is obtained (reference range, 9-30 ng/dL). If the free serum testosterone level is low, then there is good evidence to support a diagnosis of primary hypogonadism. To further document this assumption, LH and prolactin levels are obtained (see Approach to Pituitary Diseases [Clinical Manifestations]). These tests are sufficient to determine if the testosterone level is truly low and whether it is due to testicular failure (primary) or failure somewhere along the HPA (secondary). Further workup, if any, is determined by these results.

Screening. There are clear instances in which hypogonadism is a defined entity (i.e., secondary to pituitary failure, congenital hypogonadism, premature aging of the testes, testicular cancer, intraabdominal cryptorchidism). In these patients, screening of testosterone is warranted. But in the primary care setting, the large majority of patients interested in testing their serum testosterone level

are concerned about decreased libido, strength, and stamina; loss of muscle mass (sarcopenia); increasing truncal obesity; frailty; and overall lethargy in the absence of specific common diseases and etiologies.

Data in support of screening for hypogonadism are lacking. At the present time, there are insufficient data to determine if male hypogonadism is increasing in the population or is only a phenomenon of more access to laboratory testing. So, when is it appropriate to screen for hypogonadism? One is male infertility. Screening testosterone is part of an infertility workup given appropriate history or physical findings. The American Urologic Association's (AUA's) position on endocrine testing in evaluating male infertility is discussed in its publication *The Optimal Evaluation of the Infertile Male: AUA Best Practice Statement* (Jarow et al., 2010). The AUA recommends endocrine testing when there is an abnormal semen analysis, with impaired sexual function, or with other clinical findings suggestive of endocrinopathy.

Other reasons to screen for low testosterone include clearly identified physical signs of decreased testosterone such as lack of facial hair, sparse or lacking pubic hair, atrophic testes, or clinical evidence of pituitary dysfunction. After these, however, screening for hypogonadism is not recommended. As occurs with other conditions in which screening provides a very low yield ("n" to diagnose), screening for low testosterone is not justified.

Testosterone Replacement Therapy (Risk versus Benefit)

When presented with a below published normal total serum testosterone, especially when definitive physical findings are absent, it is essential to try and provide a precise cause before therapeutic intervention is initiated. Once a diagnosis of hypogonadism is confirmed and categorized as either primary or secondary, then consideration for hormone replacement can begin. But, before moving on to treatment, it is necessary to discuss risk versus benefit. This is especially true when the patient is elderly and/or has other disease processes that could be aggravated by testosterone therapy.

Recent data published in the *Journal of the American Medical Association* (November 2013) report on the incidence of mortality, MI, and stroke in men with low total serum testosterone levels (<300 ng/dL) who receive replacement therapy ($n = 1223$). When those treated with testosterone replacement were compared with those who did not receive exogenous testosterone ($n = 7486$), there was a statistically significant difference in outcomes for the two groups. The group receiving replacement therapy had a 25.7% higher event (death, MI, stroke) level compared with an event level of 19.9% in the untreated group (an absolute risk difference of 5.8%) (Vigen et al., 2013).

A meta-analysis by a group from University of Hong Kong had results similar to those above, although their analysis of risk was reported as odds ratio (OR) instead of relative or absolute risk. In their review of 27 trials, testosterone therapy increased risk of cardiovascular events to an OR of 1.54 (with OR of 0.0 being no difference). There was, however, an unexpected finding in their analysis. The OR for each individual study varied depending on funding source for the study. Whereas studies funded by

pharmaceutical industry had an OR of 0.89, studies funded by other entities (nonpharmaceutical) had an OR of 2.06. The conclusion was that "Appropriately prescribed testosterone is undoubtedly beneficial. However, caution needs to be exercised to ensure that the associated health benefits of testosterone therapy outweigh the potential increased risk of cardiovascular-related events, particularly in older men when cardiovascular disease is common" (Xu et al., 2013).

Treatment. Once a definitive diagnosis of hypogonadism is made, referral to an endocrinologist for management is certainly appropriate. However, if the cause is definitely primary hypogonadism, and the risk to benefit analysis has been completed, initiation of treatment and ongoing management can be done by the primary care physician.

In some cases, such as Klinefelter and Kallmann syndromes, hormone replacement is aimed at specific end points. In Klinefelter syndrome, treatment is directed to preventing the sequelae of androgen deficiency. For Kallmann syndrome, treatment is directed at virilization by the administration of testosterone. In both of these, the primary care physician may want to refer to an endocrinologist, at least for initiation of therapy. This may also be the best choice for secondary hypogonadism when restoration of fertility is the goal. In these cases, gonadotropin replacement or human chorionic gonadotropin therapy is required. If the defect is in the hypothalamus, GnRH is the treatment of choice.

In primary hypogonadism, testosterone replacement is the treatment of choice. Many preparations are now available for testosterone replacement (Mooradian and Korenman, 2006). The currently used injectable testosterone esters, such as testosterone enanthate or testosterone cypionate, act similarly. The usual replacement dose is 200 mg intramuscularly every 2 weeks. In older men, it may be prudent to start at 50 to 75 mg weekly. Testosterone undecanoate is available as an oral preparation that does not have hepatotoxicity; however, because of its short half-life, it must be taken three times daily. Transdermal preparations can be given as patches or gels. Some androgen skin patches are associated with a high incidence of skin reactions. The commercially available transdermal gel preparations (AndroGel 1% or 1.62%, Testim 1%, Fortesta 2%, and Axiron 2%) are applied over the trunk of the body daily (Mooradian and Korenman, 2006). Subcutaneous pellets, sublingual preparations, and buccal preparations of testosterone are also available for replacement therapy (Mooradian and Korenman, 2006).

Side effects of testosterone replacement should be monitored carefully. Digital rectal examinations, hematocrit (Hct), and prostate-specific antigen (PSA) should be measured at 3, 6, and 12 months of follow-up and then annually or semiannually (preferable). Bone density measurements should be obtained at baseline and, if low, at 2-year intervals to monitor improvement. In addition to monitoring clinical response, serum testosterone levels should be measured with the goal of achieving a midnormal range midway between injections of testosterone enanthate or cypionate, at 3 to 10 hours after application of a testosterone patch, or at any time after application of a testosterone gel.

Absolute contraindications to testosterone therapy currently are history of prostate or breast cancer, Hct of 55%

or greater, elevated PSA level that has not been completely investigated by a qualified urologist, or sensitivity to ingredients of the testosterone preparation (Mooradian and Korenman, 2006). There are currently no data to suggest testosterone replacement aggravates subclinical prostatic cancer.

Relative contraindications include obstructive sleep apnea, CHF, obstructive symptoms of prostatic hyperplasia, and Hct of 52% or greater. Patients with hyperlipidemia, atherosclerotic vascular disease, diabetes, and morbid obesity should be treated with caution and careful follow-up.

Cryptorchidism

See [eAppendix 35-5](#) online.

Male Infertility

Infertility is defined as failure to achieve pregnancy after 1 year of unprotected intercourse. A specific cause can be identified in approximately 80% of couples, one third of which are female factors alone, one third male factors alone, and one third a combination of both. Unexplained infertility, in which no specific cause can be identified, occurs in approximately 20% of infertile couples. The initial step in evaluation of the male is a thorough medical history, focusing on general health, erectile function, STD history, medications, surgical history, previous successful pregnancy, contraception use, drug or alcohol use, and family history of genetic diseases. The first, and often only, test needed in evaluating male factors is semen analysis. If two consecutive analyses indicate oligospermia or azoospermia, ordering blood tests for testosterone, LH, FSH, and prolactin levels is warranted. *Varicocele* is the most common cause of male infertility (Griffin and Wilson, 2003) (Table 35-14).

Management consists of treating the underlying infection with appropriate antibiotics, varicocelectomy, appropriate counseling about environmental factors, and referral to an infertility specialist for more extensive therapy (Frey and Patel, 2004).

Table 35-14 Common Diagnoses in Men Evaluated for Infertility

Diagnostic Category	Incidence (%)
Idiopathic infertility	50-60
Primary testicular failure (chromosomal disorders, including Klinefelter syndrome, Y chromosome microdeletions, undescended testis, irradiation, orchitis, drugs)	10-20
Genital tract obstruction (congenital absence of vas, vasectomy, epididymal obstruction)	5
Coital disorders	<1
Hypogonadotropic hypogonadism (pituitary adenomas, panhypopituitarism, idiopathic hypogonadotropic hypogonadism, hyperprolactinemia)	3-4
Varicocele	15-35
Other (sperm autoimmunity, drugs, toxins, systemic illness)	5

Gynecomastia

Key Point

- Although breast cancer is an uncommon cause of breast enlargement in men, this diagnosis must be ruled out because the prognosis is worse for men diagnosed with breast cancer than for women.

Gynecomastia refers to a benign enlargement of the male breast resulting from proliferation of breast glandular tissue. When the male breast is enlarged from adipose tissue, it is called *lipomastia* or *pseudogynecomastia* and is not caused by proliferation of breast tissue. Gynecomastia can be unilateral, bilateral, or asymmetric. Any palpable breast tissue in men is abnormal except for three physiologic situations: transient gynecomastia of the newborn (caused by maternal or placental estrogens), pubertal gynecomastia (observed in 40%-70% of adolescent boys, resolving by 18 years of age), and gynecomastia that occasionally occurs in older adult men (resulting from changes in estrogen and androgen metabolism). Gynecomastia can also be iatrogenic, caused by use of some medications. Gynecomastia is occasionally seen in male adolescents from marijuana use (Mayo Clinic Health Information, 2014).

Gynecomastia occurs as concentric, palpable glandular tissue beneath the areola that is not fixed to underlying structures. The prevalence is highest in men 50 to 80 years old and generally presents as bilateral. The cause of pathologic gynecomastia is a relative or absolute increase in circulating estrogen compared with androgen. Careful history (including drugs, legal and illegal) and physical examination can usually rule out Klinefelter syndrome, androgen insensitivity syndrome, and testicular tumors (Griffin and Wilson, 2003) (Table 35-15).

Breast cancer is rare in men, but it does occur, and generally the prognosis is much worse for men than for women diagnosed with breast cancer. Typically, breast cancer presents as a painless, central breast lump that may advance to pain, bloody discharge, and skin ulceration. Although there may be some benefit to obtaining breast ultrasonography or mammography, definitive diagnosis must be confirmed by biopsy (Wise et al., 2005).

Treatment of nonphysiologic gynecomastia involves removal of the offending drug or correction of the underlying condition, either of which usually results in regression of the glandular breast tissue. If the gynecomastia persists, a trial of antiestrogen therapy may be considered. Gynecomastia present for more than 1 year will undergo fibrosis and usually not respond to medications. Surgical correction is required for alleviation of symptoms.

PROBLEMS OF THE OVARY AND OTHER FEMALE ENDOCRINE ISSUES

Menopause and Hormone Replacement Therapy

Normal menopause is defined as the cessation of menstruation for 12 months after the age of 40 years without other known (physiological or pathological) causes of amenorrhea (Table 35-16). Perimenopause refers to an indefinite period before, during, and after cessation of menstruation.

35-5 Cryptorchidism

Key Points

- Morbidity associated with cryptorchidism includes infertility, testicular torsion, and malignancy.
- Intraabdominal testes carry the highest risk for testicular cancer.
- Management options include surgery, hormonal therapy, or both and should be offered early after diagnosis.

Cryptorchidism describes a testis (testes) not in the scrotum or one that cannot be manipulated into the scrotum. The incidence is about 5% in term infants and much more common (~30%) in preterm infants. Approximately 10% of cryptorchidism is bilateral, and about 80% of these testes descend into the scrotum in the first year of life. Cryptorchidism may be associated with disorders such as Prader-Willi syndrome, Reifenstein syndrome, Kallman syndrome, cystic fibrosis, and pituitary hypoplasia. Cryptorchidism, in association with hypospadias, has a higher incidence of intersex disorders, including mixed gonadal dysgenesis.

The initial diagnosis of cryptorchidism should include a complete medical history, noting prematurity, family history of cryptorchidism, maternal use of estrogens, central nervous system abnormalities, and prior surgeries. A thorough examination with a warm hand in a warm room should document the location of the testis (upper scrotum, inguinal pouch, canal, or abdomen) and should differentiate a retractile testis from an undescended testis. By pulling the palpable testis into the scrotum and maintaining this position for 1 minute, the cremaster muscle will fatigue. When it is released, a retractile testis will stay in the scrotum, but an undescended testis will return to its original position, thus differentiating between the two conditions. In patients with cryptorchidism, generally 40% of cases can be classified as a high scrotal testis, 20% as inguinal canal testis, and 10% as intraabdominal testis.

The remaining 30% are retractile or not identified. In patients with bilateral nonpalpable testes, a human

chorionic gonadotropin (hCG) stimulation test, with luteinizing hormone, follicle-stimulating hormone, and testosterone level, will aid in determining the presence of testes. Imaging studies, such as ultrasonography (high specificity, low sensitivity) or magnetic resonance imaging, are beneficial in locating the testes.

The most significant complications from cryptorchidism are infertility, subfertility, testicular torsion, and malignancy. The combined risk of testicular cancer for all cryptorchid boys is 20 to 46 times higher than for boys with normally descended testicles (Kolon et al., 2004). Because of the location, intraabdominal testes have the highest risk for testicular cancer.

Early management of the undescended testicle is warranted to preserve the fertility and lower the risk for testicular malignancy. Repeat examination at 3 months of age is beneficial to confirm the descent. By 6 months of age, an infant with undescended testicles should be referred to a pediatric urologist or other qualified subspecialist. Hormonal therapy with hCG or gonadotropin-releasing hormone (GnRH) can be used to increase the likelihood of testicular descent, but this should not be added until a thorough evaluation has been completed (Kollin et al., 2006). Inguinal orchiopexy is a well-established operation for palpable undescended testicles and is currently the standard of care for cryptorchidism in the United States. Treatment for an undescended testis is recommended as early as 6 months of age and should be completed before the age of 2 years (Henna et al., 2004).

KEY TREATMENT

- Hormonal therapy with hCG or GnRH can be used to increase the likelihood of testicular descent (Henna et al., 2004) (SOR: A).
- Inguinal orchiopexy is a well-established procedure for palpable undescended testicle and is generally considered the standard of care for cryptorchidism in the United States (Kollin, 2006) (SOR: A).

ET, Estrogen therapy; EPT, cyclic combined estrogen-progestogen therapy; SOR, strength of recommendation.

Modified from NIH State of the Science Conference on Management of Menopausal-Related Symptoms. Bethesda, Maryland, 2005.

<http://consensus.nih.gov/2005/menopausestatement.htm>.

The term *climacteric* refers to the period of time after the cessation of reproductive function. Premature menopause, sometimes referred to as premature ovarian failure, is the same syndrome but occurring before age 40 years and is often thought to be the result of an autoimmune process. Premature menopause can also be the result of surgical removal of the ovaries or chemotherapy. When amenorrhea is associated with a negative pregnancy test result, elevated levels of FSH (≥ 35 mIU/mL) and low estradiol levels (≤ 35 pg/mL), it is primary ovarian failure until proven otherwise. Fluctuations in the level of various hormones (FSH, LH, estrogen, progestin) are common during the perimenopausal period. A single reading of these hormones during this period may be unreliable for a definitive diagnosis of menopause. The combination of clinical presentation plus laboratory test results in these circumstances is useful.

Menstrual Patterns and Symptom Overview

Decreasing levels of estrogens and androgens are responsible for most menopausal symptoms. Typical hormonal changes include increases in FSH and LH with a significant reduction in estradiol (E2), a moderate reduction in estrone (E1) and androstenedione, a mild reduction in testosterone, and changes in cortisol levels that are insignificant. Not all women experience symptoms associated with hormone deprivation. Obese women may experience no or relatively few symptoms of hormone deficiency and are at reduced risk of osteoporosis, but they are at increased risk for cancer (e.g., uterine cancer) and cardiovascular disease (CVD).

The most common symptoms of menopause are hot flashes (vasomotor symptom complex with sudden sensations of intense heat, sweating, and flushing, typically lasting 5 to 10 minutes, and night sweats), sleep and mood disturbances, decreased libido, and vaginal dryness. Hot flashes tend to be most intense in duration, severity, and frequency in younger women and during the first year of menopause, generally tapering thereafter. A small percentage of women have hot flashes on a lifelong basis.

Treatment of Hormonally Mediated Symptoms

Key Points

- Hormone replacement therapy (HRT) may be appropriate for the relief of severe vasomotor symptoms in selected postmenopausal women.
- HRT has previously been used for broad segments of the population. Currently, individualized therapy, predominantly nonhormonal, is advised.

- HRT increases the risks of breast cancer, CVD and stroke, deep vein thrombosis (DVT), and cognitive decline (much of this is contrary to previous findings).
- If HRT is used, the lowest dose for the shortest duration should be administered.
- HRT has been shown to improve bone density and osteoporosis and decrease colon cancer risk.

Beliefs about HRT for menopausal women have shifted substantially in recent years because of randomized clinical studies, including the landmark Women's Health Initiative (WHI) study (Anderson et al., 2004). These studies showed that hormonal therapy, particularly with combined conjugated estrogen and medroxyprogesterone regimens, not only increases the risk for developing breast cancer and thromboembolic disease but also increases the risk of cardiovascular events (Anderson et al., 2004; Hulley et al., 1998; Nelson et al., 2002; Rossouw et al., 2002; Tomson et al., 2005).

Side effects of HRT are related to the age of the patient, her baseline disease risk strata, age at time of menopause, time interval since menopause, duration and dosage of estrogen administered, and emerging medical conditions during treatment. WHI also showed hormone therapy initiated less than 10 years since menopause had a lower incidence of CHD compared with that initiated 10 years after menopause. Although the absolute risk for any individual woman for severe complications was low, the cumulative risk over large populations has led to substantial changes in prescribing patterns and recommendations for postmenopausal therapy (Anderson et al., 2004).

Recent analysis has raised the question of whether unopposed estrogen may actually be safer than combined estrogen and progesterone even in women who still have their uteruses (Rossouw et al., 2002). Prescribing progesterone to prevent endometrial cancer may be incorrect in that an increased incidence of breast cancer and other risks from adding progesterone might actually outweigh the benefit of preventing uterine cancer—the incidence of breast cancer is actually substantially higher than that of uterine cancer. The WHI estrogen-only therapy arm for hysterectomized women (average follow-up, 6.8 years) revealed reduced breast cancer (0.77 [0.59-1.01]; 95% confidence interval [CI]) and hip fracture (0.61 [0.41-0.91]), but there was a small increase in total CVD (1.12 [1.01-1.24]) and an absolute increase in strokes (12 in 10,000 person-years) with six fewer fractures per 10,000 person-years. Conjugated equine estrogen is not recommended for chronic

Figure 35-7 Female reproductive physiology. *FSH*, Follicle-stimulating hormone; *LH*, luteinizing hormone. From Brown, JB: *Hormones of a woman's reproductive cycle* [Epub, www.pearsoncustom.com].

disease prevention in post-menopausal women (Anderson et al., 2004).

Transdermal preparations of progesterone-only creams have helped relieve hot flashes (Leonetti et al., 1999). Their risks are poorly defined but may include an increased risk of breast cancer because many postmenopausal breast cancers are positive for estrogen and progesterone receptors.

Hormone therapy with estrogen-containing regimens is the most effective treatment for vasomotor symptoms. However, the **U.S. Preventive Service Task Force (USPSTF) recommendations (2005)** warn against the routine use of unopposed estrogen or combined estrogen and progestin for the prevention of chronic conditions in postmenopausal women (USPSTF, 2005). The use of SSRIs, clonidine, and gabapentin is recommended. Although studies are smaller and efficacy appears to be lower, the associated risks, particularly of serious complications, are lower.

Depressed Libido in Women

See [eAppendix 35-6](#) online.

Amenorrhea

Key Points

- Amenorrhea is categorized as primary or secondary; however, this distinction may be misleading in certain patients.
- Primary amenorrhea can be caused by obstruction of the outflow tract; androgen insensitivity; gonadal dysgenesis; hyperprolactinemia; and dysfunction of the hypothalamus, pituitary, or thyroid.
- Pregnancy is the most common cause of secondary amenorrhea.

Primary Amenorrhea. Menses is a normal, physiologic function in a sexually mature female. Amenorrhea is the absence of menses in a sexually mature woman. Amenorrhea is divided into two large categories, primary and secondary, depending on whether the female has ever had menarche, with attendant menstrual flow. *Primary* amenorrhea is defined as failure of menarche by age 16 years in a female with apparently normal sexual development or in a female age 14 years who does not demonstrate evidence of developing secondary sexual characteristics. *Secondary* amenorrhea is failure of menstruation after normal menses are established with the caveat that at least 3 months have passed with apparently normal menses or 9 months have passed in a woman with oligomenorrhea.

Menstruation is a very complex process, with many interacting and codependent processes that must occur in specific chronologic order (Figure 35-7). Dysfunction of any organ or system involved with these processes has the potential to disrupt the menstrual cycle and cause amenorrhea. The organs and systems that are involved in the menstrual cycle are the CNS (influenced by environment, stress), hypothalamus (through GnRH), anterior pituitary (FSH, LH), thyroid gland, adrenals, ovary (estrogen, progesterone), and uterus. Secondary amenorrhea is more common than primary amenorrhea, with the most common cause being pregnancy. The distinction between etiologies of primary and secondary amenorrhea may be misleading, as in the case of a woman with PCOS who presents with primary amenorrhea or a woman with partial gonadal dysgenesis who has rudimentary ovarian development and may initially ovulate, thus presenting with secondary amenorrhea (Table 35-17; see Figure 35-8).

The more common causes of primary amenorrhea fall into congenital or anatomical abnormalities. Congenital

35-6 *Depressed Libido in Women*

Key Points

- Androgens may benefit some women with low libido.
- Low blood levels do not consistently identify those who would benefit.
- Monitoring blood levels to avoid exceeding physiologic levels may decrease the risk of complications.
- Risks include clitoromegaly, voice changes, and acne, as well as worsening lipid and cardiovascular (CV) risk profiles; some of these may not be reversible.

Testosterone therapy to improve libido and sexual function in women is now being prescribed. Use of these preparations remains controversial because there have been no clear and consistent studies defining specific androgen levels in women with low sexual function. Most women with low levels of androgens do not have sexual dysfunction (Davis et al., 2005). A potential side benefit from testosterone therapy is increased bone density, and it does help ameliorate hot flashes. Androgen replacement therapy may be beneficial in established cases of severe androgen deficiency, surgical menopause, or adrenal insufficiency or for patients on chronic glucocorticoid therapy, as well as for those who have impaired mood or libido (Arlt, 2006)

The cause and pathophysiology of impairment of libido or hypoactive sexual dysfunction are multifactorial, and therapy should be directed toward common correlates, including relationship distress, emotional distress, and dyspareunia, rather than relying solely on androgen replacement therapy as the only course (Schover, 2008)

Dehydroepiandrosterone (DHEA) is used by some for mood and libido enhancement in postmenopausal women, but its use is controversial. DHEA has similar risks and

benefits to testosterone, but monitoring of relevant hormone blood levels may be more difficult. Tibolone has been used for menopausal symptoms and to reduce bone loss in postmenopausal women in many countries (≈ 90); however, it is not available in the United States. It has estrogenic, progestogenic, and androgenic properties. A recent randomized controlled trial revealed that tibolone reduced the risk of fracture and breast cancer but increased the risk of stroke (Cummings et al., 2008).

Conclusion

Treating postmenopausal women with hormone replacement therapy (HRT) has changed dramatically in recent years. It is no longer recommended to reduce risk of coronary artery disease nor as a primary management tool for osteoporosis. Although effective in treating vasomotor symptoms and osteoporosis, safer alternatives to HRT exist. Transdermal preparations and low-dose estrogen replacement therapy are being increasingly used. When estrogen is used, lower doses are recommended for the majority of patients. Present clinical practice calls for treating each patient's symptoms and risks on an individual basis.

KEY TREATMENT

- Selective serotonin reuptake inhibitors, clonidine, and gabapentin are recommended for treatment of menopausal symptoms (U.S. Preventive Service Task Force, 2005) (SOR: C).
- Tibolone is effective in controlling menopausal symptoms and reduces the risk of fracture and breast cancer but increases the risk of stroke (Cummings et al., 2008) (SOR: A).

absence of the uterus and vagina, known as müllerian agenesis or Mayer-Rokitansky-Küster-Hausler (MRKH) syndrome, is a significant cause of amenorrhea. Other congenital causes of primary amenorrhea include chromosomal abnormalities, prenatal adrenal hyperplasia, and female virilization syndrome. An anatomic cause of primary amenorrhea, usually discovered at time of menarche, is imperforate hymen.

To evaluate a patient with primary amenorrhea, after a thorough clinical history, the physical examination must focus on development of hormonally mediated secondary sexual characteristics (breast development, pubic or axillary hair). Although rare as a cause of primary amenorrhea, pregnancy occasionally does occur before a woman's first menstrual period, therefore, it should always be excluded before any testing or imaging is initiated.

Laboratory testing includes FSH, LH, TSH, and prolactin. If FSH is normal or reduced, this may mean the patient has chronic anovulation, functional hypothalamic amenorrhea, or PCOS. Increased FSH with breast development is likely secondary to ovarian failure. Increased FSH without secondary sexual characteristics may be caused by congenital agenesis of the ovaries. In a patient without a uterus, serum testosterone level and karyotype should be determined. In the presence of a uterus and normal secondary sexual characteristics, serum TSH levels should be evaluated (Sybert and McCauley, 2004) (Table 35-18).

Secondary Amenorrhea. Pregnancy is the most common cause of secondary amenorrhea and must always be ruled out at the initial clinical visit. Structural changes may cause amenorrhea, such as adhesions after instrumentation (Asherman syndrome) or infection in the form of TB or endometritis. Patients with PCOS present with irregular or absent menses, hirsutism, acne, subfertility secondary to a hyperandrogenic state, or a combination. Adrenal or ovarian tumors, hyperthecosis, and late-onset or mild congenital adrenal hyperplasia may also result in secondary amenorrhea and hyperandrogenism. Hypergonadotropic hypogonadism (premature ovarian failure), HH, thyroid disease, menopause, extreme exercise, anorexia nervosa, bulimia, and hyperprolactinemia are all potential causes of secondary amenorrhea.

A thorough history and physical examination will provide the diagnosis, with laboratory studies and imaging serving as collaborative evidence. Particular attention should be paid to menstrual history, diet, exercise, medications, pubertal development, hirsutism, acne, galactorrhea, and other medical conditions. Initial laboratory evaluation includes a pregnancy test and determination of TSH and prolactin levels. If these are normal and there are no signs of hyperandrogenism (e.g., hirsutism, acne, voice change), proceed with progesterone challenge by using medroxyprogesterone (Provera) 10 to 20 mg/day for 5 to 10 days. In the presence of a uterus, the progesterone withdrawal test will induce withdrawal bleeding within 10 days in a woman with adequate estrogen production. If there is no withdrawal bleed, consider repeating the test with progesterone in oil (100-200 mg intramuscular) or with norethindrone or micronized progesterone. If these test results are also negative, a 21-day course of conjugated estrogen (1.25 mg/day) or a cycle of combined oral contraceptives (OCs) should provide adequate stimulation of the endometrium to support a withdrawal bleed. If all of these fail to result in menstrual flow, additional tests may be ordered, beginning with FSH, and if there are clinical signs of hyperandrogenism, a check for DHEA-S and testosterone levels. Elevated FSH level indicates ovarian failure (including gonadal dysgenesis and secondary ovarian failure or menopause); normal or low values indicate HH or uterine abnormality (Asherman syndrome). Proceed with a workup for PCOS (discussed later), late-onset congenital adrenal hyperplasia, or Cushing syndrome if there are features consistent with these illnesses. Features of hyperandrogenemia or substantially increased serum testosterone levels should prompt appropriate studies to rule out a neoplastic source of androgen. Figure 35-8 is a diagnostic algorithm for evaluating a patient with primary or secondary amenorrhea.

Management of amenorrhea depends on establishing a diagnosis, specific treatment directed to the underlying cause, restoration of ovulatory cycles, and treating infertility if desired. Also, appropriate treatment must be provided for hypoestrogenemia and hyperandrogenemia, both medical and surgical.

Female Infertility

Infertility is defined as failure of conception after 1 year of unprotected intercourse. From 15% to 20% of all couples are infertile. In women, fertility peaks between ages 20 and 24 years. After this, there is progressive decline in fertility

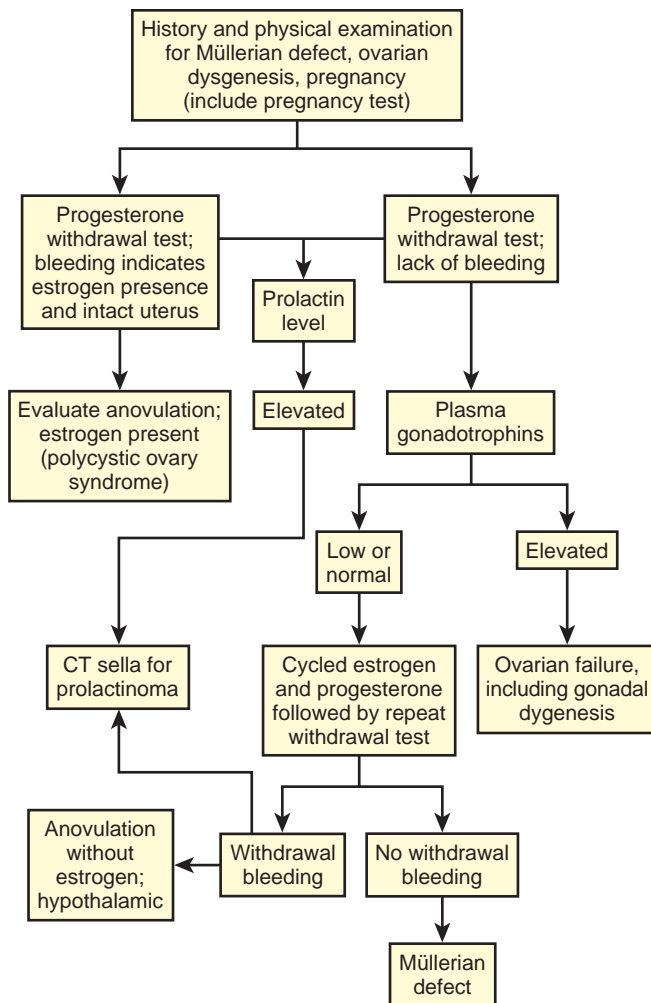

Figure 35-8 Diagnostic algorithm for evaluating a patient with primary and secondary amenorrhea. CT, Computed tomography. (Modified from Carr BR. Disorders of the ovaries and female reproductive tract. In Wilson JD, Foster DW, eds. *Williams' textbook of endocrinology*. 8th ed. Philadelphia: Saunders; 1992.)

until about age 32 years followed by a steep decline after 40 years. Causes of infertility in couples tend to be one third male factors, one third female factors, and one third combination. Female causes of infertility include ovarian dysfunction (40%), tubal factors (20%), cervical factors (infection, stenosis), uterine factors (infection, fibroids), and other (endometriosis, adhesions). The course of investigation for infertility should be based on a couple's wishes for fertility, their age, the duration of infertility, and unique features in the history and physical examination.

After congenital and other nonhormonal causes are excluded, ovulation should be verified by urinary ovulation prediction kits that detect the LH surge, determination of the midluteal phase serum progesterone level (7 days before anticipated menses), or both. Daily rectal temperature measurements to establish ovulation are no longer recommended. Women older than the age of 35 years should have a serum FSH level checked on day 3 of the menstrual cycle. A value higher than 12 IU/L is associated with poor ovarian response, and referral to a reproductive endocrinologist should be considered.

Table 35-19 Tests for Evaluating Female Infertility

Female Infertility	Common Tests
Ovulatory factors	Basal body temperature or urinary LH test (ovulatory predictor test); serum progesterone (during luteal phase); transvaginal ultrasound; TSH, FSH, prolactin, and androgens
Cervical factors	Cervical mucus evaluation; postcoital test (not sensitive)
Uterine factors	Ultrasonography, hysterosalpingography, hysteroscopy, sonohysterography (for submucosal myomas and endometrial polyps), MRI
Tubal factors	Hysterosalpingography; laparoscopy and chromotubation; fluoroscopic or hysteroscopic tubal cannulation
Peritoneal factors	Ultrasonography, laparoscopy

FSH, Follicle-stimulating hormone; LH, luteinizing hormone; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone.

Modified from Brassard M, AinMelk Y, Baillargeon JP. Basic infertility including polycystic ovary syndrome. *Med Clin North Am*. 2008;92:1163-1192.

Treatment should be directed toward the underlying cause. Ovulatory dysfunction is treated based on the underlying cause: bromocriptine for prolactinoma, metformin or clomiphene citrate for PCOS, human menopausal gonadotropin for HH, clomiphene citrate plus glucocorticoids for adrenal hyperplasia with elevated levels of androgens, and antibiotics for infection. The family physician should strongly consider early referral to a reproductive specialist if the patient or couple has complex medical histories or advanced reproductive age.

Women who have secondary infertility (pituitary) wishing to restore fertility should be referred to specialized centers for pharmacologic induction of ovulation with exogenous pulsatile GnRH and exogenous FSH and LH treatment. GnRH can be used to restore fertility when hypothalamic disease and tertiary hypogonadism are present. Women older than the age of 50 years with secondary hypogonadism should be treated as menopausal, taking into consideration the risk-to-benefit ratio of estrogen replacement therapy in this age group.

Assessment of fallopian tube patency is accomplished by hysterosalpingography (first choice) or laparoscopy (if history strongly suggests prior tubal damage). Postcoital tests, endometrial biopsies, and basal body temperature records are no longer recommended as routine studies in the initial evaluation (Mancini et al., 2008; Practice Committee of the American Society of Reproductive Medicine, 2004) (Table 35-19).

Galactorrhea and Hirsutism

See eAppendix 35-7 online.

Polycystic Ovary Syndrome

Polycystic ovary syndrome is the clinical condition seen most commonly with androgen excess. Women with PCOS present with complaints of abnormal menses, infertility, hirsutism, acne, and obesity, all of which are related to excess androgen. PCOS is the single most common endocrine abnormality of women of reproductive age and affects

35-7 Galactorrhea and Hirsutism

Galactorrhea

Galactorrhea is inappropriate secretion of milk or milklike fluid from the breast in the absence of parturition or beyond 6 months postpartum in a non-breastfeeding woman (Leung and Pacaud, 2004).

It may occur unilaterally or bilaterally in both sexes. Galactorrhea is commonly medication induced (e.g., antipsychotics, antidepressants, opiates, calcium channel blockers, and H₂ receptor antagonists); however, pathologic causes are numerous and include pituitary tumor (prolactinoma being the most common), hypothalamic and pituitary stalk lesions, thyroid disorders, chronic renal failure, neurogenic causes, transient neonatal galactorrhea, manipulation, and idiopathic causes (the largest category).

The patient history should focus on the age of onset, duration, appearance of discharge, associated symptoms (e.g., headache, vision changes, temperature intolerance, weight changes, amenorrhea, infertility), medication use, obstetric and gynecologic history, precipitating factors, and family history. Physical examination should include vital signs, height, weight, and thorough breast examination. Special attention should be accorded to identifying visual field defects and papilledema, and evidence of thyroid disorders (goiter, coarse hair, skin changes), hirsutism, and acne need to be recognized.

Laboratory evaluation is indicated when no obvious source is identified. If the patient with galactorrhea is having normal menses, thyroid-stimulating hormone (TSH) and prolactin should be measured. If the patient has abnormal menses or amenorrhea, a pregnancy test to exclude or confirm an unsuspected pregnancy should be performed (regardless of age, pregnancy must always be excluded as an initial step in evaluating menstrual abnormality). If both TSH and prolactin are normal, the patient may be monitored. If the patient has an elevated prolactin level, investigation for prolactinoma with computed tomography (CT) or magnetic resonance imaging (MRI) is indicated. A serum prolactin level above 200 ng/mL virtually confirms the presence of a prolactinoma (Leung and Pacaud, 2004).

Treatment of galactorrhea is directed at the underlying cause. Underlying disorders, such as hypothyroidism, should be treated, and follow-up after the TSH level is in therapeutic range.

Hirsutism

Hirsutism is the presence of excess terminal (coarse) hairs in androgen-dependent areas on a woman. It affects approximately 5% to 15% of women. This male-like pattern includes hair on the upper lip, chin, chest, lower abdomen,

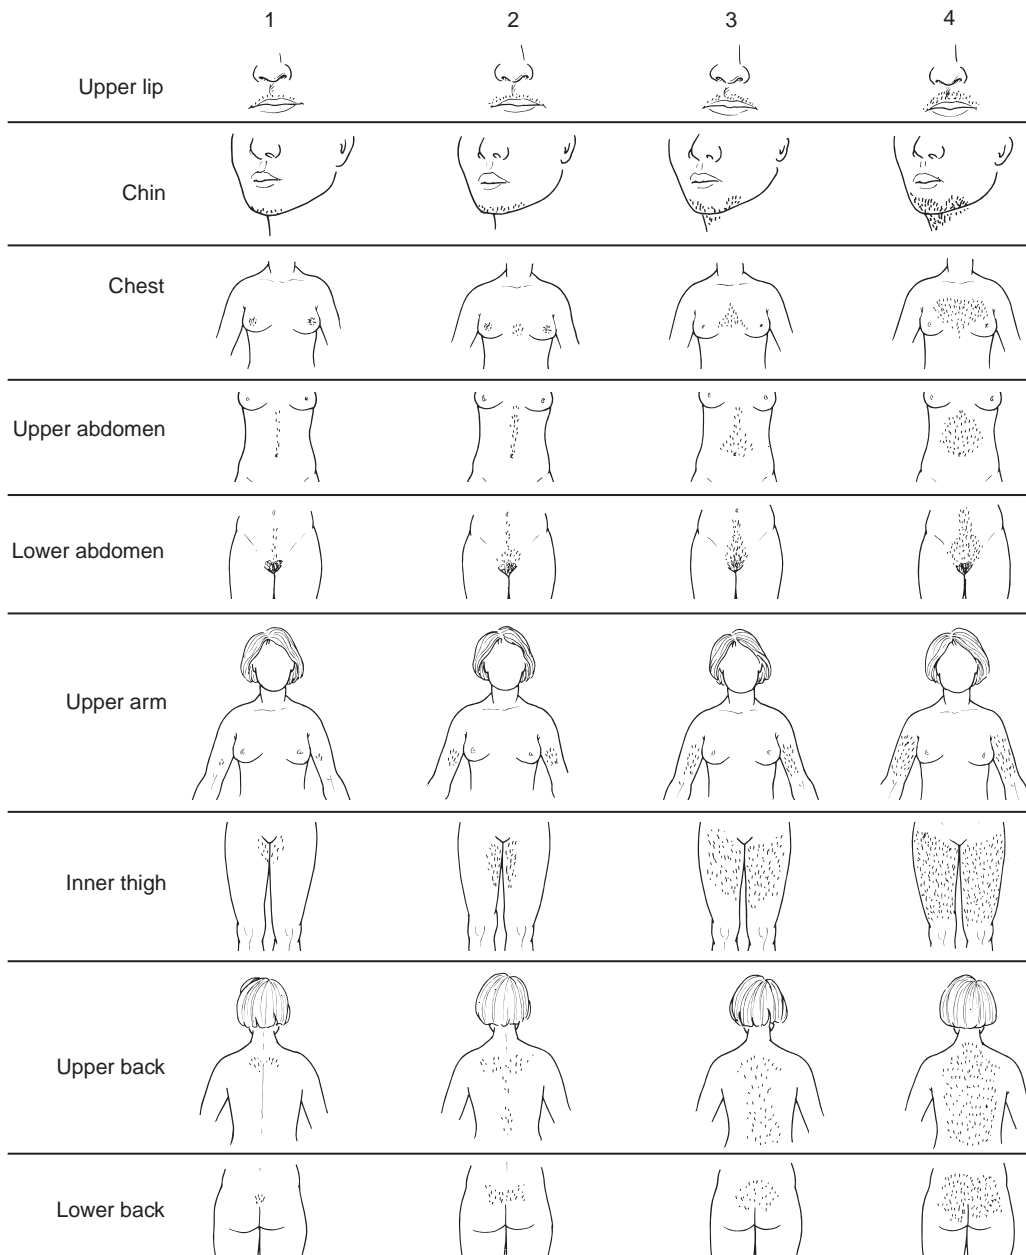

and extremities. Assessment of hirsutism is highly subjective, and it is recommended that a standard be applied when evaluating a patient for hirsutism. The modified Ferriman-Gallwey score is an objective scoring system used to determine hirsutism. In this system, hair from nine different body locations is scored on a scale of 1 to 4. No hair corresponds to a score of 0, and frankly virile hair corresponds to a score of 4. A score greater than 8 qualifies as hirsutism, but it is important to take into consideration normal ethnic and racial variations such as are found in women from southern European countries, who tend to have more and finer body hair (Curran and Moore, 2005). In this example, a high Ferriman-Gallwey score may not represent virilization, in which one would also expect to find deepening of the voice and clitoral hypertrophy in addition to hirsutism (eFigure 35-1).

True hirsutism is usually a sign of androgen excess in the form of testosterone, androstenedione, dehydroepiandrosterone (DHEA), DHEA sulfate (DHEA-S), or a combination. The most common causes of hirsutism are idiopathic and polycystic ovary syndrome. Other causes include congenital adrenal hyperplasia, 21-hydroxylase-deficient nonclassic adrenal hyperplasia, androgen-secreting tumors, ovarian tumors, hyperthecosis, adrenal tumors, hyperandrogenic insulin-resistant acanthosis nigricans syndrome, hyperprolactinemia, and androgenic drug intake (anabolic bodybuilding steroids) (Azziz, 2003).

Clinically, significant hirsutism (terminal, coarse hair in androgen-dependent areas) may be confused with hypertrichosis (diffuse increase in fine, vellus hair that is not androgen dependent). Hypertrichosis may be congenital or associated with other medical disorders such as hypothyroidism or anorexia nervosa or with certain medications (e.g., diazoxide, minoxidil, diphenylhydantoin).

The evaluation should begin with an appropriate history and physical examination focused on identifying possible signs and symptoms of disorders that may cause hirsutism. Patients should be asked about their ethnic background, age of onset, menstrual irregularities, hypertension, virilization, and pelvic masses. If evaluation to this point is unremarkable, proceed with testing of total and bioavailable testosterone levels, serum DHEA levels, and 24-hour urine sample for 17-ketosteroids. Ultrasonography, CT, or MRI will usually identify ovarian or adrenal masses. Treatment is unnecessary in mild cases except for strong patient preference. Cosmetic amelioration and destruction can be achieved by electrolysis, bleaching, laser, topical cream, or mechanical means. Hormonal suppression includes the use of oral contraceptives, long-acting gonadotropin-releasing hormone analogues, and insulin sensitizers. Peripheral androgen blockade can be achieved with spironolactone, flutamide, cyproterone acetate, or finasterid (Curran and Moore, 2005).

Low-dose steroids can be used to suppress androgen secretion in mild or late-onset congenital adrenal hyperplasia.

eFigure 35-1 Hirsutism scoring scale of Ferriman and Gallwey helps in determining whether the amount and location of body hair in a female patient are clinically significant in suspected hyperandrogenism. The nine body areas possessing androgen-sensitive pilosebaceous units (PSUs) are graded from 0 (no terminal hair) to 4 (frankly virile) and the sum totaled. Normal hirsutism score is less than 8. (Modified from Ehrmann DA, Barnes RB, Rosenfeld RL. Hyperandrogenism, hirsutism, and the polycystic ovary syndrome. In DeGroot LJ, Jameson, JL, eds. *Endocrinology*. 5th ed, vol 2. Philadelphia: Saunders; 2006.)

From Ehrmann DA, Barnes RB, Rosenfield RL. Hyperandrogenism, hirsutism, and the polycystic ovary syndrome. In DeGroot LJ, Jameson, JL, eds. *Endocrinology*. 5th ed, vol 3. Philadelphia: Saunders; 2006.

6% to 8% of women worldwide (Azziz et al., 2009). The definition of PCOS is constantly being revised. The latest Task Force on the Phenotype of the Polycystic Ovary Syndrome from the Androgen Excess and PCOS Society (AE-PCOS Society) defines PCOS by the presence of hyperandrogenism (clinical or biochemical), ovarian dysfunction (oligo-anovulation or polycystic ovaries), and the exclusion of related disorders (Azziz et al., 2009) (Table 35-20).

The typical presentation of PCOS includes hirsutism, menstrual dysfunction, obesity, insulin resistance, acanthosis nigricans, decreased fertility, and polycystic appearance to the ovaries. The onset of symptoms is usually around the time of menarche, but it may occur after puberty as a result of weight gain or other environmental factors. The differential diagnosis includes idiopathic hirsutism, ovarian hyperthecosis, ovarian tumor, adrenal tumor, nonclassic adrenal hyperplasia, Cushing syndrome, glucocorticoid resistance, and androgen-producing neoplasms.

A patient with PCOS is at higher risk for infertility, dysfunctional bleeding, obesity, endometrial hyperplasia, endometrial carcinoma, type 2 diabetes mellitus, dyslipidemia, hypertension, obstructive sleep apnea, and possibly CVD with a familial tendency (increased risk for mother and daughter) (Azziz et al., 2009; Ehrmann, 2005) (Table 35-21).

The diagnosis of PCOS is made with evidence of hyperandrogenism (clinical or biochemical), presence of ovarian dysfunction (clinical or anatomic), and excluding other conditions producing hyperandrogenism and ovarian dysfunction. Initial laboratory testing should include the determination of serum free testosterone, androstenedione, DHEA-S, and 17-hydroxyprogesterone. Other studies include prolactin, TSH, fasting glucose and insulin, and serum lipid profile. Obtaining circulating levels of LH and FSH does not contribute significantly to the diagnosis of PCOS, so these laboratory tests are not indicated with initial evaluation. Pelvic or transvaginal ultrasonography should

The Androgen Excess and PCOS Society criteria for the polycystic ovary syndrome: the complete task force report. *Fertil Steril*. 2009;91:456-488.

be performed to identify the ovaries and determine their size and shape and the presence of cysts; typical PCOS ovaries have increased volume and contain 10 to 12 subcapsular follicular cysts 2 to 9 mm in diameter.

Treatment of hirsutism and acne in PCOS focuses on decreasing androgen levels, production, and effects. Metformin is used extensively to reduce insulin resistance and hyperinsulinemia related to hormonal changes and ovulation (Nestler, 2008). To decrease the risk of endometrial hyperplasia and carcinoma, cyclic progestin or a combination OC should be considered to inhibit endometrial proliferation.

In the long-term management of PCOS, steps should be taken to reduce CV complications, diabetes, obesity, and psychosocial morbidities (Figure 35-9). Screening for glucose intolerance with a 75-g 2-hour FTT and determination of serum lipid levels (total cholesterol, LDL, HDL, triglycerides) should be carried out. Lifestyle management changes include weight loss, exercise, and use of metformin and thiazolidinediones for those individuals with abnormal GTT results. In addition, clinicians should consider cardiovascular risk reduction, psychosocial issues, management of subfertility and hirsutism, and other lifetime management with insulin sensitizers and protection of the endometrium with hormonal manipulations (Figure 35-9).

KEY TREATMENT

- Patients with PCOS require cardiovascular risk reduction, psychosocial counseling, management of subfertility and hirsutism, and possible insulin sensitizers and protection of endometrium with hormonal manipulations (Azziz et al., 2009; Ehrmann, 2005; Nestler, 2008) (SOR: A).

Disturbances in Calcium and Phosphate

Calcium homeostasis is a delicate balance among a number of organ systems and functions. These include the kidneys, thyroid, parathyroid, bone, adrenal glands, GI tract, nutrition, infectious disease, and medication. Malfunction in any of these modalities can result in hypercalcemia or hypocalcemia with the potential for serious morbidity and mortality. Total body calcium is balanced between plasma and the bony skeleton in a state of dynamic equilibrium. Approximately 1% of total calcium is in circulation, and the remaining 99% is stored in bone. In plasma, circulating calcium is approximately 40% protein (albumin) bound, 45% exists in an ionized state (Ca^{++}), and roughly 15% is found as various salts (calcium citrate, calcium lactate, calcium phosphate, and calcium sulfate). Bony calcium exists in an active state with constant deposition and resorption under the influence of parathyroid hormone (PTH, parathormone), calcitonin, osteoclastic and osteoblastic activity, and neoplastic disease.

The primary factor driving increases in circulating calcium is PTH, which increases bone resorption and converts vitamin D₃ (cholecalciferol) into 1,25-dihydroxycholecalciferol, the active form of vitamin D₃. Cholecalciferol is primarily formed in the skin from solar irradiation, and some evidence suggests that ultraviolet radiation exposure

of tanning beds can raise vitamin D levels. However, the latter is not recommended as an appropriate source of vitamin D₃ (Tangpricha et al., 2004). Dietary sources of vitamin D₃ are also important and can be obtained from fortified milk, fruit juices, fish oil, and other sources. The active form of vitamin D₃ is required to facilitate calcium absorption from the gut. Calcium homeostasis is further maintained by circulating levels of ionized calcium and calcitonin's negative effect on osteoclastic bone resorption (Guyton and Hall, 2006) (Figure 35-10).

Normal levels of total circulating calcium, with normal albumin levels, range between 8.5 and 10.5 mg/dL (≈ 2.4 mmol/L). Ionized levels, which are not albumin dependent, will range between 1.17 and 1.33 mmol/L (≈ 4.7 mg/dL) (Brighurst and Leder, 2006).

HYPERCALCEMIA

Causes of hypercalcemia are generally divided into two types: primary and secondary. Primary causes are due to excessive parathormone secretion, and secondary causes include disease processes that directly affect bone metabolism and calcium excretion. The most common cause of primary hyperparathyroidism (PHPT) is a solitary parathyroid adenoma, accounting for approximately 80% of cases. Multiple adenomas are found in 2% to 4% of cases. The second most common cause of PHPT (15%) is parathyroid hyperplasia of multiple (usually ≥ 4) parathyroid glands.

The etiologies for these include a mix of congenital and familial diseases such as MEN-I and MEN-IIA. Fewer than 1% of cases of PHPT are caused by primary parathyroid malignancy (Silverberg and Bilezikian, 2006) (Table 35-22).

Primary hyperparathyroidism does not present with classic symptoms. Symptoms may be as nonspecific as generalized weakness in the proximal muscles, fatigue, headache, weight loss, and constipation all the way to being as profound as renal failure, hypovolemic shock, and death (usually in patients with malignancy but sometimes previously undiagnosed). Patients rarely present with signs and symptoms immediately suggesting hypercalcemia. PHPT is

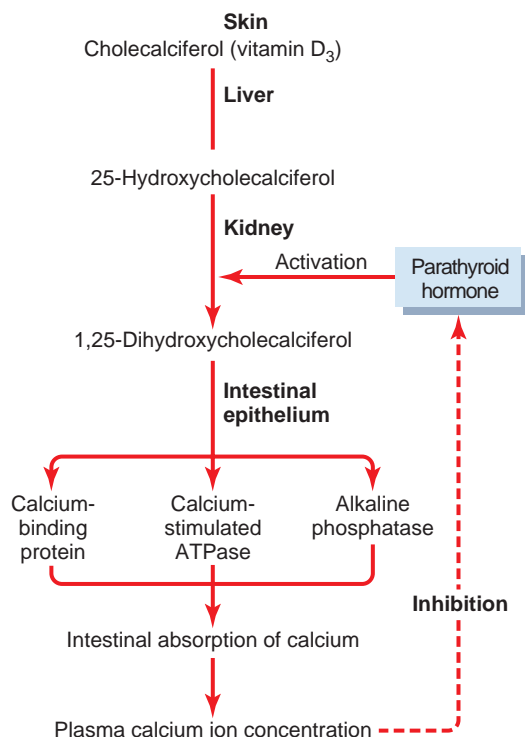

Figure 35-10 Pathway for conversion of vitamin D₃ into its active form (1,25-dihydroxycholecalciferol) and the role vitamin D plays in control of plasma calcium concentration. (From Hall JE. Parathyroid hormone, calcitonin, calcium and phosphate metabolism, vitamin D, bone, and teeth. In Guyton AC, Hall JE, eds. *Textbook of medical physiology*. 12th ed. Philadelphia: Saunders; 2011.)

usually uncovered through routine, nonspecific screening laboratory tests; during evaluation for nephrolithiasis; or, occasionally in a patient with accelerated osteoporosis and pathologic fracture (Silverberg and Bilezikian, 2006) (Table 35-23).

There is a classic “quadrad” of symptoms associated with hypercalcemia that, although seen in many disease processes, may be helpful in a patient with hypercalcemia, irrespective of etiology. The mnemonic is “bones, stones, moans, and abdominal groans,” representing the four symptoms of the classic quadrad, which are bone pain, renal calculi, psychiatric disorder, and nausea and vomiting (Silverberg and Bilezikian, 2006).

The primary dysfunction in PHPT is an excess of circulating PTH. However, with bony metastases, PTH levels will be appropriately suppressed in the presence of elevated serum calcium levels because of osteolytic metastases. When the cause of hypercalcemia is malignancy, the patient usually has a history; an exception is unsuspected multiple myeloma, which may present with chronic low back pain and an elevated serum calcium level. Calcium levels in malignancy are typically higher (>14 mg/dL) than those

found with parathyroid adenomas (<13 mg/dL), although this is not always the case.

Thiazide diuretics, lithium, and calcium carbonate are common medications seen in primary care that, if not properly monitored and prescribed, can result in hypercalcemia. It is also important to inquire about nonprescription medications (OTC) because excess vitamin D (intoxication) can be a cause. If a patient is taking any of these substances, the patient is asymptomatic, and the serum calcium level is less than 14 mg/dL, the approach is to discontinue the medication and repeat the calcium level in 1 week. If the serum calcium is stable or declining, continue to monitor it until it returns to normal. Occasionally, adrenal insufficiency and hyperthyroidism are uncovered in the evaluation of a patient with an elevated serum calcium level.

Patients who have symptoms consistent with hypercalcemia or serum calcium levels in excess of 13.5 mg/dL may

require more aggressive treatment. These patients will almost always be volume depleted as a result of hypercalcemia with resultant polyuria. Treatment is aimed initially at aggressive rehydration. Isotonic saline, at the rate of 2 to 4 L/day until the calcium level returns to normal, is appropriate. Furosemide (loop diuretic) can be used in conjunction with fluid replacement in older patients and those with renal or cardiac disorders to prevent fluid overload. Careful fluid management must be maintained to prevent inadvertent fluid overload or depletion. Other treatments include IV bisphosphonate, calcitonin, and gallium nitrate or plicamycin (Tables 35-24 and 35-25).

Parathyroidectomy is indicated in symptomatic patients and is considered to be the first and generally the only option to cure PHPT. In addition, surgical treatment is recommended for asymptomatic patients who meet any of the following conditions: serum calcium more than 1 mg/dL or more above the upper limit of normal,

Table 35-24 Summary of the Most Generally Useful Medical Therapies for Hypercalcemia

Treatment	Onset of Action	Duration of Action	Advantages	Disadvantages
Rehydration	Hours	During treatment	Rapid action Rehydration invariably needed	None
Forced saline diuresis (with or without loop diuretics)	Hours	During treatment	Rapid action	Modest calcium-lowering effect Potential for volume overload Electrolyte disturbance Transient efficacy Inconvenient for patients
Calcitonin	Hours	1-2 days	Rapid action	Modest calcium-lowering effect Tachyphylaxis develops in a few days
BISPHOSPHONATES				
Etidronate	1-3 days	5-7 days	First-generation bisphosphonate Well tolerated	3-day infusion protocol Less effective than other bisphosphonates
Pamidronate	1-2 days	Weeks to months	Second-generation bisphosphonate Normalizes calcium levels in many patients	Fever Occasional hypocalcemia, hypophosphatemia, and hypomagnesemia
Zoledronate	1-2 days	Weeks to months	Third-generation bisphosphonate More potent than second-generation bisphosphonates Normalizes calcium levels in 90% of patients Can be given in 30 min	Fever Hypophosphatemia Hypocalcemia Renal toxicity occasional

Table 35-25 Summary of Therapies for Hypercalcemia Useful in Special Circumstances

Treatment	Onset of Action	Duration of Action	Advantages	Disadvantages
Gallium nitrate	5 days	7-10 days	May normalize calcium in patients resistant to bisphosphonates	Must be infused continuously over 5 days Occasional nephrotoxicity or hypophosphatemia
Glucocorticoids	Days	Days to weeks	Oral administration	Effective in granulomatous disorders and certain types of malignancies, especially hematologic
Dialysis	Hours	During use and for 24-48 hr afterward	Rapid onset of action Useful in patients with renal failure and heart failure Useful to treat life-threatening hypercalcemia	Complex procedure Reserved for extreme or special circumstances
Oral phosphate	24 hr	During use	Minimal toxicity if serum phosphate low Oral administration	Modest calcium-lowering effect Diarrhea

From Finkelstein JS, Potts JT. Medical management of hypercalcemia. In DeGroot LJ, Jameson, JL, eds. *Endocrinology*. 5th ed, vol 2. Philadelphia: Saunders; 2006.

creatinine clearance less than 60 mL/min, osteoporosis, and age younger than 50 years (Bilezikian et al., 2009; Silverberg and Bilezikian, 2006).

For patients who have failed surgery and those who do not meet surgical criteria, medical treatment includes calcimimetics (cinacalcet), moderate calcium intake, estrogen replacement (when applicable), bisphosphonates, and selective estrogen receptor modulators (SERMs) (Bilezikian et al., 2009; Silverberg and Bilezikian, 2006).

For a patient with PHPT not caused by malignancy, determining if there is one adenoma or multiple functioning adenomas and the location(s) is important in minimizing both the duration and extent of surgery. It is possible to determine preoperatively which parathyroid gland(s) may be the source of the PTH using technetium-labeled (Tc-99m) sestamibi nuclear scan. If the latter did not provide definitive results, then ultrasonography, CT, or MRI may be used to localize the adenoma (Silverberg and Bilezikian, 2006).

HYPOCALCEMIA

Hypocalcemia has a number of primary and secondary causes. Primary causes are due to some defect in PTH availability, including (1) a lack of production (surgical removal of the parathyroid gland or hypoparathyroidism due to autoimmune disease), (2) impaired secretion (with profound hypomagnesemia), and (3) end-organ resistance. With the first two, there is a deficit in circulating PTH, but with the third, the PTH is elevated, in contrast to a low serum calcium level and hypophosphatemia. An example of end-organ resistance is Albright syndrome. Secondary causes include severe vitamin D deficiency, “hungry bone syndrome” with chondrosarcoma, and HIV/AIDS (Table 35-26).

Signs and symptoms of hypocalcemia are generally lacking in the outpatient setting. The primary clinical findings are caused by neuromuscular irritability. If hypocalcemia is suspected, two physical tests can be performed, which may help to make the diagnosis, although negative responses do not rule out hypocalcemia: the Chvostek sign (tapping the facial nerve across the cheek with contraction of the facial muscle) and Trousseau sign (carpal spasm via a BP cuff). Deep tendon reflexes may be hyperactive, and the patient may appear anxious, confused, demented, or psychotic. The signs and symptoms of hypocalcemia are related to the level of ionized calcium rather than total calcium, as well as the rapidity of decline (Levine, 2006). Alkalosis, either primary or compensatory, can cause a shift in ionized calcium to a bound state, thus exacerbating a borderline hypocalcemia situation.

Cardiac changes caused by hypocalcemia include prolongation of the QT interval, resulting in life-threatening dysrhythmia and cardiac dysfunction. Generalized seizures are also possible. The cardiac dysfunction is generally reversible with normalization of the ionized calcium levels. In acute and severe cases, IV calcium is the treatment of choice. Concurrent management of hyperphosphatemia, alkalosis, and hypomagnesemia is required. Long-term management is with oral calcium and vitamin D. Although use of thiazide diuretics is contraindicated in patients with hypercalcemia, they can be used with hypocalcemia and may, in

fact, have somewhat of a beneficial effect. On the other hand, loop diuretics must be used very cautiously because they increase renal excretion of calcium and may exacerbate the problem.

Pseudohypoparathyroidism is a rare phenomenon representative of several congenital, endocrinologic disorders in which tissue resistance to PTH is present. The classic form of this disorder is *Albright hereditary osteodystrophy* (AHO). Patients with AHO have short stature, mental retardation, brachydactyly, and PTH resistance (elevated PTH levels). Another form of AHO, called pseudopseudohypoparathyroidism, does not have PTH dysfunction. Although the clinical course for these diseases may be variable and, in some cases, is protracted, AHO usually is associated with a shortened life expectancy. Treatment is primarily supportive (Levine, 2006).

HYPERPHOSPHATEMIA

The most common cause of hyperphosphatemia, and most familiar to primary care physicians, is impaired renal function. It is also a characteristic of all forms of hypoparathyroidism from the loss of inhibitory effect of PTH on phosphate reabsorption at the proximal renal tubule (Kolon et al., 2004). High-phosphate formula provided to infants can result in hypocalcemia and tetany (Table 35-27).

HYPOPHOSPHATEMIA

Dietary causes of hypophosphatemia are virtually nonexistent, although excessive use of oral phosphate binders (aluminum and magnesium hydroxide antacids) can result in binding of phosphate in the intestine, thus preventing absorption. Generally, when use of oral antacids is excluded, the most common cause of hypophosphatemia is elevated levels of serum calcium caused by increased PTH or malignancy (Silverberg and Bilezikian, 2006). Hypophosphatemia, in association with hypocalcemia, is usually attributable to renal wasting or seen in severe illness. One form of infant hypophosphatemic rickets is transmitted as an autosomal dominant trait (Table 35-28).

35-8 Osteoporosis and Osteomalacia

Skeletal mass peaks around the beginning of the third decade of life, after which calcium deposition decreases steadily with advancing age. By the fifth decade of life, this process is occurring at a rate of approximately 4% per year (Perry, 2006).

With age, bone structure changes, and the direction of the change depends on which process is involved. Paget disease of the bone is caused by abnormal bone formation; loss of trabecular bone leads to osteoporosis; and loss of bony substrate causes osteomalacia. A number of factors can impact significantly on these processes, both positively and negatively. Some are controllable and some not. Those that are controllable include decreased physical activity, decreased calcium intake, decreased sun exposure (less available vitamin D₃), smoking, and excessive alcohol use. In addition, changes in circulating levels of testosterone and estrogen, thyroxine, growth hormone, parathormone, and calcitonin can also have dramatic effect on bone metabolism. Iatrogenic causes such as use of exogenous steroids or excess thyroid hormone replacement and vascular disorders such as vasculitis and peripheral vascular disease are also important (Perry, 2006).

Pharmacologic treatments of bony demineralization, including calcitonin via nasal inhalation; parathormone via injection; oral selective estrogen receptor modulators, either oral or injectable bisphosphonates; and monoclonal antibodies such as denosumab, are all effective, albeit used in different clinical situations. It was once thought estrogen replacement therapy (HRT) was a good treatment for osteoporosis, but this has become less acceptable because of other, more significant, negative aspects to HRT. Testosterone has been shown to slow, and even reverse, bone loss in hypogonadal men.

Although the majority of demineralization of bone is a process of aging, there are some instances in which hormonal abnormalities can be the cause, so a careful review of the patient's history and symptoms and an occasional laboratory analysis in select cases is required. To monitor adequacy of treatment, bone density studies are the method of choice (Perry, 2006).

Osteoporosis in Men

Osteoporosis is a major public health problem affecting all ages, populations, and ethnic groups as well as both genders. Although a man's androgens do not wane abruptly, as occurs in menopause, men still experience clinically significant effects of osteoporosis with aging as a result of a

declining bioavailable testosterone and estrogen levels. However, the risk of fracture rises in men 5 to 10 years after women (Orwoll, 1998).

The lifetime risk of nontraumatic fracture in a 60-year-old man is 25.6%, and the cumulative lifetime hip fracture risk is 17%, which carries with it a 20% first-year mortality rate (Nguyen et al., 1996). The mortality rate of older men with hip fractures is higher than that of women (Myers et al., 1991).

Approximately 90% of men with a high likelihood of osteoporosis are not investigated. About 50% of men with osteoporosis have risk factors and conditions contributing to their osteoporosis other than advancing age. These common, underlying risk factors include hypogonadism, hyperthyroidism, gastrointestinal disorders, anticonvulsant medications, excess alcohol intake, hypercalciuria, immobilization, and glucocorticoid therapy representing the most common underlying risk factors. Pharmacologic therapies such as bisphosphonates and parathyroid hormone are possible options for treatment.

The American College of Physicians recommends; clinicians periodically assess older men for osteoporosis risk factors and obtain dual-energy x-ray absorptiometry for men at increased risk of osteoporosis (Qaseem et al., 2008). Primary treatment is supplemental calcium and vitamin D (Watts et al., 2010).

KEY TREATMENT

- Estrogen replacement therapy (HRT) is no longer considered first-line therapy for women with osteoporosis because of significant cardiovascular risk (Anderson et al., 2004) (SOR: A)
- Supplemental calcium and vitamin D are first-line therapy for prevention of osteoporosis (Watts et al., 2010) (SOR: A).
- Lifestyle changes effective in prevention of osteoporosis include resistance and high-impact exercise throughout life and smoking cessation (Watts et al., 2010) (SOR: B).
- Bisphosphonates and denosumab are currently considered first-line therapy for osteoporosis (Watts et al., 2010) (SOR: A).
- Parathormone and selective estrogen receptor modulators are generally second-line therapies for osteoporosis (Watts et al., 2010) (SOR: A).
- Calcitonin is the last line of therapy for osteoporosis (Watts et al., 2010) (SOR: C).
- Primary treatment is supplemental calcium and vitamin D₃ (Watts et al., 2010) (SOR: A).

Intervention, 881

Summary, 890

Overview

Key Points

- The prevalence of obesity is a global concern.
- Obesity leads to increased health risks.
- Obesity is associated with increased economic burden on a nation's health care system.

The prevalence of obesity is a growing health concern globally (Swinburn et al., 2011). For the United States, data reported from the ongoing National Health and Nutrition Examination Survey (NHANES) suggest that more than one third of adult men and women age 20 years or older (35.7%, 78 million) and almost one fifth of young people age 2 to 19 years (17.9%, 12.5 million) are obese (Ogden et al., 2012, 2013). Overall, older adults (≥ 60 years), particularly older women, are more likely to be obese than younger adults. Among young people, a greater proportion of boys was found to be obese compared with girls (Ogden et al., 2012).

The high prevalence of obesity is of concern from several perspectives. Being obese increases the risk for developing chronic disorders such as heart disease, stroke, hypertension, type 2 diabetes, and some cancers, which in turn impairs an individual's quality of life. The economic burden to the United States of having a large percentage of the population with obesity can be measured in direct and indirect costs. The direct costs for obesity-related services such as inpatient and outpatient care, medical tests, and drug therapy have been reported to be \$190 billion per year, with a per capita medical spending of \$2741 higher (in 2005 dollars) for obese individuals than for those who are not obese (Cawley and Meyerhoefer, 2012). Indirect costs caused by workplace absenteeism, lost economic productivity, and higher insurance premiums are more difficult to estimate but are widely considered to be of equal concern (Dall et al., 2009).

A 2012 report projects that, over the next two decades, the prevalence of obesity in the United States will increase by 33% and 130% for severe obesity (Finkelstein et al., 2012). Just holding obesity prevalence at the 2010 level is estimated to save \$549.5 billion in obesity-related direct

medical costs alone. Family medicine physicians are well positioned to assist patients in attaining and maintaining a desirable weight. However, effective strategies and tools are needed. This chapter explores the approaches to caring for patients with excess weight and proposes a functional medicine approach to healthy weight management.

Defining Obesity

Key Points

- Obesity is derived differently for adults and children.
- In adults, obesity is defined as a body mass index (BMI) of 30.0 kg/m² or greater.
- Adult obesity is further categorized as class I, BMI of 30.0 to 34.9; class II, BMI of 35.0 to 39.9; and class III, BMI of 40.0 or greater.
- In children, obesity is defined as weight exceeding the 95th percentile on standard growth charts.

The BMI is derived from height and weight and expressed in kg/m². BMI is a convenient measurement used worldwide. For adults, BMI is age independent and the same for both sexes. In the United States, adults with a BMI of 18.9 to 24.9 are considered to be of normal weight. Overweight is a BMI of 25.0 or greater but less than 30.0, and obesity is defined as a BMI of 30.0 or greater. The World Health Organization (WHO) subdivides obesity into three classes according to BMI: 30.0 to 34.9 for class I, 35.0 to 39.9 for class II, and 40.0 or greater for class III, often referred to as extreme obesity (WHO Global Database, 2013) (Table 36-1).

In contrast to adults, weight for children varies with height but also age and sex. Growth charts issued in 2000 by the Centers for Disease Control and Prevention (CDC) for U.S. children provide sex- and age-specific reference values and allow determination of a BMI percentile (CDC, 2000; Kuczmarski et al., 2002). Obesity is defined as a BMI percentile at or greater than the 95th percentile on the sex-appropriate growth chart, and overweight is between the 85th and 95th percentiles (Krebs et al., 2007; Ogden and Flegal, 2010). Additional approaches to assessing the composition of the body mass of overweight and obese patients are discussed in the Assessment section.

Table 36-1 Classification and Types of Obesity

Class	BMI
I	30.0-34.9
II	35.0-39.9
III	≥40.0

Determinants of Obesity

Key Points

- A number of factors have been found to affect weight regulation, including genes and their epigenetic modifications; maternal weight during pregnancy; metabolic imbalances; and environmental factors, including food intake, movement and physical activity, sleep, psychosocial stress, toxin exposure, and microbiome composition.
- These factors can provide leverage points for successful weight regulation.

Many factors contribute to a person's susceptibility to becoming overweight or obese (Barabas, 2007; NHLBNA, 2000). Overconsumption of calories and insufficient physical activity are two common contributors to weight gain, but several additional factors appear to be at play as well, including the quantity and quality of calories consumed; genetics and epigenetics; mother's weight gain during pregnancy; inadequate amount and quality of sleep; a wide variety of psychosocial stressors; exposure to environmental toxins; and the composition of the various body cavities in which microbiota exist, such as the intestinal, vaginal, respiratory, and oral cavities. Increasingly, no one component appears to be solely responsible for obesity. Rather, interactions among our genome, epigenome, and environment throughout our lifespan mutually influence weight regulation.

GENES AND THEIR EPIGENETIC MODULATION

There is general confusion as to contribution of genes in terms of developing obesity. A certain percentage is often assigned to the contribution of genes. This percentage reflects the balance between the relative contribution of genes and environment in the risk of someone becoming overweight or obese. It appears that the susceptibility for becoming obese is a continuum ranging from highly likely to highly unlikely, depending on one's particular genome (set of genes). Each of us has our individual genetic susceptibility with respect to becoming obese. There are genes that, when mutated, provide a high risk for developing obesity, even under environmental conditions that promote normal weight. These genes would contribute to the 100% (high risk) end of the spectrum. Fortunately, the prevalence of these genes appears to be rare, so only a minority of people have such a high risk for obesity. The vast majority of us appear to have a number of mutations (genetic variations) whose contributions are not strong enough in

themselves to lead readily to obesity, but when these variants interact with particular environmental factors, the chance for weight gain increases. In this case, genetics would fall at the low-risk end of the spectrum, and the influence of the environment would fall towards the high end. It's the extent of interaction among various genes and environmental factors that appears to determine our susceptibility to gain and maintain excess weight.

Severe early-onset obesity results from a strong genetic influence on weight regulation and is typically accompanied by hyperphagia. In this case, single gene mutations (monogenic obesity) have been identified that, when present, tend to result in obesity that manifests in childhood. Although the genetic influence is much stronger than the environmental influence, excessive consumption of calories and insufficient physical activity can further exacerbate the situation. Examples of genes that have been identified as conferring a high risk for early-onset obesity include leptin (*LEP*) and the leptin receptor (*LEPR*) (Dubern and Clement, 2012), proopiomelanocortin (*POMC*) (Raffin-Sanson et al., 2003), and melanocortin-4 receptor (*MC4R*) (Panaro and Cone, 2013). These genes are collectively referred to as the leptin–POMC–melanocortin axis, a major hypothalamic circuit controlling energy homeostasis and food intake.

More recently, a number of gene variants have been described that, in the presence of an obesogenic environment, can promote overweight and obesity. These variants may influence any of the key components that factor into weight regulation, such as appetite control, energy metabolism, or physical activity, and interact with environmental factors such as dietary fats or carbohydrates. Examples of such variants include those that promote an increased absorption of dietary fat (e.g., *FABP2*); those involved with increased storage of fat in adipocytes (e.g., *ADRB2*, *ADRB3*); those that regulate transcription of key genes (e.g., *PPARG2*, *TCF7L2*); those that uncouple energy metabolism (e.g., the *UCP* gene family); and genes such as *FTO*, which is the most common weight-associated variant but whose function is not yet understood. Numerous other variants are being investigated for their role in weight regulation, including variants of genes involved with circadian rhythm (*CLOCK*, *REV-ERB-ALPHA*), which affect feeding behavior and weight regulation (Garaulet et al., 2013a, 2013b). Abete and colleagues (2012) provide a current review of the spectrum of genetic mutations associated with weight management.

Several of these variants form the basis of the weight management genetic tests that are presently on the market. However, these variants represent only a fraction of the many genes that are involved in the myriad of underlying biochemical mechanisms that can lead to obesity. As research continues to explore the numerous genes involved in all aspects of excessive weight, many more gene variants that influence weight management are expected to be identified.

Learn more about epigenetic regulation in [eAppendix 36-1](#) online.

METABOLIC IMBALANCES

The adipocyte does more than store fat for future energy needs. It is a major endocrine organ that has a profound

36-1 *Epigenetic Regulation*

Various environmental factors contribute to excess weight. Studies appear regularly that describe gene–environment interactions that influence individuals’ phenotypes. Although our understanding of the underlying molecular mechanisms involved is still in the early stages, several intriguing findings have emerged. Perhaps the most intriguing is the finding that at least some, and likely most, environmental factors act epigenetically. Epigenetics relates to a set of instructions that influence gene expression without changing the nucleotide structure of the DNA so that the information expressed is not altered; only the ability to express the information is altered. One of the better understood mechanisms is the modification of DNA and histone proteins through the covalent attachment of chemical groups, which can activate or silence gene expression. Two of the more common types of modification involve the attachment (activation of expression) or removal (silencing of expression) of acetyl groups to the histone proteins around which DNA is wound in its compressed (nontranscriptional) state. Attachment of acetyl groups allows the

DNA to relax and transcription to proceed. Removal leads to compression of the DNA into a tight coil, effectively blocking the transcription process. A second common mechanism is the attachment of methyl groups directly to the DNA, which silences the expression of the associated gene. These epigenetic “markings” or “tags” are responsible for tissue-specific gene expression. In some cases, epigenetic modification of DNA expression, either histone or DNA modification, is inherited transgenerationally. MicroRNA (miRNA) represents a third type of mechanism by which small sequences of noncoding RNA bind to the messenger RNA (mRNA) that contains the information that will direct the amino acid sequence of the protein being synthesized. Binding of miRNA to mRNA prevents translation of the message into protein, thereby controlling the amount of the protein synthesized. This mechanism is also cell type specific. Research into miRNA’s influence on exercise-induced gene expression with human subjects, although limited at present, suggests that miRNA may be a contributing factor in epigenetic influence on weight regulation.

impact on the metabolism of other tissues, the regulation of appetite, insulin sensitivity, immunologic responses, and the risk of vascular disease (Ali et al., 2013). Adipocytes secrete multiple inflammatory cytokines such as interleukin-6 and tumor necrosis factor α , which can lead to increased systemic chronic inflammation. Weight gain furthers inflammation in the body, and when inflammation is present, losing weight is more difficult. Visceral adipose tissue is particularly active metabolically. Insulin resistance, present in the cardiometabolic syndrome (characterized by elevated waist circumference, low high-density lipoprotein cholesterol, elevated triglycerides, elevated blood pressure, and elevated blood sugar), is strongly associated with visceral adiposity. When insulin levels are high, as is the case in insulin resistance, the body is more likely to store calories. Weight gain in the abdominal area is associated with elevated insulin levels and inflammation. The elevated insulin levels can increase hunger levels and make it more difficult for a patient to lose weight. The interconnectivity of these metabolic factors promotes a vicious cycle that can make achieving a healthy weight difficult.

Other hormones influence weight and need to be considered when evaluating patients for weight gain and obesity. Hypothyroidism can result in weight gain. Other signs and symptoms of hypothyroidism include hair loss and hair thinning, cold intolerance, constipation, depression, arthralgias, elevated low-density lipoprotein cholesterol, dry skin, fatigue, memory impairment, menorrhagia, myalgias, and weakness (Gaitonde et al., 2012). Weight gain also influences hormone levels in the body. Estrogen can be produced in the adipocyte through the action of the enzyme aromatase. As an individual's percentage of body fat increases, dehydroepiandrosterone (DHEA) and testosterone are converted into estrogen by aromatase in adipose tissue. For men, this conversion can result in a lower testosterone level. This hormonal change has been associated with estrogen-related cancers, such as breast cancer, prostate cancer, and endometrial cancer (Williams, 2010).

MATERNAL WEIGHT DURING PREGNANCY

Maternal prenatal weight and weight gain during pregnancy have been associated with weight issues for the infant during childhood. A mother's prepregnancy weight and weight gain during pregnancy may also influence her children's weight. In a meta-analysis in which 45 studies met the researchers' selection criteria, Yu and coworkers (2013) found that children of mothers who were overweight or obese before pregnancy had a significantly increased risk of being overweight or obese during childhood. In a meta-analysis of 12 studies, Tie and colleagues (2014) found a significant association between excessive gestational weight gain and childhood overweight and obesity. Similarly, children of mothers who had gestational diabetes during pregnancy were found to have an increased risk of being overweight or obese later in life (Nehring et al., 2013). Undernutrition during pregnancy has also been associated with an increased risk of weight gain in children born to these mothers (Cunha et al., 2013). These reports suggest that maternal nutrition during pregnancy may be an important factor in weight management of offspring. Other contributing factors that should also be considered include

features of infant feeding, the overall nutritional sufficiency during childhood, and how health promoting the eating patterns are within the home.

ENVIRONMENTAL FACTORS

Food Intake

Over the past 40 years, the tendency in the U.S. population has been to consume more calories than needed. Per capita consumption of calories increased from 2200 kcal in 1970 to 2680 kcal in 1997 (Putnam, 2000). Increased portion sizes, the energy density of today's commonly eaten foods, and the trend in consuming meals outside the home where food portions tend to exceed standard serving sizes all contribute to the increase in calorie consumption. Satiety helps determine food intake and is partially determined by the volume and weight of the food consumed. Foods that are high in calorie content for a given volume, such as highly processed, low-fiber foods, can lead to excessive calorie intake.

It is important to recognize that the reasons a person gains or loses weight are not always simple. In a laboratory setting, 3500 calories equals 1 lb, and so it has been assumed that if a person consumes 3500 fewer calories than his or her body requires, they will lose 1 lb. In the office setting, this calculation does not always hold, and it is important to recognize and accept this when working with patients. Why does someone overeat? Many factors contribute to overeating, including stress, boredom, nutritional insufficiencies, emotional lability, access to food, and the changing of our diet to one that is highly processed. In a randomized, blinded crossover design study by Lennerz and colleagues (2013), overweight or obese young men age 18 to 35 years ate test meals that differed only in glycemic index (GI). The high-GI meal contained rapidly digested carbohydrate; the low-GI meal contained slowly digested carbohydrate (see [Glycemic Index and Glycemic Load](#)).

Plasma glucose, serum insulin, and hunger were monitored after each test meal and compared between those who ate the high-GI meal and those who ate the low-GI meal. After the low-GI meal, plasma glucose initially rose and by 1 hour had dropped to a relatively steady plateau over the next 3 hours. In those who ate the high-GI meal, plasma glucose initially surged and then dropped steeply over the next 3 hours to a level lower than seen with the low-GI meal. A similar pattern was seen with serum insulin levels. At the 4-hour mark, subjects who had eaten the high-GI meal reported greater hunger, and brain imaging showed intense activation of the nucleus accumbens, the brain region considered "ground zero" for conventional addiction (e.g., involving drug abuse or gambling). Remarkably, every subject who ate the high-GI meal responded in exactly the same way on the brain scans, producing extremely strong confidence in the results ($P < 0.001$).

This study showed that highly processed carbohydrate foods can cause food cravings in susceptible individuals, providing qualified support for the notion of "food addiction." The findings suggest that limiting consumption of highly processed carbohydrates, such as white bread, white rice, white potato products, and products with concentrated sugar, could help weight gain-prone individuals avoid overeating.

Glycemic Index and Glycemic Load

- Two values are commonly used to describe how rapidly a food or meal is digested. The GI value of a food is measured by the rise in blood glucose after consumption of 50 g of that food. This is then compared with the rise in blood glucose after consumption of 50 g of sugar. Carbohydrates that break down quickly have high GI values. Carbohydrates that break down slowly have low GI values.
- The glycemic load describes the rise in blood glucose after an edible portion of that food is consumed along with other foods. For example, carrots may have a high GI, but because it is very difficult to consume 50 g of carbohydrate from carrots, they have a low glycemic load.
- Examples of foods with high GIs include candy, soda, and fruit juice. Broccoli is an example of a food with a low GI. A meal with a high glycemic load would be pancakes with syrup and orange juice; fish with $\frac{1}{2}$ cup of brown rice and 2 cups of mixed greens would be a meal with a low glycemic load.

Movement and Physical Activity

In a recent review, [Denham et al. \(2013\)](#) summarized the ability of physical activity to influence epigenetic modifications of histones or DNA in the brain, skeletal muscle, and peripheral blood. Aerobic exercise over many weeks was the primary variable studied that led to activity-induced benefits. Several of the studies found benefits with 30 minutes of daily moderate activity.

Yoga also appears to be an effective type of movement activity for improving weight, mental well-being, and health in general. In a narrative review of yoga intervention clinical trials, [Rioux and Ritenbaugh \(2013\)](#) reported that overall therapeutic yoga programs were effective in reducing body weight and improving body composition. A community-based 12-week yoga and Pilates program was found to be helpful for weight loss in postpartum women ([Ko et al., 2013](#)). In a small 8-week randomized controlled trial of 20 obese adolescent Korean boys, yoga was found to significantly decrease body weight, BMI, body fat mass, and percentage of body fat and to significantly increase fat-free mass and basal metabolic rate ([Seo et al., 2012](#)). Although the trends appear positive in terms of yoga's health benefits, larger controlled trials are needed to explore the full potential of yoga for health promotion.

Sleep

There is an association between too little or too much sleep and overweight and obesity. In a survey of more than 54,000 U.S. adults age 45 years or older, sleeping too little (≤ 6 hours) and sleeping too much (≥ 10 hours) were significantly associated with obesity ([Liu et al., 2013](#)). Throughout the life cycle, a short sleep duration is independently associated with weight gain ([Gillman and Ludwig, 2013](#); [Patel and Hu, 2008](#)). When sleep duration and BMI were followed for 7.5 years in more than 83,000 U.S. adults age 51 years or older, researchers found an inverse relationship between the length of sleeping and BMI ([Xiao et al., 2013](#)). Sleep deprivation is associated with elevated ghrelin, elevated cortisol, elevated insulin, decreased leptin, and increased hunger ([Patel and Hu, 2008](#)). These hormonal

changes are associated with weight gain and can result in less than expected weight loss in patients who are sleep deprived, even when they are restricting their caloric intake ([Nedeltcheva et al., 2010](#)). In a longitudinal study of adolescents, sleep duration and BMI were followed at 6-month intervals between age 14 and 18 ([Mitchell et al., 2013](#)). Shorter sleep duration was associated with greater BMI. [Mesarwi and colleagues \(2013\)](#) found a correlation between short duration of sleep, obesity, and type 2 diabetes and recommended assessing sleep quantity and quality during patient visits.

We must assess our patients' sleep when addressing weight gain and obesity. In addition, we must be alert to signs of obstructive sleep apnea (OSA) because this process is proinflammatory. Patients with OSA have higher inflammatory markers than BMI-matched individuals without OSA ([Steiroopoulos et al., 2010](#)). Insulin resistance, type 2 diabetes, obesity, and weight gain are frequently associated with sleep apnea, which can result from weight gain and can also cause weight gain through the increase in inflammation and changes in metabolism that result from inadequate sleep ([Alam et al., 2007](#)). Signs and symptoms of sleep apnea include elevated blood pressure, difficulty in controlling blood pressure, fatigue, hypersomnolence, retrognathia, snoring, mood changes, and attention issues. When a child is gaining weight, it is important to screen for sleep apnea by asking the parents about snoring and examining the tonsils and adenoids for enlargement.

PSYCHOSOCIAL STRESS

In addition to the negative influences of physiological stress from poor nutrition, insufficient appropriate activity, and inadequate sleep, psychosocial stress can also contribute to excess weight. Psychosocial stress can arise from a wide variety of environmental stressors, such as change in routine, difficult decisions, depression, chronic health issues, lack of access to health care, economic challenges, a dysfunctional home environment, an unsafe neighborhood, inadequate social support, abusive relationships, illiteracy, job dissatisfaction, poor adjustment to life-cycle transitions such as retirement, and legal problems.

This type of stress is often associated with weight gain, elevated BMI, and poor food choices. The amount of weight someone gains when exposed to stress depends on the intensity of the stress, the duration of the stress, and the type of food available for consumption during stressful times ([Block et al., 2009](#)). Increased cortisol levels can lead to weight gain around the abdominal region (central adiposity). It is important to screen for emotional stress with patients, identify how this stress may be negatively impacting their weight, and help them incorporate stress reduction programs to achieve their weight loss goals. Even when we are unable to control the existence of stressors, controlling our response to stress can positively influence our weight and our overall health.

Similarly, cultivating supportive relationships with oneself and with friends and family is particularly helpful when undergoing behavioral change, which is often necessary with weight loss. Persons of the same sex have a greater

influence on each other than those of the opposite sex (Christakis and Fowler, 2007). Our social networks can be a positive influence as well. People who exercise together are more likely to exercise. If you tell a friend, colleague or spouse that you are making a change in your lifestyle, you are more likely to maintain those changes.

TOXIN EXPOSURE

One environmental toxin in particular, the family of endocrine-disrupting chemicals (EDCs), is being investigated for its contribution to the high prevalence of obesity. Examples of EDCs include polychlorinated bisphenyls (PCBs), diethylstilbestrol (DES), bisphenol A, and persistent organic pollutants (POPs) such as tributyltin (TBT). This group of chemicals can interfere with the normal functioning of the endocrine system, which can affect development, reproduction, insulin production and utilization, and metabolic rate. Recent reviews of the literature suggest that exposure to EDCs during development is associated with excessive weight later in life and that these chemicals should be given serious consideration as potential contributors to obesity (Engel and Wolff, 2013; Newbold 2010; Tang-Péronard et al., 2011). Furthermore, these toxins have also been associated with insulin resistance and its associated obesity. An examination of selected POPs in the NHANES 1999 to 2002 data showed that elevated BMI and waist circumference were associated with POPs levels (Elobeid et al., 2010). BPA has also been linked to increased insulin levels and weight gain (Nadal et al., 2009).

MICROBIOME COMPOSITION

The microorganisms that inhabit the body cavities, such as the mouth, vagina, and respiratory and gastrointestinal tracts, appear to play an active role in our overall health. The gastrointestinal tract has been the subject of considerable interest in this regard. Multiple studies have suggested an association between our intestinal microbiota and weight. Fecal microbial cultures from healthy donors transplanted into recipients with metabolic syndrome were found to ameliorate the insulin resistance phenotype (Vrieze et al., 2012). High numbers of Bifidobacteria and low numbers of *Staphylococcus aureus* in the digestive tract in infancy may provide protection against the development of weight gain and obesity later in life. Bifidobacteria typify the gut microbiota composition of a healthy breastfed infant. Breastfeeding is associated with a 13% to 22% reduced likelihood of being overweight or obese in childhood (Kalliomäki et al., 2008).

However, just how the microbiota influence obesity remains unclear. What is clear so far is that the microbes are readily transmissible between individuals, after being transmitted can alter the outcome (obese vs. lean), and diet can further influence the outcome. The quality of the food we eat, as well as the influence our food has on our microbiota, have implications for the level of inflammation in our body and subsequent weight gain (Badman et al., 2005). Again, we see that all calories are not created equal.

See [eAppendix 36-2](#) online to learn more about current research on how the microbiome can influence weight.

Assessment

Key Points

- Many of the environmental factors that lead to excess weight are lifestyle related.
- The patient's readiness to change is an important predictor of successful weight management.
- A thorough patient history provides important clues to the root cause of obesity.
- The patient assessment is conducted through a nutrition-oriented lens.
- Assessing percent body fat and its distribution helps inform the therapeutic intervention.
- Beyond nutrition, multiple modifiable lifestyle factors are also assessed.

Many of the environmental factors that lead to excess weight are lifestyle related. Typically, these factors are modifiable through an individual's actions, which provides the physician and patient with multiple leverage points in developing a personalized plan that can lead to successful weight management. The components of a thorough assessment are described in this section. Each of the chapter authors uses a nutrition-oriented approach to enhancing the standard patient health assessment, and key aspects are described here. Poetic license is taken with the term "nutrition" because it not only encompasses valuable clues as to nutritional status but also other lifestyle factors such as physical activity, sleep, thoughts and emotions, and relationships and system of meaning that can contribute to the root cause of overweight and obesity. Assessing your patient's readiness to change will help you decide where best to begin the journey toward attaining and maintaining a desirable weight.

READINESS TO CHANGE

The majority of the determinants of overweight and obesity are related to choices that can be modified. However, unless patients are ready to change their habits, successful weight management is not likely. Therefore, it is helpful to assess a patient's readiness to change. One particularly successful approach has been the transtheoretical or stages of change model pioneered by psychologist James Prochaska and colleagues (1992). This model describes the stages that a person passes through while changing a behavior: pre-contemplation, contemplation, preparation, action, and maintenance. Unless patients are ready to take action, they frequently are not able to sustain behavioral change. Validated questionnaires are available to help you determine the patient's stage (University of Rhode Island Change Assessment Scale, 2013). You can also get a quick feel for patient readiness with the question: "On a scale of 1 to 10, with 1 being not ready and 10 being very ready, how would you rate your readiness to change?"

In addition to using an open-ended questioning approach, motivational interviewing is particularly helpful when working with patients with chronic disorders in whom behavioral change is a key factor (Miller and Rollnick,

Current Research on How the Microbiome Can Influence Weight

In work by [Cani and associates \(2007\)](#) using mice as a model to study mechanisms pertinent to human health, microbiota from obese mice transplanted into thin mice resulted in the thin mice gaining weight. Using adult female twin pairs that were discordant for obesity, [Ridaura and colleagues \(2013\)](#) took fecal cultures from the obese females and from their lean twins and transplanted the two sets of microbes into germ-free mice fed a low-fat diet or diets with varying amounts of saturated fat, fruits, and vegetables that were typical of the U.S. diet. Mice that received the obese twins' gastrointestinal tract microbiota had increased size and body fat as well as obesity-associated metabolic phenotypes. Mice that received the microbiota from the lean twin population became lean. When the mice transplanted with the microbiota from the obese females were co-housed with the mice transplanted with the microbiota from the lean females, the body composition and metabolic phenotype characteristic of obesity did not develop in the mice with the microbiota from the obese twins. This "rescue" phenomenon occurred when the mice were fed a low-saturated fat, high-fruit and high-vegetable diet but not with a high-saturated fat, high-fruit and high-vegetable diet. These results suggest that something in the lean twins' microbiota was transmissible and could prevent obesity from developing but that the diet could influence the degree to which the obesity phenotype could be prevented.

Identification of potential mechanisms by which the response of the mice with the obesity-related microbiota is

being investigated by various research groups. In the study by [Ridaura and colleagues \(2013\)](#), the researchers found the expression of numerous genes, particularly those related to detoxification and stress, were increased in the microbes receiving the obese twins' microbiota. They also found an association with specific members of the Bacteroidae, gram-negative anaerobes readily found in the environment and in the respiratory and digestive tracts and skin of animals. The lipopolysaccharides released by gram-negative bacteria have been associated with metabolic endotoxemia and inflammatory disorders, such as type 2 diabetes, insulin resistance, nonalcoholic steatohepatitis, and obesity ([Geurts et al., 2013](#)). Proposed mechanisms include pattern recognition receptors in the innate immune system that can sense pathogens and influence the metabolic stress response. Activation of the pattern recognition receptors can cause a chronic low-grade inflammation throughout the body that can go on to promote fatty liver disease, insulin resistance, obesity, type 2 diabetes, and atherosclerosis ([Jin and Flavell, 2013](#)). Pathogen-associated molecular patterns (PAMPs) can come from viruses, bacteria, parasites, and fungi. Danger-associated molecular patterns (DAMPs) can sense stress signals and may be activated by certain components of our diet. PAMPs and DAMPs can go on to cause an inflammatory process in the body, which can establish a vicious cycle within the body.

Table 36-2 Antecedents, Triggers, and Perpetuators in Obesity

Antecedents (genetics)	<p><i>Ob</i> gene (chromosome 7)</p> <p>FTO (fat mass and obesity-associated gene) is located on chromosome 16 and is associated with being overweight or obese (Fawcett et al., 2010; Frayling et al., 2007)</p> <p>A defect in the melanocortin-4 receptor is the most common single gene mutation associated with severe obesity in 5% of the population (Chambers et al., 2008)</p> <p>Brain-derived neurotrophic factor (BDNF) gene has been shown to cause spontaneous mendelian obesity in humans (Fisler et al., 2013)</p> <p>Fatty acid binding protein gene (<i>FABP2</i>) is associated with fat absorption</p> <p>Peroxisome proliferator receptor-γ gene (<i>PPAR-γ</i>) plays a key role in the formation of fat cells</p> <p>Adrenergic β_2-receptor gene (<i>ADRB2</i>) mobilizes fat cells for energy</p> <p>Adrenergic β_3-receptor gene (<i>ADRB3</i>) regulates the breakdown of fat from tissues in response to exercise</p> <p>Glutamate decarboxylase 2 gene (<i>GAD2</i>) is released from pancreatic and brain cells coding for GABA neurotransmitter, which regulates food intake</p>
Triggers	<p>Food insecurity; supplemental nutrition programs with high-glycemic index foods (Leung et al., 2012; Ludwig et al., 2012; Nickols-Richardson et al., 2005); high fructose intake; infection (chronic, bacterial, viral, or parasitic); sources of injury and chronic inflammation; endocrine imbalance, adrenal insufficiency, thyroid hypofunction (consider autoimmune, radiation induced, chemical induced, or medication induced) (Hochberg et al., 2010; Thaler et al., 2013); food sensitivity or genetic overlap (celiac, food, and environmental hypersensitivity); environmental toxicity (bisphenol A; Dolinoy et al., 2007); and even cell phone use alters glucose metabolism in the brain, disrupting appetite-related chronobiology (Fragopoulou et al., 2012; Kohlstadt, 2013; Volkow et al., 2011)</p>
Perpetuators	<p>Altered sleep (disrupted chronobiology: shift work, jet lag) (Kohlstadt, 2013; Stempfer et al., 1989) and sleep apnea</p> <p>Minimal exercise (Jakicic et al., 2011; Sausse, 2013; Vincent et al., 2012; Warburton et al., 2006)</p> <p>Persistent stress (psychologic, physical, relationship, socioeconomic, environmental)</p> <p>Nutrition (high glycemic index [Ruottinen et al., 2008; Fava et al., 2013], poor vegetable or fruit intake)</p>

GABA, γ -Aminobutyric acid.

2002). Motivational interviewing focuses on identifying, examining, and resolving the ambivalence that a patient feels about behavioral change. Key web resources are listed at the end of this chapter.

PATIENT HISTORY

A careful history helps identify common antecedents, triggers, and perpetuators of obesity (Table 36-2). Multiple factors can lead to overweight and obesity, and each patient will have his or her own path leading to excess weight. Determining some of the contributing factors will help you identify an intervention that is most likely to be successful for that patient. When gathering your patient's history, ask open-ended questions that will help identify the factors that may have predisposed them towards obesity: Was he or she overweight as a child? Did he or she gain weight all of a sudden or slowly over many years? Is there a family history of overweight or obesity? Is his or her activity level low because of pain or injury, inflammation, or fatigue? A slow, steady weight gain of 2 to 5 lb per year is typical for many adults who are not exercising adequately or eating too many calories. Alternatively, if your patient gained weight quickly, it is important to rule out thyroid disorders, hormonal changes, stress, family trauma, infection, and inflammation. A variety of clues such as these can come out during the information-gathering phase of the assessment if you ask open-ended questions and listen carefully (i.e., be "present" to the patient during this process).

During the patient history, evaluate the timeline of the weight gain. When did the weight gain begin? When did it markedly increase? Through the identification of environmental triggers as well as epigenetic and metabolic drivers for the obesogenic environment, therapeutic interventions can be developed. These environmental pressures, from the prenatal period through adulthood, are associated with weight gain and obesity (Table 36-3).

Obese patients frequently have comorbidities that often require therapeutic medications. These therapeutic drug regimens for diabetes, depression, hypertension, seizures, and HIV disease can trigger weight gain and worsen obesity (Table 36-4). Additionally, many of the most commonly prescribed medications can alter nutritional biochemistry and the obesogenic environment by multiple mechanisms (Table 36-5).

THE ABCDs OF NUTRITION EVALUATION

The ABCDs of nutrition evaluation of the obese patient include anthropometrics, biochemical markers, clinical indicators, and diet and lifestyle evaluation (Institute for Functional Medicine, 2010). Anthropometrics and vital signs include the height; weight; BMI; waist circumference; hip circumference; waist-to-hip ratio or waist-to-height ratio; percent body fat (fat mass); percent fat-free mass (lean body mass); extracellular water content; intracellular water content; blood pressure; respiratory rate; temperature; pulse; and for patients with diabetes, microfilament testing of the feet to test for feeling sensation. Biochemical markers typically include the comprehensive metabolic panel that includes a fasting lipid panel, thyroid panel or at least thyroid-stimulating hormone, 25-hydroxy vitamin D, high-sensitivity C-reactive protein, hemoglobin A_{1c}, complete blood count, urinalysis, and other laboratory analyses as needed (e.g., fasting insulin). The physical examination is a standard comprehensive examination with the assessment of additional clinical indicators as seen through a nutrition lens, such as including an examination of the mouth; evaluation of the nails, skin, and hair; and peripheral sensation using monofilament, 128 Hz tuning fork, and a reflex hammer.

The ABCDs of the nutrition-oriented evaluation of the obese patient should be completed and will help clarify the role of lifestyle in the root causes of the underlying chronic condition (Jones et al., 2010; Minich et al., 2013).

Table 36-3 Environmental Influences on Obesity

Environmental Influences	Behavior, Condition, or Exposure	Associated Impact
Prenatal	Maternal smoking Higher maternal BMI at conception Maternal diabetes	Increase odds of adult obesity by 50% by age 33 Increase body weight of child Increase overweight as a child and adult
Breastfeeding	Primarily breast fed (vs. formula)	Less likely to be obese as a child Each additional month of breastfeeding can result in a 4% decrease in risk of obesity
Viruses (e.g., adenovirus-36 antibody)	Increased glucose uptake, decreased leptin secretion	Associated with increased body weight in twin studies
Toxins (e.g., endocrine-disrupting chemicals)	Bisphenol A, organotins, phytoestrogen exposure during development	Higher serum toxin levels can lead to greater obesity in children
Smoking cessation	People who discontinue smoking	Increased odds ratio of obesity by at least twofold
Sleep deprivation	Associated with increased food intake, decreased physical activity, and decreased body temperature with fatigue	Consistently associated with development of obesity in children and young adults
Movement	Increased leisure time Declining work activity Declining walking, biking, etc. as a means of transportation Declining activity at home Increased electronic interface (computers, games, TV time) High risk of inactivity	A low level of physical activity decreases total energy expenditure and unless matched by a decrease in energy intake can lead to weight gain

BMI, Body mass index.

Table 36-4 Concomitant Pharmacology That Promotes Weight Gain and Influences Body Weight

Steroid hormones	Glucocorticoids, estrogens, progestins, testosterone, tamoxifen
Diabetes therapies	Some insulins, sulfonylureas, thiazolidinediones; metformin, glucagon-like peptide agonists, sodium glucose cotransporter 2 inhibitors
Certain antiretroviral protease inhibitors	Lipodystrophy during treatment with protease inhibitors, lipohypertrophy after successful suppression of viral load
Certain β -adrenergic blockers	Propranolol
Certain antihistamines	Diphenhydramine
Certain antidepressants	Tricyclic antidepressants, MAO inhibitors, some SSRIs (paroxetine), antiserotonin agents (pizotifen)
Certain antiseizure medications	Valproate, gabapentin, carbamazepine
Certain antipsychotropic drugs	Clonazepam, olanzapine, risperidone, thioridazine

MAO, Monoamine oxidase; SSRI, selective serotonin reuptake inhibitor.

Anuurad et al., 2010; Polsky et al., 2014; Seger, 2013.

Table 36-5 Many Commonly Used Medications Promote Weight Gain

Rank in Prescriptions Written (Million)	Medication	Mechanism
2 (94.1)	Simvastatin	Reduces exercise tolerance, promotes insulin resistance, depletes CoQ10
5 (57.2)	Amlodipine besylate	Increases appetite centrally in some patients
6 (53.4)	Omeprazole	Contributes to vitamin B ₁₂ deficiency and diet indiscretion
9 (48.3)	Metformin	Lowers absorption of vitamin B ₁₂
10 (47.8)	Hydrochlorothiazide	Increases appetite, reduces cardiac response to exercise
By Sales (Billions)	Medication	Mechanism
1 (7.2)	Lipitor	Reduces exercise tolerance, promotes insulin resistance, depletes CoQ10 within muscle cells in genetically susceptible patients
2 (6.3)	Nexium	May contribute to vitamin B ₁₂ deficiency, fatigue, altered methylation, diet indiscretion
4 (4.7)	Advair Discus	Potentially protects against weight gain by reducing need for corticosteroids
5 (4.6)	Abilify	Increases appetite centrally
6 (4.4)	Seroquel	Increases appetite centrally
8 (3.8)	Crestor	Reduces exercise tolerance, promotes insulin resistance, depletes CoQ10
9 (3.5)	Actose	Associated with weight gain

CoQ10, Coenzyme Q10.

Table 36-6 Anthropometric Evaluation

	COMMONLY USED
Quantitative direct measurements	Weight, height (length) Waist circumference (<35 in women; <40 in men) Hip circumference Skinfold thickness measurements (three sites) Reactance/resistance (BIA)
Calculations	BMI (normal, 18.5-24.9; overweight, >25; obese, >30) Waist-to-hip ratio (<0.8 in women; <0.9 in men) Waist-to-height ratio (<0.5) Deurenberg Equation (BMI, Age, Gender) % Body fat = $(1.2 \times \text{BMI}) + (0.23 \times \text{Age [yr]}) - (10.8 \times G) - 5.4$ G = 1 for male; G = 0 for female Bioelectrical impedance analysis Fat mass, fat-free mass, extracellular water, intracellular water, phase angle, BMR (weight, height, and activity dependent)
Quantitative testing	LESS COMMONLY USED
	BOD POD Quantitative magnetic resonance Underwater weighing Deuterium dilution

BIA, Bioelectrical impedance analysis; BMI, body mass index; BMR, basal metabolic rate; BOD POD, whole-body air displacement plethysmography (Deurenberg et al., 2003; Srikanthan et al., 2009; Wang et al., 2010).

Anthropometrics

Assessing anthropometrics is the first step in the nutritional evaluation of the patient. Starting with birth, the weight and height are determined and then routinely checked throughout the lifespan. The use of these basic measurements and associated ratios that can be calculated, such as waist-to-hip ratio, are commonly used in clinics. The initial stratification is by BMI calculation from height and weight (underweight, <18.5; normal, 18.5-24.9; overweight, 25-29.9; obese, >30), waist circumference (women, <35 in; men, <40), and waist-to-hip ratio (women, <0.8; men, <0.9) or waist-to-height ratio (<0.5 ideal). BMI is the primary parameter used to categorize weight for height ($\text{Weight/Height/Height} \times 703$) and, in fact, has recently been mandated to be included in all patient charts. The BMI is bimodal. There is increased risk of mortality and morbidity when BMI is below 18.5 and above 24.9. The risk of inflammatory disease, including cardiovascular disease, occurs at both ends of the bimodal curve.

Body mass index is a quick and easy screening tool to use in the office setting but is imperfect. For muscular individuals, the BMI overestimates risk. For patients with too little lean muscle mass (sarcopenia), the BMI underestimates risk. Table 36-6 lists the many ways to assess body composition. A comparison of the various assessment methods is provided by Saltzman et al. (2013).

A more informative assessment of adiposity as well as risk for disease than BMI is body fat percentage. Table 36-7 lists the fat percentage in healthy individuals. Although underwater (hydrostatic) weighing and dual-energy X-ray absorptiometry (DXA) scan are considered the preferred methods for measuring percent body fat, these methods are not readily available in most clinics. Each method has its own confounders and advantages (Carroll et al., 2008;

Table 36-7 Classification by Percentage Body Fat

Classification	Female (%)	Male (%)
Essential fat	10-13	2-5
Athletes	14-20	6-13
Fitness	21-24	14-17
Acceptable	25-31	18-24
Obesity	>32	>25

Adapted from ACE Pro. Percent body fat calculator: skinfold method. http://www.acefitness.org/acefit/healthy_living_tools_content.aspx?id=2.

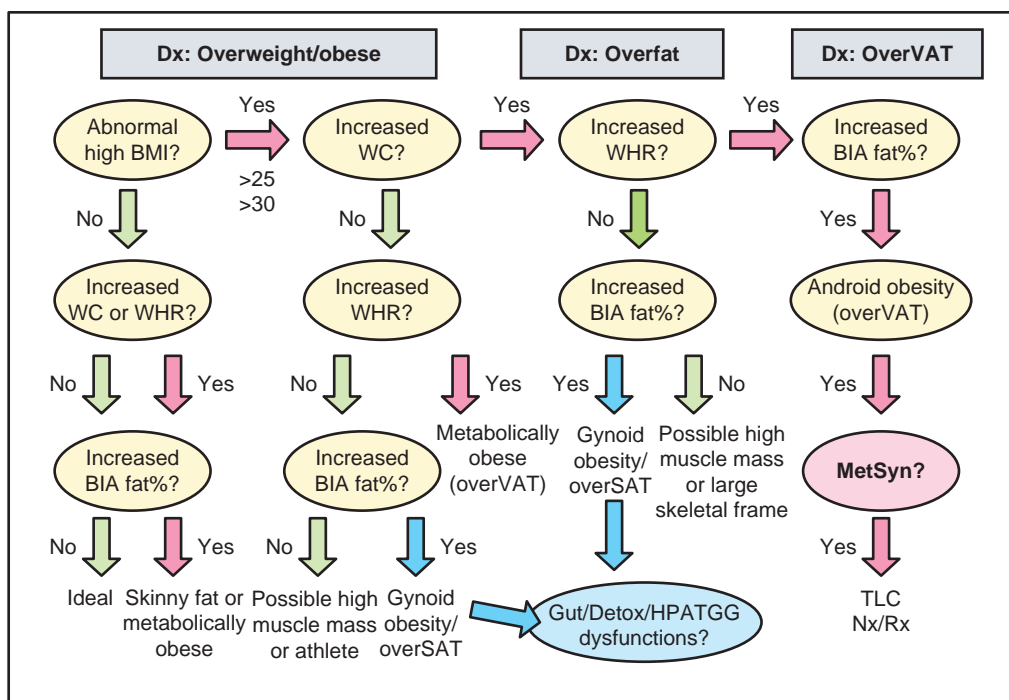

Kushner and Blatner, 2005; Wang et al., 2010). Bioelectrical impedance analysis (BIA) has emerged as a more convenient technique for in-office measurements of body fat and fat-free mass, of particular interest in detecting malnutrition. The inclusion of BIA in the NHANES with comparison with the more traditional multisite skinfold measurements has validated the use of this tool. BIA is best used as a tool for tracking a patient's progress from one time point to another rather than as a precise measurement of any one component of body composition. Many practitioners use sequential BIA analysis to follow the progression of treatment, which allows for determining that the weight loss is the desired fat mass and not muscle mass loss or excessive water loss.

Additional anthropometric measurements, waist and hip circumference, and the calculated waist-to-hip ratio help to further stratify obesity by location of fat accumulation (Figure 36-1). If a man's waist circumference is greater than 40 inches (102 cm) and a woman's abdominal circumference is greater than 35 inches (>89 cm), then they are considered obese. The presence of android obesity (visceral adiposity) with a waist-to-hip ratio of greater than 0.8 in women and greater than 0.9 in men portends of a more inflammatory metabolism and is characterized by the apple shape. The gynoid obesity (increased BMI, increased body fat percentage) hallmark is subcutaneous obesity with a waist-to-hip ratio of less than 0.8 for women and less than 0.9 for men and a characteristic pear-shaped body type. Android obesity (increased BMI, increased percentage of body fat with an elevated waist-to-hip ratio) correlates with adiposopathy and with metabolic disease (insulin resistance, metabolic syndrome). Those with android obesity have an increased visceral adipose tissue percentage. The waist measurement accuracy depends on the use of the same landmarks. Some suggest the waist at the top of the iliac crest (Anderson and Hensrud, 2011); others use the waist as the midpoint between the bottom of the 10th rib and the superior iliac crest at the midaxillary line.

Figure 36-2 provides a case example in which the combined use of multiple anthropometric measures, including BIA, is helpful in following treatment progression.

After the pattern of fat distribution has been determined (android or gynoid distribution), the necessary biochemical indicators are ordered to help determine drivers of the obesity-promoting condition (Table 36-8). This approach helps improve the metrics for health risk analysis (Ahima and Lazer, 2013).

The pattern of morbidity in an obese patient is influenced by whether the patient has the sequel of adiposopathy (dysmetabolic syndrome), which is associated with elevated

Abnormal BMI	Increased Waist Circumference	Increased Waist-to-Hip Ratio	Increased % Body Fat	Obese/Fat Distribution	Workup
No	No	No	No	No	Ideal normal health monitoring
No	No	No	Yes	Skinny fat—sarcopenic adiposity	Metabolically obese inflammatory workup; workup for causes of sarcopenia or sarcobesity (Parr et al., 2013)
Yes	No	No	No	No	High-muscle athlete; normal health monitoring
Yes	No	Yes	Yes	Yes: android obesity, visceral adiposity	Inflammatory workup; root causes of inflammation associated with weight gain and adiposopathy (e.g., infection, glucose dysregulation, toxins)
Yes	No	No	Yes	Yes: gynoid obesity, subcutaneous fat adiposity	Gastrointestinal, biotransformation, HPATGG dysfunction, toxicity, and endocrine evaluations
Yes	Yes	No	No	No: large frame; high muscle mass	No intervention; normal health monitoring
Yes	Yes	No	Yes	Yes: gynoid obesity subcutaneous fat adiposity	Gastrointestinal, biotransformation, HPATGG dysfunction, toxicity, and endocrine evaluations
Yes	Yes	Yes	Yes	Yes: android obesity, visceral adiposity	Therapeutic lifestyle change, nutritional and inflammatory workup, root causes of inflammation associated with weight gain and adiposopathy (e.g., infection, glucose dysregulation, toxins)

Figure 36-1 Assessing body composition by body mass index (BMI), waist circumference, waist-to-hip ratio, and percent fat mass. *BIA*, Bioelectrical impedance analysis; *fat %*, bioelectrical impedance analysis fat percentage; *HPATGG*, hypothalamic–pituitary–adrenal–thyroid–gonadal–gastrointestinal axis; *METSyn*, metabolic syndrome; *overSAT*, high percentage of subcutaneous adipose tissue; *overVAT*, high percentage of visceral adipose tissue; *TLC Nx/Rx*, therapeutic lifestyle change and intervention, nutritional and pharmacologic treatment; *WC*, waist circumference; *WHR*, waist-to-hip ratio. (From Saxena S: Cardiovascular advanced practice module, *Institute for Functional Medicine*, 2012, Federal Way, WA, and Stone PM: Functional nutrition—head to toe. Toolkit, *Institute for Functional Medicine*, 2013, Federal Way, WA.)

Case Study:

Anthropometrics: height, 72 in; weight, 202 lb

BMI: 27.4

Waist circumference: 39 in

Hip circumference: 38 in

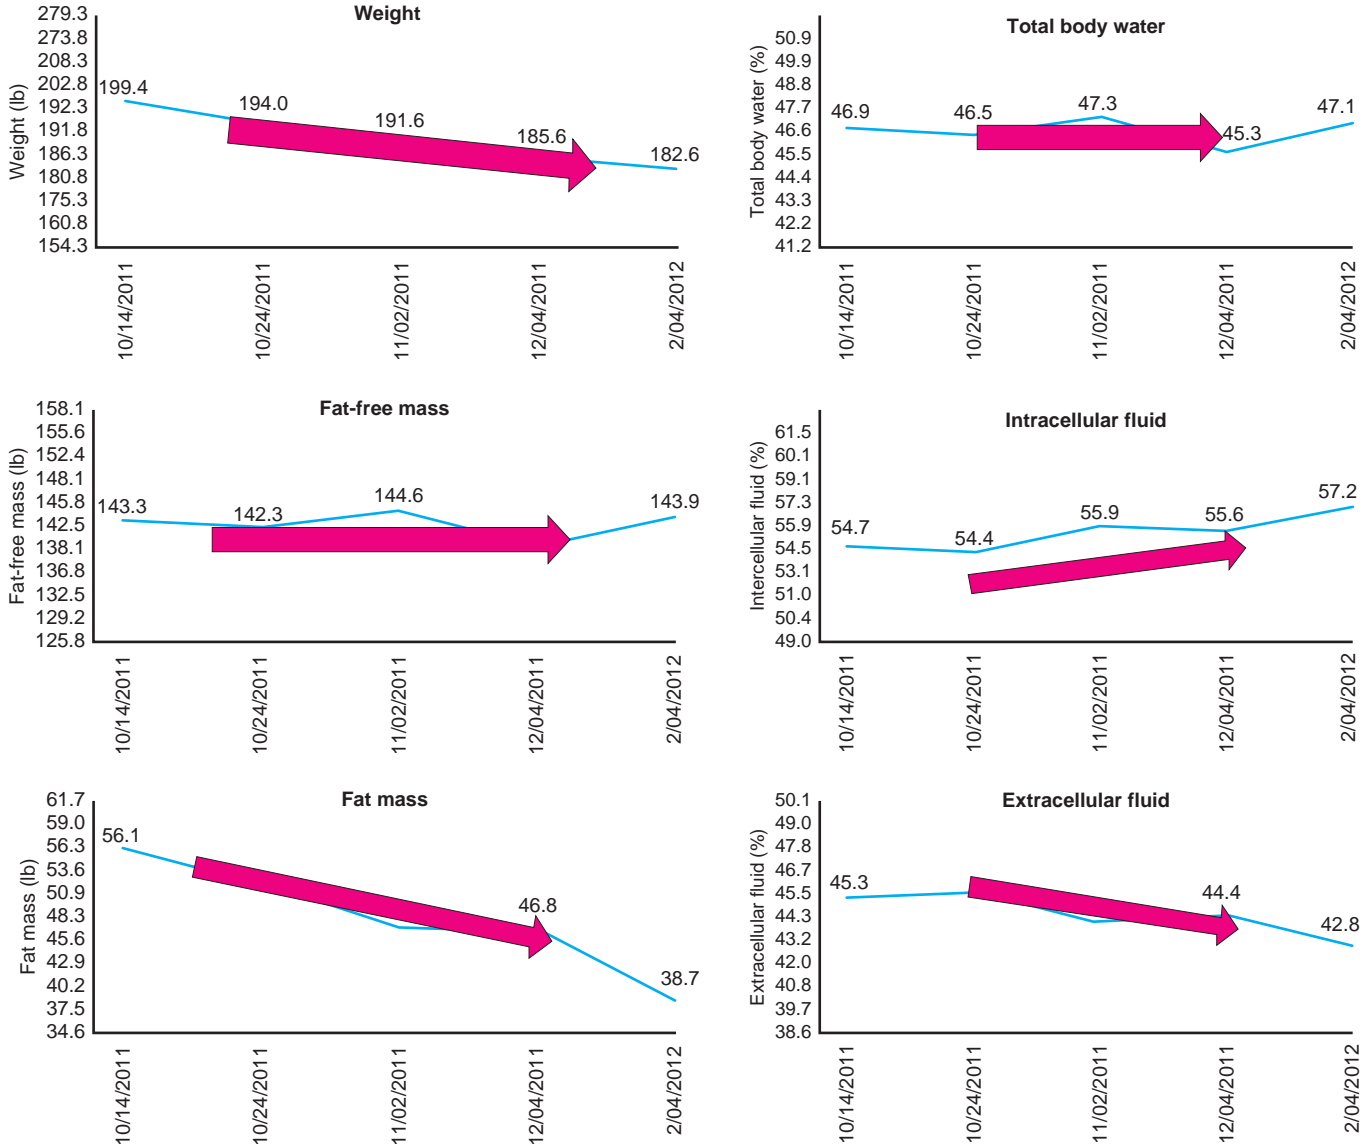

Waist-to-hip ratio: 10.02; **waist-to-height ratio:** 0.54

BIA: fat mass, 28.1%; **fat-free mass:** 71.9%

Assessment: android body type, increased abdominal visceral body fat, grade 1 obesity

Treatment: low glycemic impact diet

WEIGHT AND BODY COMPOSITION WITH 4 MONTHS OF DIET CHANGE AND EXERCISE

Case Study:

Anthropometrics: height, 72 in; weight, 182.3 lb

BMI: 24.7

Waist circumference: 33 in

Hip circumference: 37.5 in

Waist-to-hip ratio: 0.88; **waist-to-height ratio:** 0.45

BIA: fat mass, 20.9%; **fat-free mass:** 78.1%

Figure 36-2 Case Study: Case example using sequential bioelectrical impedance analysis (BIA) to follow treatment progression. The patient was a 56-year-old man with hyperlipidemia and erectile dysfunction taking prevastatin and Viagra. BIA was used over the 4-month period of increased exercise, food choice, and quantity intervention to follow anthropometric changes in weight, fat-free mass, and fat mass to confirm that the weight loss was composed of fat mass loss and not loss of muscle mass or total body water. The shift in extracellular fluid to intracellular fluid is considered a healthy sign.

Table 36-8 Physical Examination Findings in the Obese with Associated Comorbidities

System	Condition
Body composition	Monitoring fat and muscle mass with weight, waist circumference, waist-to-hip ratio, BIA, and resting metabolic rate; DEXA assesses bone densitometry and body composition (Heber et al., 1996; Kohlstadt, 2013) Age of onset in adolescence: increased BMI (23-25) strongly associated with obesity in adulthood Age 25-40 yr: increases in BMI associated with worse profile biomarkers later in adulthood
Hydration	Dry mucous membranes, pedal edema, poor skin turgor, dry mouth generally indicative of intracellular dehydration; need corroboration with urine specific gravity Poor hydration is associated with less favorable BIA and alters accuracy of skinfold measurements (Kohlstadt et al., 2013)
Oral cavity	Xerostomia, periodontal disease, tooth decay, amalgam fillings, and odor may indicate barriers to weight reduction, inducing dehydration unfavorable microbiota, inadequate mastication, undermethylation, and insulin resistance (Kohlstadt, 2013)
Neck circumference	Predictor of OSA and severity which is obesogenic (men, >17 in [43 cm]; women, >16 in [41 cm]) (Pinto et al., 2011)
Cardiovascular	Hypertension, CAD, essential hypertension, LVH, CHF, cor pulmonale, obesity-associated cardiomyopathy, accelerated atherosclerosis, pulmonary hypertension of obesity, thromboembolic pulmonary emboli Peripheral vasculature: venous varicosities, thrombophlebitis, lower extremity venous and or lymphatic edema, lower limb circulatory stasis
Pulmonary	Predisposition to respiratory infections, increased bronchial asthma, obesity hypoventilation syndrome (Pickwickian syndrome), dyspnea, OSA, hypoventilation syndrome, Pickwickian syndrome, asthma
Neurologic	Cranial nerve I: olfactory nerve function loss is associated with altered food choices, including oversalting and oversweetening of food (Hirsch and Whitman, 2013; Kohlstadt, 2013) Intracranial hypertension caused by increased abdominal pressure, sleep apnea, and so on Stroke, nerve entrapment (meralgia paresthetica, carpal tunnel syndrome)
Gastrointestinal	Gallbladder disease (cholecystitis, cholelithiasis), NASH, fatty liver infiltration, reflux esophagitis, hernias
Genitourinary	Urinary stress incontinence, nephrotic syndrome, focal glomerulosclerosis, erectile dysfunction
Reproductive	Obstetric and perinatal complications: pregnancy-induced hypertension, increased risk of gestational diabetes, shoulder dystocia, fetal macrosomia, pelvic dystocia Women: anovulation, early puberty, infertility, hyperandrogenism, polycystic ovaries Men: hypogonadotropic hypogonadism
Musculoskeletal	Musculoskeletal: general: abdominal hernias, ventral and inguinal, immobility Musculoskeletal and orthopedic: osteoarthritis of major joints, coxa vera, slipped capital femoral epiphysis, Blount disease, Legg-Calvé-Perthes disease, chronic lumbago Pain with moderate pressure over adult patients' shin bones or ribs: associated with osteomalacia; vitamin D deficiency, which perpetuates insulin resistance; can lower mood and limits physical activity, increasing fall risk (Brady et al., 2013; Holick, 2006; Kimmons et al., 2006; Wicherts et al., 2007)
Integument	Intertrigo (bacterial or fungal), acanthosis nigricans, hirsutism, increased risk of cellulitis and carbuncles, skin tags (epiliths) secondary to insulin resistance, stasis dermatitis, ulcerations, stria distensae (skin stretch mark), stasis pigmentation, venous stasis ulcers
Metabolic and endocrine	Type 2 diabetes mellitus, prediabetes, metabolic syndrome, dyslipidemia
Psychologic	Social stigmatization and depression
Malignant	Associations with endometrial, prostate, colon, breast, gallbladder, and lung cancer
Lifestyle	Sleep duration <5 hr to >8 hr associated with increased visceral and subcutaneous body fat with decreased leptin hormone and increased ghrelin hormone levels
Obesity in women	Being overweight contributes to menstrual disorders, infertility, miscarriage, poor pregnancy outcome, impaired fetal well-being, and type 2 diabetes; changes in sensitivity to insulin may occur Pregnant women who are obese are more at risk for pregnancy-induced hypertension and preeclampsia (Escott-Stump, 2012)
Age of onset	History of rapid weight gain in infancy, childhood, or early puberty, and excessive weight gain in pregnancy increase the risk for obesity (Johnson et al., 2006) Total energy expenditure and physical activity level declines progressively in both overweight and normal weight men and women, falling ≈150 kcal/decade; the thermic effect of food does not change (Roberts and Dallal, 2005)
Obesity in elderly adults	Increasing prevalence along with related macro and micronutrient deficiencies (Flood and Carr, 2004)

BIA, Bioelectrical impedance analysis; BMI, body mass index; CAD, Coronary artery disease; CHF, congestive heart failure; DEXA, dual-energy x-ray absorptiometry; LVH, left ventricular hypertrophy; NASH, nonalcoholic steatohepatitis; OSA, obstructive sleep apnea. Hamby and Griffing, 2013; Kushner and Roth, 2003.

blood sugar, elevated blood pressure, and dyslipidemia. Fat mass disease is associated with stress on the weight-bearing joints, immobility, tissue compression (sleep apnea, gastro-intestinal reflux, high blood pressure), and tissue shear forces (intertrigo) (Allende-Vigo 2010; Bays et al., 2005, 2008; Bays, 2009, 2012; Seger et al., 2013).

Bioelectrical impedance analysis provides additional information on fat-free mass (lean body and muscle mass), extracellular water, and intracellular water. Being able to monitor whether body fat, rather than lean muscle mass, is being lost is a particularly valuable contribution of BIA testing. There is often a lower than predicted metabolic rate

observed in extremely obese individuals (Livingston and Kohlstadt, 2005). This is because muscle caloric burn rate per pound per day is 6 calories for muscle and 2 calories for fat. The coincident loss of muscle and replacement weight fat leads to a 66% decrease in resting burn rate per pound of tissue (Kohlstadt, 2013).

In morbidly and super obese individuals, there is a shift in percentage of body water, and body fat percentage increases. Whereas an adult with a healthy weight is 60% to 65% body water, someone who is extremely obese tends to have a total body water of 35% to 45%. This shift places the obese at an increased vulnerability for volume depletion (dehydration), which is a common problem in obese individuals (Batmanghelidj and Kohlstadt, 2006; Kohlstadt, 2013; Livingston and Kohlstadt, 2005).

Biochemical Indicators

The distribution of fat, percent body fat, and associated muscle mass help the clinician determine which laboratory and biochemical indicators would be most revealing and helpful for determining interventions (see Figure 36-1 and Table 36-9). Using this sorting of fat distribution determined by BMI, waist circumference, waist-to-hip ratio, and bioimpedance analysis, the laboratory tests considered extend beyond the evaluation of simply thyroid function. See Table 36-9 for further clarity on how body fat percent and distribution inform the intervention.

Clinical Indicators

The clinical indicators (see Table 36-8) uncovered during the physical examination of the obese patient help identify comorbidities and physical examination features unique to the patient with android or gynoid obesity caused by adiposopathy or fat mass disease (see Table 36-9). The pathology of cardiovascular, pulmonary, rheumatologic, neurologic, and endocrinologic comorbid disease drives the obesogenic metabolic environment within the patient. The physical examination is a key component to the nutritional evaluation of the obese patient.

Diet and Lifestyle Evaluation

At a minimum, include a food diary in your patient information packet and, preferably, a broader diet and lifestyle assessment to assess your patient's risk of becoming overweight or obese. The diet and lifestyle evaluation should include a diet record from the patient that ranges from 1 to 7 days in length. The diet is evaluated for adequacy of protein; essential fats; and complex carbohydrates, including fiber. The overabundance of any major nutrient or the imbalance of saturated or transaturated fats, simple carbohydrates, or incomplete protein is identified. Also assess whether your patient has adequate intake of water and a wide variety of colorful vegetables and fruits, which are rich in phytonutrients. Assuring that these aspects of the diet are adequate will increase the likelihood of sufficiency of minerals and vitamins.

The diet and lifestyle assessment helps uncover and improve understanding of the obesogenic drivers. During the gathering of the patient history, the antecedents, triggers, and perpetuators combine with the anthropometrics, biochemical indicators, and clinical findings to direct the development of an intervention and its treatment plan.

If possible, make the information packet available so the patient can complete it in advance. You can create a simple 7-day diet and lifestyle assessment form by listing the days of the week across the top and down the left side listing food intake (breakfast, snack, lunch, snack, dinner, optional snack), water intake (cups or ounces), physical activity (time, type), sleep (quality), emotional stress (thoughts and emotions), and one thing patients did for themselves each day that brought them joy. If, however, you use only a food and activity log, include room to note activity for each day of the week and at least 3 days of food intake that includes two weekdays and one weekend or nonwork day because people tend to eat differently when their schedules are more flexible. Have patients indicate the type of activity and length as well as which foods and beverages and how much was consumed.

Below are recommendations for ways to assess each of the key modifiable lifestyle factors that contribute to disease.

Food Diary. Key information you can obtain from the food diary includes whether the patient eats breakfast, snacks at night, or drinks an excessive amount of sugar-sweetened beverages. Skipping breakfast has been associated with increased calories eaten later in the day and with weight gain. Nighttime snacking is a common pattern that you want to fully assess and help curtail. How much soda, juice drinks, 100% fruit juice, or sweetened caffeinated beverages are drunk most days? Drinking your calories through high soda or juice intake is associated with obesity. An easy recommendation that you can make during many office visits is to have your patients stop drinking all sugar-sweetened beverages. It is important to ask about all sugar-sweetened beverages, including soda, sports drinks, juice drinks, and coffee and tea (Han and Powell, 2013) (see Figure 36-1). Table 36-9 reviews key diagnostic nutritional tests that can be considered in weight loss therapy. The calories from these beverages can add up quickly and should not be included on a daily basis.

A food diary can also help determine the quality of the carbohydrates eaten, which may come from foods with a high GI or from sugar-sweetened beverages. There is compelling evidence that carbohydrate quality has important influences on obesity as well as on comorbidities associated with obesity, such as cardiovascular disease, metabolic syndrome, and type 2 diabetes. Dietary fiber is an important determinant of satiety and weight gain and helps protect against hyperlipidemia and hyperglycemia. Vegetables and fruits are excellent sources of fiber and phytonutrients and help protect against cardiovascular disease, diabetes, and cancer. Assess the record for high-GI carbohydrates (see **Glycemic Index and Glycemic Load** earlier in the chapter). It is common for patients to replace saturated fat with high-GI carbohydrates, which may increase the risk of developing type 2 diabetes and cardiovascular disease. As noted earlier, soft drink consumption is a proven cause of weight gain, which may relate to the lack of satiety provided by these drinks. In large amounts, the fructose contained in these drinks leads to greater adverse metabolic changes than equivalent amounts of glucose (Slyper, 2013).

Another aspect of food intake that can lead to excess weight (not necessarily excess body fat) is the presence of food sensitivities, as measured by elevated IgG antibodies

Table 36-9 Nutritional Diagnostic Tests to Guide Weight Loss Reduction

Testing	Interpretation	Mechanism	Treatment	Relevance to Weight Loss
Albumin (serum)	Low level suggests protein malnutrition	Inadequate intake, malabsorption	Dietary protein, supplemental amino acids, digestive enzymes	Maintain lean body mass, avoid sarcopenia (Kohlstadt, 2008)
C-reactive protein (CRP)	High-sensitivity CRP should be <10 mg/L	Inflammation from various sources, including food allergies, infection, autoimmune issues, and weight reduction	Supplemental fiber, alkaline diet, avoidance of food allergens, multiple vitamin, supplemental curcumin 2-4 g/d	Inflammation exacerbates sarcopenia
Carnitine	Deficiency if low plasma carnitine or elevated urinary adipic, suberic, and ethylmalonic acids	Impaired absorption; decreased synthesis, associated with Fe deficiency, high demand during fat metabolism	L-acetyl carnitine 2 g/day	Fat metabolism increases demand for carnitine; carnitine drop is associated with fatigue in pregnancy; carnitine is needed to transport free fatty acids into the mitochondria
Carotenes	α -Carotene, 9-101 mcg/L β -Carotene, 42-373 mcg/L, lutein, 50-250 mcg/L, zeaxanthin, 8-80 mcg/L	Nutrient deficiencies (i.e., Zn) and medications can interfere with synthesis	Green leafy vegetables; cooking with spices, phytonutrient-rich supplements	Obesity is a risk factor for reduced fat-soluble nutrients
Coenzyme Q10 (CoQ10)	Low serum CoQ10 signifies depletion of tissue CoQ10; high levels of pyruvate, succinate, fumarate, and malate in the urine suggest insufficient CoQ10 to meet energy needs	Nutrient deficiencies and medications can interfere with synthesis	Supplemental CoQ10 up to 300 mg/day	Fat metabolism increases demand for CoQ10
Fatty acid profile	RBC fatty acid profiles can identify omega-3, omega-6, trans, very long chain, and saturated fatty acids	Skewed dietary intake; inappropriate supplement use; reduced delta 6 desaturase enzyme activity; fat malabsorption	Balance mono- and polyunsaturated fatty acids with diet and supplements	Guides strategic use of dietary and supplemental fatty acids for weight reduction; fatty acid imbalances may stem from prior medical or surgical treatment for obesity
Homocysteine	Elevation signifies deficiency in vitamin B ₁₂ , folate, vitamin B ₆ , or interactive insufficiencies of riboflavin, niacin, and thiamine	Impaired absorption and inadequate intake of the B vitamins (B ₁ , B ₂ , B ₃ , B ₆ , B ₁₂ , folate)	Supplementation of methyl folate, folacin, and vitamin B ₁₂ can improve methylation	Maintain energy metabolism and harvest of calories through intermediary metabolism of carbohydrates and proteins
Iron studies	Low ferritin and percent saturation ≤ 15 suggest iron-deficient erythropoiesis even when HCT is normal; elevation suggests hemochromatosis	Deficiency from impaired absorption; inadequate intake excess from primary hemochromatosis, a nutrient-gene interaction	Treat deficiency with supplemental minerals, dietary iron, and cooking with an iron skillet with citrus; hemochromatosis is managed medically and by minimizing dietary iron intake	Deficiency tends to coexist with other mineral deficiencies, exacerbated by some diets; iron, zinc, and chromium alter food preferences; hemochromatosis contributes to the inflammatory component of obesity
Magnesium	RBC magnesium below laboratory-specified range	Impaired absorption, inadequate dietary intake, competitive absorption with calcium	Increase fruit and vegetable intake; supplement calcium and magnesium in a ratio of 2:1	Optimizing magnesium supports hydration, fat metabolism, and extracellular-intracellular fluid flux
Triglycerides	Fasting values >100 mg/dL or even 75 mg/dL suggest impaired fat metabolism	Steatosis, increased oxidative stress, consumption of synthetic fats, and refined carbohydrates	Diet low in refined carbohydrates and no trans or highly processed fats; liver support; supplemental L carnitine 2 g/d	Elevated triglycerides represent a treatable impairment in fat metabolism; also may indicate increased intestinal production of lipids from simple carbohydrates

Continued on following page

Table 36-9 Nutritional Diagnostic Tests to Guide Weight Loss Reduction (Continued)

Testing	Interpretation	Mechanism	Treatment	Relevance to Weight Loss
Vitamin D	25-OH vitamin D: 30-50 ng/mL throughout the year <10 ng/mL deficient, <30 ng/mL insufficient, <36 ng/mL associated with insulin resistance, <50 ng/mL associated with double the solid cancer incidence; when associated with a high normal or high 1,25-DHCC, associated with underlying infection	Low vitamin D associated with decreased innate immunity function, increased insulin resistance; impaired absorption is associated with certain medications, sunblock use, or inadequate outdoor sunlight exposure Obesity increases the demand for preactivated vitamin D	Food rich in vitamin D; augment digestive enzymes if postsurgical or pancreatic insufficiency; consider supplementation as needed to address deficiency states Dietary sources include cold water fish, dairy (if supplemented), mushrooms (ergocalciferol)	Obesity is associated with lower serum levels of vitamin D and plays a role in the mechanism of hyperparathyroidism and bone loss in obesity; low vitamin D levels are associated with increased musculoskeletal pain, increased fall risk, and increased insulin resistance Optimizing vitamin D may facilitate weight loss
Vitamin B ₁₂	Serum concentration <540 mg/mL and elevated urine methyl malonate, homocysteine, and mean cell volume suggest deficiency	Impaired absorption partly from drug interactions; reduced intake from some diets Impaired absorption caused by age-related decrease	Oral, sublingual, or IM supplementation	Maintain energy metabolism
Uric acid	Serum uric acid >5.9 mg/dL needs further evaluation	If increased TG, LDL, homocysteine, platelets >385,000 consider atherosclerotic disease	Quercetin and folic acid inhibit xanthine oxidase	Consider low-purine diet; address oxidative stress; look for confounders (fructose intake >100 g/day) associated with metabolic syndrome; chronic inflammation promotes weight gain via insulin resistance
Hemoglobin A _{1c}	<5.4, good; 5.5-6.0, increased oxidative stress, age; >6.0, insulin resistance; and >6.5, diabetes	Low-glycemic index diet change; consider adequacy of protein intake; evaluate root causes	Consider adequacy of vitamin D; evaluate and treat root pathology, oral hypoglycemia, and insulin if necessary Low-glycemic index foods; reduce simple sugars; increase exercise	Elevated HgA _{1c} as an advanced glycosylation endproduct is a marker of prolonged oxidative stress and can decrease as BMI drops into normal range if diabetes is under control Hypertriglyceridemia artificially raises HgA _{1c} readings (Xavier and Carmichael, 2013)
Thyroid-stimulating hormone	>2 mIU/L requires further evaluation	Lowered metabolic rate and marked decrease in exercise tolerance	Consider appropriate treatments for diminished thyroid function; nutritional evaluation of zinc, iodine, selenium, and protein adequacy should be considered	Maintain optimal metabolic rate; reduce myalgias, fatigue, and gastrointestinal symptoms
Urinalysis	Specific gravity >1.025 suggests inadequate hydration; the presence of protein may require additional evaluation	Medical barriers to adequate hydration may be present; urinary protein losses can suggest chronic kidney disease	Address medical barriers to hydration; diet may need to be modified if chronic kidney disease	Hydration facilitates weight reduction; urine protein loss may require modifying the patient's diet

1,25-DHCC, 1,25-Dihydroxycholecalciferol; BMI, body mass index; HCT, hematocrit. IM, intramuscular; LDL, low-density lipoprotein; RBC, red blood cell; TG, triglyceride.

against foods. Elevated levels of food sensitivities have been associated with obesity in children. Obese children have been found to have higher serum C-reactive protein values, more IgG food sensitivities, and higher carotid intimal thickness on ultrasonography (Wilders-Truschnig et al., 2008). Could it be that the inflammation resulting from the immune response is a trigger or perpetuator in the development of obesity? A food diary and careful questioning of the patient can detect gastrointestinal dysfunction. Sometimes the patient can associate symptoms such as bloating, gas, cramping, or increased motility to particular foods, but often the effects of food sensitivities are delayed and appear

24 to 48 hours after ingesting the problem food. In the authors' opinion, there is no one test that provides unequivocal identification of foods that cause delayed hypersensitivity, but many practitioners have found IgG4 testing, mediator release testing, and the antigen leukocyte cellular antibody test helpful in identifying problem foods. Often an elimination diet is the best test to determine if food sensitivities or allergies are present.

As discussed earlier, modifiable lifestyle factors, including sleep and relaxation, exercise and movement, and stress and relationships, need to be assessed as well to determine the causes of the individual patient's weight gain.

Intervention

Key Points

- The 5 A's of obesity treatment provide a useful framework for approaching long-term weight management.
- Lifestyle therapy offers numerous opportunities to engage the patient and to personalize the intervention.
- Specific modifiable lifestyle factors are addressed within the intervention, such as food intake, movement and physical activity, sleep, psychosocial stress, toxin exposure, the microbiome, pharmacotherapy, and surgery.

How best to counsel a patient about long-term weight management is as individual as each patient. Many patients are uncomfortable discussing their weight. They may be ashamed of their size if they believe that it reflects weak self-control. Often speaking with patients about the role of a healthy weight in overall health as simply another valuable component of a multipronged approach to being healthy in the same way that not smoking, regular seatbelt use, and washing hands regularly help protect one's health can be nonthreatening. Asking patients whether they would like to discuss weight management also helps to establish a nonjudgmental environment in which patients will feel comfortable voicing their concerns. Ask patients what has worked for them in the past. Help patients identify their strengths and discuss ways to build on these strengths from a weight management perspective. [Alexander and colleagues \(2011\)](#) have proposed the 5A's of obesity treatment as a recommended framework for approaching weight management with overweight and obese patients ([Table 36-10](#)).

LIFESTYLE THERAPY

Interventions for overweight and obese patients are tailored to each patient's needs and include lifestyle therapy, either alone or in combination with pharmacotherapy, and when appropriate, bariatric surgery. Lifestyle therapy, including

Table 36-10 The 5 A's of Obesity Treatment

Ask	Ask for permission to discuss body weight and explore readiness for change.
Assess	Assess body mass index, waist circumference, and obesity stage; explore drivers and complications of excess weight.
Advise	Advise the patient about the health risks of obesity, the benefits of modest weight loss, the need for a long-term strategy, and treatment options.
Agree	Agree on realistic weight-loss expectations, targets, behavioral changes, and specific details of the treatment plan.
Arrange or assist	Assist in identifying and addressing barriers, provide resources, assist in finding and consulting with appropriate providers, and arrange regular follow-up.

Adapted from Alexander SC, Cox ME, Boling et al. Do the five A's work when physicians counsel about weight loss? *Fam Med*. 2011;43:179-184.

behavioral change, is the cornerstone of evidence-based weight control. Using a slow, steady approach, as many of the modifiable lifestyle factors as possible are addressed so that patients come to adopt health-promoting habits and eliminate health-detracting ones. This process can be challenging for patients and, ideally, the physician and patient will work together as partners in this endeavor. The physician or other team members supply the guidance, tools, and encouragement, and the patient supplies the long-term commitment to achieving a healthy weight. Health care practitioner support and peer group support are powerful modalities for effecting behavioral change.

The most successful treatments for obesity incorporate nutrition professionals in the care and counseling of the patient. The diet and lifestyle evaluations are most frequently completed by a nutrition professional, lifestyle educator, or counselor involved in the team approach to helping the obese patient successfully intervene in his or her condition. When the physician partners with the nutritionist and other treatment team members, the patient is more successful in addressing the multifactorial aspects of obesity ([Table 36-11](#)).

DIET

A health-promoting diet is an integral part of weight management. Numerous diets are available; the challenge is to select one that meets the individual nutritional needs and food preferences of each patient. In general, the food plan should include adequate quantity (i.e., sufficient calories) and quality, which includes macronutrients (protein, fats, and carbohydrates) and micronutrients (minerals, vitamins, and phytonutrients). Basic principles of a health-promoting diet include consuming sufficient calories to support a healthy weight; eating a variety of foods to maximize nutritional value; meeting macronutrient needs with food selections of high nutritional value; consuming at least one and preferably two servings of each of the six categories of richly colored foods each day (6-10 total servings/day); and drinking adequate amounts of clean, filtered water. Protein content should range from 10% to 25% of calories, fats 30%, and carbohydrates 40% to 55%. A diet high in fiber and low in sodium is commonly recommended as part of a health-promoting eating plan. For starters, however, virtually all of these details can be rolled into the following simple guidelines: become familiar with serving size so as not to overeat; select whole foods rather than processed foods; choose plant foods over animal foods as often as possible; and drink clean, filtered water (measured in ounces) equal to approximately half your desirable weight (in pounds).

For patients who meet criteria for dysmetabolic syndrome or android obesity, a low glycemic impact diet has been shown to result in more weight loss ([Pittas et al., 2005](#)) and improvement in blood sugar, insulin, and lipids. In this population, limitation of refined carbohydrates is especially important.

CALCULATING IDEAL WEIGHT

We caution against using the life insurance tables of weight for height. These values are observational and reflect what

Table 36-11 Interventions

Dietary	Moderately energy-deficit diets Low-calorie diets Very-low-calorie diets Low-carbohydrate, high-protein diets Low-fat, low-energy-dense diets Low-glycemic index diets Balanced-deficit/portion-control diets Meal replacement diets	Requires a nutrition professional partnering with the patient and medical provider
Physical activity	Moderate intensity: 30 min 5 days a wk Vigorous activity: 30 min 3 days a wk (>6 MET) >200 min a wk (moderate exercise) 90 to 150 min a wk (vigorous activity) Resistance training	Often requires partnering for accountability and persistent change
Behavior therapy	Readiness to change Setting goals Reliable support system Building in maintenance Making gradual changes Keeping records Making it enjoyable Being flexible	Often requires counselors, lifestyle educators, awareness and desire to change health trajectory
Pharmacologic	Orlistat Phentermine-topiramate ER Lorcaserin	Requires monitoring from informed physician
Surgical	LAGB Vertical sleeve gastrectomy Roux-en-Y gastric bypass Distal-roux-en-Y gastric bypass Duodenal switch with biliopancreatic diversion Jejunioileal bypass	Requires surgical and bariatric specialty BMI >40 kg/m ² BMI 35-40 kg/m ² with significant obesity-related comorbidities such as hypertension or type 2 diabetes Unsuccessful attempt at weight loss by nonoperative means Clearance by dietitian and mental health professional No contraindications for surgery

BMI, Body mass index; LAGB, laparoscopic adjustable gastric band; MET, metabolic equivalent. Adapted from Cheskin and Poddar, 2014.

the people surveyed actually weighed rather than derived through research studies of what desirable weight for height would be. Typically, these tables overestimate desirable weight. Instead, use the Hamwi formula, which is a quick method that has been in use clinically since it was introduced in 1964 by the American Diabetes Association (Hamwi, 1964). It is a handy way to get an estimate of desirable weight during a brief office visit. For women, assign 100 lb to the first 60 in and 5 lb for each additional inch of height (for those under 60 inches, subtract 2.5 lb for each inch under 60 in). This calculation will yield an approximate ideal weight. Adjust this weight to a desirable weight by discussing with the patient what she believes has been a comfortable weight for her in the past, her goal weight (which may be much lower than her comfortable weight), and your clinical judgment. If she is 64 in and 200 lb and wants to get down to 140 lb, talk with her about the advisability of losing 1 to 2 lb per week for a healthy approach and to increase the success for long-term maintenance of weight lost and then stage the weight loss using 1 to 2 lb per week weight loss. Perhaps discuss a first goal of losing 20 lb and be sure she understands that will take approximately 3 months. To estimate desirable weight for men, use 106 lb for the first 60 inches and 6 lb for each additional inch. These are estimates for medium frames and can be adjusted $\pm 10\%$ to accommodate small or large frames as needed.

CALCULATING CALORIES

To calculate an appropriate calorie level, the Mifflin–St. Jeor modification of the Harris-Benedict equation (Mifflin et al., 1990) is commonly used because it takes into account age, sex, and activity level (including metabolic needs resulting from medical conditions). It does, however, underestimate calories needed for muscular individuals and overestimates calories for obese individuals. For office visit purposes of arriving at a reasonably good estimate of calorie levels, use the rule of thumb of 10 calories per pound of desirable weight as being the least amount of calories to recommend to keep metabolism humming along. A range of 12 to 13 calories per pound is appropriate for active women and 13 to 15 calories per pound for an active man. This approach guards against recommending calorie levels below 1200 for women and below 1500 for men. Again, the nutrition professional will make any needed adjustments and develop a longer-term plan.

Address weight and healthy eating at each office visit, even if only briefly. Success with weight management is associated with the patient making behavioral changes in small steps. For most physicians, the goals will be to point the patient in the right direction; provide basic guidelines of healthy eating (and physical activity); and refer the patient to a nutrition professional who can personalize the diet to the patient's weight loss needs, comorbid conditions, food preferences, economic status, family requirements

Table 36-12 Centers for Disease Control and Prevention's Physical Activity Guidelines for Americans

Age	Duration and Frequency (Total Time Includes All Three Types of Activity)	Weekly Time (Includes All Three Types of Activities)		
		Aerobic Activity*	Muscle-Strengthening Activities*	Bone-Strengthening Activities*
Children, 6-17 yr	60 min at least 3 days per wk	Moderate or vigorous	Push-ups, gymnastics	Jumping rope, running
Adults, 18-64 yr	Regular activity throughout the week rather than as a single session	150 min per wk of moderate activity, 75 min of vigorous activity, or an equivalent mix of moderate and vigorous activity	2 or more days per week	Not specifically addressed
Older adults, ≥65 yr	Regular activity throughout the week rather than as a single session	150 min per wk of moderate activity, 75 min of vigorous activity, or an equivalent mix of moderate and vigorous activity	2 or more days per week	Not specifically addressed

*Examples of *moderate activities* include brisk walking, water aerobics, riding a bike on level ground or with few hills, playing doubles tennis, pushing a lawn mower, and dancing. Examples of *vigorous activities* include running, swimming laps, riding a bike fast or on hills, playing singles tennis, and playing basketball. *Muscle-strengthening activities* work all major muscle groups (legs, hips, back, abdomen, chest, shoulders, and arms). Examples include lifting weights (machines or hand weights), working with resistance bands, exercises that use your body for resistance (sit-ups, push-ups, pull-ups, gymnastics), heavy gardening (digging, shoveling), climbing wall, and yoga. Bone-strengthening activities include hopping, skipping, jumping, running, jumping rope, tennis, basketball, and gymnastics.

From Centers for Disease Control and Prevention. <http://www.cdc.gov/physicalactivity/everyone/guidelines/children.html>.

(e.g., whether there are children, elders, or other family members with specific health requirements in the home), and overall lifestyle. It is common today for patients not to be skilled in planning, shopping for, and preparing healthy meals. Many need education concerning basic nutrition and the role of food in health. The nutrition professional will be able to address each of these issues and help the patient plan meals appropriate to his or her needs.

If you have reason to believe the patient has food sensitivities, an elimination diet is an inexpensive way to help identify which foods are problematic for the patient. This type of food plan typically eliminates the most common food sensitivities (e.g., dairy, gluten, nuts, citrus, seafood, beef) and environmental toxins for a 21-day period. Each eliminated food category is then added back systematically and the patient's response noted. After suspect foods have been identified, these foods can be removed from the diet or rotated so they are infrequently eaten. If symptoms persist with a food or food grouping, these foods are eliminated for a longer period (e.g., 6-9 months), and reintroduction is again tested and recorded by the patient. If no symptoms are noted, these foods are added back to the diet. If symptoms are noted, the foods are eliminated and may need to be avoided indefinitely.

MOVEMENT AND PHYSICAL ACTIVITY

Physical activity is a key component of a healthy lifestyle for reasons ranging from stress reduction to decreased risk of cardiovascular disease. It is also an important component of preventing and treating overweight and obesity. Movement should be a normal part of life, from a formal exercise program to becoming more physically active in daily routines. Exercise itself burns calories but also promotes the development of lean muscle mass that in turn can increase the amount of calories used even when we are at rest. In general, the goal should be 30 minutes of moderately vigorous physical activity most days of the week. To promote weight loss, a goal of 60 minutes per day may be more appropriate and, to maintain weight loss, up to 90 minutes a day may be necessary. A popular program

promoting physical activity encourages people to walk 10,000 steps each day or at least an initial increase of 2000 steps over baseline. A pedometer is a great way for patients to track their progress. The National Weight Control Registry, which was started in 1993, is the longest ongoing study of individuals who have lost at least 30 lb and have kept it off for a minimum of 1 year. Registry participants who have been successful at weight loss maintenance report exercising at least 1 hour per day every day (Phelan et al., 2007).

Physical activity has three key components: aerobic activity, muscle strengthening (resistance) activity, and bone-strengthening activity. Table 36-12 shows guidelines from the CDC for duration and frequency for physical activity and recommendations for the types of activities to engage in while physically active.

In addition to traditional aerobic and resistance exercise, many people are turning to yoga as a way to strengthen muscles and bones and to combat stress, improve feelings of self-worth, and develop a sense of community with others. See previous discussion on yoga under the heading Environmental Factors.

SLEEP

As discussed earlier, too little sleep, too much sleep, and poor-quality sleep in adults and children have been associated with weight gain, overweight, and obesity (Liu et al., 2013; Mesarwi et al., 2013; Xiao et al., 2013).

The amount of sleep needed varies with the individual. Recommendations for the amount of sleep needed per day are typically given by age and are intended to be guidelines only. The National Sleep Foundation's recommendations for sleep durations across the lifespan are shown in Table 36-13.

Many patients are counseled to lose weight to help their sleep-disordered breathing. Although this approach can be helpful, it is important to remember that for some patients, sleep apnea is the cause or at least a contributing factor for their weight gain. As a result, these patients will have a difficult time losing weight if they have untreated sleep apnea.

Table 36-13 National Sleep Foundation Recommendations for Sleep Durations across the Lifespan

Age	Duration (hr/day)	Schedule
Infants, 1-2 mo	10.5-18	As needed (irregular schedule)
Infants, 3-11 mo	9-12	Naps of 0.5-2 hours
Toddlers, 1-3 yr	12-14	Nap of 1-3 hours
Preschoolers, 3-5 yr	11-12	Nap up to 5 years
School-age children, 5-10 yr	10-11	Nighttime
Teens, 10-17 yr	8.5-9.25	Nighttime
Adults, ≥18 yr	7-9	Nighttime

Adapted from information provided by the National Sleep Foundation.
<http://www.sleepfoundation.org>.

A referral to a sleep specialist is often necessary to help patients reach their goals.

Additionally, the discussion of good sleep hygiene should be included in the office visit. Remind patients to stop work and turn off their computers, phones, and TV an hour before bedtime and keep to a similar schedule to go to bed and to get up. Yoga is being examined as a beneficial modality to improve sleep quality (Afonso et al., 2012; Innes and Selfe, 2012; Taibi and Vitiello, 2011). Add in relaxation exercises such as breathing, yoga, or a calming bath before bedtime to help quiet the mind and body and assist with the transition to sleep.

PSYCHOSOCIAL STRESS

Many patients would benefit from assistance with identifying their stressors, reducing the intensity and number of stressors experienced, learning skills for coping with stressful situations, and changing their maladaptive perceptions. As with improving nutrition, the behavioral changes needed require a slow, steady approach to changing long-term perceptions and behaviors. Most patients are likely to be more successful making these changes for the long term if they are able to work with a behavioral medicine professional, either individually or in a group setting. If you do not have such a professional available to your practice, either as a member of the health care team or on contract, there may be hospital- or community-based programs that host stress management programs. These programs can be quite effective when the patient is at the action stage of the readiness to change continuum.

Mindfulness programs are showing promise for long-term weight management as well as stress reduction. A mindful approach to each of the modifiable lifestyle factors can help overweight and obese patients identify the root cause of their excess weight and develop effective strategies for building resiliency in multiple areas of their lives. The mindfulness approach to behavior change originated in 1985 at the University of Massachusetts Medical Center under the guidance of Jon Kabat-Zinn. Mindfulness means paying attention in a particular way: on purpose, in the present moment, and nonjudgmentally. Mindfulness has been used successfully for therapeutic applications for more than 30 years. Among the better researched mindfulness programs are mindfulness-based stress reduction (MBSR)

(Kabat-Zinn et al., 1985), mindfulness-based cognitive therapy (MBCT) developed by Segal and colleagues (Bieling et al., 2012), and mindfulness-based eating (MB-EAT) (Kristeller and Wolever, 2011).

In a recent overview, Kabat-Zinn and colleagues discuss the current state of MBSR and the neuroscience underlying mindfulness (Paulson et al., 2013). The MBSR program was adapted by Zindel Segal, Mark Williams, and John Teasdale to develop a MBCT program that focuses on thoughts and emotions, particularly in reference to recurring depression and unhappiness. The approach has been incorporated into the clinical guidelines established by the American Psychiatric Association (2000). Although rooted in the Buddhist philosophy, mindfulness programs have been carefully developed as secular programs designed to be acceptable to everyone, regardless of religious orientation.

As with many emerging modalities, mindfulness-based programs originally lacked strong scientific documentation for their efficacy. However, more recently, the studies have used rigorous scientific methodology and integrated the latest in understanding the neuroscience principles that underlie mindfulness. In a review of the current status of mindfulness programs, Marchand (2012) reviewed the studies conducted to date and concluded that the research was of very high quality and published in journals with very high impact factors. Mindfulness approaches singled out as particularly efficacious included conditions commonly seen in primary care, such as depression, anxiety, and pain.

More recently, the field of positive psychology has emerged, founded by Martin Seligman at the University of Pennsylvania (Seligman and Csikszentmihalyi, 2000). This approach came from the realization that the field of psychology focused primarily on what was wrong, identifying and repairing damage to human functioning within a disease model, rather than on what made individuals and communities thrive and flourish. Seligman and his colleagues have worked to turn this orientation around and created a strong movement within academia and clinical practice. Clinicians are particularly subject to focusing on what's wrong as patients tend to come to them when they have a problem. Rather than asking, "What are your concerns?" try asking, "What's going well for you today (or in your life)?" Simple changes such as this one change the tenor of the physician-patient interaction. Focus on what works. Similarly, identify positive psychology-based programs in your community that can assist patients in becoming more positive in spite of their medical challenges.

The physician should also encourage patients to rethink their relationships with themselves and others. Are they comfortable with themselves? Are they able to tap into and trust their own inner wisdom? Do they feel worthy and able to set aside time each day to do one thing that brings them joy? Do they have a strong social support network? If not, what is one thing they could do today that would begin to strengthen existing relationships or develop a new one? Again, mindfulness practice can help significantly in developing relationships with oneself and others. You can find helpful resources at Dr. Seligman's website (<http://www.pursuit-of-happiness.org>) and the Wholebeing Institute (<http://www.wholebeinginstitute.com>).

ENVIRONMENTAL TOXIN EXPOSURE

As discussed previously, the environment presents numerous toxins that can enter our bodies through the food we eat, the water we drink, and the air we breathe. Toxins are potential triggers for harmful effects within the body. Help patients identify the sources of potential toxins and ways to eliminate them. In parallel, consider ways to lower the level of toxins that already exists within the patient. Here, nutrition is key. The detoxification and biotransformation process that occurs in the gut and the liver is dependent on nutrients as cofactors for the various reactions. If you are able to assess whether the patient has one or more genetic variants in the phase I cytochrome P450s (*CYP* genes) or phase II glutathione-S-transferase (*GST*) or N-acetyltransferase (*NAT*) genes, use nutrition therapy to compensate for any genetic limitations that in turn affect activity of the key biotransformation enzymes coded for by these gene variants. Use the cruciferous (cabbage family) vegetables to upregulate other *GST* genes that are unimpaired. Examples of appropriate foods are broccoli, Brussels sprouts, cabbage, greens (e.g., beet, collard, kale, mustard, turnip), and horseradish root.

MICROBIOME

Although it is not yet clear whether the intestinal microbiome plays a significant role in the risk of becoming overweight or obese, it is becoming clear that the human microbiome does contribute to our overall health status. Clues that an overweight or obese patient's microbiome may be unbalanced include gastrointestinal distress, such as gas, bloating, cramping, or motility issues, and a strong history of antibiotic use. Promoting a healthy microbiome through attention to sufficiency of both prebiotics and probiotics would seem to be prudent. Microorganisms enter the digestive tract primarily through the food we eat. Whether the overall microbial composition is pathogenic or beneficial depends in large part on the types of foods eaten. Consuming fermented foods that contain live active cultures is one approach. Examples of such foods include various dairy foods (yogurts, kefir) and nondairy foods (fermented soy, kim chi, natto, miso, sauerkraut, tempeh, and various pickled vegetables). How much of a food containing live active cultures will be needed depends on the patient's beginning microbiome, but a serving a day can be helpful for maintaining a healthy microbial community in the gut. When it is clear that the patient needs to eliminate pathogenic organisms and recolonize the gut with beneficial ones, it is typically more efficient to use a concentrated form of live active cultures, called a "probiotic," available in dietary supplement form. A probiotic will provide a higher titer of microorganisms and appears to colonize the gut more quickly than most food sources. Probiotics come in liquid and capsule forms and may or may not need to be refrigerated, depending on the brand selected. Also depending on the brand, products can be obtained that are dairy free and do not contain ingredients such as wheat, gluten, soy, egg, peanuts, tree nuts, fish, crustacean shellfish, colors, artificial sweeteners, artificial flavors, or preservatives for patients with food sensitivities. A probiotic should contain titers in the billions of organisms per serving. All of this

information can be found on the Dietary Supplement Facts panel on the product. These live organisms thrive on soluble fiber, which is often referred to as a "prebiotic." One or more prebiotic ingredients may be included in the probiotic, but they can also be obtained through a health-promoting diet that includes daily servings of foods such as fruit, vegetables, legumes, and grains.

Caution your patients that they may initially experience some gas and bloating as the microbial population expands within the digestive tract but that the situation will usually fade away within 1 week or so. Allow approximately 1 month for a healthy microbiome to become established and then cut back on the therapy. Daily use of live active cultures of probiotics can be continued because this practice appears to have no known adverse effects. Alternatively, patients may wish to reseed their guts periodically or after antibiotic use with the same protocol they used initially to support the ongoing health of their gut microbiome.

INTERVENING WITH OUR PEDIATRIC POPULATION

Of increasing concern is the growing excessive weight in children. Research shows that children who are obese or overweight rate their well-being as similar to that of children with cancer. Helping our families with prevention of weight gain is of utmost importance. The American Heart Association recently analyzed NHANES data and discovered that fewer than 50% of our adolescents exhibited more than five of seven ideal cardiovascular markers. Markers analyzed included blood pressure, blood sugar, cholesterol, level of physical activity, weight, use of tobacco, and health of their diet (Shay et al., 2013). Poor diet and lack of physical activity in adolescents increases their risk of obesity throughout their lives. Prevention is key, and a family physician is the ideal person to help our children get set up for a healthy life. A good resource for families is *Ending the Food Fight* by David Ludwig, MD, PhD. It is important that we encourage parents to act as good role models and that the family become active together.

In an infant, breastfeeding should be encouraged up to the age of 1 year. Restriction or elimination of sweetened beverages such as soft drinks and sports drinks can greatly reduce caloric consumption in children. The American Academy of Pediatrics (AAP) recommends that even 100% fruit juices be limited to 4 to 6 oz daily for children age 1 to 6 years.

For children age 2 to 5 years, whether they are overweight or obese, the goal is weight maintenance and not weight loss. They will have improvement in their BMI as they grow taller. For overweight children between the ages of 6 and 11 years old, the goal is also weight maintenance. If they meet the criteria for obesity, the goal is 1 lb of weight loss every 2 weeks. For overweight or obese children between the ages of 12 and 18, up to 2 lb of weight loss per month is an acceptable goal (Rao, 2008). It is important to focus on long-term behavioral patterns and lifestyle change with a slow, steady weight loss that can be maintained. Healthy lifestyle modification should be the goal. Overly restrictive diets have the potential of interfering with growth rate, bone mineralization, and menstruation. For a child with a BMI above the 95th percentile (obesity), a more structured

and aggressive approach may be appropriate. Many children and families benefit from working with nutrition professionals. It is very important that the whole family is involved in the lifestyle change to prevent the overweight child from feeling uncomfortable. When the whole family focuses on eating more vegetables and incorporating 60 minutes of exercise every day, it is more likely that the child will be successful. Small, specific, measurable goals will make everyone more successful.

Also encourage parents to make meal time be family time, a time when the family gathers to eat together without distractions, such as television or electronic devices. This practice can help to improve the nutritional status of parents and children alike, encourages interpersonal connections among family members, and provides space for each member to share his or her successes and concerns. Establishing a positive environment is essential for many reasons, including optimal digestion as well as providing a safe space for children to express their concerns and feel heard. Avoiding squabbles over the child's food choices is essential to preserving the positive environment sought. [Table 36-14](#) provides meal time guidelines for parents and children that can promote harmony along with good nutrition.

Prevention is key and can be implemented in every primary care office. Encourage your families to remember the 5-2-1-0 rule recommended by the AAP as part of the White House Obesity Initiative:

- Five servings of fruits and vegetables per day
- Two hours or less of screen time per day
- One hour of physical activity per day
- Zero sweetened beverages per day

The AAP provides prescription forms for the 5-2-1-0 program for use in the clinic (<http://www.aap.org/en-us/professional-resources/practice-support/Patient-Management/Pages/Healthy-Active-Living-Prescriptions.aspx>).

Table 36-14 A Suggested Division of Responsibility at Meal Time

3 Ps for parents	<ol style="list-style-type: none"> 1. Plan healthy meals and snacks. Have healthy food options in the home. 2. Prepare and serve meals. 3. Provide support so your child can make healthy choices.
3 Cs for the children	<ol style="list-style-type: none"> 1. Choose to eat or not. The child chooses whether to eat the healthy meal the parent has prepared and does not have the option to eat other foods not served. 2. Choose what to eat from what is served. It is healthier for the child to choose, and often the child will take a smaller portion than the parent would serve. 3. Choose how much to eat. The child eats until full. The parent should not instruct the child to clean the plate or restrict the quantity of food.

Adapted from [Dunlop A, Blount B](#). Childhood obesity: management. FP Audio 405 (AAFP). Feb 2013.

Weight loss targets depend on many factors, such as the age of the patient and his or her health status. Even small amounts of weight loss can have a profound impact on a patient's health. In multiple studies, 5% to 10% of weight loss has been associated with a reversal of metabolic syndrome, type 2 diabetes, heart disease, and cancer ([Liebermeister, 2003](#)). This is important when counseling patients to make changes. When obesity is approached non-judgmentally from the perspective of health risk, patients may be more accepting of the need to change and more willing to partner with the physician in addressing the problem. A patient does not need to lose weight to reach a normal BMI in order to achieve the health benefits. It also may not be possible for some patients to achieve a normal BMI. That does not mean that they cannot be successful. Have many markers to follow your patient outside of weight, including waist circumference, fasting blood glucose, blood pressure, fasting insulin and triglyceride levels as well as their energy level and how clothes fit for them. If we just focus on weight, patients may feel that they failed if the scale does not decrease enough, when in fact they may have made substantial changes in biomarkers and health risk. What we eat and how active we are is often more important than the amount we weigh. Include more markers to follow so you can motivate your patients with their improvements. Readiness to change should be addressed, and addressing barriers to success is key in weight loss and maintenance. Barriers may include emotional factors (stress, depression) or time constraints that limit exercise or proper food preparation. A support system can be helpful for someone attempting weight loss, including friends, a spouse, or an organized program put together by a local nutritionist.

WHEN LIFESTYLE THERAPY IS NOT SUFFICIENT

Treatment interventions of adult patients with overweight or obesity as a disease are multifactorial depending on the underlying causes and the timeline of weight excess onset. Patients are weighed every day in clinic, and certain weight markers should trigger nutrition and lifestyle counseling and intervention ([Table 36-15](#)). For the best results, the interventions should include many aspects of personal lifestyle: nutrition, physical activity, behavior therapy, pharmacotherapy, and, in certain cases, bariatric surgery. The pharmacologic and bariatric treatments for obesity are discussed here.

Pharmacotherapy

Adding weight loss medication to lifestyle counseling increases average weight loss ([Carvajal et al., 2013](#); [Garvey et al., 2012](#)), but they have been approved for only short-term use. Until the mid 1990s, diet, physical activity, and behavior modifications were the key components of a weight loss program, but the pharmacotherapy option was added as the understanding of the metabolic risks of disease that occurred when the BMI was greater than 27 ([Seagle et al., 2013](#)). Many medications have appeared on the market and have been subsequently withdrawn because of side effects. Three classes of medications continue to be available in the United States approved by the U.S. Food and Drug Administration: (1) decreasing fat digestion and absorption (e.g., Orlistat, a gastric and pancreatic lipase

Table 36-15 Nutritional Biomarkers to Check before Bariatric Surgery, 6 Months after Surgery, then Annually

Nutrient	Biomarker	Primary Symptoms/Signs
Thiamin (vitamin B ₁)	Serum thiamin	Ophthalmoplegia, nystagmus, ataxia, rapid vision loss, Wernicke encephalopathy, peripheral neuropathy with proximal weakness
Folate	RBC folate, homocysteine	Megaloblastic anemia, glossitis
Vitamin B ₁₂	Serum vitamin B ₁₂ , methylmalonic acid	Megaloblastic anemia, neuropathy, memory loss, vision loss, darkening of the skin, decreased vibratory and position sense
Iron	Serum ferritin, TIBC, CBC	Microcytic anemia, fatigue, pallor, koilonychias, glossitis
Vitamin D	25-OH vitamin D, calcium, phosphorus, parathyroid hormone	Decreased bone density, secondary hyperparathyroidism, tender anterior tibia, increased inflammation, periodontal disease
Protein	Serum albumin, plasma amino acids	Edema, excessive alopecia, poor wound healing, sarcopenia, neurotransmitter inadequacy, poor biotransformation
Vitamin A	Plasma retinol	Reduced night vision, hyperkeratosis pilaris, poor immune function
Vitamin E	Plasma α -tocopherol	Neuropathy, ataxia
Vitamin K	PT, serum uncarboxylated osteocalcin	Bleeding tendency, easy bruising, osteoporosis

CBC, Complete blood count; PT, prothrombin time; TIBC, total iron-binding capacity.

Adapted from Xanthakos SA. Nutritional deficiencies in obesity and after bariatric surgery. *Pediatr Clin North Am* 2009;56:1105-1121 and Stone PM. Physical signs indicative or suggestive of undernutrition. In Jones DS, ed. *Textbook of functional medicine*. Gig Harbor, WA: Institute for Functional Medicine; 2005:786-788.

inhibitor for long-term use and available over the counter), (2) norepinephrine reuptake inhibitor as an appetite suppressant (e.g., phentermine), and (3) 5-hydroxytryptamine agonist (e.g., lorcaserin, also used as a centrally acting appetite suppressant).

Orlistat works by inhibiting lipases in the gastrointestinal tract, which partially blocks fat absorption. It is approved for up to 2 years of continuous use and has been shown to improve weight loss and lipids, lower blood pressure, and enhance glucose metabolism. In a combined lifestyle intervention study involving Orlistat, the study treatment for 4 years delayed development of type 2 diabetes in obese subjects by 37% (Nicolai et al., 2012).

Phentermine as a norepinephrine reuptake inhibitor is a schedule 4 medication. It has been approved for use for up to 12 weeks since its release in 1959. A continuous off-label use pattern in bariatric medicine has validation in the international literature (Nicolai et al., 2012). The side effect precautions include dry mouth, palpitations, hypertension, constipation, and insomnia.

Phentermine HCl-topiramate extended release is also a schedule 4 medication. It is a combination shorter- and longer-acting medication that combines a shorter-acting sympathomimetic amine and a longer-acting neurostabilizer approved as monotherapy for seizure disorders and migraine headache prevention. Phentermine is metabolized by the liver and excreted by the kidney; topiramate is excreted by the kidney (Garvey et al., 2012; Seger et al., 2013). This combination has been associated with up to a 10% weight loss in phase 3 trials (Garvey et al., 2012).

Lorcaserin is a 5-hydroxytryptamine 2c receptor agonist weight management agent that is a schedule 4 medication used twice a day. Serotonin (5-HT) has been implicated as a critical factor in the short-term (meal-by-meal) regulation of food intake. Its safety profile with coadministration with other serotonergic, antidopaminergic agents has not been established. The drug has multiple multisystem potential side effects (Seger et al., 2013) and should not be used in pregnancy. When combined with a 600-kcal decrease in food intake, lorcaserin twice a day was associated with a 10% weight loss in 20% of patients compared

with 7% in the placebo group in phase 3 trials (Redman and Ravussin, 2010).

Indications for consideration of pharmacotherapy include obesity with a BMI greater than 30; overweight patients (BMI >27) with presence of obesity complications, including type 2 diabetes, hypertension, and dyslipidemia; and no improvement in a 12-week program of therapeutic lifestyle change, including consultation and routine evaluation with a behavioral therapist, nutritionist, and exercise program specialist. When used as an isolated therapy, pharmacotherapy to reduce obesity is not cost effective (Veerman et al., 2011).

Surgery

Indications. Bariatric surgery for patients with BMIs of greater than 40 or patients with BMIs greater than 35 with multiple comorbid conditions is now endorsed by different groups (Buchwald et al., 2004; Buchwald 2005). Over the past 2 decades, the prevalence of severe obesity (BMI >40 kg/m²) has increased from 1 in 200 to 1 in 50 Americans. A new category of the extremely obese (BMI >50) was developed by the CDC to better inform the spectrum of disease and varies in frequency from state, gender, and ethnic background (Kushner and Herrington, 2013). Nearly 6% of adult Americans are severely obese, with the highest prevalence (nearly 14%) in adult African American women. Weight loss surgery has been found to be effective in carefully selected patients and has been reviewed elsewhere (Anderson and Hensrud, 2011; Medical Advisory Secretariat, 2009).

Evaluation for a patient with a BMI greater than 30 and one or more adverse health conditions caused by excessive fat or a BMI greater than 40 with or without adverse health conditions caused by fat mass disease or excessive body fat are the basic considerations now outlined for bariatric surgery (Seger et al., 2013). A thorough medical evaluation, including a bariatric surgery specialty consultation, with cardiology, pulmonary, gastroenterology, nutrition, and mental health evaluations, should be completed (Mechanick et al., 2013). Surgery alters the morbidity of obese patients with diabetes by varying mechanisms

(Cummings et al., 2004). There has been a recent meta-analysis review noting that after bariatric surgery, there was 76.8% complete resolution of type 2 diabetes in the 1846 patients evaluated (Medical Advisory Secretariat, 2009). The patients with gastric banding had a 47.9% resolution of their diabetes; gastropasty, 71%; gastric bypass, 83.7%; and biliopancreatic diversion or duodenal switch, 98.9% (mean change in HbA_{1c} was -2.7%; Medical Advisory Secretariat, 2009).

Techniques and Procedures

PREOPERATIVE. The guidelines for weight loss surgery suggest that patients who cannot comprehend the nature of the surgical interventions and the lifelong measures required to maintain an acceptable level of health should be excluded from surgery (Consensus Development Conference Panel, 1991). Often the patient must show documentation of a 6 to 18 month supervised diet program before insurance authorization for the bariatric procedure (Brethauer, 2011). Exclusion criteria usually include previous weight reduction surgery; previous gastric operations, including gastric or duodenal ulcer, in the past 6 months; active malignancy in the past 5 years; myocardial infarction in the past 6 months; bulimic eating pattern; abuse of alcohol or drugs; psychological problems resulting in poor cooperation; regular use of cortisone or nonsteroidal anti-inflammatory drugs; and other severe illness, including certain autoimmune conditions (Sjostrom et al., 2004).

TYPES OF PROCEDURES. The types of bariatric procedures are illustrated in Figure 36-3. The procedures create one of three post-bariatric surgical states: malabsorptive (Figure 36-3, A to C), restrictive (Figure 36-3, D and E), or a combined malabsorptive and restrictive state (Figure 36-3, F

and G). The malabsorptive conditions are more effective at weight loss, but they have a higher morbidity complication rate. The goal of the restrictive procedures is to limit food intake capacity and to slow the rate of stomach emptying. These include the laparoscopic adjustable gastric banding (LAGB) versus the vertical banded gastroplasty. Because of the ease of procedures and the lack of effectiveness of the vertical banding in trials, gastric banding is common and routinely completed. The adjustable gastric band involves the placement of the banded sleeve that can band a reservoir around the upper quarter of the upper stomach. Gastric banding is followed by the gastric sleeve and finally the roux-en-Y gastric bypass (RYGB) procedure for the lowest cost effectiveness (Seger et al., 2013).

The laparoscopic adjustable gastric band is a silicone ring placed around the proximal portion of the stomach and inflated to create a small proximal gastric pouch and a narrowed opening between the proximal and distal stomach with the gastric pouch holding approximately 30 cc (DeLegge et al., 2013; Shikora et al., 2007). This has been advocated for obese adolescents and those with a lower obese BMI (DeLegge et al., 2013). The lap band procedure is less complicated and is the most often performed in the United States. Weight loss occurs more slowly. Most patients can expect to lose 30% to 50% of their excess weight over 3 to 5 years, with an average of 47% (Buchwald et al., 2004; DeLegge et al., 2013). Laparoscopic adjustable banding is generally an outpatient procedure (Seger et al., 2013). The recovery is usually 1 week, and the contraindications include being a poor surgical candidate because of nutritional status or having severe comorbidities, severe psychiatric disorder, intolerance to general anesthesia, pregnancy, untreated esophagitis, or drug or alcohol

Figure 36-3 Malabsorptive, restrictive, or combined restrictive, and malabsorptive bariatric procedures. (Reprinted with permission from Xanthakos SA. Bariatric surgery for extreme adolescent obesity: indications, outcome and physiologic effects on the gut-brain axis. *Pathophysiology*. 2008;15:135.)

addiction. The acute complications include the band being too tight with gastrointestinal obstruction symptoms, leakage of gastric contents into the abdomen, hemorrhage, gastrointestinal bleeding, infection, cardiac dysrhythmias, atelectasis and pneumonia, deep vein thrombosis (DVT), and occasional death. The chronic complications can include weight regain with no weight loss, band slippage erosion, ulceration, port infection, disconnection, and displacement. The patients may develop esophageal dilation, and there are rarer nutrient deficiencies that can occur if persistent vomiting is marked and there is a sustained decrease in nutritional intake. Depression may also develop.

The sleeve gastrectomy involves surgically reducing the stomach to about 25% of its original size with the surgical removal of a large portion of the stomach along the greater curvature, resulting in a narrower sleeve or tube like structure. The vertical sleeve gastrectomy removes 85% of the stomach, leaving a narrow, tubular, banana-shaped portion of the stomach (stomach capacity, 50-150 cc), and is sometimes advocated for those with a very high BMI (>55 kg/m²). The detached section of the stomach is primarily responsible for production of ghrelin, and weight loss is further enhanced by the lower levels of this hormone that result after the surgery (Frezza, 2007). In general, the hospital stay is 1 to 2 days, with recovery in 1 to 2 weeks. The contraindications are similar to those for the LAP-BAND with the additional contraindications of Barrett esophagus, severe gastroparesis, achalasia, previous gastrectomy, and gastric bypass surgery. The acute complications are similar with addition of pulmonary emboli, rhabdomyolysis, or dehydration. Long-term complications may include marginal ulcers, dumping syndrome with reactive hypoglycemia, and small bowel obstruction caused by internal hernias or adhesions. Additional documented complications include luminal stenosis, anastomotic staple line leak, fistula formation, gallstones, calcium deficiency, secondary hyperparathyroidism, iron deficiency, protein malnutrition, and nutritional and mineral deficiencies (including vitamins A, C, D, E, K, B, and B₁₂, folate, zinc, magnesium, and thiamin). Anemia related to mineral and nutrition deficiencies, metabolic acidosis, bacterial overgrowth, and kidney stones (oxalates) may also develop. Increased frequency of neuropathies, osteoporosis, and depression is seen in this post-surgical population without ongoing assessment and appropriate interventions (Seger et al., 2013; Xanthakos, 2009).

The purely malabsorptive procedures such as the biliopancreatic diversion with or without the duodenal switch (stomach capacity, 50-150 cc) are not commonly performed because of the significant nutritional complications that develop after the procedure, including significant protein, essential fat, vitamin, and mineral deficiencies (DeLegge et al., 2013). The RYGB, the combined malabsorptive and restrictive procedure, usually leaves a gastric pouch of 20 to 30 cc. The patient generally has a hospitalization of 2 to 4 days, with a recovery 2 to 4 weeks or longer. The contraindications are poor surgical candidate, severe psychotic disorder, intolerance to general anesthesia, pregnancy, drug or alcohol addiction, untreated esophagitis, and unwillingness or inability for appropriate long-term follow-up. The acute complications include gastrointestinal obstruction, hemorrhage, gastrointestinal bleeding, anastomotic leaks, infection, cardiac dysrhythmia, atelectasis

and pneumonia, DVT, pulmonary emboli, rhabdomyolysis, dehydration, and death. Chronic complications can include weight regain, marginal ulcers, esophageal dilation, dumping syndrome with reactive hypoglycemia, small bowel obstruction caused by internal hernias or adhesions, anastomotic stenosis, gallstones, calcium deficiency, secondary hyperparathyroidism, iron deficiency, protein malnutrition, other nutritional mineral deficiencies, anemia, metabolic acidosis, bacterial overgrowth, kidney stones (oxalates), neuropathies resulting from nutritional deficiencies, osteoporosis (often caused by calcium deficiency and chronically elevated parathyroid hormone levels), and depression (Seger et al., 2013). The efficacy of the more aggressive surgeries is partially tied to the gastrointestinal endocrine system effects, which are significant. Gut hormones (glucagon-like peptide 1, peptide YY, leptin, and ghrelin) are not affected by restrictive operations such as LAGB and therefore do not contribute to weight loss. The adiposity hormones (leptin and insulin) are elevated in obese individuals and decrease with weight loss. It is suggested that RYGB surgery restores leptin sensitivity (DeLegge et al., 2013). Ghrelin is a known appetite stimulant produced by the stomach and duodenum and increases before eating and decreases afterward (DeLegge et al., 2013). It stimulates mealtime hunger associated with initiation of a meal. Successful weight loss surgery is not associated with lowering of the ghrelin levels.

Dumping Syndrome. Dumping syndrome following RYGB or other gastric surgeries that bypass the pylorus or interfere with gastric innervation is common. Up to 70% of RYGB patients report dumping in the postoperative period (DeLegge et al., 2013), but a minority will have an ongoing problem. It is categorized into early or late dumping syndrome. The early dumping syndrome is handled with low-volume, high-protein, carbohydrate-controlled mini meals (DeLegge et al., 2013) and the addition of soluble fiber from guar gum, glucomannan, or pectins to delay gastric emptying and alter the transit time in the bowel (DeLegge et al., 2013). A host of medications have been used to help alleviate the issue. Octreotide has been used to improve the symptoms of dumping syndrome (Ukleja, 2006)

A successful outcome from bariatric surgery is the loss of 50% of excess weight. A meta-analysis of 22,000 patients demonstrating outcomes reported a weight loss of 61.6% for RYGB and 47% for LAGB. Weight regain occurs in 30% to 50% of the patients, with significant weight regain of 15% to 30% (DeLegge et al., 2013; Hsu et al., 1998; Magro et al., 2008). There is significant success with the correctly selected patient in undergoing a significant body composition change and reductions in type 2 diabetes, hypertension, and dyslipidemia (Table 36-16). The morbidity and mortality from the procedures are markedly affected by the discernment and preoperative screening of the potential surgical patient (Table 36-17). The advantages and disadvantages of the different procedures have been reviewed elsewhere (Anderson and Hensrud, 2011; DeLegge et al., 2013; Medical Advisory Secretariat, 2009; Xanthakos, 2009).

Postprocedure Treatment and Monitoring

There is no doubt that the success of continued weight loss after bariatric surgery requires multiple team members,

Table 36-16 Summary of Findings on Excess Weight Loss and Resolution of Comorbid Conditions

Procedure	Excess Weight Loss (%) [*]	Resolution of Comorbid Conditions (Range %) [†]
MALABSORPTIVE		
Roux-en-Y gastric bypass	60-90	Diabetes mellitus: 74-99 Hypertension: 67-93 Dyslipidemia: 73-99
RESTRICTIVE		
Adjustable gastric banding	42-60	Diabetes mellitus: 29-92 Hypertension: 29-40 Dyslipidemia: 24
Vertical banded gastroplasty	58-67	Diabetes mellitus: 100 Hypertension: 50-60 Dyslipidemia: 14-72

*Percentage of excess weight loss = (Weight loss/Excess weight) × 100 (where Excess weight = Total preoperative weight – Ideal weight)

†Defined as the stopping of medication taken for comorbid condition. From Medical Advisory Secretariat. Bariatric surgery: an evidence-based analysis. *Ont Health Technol Assess Ser.* 2005; 5(1).

Table 36-17 Mortality and Adverse Effects from Bariatric Surgery

Procedure	Mortality Range (%)	Adverse Effects Range (%)
MALABSORPTIVE		
Roux-en-Y gastric bypass	0.1-4.1	0.1-70
RESTRICTIVE		
Adjustable gastric banding	0-0.9	1.1-18
Vertical banded gastroplasty	0-0.8	1.0-30.4

Medical Advisory Secretariat. Bariatric surgery: an evidence-based analysis. *Ont Health Technol Assess Ser.* 2005;5(1).

including the patient with the will for prolonged lifestyle and nutrition habit change; the nutrition professional for continued counseling and education about diet and nutritional interventions; often input from a counselor involved in behavior change; the primary care physician, who continues to be alert to monitor nutrition and disease-associated laboratory and physical examination findings suggestive of under- or malnutrition; and the surgeon, who is involved in any procedural issues associated with the ongoing monitoring and adjustment of the postsurgical patient. Nutrition-directed biomarker tracking needs to be completed before bariatric surgery, at 6 months, and annually after bariatric surgery (see Table 36-15). It is noted that the increased use of malabsorptive and restrictive bariatric surgical procedures has increased the incidence of nutrition deficiency signs and symptoms in the treated obese population (Kumar, 2010; Xanthakos, 2009). Depending on the procedure location in the patient, the full range of nutritional mineral, vitamin, and major nutrient deficiencies can develop over time. The routine and consistent application of the ABCDs of nutrition assessment of obese and postoperative obese patients will aid in their healthful recovery.

Summary

Overweight and obesity and their reduction in quality of life and increase in economic burden are global concerns. Family medicine physicians can make a valuable contribution to decreasing the prevalence of weight-related diseases by addressing weight issues at each office visit. Through the evaluation of the basis for the patient's overweight or obesity and the patient's readiness to change, the physician can identify appropriate ways to move patients in a positive direction along their journey to achieving and maintaining a healthy weight. A number of environmental factors contribute to why a patient is overweight or obese, and a number of modalities are available. It is critical that patients not be overwhelmed with the magnitude of the journey ahead. Help them to take one step at a time. For example, have patients identify one modifiable lifestyle factor each day and ask, "What can I do for myself today that would move me in the direction of the goals I set in partnership with my physician?" Alternatively, if addressing each of the modifiable lifestyle factors is overwhelming, have patients focus on just one domain and select a different one tomorrow. Help them to think in terms of small steps. For example, have them think about making just a small change: eating 5% less today than they typically eat, increasing their physical activity by 5% today, increasing their sleep time by 5% tonight, keeping a gratitude journal for 30 days, or making a commitment to phoning a friend today or attending their church social hour this week to strengthen relationships.

Overview

The goal of improving the health of the U.S. population through approaches such as physical activity and nutrition has come to the forefront of public and medical attention. The efforts of public health and other health care professionals in promoting nutrition's potential to improve health are beginning to result in constructive action, but the majority of the public still reports being confused by what a healthy diet is. The public health approach to improving diet through education is part of the focus on preventing chronic diseases in an aging population, and clinical medicine should join in this effort. Additionally, the clinical medicine approach to nutrition may implement nutritional therapies as part of disease management. For these approaches to work for the public, a unified approach between public health and clinical medicine for improving the nutritional health of the public is necessary. This chapter discusses both approaches.

CURRENT DIETARY GUIDANCE

The latest version of the public health dietary program was introduced in 2013. This is in connection with the MyPlate food system (www.MyPlate.gov).

The new ChooseMyPlate.gov incorporates food choices and other ways to customize the food plan, as well as key concepts, into a visual image (see [Web Resources](#)). Although there is general agreement, many argue that the recommendations are vague and that food amounts and groupings are inappropriate. The major omission in this version of the dietary system has been *physical activity*, which the last version (MyPyramid.gov) had and seems to be critical in the considerations of diet and the balancing of energy needs with intake. The overarching concepts of the 2010 Dietary Guidelines (www.dietaryguidelines.gov) explain the educational framework for the MyPlate, as follows:

- Maintain calorie balance over time to achieve and sustain a healthy weight.
- Focus on consuming nutrient-dense foods and beverages.

There are more than 23 key recommendations in the latest 2010 Dietary Guidelines (which will be revised in

2015) for the general population and six additional key recommendations for specific populations. The Dietary Guidelines that are emphasized in this version of the public guidance are as follows:

- Build a healthy plate.
- Cut back on foods high in solid fats, added sugars, and salt.
- Eat the right amount of calories for you.
- Be physically active your way.

Along with providing the 10 tips to help the public and professionals who educate the public, the goal is to improve the nutritional quality of the American diet to prevent the leading chronic diseases of obesity, heart disease, and type 2 diabetes. The 10 tips that go along with ChooseMyPlate are as follows:

1. Balance calories.
2. Enjoy your food but eat less.
3. Avoid oversized portions.
4. Foods to eat more often include vegetables, fruits, whole grains, and low-fat milk and dairy products.
5. Make half your plate fruits and vegetables.
6. Switch to fat-free or low-fat (1%) milk.
7. Make half your grains whole grains.
8. Foods to eat less often include foods high in solid fats, added sugars, and salt.
9. Compare sodium in foods.
10. Drink water instead of sugary drinks.

There are additional recommendations for women capable of becoming pregnant, women who are pregnant or breastfeeding, infants and children, and individuals ages 50 years and older.

The specifics of the ChooseMyPlate are many, and the latest dietary guidelines might be as confusing as previous guidelines. The American plans are a combination of food- and nutrient-based recommendations, the latter of which are often difficult to explain to and are not well understood by the public. Both the professional community and the general public recognize the important role of proper nutrition in maintaining health, but neither always heeds current evidence. Physical activity also needs to be part of any discussion about nutrition. This chapter highlights the current evidence for supporting nutritional approaches to

common medical and health concerns. Recent research emphasizes that the whole-food diet (rather than specific nutrients or supplements) seems to be most important to influencing positively the prevention and treatment of chronic diseases.

Nutrition Assessment

A nutrition assessment is the process of determining an individual's nutritional status or whether adequate amounts of required nutrients are available to and absorbed by the body. Every patient in a family medicine practice deserves some level of nutrition assessment. This assessment can be a brief screen when the patient is relatively healthy or more in-depth if the patient appears to have nutritional inadequacy or risk factors for malnutrition. The depth of the assessment is based on the patient and the presenting situation. Those who may require a more in-depth evaluation include patients who are grossly overweight or underweight, patients with a chronic or severe acute illness, growing infants and children, patients in poverty or otherwise unable to obtain a variety of foods, most frail older adults, and patients who maintain nontraditional diets such as recent immigrants or fad dieters ([American Dietetic Association, 2012](#)).

HISTORY

Patients with chronic illness deserve a more thorough history assessment, as do patients with symptoms or signs potentially related to poor nutrition ([Table 37-1](#)). Physicians should review gastrointestinal (GI) symptoms and elicit information about supplemental vitamins and other nutritional products, alcohol and illicit drugs, appetite suppressants or stimulants, glucocorticoids, and laxatives. In at-risk patients and those with clinical evidence of poor nutrition, clinicians should consider the presence of conditions that may increase nutritional requirements. Physicians should also investigate the patient's ability to obtain, ingest, digest, metabolize, and absorb nutrients; consider whether a treatment or medication will require modification of the diet; and use information obtained in the history to plan for that change.

Conditions That May Increase Nutritional Requirements

Any condition that increases the metabolic rate of the patient is likely to increase nutritional requirements ([Table 37-2](#)).

Ability to Obtain Food. Patients in poverty and who cannot or do not receive financial assistance are at risk for poor nutrition because of an inability to obtain enough food or a variety of foods. Those who lack transportation or have other shopping access issues, such as language barriers or distance from a store, may also not be able to acquire sufficient food. Patients who rely on others to provide food, prepare food, or both may have inadequate dietary intake. Many patients, because of poor mobility and declining health, gradually lose the ability to perform activities of daily living, such as shopping, cooking, and cleaning, so the

history should contain specific questions directed at these activities. Individuals with substance abuse problems or poor mental health may lack the initiative or ability to acquire healthy foods.

Ability to Ingest Nutrients. Various conditions may contribute to a patient's inability or lack of desire to eat (see [Table 37-2](#)).

Digestion. A number of processes can affect the normal digestive process. Any factor that interferes with the secretion of acid or enzymes into the stomach or small intestine may impair digestion. For example, patients with partial gastrectomy or even vagotomy for peptic ulcer disease may have maldigestion and nutritional deficiencies. Similarly, patients with chronic pancreatitis or on chronic acid-suppressing medicines may lack acid and certain digestive enzymes and thus cannot absorb all nutrients.

Absorption. Patients may demonstrate poor absorption of nutrients for a variety of reasons, including loss of absorptive surface area in the intestinal tract from surgery; Crohn disease; infectious processes; or other inflammatory conditions, such as celiac disease. It is important to be aware of hidden sources of gluten in a variety of foods ([National Digestive Diseases Information Clearinghouse, 2008](#)) ([Table 37-3](#)). Incomplete digestion and processing of fats, carbohydrates, proteins, and vitamins can also lead to decreased absorption of those nutrients. [Table 37-4](#) lists various nutrients and their sites of metabolism and absorption.

Metabolism and Excretion. Many chronic diseases result in poor metabolism of foods, which leads to poor availability of calories and other nutrients. Additionally, any condition that results in excessive losses of nutrients through the intestinal tract or kidneys may also result in malnutrition. Certain foods, such as nonabsorbable fat substitutes, cause excessive loss of fat-soluble vitamins, with steatorrhea caused by the fat not being absorbed ([Table 37-5](#)).

Dietary History

It is important to obtain information about the patient's usual and recent diet as part of the history. The dietary history refers to a patient's usual pattern of food intake and any factors that may influence food choices and availability. Screening questions include number of daily meals and examples of food consumed. A more thorough evaluation delves into cultural or religious food practices, personal preferences, and use of a table or picture of the food groups as a tool to help patients identify food groups from which they may be consuming too few or too many servings.

A specific part of the dietary history is a *nutrient intake* analysis. This history relies on a food diary kept by the patient for a specific period, usually 3 to 7 days, including times, food and beverages consumed, and activity. Clinicians also use *dietary recall* as a method to assess nutrient intake. With this tool, patients report foods and beverages consumed over the past 24 to 48 hours. This retrospective analysis has less validity than the prospective food diary because people typically are unable to remember the details

Text continued on page 898

Table 37-1 Summary of Major Nutrients

Nutrient	Major Dietary Sources	Major Functions	Signs of Deficiency	Usual Causes of Deficiency	Effects of Excess	Normal Laboratory Value
Protein (supplies 4 kcal/g)	Fish, chicken, beef, other animals; lentils, seeds, legumes, dried beans; dairy products; eggs; nuts	Building materials (AAs) for growth, maintenance, repair of all cells; regulates fluid balance between blood and cells; provides energy; essential AAs are threonine, tryptophan, histidine, lysine, leucine, isoleucine, methionine, valine, and phenylalanine	Kwashiorkor (protein malnutrition); decreased immune response; edema; stunted growth and development; poor musculature; marasmus (protein-energy malnutrition)	Poor intake of protein, especially high-quality protein; too few calories so that protein is used for energy; malabsorption; genetic diseases of protein, AAs (e.g., PKU)	Reduced calcium retention; weight gain; obesity	Albumin, 3.5-5.0 g/dL; BUN, 9-20 mg/dL; creatinine, 0.3-1.3 mg/dL; prealbumin, 10-40 mg/dL; total protein, 6.0-8.0 g/dL
Carbohydrates (CHO) (supply 4 kcal/g)	Cereal grains, dried peas and beans, bread, pasta, vegetables, fruits, dairy products, sugar, jellies, other sweets	Provide energy for body processes and physical activity; aid in use of fat and spare protein; provide energy; many vitamins and most fibers are CHO	Growth retardation; weight loss	Poor intake; malabsorption; genetic diseases of CHO (e.g., glycogen storage disease)	Weight gain; obesity; increased blood triglyceride levels	None
Fat (supplies 9 kcal/g)	Saturated fats: meats, dairy fats (e.g., ice cream, sour cream, butter), bacon, sausages Unsaturated fats: avocado, oils (e.g., corn, safflower, vegetable) Monounsaturated fats: olive oil, canola oil	Supplies concentrated source of energy; carries fat-soluble vitamins; supplies essential fatty acids (e.g., linoleic, linolenic, arachidonic acids); membrane structures; transport processes of cells Provides substrate for most of body's reactions; helps move materials to and waste from cells; helps control body temperature; lubricates joints in body	Flaky, scaly skin; poor growth; hair loss; impaired wound healing and immune functioning	Poor intake; malabsorption; extreme diets or supplementary feedings for long periods (e.g., IV lines, TPN without fats)	Increased blood cholesterol or triglyceride levels; weight gain; obesity	Total cholesterol, <200 to >140 mg/dL; HDL >45 mg/dL; LDL <100-130 mg/dL
Water	Water, beverages, fruits; almost all foods contain some water		Dehydration; death	Poor intake; medications; diarrhea; vomiting; high temperatures	Excess retention of fluid related to imbalance of minerals; overconsumption is rare but can result in death	Dehydration: increased albumin, BUN Fluid overload: decreased albumin, BUN
VITAMINS						
Water-Soluble Vitamins						
Vitamin B ₁ (thiamin)	Lean pork, wheat germ, whole or fortified cereals, legumes, bread products	Assists in use of CHO and fat for energy; promotes growth, appetite, and muscle tone; promotes normal functioning of nervous system; coenzyme in metabolism of CHO branched-chain AAs	Beriberi; changes in nerves; excessive water retention; loss of appetite; depression; muscle tenderness; high-output cardiac failure; polyneuritis	Poor intake; malabsorption; hemodialysis	None reported	Thiamine pyrophosphate (TPP); stimulation >20% (index >0.2% indicates deficiency)

Continued on following page

Table 37-1 Summary of Major Nutrients (Continued)

Nutrient	Major Dietary Sources	Major Functions	Signs of Deficiency	Usual Causes of Deficiency	Effects of Excess	Normal Laboratory Value
Vitamin B ₂ (riboflavin)	Dairy products, liver and other organ meats, meat, fish, dark green vegetables, fortified grain products	Functions as part of energy release; essential for growth; part of flavin coenzymes required in cellular oxidation	Cheilosis; photophobia; angular stomatitis; magenta tongue; glossitis; seborrhea; corneal vascularization	Poor intake; malabsorption	None reported	FAD; stimulation >40% (index >1.4% indicates deficiency)
Vitamin B ₆ comprises six compounds: pyridoxal, pyridoxine, pyridoxamine, and three 5'-phosphates: pyridoxal (PLP), pyridoxine (PNP), and pyridoxamine (PMP)	Liver, pork, poultry, whole or fortified grain products, bananas, legumes, lentils, fortified soy-based meat substitutes, nuts	Cofactor for many enzymes in metabolism of protein and AAs; functions in hemoglobin synthesis	Anemia; irritability; convulsions (in infants); skin lesions; smooth red tongue (glossitis); peripheral neuropathies; impaired all-mediated immunity	Poor intake; malabsorption; aging (increased need); medications	Sensory neuropathy marked by changes in gait and peripheral sensation	—
Vitamin B ₁₂ * (cobalamin)	Liver, beef, poultry, fish, eggs, brewer's yeast (not present in plant foods) Oral initial dose: 1000-2000 µg per 1-2 weeks Maintenance: 1000 µg daily for life IM initial dose: 100-1000 µg daily or every other day for 1-2 weeks Maintenance: 100-1000 µg every 1-3 months	Maintenance of nervous tissue and blood formation; nucleic acid synthesis; recycling of tetrahydrofolate	Megaloblastic anemia (pernicious anemia); permanent damage to nervous system; peripheral neuropathy; weight loss; glossitis	Deficiency of hydrochloric acid in stomach (as occurs with aging); strict vegetarians; high intakes of folate can mask deficiency of vitamin B ₁₂	None reported	Schilling test: 8% of radioactivity per 24-hour urine [†]
Vitamin C (ascorbic acid)	Citrus fruits and juices, tomatoes, potatoes, cabbage, broccoli, strawberries, spinach	Cofactor for reactions requiring reduced copper or iron metalloenzymes; protective antioxidant	Scurvy; easy bruising; slow wound healing; degeneration of skin, teeth, gums, blood vessels	Smokers have increased need, poor intake	GI disturbances; kidney stones; excess iron absorption	Plasma or leukocyte vitamin C measured by chromatography; plasma vitamin C, 0.50-1.40 mg/dL (30-80 µmol/L)
Folate (folic acid, folacin, pteroylpolyglutamates)	Dark-green leafy vegetables, whole grains, legumes, nuts, organ meats, orange juice, fortified cereal products	Assists in red blood cell maturation; cofactor for synthesis of purine and pyrimidine; coenzyme in metabolism of nucleic acids and AAs	Megaloblastic anemia; general weakness; depression; polyneuropathy; GI upset; deficiency linked to neural tube defects in fetus (400 µg/day recommended pre-pregnancy)	Poor intake; malabsorption	Masks deficiency of vitamin B ₁₂	Red blood cell folate, 4-20 ng/mL
Niacin (includes nicotinic acid amide, nicotinic acid, nicotinamide)	Liver, meat, bran or fortified cereal products, fish, poultry, whole or fortified grains, peanuts, tuna	Part of coenzymes for oxidation-reduction reactions; active in release of energy and biosynthesis of fatty acids	Pellagra; pigmented dermatitis; dementia; diarrhea; inflammation of mucous membranes; weakness; tremors	Poor intake; malabsorption; consumption of processed grains that have niacin removed; hemodialysis	Flushing, burning, tingling around face, neck, hands; liver damage; GI distress	—

Nutrient	Major Dietary Sources	Major Functions	Signs of Deficiency	Usual Causes of Deficiency	Effects of Excess	Normal Laboratory Value
Pantothenic acid	Liver, egg yolks, meat, mushrooms, whole grains, brewer's yeast, broccoli, skim milk, sweet potatoes, avocados	Component of coenzyme A; functions in release of energy from CHO, protein, and fat; coenzyme in fatty acid metabolism	Fatigue; malaise; insomnia; burning paresthesias; depression; weakness (rare)	Poor intake; malabsorption; incomplete PEN or TPN formulas	Unknown	—
Biotin	Nuts, soy, eggs, nonfat milk, sweet potatoes	Coenzyme for carboxylation reactions; plays a role in CHO and fat metabolism; coenzyme in synthesis of fat, glycogen, and AAs	Dermatitis; neuritis; appetite loss; nausea; glossitis; insomnia; thin hair; depression; hypercholesterolemia (few known cases)	Incomplete PEN or TPN formulas	Unknown	—
Fat-Soluble Vitamins						
Vitamin A (includes provitamin A such as retinols, carotenoids)	Liver, dairy products, fish; turkey (carotene), carrots, dark-green leafy vegetables, sweet potatoes, cantaloupe, apricots, broccoli, tomatoes	Maintenance of skin and mucous membranes; component in visual process; particular adaptation to darkness; immune function	Night blindness; xerophthalmia; keratomalacia; Bitot spots; follicular hyperkeratosis; reduced immunity; poor growth	Poor intake; malabsorption with steatorrhea; liver disease	Loss of appetite; headache; vomiting; blurred vision with eventual eye damage; liver toxicity; teratogen in fetal growth	Serum retinol and retinol ester vitamin A, 30-80 µg/dL (1.0-2.8 µmol/L)
Vitamin D (calciferol) uptake; glucocorticoid	Fortified dairy products, [‡] fish, eggs; sunlight (15 min/day for 3-4 days/wk)	Mineralization of bones and teeth; intestinal regulation of calcium and phosphorus	Rickets (children); osteomalacia (adults); costochondral beading; muscle weakness and twitching; low serum calcium	Poor sunlight exposure; poor intake; with aging, poor uptake glucocorticoid therapy may need additional vitamin D	Poor growth; weight loss; poor appetite; calcium deposits in soft tissues	25-hydroxy-vitamin D test, costochondral
Vitamin E (also called α-tocopherol)	Nuts, fats, polyunsaturated vegetable oils, margarine, seeds, whole grains	Antioxidant; prevents peroxidation of polyunsaturated lipids; free radical scavenger	Hemolytic anemia of newborn; increased fragility of red blood cells; nerve and muscle disturbances in severe malabsorption	Lipid malabsorption	Interferes with vitamin K (risk of bleeding, especially in trauma); hemorrhagic toxicity; monitor patients taking anticoagulants and vitamin E supplements	Serum tocopherol measured by chromatography, 0.5-1.8 mg/dL (12-42 µmol/L)
Vitamin K	Dark-green leafy vegetables, liver, vegetable oils, margarines, cabbage family	Synthesis of prothrombin and clotting factors II, VII, IX, and X	Bleeding (especially in newborns); ecchymosis; epistaxis; prolonged clotting time	Bacteria destroyed in gut that produce vitamin K; liver disease; lipid malabsorption	Unknown; monitor patients taking anticoagulants with vitamin K intake	PT to assess vitamin K indirectly
MINERALS						
Calcium	Dairy products, fish with small bones, dark-green leafy vegetables (mustard greens, kale), corn tortillas, calcium-set tofu	Structure of bones and teeth; nerve transmission; muscle contraction; essential role in blood clotting	Stunted growth; bone loss; rickets; osteomalacia; osteoporosis; tetany; possibly hypertension	Poor intake; poor consumption of vitamin D; poor sunlight exposure; lack of physical activity; high phosphorus intake	Decreased absorption of other minerals; kidney stones; hypercalcemia; milk-alkali syndrome; renal insufficiency	8.5-10.5 g/dL

Table 37-1 Summary of Major Nutrients (Continued)

Nutrient	Major Dietary Sources	Major Functions	Signs of Deficiency	Usual Causes of Deficiency	Effects of Excess	Normal Laboratory Value
Chloride	Table salt; seafood, meat	Acid-base balance; constituent of gastric juice; major anion of ECF	Rare; mental apathy, muscle cramps, usually seen with sodium depletion	Rare in United States (has occurred in babies whose formula did not have chloride)	None reported	96-106 mEq/L
Chromium	Fish, cheese, meat, poultry, whole-grain cereals, beer	Insulin cofactor; glucose and energy metabolism	Insulin resistance; glucose intolerance	Unknown	None reported	—
Cobalt	Organ and muscle meats, dairy products	Constituent of vitamin B ₁₂	Only as vitamin B ₁₂ deficiency; pernicious anemia	Those associated with vitamin B ₁₂	None reported	—
Copper	Liver, shellfish, nuts, whole grains, cereals, legumes, cocoa products	Absorption and use of iron; enzyme cofactor; in myelin nerve sheath	Anemia; kinky hair; neutropenia; disturbance of bone formation	Usually genetic	Wilson disease (genetic); iron-deficiency anemia; chronic renal failure	—
Fluoride	Fluoridated drinking water, fluoridated dental products, seafood	Structure of bone and teeth enamel; reduces dental caries	Dental caries	Nonfluoridated water or dental products	Mottled teeth; enamel and skeletal fluorosis	—
Iodine	Iodized salt; seafood, saltwater fish	Constituent of thyroid hormone	Goiter; cretinism	Lack of iodine in food or in soil where food is grown	Rare; goiter may be caused by excess iodine; elevated TSH	—
Iron	Liver, lean meats, legumes, egg yolk, fortified cereals and breads	Constituent of hemoglobin; involved in oxygen and electron transport	Microcytic hypochromic anemia; fatigue; decreased immune response	Poor intake; blood loss	Liver and pancreas damage; large dose at one time: shock, death; GI distress	Serum iron, 50-150 µg/dL
Magnesium	Bran cereals, nuts, legumes, green leafy vegetables, meat	Part of protein synthesis; helps muscles contract and helps nerve impulse transmission	Rare; behavioral disturbances, tremor, spasms, neuromuscular irritability	Rare	Rare; diarrhea; fatigue; nervous system disturbances (usually from pharmacologic agents; not food sources)	1.5-2.5 mEq/dL
Manganese	Nuts, legumes, whole-grain cereals	Involved in formation of bone and enzymes in AAs, cholesterol, and CHO metabolism	Rare; dermatitis; weight loss	Rare	Rare; inhaled manganese linked to CNS disorders, neurotoxicity	—

Nutrient	Major Dietary Sources	Major Functions	Signs of Deficiency	Usual Causes of Deficiency	Effects of Excess	Normal Laboratory Value
Molybdenum	Whole-grain cereals, legumes, nuts	Oxidation-reduction reactions; enzyme helps in catabolism of sulfur AAs; metabolism of purine, pyrimidines	None	None	Unknown	—
Phosphorus	Dairy products, eggs, meat, whole-grain cereals, soda	Structure of bone and teeth; component of phospholipids; helps regulate acid–base balance; energy metabolism	Rare; demineralization of bone; weakness; poor growth; paresthesias of hands and feet	Rare in United States	May cause deficiency of calcium, skeletal porosity; interference with calcium absorption	2.5–4.5 mg/dL
Potassium	Fruits (particularly bananas, citrus juices), dairy products, potatoes, vegetables	Major component of intracellular fluid; regulates acid–base and water balance; maintains heart and nerve function	Muscle weakness; rapid, irregular heart rate; paralysis; death	Medications (e.g., diuretics), especially with poor intake	Electrolyte imbalance; muscle weakness; disturbed heart function; death	3.5–5.0 mEq/dL
Selenium	Organ meat, seafood, plants from selenium-containing soil	Antioxidant; constituent of glutathione oxidase	Rare; cardiac myopathy; muscle tenderness	Rare	Rare; hair and nail brittleness and loss	—
Sodium	Table salt, processed foods, in most foods except fruits	Maintains water balance; influences muscle contraction and nerve irritability	Rare; muscle cramps; reduced appetite	Rare; restricted diet with excessive medication	In some people, retention of fluids and hypertension	135–145 mEq/dL
Sulfur	Protein foods (e.g., meat, dairy, legumes)	Constituent of coenzyme A, AAs, hair, cartilage	No dietary deficiency with adequate protein	Rare	Rare	—
Zinc	Meat, seafood, dark meat of poultry, whole grains, legumes	Component of enzymes and proteins; involved in regulation of gene expression	Growth failure; impaired wound healing; taste changes; decreased immune response	Poor consumption of protein foods; phytate consumption inhibits absorption	Fever, nausea, vomiting, diarrhea; reduction in copper	115 ± 12 ng/dL

Table 37-2 Select Conditions That Increase Nutrient Requirements

Pregnancy
Lactation
Healing wounds, including skin ulcers
Surgery
Trauma
Burns
Chronic lung disease
Cancer
AIDS
Infection
Inflammatory diseases
Hyperthyroidism

Table 37-3 Celiac Disease: Grains with and without Gluten

Grains or Flours Allowed		Grains or Flours with Gluten: Not Allowed
Rice	Millet	Wheat (e.g., durum, semolina, kamut, spelt)
Soy	Buckwheat	Rye
Potato	Arrowroot	Barley
Tapioca	Amaranth	Triticale
Beans	Tef	Oats (most likely because of contamination)
Garfava	Wild grass seeds (Montina)	
Sorghum		
Quinoa	Nut flours	

Table 37-4 Nutrients and Sites of Metabolism and Absorption

Nutrient	Site of Absorption
MACRONUTRIENTS	
Amino acids	Throughout small intestine (more rapid proximally)
Sugars	Throughout small intestine
FATS	
Fatty acids	Throughout small intestine (mostly proximal)
Bile acids	Ileum
Short-chain fatty acids	Colon
MINERALS	
Calcium	Duodenum, jejunum
Iron	Duodenum
Magnesium	Small intestine
VITAMINS	
Folic acid	Proximal small intestine
Vitamin B ₁₂	Ileum
Fat-soluble vitamins (A, D, E, K)	Small intestine

of their past eating habits accurately (Hammond, 2004). There are currently several smartphone applications and software programs that allow patients to track their own food intake. A recent study evaluated the content of several of these apps to determine which best aligned with weight loss theory, including providing motivation, diet tracking, healthy cooking, wise grocery shopping choices, and weight and body mass index (BMI) tracking. Lose It by FitNow, Inc. best fulfills those criteria (Azar et al., 2013). Another useful app is the eTools app from Weight Watchers, which allows members to track meals online or through the app, as well as document activity, find ideas for healthy recipes,

Table 37-5 Conditions Affecting Metabolism and Excretion

Type of Impairment	Possible Contributing Condition
Impaired dietary intake	AIDS
	Anorexia nervosa
	Cancer
	Depression
	Dental problems
	Hyperemesis gravidarum
	Poverty
	Stroke
	Substance abuse
	Maldigestion
Enzyme deficiencies	
Intestinal bacterial stasis	
Pancreatitis or insufficiency	
Radiation enteritis	
Malabsorption	Short bowel syndrome
	AIDS
	Celiac disease
	Intestinal lymphoma
Impaired metabolism	Radiation enteritis
	AIDS
	Cancer
	Chronic disease (liver, kidney)
	Corticosteroid use
Increased excretion of nutrients	Diarrhea (zinc, magnesium)
	Glucosuria
	Inflammatory bowel disease
	Protein-losing enteropathy
	GI bleeding (iron)
Increased requirements	Burns
	Trauma
	Surgery
	Chronic infection
	Inflammation
	Chronic lung disease
	Hyperthyroidism
	Sepsis

AIDS, Acquired immunodeficiency syndrome; GI, gastrointestinal. Modified from Newton JM, Halsted CH. Clinical and functional assessment of adults. In Shils ME, Olson JA, Shike M, Ross AC, eds. *Modern nutrition in health and disease*. 9th ed. St. Louis: Lippincott-Williams & Wilkins; 1999.

and read tips on how to choose healthy options while eating out. A recent study demonstrated that individuals enrolled in Weight Watchers with access to the eTools mobile app and online system as well as the support meetings were more successful with weight loss than individuals enrolled in a self-help system (Johnston et al., 2013). Both Lose It and eTools include bar code scanner capability, which allows automatic logging of nutritional information on packaged foods.

HealthyOut is an app and website that was developed for New York City and is now available as a resource listing different restaurant food options throughout the country. HealthyOut allows the user to select a type of dietary pattern (healthy, low carbohydrate, vegan, and many others) and find nearby restaurants offering appropriate foods. The application gives ideas for what to order at a particular restaurant, as well as nutritional information (see [Web Resources](#)).

Although these apps and websites facilitate the process, studies have shown that patients continue to struggle to accurately determine portion size when reporting (Nelson et al., 1994).

PHYSICAL EXAMINATION

Key Points

- Significant weight loss—5% in 1 month, 7.5% in 3 months, or 10% in 6 months, from usual weight—indicates the need for further evaluation to determine the cause.
- Although BMI is a validated independent measure of body fat, it may not accurately reflect body composition in certain subsets of individuals, such as trained athletes and elderly adults.

A systematic physical examination is important in evaluating nutritional status. General inspection may immediately reveal obvious overweight or underweight. Anthropometry, or physical measurements of an individual that are compared with reference standards, plays a role as well. These parameters include height, weight, skinfold thickness, head circumference (especially in infants and children), and waist and hip circumferences. These measurements are most helpful when taken at several intervals over time.

Height and Weight

It is useful to measure height and weight to assess nutrition. Patients tend to overestimate their height and underestimate their weight. In considering weight alone in adults, the *usual body weight* is a more useful parameter than ideal body weight obtained from published tables. In children, body weight is more useful than height in estimating body fat and provides information about recent nutrient intake (Hammond, 2004). Changes in weight over time from the usual body weight may reflect a change in nutritional status. However, it is important to remember that acutely, weight loss or gain may signify a change in fluid status rather than in nutritional well-being. In an obese individual or older adult, loss of lean body mass indicating malnutrition may be masked by the presence of excess body fat.

Significant weight loss is defined as a 5% loss in 1 month, a 7.5% loss in 3 months, or a 10% loss in 6 months. A severe weight loss is defined as any loss higher than those percentages in the same interval. The following method is also used to assess nutritional status as a function of weight loss (Hammond, 2004):

- Weight within 85% to 90% of usual body weight—*mild malnutrition*
- Weight within 75% to 84% of usual body weight—*moderate malnutrition*
- Weight less than 74% of usual body weight—*severe malnutrition*

Both height and weight are needed to calculate BMI, which is highly correlated with independent measures of body fat in adults (Balcombe et al., 2001; Keys et al., 1972). The formula for calculating BMI is $\text{Weight (kg)}/[\text{Height (m)}]^2$. Table 37-6 lists parameters for overweight, obesity, and underweight according to the BMI (see Web Resources for a BMI calculator).

It is important to note the limitations of the BMI as a nutritional assessment tool. It may overestimate body fat in trained athletes, and it may underestimate body fat in older

Table 37-6 Weight Categories According to Body Mass Index (BMI)

Category	BMI (kg/m ²)
Underweight	<18.5
Normal	18.5-24.9
Overweight	25-29.9
Obese	≥30

From National Heart, Lung, and Blood Institute (NHLBI). Clinical guidelines on the identification, evaluation, and treatment of overweight and obesity in adults, BMI calculator. <http://www.nhlbisupport.com/bmi/bmicalc.htm>.

patients and in those who have lost lean body mass because of nutritional deficiency. Studies show that body composition is probably more predictive than BMI of chronic diseases such as metabolic syndrome (Gomez-Ambrosi et al., 2012). Additionally, there is fairly strong evidence that individuals who are overweight by National Heart, Lung and Blood Institute (NHLBI) guidelines (BMI, 25 to <30 kg/m²) actually have lower age-related all-cause mortality than individuals at normal BMI (18.5 to <25 kg/m²) (Flegal et al., 2012; Flegal et al., 2013; Ogden et al., 2012).

Body Composition

Assessment of body composition reveals the relative amount of body fat and lean body mass. One common method for assessing subcutaneous fat is the measurement of *skinfold thickness*. Several areas of the body have demonstrated good correlation with body fat, including the triceps, biceps, subscapular tissue, and tissue above the iliac crest. Measurements are taken with calipers and compared with standardized tables to determine the percentage of body fat. This type of assessment can be limited by the accuracy of the measuring technique. Changes in skinfold thickness take place over 3 to 4 weeks, so this measurement is not a useful gauge for determining acute changes in nutritional status.

Circumference measurements are useful in assessing nutritional status. The waist circumference correlates with abdominal fat content. Increased waist circumference has been associated with cardiovascular disease risk factors (Dalton et al., 2003). The correct method for waist circumference is to measure the distance around the smallest area below the rib cage and above the umbilicus. Waist measurements of more than 40 inches in men and 35 inches in women are independent risk factors for disease (NHLBI, 2005). The waist circumference has less predictive value in patients shorter than 5 feet tall and in those with BMI greater than 35.

General Physical Examination

Certain findings on physical examination may alert the physician to the potential for malnutrition. Many of the physical signs of nutritional deficiency are age dependent. General findings include loss of subcutaneous fat (orbital or in triceps area), temporal wasting, decreased muscle mass in general, proximal muscle weakness, reduced grip strength, and certain skin changes (e.g., scaling, poor wound healing, bruising). Tissues in the body that undergo rapid cell turnover, such as mucous membranes, skin, and hair, may be the first to show signs of nutritional

insufficiency (see [Table 37-1](#)). In children, decelerating linear growth, lethargy, and fat depletion may signal malnutrition.

Macronutrient deficiencies present with specific signs, depending on the nutrient. For example, dietary fat deficiency, which may be seen with disordered eating, may be evidenced through flaky skin, hair loss, or poor wound healing. A deficiency of protein (kwashiorkor) that is severe will present with a protuberant abdomen, hair loss, loss of skin pigmentation, and growth retardation ([Hoffer, 2012](#)).

Overall, most vitamin deficiencies are uncommon in the United States, but some signs should alert physicians to evaluate for those nutritional deficits or malabsorption. For example, several B vitamin deficiencies may result in glossitis, or a smooth tongue appearance. A niacin deficiency (seen in individuals with alcoholism or malabsorption) may cause diarrhea, inflamed mucous membranes, and skin ulcerations. Thiamine deficiency (most commonly seen in those with alcoholism) may present with peripheral neuropathy, gait disturbance, and nystagmus. Iron deficiency from nutritional or non-nutritional causes may present with koilonychias (spooning of the nails).

LABORATORY EVALUATION

Key Points

- Albumin and transferrin can be artificially low when C-reactive protein (CRP) level (inflammation) is high. Prealbumin is a more accurate marker of nutritional status with systemic inflammation.

Physiologic changes related to adequacy of nutrition occur slowly; the first signs of a change in nutritional status usually appear at the cellular level. These changes may be detected by a variety of laboratory tests. Single laboratory tests may have value in screening for nutritional problems, but a series of values is important for assessing ongoing nutritional problems and treatment.

What to Order to Assess Malnutrition

No general laboratory studies will diagnose malnutrition. Laboratory investigation should be directed toward specific nutrients that the physician suspects may be missing from a patient's diet, for which the patient may be at risk based on disease or because of history or physical examination findings that suggest a nutritional deficiency (see [Table 37-1](#)).

Unexplained weight loss with no other specific symptoms is often associated with inflammation, and inflammatory markers such as CRP and erythrocyte sedimentation rate may be elevated. [Table 37-7](#) lists common laboratory evaluations for frequently encountered micronutrient deficiencies.

Measuring Visceral Protein: Albumin. The protein contained in visceral organs constitutes about 10% of total body protein, and the protein in plasma and extravascular body fluids makes up about 3% of total protein. *Albumin*

Table 37-7 Laboratory Tests for Nutritional Deficiencies

Nutrient Deficiency	Laboratory Evaluation
Vitamin A	Serum retinol
Vitamin D	25(OH)D
Vitamin E	Not usually assayed for diagnosis
Vitamin K	PT, INR
Vitamin B ₁₂	MMA, tHcy
Folate	MMA, tHcy
Vitamin B ₂ (riboflavin)	Serum EGRAC
Vitamin B ₁ (thiamine)	Erythrocyte thiamine diphosphate level
Iron	CBC, serum ferritin, total iron binding capacity
Zinc	Serum or plasma zinc level (not good assessment of zinc stores)

CBC, Complete blood count; EGRAC, erythrocyte glutathione reductase activity coefficient; INR, international normalized ratio; MMA, methylmalonic acid; PT, prothrombin time; tHcy, total homocysteine; 25(OH)D, 25-hydroxy-vitamin D.

is a plasma protein produced by the liver that can be used as an indicator of visceral protein balance. The measurement of serum albumin reflects changes in the protein status over time because albumin has a serum half-life of 2 to 3 weeks.

Using serum albumin as a marker for protein nutrition status has limitations. Albumin is a negative acute-phase reactant and tends to decrease in concentration under conditions of inflammation. Because of its long half-life, this change may be misleading. In protein-calorie starvation, albumin levels tend to decrease, but in total-calorie deprivation, albumin levels may remain more stable ([Hammond, 2004](#)). Finally, there is a large extravascular albumin pool, which tends to equilibrate by entering the vascular system when plasma concentration of albumin decreases.

Transferrin. Transferrin is another plasma protein that reflects overall protein balance. Similar to albumin, transferrin is a negative acute-phase reactant, but because of its shorter half-life (8 days), it may be somewhat more accurate than albumin as a tool for assessing nutritional status. Transferrin has limitations, however, in that its concentration is related to the patient's overall iron status. Also, as with albumin, serum concentration of transferrin does not change rapidly with changes in protein-calorie intake.

Other Plasma Proteins. Several other plasma proteins have been proposed as good markers for protein energy status. The level of transthyretin (TTY), also known as *prealbumin*, has been shown to correlate with visceral protein status, but it is an acute-phase reactant and is also affected by zinc concentrations. It has a half-life of 2 to 3 days. Retinol-binding protein (RBP) has a short serum half-life (12 hours) and correlates with protein energy status in some patients with malnutrition, but it also is a negative acute-phase reactant and has limitations for the assessment of nutritional status.

It is possible to circumvent the problems raised by inflammation in interpreting the plasma levels of the proteins mentioned. CRP level provides an indication of the amount of inflammation present at a given time. Some clinicians

may ascribe more usefulness to levels of albumin, transferrin, TTY, and RBP when the CRP level is low.

Urinary Creatinine and Creatinine-to-Height Ratio

The urinary creatinine level reflects the amount of ongoing muscle metabolism. The amount of creatinine excreted in the urine is proportional to the muscle mass of an individual. Using a mathematical formula, it is possible to derive an expected amount of creatinine excretion over 24 hours based on a person's height. This formula is limited in the case of a tall, thin subject or short, muscular subject. The amount of urinary creatinine also varies depending on the diet; diets high in meat will result in increased urinary creatinine excretion.

Vitamin and Mineral Assays

In general, protein-calorie malnutrition is associated with low levels of vitamin A, zinc, and magnesium. Fat-soluble vitamins may be deficient in conditions of malabsorption of fat. Folic acid and iron are not well absorbed in celiac disease.

Hematologic Tests

Changes in red blood cell production may result from insufficient levels of iron, vitamin B₁₂, folic acid, and other vitamins. It is important to note that determining the complete blood count (CBC) is important in assessing nutritional status. Patients with poor nutritional status may also demonstrate weak immune status. T cell-mediated responses are more severely affected by nutritional inadequacy than B-cell functions, such as immunoglobulin function. Evaluating the total lymphocyte count can be helpful in assessing T cells. Using skin testing for anergy is one method of testing T-cell immune competence.

Nutrition in the Life Cycle

Key Points

- Recommendations regarding vitamin D and calcium supplements for prevention of osteoporosis continue to evolve, but the United States Preventive Services Task Force (USPSTF) currently recommends against routine supplementation in healthy men and premenopausal women.
- The USPSTF finds insufficient evidence to determine the benefits and harms of daily supplementation with more than 400 IU of vitamin D₃ and more than 1000 mg of calcium for primary prevention of fractures in healthy men and postmenopausal women.

PREGNANCY AND LACTATION

Pregnancy has long been recognized as a time of increased nutritional needs. Recommendations vary, but one constant remains: with adequate caloric intake comes a greater likelihood of ingesting adequate nutrients. Weight checks are a standard part of all prenatal visits. In recent years, concern has focused on the woman's health status after the pregnancy. As [Table 37-8](#) demonstrates, in older pregnant

Table 37-8 Pregnancy Outcomes Linked to Weight Gain

Increased Risk of LBW Infant	Best Outcomes		Increased Risk of Gestational Diabetes*
Biologically immature or too thin (BMI <18.5 kg/m ²)	BMI 18.5-24.9 kg/m ²	BMI 25-29.9 kg/m ²	BMI ≥30 kg/m ² or older than 35 years
RECOMMENDED WEIGHT GAIN			
≈28-40 pounds (1.1 lb/wk)	25-30 lb (0.7 lb/wk) Not nursing: 0.8 lb/wk Nursing: 0.9 lb/wk Twins: 1.4 lb/wk	15-25 lb	11-20 lb

*Increased risk of low-birth-weight (LBW) infant or infant too large.

BMI, Body mass index.

Data from Institutes of Medicine. *Report on weight gain during pregnancy: reexamining the guidelines*. Washington, DC: Institutes of Medicine; 2009.

women or biologically immature women (those who become pregnant within 5 years of starting to menstruate), the caloric intake and weight gain are specific to the particular health needs of the woman during as well as after the pregnancy. The usual weight retained with each pregnancy by women in the United States is 10 lb ([McGanity et al., 1999](#)). This retained weight may have a significant influence on future chronic disease development for women.

It is now known that the nutritional needs for pregnancy begin before conception. The state of nutrition 60 to 90 days before conception influences pregnancy outcomes. The major nutrient changes from conception through the first trimester are increases in folic acid, iron, and calories. The overall nutritional needs throughout the pregnancy are as follows:

- Adequate calories for development of the fetus, placenta, and lactation after delivery (with adequate calories increasing the opportunity for adequate nutrients)
- Adequate protein
- Adequate iron
- Adequate folic acid, vitamin C (especially critical if the woman is a smoker because there is a much higher need in smokers), and vitamin B₁₂
- Adequate calcium and iodine

Community-based programs such as Women, Infants, and Children (WIC) can be resources for helping women in need. It has been demonstrated that infants of women who participate in these programs have higher birth weights than those who were not in the programs and who are in the same social, economic, or other problematic circumstances.

Although not well understood yet, there seems to be some evidence indicating that what occurs nutritionally before pregnancy and during pregnancy for the mother may affect the potential for chronic diseases later in the life of the child. Such diseases as hypertension and diabetes may have their start in the embryonic stage of life ([Roseboom et al., 2006, 2011](#)).

Many of the nutritional issues in *lactation* are influenced by the nutritional status of the pregnant woman. The

nutritional stores of the postpartum woman are an important source of supplies for her and the infant. Certain nutrients are stable regardless of the maternal diet. Studies of lactation have found that after about 6 months of breastfeeding, maternal weight decreases by about 10 lb without any changes in the composition or production of breast milk (Barbosa et al., 1997). This may be important when considering that the average weight retained with each pregnancy is about 10 lb.

INFANCY AND CHILDHOOD

An excellent summary of the nutrients and development needs for food in this age group is available in Figure 37-1. This figure provides guidance about major nutrient needs and how the infant and child can meet these needs. These evidence-based guidelines were developed by a panel of pediatricians, nutritionists, and the U.S Department of Agriculture (USDA) after comprehensive review of the literature.

It is important to help parents understand that the introduction of new foods takes time. Researchers have found that it takes at least eight different attempts of introducing a new food before a child will show true acceptance or rejection (Birch et al., 1991; Satter, 2000). Parents must understand that their role is to provide a healthy range and variety of foods in a pleasant eating environment, and the child's role is to consume the food in the amounts that he or she needs and wants. This foundation of good food habits will carry through to the adolescent stage, in which independence and finding ways of expressing this independence are achieved not only in social functioning but also in food and health habits.

ADOLESCENCE

Adolescents gain independence by taking a greater role in food choices and amounts eaten. It is frustrating for parents who worked to establish standards to see the young person seek independence even with foods consumed. This is a stage in life that demands high caloric intake because growth needs are second only to those in infancy—more kilocalories per kilogram are required than in any other life stage. This high caloric consumption is favorable to nutritional status because with high calories comes the increased likelihood of taking in more nutrients. Parents must remain hopeful that good health habits will guide the teenager. There may be concern over peer pressure leading to “strange” or different food habits, such as disordered eating, sports nutrition, and vegetarian diets, which many teens attempt. Such exploration is often a natural part of expressing independence. These food patterns can be healthy, such as improving food habits with vegetarianism or sports nutrition. The family physician needs to determine when the teen's exploration could become harmful. Nutrition assessment is appropriate in this life stage in regard to determining whether a nutritional problem is present.

ADULTHOOD

The study of adult nutrition tends to focus on prevention and treatment of chronic diseases. There is new interest in

optimizing nutrition during this stage to enhance older adults' quality of life. Many individuals attempt to use foods and nutritional products as a type of alternative medicine. Some of these developments, such as increased ingestion of supplemental antioxidant vitamins, plant-based estrogens, and other functional foods, have not had the desired outcomes (i.e., longer life, enhanced functional status). The *Dietary Reference Intakes* (National Academy of Sciences, 2005) has addressed the concept of enhanced nutrient intakes through supplements and other products by introducing a new category called *tolerable upper intake levels* (see *Terminology*). Many values in this category of nutrient levels are still under investigation.

Osteoporosis (“Holes in Bones”)

With the possibility of a 20% bone mass loss in the 5 to 7 years after menopause, the best treatment for osteoporosis (reduction in amount of bone mass) is the prevention of bone loss. The following three steps are recognized as most helpful for women (80% of osteoporosis population). It is important to realize that all foods that have calcium (e.g., cheeses) do not necessarily have vitamin D unless they are fortified (see Table 37-1).

1. Balanced diet rich in calcium and vitamin D (see Table 37-1)
2. Weight-bearing exercise, such as walking
3. Healthy lifestyle, with no smoking or excessive alcohol intake

Peak bone development occurs throughout adolescence, with smaller bone gain during the 20s, and thus less calcium is needed at this age. Bone loss starts with menopause for women, which increases the need for calcium and vitamin D to prevent bone loss. High dietary intake of calcium does not seem to present any risk; previous concern about kidney stone formation with increased calcium intake appears to be unfounded (Curhan et al., 1997). Side effects of high amounts of calcium supplement intake include constipation and dyspepsia. There is evidence that high supplemental calcium intake is associated with cardiovascular disease (Xiao et al., 2013).

Calcium supplementation with more than 2000 mg/day of vitamin D may lead to soft tissue calcification. Currently, the USPSTF recommends *against* supplementation with 400 IU or less of vitamin D₃ and 1000 mg of calcium or less per day for primary prevention of fractures in postmenopausal women (level D recommendation). The USPSTF finds insufficient evidence to determine the benefits and harms of greater amounts of supplementation in postmenopausal women or any supplementation in premenopausal healthy women (USPSTF, 2013).

Osteomalacia (“Soft Bones”)

Adult-onset osteomalacia (adult form of rickets) is being studied more and seems to be identified more frequently. This is of concern in northern climates with low sunlight and in climates where intense sun blocks are used because of low levels of vitamin D.

Cancer Prevention Through Nutrition

Caloric Restriction. In animal studies, caloric restriction has shown promise in increasing the life span of the animals

Development stage	Newborn	Head up	Supported sitter	Independent sitter	Crawler	Beginning to walk	Independent toddler
Physical skills	<ul style="list-style-type: none"> Needs head support 	<ul style="list-style-type: none"> More skillful head control with support emerging 	<ul style="list-style-type: none"> Sits with help or support On tummy, pushes up on arms with straight elbows 	<ul style="list-style-type: none"> Sits independently Can pick up and hold small object in hand Leans toward food or spoon 	<ul style="list-style-type: none"> Learns to crawl May pull self to stand 	<ul style="list-style-type: none"> Pulls self to stand Stands alone Takes early steps 	<ul style="list-style-type: none"> Walks well alone Runs

Figure 37-1 Summary of physical and eating skills, hunger and fullness cues, and appropriate food textures for infants and children. (From Butte N, Cobb K, Dwyer J, et al. The Start Healthy feeding guidelines for infants and toddlers. *J Am Diet Assoc.* 2004;104:455-467.)

studied, but human studies have not been as encouraging. This may be an extremely difficult area to investigate because there is no clear understanding of where in the human life span caloric restriction would be the most beneficial. In humans, the balance between starvation and overnutrition seems to be more difficult to determine. People with a BMI less than 18 kg/m² seem to have a higher mortality rate, but those who are obese (BMI >30) also probably do less well. Currently, there is insufficient evidence to recommend caloric restriction as a means of treatment or prevention of cancer, although evidence does suggest that a high BMI (>30) may be a cancer-promoting factor. Physical activity to balance the energy intake is probably the best preventive measure against cancer at this time.

Vitamin Supplementation. Epidemiologic studies note that populations who consume diets high in vitamins and minerals have a lower incidence of cancer. Three studies, the [Alpha-Tocopherol Beta-Carotene Cancer Prevention Study Group \(1994\)](#), [β-Carotene and Retinol Efficacy Trial \(CARET; Omenn et al., 1996\)](#), and [Physicians' Health Study \(Hennekens et al., 1996\)](#), investigated smokers and asbestos workers to see whether provitamin A and beta-carotene supplementation would decrease the incidence of cancer. Those who received supplementation developed cancers earlier than those who did not, and the studies were suspended. The USPSTF currently recommends against supplementation with beta-carotene, either alone or in combination with other supplements, for the prevention of cardiovascular disease and cancer ([USPSTF, 2003](#)). It is important to understand that current research on the importance of these nutrients is furthering the understanding that the individual nutrients have a food basis of enhancement of health. The disease–mortality response curves are U-shaped for many nutrients (i.e., there is an increased risk of adverse outcomes if the nutrient is ingested in either too low or too high amounts) ([Alexander et al., 2013](#); [Ohlhorst et al., 2013](#)).

Therefore, the dietary elements that seem to be the most favorable, according to epidemiologic studies, are as follows:

- More fruits, vegetables, whole-grain products, and calcium-containing foods
- Less saturated fats, particularly those found in red meats

Aging

The only difference in the nutritional needs of older adults was long thought to be the decrease in caloric needs, about a 2% to 5% decrease with each decade of life. The smaller decrease in caloric need (2%) is for those who exercise and the higher decrease (5%) is for those who do not exercise. A decrease in caloric need is complicated by the well-established phenomenon that weight gain tapers as humans age. Peak weights for men are at around 55 years, with weight loss after that age (slowly because rapid weight loss has significant risks in the older adult) ([Sperrin et al., 2013](#)). Peak weights for women are at around 65 years with decreases after that age. Rapid weight loss can identify critical problems; one of the first signs of dementia is often unintended weight loss. Additional changes in nutrient needs occur mainly because of the physiologic changes of aging ([Table 37-9](#)). The Tufts University USDA Human

Table 37-9 Different Nutrient Needs in Aging

Decreased Need	Calories Vitamin A
Increased Need	Fluid needs Protein (slightly increased) Vitamin D Calcium Vitamin B ₁₂ Vitamin B ₆ (pyridoxine)

Nutrition Center on Aging has developed a food pyramid based on the different nutrient needs that are critical to older adults ([Russell et al., 1999](#)). A part of aging is muscle loss, and fat stores increase. Current research supports the need for adequate (not excessive) calorie intake for protein sparing, as well as adequate protein intake (0.9-1.0 g/kg body weight) and muscle-retaining exercise to retain or lessen loss of muscle mass with aging. Diet with protein alone, or exercise alone, does not seem to retain muscle as well as the combination of exercise and protein intake.

Because psychosocial components are so important in determining nutritional status in older adults, reliable nutrition assessment includes consideration of these elements for evaluation ([Figure 37-2](#)). Functional status and mental status influence nutrition and well-being. Undernutrition in older individuals is defined by the type of body tissue loss. *Wasting* is an unintentional weight loss caused by insufficient intake of calories. *Cachexia* is loss of fat-free body mass (from muscle, bone, organs) caused by catabolism (e.g., in cancer or heart failure) and results in a change of body composition accompanied by an ongoing inflammatory process. *Sarcopenia* is the loss of skeletal muscle mass and is a common condition in aging adults. The causes of sarcopenia are multifactorial, including a decline in physical activity, changes in anabolic hormone levels, and chronic inflammation ([Hoffer, 2012](#)).

Dietary Patterns in Prevention and Management of Major Diseases

Key Points

- The Mediterranean diet has been shown to be more effective than a low-fat diet in primary prevention of cardiovascular events in patients at high risk (SOR: A).
- Consuming a Mediterranean diet is associated with a decrease in all-cause mortality as well as a reduced risk for cardiovascular disease, neurodegenerative disease, and cancer (SOR: B).
- The DASH (Dietary Approaches to Stopping Hypertension) diet significantly reduces systolic (>11 mm Hg) and diastolic (>5 mm Hg) blood pressure (BP) in persons with stage I hypertension ([Appel et al., 1997](#); [Svetkey et al., 1999](#)) (SOR: A).
- Patients following the DASH diet may have a lower risk of developing stroke and myocardial infarction and may have a lower risk of cardiovascular mortality (SOR: B).
- A low-carbohydrate diet (high protein and fat) is as effective as low-fat diets in weight loss and may be associated with a better lipid profile.

Mini Nutritional Assessment MNA[®]

Last name:	First name:	Sex:	Date:
Age:	Weight, kg:	Height, cm:	I.D. Number:

Complete the screen by filling in the boxes with the appropriate numbers.
Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening	
A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties? 0 = severe loss of appetite 1 = moderate loss of appetite 2 = no loss of appetite	<input type="checkbox"/>
B Weight loss during last months 0 = weight loss greater than 3 kg (6.6 lbs) 1 = does not know 2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs) 3 = no weight loss	<input type="checkbox"/>
C Mobility 0 = bed or chair bound 1 = able to get out of bed/chair but does not go out 2 = goes out	<input type="checkbox"/>
D Has suffered psychological stress or acute disease in the past 3 months 0 = yes 2 = no	<input type="checkbox"/>
E Neuropsychological problems 0 = severe dementia or depression 1 = mild dementia 2 = no psychological problems	<input type="checkbox"/>
F Body Mass Index (BMI) (weight in kg)/(height in m) ² 0 = BMI less than 19 1 = BMI 19 to less than 21 2 = BMI 21 to less than 23 3 = BMI 23 or greater	<input type="checkbox"/>
Screening score (subtotal max. 14 points)	<input type="checkbox"/> <input type="checkbox"/>
12 points or greater Normal – not at risk – no need to complete assessment	
11 points or below Possible malnutrition – continue assessment	
Assessment	
G Lives independently (not in a nursing home or hospital) 0 = no 1 = yes	<input type="checkbox"/>
H Takes more than 3 prescription drugs per day 0 = yes 1 = no	<input type="checkbox"/>
I Pressure sores or skin ulcers 0 = yes 1 = no	<input type="checkbox"/>

Figure 37-2 The mini nutritional assessment (MNA). (From Vellas B, Garry PJ, Guigoz V, eds. *Mini nutritional assessment [MNA]: research and practice in the elderly*. vol 1. Nestlé Nutrition Workshop Series. Basel, Switzerland: Karger; 1999:158.)

- Diet as a whole should be considered in the balanced food intake (with energy expenditure and basal metabolic rate) for determining needs of patients with diabetes. Diet should be individualized to the patient's unique needs ([American Diabetes Association \[ADA\], 2008](#)) (SOR: A).
- Lifestyle changes (increased activity, weight loss, smoking cessation, decreased saturated fat and increased fiber intake, moderation in alcohol intake) are the only treatments shown to affect all components of the metabolic syndrome and should be implemented in all patients ([Finnish Medical Society, 2007](#)) (SOR: A).

MEDITERRANEAN DIET

The Mediterranean diet is used extensively as a regional diet in southern Europe, northern African, and the Middle Eastern countries. Although it has many cultural variations, such as the types of seasonings, use of different starches (rice to pasta to couscous), and use or non-use of alcohol, most of the research and popular use of the term Mediterranean diet relates to the diet commonly found in southern Italy, Sicily, and Corsica during the late 1950s to 1960s. It is not currently what is practiced in these regions to the extent it was during the research of Ancel Keyes, who first described its effects on prevention of many of the chronic diseases common to Western countries. Currently, research has shown positive effects on the prevention and to a lesser extent treatment of diseases such as cardiovascular, diabetes, Parkinson disease, dementia, and cancer.

The foods commonly used in the Mediterranean diet are as follows:

- Eating primarily plant-based foods, such as fruits and vegetables, whole grains, legumes, and nuts as the basis of the diet
- Replacing butter with healthy fats, such as olive oil
- Eating fish and poultry at least twice a week
- Drinking red wine in moderation (optional)
- Including regular exercise and physical activity
- Limiting red meat and sweets to no more than a few times a month

Several Mediterranean Diet Pyramid schematics may be helpful in directing patients toward this type of eating pattern. In most representations of the Mediterranean diet, exercise is considered an important component to the diet to maintain energy balance. This is critical to the health outcomes with the diet (see [Web Resources](#)).

The Mediterranean diet has been shown to reduce cardiovascular events compared with a traditional low-fat diet in patients at high risk for disease ([Estruch et al., 2013](#)). Several observational studies have strongly suggested a decrease in all-cause mortality and in morbidity. These studies include evidence of reduction in cardiovascular disease, neurodegenerative disease, and cancer ([Sofi et al., 2010](#)). Another study has shown that when patients with cardiovascular risk factors and at risk for developing type 2 diabetes followed the Mediterranean diet, the risk of developing type 2 diabetes actually decreased ([Salas-Salvado et al., 2011](#)). In fact, the Mediterranean diet can be very effective in helping patients with diabetes maintain appropriate blood glucose control. Specific studies have demonstrated that following a Mediterranean diet may

decrease the risk for developing cancer ([Cottet et al., 2005](#); [Couto et al., 2011](#)). There is also evidence that patients who adhere to the Mediterranean diet have a decreased risk of developing dementia, especially when the diet is combined with physical activity ([Scarmeas et al., 2009](#)). The risks of following a Mediterranean diet are few and include deficiencies in calories (because of the filling nature of high-fiber foods).

Dietary Approaches to Stopping Hypertension Diet

A combination diet known as DASH is low in saturated fat, high in fruits and vegetables (8-10 servings, or 4-5 cups/day), and high in low-fat dairy products, with physical activity and some salt restriction. DASH resulted in significant reductions in systolic (>11 mm Hg) and diastolic (>5 mm Hg) BP in persons with stage I hypertension ([Appel et al., 1997](#); [Svetkey et al., 1999](#)). With the addition of sodium restriction (<2 g daily), further BP reductions have been observed ([He and MacGregor, 2004](#); [National Institutes of Health \[NIH\], 2006](#)). A recent meta-analysis confirmed the finding that low-sodium diets result in lowered BP but also found that sodium-restricted diets were associated with an increase in plasma levels of renin, aldosterone, cholesterol, and triglycerides compared with a non-sodium-restricted diet ([Graudal et al., 2011](#)). The DASH diet, or a similar combination, with modest sodium restriction should be considered as first-line treatment for prehypertension and early stage I hypertension. There is some evidence that patients following the DASH diet have lower risk of stroke, cardiovascular mortality, and myocardial infarction ([Fung et al., 2008](#)).

The foods commonly used in the DASH diet are as follows (serving range is because of different calorie consumption—lower number of servings for lower caloric intake and higher number for higher caloric consumption):

- Whole grains: 6 to 11 servings per day (1 serving = 1 slice bread; 1 oz dry cereal; ½ cup cooked rice, pasta or cereal)
- Vegetables: 3 to 6 servings/day (1 serving = ½ cup cut up raw or cooked; 1 cup leafy green)
- Fruits: 4 to 6 servings/day (1 serving = 1 medium piece; ½ cup juice or cut up)
- Low-fat dairy: 2 to 3 servings/day (1 serving = 1 cup yogurt, milk; 1½ oz cheeses)
- Lean meats: 3 to 6 servings (1 serving = 1 oz meat or 1 egg for a total of 3 to 6 oz/day)
- Nuts and legumes: 1 serving per day to 3 servings per week (1 serving = 1/3 cup nuts; 2 Tbsp peanut butter; ½ cup legumes)
- Fats and oils: 2 to 3 servings per day (1 serving = 1 tsp oils or soft margarine; 2 Tbsp salad dressings)
- Sweets: 0 to no more than 2 per day (1 serving = 1 Tbsp sugar or jam or jelly; ½ cup gelatin or sorbet; 1 cup lemonade)

There are many similarities between the Mediterranean and DASH diets, such as the high use of whole grains, vegetables, fruits, nuts, and legumes and the limited use of red meats and sweets. The DASH plan does include the consumption of more dairy products than does the Mediterranean diet. The DASH diet does not explicitly include fish or olive oil as the Mediterranean plan does. Whether these are significant differences is yet to be determined.

Low-Carbohydrate Diets (Higher in Fat and Protein)

The low-carbohydrate diet plan—for example, the Atkins Diet (and variations) or the South Beach Diet—has few similarities to either the DASH diet or the Mediterranean diet. It prescribes much more protein than either of the previously discussed dietary patterns. The South Beach Plan is not as high in saturated fat because the protein source is mainly fish. Research actually shows that low-carbohydrate diets may have a more favorable effect on serum lipids than do low-fat diets (Foster et al., 2010; Shai et al., 2008). Some evidence indicates that recommending an increase in some types of dietary fat, such as olive oil and fish oil, may be helpful in managing diabetes (Shai et al., 2008). There are a few hypotheses as to why low-carbohydrate diets confer less cardiovascular risk than low-fat diets. One idea is that low-fat diets are high-carbohydrate diets, which often means that individuals substitute refined carbohydrates for fat. This type of carbohydrate consumption contributes to the risk of type 2 diabetes and hence cardiovascular disease. A second hypothesis is that energy balance is more important than the specific macronutrient in the diet (Schwingshackl & Hoffman, 2013). This means that whether the diet is high in fat, protein, or carbohydrate, the important issue is that the patient maintains energy balance by not consuming more calories than are expended each day. Energy balance is more important to chronic disease prevention than is consumption of a high- or low-macronutrient content diet (Sacks et al., 2009).

Risks of the low carbohydrate diets include potential deficiencies in the B vitamins, vitamin C, and possibly fat-soluble vitamins D and K, depending on the sources of fat and protein in the diet.

Vegetarian Diets

For a variety of reasons, many people follow a vegetarian dietary pattern. These dietary patterns may or may not include animal products such as milk (lactovegetarians), cheese, or eggs (lacto-ovo vegetarians). Strict vegans consume no animal products at all. Children and adolescents are at a particular risk for micronutrient deficiencies when adhering to vegetarian dietary practices. For example, adolescents may consume too little zinc, iron, and vitamin C and are also at risk for having low vitamin B₁₂ levels. Individuals who completely exclude animal and fish food sources from their diets may be at risk for deficiencies of essential fatty acids and vitamin D, although there are some mushroom sources as well as sunlight for vitamin D. Family physicians should ask about specifics of dietary intake in patients who claim to be vegetarian to ensure that adequate levels of calcium, micronutrients, and an adequate mix of plant proteins are being consumed. Additionally, adolescents and young adults who follow a restrictive vegetarian diet may have a higher prevalence of unhealthy dieting behaviors and disordered eating (American Dietetic Association, 2009).

When properly incorporated, vegetarian diets have been shown to be effective in lowering total cholesterol and low-density lipoprotein cholesterol in patients with hyperlipidemia (American Dietetic Association, 2009). Vegetarian diets can also be effective for weight loss.

Nutrition Decisions in the Hospitalized Patient

Key Points

- The Joint Commission requires a nutritional screen be completed on each patient within 24 hours of admission (SOR: C).
- If nutrition screening and assessment indicate that a patient is at risk for malnutrition or malnourishment, then nutrition support intervention is indicated (SOR: B).

Patients who are hospitalized require appropriate nutritional support to heal wounds and recover from illness. Up to 40% of hospitalized patients have some degree of malnutrition (Coates et al., 1993). Clinical studies have shown that length of stay and hospital costs are higher in patients at risk for poor nutrition than patients who are not at risk (Chima et al., 1997). The Joint Commission (formerly Joint Commission on Accreditation of Healthcare Organizations, JCAHO) requires a nutritional screen to be completed on each patient within 24 hours of admission, although evidence to support this practice is not of top quality (Mueller et al., 2011). The Malnutrition Screening Tool (MST) and the Short Nutritional Assessment Questionnaire (SNAQ) have both been shown to have specificities and sensitivities of greater than 70% (Neelemaat et al., 2011) and are considered “quick and easy” screening tools, as is the Mini Nutritional Assessment (see Figure 37-2). When a screen indicates that a patient is at nutritional risk, the patient should undergo a complete nutrition assessment. The rationale for this is that malnourished patients tend to have longer hospital stays and more complications as well as potentially higher mortality rates. Often, patients with chronic illness are nutritionally depleted before hospitalization, and trauma and surgery increase nutritional demands significantly. Patients, particularly older adults, may rapidly fall behind in caloric and nutrient intake.

SUBJECTIVE GLOBAL ASSESSMENT

A useful instrument for the more detailed assessment of nutritional status in hospitalized patients is the subjective global assessment (SGA) (Brugler et al., 2005). The SGA incorporates five features of the history and four components of the physical examination findings, enabling the physician to make a rapid determination of a patient's nutritional status (Figure 37-3). The history components are weight loss, food intake, presence of significant GI symptoms, functional status or energy level, and metabolic demand of the underlying disease state. The physical components are depletion of subcutaneous fat, muscle wasting in the quadriceps and deltoid muscles, edema, and ascites. Each component is evaluated as category A (patient well nourished), B (mildly malnourished), or C (severely malnourished).

Weight loss is one of the most important components of the assessment. Generally, if the patient loses at least 5% of

Table 37-10 Estimated Caloric Need*

Weight Goal	Level of Activity or Severity of Illness		
	Low kcal/kg	Moderate kcal/kg	High kcal/kg
Lose weight	15	20	25
Maintain weight	20	25	30
Gain weight	25	30	35

*Examples: A 165-lb woman (height 5 ft, 2 in; BMI, 30.2) needs to lose weight but does not want to do any physical activity (low activity, lose weight); 165 lb = 75 kg, $75 \times 15 = 1125$ kcal estimated. A 200-lb man (height 6 ft, 4 in; BMI, 24.3) is hospitalized with sepsis and needs to maintain his weight (moderate activity, maintain weight); 200 lb = 91 kg, $91 \times 25 = 2275$ kcal estimated.

BMI, Body mass index.

of predictive equations for determining *resting metabolic rate* (RMR) in kilocalories per day (kcal/day), which is the largest component of overall calorie expenditure. One frequently used model is the *Harris-Benedict equation* (1919), as follows:

$$\begin{aligned} \text{For men: RMR} &= 66.47 + (13.75 \times \text{Weight [kg]}) \\ &\quad + (5.0 \times \text{Height [cm]}) - (6.75 \times \text{Age [yr]}) \\ \text{For women: RMR} &= 665.09 + (9.56 \times \text{Weight [kg]}) \\ &\quad + (1.84 \times \text{Height [cm]}) \\ &\quad - (4.67 \times \text{Age [yr]}) \end{aligned}$$

Frankenfield and colleagues (2005) compared validation studies on several equations and found that the *Mifflin–St. Jeor equation* performed best in terms of predicting RMR compared with calorimetry. Although all the equations are less accurate for obese subjects, the following Mifflin–St. Jeor equation is least affected by obesity.

$$\begin{aligned} \text{For men: RMR} &= (9.99 \times \text{Weight [kg]}) \\ &\quad + (6.25 \times \text{Height [cm]}) \\ &\quad - (4.92 \times \text{Age [yr]}) + 5 \\ \text{For women: RMR} &= (9.99 \times \text{Weight [kg]}) \\ &\quad + (6.25 \times \text{Height [cm]}) \\ &\quad - (4.92 \times \text{Age [yr]}) - 161 \end{aligned}$$

In critically ill patients (on ventilators), the Penn State 2003 equation or the Penn State 2010 equation for obese patients is most appropriate (Academy of Nutrition and Dietetics, 2012). (See [Web Resources](#) for RMR/BMR and resting energy/basal energy expenditure calculators.) Many online and handheld device BMR and RMR calculators are available ([Table 37-10](#)).

These predictive equations do have weaknesses. They have not been validated in all subsets of the population, such as elderly adults and nonwhite ethnic groups. Chronic illness can affect the relationship between RMR and body size, with loss of lean body mass in chronic illness.

These equations predict the *resting metabolic rate*, and caloric requirements increase beyond this figure, based on the patient's illness and other metabolic demands. The *resting energy expenditure* (REE) is 1.2 to 1.3 multiplied by the RMR. This figure is further altered by the level of stress. An example is to multiply REE by 1.1 by the number of degrees (Celsius) above normal in a patient with fever. Other multiples are 1.2 for mild stress, 1.4 for moderate stress, and 1.6 for severe stress. It is important to remember that all these calculations only *estimate* caloric requirements

Table 37-11 Determining Total Daily Needs

- To determine total daily calorie needs, multiply the BMR by the appropriate activity factor:
 - Sedentary (little or no exercise; mild stress): $\text{BMR} \times 1.2$
 - Light activity (light exercise, sports 1-3 days/wk; moderate stress): $\text{BMR} \times 1.4$
 - Moderately active (moderate exercise, sports 3-5 days/wk; severe stress): $\text{BMR} \times 1.6$
 - Very active (hard exercise, sports 6-7 days/wk): $\text{BMR} \times 1.725$
 - Extra active (very hard exercise, sports + physical job or cross-training): $\text{BMR} \times 1.9$
- To determine the BMR or BEE, use the online calculator (<http://www.calculator.org/bmr.html>).
- Whenever possible, nutritional supplementation should be through the enteral route rather than parenteral.

BEE, Basal energy expenditure; BMR, basal metabolic rate.

and should be considered as a starting point in nutrition repletion rather than the goal ([Table 37-11](#)).

Macronutrient Requirements

Hospitalized patients, and especially surgery and trauma patients, often develop *protein-calorie malnutrition*. It is important that patients in the hospital receive adequate calories to meet energy needs and adequate protein to maintain cellular integrity. Caloric requirement can be estimated by a formula, as noted earlier. Protein should make up 1.5 to 2 g/kg/day of that caloric requirement. Specific amino acids (e.g., glutamine, arginine) may be especially important in catabolic states (e.g., cancer, burns). These amino acids are therefore called *conditionally essential* amino acids. Carbohydrates make up about 70% of the remaining total caloric requirement and lipids about 30%.

When to Start Nutritional Supplementation

There is a general trend to delay nutritional supplementation in hospitalized patients in the belief that oral intake will improve imminently, but this may exacerbate the existing malnutrition. The decision to initiate supplemental feeding (over what the patient willingly consumes at meals) must be individualized according to the patient's overall health and likely clinical outcome.

Calorie counts can be obtained for patients receiving oral nutrition. If the patient is falling short on caloric or protein intake, oral supplements are appropriate, given one to three times daily. The commercially available, canned oral supplements provide about 250 kcal and 9 g of protein per can.

For a variety of reasons, hospitalized patients are often unable to consume the calories and protein required to maintain nutrition. At some point, a patient may require enteral or parenteral nutrition. The American Society for Enteral and Parenteral Nutrition has published evidence-based guidelines for assessment and management of supplemental nutrition in patients with various disease states and surgical procedures (available through the National Guideline Clearinghouse, <http://www.guideline.gov>). Depending on the disease state, these guidelines recommend that hospitalized patients begin *specialized nutrition support* (SNS) (enteral or parenteral feeding) when it is anticipated that patients will not otherwise be able to meet their nutritional needs for 7 to 10 days and within 24 to 48 hours

of admission to an intensive care unit as long as enteral nutrition is not contraindicated (Academy of Nutrition and Dietetics, 2012).

Enteral Nutrition

Most experts agree that when SNS is required, enteral feeding is the most appropriate method as long as the GI tract is competent (ADA, 2006; SOR: A). This is partly because enteral feeding can supply complex nutrients such as fiber and intact proteins that parenteral nutrition cannot supply. Also, evidence indicates that enteral feeding has beneficial effects on the GI mucosa. Some cells lining the GI tract rely on luminal nutrients to flourish, and enteral feeding maintains the absorptive capacity of the epithelial cells. Enteral feeding also stimulates the immune function of the gut. Enteral feeding is usually safer and less expensive than parenteral feeding.

Delivery Methods. Nasogastric feeding is the least invasive form of enteral feeding and is appropriate when there is no gastric outlet obstruction, delayed gastric emptying, or elevated risk for aspiration. If a patient does not tolerate gastric feeding, has one of the previous contraindications, or requires prolonged nutritional supplementation, as is often the case with head and neck cancers, a *postpyloric feeding method* such as duodenal or jejunal tube placement is appropriate. Jejunal tubes are preferred to duodenal tubes because the latter still pose a reasonably high risk for aspiration.

FORMULAS. One type of tube-feeding formula is blenderized food, which can be any type of food that can be successfully liquefied. There are also nutritionally complete commercial formulas that are sterile, easy to use, and appropriate for patients with normal digestive and absorptive function. Elemental formulas contain predigested, chemically formulated nutrients in low-molecular-weight form and may be useful in patients with stressed GI tracts that cannot digest and absorb nutrients in a more complex form. Specialized modular formulas are available for specific disease states, such as a formula appropriate for a patient with chronic kidney or lung disease.

Complications. Clinicians should be aware of the potential complications of enteral feeding, such as aspiration (especially with gastric feeding), gut perforation, and functional problems (e.g., gastric distention, nausea, vomiting, diarrhea). Current guidelines recommend that unless contraindicated, the head of the bed should be elevated 30 to 40 degrees for a patient receiving enteral nutrition (Academy of Nutrition and Dietetics, 2012). Serum electrolyte and glucose level abnormalities are common in patients receiving enteral nutrition, and monitoring of these parameters is important.

Parenteral Nutrition

Most hospitals now use multidisciplinary teams to help plan and implement parenteral nutrition when it is deemed appropriate. *Peripheral parenteral nutrition* (PPN), using a peripheral vein, is appropriate for short-term administration of nutrients (7-10 days) when the GI tract is not functional. *Total parenteral nutrition* (TPN) is administered through a more central vein and is used longer term (>10

days). TPN may be used to administer higher concentrations of glucose and protein than PPN, as well as for infusion of lipids.

Complications. The complications of PPN and TPN include phlebitis and other local reactions to infusion, maintenance of venous access, infection, air embolism, and refeeding syndrome. The *refeeding syndrome* is more common with TPN and may result in sudden death, more often affecting severely malnourished patients as they transition suddenly from deriving energy from stored fat to obtaining energy from infused glucose. This can cause a sudden depletion of phosphate stores, resulting in cardiac dysfunction. Patients who have lost more than 30% of their body weight should undergo gradual repletion of nutrients, with a slow increase in the rate of TPN over several days.

Future in Nutrition

MICROBIOME: GUT BACTERIA AND NUTRITION

Recent research on the synergistic relationship between the hundreds of bacteria that live symbiotically with each human has taken on new understandings with the NIH Human Microbiome Project (The [NIH HMP Working Group, 2009](#)). The understanding that different bacteria may have different effects on diseases, such as obesity, antibiotic resistance, and other conditions, has led to revision in how diseases are treated. In the past, we have seen such a paradigm shift with ulcers going from a disease related to stress (and bland diets) to a disease of bacterial origin, resulting in the appropriate change in focus of the treatment. The microbiome of an individual changes with age and diet, and there is ongoing research into how diet and disease influence and are influenced by the individual's microbiotic makeup.

CONSUMER TECHNOLOGY AND NUTRITION

With the wide availability of smartphones and just-in-time information, there has also been a proliferation of applications designed to help with health and fitness, including weight loss. The appropriate research to determine the effectiveness of these applications to affect sound nutrition is just beginning. A recent study has determined that of the more than 10,000 weight loss and fitness applications, none is very strong at incorporating theory-based behavior change concepts. Food tracking has been shown to be effective for people attempting to lose weight, and many tracking applications are available. However, these apps are currently weak at providing motivation (other than positive reinforcement) or helping dieters identify eating triggers ([Azar et al., 2013](#)).

In addition to consumer-based technology, there is currently a great deal of research underway to look for better ways for professionals (nurses, physicians, dietitians) to assess nutrition in vulnerable groups. The use of digital photography and electronic databases has the potential to enhance customization of diets for community-dwelling patients by more accurately documenting intake and micro-nutrient content.

Terminology

The following list of definitions is taken from *Dietary Reference Intakes* (National Academy of Sciences, 2004).

- **Recommended daily allowance (RDA):** Average daily nutrient intake level sufficient to meet the nutrient requirements of nearly all those (97%-98%) in a life stage and gender group. It is intended to be used for assessing the diets of healthy subjects, not for assessing or planning diets for groups.
- **Estimated energy requirement (EER):** Dietary energy intake that is predicted to allow for a level of physical activity consistent with normal health and development and for the deposition of tissues at a rate consistent with growth
- **Acceptable macronutrient distribution range (AMDR):** Range of macronutrient intakes for a particular energy source associated with reduced risk of chronic disease while providing adequate intakes of essential nutrients
- **Tolerable upper intake levels (TULs):** Highest average daily nutrient intake likely to pose no risks of adverse health effects to almost all those in a life stage and gender group
- **Adequate intake (AI):** Recommended average daily nutrient level based on observed or experimentally determined estimates of average nutrient intakes by a group of healthy subjects. It is used when an RDA cannot be determined and may be used to plan and evaluate diets of individual subjects or groups.
- **Estimated average requirement (EAR):** Nutrient intake value estimated to meet the requirement defined by a specific indicator of adequacy in 50% of those in a life stage and gender group, expressed as a daily value over time (for most nutrients, at least 1 week). It includes an adjustment for bioavailability, is intended to be used as one factor in assessing the adequacy of intake of groups or individual subjects, and should not be used as an intake goal for just one person.

Conclusion

Nutrition is a foundation for human health. In the future, as more is understood about genetics, nutritional needs will become more tailored to individual diverse needs. In the review of a person's nutritional status, the clinician should consider food and supplements, as well as how these balance

with exercise, diseases, and other environmental factors (e.g., smoking). Overweight, normal-weight, and underweight people are not necessarily well nourished, and weight may not be an indicator of healthy eating. *Biologic balance* involves energy balance (between what is needed or eaten and what is used) and nutrient balance; too few nutrients can cause malnutrition and even chronic diseases, and too many nutrients may be toxic or may even cause chronic disease.

Thought depends absolutely on the stomach, but in spite of that, those who have the best stomachs are not the best thinkers.

—VOLTAIRE (1770)

Epidemiology and Social Impact of Gastrointestinal Disease

Although diseases of other organ systems (e.g., cardiovascular disease) may appear to be more dramatic illnesses with higher rates of morbidity and mortality, the overall impact of gastrointestinal (GI) disorders is often underestimated from both a biopsychosocial and a resource standpoint. Typically, diseases of the GI tract are misdiagnosed, mistreated, misunderstood, or missed altogether, ultimately leading to substantial psychological morbidity and tremendous direct and indirect expense. Digestive diseases cost an estimated \$91 billion annually in U.S. health care costs, lost days from work, and premature deaths. More than 70 million Americans are diagnosed each year with disorders of the digestive tract, including gastroesophageal reflux disease (GERD), peptic ulcer disease (PUD), inflammatory bowel disease (IBD), GI cancers, motility disorders, hepatitis, cirrhosis, and foodborne illness ([Foundation for Digestive Health and Nutrition, 2009](#)).

This chapter serves as an overview of common GI diseases and disorders encountered in family medicine practices, encompassing both adult and pediatric populations. The most recent evidence-based diagnostic and therapeutic guidelines and reviews are highlighted, and radiographs, endoscopy photos, and video segments are integrated when applicable.

APPROACH TO THE PATIENT WITH GASTROINTESTINAL COMPLAINTS

Psychosocial Factors of Gastrointestinal Disease

Locke's review in *Sleisenger and Fordtran's Gastrointestinal and Liver Disease* (8th edition) provides an excellent framework of the biopsychosocial approach to the patient with GI complaints. In caring for patients with both acute and chronic GI disorders, family physicians should obtain a patient-centered, nondirected history using open-ended questions that enable patients to tell the history in their words. Medical and social histories should be integrated so that symptomatic complaints are described in the context of the psychosocial events surrounding the presenting illness, including the setting of symptom onset and exacerbation. Throughout the encounter, the provider's questions should communicate a sincere willingness to address both biologic and psychologic aspects of the illness. Evaluation and treatment of GI symptoms depend on a strong physician–patient therapeutic relationship, allowing the family physician to elicit, evaluate, and communicate the role of potential psychosocial factors in the disease state. Patient reassurance, acknowledgment of patient adaptations to chronic illness, reinforcement of healthy behaviors, and the consideration of psychopharmacologic medication are paramount ([Locke, 2006](#)).

The failure to find a specific structural etiology for a patient's GI symptoms is usually the rule rather than the exception in the ambulatory care setting. Because functional GI disorders may represent an "illness without an evident disease," some providers do not regard these as legitimate, especially within the biopsychosocial model of disease. This phenomenon often leads physicians (and patients to coerce physicians) to pursue unnecessary, costly, and invasive diagnostic tests to find the etiology of a patient's symptoms rather than focusing directly on symptom management and potential psychological comorbidities. Family physicians must establish clear boundaries with their patients to prevent unnecessary workups and, when indicated, should consider a referral to a mental health professional skilled in the care of patients with

functional GI conditions to assist in symptom management (Locke, 2006).

THE ABDOMINAL EXAMINATION

For descriptive purposes of location, the abdomen has been divided into four quadrants, constructed by an imaginary vertical line from the tip of the xyphoid process to the pubic symphysis and an imaginary horizontal line bridging the anterior superior iliac crests referred to as the right upper (RUQ), right lower (RLQ), left upper (LUQ), and left lower (LLQ) quadrants (Bickley, 2008). The abdomen can be further divided into the epigastric, umbilical, hypogastric or suprapubic, and right and left flank regions. Knowledge of anatomic structures that lie in each of these quadrants and regions is imperative for the clinician to form an accurate differential diagnosis in relation to a patient's presenting symptoms (Table 38-1).

Clinicians should remember that a comprehensive physical examination, not just abdominal, should be performed in patients presenting with digestive complaints. The clinician should ensure patient comfort and modesty because the abdominal examination (and pelvic, if indicated) may cause significant pain, anxiety, and embarrassment to the patient. Infants, young children, and pregnant women may require additional care during the abdominal examination. A thorough explanation of examination techniques and findings is necessary to minimize patient anxiety.

The anorectal examination is an important component of the abdominal examination that may often be omitted. Although uncomfortable and embarrassing to the patient, it should not be neglected and should be approached with a calm, gentle attitude on the part of the clinician. The examiner should comment on both external and internal components of the anorectal examination, specifically anal sphincter tone; presence or absence of hemorrhoids, fissures, fistulas, or masses; prostatic abnormality in male patients; and consistency of the stool. Anoscopy should be considered as an adjunct to the anorectal examination when indicated, allowing for direct visualization of the internal anorectal canal. In female patients, the pelvic examination may provide additional information in the diagnosis of abdominal symptoms because it is often challenging to differentiate between GI and genitourinary complaints.

Common Pediatric Gastrointestinal Disorders

INFANTILE REGURGITATION

In an infant with recurrent vomiting, a thorough history and physical examination are often sufficient to establish a diagnosis of uncomplicated GERD, labeling the infant as "the happy spitter." Diagnostic evaluation is indicated if there are signs of poor weight gain, GI obstruction, excessive crying and irritability, disturbed sleep, or feeding or respiratory problems suggesting suspected asthma or recurrent pneumonia. In an infant with uncomplicated GERD, parental education, reassurance, and anticipatory guidance are recommended; no specific intervention is

necessary because the process is usually self-limited. Thickened formula and a trial of a hypoallergenic formula are the best treatment options. A trial of time-limited acid-suppression therapy, usually with histamine-2 receptor antagonists (H₂RAs), is useful in determining if GERD is causing vomiting and regurgitation. If symptoms worsen or do not improve by 18 to 24 months of age, reevaluation for complications of GERD is recommended, including an upper GI series (barium swallow study) and consultation with a pediatric gastroenterologist. In otherwise normal children who have recurrent vomiting or regurgitation after age 2 years, management options include an upper GI series, upper endoscopy with biopsy, and anti-secretory therapy (National Digestive Diseases Information Clearinghouse, 2006).

DIARRHEA AND DEHYDRATION

Diarrhea is exceedingly common in pediatric and adult populations worldwide. Dehydration and electrolyte (e.g., sodium, potassium, bicarbonate) losses associated with severe diarrhea account for significant morbidity and may lead to mortality in cases of acute gastroenteritis, especially in countries with poor access to adequate health care. Rotavirus infection is the most common cause of diarrhea in U.S. infants and children, especially in winter months and temperate climates; Norwalk-like virus is the most common agent in adults (King et al., 2003).

A thorough history should be the first step in evaluating a patient who presents with a significant diarrheal illness, including the following (Guerrant et al., 2001):

- When and how the illness began (abrupt or gradual onset and duration of symptoms)
- Stool characteristics (watery, bloody, mucous, purulent, greasy)
- Frequency of bowel movements and relative quantity of stool produced
- Presence of dysenteric symptoms (fever, tenesmus, blood or pus in stool)
- Symptoms of volume depletion (increased thirst, tachycardia, orthostasis, decreased urine output, lethargy, decreased skin turgor, decreased tear production)
- Associated symptoms and their frequency and intensity (nausea, vomiting, abdominal pain, cramps, headache, myalgias, altered sensorium)

In addition, all patients should be asked about potential epidemiologic risk factors for diarrheal diseases, including the following:

- Travel to an underdeveloped area
- Daycare center attendance or employment
- Consumption of unsafe foods (e.g., raw meats, eggs, or shellfish; unpasteurized milk or juices) or swimming in or drinking untreated fresh surface water from a lake or stream
- Visiting a farm or petting zoo or having contact with reptiles or with pets with diarrhea
- Knowledge of other ill persons (e.g., in a dormitory, office, or social function)
- Recent or regular medications (e.g., antibiotics, antacids, antimotility agents)

Table 38-1 Differential Diagnosis for Abdominal Pain Based on Location

Left upper quadrant	<p><i>Cardiac:</i> angina pectoris, myocardial infarction <i>Dermatologic:</i> herpes zoster <i>Gastric:</i> peptic ulcer disease, gastritis, pyloric stenosis, hiatal hernia <i>Intestinal:</i> high fecal impaction, perforated colon, diverticulitis <i>Pancreatic:</i> pancreatitis, neoplasm, stone in pancreatic duct or ampulla <i>Pulmonary:</i> pneumonia, empyema, pulmonary infarction <i>Renal:</i> calculi, pyelonephritis, neoplasm <i>Splenic:</i> splenomegaly, rupture, abscess, splenic infarction Trauma <i>Vascular:</i> dissecting or ruptured aortic aneurysm</p>
Right upper quadrant	<p><i>Biliary:</i> calculi, infection, inflammation, neoplasm <i>Cardiac:</i> myocardial ischemia or infarction (particularly involving the inferior wall), pericarditis <i>Dermatologic:</i> herpes zoster Fitz-Hugh-Curtis syndrome (perihepatitis) <i>Gastric:</i> peptic ulcer disease, pyloric stenosis, neoplasm, alcoholic gastritis, hiatal hernia <i>Hepatic:</i> hepatitis, abscess, hepatic congestion, neoplasm, trauma <i>Pancreatic:</i> pancreatitis, neoplasm, stone in pancreatic duct or ampulla <i>Pulmonary:</i> pneumonia, pulmonary infarction, right-sided pleurisy <i>Renal:</i> calculi, infection, inflammation, neoplasm, rupture of kidney <i>Intestinal:</i> retrocecal appendicitis, intestinal obstruction, high fecal impaction, diverticulitis Trauma</p>
Left lower quadrant	<p><i>Intestinal:</i> diverticulitis, intestinal obstruction, perforated ulcer, inflammatory bowel disease, perforated descending colon, inguinal hernia, neoplasm, appendicitis Psoas abscess <i>Renal:</i> renal or ureteral calculi, pyelonephritis, neoplasm <i>Reproductive:</i> ectopic pregnancy, ovarian cyst, torsion of ovarian cyst, salpingitis, tuboovarian abscess, mittelschmerz, endometriosis, seminal vesiculitis Trauma <i>Vascular:</i> dissecting, ruptured, or leaking aortic aneurysm</p>
Right lower quadrant	<p>Cholecystitis <i>Intestinal:</i> acute appendicitis, regional enteritis, incarcerated hernia, cecal diverticulitis, intestinal obstruction, perforated ulcer, perforated cecum, Meckel diverticulitis Psoas abscess <i>Reproductive:</i> ectopic pregnancy, ovarian cyst, torsion of ovarian cyst, salpingitis, tuboovarian abscess, mittelschmerz, endometriosis, seminal vesiculitis <i>Renal:</i> renal or ureteral calculi, pyelonephritis, neoplasm Trauma <i>Vascular:</i> dissecting, ruptured, or leaking aortic aneurysm</p>
Other regions	<p>EPIGASTRIC <i>Biliary:</i> cholecystitis, cholangitis <i>Cardiac:</i> angina, myocardial infarction, pericarditis <i>Duodenal:</i> peptic ulcer disease, duodenitis <i>Gastric:</i> peptic ulcer disease, gastric outlet obstruction, gastric ulcer <i>Hepatic:</i> hepatitis, abscess <i>Intestinal:</i> high small bowel obstruction, early appendicitis Pancreatitis <i>Pulmonary:</i> pneumonia, pleurisy, pneumothorax Subphrenic abscess <i>Vascular:</i> dissecting, ruptured, or leaking aortic aneurysm, mesenteric ischemia</p> <p>PERIUMBILICAL <i>Intestinal:</i> small bowel obstruction or gangrene, early appendicitis <i>Vascular:</i> mesenteric thrombosis, dissecting, ruptured, or leaking aortic aneurysm</p> <p>SUPRAPUBIC <i>Genitourinary:</i> cystitis, rupture of urinary bladder <i>Intestinal:</i> colonic obstruction or gangrene, diverticulitis, appendicitis <i>Reproductive:</i> ectopic pregnancy, mittelschmerz, torsion of ovarian cyst, pelvic inflammatory disease, salpingitis, endometriosis, rupture of endometrioma</p>
Diffuse	<p><i>Genitourinary:</i> urinary tract infection, pelvic inflammatory disease <i>Intestinal:</i> diverticulitis, early appendicitis, gastroenteritis, inflammatory bowel disease, intestinal obstruction, irritable bowel syndrome, mesenteric adenitis, insufficiency, or infarction <i>Metabolic:</i> toxins, lead poisoning, uremia, drug overdose, diabetic ketoacidosis, heavy metal poisoning Pancreatitis Peritonitis Pneumonia (rare) Sickle cell crisis Trauma <i>Other:</i> acute intermittent porphyria, tabes dorsalis, periarteritis nodosa, Henoch-Schönlein purpura, adrenal insufficiency <i>Vascular:</i> aortic aneurysm</p>

Table 38-2 Common Pathogens and Recommended Therapy for Acute Diarrhea

Pathogen	Therapy (Adult Doses)
<i>Campylobacter jejuni</i>	Azithromycin, 500 mg QD for 3 days, or ciprofloxacin,* 500 mg BID for 7 days
<i>Clostridium difficile</i>	Metronidazole, 500 mg TID or 250 mg QID for 10-14 days, or vancomycin, 125 mg QID for 10-14 days
<i>Entamoeba histolytica</i>	Metronidazole, 500-750 mg TID for 10 days, or tinidazole, 2 g QD for 3 days, followed by paromomycin, 500 mg PO TID for 7 days, or iodoquinol, 650 mg TID for 20 days
<i>Escherichia coli</i> 0157:H7	No treatment with antimicrobials or antimotility drugs
<i>E. coli</i> (toxigenic)	Azithromycin, 1 g in 1 dose, or rifaximin, 200 mg TID for 3 days, or levofloxacin,* 500 mg for 1 dose
<i>Giardia lamblia</i>	Tinidazole, 2 g in 1 dose, or nitazoxanide, 500 mg BID for 3 days, or metronidazole, 500-750 mg TID for 5 days
<i>Salmonella</i> spp. (nontyphi) [†]	Ciprofloxacin, 500 mg BID for 5-7 days, or azithromycin, 1 g for 1 day, then 500 mg QD for 6 days
<i>Shigella</i> spp.	Ciprofloxacin, 500 mg BID for 5-7 days, or levofloxacin, 500 mg QD for 3 days, or TMP-SMX-DS, 1 tablet BID for 3 days, or azithromycin, 500 mg for 1 dose, then 250 mg QD for 4 days
<i>Staphylococcus aureus</i> (food poisoning)	No treatment with antimicrobials or antimotility drugs
<i>Vibrio cholerae</i>	Ciprofloxacin, 1 g in 1 dose, plus aggressive fluid hydration
<i>Vibrio parahaemolyticus</i>	No treatment with antimicrobials or antimotility drugs
<i>Yersinia enterocolitica</i>	No treatment unless severe; if severe: Doxycycline, 100 mg IV BID, and tobramycin or gentamicin, 5 mg/kg/day QD, or TMP-SMX and fluoroquinolones as alternatives

*Avoid fluoroquinolones in pediatric patients and pregnant women.

[†]Antimicrobial therapy not indicated in asymptomatic patients or those with mild illness. Treatment is advised in patients younger than 1 year old or older than 50 years old, if immunocompromised, or if patient has a vascular graft or prosthetic joints.

BID, Twice daily; DS, double strength; IV, intravenous; PO, oral; QD, once daily; QID, four times daily; TID, three times daily; TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Gilbert DN, Moellering RC, Eliopoulos GM, et al. *The Sanford guide to antimicrobial therapy*. 39th ed. Sperryville, VA: Antimicrobial Therapy, 2009.

- Underlying medical conditions predisposing to infectious diarrhea (AIDS, immunosuppressive medications, prior gastrectomy, extremes of age)
- Receptive anal intercourse or oral-anal sexual contact
- Occupation as a food handler or caregiver

In the majority of patients with acute gastroenteritis, the “gold standard” stool cultures and ova and parasite testing are seldom required because the disease is most often viral in etiology and self-limited. In more severe cases with dehydration, metabolic derangement, longer duration, bloody stools (dysentery) and mucus in the stool, or known or suspected transmission of a pathogen, these tests are often required to identify the pathogen and to direct appropriate antimicrobial therapy (Table 38-2). Viral cultures are rarely performed and are unnecessary except in rare cases and immunocompromised patients. Although fecal leukocytes and lactoferrin often suggest an inflammatory etiology of diarrhea, there is no consensus regarding the routine use of these tests in the initial testing of patients with either community-acquired or nosocomial diarrhea. Hospitalized patients with diarrhea, especially those with abdominal pain, should be tested for *Clostridium difficile* toxin (Surawicz et al., 2013). Therapy with metronidazole remains the choice for mild to moderate disease but may not be adequate for patients with severe or complicated disease. Oral vancomycin is significantly more expensive and may select for colonization with vancomycin-resistant enterococci but may be required when a patient has had multiple bouts of *C. difficile*-associated diarrhea treated with metronidazole.

Nonpathogenic causes of diarrhea should be considered when a viral etiology is unlikely and a diagnostic evaluation has not identified a pathogen. The differential diagnosis includes irritable bowel syndrome (IBS), inflammatory or

ischemic bowel disease, laxative abuse, partial bowel obstruction, rectosigmoid abscess, Whipple disease, pernicious anemia, diabetes mellitus, malabsorption syndromes (e.g., celiac disease), small bowel diverticulosis, and scleroderma in primarily adult patients, and an appropriate workup should be considered.

KEY TREATMENT

- Oral metronidazole is the first-line therapy for treatment of *C. difficile*-associated diarrhea; oral vancomycin is reserved for resistant cases (Surawicz et al., 2013) (SOR: A).
- In cases of traveler's diarrhea, (e.g., enterotoxigenic *Escherichia coli*, *Shigella* spp., *Salmonella* spp., or *Campylobacter* spp.), prompt treatment with a fluoroquinolone or, in children, trimethoprim-sulfamethoxazole (TMP-SMX) has been shown to reduce the duration of the illness from 3 to 5 days to less than 1 to 2 days (Guerrant et al., 2001) (SOR: A).

APPENDICITIS

A diagnosis of appendicitis should be considered in any pediatric patient presenting with acute abdominal pain. Acute appendicitis often presents with a constellation of signs and symptoms, including fever, anorexia, nausea, vomiting, tenesmus, migratory RLO abdominal pain, abdominal tenderness and guarding, and signs of peritoneal irritation. Classically, hours after onset, the pain migrates to the *McBurney point*, defined as the point two thirds the distance from the umbilicus along a straight line toward the anterosuperior iliac spine of the pelvis. The

Figure 38-1 Appendicolith (A to C). (Courtesy Dr. Perry Pernicano, Clinical Assistant Professor, Department of Radiology, University of Michigan Medical School, Ann Arbor, MI.)

Rovsing sign (referred tenderness from LLQ to RLQ during palpation), *psoas sign* (pain elicited by extending hip posteriorly with patient lying prone), and *obturator sign* (pain elicited by abducting right hip with patient lying supine) are often conducted but are of little diagnostic value. No sign or combination of signs has accurately predicted acute appendicitis in children (Cincinnati Children's Hospital Medical Center, 2002).

Although none has proved adequately predictive of acute appendicitis in the pediatric population, laboratory studies are typically performed in the emergency department because other diagnoses may need to be excluded. A series of studies discovered an elevated white blood cell (WBC) count in 87% to 92% of patients with acute appendicitis, although 8% to 13% of patients with appendicitis had normal WBC counts (Cincinnati Children's Hospital Medical Center, 2002). The abdominal examination is particularly unreliable in women of reproductive age, so pelvic examination, urinalysis, and urine pregnancy test represent a reasonable clinical strategy to exclude genitourinary pathology.

Diagnostic imaging is not routinely recommended in patients with a high or a low probability of appendicitis because it can alter management strategies and has not proved cost effective; imaging is most helpful when the clinical assessment is equivocal. Controversy exists over the superiority of ultrasonography versus computed tomography (CT) in accurately diagnosing appendicitis, and both tests have a positive predictive value approaching 100%. Although ultrasonography may be advantageous in thin patients, CT is preferred in the evaluation of a more obese child (Halter et al., 2004). Typical radiographic findings in the evaluation of acute appendicitis include appendicoliths (Figure 38-1), dilation of the appendix with adjacent hazy fat (Figure 38-2), and periappendiceal abscesses (Figure 38-3). If the abdominal CT does not show evidence of acute appendicitis, the patient may either be admitted for observation or discharged at the discretion of the examiner and parents, with instructions for follow-up if symptoms worsen. Expert opinion states that if there is high suspicion

Figure 38-2 Appendicitis. Dilated thickened appendix (A), with adjacent hazy fat (B). (Courtesy Dr. Perry Pernicano.)

Figure 38-3 Periappendiceal abscess (arrow). (Courtesy Dr. Perry Pernicano.)

of appendicitis on the basis of history, physical examination, and laboratory studies, the patient should go directly to the operating room for an exploratory laparotomy to evaluate the appendix, without an imaging study.

Common Adult Gastrointestinal Disorders

ESOPHAGUS

Barrett Esophagus and Esophageal Adenocarcinoma

Barrett esophagus (BE) is a premalignant condition related to chronic GERD. The hallmark is a change in the mucosal lining of the distal esophagus from the normal squamous epithelium to columnar-appearing mucosa resembling that of the stomach and small intestines, referred to as *intestinal metaplasia* (Figure 38-4). The estimated risk of progression to adenocarcinoma of the esophagus with BE is approximately 0.5% per year, but without BE, the risk is 0.07%, prompting development of clinical practice guidelines for surveillance endoscopy. The risk of development of BE increases linearly with age; if a patient has GERD symptoms for fewer than 20 years with an age of onset of symptoms between 30 and 49 years of age, the odds ratio for development of BE is 6.93 (Thrift et al., 2013).

Adenocarcinoma of the esophagus has had the fastest rising incidence of any cancer in the United States and Western Europe over the past 2 decades. Family and other primary care physicians who see the vast majority of patients with GERD in its nonerosive and more complicated forms are charged with the task of suspecting and appropriately referring patients with BE for esophagogastroduodenoscopy (EGD). Although risk factors for BE and adenocarcinoma are not evidence based, there is suggestive evidence that male gender, white race, older age, dysplasia,

Figure 38-4 Barrett esophagus. (Courtesy Dr. Erik-Jan Wamsteker.)

smoking, and obesity place patients at a higher risk (Wang and Sampliner, 2008). Current evidence-based guidelines exist for the assessment and surveillance of patients with BE, yet routine screening will not be cost effective unless criteria can be identified to select patients at high risk. Recommendations from the American College of Gastroenterology (ACG) state that screening EGD for BE should be considered in select patients with chronic, long-standing GERD. After a negative screening examination result, further screening endoscopy is not indicated. For patients with established BE of any length and with no dysplasia, after two consecutive examinations within 1 year, an acceptable interval for additional surveillance is every 3 years. Surveillance in patients with low-grade dysplasia is recommended, although the optimal interval and biopsy protocol have not been established. A follow-up EGD at 6 months should be performed, and if low-grade dysplasia is confirmed, surveillance at 12 months and yearly thereafter as long as dysplasia persists is advised (Wang and Sampliner, 2008).

STOMACH AND DUODENUM

Dyspepsia

Dyspepsia (“bad digestion”) accounts for approximately 5% of all visits to family practitioners and is the most common reason for referral to a gastroenterologist in the United States, accounting for 20% to 40% of consultations (Jones and Lacy, 2004). The term *dyspepsia* refers to episodic or recurrent pain or discomfort arising from the proximal GI tract related to meals and is associated with heartburn, reflux, regurgitation, indigestion, bloating, early satiety, and weight loss. The lack of a standardized definition affects accurate prevalence data, given the challenge of clearly defining dyspepsia as either *functional* or *nonulcer dyspepsia* (NUD) (~60% of cases) or that caused by structural or biochemical disease (40%) (Dickerson and King, 2004). Regardless of cause, dyspepsia has a profoundly negative impact on patients’ health-related quality of life (HRQOL) and results in significant economic burden.

Nonulcer dyspepsia is defined in patients who have undergone either formal radiographic or endoscopic evaluation and who do not have an organic lesion (e.g., ulcer, tumor) to explain their symptoms. Potential etiologies for NUD include gastric acid hypersecretion, gastroduodenal dysmotility, visceral hypersensitivity, emotional stress, and psychological factors. As with other functional GI disorders, the potential for underlying psychosocial and lifestyle factors must be addressed. There is no current recommendation on the role of prokinetics, cytoprotectives, or antidepressants in the management of functional dyspepsia; similarly, no clear evidence supports specific diet and lifestyle modifications or psychosocial interventions.

Peptic Ulcer Disease

Key Points

- A noninvasive *Helicobacter pylori* “test and treat” strategy is as effective as endoscopy in the initial management of patients younger than age 45 with uncomplicated dyspepsia.

- Eradication of *H. pylori* infection in patients with a duodenal or gastric ulcer reduces symptom recurrence.
- Ulcer prophylaxis with an H₂RA or proton pump inhibitor (PPI) should be considered in patients at high risk for nonsteroidal antiinflammatory drug (NSAID)-associated PUD, including those with a history of PUD, elderly patients, and patients taking corticosteroids or anticoagulants.

Peptic ulcer disease is the most common cause of *upper gastrointestinal bleeding* (UGIB) and a leading cause of dyspepsia (Table 38-3), with a cumulative lifetime prevalence of 8% to 14% (Figure 38-5). Although up to 70% of patients with gastric and duodenal ulcers are 25 to 64 years old, the peak prevalence of complicated ulcer disease requiring hospitalization is age 65 to 74 years (Saad and Scheiman, 2004).

Numerous options exist for the management of uninvestigated dyspepsia in primary care (Figure 38-6). Given the high cost and often limited access to endoscopy testing, not all patients with uninvestigated dyspepsia should undergo an invasive investigation of their symptoms. The presence of “alarm symptoms” for PUD raises concern for a gastric malignancy. The *American Gastroenterological Association* (AGA, 2005) endorses prompt endoscopic evaluation in any patient older than age 45 years with new-onset dyspepsia.

The most common complications of PUD include UGIB, perforation, penetration, and gastric outlet obstruction. An upper GI hemorrhage can occur in up to 15% of patients with PUD and is most common in patients older than 60 years, with mortality rate as high as 10%. Perforation occurs in approximately 7% of patients with PUD, again classically in elderly patients receiving long-term NSAIDs. Perforation can be confirmed on plain abdominal radiography; barium contrast studies and upper endoscopy are contraindicated with suspected perforation, and urgent surgical consultation is mandatory. The mortality rate may be as

high as 30% to 50% in patients with perforation, particularly in elderly and debilitated patients. Penetration occurs when the ulcer crater erodes through and into adjacent organs, including the small bowel, pancreas, liver, and biliary tree. Often subtle, it typically presents as acute pancreatitis. Gastric outlet obstruction occurs in 1% to 3% of PUD patients, resulting from acute inflammation or mechanical obstruction caused by scarring at the gastroduodenal junction (Saad and Scheiman, 2004).

Approaches to confirm a diagnosis of PUD include double-contrast barium esophagography (upper GI series) and upper endoscopy. Although the upper GI series has accuracy of 80% to 90%, upper endoscopy is the preferred diagnostic modality, with multiple studies showing consistent diagnostic superiority in identifying gastric and duodenal ulcers. Despite a higher procedural cost and a slightly increased risk in procedure-related complications (bleeding, perforation, oversedation), upper endoscopy should be the initial diagnostic study performed in suspected PUD. Most important, upper endoscopy provides the distinct advantage of permitting biopsies and brushings to identify underlying pathology.

Fecal-oral infection with the bacterium *H. pylori* is a major risk factor for the development of PUD. Its prevalence and association with PUD is higher in populations who have a lower standard of living than in the United States, especially in Africa and Central America, although this may be declining. Approximately 90% of patients worldwide with duodenal ulcers are infected with the *H. pylori* pathogen, but 30% to 40% of U.S. ulcer patients are infected (Chey and Wong, 2007). The strongest evidence to support the role of *H. pylori* as an etiology of PUD is the elimination of ulcer recurrence when the infection has been successfully eradicated.

The evidence-based standard of care dictates that patients with dyspepsia and no alarm symptoms should be tested for *H. pylori* infection and then given eradication therapy if the

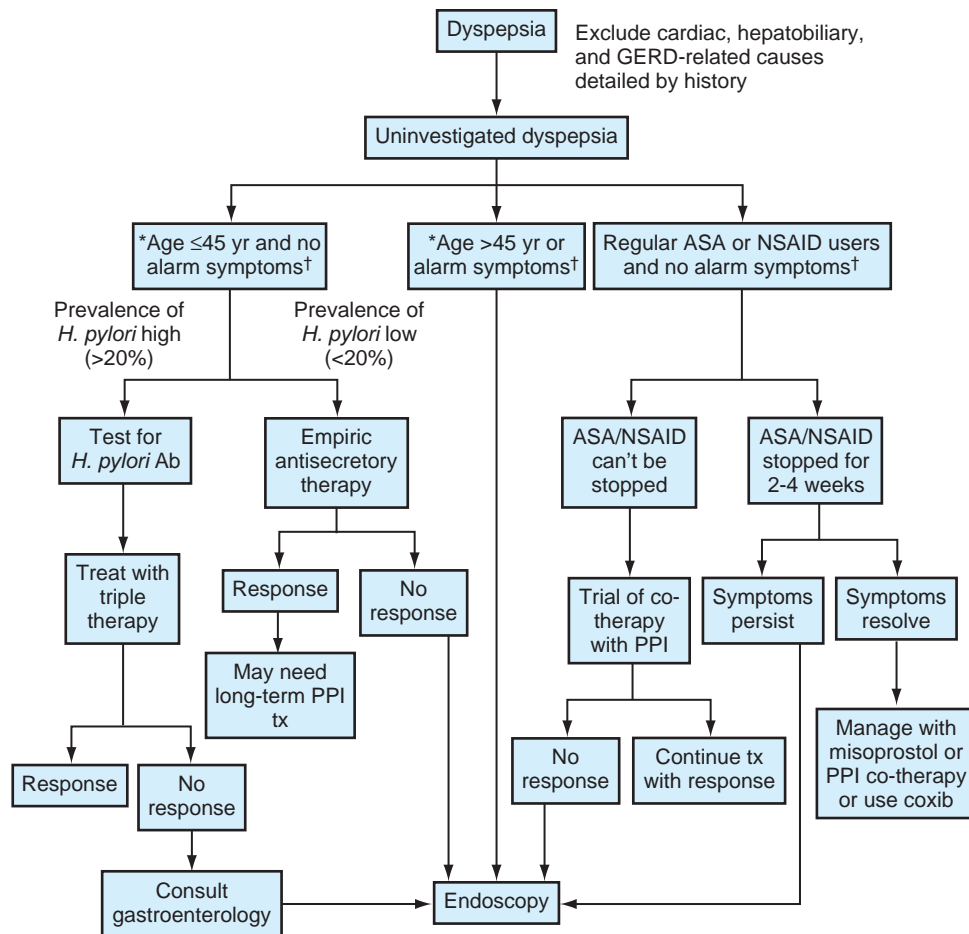

Figure 38-6 Evaluation of uninvestigated dyspepsia. *Age cutoff is controversial. Risk of pathology increases slightly with age but older age (50-55 years) cutoff is used in many guidelines. †Alarm symptoms include rectal bleeding or melena, weight loss, anorexia, early satiety, persistent vomiting, and anemia. The presence of an abdominal mass, lymphadenopathy, dysphagia, odynophagia, family history of upper gastrointestinal cancer, personal history of peptic ulcer, prior gastric surgery, or malignancy should eliminate consideration of noninvasive approaches. ASA, Acetylsalicylic acid; GERD, gastroesophageal reflux disease; NSAID, nonsteroidal antiinflammatory drug; PPI, proton pump inhibitor; tx, treatment. (Modified from Saad R, Scheiman JM. Diagnosis and management of peptic ulcer disease. *Clin Fam Pract* 2004;6:569-587.)

result is positive (“test and treat”) (Chey and Wong, 2007). *H. pylori*-positive or *H. pylori*-negative patients who do not undergo endoscopy initially should do so if their symptoms persist. The effectiveness of this approach depends on the prevalence of *H. pylori* infection in patients with ulcers in the community; as in some geographic areas, the prevalence may be too low to make this approach effective.

Nonendoscopic testing for *H. pylori* includes a quantitative assay for serum immunoglobulin G (IgG) antibodies, the radiolabeled urea breath test, and the stool antigen test. The median sensitivity and specificity for serologic IgG tests are 92% and 83%, respectively (Scottish Intercollegiate Guidelines Network, 2003). Some patients may have persistently positive IgG antibodies for months to years after eradication therapy, yielding a false-positive result during that period if retested. In comparative studies, urea breath tests are more accurate than serologic tests. The stool antigen test is recommended as the preferred initial noninvasive diagnostic test. The urea breath test is the recommended standard to determine if *H. pylori* has been successfully eradicated (Chey and Wong, 2007).

Several medication regimens have been developed for the treatment of confirmed *H. pylori* infection based on

data from randomized controlled trials (RCTs), meta-analyses, and systematic reviews (Table 38-4). The best evidence-based recommendation for *H. pylori* eradication is for 14-day triple therapy with the use of a PPI, clarithromycin, and either amoxicillin or metronidazole, yielding eradication rates from 70% to 85%. The most common salvage regimen in patients with persistent *H. pylori* is bismuth quadruple therapy. Recent data suggest that 10-day therapy with a PPI, levofloxacin, and amoxicillin is more effective and better tolerated than bismuth quadruple therapy for persistent *H. pylori* infection (Chey and Wong, 2007).

Another major etiology of PUD is the increasing and widespread use of both NSAIDs and aspirin. The use and overuse of these medications is the most common cause of PUD in *H. pylori*-negative patients, and up to 60% of unexplained cases of PUD are attributed to unrecognized NSAID use. In a meta-analysis of observational studies of GI bleeding risk from various NSAIDs, a fourfold increased risk associated with NSAID-use persisted throughout therapy and fell to baseline within 2 months of discontinuation of the drug (Hernandez-Diaz and Rodriguez, 2000). Although both *H. pylori* and aspirin and NSAIDs are involved in the

overwhelming majority of PUD cases, other factors contribute to the remaining 1% to 5% (Table 38-5).

Independent risk factors that augment the impact of *H. pylori* and NSAID-related PUD risk and may promote ulcer complications include advancing age; history of PUD or complicated ulcer disease with perforation, penetration, or gastric outlet obstruction; use of multiple NSAIDs (including concomitant use of low-dose aspirin and an NSAID); and concurrent warfarin or corticosteroid use. Evidence suggests that smoking may increase the risk of PUD and ulcer complications by impairing gastric mucosal healing. Alcohol use may increase the risk of ulcer complications in NSAID users, but its overall effect in patients without concomitant liver disease has not been clearly defined. Currently, no solid evidence implicates dietary factors in the development of PUD.

Use of NSAIDs and aspirin is frequently associated with symptoms of dyspepsia even in the absence of PUD. Empiric antisecretory therapy with PPIs is an attractive strategy that involves subjecting to upper endoscopy only patients who fail to respond to a 4-week course of pharmacotherapy. The rationale for this approach is that most patients with dyspepsia do not have *H. pylori* infection or PUD (most typically have GERD), and their response to antisecretory

therapy eliminates the need for further expensive and invasive diagnostic testing (Saad and Scheiman, 2004).

KEY TREATMENT

- The most efficacious therapy for *H. pylori* eradication consists of 14-day triple therapy with a PPI, clarithromycin, and amoxicillin or metronidazole, yielding eradication rates of 70% to 85% (Chey and Wong, 2007) (SOR: A).

Gastroesophageal Reflux Disease

Key Points

- The PPIs provide the most rapid symptomatic relief and healing of esophagitis in the highest percentage of patients.
- Although less effective than PPIs, H₂RAs given in divided doses may be effective in some patients with less severe symptoms of GERD; continuous therapy to control symptoms and prevent complications is appropriate.
- Chronic acid suppression has been associated with malabsorption of iron, magnesium, vitamin B₁₂, and calcium; small bowel bacterial overgrowth; increased risk of hip fracture; *C. difficile* colitis; and community-acquired pneumonia.

A complex, chronic, and relapsing condition, GERD carries a risk of significant morbidity and resultant complications. Population-based studies revealed that 40% of U.S. adults experience heartburn at least once a month; age- and gender-adjusted prevalence of weekly heartburn or acid regurgitation approaches 20% (Heartburn Across America, 1998; Locke et al., 1997). Most patients with GERD self-treat with over-the-counter medications and do not seek medical attention for their symptoms.

Most patients with GERD evaluated in primary care practices have *nonerosive reflux disease* (NERD), although some progress to *erosive esophagitis* (Figure 38-7) and even fewer to more severe disease resulting in esophageal strictures, BE, and adenocarcinoma of the esophagus (Katz et al.,

2013). Patients with NERD are prone to develop atypical or extraesophageal manifestations of disease (Table 38-6). Because of a small risk of disease progression, however, they generally do not require long-term surveillance despite persistent reflux symptoms. Symptom relapse rates in patients with NERD are similar to those in patients with erosive esophagitis, and although many require continuous pharmacotherapy to control their symptoms, almost all continue to exhibit no definable erosive esophagitis on upper endoscopy (Fass, 2002).

Upper endoscopy is considered the gold standard in assessing esophageal complications of GERD (e.g., erosive esophagitis, BE) but lacks an appreciable sensitivity and specificity for identifying pathologic reflux (DeVault & Castell, 2005). Double-contrast barium radiography has limited usefulness in making an accurate diagnosis of GERD but may be useful in defining the presence of anatomic abnormalities, such as pyloric stenosis, malrotation, and annular pancreas in vomiting infants, as well as hiatal hernia and esophageal strictures in children and adults.

The goals of GERD treatment are to relieve symptoms, heal erosive esophagitis if present, manage and prevent

complications, and avoid recurrence and progression of disease using acid-suppressive medications. Clinicians should recommend lifestyle and dietary modifications before consideration of pharmacotherapy, including limitation and avoidance of caffeine, smoking, alcohol, chocolate, carbonated beverages, and citrus and spicy foods, as well as weight reduction and exercise (Katz et al., 2013). Lifestyle modifications should be recommended as adjunctive therapy in all patients with GERD (Table 38-7). Evidence is lacking to support the use of nonpharmacologic measures as the sole initial or long-term therapy for GERD, but expert opinion considers these to be of some potential benefit and no proven harm, although they are not sufficiently effective in treatment.

Initial empiric pharmacotherapy should consist of either an H₂RA or a PPI without the need for immediate diagnostic testing in the vast majority of cases. Expert opinion supports either step-up or step-down therapy for the initial treatment of patients with GERD (Inadomi, 2002). In patients who incompletely respond to H₂RAs, PPIs taken once daily 30 minutes before the first meal of the day are preferred over continuing H₂RA therapy because of greater efficacy and faster symptom control with PPIs. An inadequate response to a 4- or 8-week trial of standard-dose PPI may indicate the need for longer treatment, more severe disease, or an incorrect diagnosis (Figure 38-8). Additional benefit may be obtained by extending treatment for another 4 to 8 weeks with the same or a double dose of PPI (Medical Advisory Panel for the Pharmacy Benefits Management Strategic Healthcare Group, 2003).

Diagnostic testing is recommended in patients with GERD who have an inadequate response to PPI therapy, need continuous chronic therapy to control frequent GERD symptoms, have chronic symptoms (>5 years) and are at risk for BE, have atypical or extraesophageal manifestations suggesting complicated disease, or have alarm symptoms suggesting cancer (Table 38-8).

The basic tenets of antireflux surgery include reduction of the hiatal hernia, repair of the diaphragmatic hiatus, strengthening of the gastroesophageal junction–posterior

Table 38-7 Suggested Lifestyle Modifications in the Management of Gastroesophageal Reflux Disease

Avoid acidic foods (citrus and tomato-based products), alcohol, caffeinated beverages, chocolate, onions, garlic, salt, and peppermint.
Avoid large meals.
Avoid medications that may potentiate GERD symptoms (calcium channel blockers, β -agonists, α -agonists, theophylline, nitrates, sedatives).
Avoid recumbency 3 to 4 hours after meals.
Avoid tight clothing around the waist.
Decrease dietary intake of fat.
Elevate the head of the bed 4 to 8 inches (10-20 cm).
Lose weight.
Stop smoking.

diaphragm attachment, and strengthening of the antireflux barrier by adding a gastric wrap around the gastroesophageal junction (Nissen or Toupet fundoplication). In controlled studies comparing antireflux surgery with *H₂RAs* and *PPIs*, surgery has shown marginal superiority as measured by heartburn relief, esophagitis healing, and improved quality of life in patients with erosive esophagitis. Long-term follow-up trials found that more than half of patients resumed taking antireflux medications 3 to 5 years after surgery, most likely as a result of poor patient selection and surgical breakdown (Heidelbaugh and Nostrant, 2004).

KEY TREATMENT

- Lifestyle modifications, including weight management, elevation of the head of the bed, and improving nutrition with eliminating triggering foods should be recommended to patients with GERD (Katz et al., 2013) (SOR: B).
- Acid suppression with *PPIs* is the mainstay of pharmaceutical therapy for esophagitis (Katz et al., 2013) (SOR: A).

Upper Gastrointestinal Bleeding

Key Points

- Comorbid risk factors for GI bleeding severity, including advanced age, shock, congestive heart failure, ischemic heart disease, and stigmata of recent hemorrhage, accurately predict the likelihood of death or rebleeding.
- UGIB is confirmed by upper endoscopy, permitting direct visualization of the cause and location of the bleeding and allowing an attempt at immediate hemostasis.

Significant UGIB is defined as bleeding that results in hemodynamic instability and a decrease in the hemoglobin and hematocrit. Although most patients with UGIB resolve

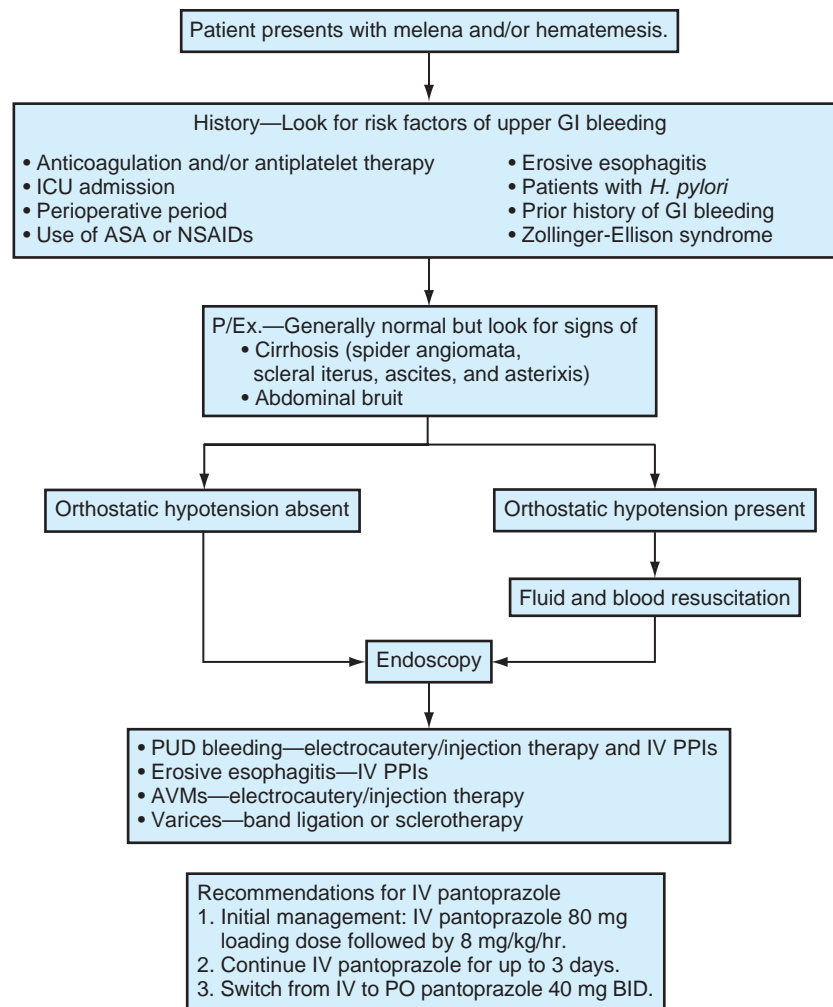

Figure 38-9 Algorithm for the evaluation of acute upper gastrointestinal (GI) bleeding. ASA, acetylsalicylic acid; AVM, arteriovenous malformation; BID, twice daily; ICU, intensive care unit; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PO, oral; PPI, proton pump inhibitor; PUD, peptic ulcer disease. (Modified from Oh DS, Pisegna JR. Management of upper gastrointestinal bleeding. *Clin Fam Pract* 2004;6:631-645.)

spontaneously, those with an acute UGIB requiring hemostasis often present with a recent history of hematemesis (vomiting fresh blood) or “coffee ground” emesis (black, partially digested blood). UGIB has an incidence of 40 to 150 episodes per 100,000 persons annually in the United States, with mortality of 6% to 10% (Oh and Pisegna, 2004). Table 38-9 lists the most common causes of UGIB.

It is important to characterize patients with risk factors for the development of UGIB to identify potential preventive measures, including aspirin or NSAID use and anticoagulation or antiplatelet therapy. *H. pylori* infection, erosive esophagitis, history of UGIB, perioperative period, intensive care unit (ICU) admission, and Zollinger-Ellison syndrome are also significant risk factors for UGIB. Figure 38-9 outlines an algorithm for the diagnosis and management of acute UGIB. Hemodynamically unstable patients should be admitted to the ICU, have a large-bore intravenous (IV) and nasogastric tube placed, and should not be fed orally.

Confirmation of UGIB is by upper endoscopy, permitting direct visualization of the cause and location of the bleeding and an attempt at immediate hemostasis. During the diagnostic evaluation, the endoscopist can treat the source

of UGIB by using electrocautery, injection of 0.9% saline or 100% ethanol, or a combination of these techniques. Alternative methods include laser photoablation, band ligation, and sclerotherapy and balloon tamponade for esophageal and gastric variceal bleeding. The risk of rebleeding after therapy can be predicted by the morphology and size of the ulcer at upper endoscopy. Most cases of rebleeding occur within the first 72 hours after hospital admission; patients at increased risk for upper GI rebleeding should have ICU monitoring during their admission (Oh and Pisegna, 2004). The use of PPIs in reducing the risk of UGI rebleeding was demonstrated in a landmark study with IV omeprazole, showing the clinical efficacy of acid reduction therapy in preventing the complications of PUD rebleeding (Lau et al., 2000).

Gastroparesis

Clinical symptoms suggesting gastroparesis, or impaired and delayed gastric emptying, include nausea, vomiting, and postprandial abdominal fullness. Most often, gastroparesis is related to poorly controlled diabetes mellitus, autonomic neuropathies, postsurgical conditions (e.g., vagotomy, Billroth pyloroplasty), and anorexia nervosa. Vomiting needs to be differentiated from regurgitation, rumination, and even bulimia; the duration, frequency, and severity of symptoms together should be described along with any associated symptoms.

Gastric-emptying scintigraphy of a radiolabeled solid meal is the most accepted method to test for gastroparesis. Conventionally, the test is performed for 2 hours after ingestion of a radiolabeled meal; however, performing the test for up to 4 hours may increase the yield in detecting delayed gastric emptying in symptomatic patients. Breath testing can be used to measure gastric emptying using the nonradioactive isotope carbon 13 (^{13}C) (Parkman et al., 2004).

Primary treatment of gastroparesis includes dietary manipulation and administration of antiemetic and prokinetic agents. Dietary recommendations include eating more frequent and smaller meals and replacing solid food with liquids, such as soups. Foods consumed should be low in both fat and fiber content. Common antiemetic agents include prochlorperazine, trimethobenzamide, and promethazine. Currently used prokinetic agents include metoclopramide and erythromycin, administered orally or intravenously. Domperidone, a dopamine (D_2) receptor antagonist, is not approved in the United States for treatment of gastroparesis but is available in Canada, Mexico, and Europe (Parkman et al., 2004). Endoscopic injection of botulinum toxin into the pyloric sphincter can aid in relaxing pyloric sphincter resistance, allowing more food to empty from the stomach. No placebo-controlled trials have yet been reported for this therapy, and long-term control of gastroparesis should not be expected from using botulinum toxin.

Gallbladder

CHOLELITHIASIS AND CHOLECYSTITIS

Gallstones are exceedingly common among women and men of all ages, affecting approximately 20% of Americans

during their lifetimes. Population-based studies reveal a prevalence of gallbladder disease in women age 20 to 55 years of 5% to 20%, increasing to 25% to 30% after age 50 years. By age 75 years, an estimated 35% of women and 20% of men develop either symptomatic or asymptomatic gallstones (Attili et al., 1995). The prevalence for men is approximately one third to half that for women in any given age group. The traditional clinical picture of a patient likely to have gallstones is an obese woman older than 40 years of age (the four Fs: female, "fat," 40, and fertile). Prevalence is also increased in patients with cystic fibrosis with pancreatic insufficiency, diabetes mellitus, or family a history of biliary colic; pregnancy; rapid weight loss; Native American Pima Indian or Scandinavian descent; patients taking estrogens, progestins, or ceftriaxone; and those requiring total parenteral nutrition.

The Rome Group for the Epidemiology and Prevention of Cholelithiasis (GREPCO, 1984) found that the overall cumulative probability of developing biliary colic in those with gallstones over time was 11.9% at 2 years, 16.5% at 4 years, and 25.8% at 10 years, with a cumulative probability of 3% of developing complications at 10 years. The incidence of the development of biliary complications as the presenting complaint of gallstone disease is rare, ranging from 0% to 5.5%. Based on these data, evidence from well-designed cohort and case-control studies summarized by GREPCO favors expectant treatment of asymptomatic gallstones.

In the approach to patients with symptomatic gallstones, clinicians should effectively rule out other potential causes of RUQ and epigastric abdominal pain, distinguishing biliary from nonbiliary etiologies as the primary source of disease (see Table 38-2). A gallstone blocking the cystic duct or common bile duct (CBD; *choledocholithiasis*) results in acute biliary colic, which can evolve into acute suppurative cholecystitis or cholangitis. The onset of pain from biliary colic is rarely related to meals or the type of food consumed, contrary to popular opinion. Many patients with postprandial abdominal pain believe that they have gallbladder disease, but many of them actually have dyspepsia or GERD. One meta-analysis found that heartburn, flatulence, regurgitation, and fatty food intolerance were not associated with gallstones but that epigastric pain, nausea, and vomiting were associated with a higher odds ratio of having gallstones (Kragg et al., 1995).

In cases of acute cholecystitis, laboratory tests frequently lack adequate predictive value in making an accurate diagnosis. A complete blood count (CBC) usually reveals a moderate leukocytosis, often with a "bandemia" in cases of ascending cholangitis. Serum amylase and lipase values are usually normal but may be elevated if there is associated pancreatitis. Serum alkaline phosphatase (ALP), liver transaminases, and bilirubin levels are rarely elevated except when CBD stones are causing obstruction. Patients with choledocholithiasis often present similar to those with cholelithiasis, although they may also have obstructive jaundice, cholangitis, and pancreatitis.

The evaluation of gallstones using abdominal ultrasonography is currently the best screening modality, with sensitivity and specificity above 90%. When calculi, gallbladder wall thickening, and gallbladder sludge are found, the diagnosis of acute cholecystitis is almost certain, yet the

Figure 38-10 Radiographs of gallstones (arrows; **A** and **B**). (Courtesy Dr. Perry Pernicano.)

presence of stones by itself does not ensure the diagnosis of acute cholecystitis. Only 10% to 15% of gallstones are visible on plain radiographs (Figure 38-10). A CT scan of the upper abdomen is more sensitive than conventional radiography but may miss a significant amount of cholesterol gallstones and biliary sludge readily seen on ultrasonography (Figure 38-11). Biliary scintigraphy (HIDA scan) uses technetium 99m (^{99m}Tc)–labeled derivatives of excreted bile acids to determine CBD obstruction. Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement or sphincterotomy (or both) is useful in identifying and treating CBD stones but is invasive; expensive; and often fraught with complications, including iatrogenic pancreatitis (Figure 38-12).

Endoscopic ultrasonography is a widely used, noninvasive method with excellent sensitivity and specificity for detecting and evaluating CBD stones. Magnetic resonance cholangiopancreatography (MRCP) is another noninvasive modality for identifying gallstones and CBD stones, but it often has lower sensitivity and specificity than ultrasonography and is more costly (Browning and Sreenarasimhaiah, 2006). The natural history of CBD stones suggests that 70% will pass safely into the duodenum and will not require ERCP for stone extraction.

Most surgeons advocate expectant management in patients with asymptomatic gallstones. Nonsurgical treatments include pain relief with narcotic analgesics, excluding morphine and its derivatives (which may precipitate sphincter of Oddi spasm and worsen symptoms), extracorporeal shock-wave lithotripsy, and gallstone dissolution using oral bile acid therapy and contact solvents such as methyl tert-butyl ether (MTBE). Numerous RCTs have

confirmed the adoption of laparoscopic cholecystectomy as the gold standard for the treatment of gallstone disease over the open procedure (Glasgow and Mulvihill, 2006).

Liver

HEPATITIS

Hepatitis is defined as acute inflammation of hepatic parenchyma. In the United States, the most common types of hepatitis are secondary to viral etiologies and are labeled as hepatitis A, B, and C. Table 38-10 outlines the various serologic markers for viral hepatitis. Viral hepatitis is less frequently attributed to Epstein-Barr virus, toxoplasmosis, and cytomegalovirus. Additional causes of hepatitis include bacterial and fungal sources, autoimmune and metabolic disorders, toxic poisoning, and various hepatotoxic medications (e.g., isoniazid, acetaminophen) and alternative supplements. Acetaminophen overdose should be considered in acute nonviral hepatitis and treated immediately with *N*-acetylcysteine to avoid permanent hepatic damage and death. Patients presenting with acute hepatitis often exhibit low-grade fever, fatigue, lethargy, anorexia, RUQ pain, nausea, vomiting, diarrhea, arthralgias and myalgias, and (in severe cases) dark urine and jaundice.

Serum bilirubin, transaminases, and ALP levels can be greatly elevated in all forms of acute hepatitis, but the specific values have poor prognostic value. Alarm symptoms of severe hepatic parenchymal destruction include mental status changes (hepatic encephalopathy), asterixis, ascites, and prolongation of prothrombin time (PT). These patients

Figure 38-11 Computed tomography scans (A, B) and ultrasonography (C-E) of gallstones (arrows). (Courtesy Dr. Perry Pernicano.)

Figure 38-12 A to C, Endoscopic retrograde cholangiopancreatography (ERCP) with stent placement to identify and treat gallstones (*arrows*). (Courtesy Dr. Perry Pernicano.)

may require hospitalization, with attention toward improving nutritional status and specialist referral for liver transplantation evaluation. Most cases of acute hepatitis resolve without complications, so most patients can be managed as an outpatient, although they must take proper contact isolation precautions and allow for a slow return to usual activity. A patient's symptomatic improvement usually precedes the resolution of liver function serologies.

Viral Hepatitis

Hepatitis A is endemic worldwide, with 10% of U.S. children seropositive and up to 100% of preschool children seropositive in areas where sanitation and socioeconomic status

are poor in less developed countries (Marsano, 2003). The virus has received sporadic national attention in the United States from outbreaks in restaurants from undercooked meat and vegetable sources. Spread through the fecal-oral route, severe hepatitis can be seen after an incubation period of 2 to 6 weeks, but the vast majority of patients recover completely within this time frame and without permanent hepatic damage. When a patient contracts hepatitis A, immunity follows with the appearance of anti-hepatitis A virus (HAV) IgG antibodies, and there is no chronic carrier state. If exposed to HAV during a known incubation period, the patient should be passively immunized with immune globulin. Vaccination is recommended in high-risk

Table 38-10 Viral Hepatitis Serologic Tests and Definitions

Test	Description
HEPATITIS A VIRUS (HAV)	
Anti-HAV IgM	Immunoglobulin M (IgM) antibody to hepatitis antigen. Antibody of IgM class signifies recent acute infection. This develops at onset of symptoms and resolves in <1 yr.
Anti-HAV IgG	Immunoglobulin G (IgG) antibody to hepatitis A antigen. With negative anti-HAV IgM result, this indicates past HAV infection and that the patient is immune. It appears 1 to 2 weeks after IgM antibody.
HEPATITIS B VIRUS (HBV)	
Hepatitis B surface antigen (HBsAg)	HBsAg is the earliest indicator of acute infection. It can be present for several months before symptoms and may remain detectable for up to 6 months. Persistence after 6 months may indicate a chronic carrier state.
Antibody to hepatitis B surface antigen (Anti-HBs)	Anti-HBs is an indicator of clinical recovery and subsequent immunity. It appears 1 to 2 months after HBsAg disappears, and it may be present for life.
HBcAg	No clinical significance; not readily available.
Anti-HBc IgG	Antibody to hepatitis B core antigen is an early indicator of acute infection. It is also a lifelong marker that represents past exposure. It may precede the detection of HBsAg. This persists for years but does not necessarily confer immunity.
IgM Anti-HBc	Early indicator of acute active infection; usually short lived (3-6 wk).
HBe g	Active infection is present, and patient is highly contagious.
Anti-HBe	Seroconversion from antigen to antibody is prognostic for resolution of infection and, in a carrier, means very low infectivity.
IgM anti-HBc	IgM fraction of antibody to hepatitis B core antigen is test of choice to rule out acute HBV infection. IgM fraction disappears in first few months.
Hepatitis C Anti-HCV	An antibody to HCV that appears 3 to 12 months after exposure.
Hepatitis D Anti-HDV	This antibody to HDV may appear late and may be short-lived.
Hepatitis E (non-A, non-B)	No markers detectable; epidemiology parallels that of hepatitis B.

Modified from [Rodney WM. Gastrointestinal disorders. In Rakel RE, ed. *Textbook of family medicine*. 6th ed. Philadelphia: Saunders; 2002.](#)

populations and before travel to endemic areas ([Fiore et al., 2006](#)).

Despite the availability of a highly effective vaccine against *hepatitis B*, approximately 2 billion people worldwide are infected, 350 million with chronic active infection accounting for 600,000 attributable deaths annually worldwide ([World Health Organization, 2009](#)). Hepatitis B is spread via blood and body fluid contact through heterosexual and homosexual relations, by sharing of needles by infected drug abusers, and by accidental needle sticks in the medical setting. In areas of high disease prevalence (e.g., Southeast Asia, China), transmission is primarily from mother to child during childbirth or in early childhood. The vaccination for hepatitis B uses recombinant DNA, requires three doses on a set schedule, and confers immunity in the majority of recipients ([CDC, 1999](#)). In a child born to a mother positive for hepatitis B surface antigen (HBsAg), in addition to the vaccine, hepatitis B hyperimmune globulin should be administered during the first 12 hours of life. Patients with chronic infection can develop cirrhosis and end-stage liver disease. Antiviral treatments for hepatitis B are indicated for patients with moderate to severe disease activity diagnosed on liver biopsy. Current therapies include interferon and, more recently, lamivudine and adefovir ([Marsano, 2003](#)).

Hepatitis C affects more than 300 million people worldwide and 4 million people in the United States. At least six genotypes and 100 subtypes have been identified ([Bukh, 2000](#); [Hepatitis C Statistics, 2009](#)). The diagnosis is established with serum testing for HCV RNA antibodies; although an antibody is induced, it is not protective against disease contraction and progression. Transmission occurs via blood

or body fluid contamination through IV and intranasal drug use, blood transfusions, and in health care workers (e.g., needle stick or skin disruption with contaminated instrument). Data on sexual transmission and through tattooing have been inconsistent. Co-infection with human immunodeficiency virus (HIV) increases the risk of transmission sexually, as well as vertically from mother to child. In patients with chronic hepatitis C, alcohol use rapidly accelerates liver damage and cirrhosis. Many experts believe lifelong abstinence from alcohol and IV and intranasal drugs should be immediate on diagnosis and enforced before initiating antiviral therapies.

Therapy with pegylated interferon and ribavirin has been shown to achieve sustained viral eradication in almost 50% of patients with hepatitis C ([Shehab, 2004](#)). Patients should be monitored for side effects of antiviral treatment, which may require dose adjustments or discontinuation of therapy. The duration and success of therapy depend on viral genotype and possible downward adjustments in therapeutic doses. Sustained virologic response ranges from 42% in genotype 1 to 80% in genotypes 2 and 3 ([Marsano, 2003](#)).

Hepatitis D virus (delta hepatitis) is usually only seen in IV drug users and in former carriers of hepatitis B as a co-infection. *Hepatitis E* is an enteric virus only rarely identified in the United States, characterized by an acute self-limited illness without a chronic carrier state.

CIRRHOSIS

Cirrhosis and chronic liver failure rank as the 12th leading causes of death in the United States, accounting for 27,555 deaths (9.2 per 100,000 population) in 2006, with a slight

Figure 38-13 Cirrhosis. Ultrasonography shows lobulated shrunken liver with ascites and splenomegaly. (Courtesy Dr. Perry Pernicano.)

male predominance (National Center for Health Statistics, 2009). The vast majority of cirrhosis-related morbidity and mortality is secondary to excessive alcohol consumption, hepatitis B and C, and obesity (nonalcoholic fatty liver disease [NAFLD]) and is theoretically preventable. The term *cirrhosis* refers to a progressive diffuse, fibrosing, and nodular condition that disrupts the entire normal architecture of the liver. Portal hypertension ensues with multiple long-term complications. Approximately 40% of patients are asymptomatic, with cirrhosis often discovered during a routine examination, including laboratory and radiographic studies (Figures 38-13 and 38-14), or often at autopsy. Mortality rates in patients with alcoholic liver disease are considerably higher than in those with other forms of cirrhosis.

The incidence of NAFLD depends on definitions and populations. Risk factors include obesity, metabolic syndrome, dyslipidemia, and type 2 diabetes mellitus. Conditions with emerging association include polycystic ovary syndrome, hypothyroidism, sleep apnea, and hypogonadism. When patients with unsuspected hepatic steatosis detected on imaging have symptoms or signs attributable to liver disease or have abnormal liver biochemistries, they should be evaluated as though they have suspected NAFLD and worked up accordingly (SOR: A). Screening for NAFLD in adults attending primary care clinics or high-risk groups attending diabetes or obesity clinics is not advised at this time because of uncertainties surrounding diagnostic tests and treatment options along with lack of knowledge related to the long-term benefits and cost-effectiveness of screening (SOR: B; Chalasani et al., 2012). Treatment is aimed at weight loss (e.g., Mediterranean diet) and omega-3 fatty acid supplementation (e.g., >830 mg/day). There are no current recommendations for continued monitoring of patients with NAFLD, specifically with monitoring of serum transaminases or liver ultrasonography.

The major complications of cirrhosis that affect HRQOL and survival include ascites formation, spontaneous bacterial peritonitis, hepatorenal syndrome, encephalopathy, and GI bleeding secondary to portal hypertension and varices. Another serious complication of cirrhosis is the development of hepatocellular carcinoma, for which screening protocols with ultrasonography and serum α -fetoprotein testing are effective (Marrero, 2005). All patients with ascites should be evaluated for liver transplantation because of poor 5-year survival rates (30%-40%) (Gines et al., 2004) (Figure 38-15).

Pancreas

ACUTE PANCREATITIS

Acute pancreatitis continues to cause significant morbidity and mortality despite dramatic advances in the understanding of its pathophysiology and its critical care management. Some studies suggest a high rate of undiagnosed pancreatitis, with approximately 40% of acute cases recognized only at autopsy. Thus, it is imperative for primary and emergency care physicians to make the diagnosis of pancreatitis within the first 48 hours of admission (AGA, 2007). The diagnosis of acute pancreatitis is typically defined by at least two of the following criteria: (1) abdominal pain consistent with the disease, (2) serum amylase or lipase greater than three times the upper limit of normal, or (3) characteristic findings from abdominal imaging (Tenner et al., 2013). In severe acute pancreatitis, parenchymal and fat necrosis ensues, as well as profound multisystem organ failure, infection, and life-threatening hemodynamic instability.

The causes of acute pancreatitis are diverse and demonstrate changing trends over time and variation by geography. Gallstones, biliary sludge, and microlithiasis are

Figure 38-14 Cirrhosis. Computed tomography scans show lobulated contour of liver (A), splenomegaly (B), and ascites (C). Arrows show fluid collections (ascites). (Courtesy Dr. Perry Pernicano.)

Figure 38-15 Ascites (arrows). (Courtesy Dr. Perry Pernicano.)

Figure 38-16 Computed tomography scans (**A** and **B**) of dilated pancreatic duct secondary to stone pancreatitis (*arrows*). (Courtesy Dr. Perry Pernicano.)

recognized as the proximate cause in more than half of reported cases, and therefore, abdominal ultrasonography is recommended in all patients with acute pancreatitis (Tenner et al., 2013). Ethyl alcohol ingestion is the second most common reported cause of acute pancreatitis ($\approx 30\%$ of cases), although it is unclear whether alcohol is a toxin or an exacerbating factor in individuals who have compromised pancreatic function. The remaining causes of acute pancreatitis account for fewer than 15% of total cases, including hypertriglyceridemia, trauma, medications, ERCP, neoplasms, perforated PUD, viral infection, and idiopathic causes. Hypertriglyceridemia should be considered the etiology when serum triglycerides are greater than 1000 mg/dL and there is no evidence of cholelithiasis or significant alcohol use (Tenner et al., 2013). Pancreatic neoplasm should be considered on the differential especially in anyone older than the age of 40 years (Tenner et al., 2013).

Serum markers of acute pancreatitis have high sensitivity and specificity but no role in predicting the severity or course of disease. The most common enzymes assayed, amylase and lipase, are released at approximately the same time after the initial insult to the pancreas but are cleared from the bloodstream at different rates. Therefore, relying on total serum amylase alone to make an accurate diagnosis of acute pancreatitis is error prone because it is cleared almost totally from the blood within 48 to 72 hours. The sensitivity of pancreatic amylase for the diagnosis of acute pancreatitis decreases to less than 30% between the second and fourth day after onset of the acute episode. By contrast, an elevated serum lipase level can be detected up to 14 days after the acute event and has sensitivity greater than 90% for acute pancreatitis (Orbuch, 2004).

Hemodynamic status should be assessed immediately on patient presentation and resuscitative measures begun as needed. Risk assessment should be performed to stratify patients into higher and lower risk categories to assist triage, such as admission to an intensive care setting (Tenner et al., 2013). Early prognostic factors that can be measured and indicate severity of disease include the Acute Physiology and Chronic Health Evaluation II (APACHE II) score.

The overall success at prediction of mortality from acute pancreatitis at hospital admission remains at 40%, and even at 48 hours, it is no better than 80% when all diagnostic strategies of morbidity and mortality prediction are compared (Papachristou and Whitcomb, 2004). The most important factor in the management of patients with acute pancreatitis is maintaining appropriate intravascular volume status (AGA, 2007). Aggressive hydration, defined as 250 to 500 mL/hr of isotonic crystalloid solution, should be provided to all patients unless cardiovascular or renal comorbidities exist. Those with hypotension and tachycardia may require even higher infusion rates (Tenner et al., 2013). Many predictors of pancreatitis severity are directly related to “third spacing” of fluids and include hemoconcentration and rising creatinine level. The goal of aggressive hydration should be to decrease blood urea nitrogen (Tenner et al., 2013). The hematocrit may be high as a result of hypovolemia secondary to third spacing of fluids. Early aggressive hydration is most beneficial in the first 12 to 24 hours (Tenner et al., 2013) because this may minimize or even prevent pancreatic necrosis.

If the bilirubin, liver transaminases, and ALP increase, a CBD stone may exist (Figure 38-16). It is recommended that patients with acute pancreatitis and concurrent acute cholangitis undergo ERCP within 24 hours of admission. ERCP is not needed in most patients with gallstone pancreatitis who lack laboratory or clinical evidence of ongoing biliary obstruction. In the absence of cholangitis or jaundice, MRCP or endoscopic ultrasonography, rather than ERCP, should be used to screen for choledocholithiasis if highly suspected (Tenner et al., 2013). Similar laboratory abnormalities with a less acute presentation may occur in patients with chronic pancreatitis when bile duct stricture occurs.

Contrast-enhanced computed tomography (CECT) is the most extensively studied modality for the confirmation of acute pancreatitis (Figure 38-17) (Papachristou and Whitcomb, 2004). CECT or magnetic resonance imaging of the pancreas should be reserved for patients in whom the diagnosis is unclear or who fail to improve clinically within the first 48 to 72 hours after hospital admission (Tenner et al., 2013). Sensitivities using ultrasonography for the

Figure 38-17 Pancreatitis (computed tomography scan) (arrow). (Courtesy Dr. Perry Pernicano.)

diagnosis of acute pancreatitis range between 62% and 95% and probably reflect the failure to visualize the organ in as many as 30% of cases. When the pancreas is visualized in the setting of acute disease, tissue abnormalities are detected in 90% of those studied. The milder the disease presentation, the less likely it is that abnormalities will manifest that are detectable on CT examination.

Medical therapy of acute pancreatitis is primarily supportive, with the major objective being hemodynamic stabilization. Antibiotics should not be started routinely but should be given for extrapancreatic infection. In mild acute pancreatitis, oral feedings can be started immediately if there is no nausea and vomiting and abdominal pain has resolved. In mild pancreatitis, initiation of a low-fat solid diet appears as safe as a clear liquid diet (Tenner et al., 2013). Nutritional support should be provided for patients likely to remain “nothing by mouth” (NPO) for more than 7 days. Enteral feeding is preferred over parenteral nutrition to help prevent infectious complications. Nasogastric and nasojejunal delivery of enteral feeding appear comparable in safety and efficacy (Tenner et al., 2013). Pain management in the hospital setting is best achieved using morphine derivatives. Infrequently, patient-controlled anesthesia may be used for severe abdominal pain, and alternative diagnoses and complications should be considered.

CHRONIC PANCREATITIS

Permanent pathologic damage to the pancreas results in chronic pancreatitis. In addition to exocrine deficiency (with malabsorption, diabetes, or both), a chronic pain syndrome may evolve and become a management challenge. Many patients have substance abuse and other behavioral problems that require time, patience, compassion, and skill to resolve. Patients who continue to consume alcohol are more likely to have recurrent attacks. Carefully selected

Figure 38-18 Chronic pancreatitis with calcifications (arrows). (Courtesy Dr. Perry Pernicano.)

patients may benefit from therapeutic ERCP or pancreatic surgery, with some pain relief. Exocrine deficiency may be treated with pancreatic enzyme supplementation with each meal (Apte et al., 1999).

Chronic pancreatitis indicates some degree of progressive and permanent damage to the pancreas, usually visualized as calcifications on radiographs and CT (Figures 38-18 and 38-19). This damage often leads to diabetes and pancreatic insufficiency, resulting in malabsorption with chronic diarrhea. Patients with chronic pancreatitis present with repeated attacks of abdominal pain and are often admitted for acute or chronic exacerbations. Potential complications include pseudocyst (Figure 38-20) and abscess formation, fistula formation between pseudocysts and the gut, persistent pancreatic ascites caused by a disrupted pancreatic duct system, communication with the peritoneal cavity, mesenteric venous thrombosis, and arterial pseudoaneurysm (Apte et al., 1999).

PANCREATIC CANCER

More than 37,000 people in the United States were diagnosed with pancreatic cancer in 2008, and more than 34,000 died from their disease (Cancer Facts and Figures, 2008). The major risk factors are advancing age and a history of tobacco and alcohol use; the diagnosis is rarely made early in the disease course because of vague presenting symptoms of nonspecific abdominal pain, weight loss, cachexia, and painless obstructive jaundice. Approximately 85% of patients present with locally advanced or metastatic disease, with median survival period of 3 to 12 months. For these patients, conventional treatments include palliative surgery. Radiation and chemotherapy have not substantially impacted survival. Endoscopic ultrasonography and high-resolution CT allow for better preoperative selection for patients likely to benefit from exploration for resection (Figure 38-21).

Figure 38-19 A to C, Pancreatic calcifications (arrows). (Courtesy Dr. Perry Pernicano.)

Lower Gastrointestinal Tract

INFLAMMATORY BOWEL DISEASE

Key Points

- Steroids are effective for inducing but not maintaining remission in IBD.
- The 5-aminosalicylic acid (5-ASA) medications are effective in ulcerative colitis (UC) for therapy induction and maintenance therapy but largely are ineffective for Crohn disease.

Inflammatory bowel disease is a chronic condition that often requires long-term maintenance therapy for the majority of the half-million Americans affected. The two major categories include UC and Crohn disease; a more recent and less common third category of *microscopic colitis* has also been identified. The incidence of UC and Crohn disease is 1.5 to 8 new cases per 100,000 U.S. population per year, more often in whites and with no specific gender

predominance, although some suggest a male predominance in Crohn disease and a female predominance in UC. Most patients are diagnosed with IBD between ages 15 and 25 years, with a second peak between 55 and 65 years. The incidence of microscopic colitis is most likely underestimated because it is not well known; the estimated incidence ranges from 4.3 to 9.2 per 100,000 in Western European and Icelandic population studies (Loftus, 2003).

Genetic factors play an important role in the development of IBD. First-degree relatives of patients with either form of IBD have been shown to have an almost 10% lifetime risk of developing disease and often present with a similar disease type and course as the affected family member (Higgins and Zimmerman, 2004).

Ulcerative colitis involves the mucosal layer of the sigmoid colon and rectum in the vast majority of cases, causing proctitis and proctosigmoiditis (Figure 38-22). When there is proximal spread, it tends to be continuous and symmetric, causing intestinal mucosal inflammation with edema and friability that is visualized from the rectum proximally. Pancolitis is caused by inflammatory exudates producing a backwash ileitis by way of a patent ileocecal valve and can cause small bowel involvement.

Figure 38-20 A to C, Computed tomography scans showing severe pancreatitis evolving into pseudocysts (arrows) over 2 months. (Courtesy Dr. Perry Pernicano.)

Crohn disease differs from UC in that it may involve any part of the GI tract from the mouth to the anus, including the gallbladder and biliary tree, and involves the entire thickness of the bowel wall. It is most often found in the immunologically rich terminal ileum, and Crohn disease involves the rectum in less than 50% of cases. In contrast to UC, the mucosal abnormalities are discontinuous (“skip lesions”), asymmetric, and patchy, which account for obstruction, abscesses, and perianal fistulas to other organs and skin. Recurrent disease flares and healing can result in significant muscular hypertrophy and fibrosis of the intestinal wall, leading to small bowel strictures, upstream dilation of intestine and increased fistula formation, and eventual bowel obstruction and the imminent need for surgical intervention (Higgins and Zimmerman, 2004).

Most patients with UC present with mild to moderate diarrhea without constitutional symptoms. Typically, the more severe the illness, the greater the number of bowel

movements and the more likely that constitutional symptoms such as fever, fatigue, dehydration, and weight loss will also occur. UC can be intermittent with flare-ups, and remission can occur without therapy. A minority of patients with UC present with severe or fulminant panniculitis, ranging from an acute abdomen to toxic megacolon. Frequent urgent and bloody diarrhea usually suggests rectal disease and is most consistent with UC.

In patients with mild Crohn disease, abdominal pain may be vague, the diarrhea intermittent, and weight loss absent. Postprandial crampy pain can suggest transient small bowel obstruction from inflamed or fibrotic, narrowed small bowel segments. Colonic involvement with Crohn disease may present similar to UC, with predominantly bloody diarrhea. Rectal involvement produces more urgent and frequent small, bloody stools as a result of an inflamed, nondistensible rectum. Mucus in the stool is nonspecific and is found in both IBD and IBS (Higgins and Zimmerman, 2004).

Figure 38-21 A to C, Pancreatic cancer, pancreatic head mass, with biliary and pancreatic ductal dilation. Arrows show fluid collections (ascites). (Courtesy Dr. Perry Pernicano.)

Figure 38-22 A to C, Severe colitis. (Courtesy Dr. Erik-Jan Wamsteker.)

Extraintestinal manifestations may be the presenting symptoms of UC or Crohn disease. Uveitis, iritis, or episcleritis often flares concomitantly with intestinal symptoms. Large-joint pain and sacroiliitis may be a form of enteropathic arthritis. Common skin manifestations include erythema nodosum, perianal fistulas, and pyoderma gangrenosum. IBS is much more prevalent than IBD, and thus a major pitfall in the diagnosis of IBD is the mislabeling of patients with IBS.

The finding of confluent erythematous rectal inflammation is most consistent with UC and infectious colitis. Whereas pseudopolyp formations indicate chronic inflammatory colitis (Figure 38-23), solitary aphthous ulcers, “rakelike” lesions, strictures, and rectal sparing are consistent with Crohn disease. Colonoscopic evaluation should include ileal intubation and biopsies of both normal and abnormal mucosa. Anal or perianal lesions, including sinus tracts, rectovaginal fistulas, and abscesses, is consistent with Crohn disease but not with UC. The mucosa in a patient with Crohn disease may appear cobblestoned or nodular. Loss of haustra, distortion of normal architecture, or both may be found (Figures 38-24 and 38-25).

Figure 38-23 Ulcerative colitis, pseudopolyps (arrows). (Courtesy Dr. Perry Pernicano.)

A

B

Figure 38-25 A and B, Crohn disease. The arrow points to colonic wall thickening, which is indicative of Crohn disease. (Courtesy Dr. Perry Pernicano.)

Pharmacologic treatment of IBD is aimed at inducing remission and maintaining a symptom-free life, often after consultation with a gastroenterologist. Treatment of active flares with systemic steroids has been the mainstay of remission induction therapy, producing remission rates up to 70% in Crohn disease versus 30% with placebo; similar results have been shown in the remission of UC. Budesonide, a nonsystemic steroid used in an enema formulation, has been effective for induction of remission in Crohn disease and distal UC flares. Mild flares of UC are usually treated

with 5-ASA derivatives such as sulfasalazine, although RCTs have shown 5-ASA only marginally superior to placebo at controlling flare-ups of Crohn disease. 5-ASA products are thought to be inferior to budesonide and systemic steroids for remission induction in Crohn disease and generally are not used (Higgins and Zimmerman, 2004).

Azathioprine and its metabolite, 6-mercaptopurine, are slow-acting compounds proved effective for inducing remission in Crohn disease. They often are added to systemic steroids to help induce and maintain remission and to ease

steroid tapering. Methotrexate is also effective for remission induction in Crohn disease. Close monitoring of CBC and serum transaminases is recommended, with monthly testing on initiation and with dosage changes. Pregnancy and exposure to live-virus vaccines should be avoided. Infliximab, an anti-tumor necrosis factor α antibody, is remarkably effective in treating approximately 60% of steroid-resistant patients with Crohn disease. Infliximab has significant side effect risks, including infusion reactions, and, rarely, worsening of heart failure, activation of latent tuberculosis, serum sickness, and invasive fungal infections (Feagan, 2003).

KEY TREATMENT

- Systemic steroid therapy is effective in the treatment of active flare-ups of Crohn disease and UC (Hanauer and Baert, 1994) (SOR: A).
- Budesonide is effective for remission induction in Crohn disease and distal UC flares (Kuhbacher and Fölsch, 2007) (SOR: A).

IRRITABLE BOWEL SYNDROME

Key Points

- IBS likely represents the clinical expression of multiple potential pathophysiologic factors, including a genetic predisposition to the disease, disturbed central nervous system (CNS) pain processing, visceral hypersensitivity, mucosal inflammation, abnormal colonic motility, and emotional stress.
- Anxiety disorders, somatoform disorders, and a history of physical or sexual abuse have been identified in 42% to 61% of patients with IBS referred to gastroenterologists.

Irritable bowel syndrome is one of the most common conditions encountered in family practices, with a prevalence ranging from 1% to 20% worldwide and approximately 7% in the United States. IBS is characterized by abdominal pain, bloating, and disturbed defecation in the absence of known structural or biochemical abnormality. It typically appears in the late 20s, although it may present in teenagers and in patients as old as age 45 years; patients older than 45 years with suspected IBS should be evaluated for organic disease. IBS is responsible for more than \$20 billion in direct and indirect expenditures annually in the United States, and patients with IBS consume 50% more health care resources than matched control participants without IBS (ACG, 2009).

Irritable bowel syndrome likely represents the clinical expression of multiple potential pathophysiologic factors, including a genetic predisposition to the disease, disturbed CNS pain processing, visceral hypersensitivity, mucosal inflammation, abnormal colonic motility, and emotional stress. Given the degree of variation of IBS symptoms in affected patients, it is likely that the etiology of IBS is a heterogeneous combination of these factors, as well as other

Table 38-11 Diagnosis of Irritable Bowel Syndrome: Rome III Criteria

Symptoms of recurrent abdominal pain or discomfort and a marked change in bowel habit for at least 6 months, with symptoms experienced on at least 3 days of at least 3 months.

Two or more of the following must apply:

- Pain is relieved by a bowel movement.
- Onset of pain is related to a change in frequency of stool.
- Onset of pain is related to a change in the appearance of stool.

Modified from Longstreth GF, Thompson WG, Chey WD, et al. Functional bowel disorders. *Gastroenterology* 2006;130:1480-1491.

undetermined mechanisms. Psychosocial stressors likely exacerbate symptoms in patients with functional GI disorders. Anxiety disorders, somatoform disorders, and a history of physical or sexual abuse have been identified in 42% to 61% of patients with IBS who have been referred to gastroenterologists (Miller et al., 2001).

The physical examination in patients with IBS is often nonspecific and may demonstrate a normal abdomen examination, a diffusely tender abdomen, or a focally tender abdomen. Multiple diagnostic screening tests have been recommended, including a CBC, erythrocyte sedimentation rate, serum chemistries, thyroid function tests, stool cultures (including ova and parasites), fecal occult blood test, colonoscopy, and hydrogen breath testing, specifically to rule out other causes of disease (ACG, 2009). Despite these recommendations, diagnostic testing should depend on the pretest probability of organic disease.

The differential diagnosis of IBS includes IBD, lactose intolerance, acute gastroenteritis, celiac disease, small intestinal bacterial overgrowth, colorectal cancer (CRC), and motility-altering metabolic disturbances (e.g., from hypo- or hyperthyroidism). Currently, the Rome III criteria are the most widely accepted symptomatic classification of IBS (Table 38-11) (Longstreth et al., 2006).

There is no single evidence-based, consistently successful therapeutic approach for patients with IBS. Because it is largely a chronic condition, the goals of therapy should focus on patient reassurance, education about the natural course of the syndrome, and global symptomatic improvement rather than on disease cure. This is best achieved through a well-developed physician-patient relationship with a clear delineation of realistic goals and expectations.

Newer treatments of IBS include tegaserod (Zelnorm), a 5-HT₄ receptor agonist shown to be more effective than placebo in relieving global symptoms in women with constipation-predominant IBS. Alosetron (Lotronex), a 5-HT₃ antagonist, is indicated for women with diarrhea-predominant IBS and is more effective than placebo in RCTs. Reports of ischemic colitis have limited the use of alosetron to physicians participating in the manufacturer's risk management program. Treatment of diarrhea-predominant IBS can be achieved with loperamide, although no effect over placebo for global IBS symptoms has been reported (Brandt et al., 2002). Interestingly, open-label studies in which the study subjects were told they were receiving a placebo for their IBS showed similar benefits as the best alosetron study.

To date, all other classes of medications used in the management of IBS have more limited impact on the global symptoms of IBS. The tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors have been shown to reduce abdominal pain, although global symptom reduction and HRQOL did not significantly improve compared with placebo. Treatment of constipation-predominant IBS can be achieved with fiber-bulking agents but has not improved global IBS symptoms over placebo.

Cognitive-behavioral therapy (CBT), interpersonal psychotherapy, group therapy, biofeedback, and hypnosis have been shown to improve individual aspects of diarrhea-predominant IBS (see [Key Treatment](#)). Complementary and alternative medicine (CAM) techniques include acupuncture, enteric-coated peppermint oil, probiotic therapy, and Chinese herbal medicine. CAM therapies are becoming increasingly popular in the treatment of GI disorders and have shown some limited symptomatic improvement in select patients with IBS (ACG, 2009).

KEY TREATMENT

- CBT for IBS (efficacy defined as >50% reduction of symptoms) showed significant benefit with a mean number needed to treat (NTT) versus control participants of approximately two (two patients NTT for one to benefit) (meta-analysis of 17 studies; [Lackner et al., 2004](#)) (SOR: A).
- Gut-directed hypnotherapy can have long-lasting effects; of 204 patients with resistant IBS symptoms, 81% of initial responders had benefit 5 years after completion of treatment ([Gonsalkorale et al., 2003](#)) (SOR: B).
- Fiber bulking agents can help treat constipation-predominant IBS ([Mertz, 2003](#)) (SOR: B).
- Enteric-coated peppermint oil (0.2-0.4 mL [200-400 mg] three times daily in adults) reduced pain and spasm of IBS ([Ford et al., 2008](#); [Merat et al., 2009](#)) (SOR: B).
- The TCAs should be considered in the treatment of pain-predominant IBS ([Mertz, 2003](#)) (SOR: B).
- Tegaserod is more effective than placebo at relieving global IBS symptoms in female patients with constipation-predominant IBS (ACG, 2009) (SOR: A).
- Alosetron is more effective than placebo at relieving global IBS symptoms in female patients with diarrhea-predominant IBS (ACG, 2009) (SOR: A).

LOWER GASTROINTESTINAL BLEEDING

Lower GI bleeding (LGIB) is defined as bleeding arising from a source distal to the ligament of Treitz, with the resultant potential for rapid hemodynamic instability. Physical signs of hemodynamic compromise include orthostatic hypotension, fatigue, pallor, palpitations, chest pain, dyspnea, tachypnea, and tachycardia. Hemodynamic stabilization through large-bore IV fluid resuscitation should be initiated immediately if acute LGIB is suspected, and blood transfusion may be necessary. Laboratory testing should include CBC, comprehensive panel, coagulation profile, iron studies (including transferrin saturation), reticulocyte count (before transfusion), and blood type and crossmatch. Clotting disorders and anticoagulant use, including daily

Table 38-12 Causes of Massive Acute Rectal Bleeding

Cause	Frequency (%)
UPPER GI TRACT

aspirin or NSAIDs, should be identified during history taking. [Figures 38-26](#) and [38-27](#) provide a detailed algorithm for the workup of LGIB.

The American Society for Gastrointestinal Endoscopy Standards of Practice Committee recommends colonoscopy as the preferred modality for the evaluation and treatment of LGIB, allowing for direct visualization of the source of bleeding in more than 70% of cases, as well as therapeutic intervention and tissue biopsy. [Table 38-12](#) lists the frequency of the most common causes of LGIB. When no obvious colonic source of bleeding is discovered on lower endoscopy, upper endoscopy is done to evaluate potential causes of rapid, significant UGIB interpreted as LGIB. If there is still no identifiable source of bleeding, examination of the small intestine using enteroclysis or capsule endoscopy should be considered. Intubation of the terminal ileum at the time of colonoscopy may be useful, particularly when there is blood throughout the colon; fresh blood emanating from the ileum indicates small intestinal bleeding ([Eisen et al., 2001](#)).

The combination of an overall higher diagnostic yield and a lower rate of complications makes colonoscopy the preferred choice over angiography as the initial test in most patients with suspected GI bleeding. Colonoscopy may

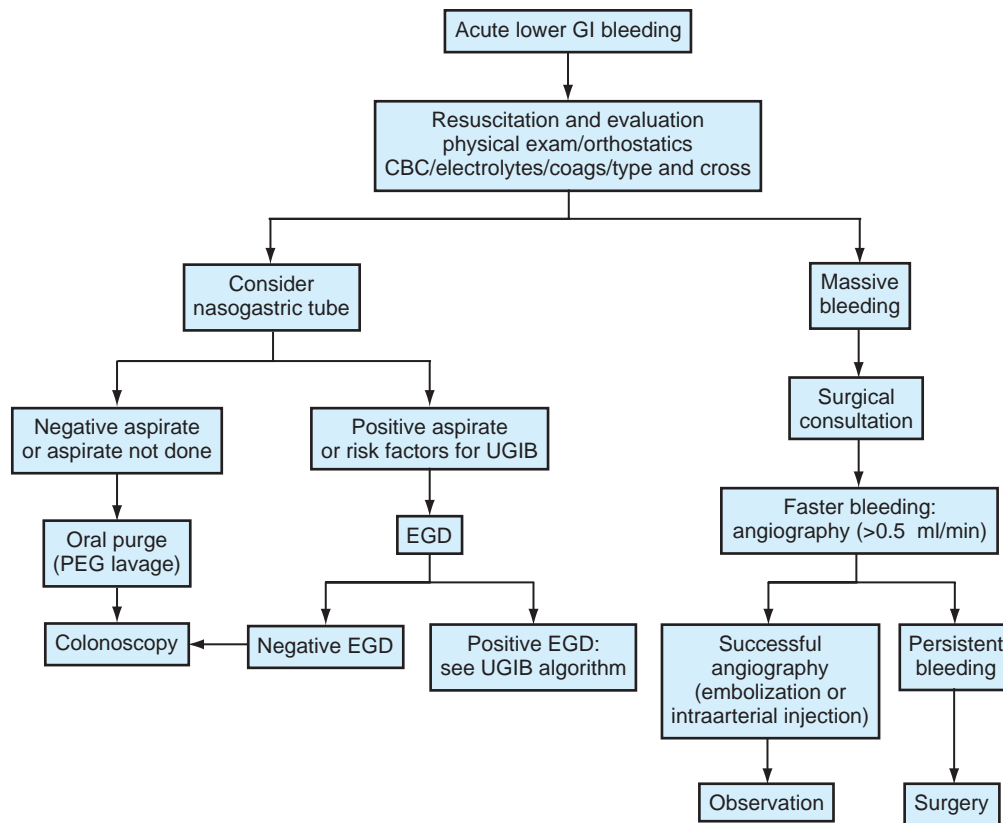

Figure 38-26 Algorithm for the management of acute lower gastrointestinal bleeding (part 1). *CBC*, Complete blood count; *EGD*, esophagogastroduodenoscopy; *PEG*, percutaneous endoscopic gastrostomy; *UGIB*, upper gastrointestinal bleeding. (Modified from Eisen GM, Dominitz JA, Faigel DO, et al; American Society for Gastrointestinal Endoscopy, Standards of Practice Committee. An annotated algorithmic approach to acute lower gastrointestinal bleeding. *Gastrointest Endosc.* 2001;53:859-863.)

be performed urgently or electively, depending on the patient's hemodynamic status and risk-stratification criteria. Comorbid risk factors for GI bleeding severity, including advanced age, presence or absence of shock, congestive heart failure, ischemic heart disease, and stigmata of recent hemorrhage, accurately predict the likelihood of death or rebleeding (Rockall et al., 1996). In patients with LGIB who are hemodynamically stable, a clean-out preparation (e.g., GoLytely) should be used before colonoscopy to increase visibility and diagnostic yield. In patients with hematochezia and hemodynamic compromise, consideration should be given to a rapidly bleeding upper GI source, the patient should be kept NPO, and a nasogastric tube should be placed. A bloody aspirate or one without blood or bile, a history of NSAID use or previous PUD, or a patient with massive bleeding may prompt performance of upper endoscopy before evaluation of the colon (Eisen et al., 2001).

The ^{99m}Tc pertechnetate-labeled red blood cell (RBC) scan is a safe and noninvasive alternative to angiography. Slower rates of bleeding may be detected with this technique, but it is not as accurate in identifying the exact location of a bleeding site. When arteriography is used in association with a ^{99m}Tc -tagged RBC blush, the sensitivity of the arteriogram is increased to 61% to 72% (Zuckerman et al., 2000). A retrospective study using these scans showed that an "immediate blush" (positive scan) had 60%

predictive value for an associated positive angiogram, and a "delayed blush" correlated with 93% predictive value for a negative angiogram.

Preoperative localization of the origin of LGIB is the standard practice, except in life-threatening cases of massive GI hemorrhage that necessitate emergency surgical exploration. Directed segmental resection is advised when the bleeding site is identified preoperatively, as seen in adenocarcinoma of the colon or diverticular disease limited to the left colon with persistent or recurrent bleeding. The removal of identified colonic lesions does not always result in effective treatment of the underlying source of bleeding. In these cases, arteriography can be used intraoperatively as an adjunct to localize a source of bleeding, facilitate segmental resection of the bowel, and prevent "blind hemicolectomy" (Manning-Dimmitt et al., 2005). A transfusion requirement of greater than 4 units of packed RBCs in 24 hours and recurrent diverticular bleeding (seen in up to 30% of patients) are common indications for surgical intervention. Other factors, such as comorbidities and individual surgical practices, play a significant role in this decision (Eisen et al., 2001).

In patients with chronic intermittent rectal bleeding, upper endoscopy is the preferred test for evaluation, with sensitivity and specificity of 92% and 100%, respectively. A barium-contrast upper GI series with small bowel follow-through (SBFT) may be considered if there is a relative

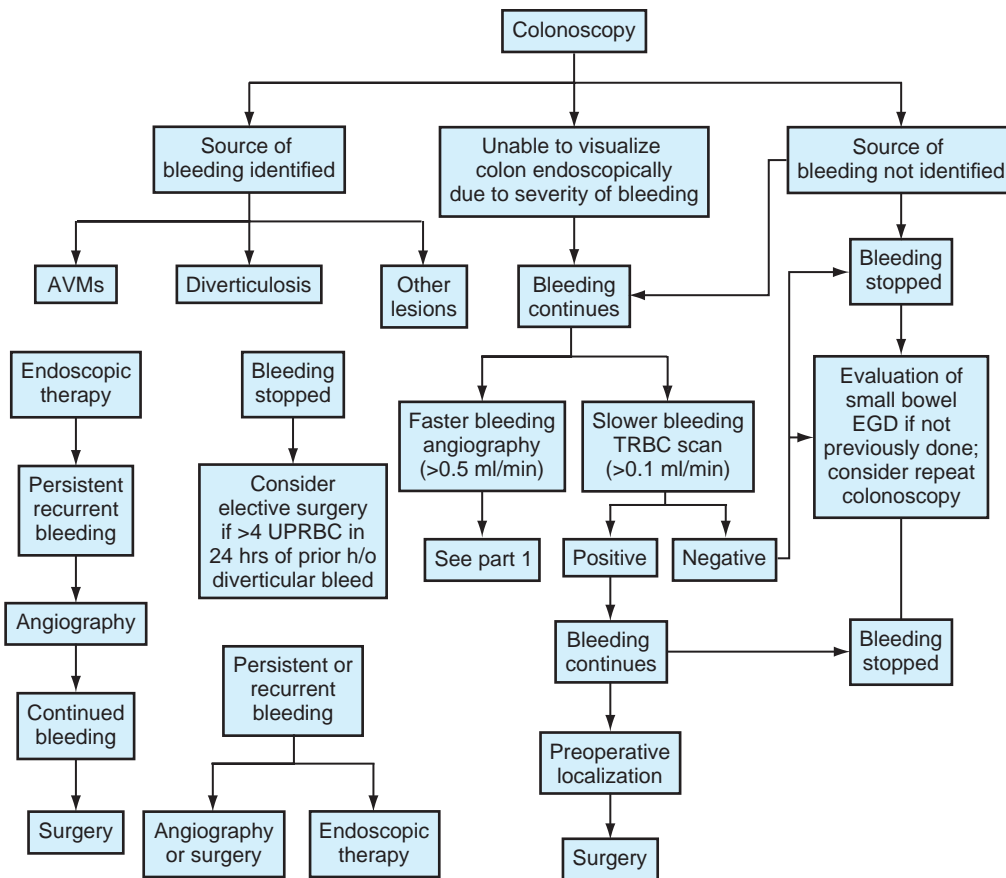

Figure 38-27 Algorithm for the management of acute lower gastrointestinal bleeding (part 2). *AVM*, Arteriovenous malformation; *TRBC*, tagged (radio-labeled) red blood cell; *UPRBC*, units of packed red blood cell. (Modified from Eisen GM, Dominitz JA, Faigel DO, et al; American Society for Gastrointestinal Endoscopy, Standards of Practice Committee. An annotated algorithmic approach to acute lower gastrointestinal bleeding. *Gastrointest Endosc*. 2001;53:859-863.)

contraindication to endoscopy (e.g., anticoagulation therapy, high risk for complications with conscious sedation, endoscopist unavailable). This test has sensitivity and specificity of 54% and 91%, respectively, in the detection of upper GI lesions located above the ligament of Treitz (Zuckerman et al., 2000). Transcatheter embolization is an alternative when vasopressin is unsuccessful or contraindicated but carries a risk of acute abdominal pain and intestinal infarction (Eisen et al., 2001).

Small intestinal sources of GI bleeding account for fewer than 10% of all cases. When upper and lower endoscopy have failed to determine the suspected cause of bleeding, the physician should consider *push enteroscopy* (extension of upper endoscopy that allows visualization of up to 160 cm of small bowel distal to ligament of Treitz), although this procedure is limited by its inability to visualize the entire small bowel and thus carries a low diagnostic yield. The barium-contrast upper GI series with SBFT carries a very low sensitivity of zero to 5.6%. *Enteroclysis* (endoscopic placement of radiopaque contrast directly into proximal small bowel) also has low sensitivity but has a shorter procedure time and can be used in the unconscious or uncooperative patient. Enteroclysis combined with push

enteroscopy has higher diagnostic sensitivity than either method alone. Arteriography can be used in challenging cases to evaluate bleeding not identified by endoscopy. It is particularly helpful in the evaluation of older patients in whom arteriovenous malformations or neoplasms are suspected because both of these lesions are associated with characteristic vascular patterns that can be identified on arteriography. Capsule endoscopy is being studied as another modality for identifying small bowel bleeding and neoplastic pathology but is limited in that biopsy samples cannot be obtained. Enhanced helical CT scanning is being explored as an alternative means of evaluating GI bleeding. Laparotomy with intraoperative enteroscopy should be considered a last resort in the diagnostic evaluation of nonemergent cases of GI bleeding because it is associated with higher rates of morbidity and mortality (Zuckerman et al., 2000).

KEY TREATMENT

- Colonoscopy is the preferred modality used in the treatment of lower GI bleeding (Zuccaro, 1998) (SOR: A).

Figure 38-28 Diverticulosis. (Courtesy Dr. Erik-Jan Wamsteker.)

Figure 38-29 Diverticulitis. (Courtesy Dr. Erik-Jan Wamsteker.)

Figure 38-30 Sigmoid diverticula. (Courtesy Dr. Perry Pernicano.)

DIVERTICULAR DISEASE

Diverticulosis refers to the presence of diverticula, or herniations of the intestinal mucosa and submucosa, most often in the sigmoid colon (Figures 38-28 and 38-29). More than half of patients older than age 50 years have incidental colonic diverticula. *Diverticulitis* is the most common complication of diverticulosis, occurring in up to 20% of patients, and results from a microperforation of a diverticulum from inspissated fecal material that often becomes a phlegmon, or a pericolic or intraabdominal abscess.

The initial assessment of the patient with suspected diverticulitis should include a thorough history and

physical examination, including abdominal, rectal, and pelvic examinations. The majority of patients have LLQ pain (93%-100%), fever (57%-100%), and leukocytosis (69%-83%). Other associated features include nausea, vomiting, constipation, diarrhea, dysuria, and urinary frequency. The differential diagnosis includes IBS, IBD, colon cancer, ischemic colitis, bowel obstruction, and gynecologic and urologic disorders (American Society of Colon and Rectal Surgeons [ASCRS], 2000). Initial evaluation of the patient with abdominal pain and suspected diverticulitis includes CBC, urinalysis, and flat and upright abdominal radiographs.

The ASCRS Standards Task Force for the treatment of diverticulitis state that if the patient's clinical picture clearly suggests acute diverticulitis, the diagnosis can be made on the basis of clinical criteria alone (ASCRS, 2000). The need for additional tests in the patient with suspected diverticulitis is determined by the severity of the presenting signs and symptoms and diagnostic confidence. When the diagnosis of diverticulitis is in question, other tests may include water-soluble contrast enema, abdominal CT, or ultrasonography.

Criteria for the diagnosis of diverticulitis on water-soluble contrast enema include the presence of diverticula (Figures 38-30 and 38-31), mass effect, intramural mass, sinus tract, and extravasation of contrast. Ultrasonography may reveal bowel wall thickening, abscess, and rigid hyperechogenicity of the colon caused by inflammation and may be helpful in female patients to exclude pelvic or gynecologic pathology. CT with oral and IV contrast is increasingly used as the initial imaging test for patients with suspected diverticulitis, particularly if disease of moderate severity or abscess is anticipated. Endoscopy is usually avoided in the setting of acute diverticulitis because of the risk of perforating the inflamed colon, either with the instrument itself or by insufflation of air. When the diagnosis of acute colonic diverticulitis is uncertain, limited flexible sigmoidoscopy with minimum insufflation of air may be performed to exclude other diagnoses.

Figure 38-31 Diverticula. (Courtesy Dr. Perry Pernicano.)

Conservative medical management of uncomplicated diverticulitis without associated abscess, fistula, obstruction, or perforation includes bowel rest and IV fluoroquinolones or extended-spectrum penicillins. If the patient does not improve after several days, an abscess should be suspected and diagnostic imaging considered. Conservative treatment results in resolution in 70% to 100% of cases (ASCRS, 2000). After recovery from an initial episode of diverticulitis, when the inflammation has subsided, the patient should be reevaluated. Appropriate examinations include a combination of flexible sigmoidoscopy and single- or double-contrast barium enema or colonoscopy. Eventual resumption of a high-fiber diet is recommended after acute inflammation resolves; long-term fiber supplementation after the first episode of diverticulitis has been shown to prevent recurrence in more than 70% of patients followed up with for more than 5 years.

The decision of whether to proceed with inpatient or outpatient treatment of diverticulitis depends on the clinical judgment of the physician, the severity of the disease process, and the likelihood that the patient's condition will respond to outpatient therapy. Patients who are able to tolerate a diet, who do not have systemic symptoms, and who do not have significant peritoneal signs may be treated on an outpatient basis with TMP-SMX or a fluoroquinolone plus metronidazole (Gilbert et al., 2009).

Primary resection and anastomosis without a protective stoma has become the surgical treatment of choice for uncomplicated diverticulitis and may also be performed for patients with localized pericolic or pelvic abscess. A single-stage procedure is associated with decreased hospital stays and has lower mortality and morbidity rates than two- and three-stage procedures. The most common two-stage operation is the Hartmann procedure, which carries a mortality rate of 2.6% to 36.8% (ASCRS, 2000). Surgical treatment of diverticulitis, in both acute and chronic settings,

has been successfully accomplished by laparoscopic and laparoscopic-assisted means.

Treatment of the patient with multiple attacks of diverticulitis or recurrent diverticulitis is individualized to minimize the morbidity and mortality of intervention. Factors considered when deciding whether to proceed with resection include the patient's age; number, severity, and interval of attacks; rapidity and degree of response to medical therapy; and persistence of symptoms after an acute attack. The risk of recurrent symptoms after an attack of diverticulitis ranges from 7% to 45%. With each episode, the patient is less likely to respond to medical therapy (70% respond to medical therapy after first attack vs. 6% after third). Thus, after two attacks of uncomplicated diverticulitis, resection is usually recommended (ASCRS, 2000).

KEY TREATMENT

- Patients who can tolerate a diet and do not have systemic symptoms or significant peritoneal signs may be treated as outpatients with TMP-SMX or a fluoroquinolone plus metronidazole (Gilbert et al., 2009) (SOR: B).
- Surgery may be necessary in some patients both in uncomplicated and complicated diverticulitis and should be individualized (Stollman and Raskin, 2004) (SOR: B).

CELIAC DISEASE

Key Points

- Tests to consider in testing for celiac disease include transglutaminase immunoglobulin (IgA), antiendomysial antibody, antigliadin antibody, and the genetic test human leukocyte antigen (HLA) DQ2/DQ8.
- A negative HLA DQ2/DQ8 test result is most helpful in ruling out celiac disease. A positive test result does not rule it in but is associated with an increased risk.
- Consider an elimination or challenge diet for 2 weeks. If symptoms improve, a rechallenge with gluten-containing foods will cause a recurrence of symptoms.
- The antibody test results (tissue transglutaminase antibody [TTG] IgA, antiendomysial, antigliadin) can become negative after elimination of gluten protein and may be false negative.

There has been a substantial increase in the prevalence of celiac disease over the past 50 years and an increase in the rate of diagnosis in the past 10 years. The adult presentation of celiac disease is characterized by weight loss, diarrhea, fatigue, and anemia. Children frequently present with failure to thrive, vomiting, diarrhea, muscle wasting, signs of hypoproteinemia (including possible ascites), and general irritability. Common comorbidities include type 1 diabetes mellitus, cerebral calcifications, Sjögren syndrome, and thyroid disease. Celiac disease should be considered in cases of unexplained folic acid, iron or vitamin B₁₂ deficiency, reduced serum albumin concentration, osteoporosis, and osteomalacia. Other presentations may include infertility or recurrent miscarriage. Splenic atrophy commonly occurs in

celiac sprue, and pneumococcal immunization should be administered in these patients.

Immunoglobulin A antiendomysial antibodies are currently the most accurate serologic test for diagnosing celiac sprue with a sensitivity of 97% to 100% and specificity of 98% to 99%. Antigliadin antibodies are also usually quantified. Enzyme tissue transglutaminase, the antigen for antiendomysial antibodies, has a sensitivity of 95% and specificity of 94% in diagnosing celiac disease (Rubio-Tapia, 2013). HLA testing can now be done to evaluate persons at risk for celiac. About 95% of patients with celiac disease are positive for HLA-DQ2 and 5% for HLA-DQ8. The majority of people who test positive for HLA-DQ2/DQ8 are at risk, but only 2% to 3% actually develop celiac disease. Celiac disease is rarely seen with a negative test result, and thus this test is most useful when the result is negative. A positive test result does not make the diagnosis. A CBC, comprehensive biochemical profile (including serum albumin concentration), transferrin saturation, serum or RBC folate, vitamin B₁₂, and liver function tests should also be obtained on diagnosis. Deficiencies of iron, folic acid, calcium, and vitamins B₁₂ and D frequently often correct after initiating a gluten-free diet (GFD) without the need for vitamin supplementation.

The diagnostic standard for celiac disease is a small intestinal biopsy using endoscopy, although this is usually not necessary to establish an accurate diagnosis. Characteristic changes include damage to the normal villous morphology with decreased villous height or crypt depth, decreased epithelial surface cell height, and increased lymphocytic infiltration of the intestinal mucosa. The accepted AGA diagnostic criteria state that small intestinal mucosa should be abnormal while patients continue on a gluten diet. A repeat biopsy should be taken 4 to 6 months after induction of treatment, and if there has been no improvement in the small intestinal mucosal morphology, the original diagnosis should be questioned. Many gastroenterologists do not obtain a subsequent biopsy specimen, and the cost effectiveness of this approach has not been demonstrated. A gluten challenge is recommended if there is any doubt concerning the correct diagnosis (AGA, 2006).

The AGA guidelines state that the cornerstone of treatment of celiac disease and its resultant complications is GFD therapy under a nutritionist's guidance. Patients should completely omit wheat, rye, barley, beer, and breakfast cereals from their diets. It is important to explain the disease process and toxicity of gluten-containing foods to the patient, including the potential for the reversal of current celiac disease-related problems, including anemia, depression, and infertility. Gluten-free breads, pasta, and other products are commercially available and should be recommended as substitutes. Given the incomplete response of many patients to a GFD as well as the difficulty of adherence to the GFD over the long term, development of new effective therapies for symptom control and reversal of inflammation and organ damage are needed.

Patients with celiac disease usually experience rapid symptomatic improvement within weeks of the exclusion of dietary gluten, providing additional diagnostic confirmation. Monitoring of antiendomysial or TTG IgA titers, which usually normalize with the institution of a GFD, may prove useful to check dietary compliance but have neither become

standard practice nor been cost effective. Life-threatening hypokalemia or hypomagnesemia rarely occurs and should be appropriately corrected. Expert panels suggest that yearly weight, CBC, ferritin, folate, calcium, and ALP levels should be obtained for disease monitoring. Oral corticosteroids may be used in unresponsive patients but only when other causes of small intestinal villous atrophy have been excluded (AGA, 2006).

Dermatitis herpetiformis is a common extraintestinal manifestation of gluten-sensitive enteropathy characterized by a pruritic, blistering, and vesicular rash. The diagnosis is made with immunofluorescent staining of granular IgA after skin biopsy. Treatment involves oral dapsone and a GFD, and with sufficient symptom relapse after 6 months, dapsone can be withdrawn and the GFD continued indefinitely. Osteopenia and osteoporosis, as well as bone pain, pseudofractures, and orthopedic deformities, are common features of celiac disease. Osteoporosis carries a significant fracture risk, and thus dual-energy x-ray absorptiometry screening of patients with celiac disease is recommended yearly. If osteoporosis is discovered, measures include strict adherence to a GFD, calcium supplementation of up to 1500 mg/day, bisphosphonate or calcitonin therapy, or consideration of hormone replacement therapy in postmenopausal women. Smoking cessation should be encouraged and an exercise regimen advised in all patients.

Ulcerative jejunitis is a serious complication of celiac disease that carries a high mortality risk after intestinal hemorrhage, perforation, or obstruction in patients with a history of significant malnutrition. The diagnosis can be challenging, and small intestine radiography often is not helpful. If small intestinal ulceration or lymphoma is suspected, enteroscopy may be used to obtain biopsy specimens for histologic assessment. Surgical resection of the ulcer, especially if localized to one part of the intestine, can be curative. Again, a strict GFD should be initiated, and treatment with steroids has shown significant benefit. If a diagnosis of enteropathy-associated T-cell lymphoma is made, the patient should be referred to an oncologist for appropriate chemotherapy.

Overall mortality risks are higher in patients with celiac disease, attributed to malignant intestinal lymphoma and adenocarcinoma. One study found a fivefold increased risk of developing malignancy in patients with celiac disease, with a relative risk of 40 for developing non-Hodgkin lymphoma. These risks decreased to the level of the normal population after patients maintained a GFD for 5 years (AGA, 2006).

COLORECTAL CANCER

Key Point

- Average-risk individuals should begin CRC screening at age 50 years and at age 45 years in African Americans.

Colorectal cancer is the third leading cause of cancer death in the United States, accounting for an estimated 9% of all cancer deaths in 2009. Risk factors include increasing age,

Table 38-13 Current Colorectal Cancer (CRC) Screening Recommendations

Preferred screening tests	Cancer prevention tests should be offered first. The preferred CRC prevention test is colonoscopy every 10 yr, beginning at age 50 yr. Screening should begin at age 45 yr in African Americans. Cancer detection test should be offered to patients who decline colonoscopy or another cancer prevention test. The preferred cancer detection test is annual FIT for blood.
Alternative CRC prevention tests	Flexible sigmoidoscopy every 5 to 10 yr CT colonography every 5 yr
Alternative cancer detection tests	Annual Hemoccult Sensa Fecal DNA testing every 3 yr
Positive family history but HNPCC evaluation not indicated	Single first-degree relative with CRC or advanced adenoma diagnosed at age 60 yr or older: <i>Recommended screening:</i> Same as average risk Single first-degree relative with CRC or advanced adenoma diagnosed before age 60 yr or two first-degree relatives with CRC or advanced adenomas: <i>Recommended screening:</i> Colonoscopy every 5 yr beginning at age 40 yr or 10 yr younger than age at diagnosis of the youngest affected relative
Familial adenomatous polyposis (FAP)	Patients with classic FAP (>100 adenomas) should be advised to pursue genetic counseling and genetic testing if they have siblings or children who could potentially benefit from this testing. Patients with known FAP or who are at risk of FAP based on family history (and genetic testing has not been performed) should undergo annual flexible sigmoidoscopy or colonoscopy, as appropriate, until colectomy is deemed by physician and patient to be the best treatment. Patients with retained rectum after subtotal colectomy should undergo flexible sigmoidoscopy every 6 to 12 mo. Patients with classic FAP, in whom genetic test results are negative, should undergo genetic testing for biallelic MYH mutations. Patients with 10 to 100 adenomas can be considered for genetic testing for attenuated FAP and if the result is negative, MYH-associated polyposis.
Hereditary nonpolyposis CRC	Patients who meet the Bethesda criteria should undergo microsatellite instability testing of their tumor or a family member's tumor or tumor immunohistochemical staining for mismatch repair proteins. Patients with positive test results can be offered genetic testing. Those with positive genetic testing or those at risk when genetic testing is unsuccessful in an affected proband should undergo colonoscopy every 2 yr beginning at age 20 to 25 yr until age 40 yr and then annually thereafter.

CT, Computed tomography; FAP, familial adenomatous polyposis; FIT, fecal immunochemical test; HNPCC, hereditary nonpolyposis colorectal cancer. Modified from Rex DK, Johnson DA, Anderson JC, et al. American College of Gastroenterology guidelines for colorectal cancer screening 2008. *Am J Gastroenterol* 2009;104:739-750.

a family history of CRC, obesity, a sedentary lifestyle, a diet high in red meat and low in vegetables, and excessive alcohol or tobacco use. Diets high in fiber, fruits, vegetables, and calcium may be protective, but data are inconclusive. African Americans have a 50% higher likelihood of dying from CRC than whites because they may have more proximal distribution of colonic adenomas and carcinomas than the general population, and these may be missed more often on suboptimal screening (ACS, 2009).

Approximately 75% of CRCs are diagnosed in individuals who have no risk factors other than advanced age; 90% of patients are older than 50 years. Other risk factors include prior or family history of CRC or adenomatous polyps, chronic IBD, and genetic syndromes. Several case-control and cohort studies found an inverse association between physical activity and risk in men and women of all ages and in various racial and ethnic groups in diverse geographic areas worldwide. The long-term use of aspirin may be associated with a decreased risk of CRC, yet the risk-to-benefit profile for chemoprevention cannot justify broad recommendations for its use in the general population (Nease et al., 2004).

Up to 30% of CRCs are believed to arise secondary to a genetic predisposition. Approximately 20% of cases occur among patients who have a history of CRC in a first-degree relative. About 6% are attributable to identifiable, inherited genetic mutations known as *hereditary CRC syndromes*, including familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer. Although these syndromes are relatively uncommon, they confer a lifetime risk of CRC ranging from 80% to 100%.

Currently accepted methods for screening of CRC include the digital rectal examination (DRE), fecal immunochemical test (FIT), double-contrast barium enema (DCBE), flexible sigmoidoscopy, and colonoscopy. According to the AGA, “the relative virtues of each screening test can be debated, but the best test is the one that gets done” (Burt et al., 2004). Screening should begin by classifying a patient's level of risk based on personal, family, and medical history, which together determine the approach to screening in that person. Table 38-13 details current CRC screening recommendations.

The DRE is a simple, inexpensive, and minimally invasive test that can be routinely performed in the office during yearly health maintenance examinations. It allows for palpation of the internal anal canal and examination of the prostate. Along with DRE, FIT should be performed to assess for occult blood. The DRE itself has a very low diagnostic yield, identifying fewer than 10% of colorectal tumors. Sensitivity of DCBE varies widely, ranging from 50% to 80% for polyps smaller than 1 cm, 70% to 90% for polyps larger than 1 cm, and 55% to 85% for Dukes stage A and B colon cancers (Winawer et al., 1997). In a comparison study with colonoscopy, sensitivity of barium enema for neoplasia was significantly lower (32% for polyps ≤5 mm, 53% for polyps 0.6-10 mm, 48% for polyps >1 cm) (Winawer et al., 2000). Any suspected lesions identified by DCBE need to be confirmed, biopsied, and removed by colonoscopy. Rarely, the classic “apple core” hallmark sign of a colonic mass may be visualized on DCBE (Figure 38-32).

Flexible sigmoidoscopy is an efficient screening tool for individuals at an average risk for CRC, allowing for direct

Figure 38-32 A and B, "Apple core" lesion (arrows) in colon cancer. (Courtesy Dr. Perry Pernicano.)

visualization and biopsy of the colonic mucosa in the rectosigmoid, descending, and distal transverse colon. To date, no RCTs or case-control studies have shown that screening with this method decreases CRC mortality for tumors within the reach of the standard 60-cm scope. The limitation of this method is that advanced lesions may be missed in the ascending and proximal transverse colon in individuals who do not have distal polyps. Although advocated as being more convenient than colonoscopy, because it is generally done in the office without the need for conscious sedation, only an estimated 30% of eligible patients undergo screening with flexible sigmoidoscopy (Nease et al., 2004). If polyps are identified during flexible sigmoidoscopy, a full colonoscopy is required to visualize the remaining colonic segments and to remove any remaining identified polyps.

Colonoscopy provides the most complete visualization of the entire colon and is the gold standard test for CRC screening. Because more than half of all individuals who have advanced proximal adenomas may not have distal polyps, many investigators advocate the use of colonoscopy as the primary modality for CRC screening. The removal of precancerous adenomas decreases CRC incidence by as much as 76% to 90% compared with no screening methodology (Figures 38-33 and 38-34). One study using colonoscopy as a screening tool in U.S. military veterans discovered advanced villous adenomas in 10.5% of subjects (Figure 38-35). Colonoscopy carries a higher risk of adverse events attributed to therapeutic interventions such as biopsy and polyp removal, compared with FIT, DCBE, and flexible sigmoidoscopy, specifically bowel perforation and postpolypectomy hemorrhage.

Newer modalities for CRC screening are being developed. Virtual colonoscopy, or CT colonography, uses thin-section helical CT scans to generate high-resolution two-dimensional images that are reconstructed into three-dimensional images of the colon to evaluate for the presence

Figure 38-33 Precancerous adenomas. (Courtesy Dr. Erik-Jan Wamsteker.)

of polyps. Direct comparison of CT colonography with colonoscopy in asymptomatic adults has shown sensitivity and specificity for polyp detection comparable with that of colonoscopy for polyps larger than 6 mm. CT colonography may be viewed as a more acceptable approach for CRC screening because it is less invasive and requires less time without the potential adverse risks of sedation or bowel perforation. Most patients prefer conventional colonoscopy, reporting more pain, more discomfort, and less respect from staff with CT colonography. As with conventional

Figure 38-35 Advanced villous adenomas. (Courtesy Dr. Erik-Jan Wamsteker.)

colonoscopy, CT colonography is limited by quality of the bowel preparation, procedural cost, lack of insurance coverage, variable physician training, and procedural time.

Capsule endoscopy is another emerging technology in the detection of CRC. The patient fasts overnight, ingests a disposable capsule, and begins water intake 2 hours after the capsule is ingested; the capsule is usually expelled within 48 hours of ingestion. The recorded information from the capsule is then downloaded and reviewed for abnormal pathology. Capsule endoscopy has become an accepted method for screening the small intestine for obscure GI bleeding. For colonic imaging, however, its use has been limited because of the larger colonic diameter, residual stool, and limited battery life of the capsule.

KEY TREATMENT

- The removal of precancerous adenomas can significantly decrease CRC incidence by as much as 76% to 90% (SOR: A).

CHAPTER OUTLINE**Terminology, 947****Specific Hematologic Disease States, 949****Anticoagulant Therapy, 959****Hematologic Malignancies, 961****The Myeloproliferative Neoplasms, 964****Clonal or Myeloproliferative Eosinophilic Neoplasms, 964****Hematology and Pregnancy, 965****Thrombocytopenia in Pregnancy, 965**

Clinical hematology encompasses a broad domain that involves, in major part, the study of the cellular elements in the circulating blood and bone marrow, mechanisms of hemostasis and thrombosis, and features of transfusion medicine. The specific disorders that involve the hematopoietic system include both hereditary and acquired illnesses, neoplasms, autoimmune conditions, vitamin and other elemental deficiency states, and consequences of pharmacologic and environmentally encountered hematopoietic toxins. Aspects of both autologous and allogeneic bone marrow transplantation also represent an important subset of modern clinical hematology. The recognition, diagnosis, and treatment of common hematologic disorders may involve interactions among physicians practicing in all medical and surgical specialties. A detailed review of the entire field of hematology is beyond the scope of this brief chapter, and we reference useful major and abbreviated modern texts for such detailed information (Greer et al., 2013; Hillman et al., 2010; Hoffman et al., 2012; Rodgers and Young, 2013). Rather, this chapter focuses on the principles of a hematologic evaluation and potential mechanisms leading to hematologic aberrations and reviews some aspects of the more commonly seen hematologic disease states, illustrating their diagnostic features, potential complications, clinical courses, and the approach to modern therapy. Because of the importance of obstetrics in the field of family medicine, aspects of hematologic diagnosis in this area are also emphasized.

Normal hematopoiesis reflects a complex production system that, in an adult, is confined to the bone marrow, with mature cells entering the peripheral blood to carry out their specific functions during a varied finite survival. In the bone marrow, a small number of pluripotential and self-renewing stem cells give rise to modified stem cells committed to either myeloid or lymphoid development. The process is nurtured by a variety of cytokine stimuli emanating from the bone marrow stromal microenvironment. The myeloid stem cells produce the highly specialized cell lines, including the erythroid, megakaryocyte, and granulocyte precursors. The lymphoid stem cells produce a variety of B- and T-cell progenitors that confer tissue-based immunity and direct immunoglobulin synthesis. The net production of blood cells by the normal bone marrow is massive and amounts to more than 10^{11} cells/kg/day.

In considering disease states involving blood cell production, the hematopoietic system may be divided into disorders primarily affecting erythrocytes, granulocytes, platelets, and lymphoid cells. In some instances, expression of the illness may be highly specific, involving only one of these cell lines. Frequently, however, multiple cell types are involved either as a primary consequence of the disorder or as a secondary phenomenon, such as occurs with hypersplenism or postchemotherapy transient myelosuppression after treatment of a nonmyeloid malignancy.

In a general hematology practice, perhaps 60% to 70% of consultations involve nonmalignant conditions. Successful therapy for all of these circumstances begins with a differential diagnosis of causation, which should direct the selection of useful confirmatory diagnostic tests. In the modern era, an increasingly complex array of molecular-based laboratory studies and specialized imaging studies may be ordered at a keystroke of the computer but often at great expense. However, often a comprehensive history and physical examination associated with a routine blood count and a careful inspection of the peripheral blood film provides a logical direction to the next level of more sophisticated diagnostic study and, ultimately, to successful evidence-based therapy.

Terminology

In clinical medicine, each specialty acquires a unique descriptive language set that allows ease and accuracy of communication among physicians and in publications. Some of these commonly used terms involving hematology are defined as follows; primary care physicians should be generally conversant with their usage:

- **Agranulocytosis:** A sudden and selective absence of granulocytes from the circulating blood usually associated with a similar absence of granulocyte precursors in the bone marrow. In an adult, this condition is most often drug related.
- **Megakaryocytic thrombocytopenia:** Thrombocytopenia consequent to a virtual absence of megakaryocytes and their platelet production. This is a rare entity, either congenital or more often acquired, and may be

associated with tumors of the thymus or a consequence of autoimmune illness.

- **Anemia:** A reduction in circulating erythrocyte mass below the normal range, adjusted for age and sex, and typically expressed in terms of hemoglobin concentration, red blood cell (RBC) count, or hematocrit value (the percentage of RBC volume in whole blood).
- **Anisocytosis:** Variation in the size of the erythrocytes, which should be uniform. Anisocytosis is characteristic of iron deficiency and many other forms of anemia. It is often accompanied by anisochromia, which refers to color variation in RBCs often striking in sideroblastic anemias in which there may be a dimorphic erythrocyte population consisting of both normochromic and hypochromic RBCs reflecting erythrocyte production by separate hematopoietic clones within the bone marrow.
- **Aplastic anemia:** A marked and persistent reduction in all bone marrow cellular precursors. The term *bone marrow hypoplasia* is applied to describe both transient episodes after chemotherapy and a persistent reduction in normal bone marrow cellularity but typically not to the profound degree present in aplastic anemia.
- **Cytopenia:** A reduction in circulating numbers of a specific blood cell line, for example, the terms *thrombocytopenia* to categorize a reduction in platelets, *neutropenia* to indicate a reduction in neutrophils, *lymphocytopenia* for a reduction in lymphocytes, and *pancytopenia* to signify a simultaneous reduction in erythrocytes, leukocytes, and platelets.
- **Cytosis:** An increase in numbers of a specific blood cell line. Thus, *erythrocytosis* for an increase in circulating erythrocytes, *leukocytosis* for an increase in total white blood cells (WBCs), *thrombocytosis* to signify an increase in the platelet count, but *thrombocythemia* when the cause for thrombocytosis is a myeloproliferative neoplasm (MPN). Similarly, the designation of *philia* to a cell line description also indicates an increase in numbers, such as *eosinophilia* to designate an increase in eosinophils, *basophilia* to indicate an increase in circulating basophils, and *thrombocytophilia* for an increase in platelet count.
- **Hematopoiesis:** Also referred to as *myelopoiesis*, it is the process by which stem cells may self-renew and differentiate into a variety of highly specialized blood cells, which then continuously populate the bone marrow and peripheral blood. On occasion, this process may occur outside the bone marrow and in the liver, lymph nodes, and spleen, for example, and is then referred to as *extramedullary* hematopoiesis.
- **Hypersplenism:** The consequence of an overactive and usually enlarged spleen that may remove, sequester, or destroy normal blood cells during their passage through the spleen. The process may be selective, as in idiopathic thrombocytopenic purpura (ITP) for platelets, or involve all cell lines, as is common in advanced hepatic cirrhosis with portal hypertension.
- **Ineffective hematopoiesis:** The normal bone marrow is highly efficient, and more than 90% of cells produced exit into the peripheral blood and circulate for their normal life span. The process is so effective that even with reduction in bone marrow cellularity to 20% of normal, the peripheral blood counts may remain in the normal range. With ineffective erythropoiesis, even with normal bone marrow cellularity, only 5% to 10% of hematopoietic cells produced may actually exit the bone marrow and support cell functions; the remainder undergo premature intramedullary cell death by various apoptotic mechanisms.
- **Karyorrhexis:** Abnormal condensation and fracture of nuclear chromatin characteristic of senescent blood cells and often evident among the atypical nuclei of granulocytes of some individuals with myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML) syndromes.
- **Leukemia:** The presence of circulating malignant cells derived from hematopoietic tissues. These illnesses are generally divided into four broad categories, which include acute myeloid leukemia (AML), acute lymphoid leukemia (ALL), chronic myeloid leukemia (CML), and chronic lymphocytic leukemia (CLL). Many other neoplastic hematopoietic disorders may manifest a leukemic phase, and these consist primarily of B-cell neoplasms such as variants of non-Hodgkin lymphoma (NHL), hairy cell leukemia, and multiple myeloma (MM).
- **Lymphoma:** A large and diverse group of malignancies of both B and T lymphocytes and often involving the bone marrow and inhibiting normal bone marrow function. They are generally divided into Hodgkin lymphoma (HL) and the far more common NHL, which includes both B- and T-cell subtypes.
- **Myelodysplasia:** Frequently, terms such as *myelodysplasia*, *dysplasia*, *dyspoiesis*, and *dysmyelopoiesis* are used by hematopathologists and clinical hematologists to describe morphologic aberrations in precursor hematopoietic cells. Many confuse myelodysplasia as equivalent to the grouping of disorders classified as the MDS, which is incorrect. Even bone marrows from patients with simple iron-deficiency anemia may exhibit marked dyspoiesis among erythroid precursors.
- **Myelodysplastic syndromes:** The MDS are generally described as clonal myeloid disorders characterized by progressive peripheral blood cytopenias typically noted early as unexplained macrocytic anemia associated with ineffective myelopoiesis. These syndromes demonstrate variable degrees of morphologic cellular dysplasia in the bone marrow and peripheral blood cells that may affect a single or multiple cell lines. They are often considered neoplasms because of frequently associated genetic mutations and patient-limited survival with progression to AML or death related to the consequences of bone marrow failure, including infection, hemorrhage, and iron overload. However, not all of these disorders are neoplasms, and some MDS respond favorably to immunosuppressive therapy (Epling-Burnette et al., 2012; Natelson et al., 2013).
- **Myeloproliferative neoplasms:** Hematopoietic states characterized by overproduction of one or more of the three major cell lines. The classical forms are polycythemia vera, essential thrombocytosis, and primary myelofibrosis. These disorders are linked by a molecular mutation in the JAK-2 locus. Originally, CML was placed in this classification, but it is now a stand-alone illness characterized by the Philadelphia chromosome t(9;22) translocation. The World Health Organization (WHO) currently considers all of these disorders and a separate group of

atypical myeloproliferative syndromes as neoplasms (Swerdlow et al., 2008).

- **Myelophthisic anemias:** The bone marrow may become infiltrated with reticulin fibrosis, metastatic tumor, or abnormal storage histiocytes, reducing the capacity for normal blood production. In these circumstances, nucleated erythrocytes and early myeloid cells may circulate in the peripheral blood, producing a *leukoerythroblastic* reaction.
- **Panmyelosis:** A marked overproduction of all bone marrow cellular precursors.
- **Poikilocytosis:** Variation among RBC shapes on the peripheral blood film and particularly striking in severe iron-deficiency anemia and RBC fragmentation syndromes.
- **Polycythemia:** This term and *erythrocytosis* have become synonyms for excess RBCs, and polycythemia does not imply simultaneous increases in multiple cell lines that may occur during the course of the MPN polycythemia vera.
- **Pure RBC aplasia:** Absence of RBC precursors from an often otherwise normal bone marrow and typically occurring on an autoimmune basis consequent to an adverse drug reaction or the presence of a thymoma. This state may also appear during the course of CLL. Other potential causes include parvovirus infection, particularly in immune-compromised individuals and riboflavin deficiency.
- **Rouleaux:** The description of groups of RBCs assuming an association on a peripheral blood film resembling a roll of coins. This is typically related to elevated plasma globulin levels, monoclonal or polyclonal, and brings to mind disorders such as MM, chronic hepatitis, Waldenström macroglobulinemia (WM), sarcoidosis, or the presence of erythrocyte cold agglutinins.
- **Xenobiotics:** Chemical compounds and their metabolites not native to the body that may interfere with normal hematopoiesis, causing various forms of *myelotoxicity*. Such chemicals may be found as therapeutic drugs, foods, and occupational or environmental chemical exposures.

Specific Hematologic Disease States

The following section describes toxicity targeting the cellular elements in the circulating blood and bone marrow by affecting their numbers, their function, or both. Such hematotoxicity may be a direct chemical consequence of various xenobiotics in the form of either an idiosyncratic host response or with an effect related to dose and duration of the toxic exposure. In some instances, the toxicity may be mediated through stimulation of the immune system, inducing production of autoantibodies in a fashion that may cause a selective cellular breakdown or with a more broad toxicity affecting all cellular elements. Deficiency of limiting reagents to blood production such as certain vitamins and iron may also cause hematologic disease. Typically, hematotoxicity is manifest by a reduction in blood cell production, but under certain circumstances, the introduction of toxic agents may stimulate excessive production of blood cells and result in clinical illness. Neoplastic diseases of the blood-forming elements may result in a variety of

cytopenias, as in MDS and AML, as well as increases in circulating blood cells, as in the MPN. Metastatic neoplasms such as breast and prostate cancer may also involve the bone marrow, crowding out or suppressing normal function and causing a myelophthisic form of anemia.

DISORDERS OF RED BLOOD CELLS

Key Points

- A diagnosis of iron-deficiency anemia mandates the search for a cause in addition to initiating therapy.
- Chronic ice hunger or other forms of pica suggest a diagnosis of iron deficiency.
- Oral preparations of iron salts such as sulfate, fumarate, and gluconate are generally equally effective, but timed-release iron formulations should not be prescribed.
- Patients with chronic iron deficiency consequent to bariatric surgery with roux-en-y anatomy and some individuals with celiac sprue may need periodic intravenous infusion of iron conjugates to avoid iron deficiency and anemia.
- Patients with sickle cell disease should receive the pneumococcal vaccination.
- Patients with sickle cell trait are typically not anemic from the illness but may experience episodic gross hematuria thought consequent to small renal infarcts.
- Chronic uncontrolled autoimmune hemolytic anemia is associated with an increased incidence of venous thrombosis.
- Corticosteroids are a primary therapy for autoimmune hemolytic anemia but may not alone effect a satisfactory remission of the illness.
- Anemia may be conveniently grouped as disorders involving reduced production, excessive hemolysis, or blood loss, recognizing that more than one mechanism may be present in any individual case.
- A very low serum ferritin level essentially confirms iron deficiency, but a markedly elevated serum ferritin level does not always indicate iron overload states.

The circulating blood cell present in greatest numbers is the erythrocyte, which, in humans, is a non-nucleated cell that contains the hemoglobin stores that are responsible for proper tissue oxygen delivery. A reduction in circulating erythrocyte mass below the normal range, adjusted for age and sex, and typically expressed in terms of hemoglobin concentration, RBC count, or hematocrit value is described as anemia. The most common acquired cause of anemia worldwide is iron deficiency, and this will be discussed in some detail, *vide infra*. Thalassemia syndromes are the most common hereditary causes of anemia. The normal mean peripheral blood values for men are a hemoglobin concentration of 15.5 g/dL, a hematocrit value of 47%, a RBC count of $5.2 \times 10^{12}/L$, and a platelet count of $250,000/mm^3$. Particularly, the hemoglobin concentration is lower among women, and the comparable normal mean values for blood counts in healthy adult women are 14.0 g/dL, 41%, $4,600/mm^3$, and $250,000/mm^3$. With aging, there is a significant but variable decrease in the hemoglobin concentration, particularly among men. Normal finite RBC survival

in the circulation is about 120 days or with a half-life of 60 days and a substantially shorter cell life span in hemolytic states.

A very useful metric in the analysis of anemia is the mean corpuscular volume (MCV), with a normal range of 86 to 90 fl. Other calculations often present on automated blood count laboratory slips, such as the mean corpuscular hemoglobin (MCH) and mean corpuscular hemoglobin concentration (MCHC), are not clinically useful. Dr. Maxwell Wintrobe, who conceptualized these measurements and wrote the first clinical textbook in hematology, was later quoted as being sorry he suggested the latter two calculations. The reticulocyte count is also a useful index of erythrocyte production and may be corrected by a simple formula to provide the reticulocyte index (% Reticulocytes \times Hematocrit/45 = Absolute reticulocyte percentage); this may be an automatic calculation performed by some laboratory equipment. An elevated reticulocyte count is usually manifest by polychromasia or a bluish hue among some erythrocytes on the stained peripheral blood film. Reticulocytes may be extremely increased in certain forms of hemolytic anemia and virtually zero in the unusual circumstance of pure RBC aplasia. Modern automated cell counters also typically provide a graphic representation of cell count versus cell volume, which can visually demonstrate a skewed erythrocyte and platelet size, although this and considerable additional information is evident on inspection of a well-prepared and well-stained blood film.

An isolated anemia may result from reduced RBC production, a shortened RBC life span generally reflecting a hemolytic state, blood loss, or some combination of these mechanisms. Of the selective acquired toxicities affecting the erythroid cell line, iron-deficiency anemia primarily is a consequence of chronic blood loss and repeated pregnancies in women. It is occasionally seen in frequent blood donors. However, malabsorption of iron occurs in children with heavy milk intake; in adults with celiac sprue; and in recent years, as a consequence of now frequently performed bariatric surgery, which bypasses the predominant sites of iron absorption in the duodenum. Inadequate nutrition in developing countries also contributes to iron deficiency. Aside from blood loss, iron is well conserved, and the oral requirement is less than 4 mg/day. Individuals with chronic iron deficiency often develop pica, which may be manifest as ice hunger (*pagophagia*) and an urge to chew on something, including clay, starch, paper, or even rubber bands. Such cravings rapidly disappear shortly after treatment is begun and long before the hemoglobin concentration returns to normal. There may also be some cheilosis and glossitis, creating oral symptoms associated with severe iron deficiency.

In iron-deficiency anemia, we think of hypochromic and microcytic erythrocytes, which are typically evident when the hemoglobin concentration falls below 10 g/dL. However, the appearance of abnormal erythroid shapes such as elliptical erythrocytes and occasional teardrop forms are common. In very severe iron-deficiency anemia, the peripheral blood film may somewhat resemble a microangiopathic hemolytic process with fragmented appearing forms (Figure 39-1). The platelet count often becomes elevated with a mean value of 450,000/mm³ in iron-deficiency anemia, and the total leukocyte count typically remains normal.

Figure 39-1 Peripheral blood film in severe iron-deficiency anemia (mean corpuscular volume, 57 fl; serum ferritin value, 3 ng/mL) showing misshapen and hypochromic erythrocytes.

It is good clinical practice to always obtain a serum ferritin value in the evaluation of patients with anemia. When the ferritin concentration is greatly reduced, iron deficiency is virtually always confirmed. Ferritin is an acute phase reacting protein. Although it is greatly elevated in hemochromatosis and transfusional iron overload, where it reflects a nonlinear increase in tissue iron stores, the highest ferritin values are seen in inflammatory illnesses such as juvenile rheumatoid arthritis and occasionally in NHL and the rare hemophagocytic syndromes. The ferritin molecule's structural configuration resembles a cylinder and may contain quite variable amounts of iron. The serum iron and iron-binding capacity are also helpful measurements in the evaluation of anemia and demonstrate a reduced serum iron and elevated iron-binding capacity with a reduced iron saturation of less than 16%.

It is well to always remember that iron deficiency should not simply be treated without consideration as to the cause. In addition to a careful history, this evaluation should involve a rectal examination, multiple stool tests for occult blood, and often a gastroenterology consultation seeking to demonstrate a potential site of intermittent blood loss. Occasionally, when upper and lower endoscopy is unproductive, the disposable so-called pill camera, which may take several hundred photos during its transit through the gut, may reveal a potential bleeding source. Although iron is a limiting reagent in blood production, individuals with an increased hemoglobin concentration may also be iron deficient. For example, patients with untreated polycythemia vera are virtually always iron deficient with low serum ferritin values and absent bone marrow iron stores. This is in contrast to a secondary polycythemia consequent to chronic hypoxemia, as in advanced lung disease, in which bone marrow iron stores and serum ferritin values are typically normal.

Treatment of iron-deficiency anemia is with oral iron salts, such as ferrous sulfate, fumarate, or gluconate. Timed-release preparations are to be avoided because the stool will turn dark, but the iron release will bypass the duodenum, and the anemia will not improve. Several intravenous iron

preparations are available, and their use may be necessary in patients with celiac sprue and after bariatric surgery because oral iron absorption may be insufficient and ineffective. Their use may also be necessary in chronic bleeding states such as Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia) and so-called watermelon stomach, in which oral iron is not sufficient to maintain a satisfactory hemoglobin concentration because of continuous blood loss from the friable gastric mucosa. If bleeding is the source of iron deficiency and this has ceased, the hemoglobin level will rise about 0.9 g/dL/week with oral iron preparations and may rise as rapidly as 1.5-1.9 g/dL/week after intravenous iron. Although the reticulocyte count will rise mildly with appropriate treatment, the bone marrow in iron deficiency is not hypercellular, and posttherapy reticulocyte counts would not be expected to rise to more than 4% or 5%, but they might reach 20% or more after appropriate treatment for megaloblastic anemia or in chronic hemolytic states in which the bone marrow is hypercellular.

Regulation of RBC synthesis is driven by erythropoietin production from the juxtaglomerular cells in the renal cortex, responding to variation in tissue oxygen delivery. In the case of chronic renal insufficiency, there is not a direct correlation between the rising serum levels of urea nitrogen and creatinine and the ability to produce erythropoietin. This disparity may be striking in patients with polycystic kidney disease and those who may have advanced renal failure without significant anemia. Thus, it is not unusual to encounter individuals with anemia responsive to parenteral erythropoietin who are not yet in need of chronic dialysis therapy. Erythropoietin levels in serum may be measured, but occasionally a therapeutic trial of parenteral erythropoietin is required to prove this mechanism for an isolated anemia in a patient with some degree of renal insufficiency. Erythropoietin is routinely given to patients receiving hemodialysis, often along with parenteral iron to maximize the response, but anemia in chronic renal disease may be multifactorial.

Another type of a selective deficit in erythroid cellular production is characterized by the disappearance of RBC precursors from the bone marrow and severe anemia referred to as pure RBC aplasia. This situation may occur as an idiosyncratic reaction to certain prescription medications, as an autoimmune illness, particularly associated with tumors of the thymus; as a consequence of infection with parvovirus; and as an association with certain neoplasms, such as CLL. It may also be induced by iatrogenic creation of a selective deficiency of the vitamin riboflavin. Selective riboflavin deficiency may be accomplished by administering an isocaloric diet very low in riboflavin and adding a competitive inhibitor of the residual dietary riboflavin, galactoflavin. Within a 3-week period, virtually all RBC precursors disappear from the bone marrow with no effect on WBC or platelet production. Even the aberrant and dyspoietic bone marrow RBC precursors present in forms of MDS and erythroleukemia will disappear with this therapy, revealing a background population of the accompanying myeloblasts, formerly hidden by the major overproduction of aberrant erythroid precursors. Aside from a sore tongue and cracking at the lip margins (*cheilosis*), there are surprisingly few short-term clinical symptoms from this unusual dietary treatment, which was used many years ago in early

Figure 39-2 Cocktail glasses with the original interior shellac coating (left) removed by dishwasher heat (right), exposing the dull lead-based paint lining (scratches made for sampling analysis).

approaches to cancer therapy in an attempt to “starve” rapidly growing tumor cells and possibly make them more sensitive to cytotoxic chemotherapy agents.

A classic example of chemical-induced selective hematotoxicity affecting the erythroid cell line is anemia consequent to lead poisoning. Excess lead may be assimilated through inhalation from refinery dusts, welding fumes and pesticides, or by ingestion of pigments used in lead-based paint or pottery or lead salts present as a contaminant in traditional medications, for example (Figure 39-2). The excess lead is incorporated into developing RBC precursors, where it interferes with several enzymes necessary for heme synthesis, including aminolevulinic acid (ALA) dehydrogenase, ferrochelatase, coproporphyrinogen oxidase, and porphobilinogen deaminase.

The mechanism of the resultant anemia is complex, as there is both a reduction in blood production by the bone marrow despite greatly increased erythroid precursors (*ineffective erythropoiesis*) and a reduction in the life span of circulating RBCs (*hemolytic anemia*). The leukocytes and platelets are not affected. The illness may be suspected by the presence of basophilic stippling or multiple bluish cytoplasmic dots commonly evident in RBCs on stained peripheral blood films (Figure 39-3). It is proven and quantified by a whole blood lead level. Urinary coproporphyrins and urobilinogens are also greatly elevated in this illness. Lead poisoning may also be suspected by the presence of ringed sideroblasts (erythroid precursors containing three or more blue-staining iron granules associated with cytoplasmic mitochondria), as highlighted by iron stains of bone marrow (Figure 39-4). Treatment with chelating agents, such as calcium disodium EDTA (ethylenediaminetetraacetic acid), is highly effective after the source of lead exposure has been identified and eliminated (Natelson et al., 1976). Over time, without specific therapy, lead may be stored in the cortex of bone and does not produce toxicity because it is hidden from the hematopoietic elements. An incorrect diagnosis leading to treatment of occult lead poisoning with corticosteroids, effective in certain types of immune hemolytic anemias, may aggravate lead poisoning by causing the lead to be mobilized from the bone cortex and again become available to cause bone marrow toxicity. An interesting feature of the

Figure 39-3 Peripheral blood film in lead poisoning showing erythrocyte basophilic stippling (arrows).

Figure 39-4 Iron stain of a bone marrow aspirate demonstrating multiple blue cytoplasmic granules ringing the nucleus in two erythroid precursor cells, confirming ringed sideroblasts.

sideroblastic anemia of lead poisoning in comparison with the sideroblastic anemia in MDS is that in lead poisoning, the MCV is usually normal, but it is typically increased in MDS.

A selective depletion primarily of circulating RBCs may also occur in most forms of hemolytic anemia, both congenital and acquired. Of the congenital types, hereditary spherocytosis is most common among white individuals and sickle cell syndromes among black individuals. In the acquired types of hemolytic states, such as autoimmune hemolytic anemia, the illness is mediated through antibody (*immunoglobulin*) production directed against antigenic sites on RBC membrane proteins, which are typically part of the Rh complex, causing breakdown of the erythrocytes, both directly in the bloodstream (*intravascular hemolysis*) or in the reticuloendothelial cells of the liver, spleen, or lymph nodes (*extravascular hemolysis*). Such events may occur as a consequence of an underlying immune-modifying illness such as lupus or CLL or by introduction of an antibody-provoking toxin in the form of prescription medications. A classic medication-induced example involves the antihypertensive drug, α -methyl dopa, which may generate formation of typically IgG immunoglobulins directed against RBC

surface antigens. Such immunoglobulins, which become immobilized on the RBC surface membrane, create a positive antiglobulin (*direct Coombs*) test result and, occasionally, significant hemolysis of the targeted cells. Only the erythrocytes are involved, and the antibody titer eventually falls with discontinuation of the medication, allowing complete hematologic recovery. Many other drugs, particularly a variety of nonsteroidal antiinflammatory drugs (NSAIDs), may cause immune-related hemolysis in a similar fashion. Occasionally, the drug must remain in the circulation as a hapten for hemolysis to be sustained by the offending immunoglobulin.

In addition to inspection of the peripheral blood film, useful laboratory tests to suggest hemolysis and its cause are the direct and indirect antiglobulin tests (Coombs tests), serum lactate dehydrogenase (LDH), total and indirect bilirubin level, and haptoglobin concentration. The latter test is very sensitive and not quantitative in terms of how much hemolysis has occurred. Free hemoglobin and haptoglobin form a complex in the plasma after intravascular hemolysis, which is removed by the liver. It takes some weeks to recover a normal serum haptoglobin level after sudden hemolysis, as may occur with a transfusion-related episode of hemolysis. With intravascular hemolysis, the LDH level is markedly elevated. However, some elevation of the serum LDH will occur even with extravascular hemolysis occurring in the spleen or with intramedullary hemolysis in the bone marrow. The LDH is a useful test to follow the results of therapy in certain chronic hemolytic states and is a good indicator of the degree of hemolysis caused by a malfunctioning mechanical heart valve, for example.

In autoimmune hemolytic anemia, the classic peripheral blood findings involving the erythrocytes include large numbers of spherocytes. Spherocytes are small cells when examined on a peripheral blood film, sometimes referred to as microspherocytes, and it may be surprising to find the MCV normal on an automated blood cell counter in an immune-related hemolytic anemia after reviewing the blood film. This occurs because the detection physics of automated cell counters oversize spheres and provide a false reading in this circumstance. Also evident on the peripheral blood film may be erythrophagocytosis by monocytes of the immunoglobulin-coated erythrocytes (*Figure 39-5*). In some instances of autoimmune hemolytic anemia, a second cell line is involved, and frequently antibody is also directed against the platelets, as occurs in Evans syndrome and in systemic lupus, causing thrombocytopenia. Generally, a dual autoimmune cytopenia suggests a more aggressive illness, but typically both cytopenias are improved by therapy with immunosuppressive agents (*Gómez-Almaguer et al., 2010*). Most examples of autoimmune hemolytic anemia are caused by “warm” reacting antibodies, meaning they are active at 37° C. Some autoantibodies are referred to as “cold” acting because their ability to attach to the RBC membrane is better demonstrated at colder temperatures. Such cold antibody or cold agglutinin autoimmune hemolytic disease is more often associated with underlying lymphoproliferative disorders and is more difficult to treat successfully (*Swiecicki et al., 2013*).

Successful treatment of patients with autoimmune hemolytic anemia may require prolonged or recurrent therapy. Aside from attempts to eliminate any underlying

Figure 39-5 Erythrophagocytosis by a peripheral blood monocyte in autoimmune hemolytic anemia.

and causative disorder, drugs such as corticosteroids, immune-modifying and immunosuppressive agents such as Imuran, Rituxan, Campath, and mofetil mycophenolate may be helpful. Splenectomy has also been advocated in refractory autoimmune hemolysis. However, although highly effective in hereditary spherocytosis, in autoimmune hemolytic states, the hemolysis may not lessen and, as a consequence of an absent spleen and a continuing hemolytic state, the platelet count may greatly increase, further predisposing to thrombosis. Indeed, the most common cause of death in patients with autoimmune hemolytic anemia is not anemia but the development of thromboembolic complications causing pulmonary thromboemboli and pulmonary hypertension. In patients with uncontrolled chronic hemolysis, oral anticoagulants are often added to the therapy until the hemolysis subsides.

In sickle cell syndromes, such as classical SS sickle cell disease, some hemolysis is constant as a consequence of the variant hemoglobin. Over time, the spleen is destroyed by the hemolytic process and by small splenic infarcts. There are many adverse clinical manifestations in addition to anemia, including cholelithiasis, pain crises, bone marrow infarction, priapism, the so-called acute chest syndrome, and even stroke. Because of the loss of the spleen and the opsonizing antibodies it produces, there is an increased risk of infection related to infections with encapsulated organisms such as pneumococcus.

The presence of fetal hemoglobin in the erythrocyte, even in small amounts, is somewhat protective against sickling. Its concentration in the sickle-cell erythrocyte may be increased by continuous use of the oral drug hydroxyurea. In some sickle syndromes, such as S-C disease and S-thalassemia, the spleen actually enlarges, causing some degree of hypersplenism, usually manifest as mild to moderate thrombocytopenia. Because of the need for frequent blood transfusion in some patients with sickle cell disease, antibodies generated to minor blood group antigens such as Kell may cause a type of alloimmune hemolysis. There also may be hemolysis consequent to alloantibodies generated against components of the Rh system (Chou et al., 2013). If transfusions are infrequent, the titer of the offending

antibody may fall below the level of detection during the routine cross match, but 10 to 14 days after transfusion, the antibody titer rises in response to the presence of the offending RBC antigen as an anamnestic response. Then what is referred to as a delayed hemolytic transfusion reaction may occur, causing severe hemolysis and destroying all of the transfused cells and even some of the native erythrocytes, worsening the anemia. Further transfusion becomes very difficult for several weeks.

Tissue iron overload is a common problem in patients with both sickle cell disease and thalassemia major syndromes consequent to increased absorption of iron, frequent blood transfusion, and the inability of the body to rid itself of excess iron. Early on, the storage sites of excess iron are primarily in the reticuloendothelial cells throughout the liver and differ from genetic hemochromatosis where iron deposition occurs first primarily in the hepatic parenchymal cells and in the pancreas. However, late in the course of all iron deposition syndromes, the liver biopsy in patients with transfusional iron overload may be difficult to distinguish from that of advanced hemochromatosis. Chelating agents may reduce iron overload by the removal of iron in the stool and urine, and the advantages of this are clear in patients with severe thalassemia, who cannot be phlebotomized periodically to reduce excess iron, in contrast to those with hemochromatosis, in whom the hemoglobin concentration is normal. In the hemochromatosis group, many blood banks are now able to use this blood for transfusion as they would normal donor blood. Iron chelators may be given by prolonged, intermittent parenteral administration for maximal effect, and newer chelators, such as Exjade, may be given orally.

Individuals with sickle cell trait such as AS hemoglobin typically will have a distribution of hemoglobin concentrations on hemoglobin electrophoresis showing a moderate increase of A over S hemoglobin and will not experience sickle crises unless placed in extremely low oxygen circumstances, such as a nonpressurized high altitude. However, they do have a propensity for episodes of periodic hematuria consequent to microinfarcts in the kidney. Experienced urologists are well aware of this phenomenon and will order a hemoglobin electrophoresis in black individuals with unexplained gross hematuria regardless of the blood count. The life span of an individual with sickle trait is the same as that observed in the general population.

Many variant hemoglobins may be associated with anemia and an abnormal peripheral blood film result. With C hemoglobin trait, target cells are frequent, and virtually all of the erythrocytes are target cells with CC hemoglobin, although the anemia is generally mild. Certain ethnic groups have particular frequency of specific aberrant hemoglobins such as hemoglobin E in Thailand, which affects about 40% of the population, producing a mild anemia with target cells. In this population, there may be various combinations of hemoglobin E and thalassemia minor syndromes producing a varying severity of anemia.

Hereditary defects in RBC enzyme systems may cause a chronic hemolytic state. The two most frequent circumstances are with pyruvate kinase deficiency and with glucose-6-phosphate dehydrogenase (G-6PD) deficiency. G-6PD deficiency is sex linked, so most affected individuals are men. The enzyme defect allows increases in oxidative

stress to affect the erythrocyte, causing hemolysis. Precipitated hemoglobin may be identified in the circulating erythrocytes with a Heinz body stain. The defect may cause continuous hemolysis among white individuals, but in black individuals, hemolysis may be more episodic and limited and seldom causes life-threatening anemia. Certain antimalarial drugs may precipitate hemolytic crises in those with G-6PD deficiency states.

Hemolysis and anemia is also a major component and consequence of a group of disorders associated with a variable degree of thrombotic microangiopathy. In this case, the hemolysis is intravascular and not immune related but rather caused by the shear stress applied to the erythrocytes as they traverse partially occluded small arterioles. Complement may play a role in the hemolytic process. The most frequent of these syndromes are thrombotic thrombocytopenia purpura (TTP); hemolytic uremic syndrome (HUS) linked to the verocytotoxin associated with acute bacterial diarrhea, sometimes occurring in an epidemic pattern; and atypical HUS. The pattern of the anemia is microangiopathic, with abundant fragmented-appearing erythrocytes evident on the peripheral blood film. A similar but less severe fragmentation pattern may also be seen in various forms of vasculitis, flares of chronic ulcerative colitis, and malignant hypertension.

Thrombotic thrombocytopenia purpura is usually associated with deficits of the plasma ADAMTS-13 enzyme, which regulates the size of circulating von Willebrand factor multimeric subunit proteins. The illness may be congenital or acquired in various clinical settings. On occasion, an autoantibody to ADAMTS-13 can be demonstrated along with a reduction in the concentration of the enzyme, suggesting an immune-related etiology. The congenital form may be controlled by periodic infusions of plasma to raise the ADAMTS-13 level. In the more common acquired form of the illness, which typically begins abruptly, the most effective initial therapy is repeated plasma exchange. If the ability to conduct an exchange is not immediately available, infusions of fresh-frozen plasma provide benefit until a formal exchange can be initiated. Corticosteroids are effective in about 25% of cases and are typically given along with the plasma exchanges. Some patients with TTP have modest favorable responses to antiplatelet aggregating agents, such as Aggrenox (aspirin + Persantine), which may be added to the treatment regimen. Platelet transfusions are to be avoided despite the often severe thrombocytopenia because they may precipitate intracerebral arterial thrombosis and seizures. Moreover, despite thrombocytopenia, life-threatening bleeding is only rarely present in TTP. Particularly in individuals with antibodies to ADAMTS-13, infusions of Rituxan, as an immune-modulating agent, have been added to the treatment program in recent years and may prevent relapses. The effects of therapy are monitored by following the hemoglobin concentration, platelet count, and the serum LDH. In the recovery phase, the platelet count begins to rise first, but hemolysis does not acutely abate, and the elevated LDH may take time to slowly recede as the partially occluded blood vessels recover. Some patients exhibit a relapsing course after months in unmaintained remission, and in many of these individuals, further recurrences may be aborted by splenectomy during a stable phase of the illness. The cause of TTP is uncertain but has clearly

been associated with pregnancy, a familial link, and certain medications such as quinine (McMinn et al., 2001), Plavix, and ticlopidine. It also may appear during the course of HIV infection, where it seems very responsive to therapy.

Hemolytic anemia simulating TTP but with a greater predilection for often irreversible renal damage may occur after infections with organisms, including strains of *Escherichia coli*, which can produce a *Shiga* toxin referred to as verocytotoxin. This illness has occurred in epidemic form with food contamination. Plasma exchange is not as effective in this group but is usually initiated. The inhibitor of the C-5 complement protein eculizumab, effective in reducing hemolysis in patients with paroxysmal nocturnal hemoglobinuria (PNH), also has a beneficial effect in some atypical HUS. A microangiopathic process simulating TTP and HUS may occur abruptly during chemotherapy treatment with certain agents, but standard therapy is not highly effective in this group.

Less common causes of major hemolysis include the rare illness of paroxysmal nocturnal hemoglobinuria (PNH). In PNH, the cytoskeleton of the erythrocyte is abnormal and sensitive to complement-induced hemolysis. PNH may arise during the course of aplastic anemia or spontaneously appear. The diagnosis may be easily made by modern flow cytometry studies identifying certain cluster designation (CD) markers present on the erythrocytes. Iron deficiency is occasionally present consequent to chronic urinary iron loss from the hemoglobinuria. However, the hemolytic state may be set off by therapy with intravenous iron, which causes a sudden outpouring of reticulocytes from the bone marrow, with these younger RBCs more sensitive to hemolysis. The C-5 complement inhibitor eculizumab may greatly lessen the severity of hemolytic episodes but must be infused every 2 weeks at a massive cost. Successful therapy of PNH also has followed allogeneic bone marrow transfusion, which may eliminate the abnormal clone producing the complement-sensitive erythrocytes. Individuals with PNH are susceptible to thrombophlebitis because of the chronic intravascular hemolysis, which has a thromboplastin-like effect. Most individuals with PNH have a normal total leukocyte count and platelet count, but others may have periodic episodes of mild pancytopenia. Marked splenomegaly may occur in patients who have had the illness for many years.

In contrast to hemolytic states and anemia, a significant increase in the numbers of RBCs may occur among chronic smokers as a consequence of increased levels of carboxyhemoglobin, reducing oxygen-carrying capacity and interfering with tissue oxygen delivery. Oxygen sensors in the kidney respond to the lack of oxygen tension by augmenting production of erythropoietin from the juxtaglomerular cells, stimulating RBC production by the bone marrow. A similar effect may be produced by the administration of certain anabolic steroids, as used among bodybuilders and other athletes. In these situations, hemoglobin concentrations may exceed 20 g/dL, increasing circulating blood viscosity. Affected individuals may experience headache and sluggishness and appear flushed. Rarely, such secondary erythrocytosis, if marked, may result in venous or arterial thrombosis (or both).

Perhaps not widely appreciated is the effect of various types of anemia on the HgA_{1c} level often used to monitor

mean blood glucose levels over the preceding several weeks in patients with diabetes mellitus. In part, this measurement depends on RBC turnover rates, which may vary widely among patients with chronic hemolytic anemias, iron-deficiency anemia, and MDS. For example, the HgA_{1c} level is falsely elevated in iron-deficiency anemia and in pure RBC aplasia and falsely lowered in hemolytic anemias and MDS, with ineffective erythropoiesis (Okawa et al., 2013). It may also be lowered in the anemia of renal disease under treatment with erythropoietin preparations. In some instances, the artifactual aberrations in HgA_{1c} values are trivial, but in sickle cell disease, some rely on glycosylated albumin values rather than HgA_{1c} levels for monitoring control of diabetes.

DISORDERS OF LEUKOCYTES AND PLATELETS

Key Points

- Splenectomy for treatment of ITP should be preceded by vaccinations for pneumococcal, hemophilus, and meningococcal infections at least 2 weeks before surgery.
- Although plasma exchange is the primary therapy for TTP, plasma infusions are of benefit and should be started immediately, along with corticosteroids, pending transfer to a facility equipped to perform apheresis (*plasmapheresis*).
- Patients with chronic thrombocythemia associated with an MPN may be treated with either hydroxyurea or anagrelide or combinations of both drugs to reduce the platelet count and reduce the risk of thrombosis and excessive postsurgical bleeding.
- Colony-stimulating factors such as Neupogen and Neulasta are helpful in chemotherapy-induced myelosuppression but generally should be avoided in those with autoimmune neutropenias.

The WBCs, or leukocytes, comprise several specialized forms. Granulocytes are the predominant circulating normal leukocyte type. These cells contain a variety of packaged cytoplasmic enzymes and are responsible for the phagocytosis and subsequent destruction of foreign organisms. In this regard, they work directly with opsonizing immunoglobulin antibodies produced by the lymphoid cells, particularly those present in the spleen, which help to immobilize encapsulated organisms such as the pneumococcus. Most of the granulocytes are mature neutrophils with lesser numbers circulating as monocytes, eosinophils, and basophils. The lymphoid cells are divided into B- and T-cell forms and have to do with support of a normal immune system. The platelets are non-nucleated cells derived from the parent bone marrow megakaryocytes by programmed fractionation and extrusion of their cytoplasm into the capillaries throughout the bone marrow. Some further division of the platelets occurs in the circulating blood. The platelet functions to ensure normal hemostasis, often acting in concert with the coagulation proteins or factors. Under normal conditions in adults, the production site for erythrocytes, granulocytes, and platelets is restricted to the bone marrow, although in certain disease states,

extramedullary hematopoiesis may occur in the liver, lymph nodes, and spleen, for example. Lymphoid cells may also be produced in the bone marrow but are primarily generated in the lymph nodes throughout the body.

A selective absence of granulocytes may occur abruptly and in this circumstance is typically consequent to various medications. Certain cardiac and antithyroid medications, for example, may cause agranulocytosis, presumably through an immune mechanism. In these cases, the period of agranulocytosis is generally short, typically around 2 weeks, after the offending medication is stopped. Similarly, a wide number of medications may cause isolated thrombocytopenia, which may be profound but is also typically a temporary phenomenon. In clinical practice, severe granulocytopenia is most commonly a predictable consequence of chemotherapy for both hematologic and solid tumor malignancies. Although recovery is expected within 10 to 14 days, depending on the type and dose of chemotherapeutic agents used, the period of severe neutropenia may be shortened by several days with the use of colony-stimulating factors such as Neupogen or Neulasta.

In thrombocytopenia consequent to a drug reaction, such as with quinine, a spontaneous recovery is predictable, and the drug should be avoided in the future. Selective thrombocytopenia is common with ITP. Here, IgG immunoglobulin coats the platelet, which usually does not interfere with its function, but the complex is removed by the spleen and other elements of the reticuloendothelial system. The process may be self-limited, particular after viral infections, in children, but in adults, remission may require therapeutic intervention. ITP may be the first sign of an underlying illness such as in systemic lupus, NHL, or HIV disease. Aside from the potential for bleeding problems, affected individuals are typically asymptomatic, a contrast with those with a sudden onset of TTP who often manifest a systemic illness as a consequence of the disease state. In the therapy of ITP, the first consideration is if any treatment is even indicated. This depends on the level of thrombocytopenia and the clinical circumstances. An individual with a chronically low but stable platelet count in the 60,000/mm³ range may require no therapy unless a surgical procedure is required, and then some intervention may become necessary.

The initial approach to treatment in ITP is with corticosteroids, which will almost immediately lessen the bleeding tendency before any rise in the platelet count as a vascular effect. A significant rise in the platelet count seldom occurs for several days and may take 2 weeks for a major improvement. In part, this may be related to corticosteroid dose and type. However, only perhaps 25% of individuals who respond will actually attain unmaintained remission when the steroids are discontinued. Infusions of large amounts of intravenous immunoglobulin (IVIG) may improve the platelet count more rapidly but seldom give a sustained response. The oral drug Promacta, which stimulates platelet production, works promptly in most individuals, but in many, the thrombocytopenia will relapse abruptly when the drug is discontinued. Immunosuppressive drugs such as the monoclonal anti-CD-20 agent Rituxan do provide favorable responses, but relapse is common. Splenectomy remains a useful therapy for ITP, with remission rates in those younger than 40 years of around 80% to 85% and around 60% in those older than 40 years. Prophylactic immunizations

against the encapsulated bacteria such as pneumococcus, *Haemophilus* spp., and meningococcus should be administered ideally at least 2 weeks before the surgery. These immunizations administered after the procedure yield a reduced serum immune titer response because splenic lymphocytes have been removed. With the advent of laparoscopic surgery, the risks of the procedure and the length of stay in the hospital are both less than with an open procedure.

Autoimmune neutropenia is occasionally seen as an isolated finding in otherwise healthy individuals and in those with underlying rheumatoid disorders and lupus. Occasionally, in those with rheumatoid disease, the neutropenia is profound and associated with some splenomegaly and referred to as Felty syndrome. Despite profound neutropenia in the peripheral blood, bacterial infections are rather uncommon in this group, but if they do present a problem, splenectomy is also effective, as in ITP. Generally, it is thought that granulocytopenia below 500 cells/mm³ strongly predisposes to infection, but this is more applicable to the myelosuppression of chemotherapy than in idiopathic autoimmune neutropenia. This may reflect the observation that neutrophils may move from the bone marrow into the tissues in an adequate manner to combat infection but cannot easily continue to circulate for their normal life span in the peripheral blood because of the presence of the autoantibodies.

PANCYTOPENIA

Hematotoxicity may affect all three cell lines simultaneously. For example, the broad-spectrum antibiotic Chloramphenicol (chloramphenicol) may damage the bone marrow permanently, causing aplastic anemia by an idiosyncratic form of toxicity that is poorly understood or by a dose-related reduction in bone marrow cellularity, which often slowly recovers after the drug is discontinued. In each instance, all three cell lines are affected, and pancytopenia occurs. The bone marrow histology in chloramphenicol poisoning is unique and illustrates the presence of multiple vacuoles in the nucleus and cytoplasm of both erythroid and myeloid precursors along with the presence of occasional ringed sideroblasts. Similar but less striking bone marrow toxicity is noted with the modern-day antibiotic linezolid, which also may cause pancytopenia. Aplastic anemia may occur from other prescription medications, including the formerly used NSAID Butazolidine and currently available products such as indomethacin. Alcohol is a prominent hematotoxin and may produce a typically reversible pancytopenia or selective thrombocytopenia. Its actions as a hematotoxin may occur through associated dietary deficiency of folic acid by induction of a sideroblastic process in the bone marrow erythroid precursors or a direct toxic effect on circulating platelets. Acute alcoholic thrombocytopenia is short lived after ingestion has ceased, but sideroblastic bone marrow toxicity is only slowly reversible upon discontinuing alcohol exposures.

The megaloblastic anemias are also often associated with pancytopenia and may be caused by deficiencies in folic acid or vitamin B₁₂. The peripheral blood film may show marked macrocytosis with the normal RBC volume (MCV) increasing from around 86 fl to as much as 125 to 130 fl. The bone

marrow is hypercellular with marked ineffective erythropoiesis causing intramedullary cell breakdown associated with elevated serum LDH and indirect bilirubin values. Treatment with the appropriate depleted element is characterized by a rapid recovery of bone marrow function, with reticulocyte counts reaching 20% to 25% in about 5 to 7 days in contrast with iron-deficiency anemia, in which the bone marrow is mildly suppressed, and correction with iron supplements, even given intravenously, seldom generates a reticulocyte response above 4-5%.

In hereditary vitamin B₁₂ deficiency, pernicious anemia, the illness in black individuals may occur at an early age whereas in white individuals, it is unusual to detect its presence before age 60. Therapy is typically parenteral with vitamin B₁₂ injections but can be effectively given with various intranasal sprays, at much greater expense. The liver stores vitamin B₁₂ very well and, although monthly injections of vitamin B₁₂ are recommended, it actually takes several years for relapse to occur after treatment is stopped and the blood counts normalize. However, if neurologic disease is present, it is important to continue a frequent administration of vitamin B₁₂ because neuropathic recovery is very slow.

Because the causes of pancytopenia are multifactorial, the indication for a diagnostic bone marrow study is far more often necessary than with investigation of a single cytopenia. Particularly if malignancy is suspected, such as MDS or AML or a form of NHL, the addition of flow cytometric studies and chromosome analysis greatly increases the ability to confirm a specific diagnosis and direct appropriate therapy. It is also useful to obtain ultrasonography of the abdomen in the investigation of pancytopenia, which is the most cost-effective and accurate way of measuring spleen size. The length of the spleen is normally 9 to 10 cm and correlates well with its total volume.

LATENT HEMATOTOXICITY

Key Points

- The diagnosis of AML does not always rely on a particular number of myeloblasts in the peripheral blood or bone marrow but can be established by the presence of certain chromosomal aberrations.
- Secondary forms of AML after chemotherapy and radiation exposures are generally a more aggressive illness than de novo forms of AML.
- Advancing age, prior exposure to chemotherapy, cigarette smoking, and underlying autoimmune disorders are major risk factors for the development of MDS.
- The currently available therapy for acute promyelocytic leukemia (APL) makes this illness the most curable form of adult AML.

Certain compounds used therapeutically as anticancer agents and immunosuppressive drugs are mutagens and may cause various cytopenias by damage to the DNA through a variety of mechanisms. These include interference with the enzyme topoisomerase II, which allows the programmed DNA fracture necessary to sustain the rapid

pace of hematopoietic cell duplication under normal circumstances. Other antineoplastic drugs such as alkylating agents, including cyclophosphamide and Alkeran, may intercalate DNA and cause stem cell genetic damage that may initially appear as a reversible pancytopenia but later predisposes the individual to AML despite apparent recovery of normal bone marrow function. Still other compounds may interfere with enzymes necessary for cell division by acting as fraudulent metabolites or interfering with the actions of vitamins such as folic acid that are necessary for normal cell division. In these circumstances, all three hematopoietic cell lines are variably affected, and although a period of pancytopenia is common, with removal of the offending agent, sustained bone marrow aplasia from chemotherapy administration is rare.

Benzene, an early and long-obsolete chemotherapeutic agent, is a mutagen that may also cause an initially reversible pancytopenia at very high dosage (Gailbraith et al., 2010; Natelson, 2007). The specific mechanism causing its hematotoxicity remains unknown. Prolonged exposure to benzene may result in a persistent pancytopenia characterized by bone marrow hypoplasia associated with atypical eosinophilia and erythrophagocytic histiocytes, suggesting an immune-related process. A true aplastic anemia from benzene would require exposures to the chemical now not likely possible in developed countries.

Acute pancytopenias consequent to mutagenic compounds may fully resolve, but years later, hematotoxicity may reappear and become progressive in the form of certain types of MDS and even AML. This event occurred after the administration of mitoxantrone, a topoisomerase II inhibitor, used as an immune-modulating agent for the treatment of multiple sclerosis. Here a significant incidence of AML involving balanced translocations, such as the t(15:17) translocation of APL, occurred within 5 years of initiating therapy.

Blood cell production requires replacement of the entire granulocyte population in the body multiple times per day, and genetic damage to precursor cells may escape the normally efficient reparative mechanisms. This may lead to continued production of small clones of hematopoietic cells with disordered sequences of maturation and natural cell death. If the abnormal clone expands, with time, it may develop additional molecular aberrations, which allow a favored growth, a reduced process of cell death, or both, creating a growth and proliferation advantage over the normal cell population. This may become evident first as a single cytopenia, often associated with subtle morphologic aberrations distinct from the normal cell line. Such a circumstance is referred to as MDS.

In MDS, ultimately, all myeloid bone marrow cell lines become affected, cell maturation may be trapped at an immature stage, and ineffective myelopoiesis becomes prominent. In MDS, aberrant cell morphology in both the peripheral blood and the bone marrow is common. Useful, although not specific, clues to the presence of MDS on the peripheral blood film are a progressive macrocytosis and the acquired Pelger-Huët bilobed neutrophil (Figure 39-6). This nuclear aberration is a robust marker for MDS, but it may be caused by medications and is reversible when they are discontinued, and it is important to be aware of this phenomenon (Wang et al., 2011). Ultimately, the presence of

Figure 39-6 Peripheral blood film in myelodysplastic syndrome showing a teardrop erythrocyte (arrow) and acquired or pseudo Pelger-Huët neutrophil aberration with a bilobed nucleus and hypogranular cytoplasm.

large numbers of immature myeloid cells, referred to as blasts, becomes the hallmark for the progression to AML. Depending on the nature of the chromosomal aberrations in the abnormal cell line, the clinical manifestations, prognosis, and treatment of the AML syndrome may vary. MDS and AML arising without known causes are referred to as *de novo*, or primary, and account for the majority of adult AML/MDS. A chemical or radiation-induced form of AML is referred to as secondary, and amounts to about 10% to 15% of all AML syndromes. A secondary form of MDS/AML generally carries a more ominous prognosis than *de novo* disease. It is often characterized by complex (>3) separate clonal chromosomal aberrations and is associated with a poor response to therapy. Prolonged cigarette smoking may also predispose to MDS/AML, but the mechanism is uncertain and the cytogenetic manifestations differ from those seen in a chemical induced secondary MDS/AML, resembling those of *de novo* MDS/AML (Vardarajan et al., 2011). Many studies have shown that the prognosis for remission induction and ultimate survival in AML is worse for a smoker versus a nonsmoker (Vardarajan et al., 2011). Figure 39-7 illustrates the frequency of causation, age, and other associations as risk factors for MDS. Figure 39-8 provides similar information for AML.

Acute myeloid leukemia and MDS syndromes caused by drugs and chemicals do not appear as an idiosyncratic reaction to brief or low-level toxic exposures and typically require a cumulative threshold dose (CTD) necessary to exceed in order to predispose to disease (Natelson, 2007; Natelson et al., 2010). Such a potentially leukemic threshold dose varies considerably among known leukemogenic chemicals, and certain agents appear potentially far more leukemogenic, milligram for milligram, than others (Table 39-1). Thus, mutagenic chemicals such as methotrexate and hydroxyurea rarely, if ever, cause AML syndromes as monotherapy, but exposures to alkylating agents such as melphalan and nitrogen mustard may cause AML in as many as 10% or more of all recipients, depending on the cumulative dose of drug received. Environmental or occupational potential leukemogens, such as benzene,

1. De novo MDS (primary): Estimates are 85% of all MDS. About 45% to 50% manifest cytogenetic abnormalities evident by standard analysis with recurring examples being del (5q), del (7q), del (20q), and trisomy 8.
2. Secondary MDS: Estimates are 7% to 10% of all MDS, with greater than 80% relating to prior therapy with mutagenic chemicals or radiation (therapy-related, t-MDS). Chromosome aberrations are present in greater than 90%, particularly involving chromosomes 5 and 7, and are often associated with complex cytogenetics and a poor prognosis.
3. Cigarette smoking is strongly associated with MDS/AML and directly relates to the total amount smoked and current smoking at diagnosis.
4. Subsets of MDS characterized by ringed sideroblasts may have different causation from other MDS syndromes, as virtually all are associated with the driver mutation SF3B1.
5. Perhaps 5% of individuals with MDS, as defined only by morphologic aberrations and cytopenias and with associated clinical features suggesting autoimmune disease, may respond favorably to immunosuppressive therapy.
6. Occupational or environmental chemical exposures are thought to cause less than 1% of all MDS with benzene-related disease some fraction of this amount.

Figure 39-7 Age-related incidence of myelodysplastic syndrome (MDS) and frequency estimates of MDS subsets. *AML*, Acute myeloid leukemia.

1. De novo (primary, endogenous): Estimate are in the 80% to 85% range, particularly associated with normal cytogenetics or balanced translocations with absence of a prodrome of myelodysplasia (MDS).
2. Smoking-induced: Estimates are in the 9% to 16% range. Aberrations of chromosome 8 are specifically cited but almost half normal cytogenetics. Risk is directly related to amount smoked and with current smoking.
3. Therapy-induced AML/MDS: Estimates are 10%. Frequent cytogenetic aberrations involve chromosomes 5 and 7. Normal routine cytogenetics in greater than 10%. Two thirds with a history of MDS.
4. Evolution from de novo MDS: Perhaps 4%. Cytogenetics are normal in greater than 50%, and balanced translocations are uncommon.
5. Evolution from MPN: With effective therapy of CML, perhaps 1%.
6. Association with underlying genetic aberrations such as familial AML, Li Fromeni syndrome, Lynch syndrome, Down syndrome, Bloom syndrome, and so on: Frequency is less than 1%.
7. Environmental or occupational exposure: Rare, with estimates from benzene exposures only 0.14%

Figure 39-8 Frequency of etiology and risk factors for acute myeloid leukemia (AML). *CML*, Chronic myeloid leukemia; *MDS*, myelodysplastic syndrome; *MGUS*, monoclonal gammopathy of unknown causation; *MPH*, maternal past history.

Table 39-1 Estimated Cumulative Threshold Dose for Several Potentially Leukemogenic Agents

Compound	Activity	CTD (mg/m ²)	Latency to MDS/AML (yr)
Temozolomide	Alkylating agent	18,000-20,000	0.75-3
Cyclophosphamide	Alkylating agent	8000-10,000	2-10
Alkeran	Alkylating agent	80	2-10
Mechlorethamine	Alkylating agent	60	2-10
Etoposide	Topoisomerase II inhibitor	2000	1-4
Mitoxantrone	Topoisomerase II inhibitor	60	0.5-5
Fludarabine	Nucleoside analog	750	0.75-7
Benzene	Unknown	46,000	2-10

AML, acute myeloid leukemia; CTD, cumulative threshold dose; MDS, myelodysplastic syndromes.

require a very large CTD to predispose to AML, and even then do so rarely. Aside from exposure to cigarette smoke, AML and MDS from potential environmental chemical exposures are thought to make up only a tiny fraction of all secondary MDS/AML syndromes (Natelson et al., 2013). There is also a latency window to MDS/AML after the CTD has been reached. Generally, most secondary forms of AML/MDS appear within 10 to 12 years of the last exposure (Natelson, 2007). Remote occurrence of AML/MDS in such exposed populations may simply reflect the greatly increasing risk of MDS/AML in the general population with advancing age.

What constitutes appropriate criteria to warrant a diagnosis of AML has undergone modifications over the years, and the initial requirement of 30% blasts in a cellular bone marrow was reduced to 20% blasts. Currently, the diagnosis of AML may be established simply by the presence of certain specific chromosome aberrations such as the t(15;17) translocation in APL and inversion 16 AML, which is often associated with an atypical eosinophilic population in the peripheral blood (Pulsoni et al., 2008). Simply the presence of the chromosome aberration without any particular increase in blast forms satisfies a diagnosis of AML in these circumstances. A full discussion of AML syndromes and their therapy is beyond the scope of this chapter but is covered in the referenced major texts.

The most important recent therapeutic breakthrough in the treatment of AML has occurred in the treatment of the t(15;17) APL variant with long-term survival rates of greater than 90% (Lo-Coco et al., 2013). Unfortunately, survival in other forms of AML, particularly cases that are secondary to chemotherapy, remains dismal. APL has a strong ethnic predisposition and is particularly common among Hispanic and Chinese populations, where it is the most common form of de novo AML. Therapy initially improved for this particular form of AML when it was demonstrated that all-trans retinoic acid (ATRA) served as a maturation agent, allowing the aberrant promyelocytes of APL to mature normally without first obliterating the bone marrow with intensive chemotherapy, as is the usual practice in AML, and that predictably caused acute disseminated intravascular coagulation (DIC) in APL. However, the major increase in survival resulted from the work with arsenic trioxide, which can be given either orally or by intravenous infusion in concert with or in sequence with ATRA and other drugs and produces sustained remissions and probable cures. The doses of arsenic trioxide given in the

modern era are not those used decades ago as an early chemotherapeutic agent and that caused major neurologic and hematologic toxicity. In fact, arsenic is not measurable in the blood a few weeks after administration of the current doses of arsenic trioxide in the treatment of APL.

CYTOPENIAS VERSUS CYTOPATHIES

Certain compounds may directly impair the function of each of the three circulating cellular elements without necessarily directly interfering with bone marrow function or through reductions in the numbers of circulating cellular elements. For example, a primary benefit of the circulating erythrocyte mass involves oxygen transport to the tissues and return of carbon dioxide to the lung. In carbon monoxide, cyanide, and hydrogen sulfide poisoning, the toxic compounds can bind with the hemoglobin molecule and prevent its normal function with gas exchange, causing an acute illness associated with severe tissue hypoxia. Similarly, platelet function may be adversely affected by commonly used medications such as aspirin and NSAIDs as well as in disease states, leading to abnormal renal function in which the accumulation of nitrogenous waste products adversely affect platelet adhesion to bleeding sites and the ability of the platelets to aggregate to each other at the site of bleeding, forming a platelet plug. In terms of the leukocytes, corticosteroids may impair granulocyte phagocytosis, prevent egress of granulocytes into the tissues, and promote infection. Such impairments in phagocytosis and destruction of bacterial pathogens are also present in granulocytes from patients with MDS, which often lack normal amounts of cytoplasmic enzyme-containing granules.

Anticoagulant Therapy

Key Points

- Although warfarin may be antagonized by vitamin K in circumstances of excessive anticoagulation and bleeding, specific antagonists for the newer direct oral anticoagulants are not yet available.
- The lupus anticoagulant is not associated with excessive bleeding but may be associated with both venous and arterial thrombosis.

Table 39-2 Oral Anticoagulants

Feature	Warfarin	Dabigatran	Rivaroxaban	Apixaban
Target	Vitamin K	Factor IIa	Factor Xa	Factor Xa
Plasma half-life (h4)	40-60	12-16	7-13	8-15
Elimination	92% renal	80% renal 20% fecal	66% renal 33% fecal	27% renal 63% fecal
Monitoring	PT/INR	Not required	Not required	Not required
Antidote	Vitamin K	None	None	None
Hemodialysis reversal	No	Yes	No	No
Typical daily dose	7.5 mg in men 5 mg in women	150 mg twice daily	20 mg daily	5 mg twice daily
Use of PT/aPTT in therapy	Yes	Yes, not linear	Yes, not linear	Weakly affected

aPTT, Activated partial thromboplastin time; INR, international normalized ratio; PT, prothrombin time.

The application and monitoring of anticoagulant therapy in clinical medicine has undergone a major change in recent years with the introduction of newer drugs that are beginning to slowly replace the vitamin K antagonist warfarin, the standard for more than 50 years (Tripodi et al., 2013). Even certain indications for low-molecular-weight heparin (LMWH) and the necessity for hospital admission in cases of thrombophlebitis and pulmonary emboli have been affected by these newer agents, which are direct anticoagulants rather than a prodrug such as warfarin (Coumadin).

The primary need for oral anticoagulant therapy is in the prophylaxis against thrombosis in high-risk circumstances such as chronic atrial fibrillation, mechanical heart valve replacement, and the continuing treatment of thrombophlebitis and pulmonary thromboembolism. Postoperative use of anticoagulant therapy has become a common event after orthopedic surgery to lessen the risk of venous thrombosis. Warfarin is a cost-effective medication, but it is a prodrug and takes several days of administration to achieve an effective steady state of full anticoagulation. Moreover, there are many drug interactions with warfarin that can modify its metabolism and activity, either lessening or potentiating its anticoagulant effect. It has a prolonged half-life in the blood, but its effects on blood coagulation can be antagonized by administration of vitamin K, although this reversal will take several hours for full effect. Thus, in circumstances of major bleeding, plasma may need to be administered to replace reduced levels of clotting factors. Warfarin administration also must be monitored with the use of the prothrombin time (PT) test to ensure an effective degree of anticoagulation as reflected in the standardized INR measurement, or a calculation that accounts for laboratory variation based on types of equipment and reagents used in performing the study. A comparison of warfarin with the properties of several now-approved oral anticoagulant drugs is shown in Table 39-2.

Dabigatran (Pradaxa), rivaroxaban (Xarelto), and apixaban (Eliquis) are all approved for use in patients with atrial fibrillation and could replace warfarin in some instances because the bleeding risk and need for follow-up laboratory monitoring are reduced (Gonzalves et al., 2013). The significant renal excretion of dabigatran and rivaroxaban would make apixaban a safer option in patients with renal insufficiency. Rivaroxaban is the only one of the three newer anticoagulants yet approved for pulmonary embolism

treatment and prevention and may be the initial therapy in uncomplicated patients presenting to the emergency department with acute-onset thrombophlebitis. This is because of its favorable pharmacodynamics and the rapid development of full therapeutic anticoagulation a few hours after an oral dose. This would eliminate the necessity of LMWH as a bridge and eliminate the necessity for inpatient admission to begin warfarin along with LMWH. Here, the dose of rivaroxaban is 15 mg twice daily for 3 weeks, which is then modified to 20 mg once daily for long-term use. If one feels the necessity to monitor or prove the anticoagulant effect of rivaroxaban or apixaban is in effect, the activated factor X assay used to monitor heparin therapy can be modified to quantify their activity as well. The thrombin time may be used to document the anticoagulant effect of dabigatran, but because the thrombin time may be prolonged for many reasons, including a low serum albumin level, such assays would not be linear or useful for anticoagulant control.

Although the effects of most anticoagulants seen in clinical practice are consequent to their therapeutic use, spontaneously occurring circulating anticoagulants may occur in certain circumstances and may or may not cause excess bleeding and may or may not require specific therapy for their control. The two most common are the lupus anticoagulant and the circulating inhibitor of factor VIII. The lupus anticoagulant is often brought to light by performance of a routine screening test such as PT, activated partial thromboplastin time, or both, which are found to be prolonged. Well less than half of the patients seen with the lupus anticoagulant actually have lupus, and the anticoagulant may have no apparent underlying causation and disappear spontaneously. There is no bleeding diathesis associated with their presence, but in some instances, there is an increased risk of thrombosis, primarily venous but occasionally arterial. The inhibitor action is caused by antibodies to the complex of phospholipid and activated factors V and X, which convert factor II to thrombin. These are immediate-acting anticoagulants and are easily identified in the laboratory by mixing studies of patient plasma with normal plasma. Their return to normal values suggests a deficiency state, and a continued prolonged result indicates the presence of an anticoagulant. Certain other tests may be done to confirm this type of anticoagulant.

The spontaneous factor VIII anticoagulant is more of a delayed action anticoagulant in the test tube, and

an incubation phase with normal plasma is necessary to document its presence and full activity. This circumstance may appear in patients with classical hemophilia consequent to antibodies generated to factor VIII after transfusions of plasma products. Rarely, such antibodies may also occur spontaneously in pregnancy and, after remission, recur again with a subsequent pregnancy. They also may appear in elderly individuals with no apparent underlying illness but occasionally are consequent to NHL or other malignancy or appear as a drug reaction. The use of combinations of corticosteroids, cyclophosphamide, and Rituxan is very effective in eliminating the circulating anticoagulant in elderly persons but is less effective if the problem is pregnancy related.

Hematologic Malignancies

The wide application of flow cytometry in the clinical laboratory has made the classification of disorders such as CLL and other B-cell and T-cell neoplasms more specific than by the simple morphologic examination of peripheral blood and bone marrow by providing a precise fingerprint of each individual disease. Lymphoid and myeloid cells bear a variety of specific antigenic surface proteins given the designation of CD markers. The application of several of these numbered markers to a peripheral blood or tissue biopsy sample identifies a typical pattern of both positive and negative reactions for each illness. As new markers are identified, the process becomes more specific. Flow cytometry is also useful in the diagnosis and treatment of myeloid malignancies along with major improvements in cytogenetic analysis, which now allow a more precise diagnosis of various forms of AML as well as among the lymphoproliferative disorders.

As the use of diagnostic cellular markers becomes more precise, the classification of hematologic malignancies will undergo constant change, seeking to identify the origin of disease and precise treatments most likely to be successful. For example, in the most recent (2008) edition of the *World Health Organization Classification of Tumours of Haematopoietic and Lymphoid Tissues*, more than 80 distinct types of neoplastic lymphoproliferative disorders are discussed making up the spectrum of HL and NHL (Swerdlow et al., 2008). Only a few of the more frequently encountered illnesses in this class are commented on here. Although we recognize general commonalities among the B-cell neoplasms, the clinical features of each specific illness may differ widely, and thus, most hematologists continue to think of each of these diseases as unique entities, particularly CLL, hairy cell leukemia, MM, WM, and so on, in the approach to diagnosis and therapy. The name may change with time, but the illness and its natural history remain constant.

In many examples of B-cell neoplasms, causation is unknown, although in certain categories, such as HL and CLL, there is a strong familial influence that is not modified by occupation (Altieri et al., 2005). This finding is much less evident among those with MM and hairy cell leukemia, for example. In selected B-cell neoplasms, infectious agents such as hepatitis C, Epstein-Barr virus, various bacteria, autoimmune illness, immunosuppression associated with posttransplantation disease, and the use of biologic disease

modifiers are strong associations. In some types of NHL, specific causation is identified in the disease designation, such as EBV-positive diffuse large B-cell lymphoma of elderly adults.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia is an easily recognized hematologic disorder characterized by the accumulation, over time, of mature-appearing B lymphocytes in various body tissues, including the circulating blood, bone marrow, spleen, and multiple lymph nodes. It is the most common form of leukemia seen in the United States, with perhaps as many as 18,000 to 19,000 new cases identified per year. The finding of a persistent lymphocytosis without a known underlying causation immediately suggests the diagnosis, but before the routine application of flow cytometry, inspection of the peripheral blood counts and blood film was accurate in confirming CLL perhaps only about 80% of the time. This is because other lymphoproliferative disorders such as mantle cell and marginal cell lymphoma and even WM and hairy cell leukemia could manifest a similar peripheral blood appearance and clinical presentation. Currently, the technique of rapidly quantifying various CD and other markers on millions of cells allows the diagnosis of CLL to be confirmed accurately and reproducibly even with only moderate elevations of the total lymphocyte count in the circulating blood. The pattern or signature of these immunohistochemically measured CD and other cell markers on lymphocyte clones in the circulating blood or solid tissues not only easily separates CLL from other B-cell neoplasms but also provides information pertinent to the probable course of the illness and may guide therapy.

About 10% of individuals with the typical CLL flow cytometry pattern only have this finding in lymphoid cells infiltrating lymph nodes or other tissues and do not manifest a leukemic picture in the peripheral blood. These individuals are considered to have small cell lymphocytic lymphoma rather than CLL. The prognosis and treatment of the two conditions are similar.

Chronic lymphocytic leukemia is often a very indolent illness, and as many as one third of affected individuals may never require specific therapy for the disorder during their lifetimes, and it is not a cause of their deaths. An example of this course in terms of the total leukocyte count is shown in one of the senior authors' patients in Figure 39-9. Indeed, for about half of patients, the diagnosis of CLL will not affect morbidity or mortality. However, depending on certain factors, including the cytogenetic pattern of the neoplastic cells and the uncommon transformation to a more aggressive cell type that occasionally is therapy related, the illness may progress rapidly in some individuals. CLL is often associated with immune-related clinically important manifestations, including thrombocytopenia and autoimmune hemolytic anemia. Herpes zoster is also common during the course of the illness. Hypogammaglobulinemia is typical among individuals with longstanding CLL. Because of the immune defects in CLL, it is inadvisable to administer live vaccines to such individuals because severe local reactions may occur, and there is the potential for complications of viremia.

The cause of CLL is entirely unknown, aside from a strong genetic familial risk. In some families, there are multiple

Figure 39-9 Peripheral blood total leukocyte count in untreated chronic lymphocytic leukemia. WBC, White blood cell.

types of B-cell neoplasms in different individuals. There is no evidence that radiation or chemotherapy or occupational or environmental toxins may cause CLL, and it is not related to smoking. In recent years, it has been well documented that a surprising number of individuals in the general population, particularly individuals who are first-degree relatives of patients with CLL, may have a clone of circulating lymphocytes that type with flow cytometry analysis such as CLL. However, the very small clone may be stable and not necessarily proliferate during life or cause the total leukocyte count to increase to clinically evident levels. This state is referred to as monoclonal B-cell lymphocytosis (MBL) and requires no therapy, only observation (Te Raa et al., 2012). For this reason, currently, CLL is defined by the presence of 5000/mm³ or greater B lymphocytes with a characteristic CLL flow cytometry phenotype in the peripheral blood.

In patients with CLL who do require therapy, there are a wide variety of active drugs of different classes, including monoclonal antibodies, corticosteroids, alkylating agents, antimetabolites, and newer medications that interfere with particular molecular pathways controlling cell growth. In selected younger patients with high-risk chromosome aberrations, allogeneic bone marrow transplantation has been used.

WALDENSTRÖM MACROGLOBULINEMIA

Similar to CLL, about 20% of individuals with WM have a family history of the illness. The WHO has established a new NHL category of lymphoplasmacytic lymphoma, in which WM is the major tenant. The presentation is variable with predominant associated features, including weakness, fatigue, and unexplained anemia or lymphadenopathy. Some patients have unusual complications relating to the very high concentrations of the characteristic IgM paraprotein, such as venous retinal thrombosis or progressive deafness. The laboratory may first call attention to the marked rouleaux on the peripheral blood film and notify the

Figure 39-10 Peripheral blood in Waldenström macroglobulinemia demonstrating erythrocyte rouleaux formation and mature-appearing lymphoid cells.

ordering physician (Figure 39-10). As with CLL, the course is often indolent, and a decision to treat may be somewhat subjective and not based on a single factor. The neoplastic lymphoid cells are variable in appearance, ranging from a near normal morphology to plasmacytoid cells or even larger cells with cytoplasmic features very close to those found in hairy cell leukemia (Figure 39-11). Aside from causing an increasing viscosity and plasma volume, the IgM paraprotein may complex with plasma clotting factors, creating a bleeding diathesis. In contrast to CLL, the flow cytometry fingerprint of this illness is not uniform; however, the involved lymphoid cells are usually CD-5 and CD-10 negative. A low serum ferritin level and reduced iron stores are common findings but do not appear to represent chronic blood loss as causative, and the mechanism of iron deficiency is uncertain.

Figure 39-11 Bone marrow aspirate in Waldenström macroglobulinemia demonstrating two atypical plasmacytoid lymphocytes with irregular cytoplasmic borders and a plasma cell (arrow).

Many drugs are active in the treatment of WM, including corticosteroids, Leustatin, pentostatin, cyclophosphamide, chlorambucil, Velcade, and Rituxan. Unlike IgG paraproteins, IgM paraproteins are confined in the circulating plasma volume and can be reduced dramatically by plasma exchange (apheresis, plasmapheresis) as dictated by the clinical circumstances. If the patient is not highly symptomatic, observation is not unreasonable to assess the pace of progression. On occasion, the neoplastic lymphocytes may transform, and the illness will then resemble a diffuse large cell form of NHL and require aggressive treatment.

HAIRY CELL LEUKEMIA

This is a usually indolent B-cell neoplasm with a striking male over female predominance, at least five to one, and classically presenting as a pancytopenia associated with unexplained splenomegaly and the absence of lymphadenopathy. To an experienced observer, the diagnosis may often be made immediately by careful examination of the peripheral blood, although it is unusual for large numbers of hairy cells to circulate (Figure 39-12). By flow cytometry, the diagnosis can be confirmed by the typical pattern of positive markers, including CD-20, -22, -25, -103 and -123. Formerly, the tartrate resistant acid phosphatase stain, positive in virtually all cases, was used as a diagnostic aid, but the slides must be freshly prepared for best results, and there must be some dedication by the laboratory to carry this study out properly. It has largely been replaced by flow cytometry fingerprints to more conveniently validate the diagnosis. Reticulin fibrosis is often present in the bone marrow.

A family history of the illness has been rarely reported, but most cases are sporadic and diagnosed among individuals older than 50 years. Splenectomy formerly was the treatment of choice but has largely been replaced by the use of drug combinations such as Leustatin or pentostatin and Rituxan, which will rapidly reduce the size of an enlarged spleen and typically produce a remission in the range of 10 years, at which time a second course of treatment may

Figure 39-12 Peripheral blood film in hairy cell leukemia demonstrating the characteristic atypical B lymphocytes.

become necessary. Patients with this illness are susceptible to granulomatous diseases, both fungal and tubercular, but are unable to form tissue granulomas, and the organisms must be identified by culture, special stains, and molecular studies. Secondary malignancies appear to be increased among patients with hairy cell leukemia.

MULTIPLE MYELOMA

Multiple myeloma is a specific B-cell neoplasm affecting about 20,000 new patients per year in the United States. Typical incidence figures reported are about 4.3 cases per 100,000 individuals. The median survival period after diagnosis remains about 4 to 7 years, although some patients may follow an indolent course and survive longer than 10 years (Alexander et al., 2007; Kyle et al., 2007; Rajkumar, 2011). It is generally considered to be an incurable illness despite recent advances in chemotherapy and bone marrow transplantation techniques. MM has its peak incidence around age 66 to 70 years and is typically sporadic in appearance. It is very unusual in individuals younger than age 40 years. The incidence of MM is higher among black individuals, and the age of onset is slightly lower than in white populations; the frequency is still lower among Chinese individuals. A known familial incidence of MM is well described but quite uncommon. There is a strong association of MM with Gaucher disease, but the mechanism is uncertain. In the case of MM, a B-lymphocyte neoplasm, the illness may be preceded by the presence of a small clone of monoclonal immunoglobulin (*monoclonal gammopathy of unknown causation* [MGUS]), which may suddenly proliferate after many years of stability, causing a major plasmacytosis in the bone marrow, replacing normal hematopoiesis and creating bone destruction. It is now well accepted that a preceding period of MGUS has been in place in virtually all newly diagnosed patients with MM (Zingone et al., 2011). Moreover, as long as 16 years may elapse before MGUS progresses into an MM phase. MGUS may occur after hepatitis B and C and be sustained or disappear. It also is seen with some frequency in liver transplantation and does not appear to predispose to MM in this setting (Naina et al., 2012). The peer-reviewed scientific medical literature has

consistently indicated that the etiology of MM remains unknown, or as stated in typical review articles from prominent medical journals, its epidemiologic pattern remains obscure (Alexander et al., 2007). No chemical exposures are known to predispose to MM, and its incidence is not increased among smokers.

Many organ systems may be affected by myeloma with anemia caused by infiltration of the bone marrow and reduced erythropoietin output by renal damage. Multiple bone fractures are frequently caused by loss of calcium from the bone matrix and isolated plasmacytomas. Renal failure may be multifactorial in causation in patients with MM but can relate to continuous excretion of free light chains and intact monoclonal proteins causing tubular damage.

In recent years, some stratification of risk is evident by cytogenetic analysis of the myeloma cells. Moreover, the availability of a number of new agents clearly has improved long-term survival. Active drugs include corticosteroids, protease inhibitors such as Velcade, alkylating agents including Alkeran, and cyclophosphamide and compounds such as lenalidomide and thalidomide. Bisphosphonates offer some bone protection and lessen the risk of hypercalcemia. The use of autologous bone marrow transplantation after high doses of intravenous chemotherapy with Alkeran may also offer a prolonged remission. Cure of the illness is rare.

CHRONIC MYELOID LEUKEMIA

The modern treatment of CML is a remarkable success story in an illness that formerly carried a uniformly fatal diagnosis. CML affects about 5000 individuals each year in the United States and is an acquired illness, present in only one of identical twin, not both. The etiology is unknown, but exposure to excess radiation is thought causative in rare circumstances. The characteristic t(9:22) chromosome aberration typically is evident in the laboratory analysis about 1 to 2 years before the disease becomes clinically evident as a rising total granulocyte count and often a rising platelet count. The illness is not familial and is not caused by chemotherapy, smoking, or any known potential environmental or occupational chemicals. CML and CLL were not increased in frequency among Aksoy's cohort of 29,000 shoe workers in Turkey who were chronically exposed to massive levels of pure benzene in the preparation of glues used in the shoe industry.

For many years, CML was placed in the category of classical MPNs because it is often associated with both marked thrombocytosis and bone marrow fibrosis, the latter two findings present in all types of MPN. The natural history of the illness is for the elevation of the total leukocyte count to plateau at around 300,000 to 350,000/mm³ associated with progressive splenomegaly and anemia. The initial therapy to reduce the total leukocyte count was with benzene, taken orally with the liquid placed in capsules. Later, drugs such as hydroxyurea and Myleran were used to control the myeloproliferation and progressive splenomegaly, but conversion to an acute leukemic state, known as blast crisis, generally occurred within a 4-year period. Cures of CML were first obtained after allogeneic bone marrow transplantation, but the long-term survival rate was only in the 65% range. With the introduction of oral tyrosine

kinase inhibitors, which antagonize the products of the BCR/ABL fusion gene produced by the translocation, long-term survival is now greater than 85%, with minimal drug-related side effects. Some patients may be cured after several years with such therapy and ultimately be able to stop all treatment. Several tyrosine kinase inhibitors are available, and some cause fluid retention and pleural effusions, which may be temporary. Today, when encountering a patient with persistent elevation in granulocytes or platelets, the BCR/ABL study on peripheral blood will easily establish the diagnosis of CML. However, classical cytogenetics and fluorescent in situ hybridization (FISH) studies on bone marrow cells are often applied to confirm the specific chromosome aberration and to quantify the percentage of affected bone marrow cells to monitor the effect of specific therapy.

The Myeloproliferative Neoplasms

The original designation of the MPN proposed by Dr. William Dameshek specifically included polycythemia vera, primary myelofibrosis, essential thrombocytosis, and CML because these disorders shared a number of clinical and laboratory features. Other known hematologic diseases involved a myeloproliferative state, but their appropriate classification was debated. As commented upon, the classification system for the MPN has been extensively revised by the WHO, with the exclusion of CML as a distinct entity separate from the other classical forms of MPN. Still other MPNs have been grouped in a diverse category referred to as MDS/MPN to emphasize that some MPN exhibit morphologic myelodysplasia of the type seen in MDS syndromes (Anderson et al., 2012; Orazi et al., 2008; Natelson, 2012; Schmidt and Oh, 2012). Nevertheless, they are MPNs and not MDS (Orazi and Germing, 2008). The most common entity among this nonclassical group of MPNs is chronic myelomonocytic leukemia. The etiology of the MPN is unknown, but all may eventuate in an illness resembling AML, often referred to as blast crisis. Although all of these illnesses are considered neoplasms, the risk for conversion to AML is very low in essential thrombocytosis, but the marked elevation in platelet counts often requires specific therapy and can cause major disability, particularly with surgery (Natelson, 2012).

Clonal or Myeloproliferative Eosinophilic Neoplasms

Key Points

- All patients with myelodysplasia do not necessarily have the MDS.
- All individuals with MPNs have an increased risk of an acute leukemia referred to as blast crisis.
- In patients with MPN, the most effective drugs for continuous use to suppress a massively elevated platelet count are anagrelide and hydroxyurea.
- Several oral tyrosine kinase inhibitor drugs are now approved for the treatment of CML.

Persistent eosinophilia of moderate degree is not an unusual finding among a general clinic population undergoing routine blood counts and only occasionally, when striking, should prompt a referral for hematologic consultation. The vast majority of such cases are reactive or polyclonal processes and generally driven by interleukin-5 (IL-5), a cytokine that promotes proliferation of eosinophilic precursor cells. Causative associations include drug reactions, asthma, a variety of dermatologic conditions (e.g., bullous pemphigoid), and allergic pulmonary conditions. Parasitic infections such as strongyloidiasis should always be considered as potential causes of eosinophilia because therapy with corticosteroids may worsen this condition. Eosinophilia is occasionally present in patients with advanced HL and solid tumors. It is also occasionally a predictable finding in certain types of AML in which it is considered a clonal event caused by specific genetic aberrations associated with the AML (Montgomery et al., 2013; Natelson et al., 2013; Pulsoni et al., 2008). Here the eosinophils are both increased in numbers and abnormal in morphology with large granules.

Some reactive hypereosinophilic syndromes are not neoplasms but may produce pulmonary, cutaneous, and other systemic symptoms that require intermittent therapy with corticosteroids or with currently available steroid-sparing molecularly targeted agents. For example, the monoclonal antibody mepolizumab is directed against IL-5 and has been effective in reducing the eosinophil count and lessening symptoms in such circumstances.

Reactive and idiopathic eosinophilia must be differentiated from the far less common myeloid neoplasms causing marked eosinophilia and sometimes referred to as myeloproliferative eosinophilia (Noel et al., 2013). Over time, these syndromes may cause irreversible tissue damage with infiltration by eosinophils and, if a consideration, require complex cytogenetic diagnostic studies, which may point the way to useful therapeutic interventions. In some affected individuals, a 4q12 chromosome deletion occurs and is involved by translocation and the creation of a fusion gene, *FIP1L1-PDGFR*, generating a product driving the eosinophilic proliferation. In this instance, treatment with low doses of the tyrosine kinase inhibitor Gleevec may result in a complete remission of the hypereosinophilic state, as it does in CML by blocking of the fusion gene product. Not all of the currently approved tyrosine kinase inhibitor drugs are as effective as Gleevec in this particular circumstance.

Hematology and Pregnancy

Certain features of pregnancy affect the hematologic system on a physiological basis, but other hematologic circumstances, more specific to pregnancy, are important to recognize and require comment. Plasma volume greatly increases during pregnancy, causing a reduction in the hematocrit value and creating an apparent anemia or magnifying an existing anemia on the basis of dilution. The latter circumstance is frequently noticed in women with thalassemia minor who begin pregnancy with a lower hemoglobin concentration than normal. In addition, many women of child-bearing age have borderline iron stores, and a pregnancy may transfer as much as 500 mg of iron, or an equivalent

iron mass of 2 units of blood, to the fetus. Thus, it is important to provide iron supplements during pregnancy and well into the postpartum period. Various forms of thrombocytopenia are seen with some frequency in pregnancy and are dealt with as a separate entity.

Thrombocytopenia in Pregnancy

Key Points

- Bleeding from thrombocytopenia during pregnancy is unusual with platelet counts above 50,000/mm³.
- In preeclampsia and the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, the most effective therapy is to facilitate delivery when safely allowed by fetal maturity.
- A bone marrow examination would be necessary to accurately separate pancytopenia of pregnancy from aplastic anemia or bone marrow infiltrative disorders.
- Gestational thrombocytopenia is the most common cause of reduced platelets during pregnancy.
- Vaginal delivery is preferred over cesarean section in acute fatty liver of pregnancy (AFLP) to reduce the risk of intraabdominal bleeding.
- A diagnosis of ITP is not a reason for cesarean section.

In addition to a marked increase in plasma volume, a modest reduction in the platelet count is a normal physiologic event during pregnancy (Gauer and Braun, 2010; Gernsheimer, 2012). Thrombocytopenia, as defined as a platelet count below 150,000/mm³, occurs in almost 10% of all pregnant patients (Gernsheimer, 2012). In a study of 6670 pregnant patients, a platelet count greater than 115,000/mm³, late in pregnancy, did not appear to cause adverse events and appeared to not require further evaluation (Boehlen et al., 2000). This should not be a surprising conclusion because a platelet count in the 75,000 to 100,000/mm³ range is not considered a significant surgical risk in a normal individual unless the platelets are dysfunctional.

The most common form of thrombocytopenia specific to pregnancy is gestational thrombocytopenia. Other well-known pregnancy-induced thrombocytopenic disorders are preeclampsia and a subset, referred to as the HELLP syndrome. Because ITP frequently affects young women, it also is not unusual for this illness to complicate pregnancy (Gauer and Braun, 2010; Gernsheimer, 2012; Webert et al., 2003). Information on previous platelet counts, particularly those before the onset of pregnancy, and a detailed medical history and examination may provide useful diagnostic information in forming a clinical differential diagnosis. Examination of the peripheral blood film is essential and may immediately suggest a specific category of disease. It will also exclude spurious thrombocytopenia, a benign phenomenon often due to transient platelet cold agglutinins causing platelets to clump with each other or to granulocytes and causing an apparent reduction in the platelet count measured in automated equipment.

Depending on its degree and causation, specific therapy for thrombocytopenia may or may not be necessary during the course of the pregnancy, but the provider must be

Table 39-3 Considerations in the Differential Diagnosis of Thrombocytopenia in Pregnancy

Gestational thrombocytopenia	DIC
ITP	Nutritional deficiency
Preeclampsia	Alcohol abuse
AFLP	Drug-induced thrombocytopenia
HELLP syndrome	Certain viral infections
TTP	Pseudothrombocytopenia
HUS	Pancytopenia of pregnancy
SLE	Antiphospholipid antibody syndrome
A primary bone marrow disorder including AML and aplastic anemia	Lupus anticoagulant

AFLP, Acute fatty liver of pregnancy; AML, acute myeloid leukemia; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low platelets; HUS, hemolytic uremic syndrome; ITP, idiopathic thrombocytopenic purpura; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

familiar with the differential diagnosis of thrombocytopenia in order to make appropriate recommendations to optimize the health of both the mother and fetus (Table 39-3).

Gestational thrombocytopenia accounts for 75% of all pregnancy-related thrombocytopenia. There is no specific diagnostic test to establish this diagnosis, which is possibly related to some combination of increased platelet turnover, dilution, or decreased production. Immune-based platelet destruction that may be difficult to differentiate from that seen in ITP may also be present in gestational thrombocytopenia, and platelet-associated antibodies are found at similar levels in both circumstances (Bockenstedt, 2011). Gestational thrombocytopenia usually presents in the second or third trimester and is typically mild and not typically associated with any adverse fetal or maternal outcome. It usually resolves spontaneously within days to weeks after delivery (Gernsheimer, 2012). Because of the benign nature of the disorder, routine obstetric management is appropriate with the caveat that a neonatologist should evaluate the newborn. There is not an absolute platelet count that defines gestational thrombocytopenia, but according to the American Society of Hematology's guidelines, if the platelet count is below the 70,000 to 80,000/mm³ range, gestational thrombocytopenia is less likely.

Severe ITP is unusual in pregnancy-associated thrombocytopenia occurring in one to two per 1000 live births (Gill and Kelton, 2000). Neither the incidence nor the severity of ITP increases in pregnancy, but it is a common condition in women of childbearing age (Sukenik-Halevy et al., 2008). Thus, it accounts for about 5% of cases of pregnancy-associated thrombocytopenia and usually presents early in pregnancy with a platelet count below 70,000/mm³. Although rare in frequency compared with gestational thrombocytopenia, it is the most common pregnancy-associated thrombocytopenia occurring in the first trimester and can be typical ITP or secondary to medications, viral illness, and neoplastic and other immune-related processes (Stavrou and McCrae, 2009).

The pathophysiology and clinical presentation of ITP in pregnancy is similar to ITP in nonpregnant patients. It is a

disorder of increased platelet destruction with an inadequate compensatory response by the bone marrow caused by the formation of IgG antiplatelet antibodies leading to the accelerated clearance of platelets by macrophages, typically most prominent in the spleen. Thrombocytopenia may be found incidentally by routine blood count or can present clinically as bruising, bleeding, or petechial lesions. The peripheral blood film will show increased numbers of enlarged platelets and typically an increased mean platelet volume. ITP remains a clinical diagnosis and, hence, it is a diagnosis of exclusion. Pregnant women with ITP may have a history of thrombocytopenia, menorrhagia, or epistaxis. Additionally, a history of excessive bleeding in the mother or fetus in previous pregnancies or a falling platelet count with onset in the first trimester makes ITP more likely.

Treatment of ITP is indicated for pregnant women with thrombocytopenia and bleeding, a platelet count less than 10,000/mm³, and for platelet counts less than 30,000/mm³ in the second and third trimesters. Generally, platelet counts above 50,000/mm³ are thought safe. Corticosteroids are the first line of treatment and, although commonly used, may be associated with pregnancy-specific side effects that include hypertension, premature labor, placental abruption, and gestational diabetes (Gernsheimer, 2012; Gill and Kelton, 2000). IVIG is also a first-line agent. The benefits and risks of each agent should be considered before initiating treatment. A combination of corticosteroids and IVIG may be used if the patient is not responding to either agent alone (McCrae, 2010). In the setting of treatment failure and severe thrombocytopenia, laparoscopic splenectomy can be performed in the second trimester.

Idiopathic thrombocytopenic purpura, per se, is not an indication for cesarean section, and fetal outcome is not determined by maternal severity of disease (Gernsheimer 2012). Rather, the best predictor of neonatal thrombocytopenia is a history of thrombocytopenia in a previous infant sibling. Neonatal thrombocytopenia with a platelet count less than 100,000/mm³ occurs in only 15% pregnancies with ITP, and the risk of neonatal intracranial hemorrhage is 1% to 2% (Bockenstedt, 2011; McCrae, 2010). The platelet count should be monitored in the neonate for about 1 week after delivery of mothers with ITP (Sukenik-Halevy et al., 2008).

As previously discussed, TTP and HUS are not unique to pregnancy, but the incidence of both increases during pregnancy. Microangiopathic hemolytic anemia (MAHA) and thrombocytopenia are seen in both disorders, as well as in preeclampsia, HELLP syndrome, and acute fatty liver, which can make distinguishing among these disorders difficult (Sibai, 2004). The pentad of MAHA, thrombocytopenia, neurologic abnormalities, fever, and renal dysfunction is classically seen in TTP, but renal dysfunction may be a later complication of the illness. HUS has a similar presentation except that renal dysfunction is more dominant and more commonly has its onset in the postpartum period (Stavrou and McCrae, 2009). The pathophysiology of TTP in nonpregnant patients has previously been discussed. HUS associated with pregnancy is generally not caused by *Shiga* toxins found in epidemic bacterial-related causes of HUS, and the etiology is unknown (McCrae, 2010).

If the diagnosis of TTP is strongly suspected, then plasma exchange should be initiated urgently. HUS, which often

results in chronic kidney disease, usually responds poorly to plasma exchange. Nevertheless a trial of plasma exchange is a reasonable approach given the overlapping features of TTP and HUS and the difficulty distinguishing between the two entities. If the diagnosis of TTP-HUS is uncertain, then efforts should also be made to distinguish these disorders from preeclampsia, eclampsia, and HELLP syndrome, and urgent delivery should be considered. Spontaneous resolution of symptoms after delivery generally excludes HUS as a diagnosis. If the MAHA and thrombocytopenia continue postpartum, infusions of the anti-CD 20 antibody Rituxan may be helpful in resolving the illness, particularly if the plasma level of the ADAMTS-13 enzyme is reduced in concentration and accompanied by antibodies to ADAMTS-13.

Preeclampsia is a syndrome that affects multiple organ systems and is the second most common cause of thrombocytopenia in pregnancy, affecting 3% to 14% of pregnancies (Bockenstedt, 2011). Thrombocytopenia, which correlates with the severity of the disorder, occurs in about half of the cases of preeclampsia and occasionally may precede the characteristic findings of proteinuria and hypertension. The onset of preeclampsia is usually in the third trimester.

The American College of Obstetricians and Gynecologists' criteria for the diagnosis of preeclampsia includes a persistent blood pressure elevation of 140 mm Hg systolic or 90 mm Hg diastolic or higher that occurs after 20 weeks of gestation in a woman with previously normal blood pressure and urinary protein excretion of 0.3 g or greater in a 24-hour collection. This latter finding usually correlates with a 1+ or greater reading on a urinary dipstick.

The pathogenesis of preeclampsia is not fully understood, but it is initiated by an abnormal placental implantation process early in pregnancy leading to fetoplacental ischemia that is responsible for the abnormal release and metabolism of prostaglandins. This in turn leads to hypertension, vascular damage, platelet activation, and placental hypoperfusion. Risk factors for preeclampsia are age younger than 20 or older than 30 years, a previous personal or family history of preeclampsia, presence of the antiphospholipid syndrome, a high body mass index, hypertension, and nongestational diabetes. The goal of management is to stabilize maternal blood pressure and proceed with immediate fetal delivery. Usually preeclampsia presents after 34 weeks when the fetal lungs are already mature, but if preeclampsia presents before 34 weeks, delivery may be undertaken after administration of betamethasone to enhance fetal lung maturity, provided maternal and fetal status is reassuring (McCrae, 2010).

HELLP syndrome is a serious obstetric complication that is characterized by a microangiopathic peripheral blood picture and emphasizing hemolysis, elevated liver enzymes, and low platelets. It shares clinical characteristics of severe preeclampsia, and the two are often placed in a spectrum of similar disorders. Interestingly, not all patients with HELLP have hypertension or proteinuria. HELLP syndrome occurs in 0.5% to 0.9% of all pregnancies and complicates 10% to 20% of cases of severe preeclampsia or eclampsia (Bockenstedt, 2011; Schmidt et al., 2012). It presents at an older maternal age compared with preeclampsia, and most affected white women are multiparous.

The pathophysiology of HELLP syndrome is not clearly understood, but it is a multisystem disease similar to preeclampsia and eclampsia. It occurs before delivery in about 70% of cases and usually occurs between the 27th to 37th weeks of gestation. It can also present in the immediate postpartum period, usually within the first 48 hours. Some women manifest incomplete criteria for a HELLP syndrome, and historically, varying diagnostic criteria have been used for HELLP syndrome, making comparison of different studies on the disorder challenging. Common associated signs and symptoms of HELLP syndrome include malaise, right upper quadrant pain, nausea, vomiting, edema, headache, and nonspecific symptoms suggestive of a viral syndrome. The symptom intensity may wax and wane.

The evaluation of a patient with suspected HELLP syndrome includes determining gestational age and fetal status with ultrasonography, cervical bishop score, and maternal status including blood pressure. Laboratory studies should include complete blood count, evaluation of a peripheral blood film, LDH, haptoglobin, transaminase values, coagulation parameters, and urinalysis. Patients should be stabilized with fluids, blood pressure management, and magnesium sulphate, with close monitoring of vital signs and volume status. The goal of treatment is to facilitate delivery, which needs to be done promptly if the gestational age is more than 34 weeks or if maternal or fetal distress is present. If the gestational age is less than 34 weeks and there is no maternal or fetal distress, then corticosteroids should be administered to promote fetal lung maturity followed by delivery within 48 hours (Katz et al., 2008). If the gestational age is less than 27 weeks, expectant management for longer than 48 hours may be considered. The routine use of corticosteroids in HELLP syndrome has not consistently been shown to improve maternal or fetal outcome, although studies have shown improvement in maternal platelet counts. In HELLP syndrome, the rapidity in the resolution of markedly elevated transaminase and LDH values after delivery is striking.

Maternal complications of HELLP syndrome include placental abruption, DIC and hemorrhage, rupture of a subcapsular liver hematoma, acute renal failure, pulmonary edema, life-threatening neurologic complications, and maternal death. As in preeclampsia, there is an increased maternal risk of recurrent disease with subsequent pregnancies. HELLP syndrome is also associated with increased perinatal morbidity and mortality, with a perinatal death rate of 7.4% to 34% and neonatal thrombocytopenia in 15% to 50% of cases. Because of the high rate of preterm deliveries, most fetal complications are related to prematurity.

Acute fatty liver of pregnancy is a rare disorder that usually presents in primiparas in the third trimester. It has an incidence of one in 10,000 to 15,000 pregnancies, and the maternal and fetal mortality rates are 18% and 23%, respectively (Bockenstedt, 2011). Patients present with nausea, vomiting, malaise, right upper quadrant pain, and signs and symptoms of cholestasis. Most patients with AFLP develop DIC. The management of AFLP is immediate resolution of pregnancy, and vaginal delivery is preferred to reduce the incidence of maternal intraabdominal hemorrhage (McCrae, 2010).

Antiphospholipid syndrome (APS) may present as a venous or, rarely, arterial thrombosis. The frequency of thrombocytopenia in APS is usually less than that seen in ITP and occurs in 30% to 46% of patients with primary APS. Treatment includes management of thrombocytopenia as well as thrombotic risk. In a woman with a history of thrombocytopenia and previous miscarriage(s), consideration should be given to underlying disorders such as APS or systemic lupus erythematosus. The frequency of miscarriage in the APS and with the lupus anticoagulant may have been overestimated (Clark et al., 2013).

A very unusual complication of pregnancy is a progressive pancytopenia with cellular bone marrow that is easily initially mistaken for either aplastic anemia or MDS and tends to recur and become more severe with successive pregnancies (Natelson, 2006; Natelson et al., 2013). The entirely different syndrome of aplastic anemia also may occur or worsen during pregnancy, but this illness is easily documented by the character of the bone marrow, which shows severe hypoplasia or aplasia. Its treatment is similar to that of idiopathic aplastic anemia and may respond favorably to immunosuppressive therapy or require allogeneic bone marrow transplantation after the pregnancy has been concluded.

In the less common instance of pancytopenia of pregnancy, there is a progressive macrocytic anemia with frequent teardrop RBCs and often profound thrombocytopenia and significant neutropenia. The bone marrow is normo- to hypercellular, with striking erythroid dyspoiesis

and ringed sideroblasts. Megakaryocytes are greatly reduced in numbers. Similar to idiopathic aplastic anemia, this illness also responds to immunosuppressive therapy, but only drugs such as prednisone and cyclosporine may be used during pregnancy, and a satisfactory remission will not occur until the pregnancy has been completed. After the pregnancy has been concluded, more potent immunosuppressive drugs such as antithymocyte globulin may be used, and typically there will be a full hematologic recovery over several months. However, relapse is predictable with subsequent pregnancies and may become more profound and not spontaneously remit. The infant is typically not affected and has a normal blood count.

Urinary Tract Disorders

CHUCK CARTER

CHAPTER OUTLINE

Evaluation of the Urinary Tract, 969
Anatomic Disorders, 978
Functional Disorders, 981

Infectious Disorders, 987
Neoplastic Disorders, 992

Urogenital health care concerns account for 4.1% of all ambulatory patient visits in the United States, more than half with primary care physicians (Schappert and Rechtsteiner, 2011). Disease in the urogenital system can be categorized into anatomic, functional, infectious, and neoplastic disorders. Although there is inevitable overlap among these categories, as in benign prostatic hyperplasia (BPH) (neoplastic) causing outflow obstruction and incontinence (functional), this framework is useful for characterizing urinary tract abnormalities.

Evaluation of the Urinary Tract

The urinary system includes the kidneys, ureters, bladder, and urethra; a system history most often focuses on *voiding*, its primary function. Other issues may include *sexual function* or areas of overlap with other systems (e.g., abdominal pain). Patients often present with or are found to have common concerns specific to the urinary tract (see later discussion). A thorough drug history is critical because many common medications have urologic side effects (Thomas et al., 2003) (see eTable 40-1 online).

PHYSICAL EXAMINATION

Physical examination is limited with urinary tract disorders, but special techniques are available. Many physical findings are helpful, if present, although their absence does not imply normalcy. For example, a renal bruit may indicate arterial stenosis, but its absence does not rule out the condition. Variations in examiner skill and patient factors also limit the accuracy and reliability of physical findings.

The kidneys are retroperitoneal organs and are difficult to palpate, except in very thin persons and children. The right kidney sits more inferior than the left because of the liver. The ureters are nonpalpable but, as with the kidneys, may radiate pain to the flank area. The bladder is typically nonpalpable unless distended with at least 150 mL of urine, and percussion is preferred over palpation for diagnosing distention (Gerber and Brendler, 2011). In women, an enlarged bladder may also be noted on bimanual examination.

Pelvic examination is useful for diagnosing *cystocele* in women. Two fingers can be placed in the introitus and opened to visualize the vaginal cavity. The patient

then performs the Valsalva maneuver. The anterior wall dipping down into the vaginal cavity may signify a cystocele. Placing a lubricated cotton swab in the urethral meatus and having the patient perform the Valsalva maneuver can detect more subtle cystoceles. If the swab moves upward (anteriorly), it may indicate movement of the bladder neck with straining.

Examination of the external genitalia in men may reveal penile lesions, regional adenopathy, or disorders of the scrotum and testicles. Uncircumcised men should have the foreskin retracted to rule out phimosis and visualize the glans. Careful palpation of the testicular complex is needed to detect and differentiate masses and anatomic abnormalities. Digital rectal examination (DRE) can estimate prostate size and detect masses or inflammation. It is usually performed with the patient leaning forward on the examination table with his elbows bent. Prostate tenderness, warmth, or a boggy consistency suggests prostatitis. Prostate enlargement consistent with BPH is typical in older men. Masses or asymmetry may indicate a tumor.

LABORATORY TESTS

Key Points

- Routine screening urinalysis is not recommended for adult or child preventive care.
- Evaluate for sexually transmitted infections (STIs) in patients with urinary tract infection (UTI) symptoms, positive leukocyte esterase results, and negative urine culture results.
- Do not use urine from a catheter bag for culture.
- Microalbuminuria screening is routine in diabetes care.

Urinalysis

Urinalysis is one of the most common office laboratory tests, with dipstick urinalysis most often used (Hsiao et al., 2010). Urinalysis is inexpensive, noninvasive, and easily carried out, and it can indicate a number of urinary and systemic conditions. Performing urinalysis in otherwise healthy people as a preventive health service is commonplace. However, screening is not recommended in asymptomatic adults for many of the conditions that urinalysis can identify (e.g., asymptomatic bacteruria, bladder cancer; see

eTable 40-1 Medications with Urologic Side Effects

Side Effect	Mechanism	Drug Class	Example(s)
Acute renal failure	Nephrotoxicity	Antimicrobial	Aminoglycosides, penicillins, cephalosporins, amphotericin
		Chemotherapeutic	Cisplatin
		NSAID	Ibuprofen
Bladder cancer	Acrolein toxicity	Anticonvulsant	Phenytoin
Ejaculatory dysfunction	Impaired bladder outlet sympathetic tone	Chemotherapeutic	Cyclophosphamide
	Multiple-receptor blockade	α -Antagonist	Doxazosin, prazosin, tamsulosin, terazosin, α -methyldopa
Epididymitis	Increased concentration in epididymal head	Antipsychotic	Phenothiazines
		Antidepressant	SSRIs
Erectile dysfunction	Decreased corporal blood flow Combined anticholinergic, peripheral sympathomimetic, and altered serotonergic effects α_2 -Adrenergic stimulation in hypothalamus Androgen receptor antagonist Decreased corporal blood flow Anticholinergic, antiadrenergic, central antidopaminergic effects, prolactin stimulation Antiandrogenic, prolactin stimulation Inhibition of steroid synthesis	Antihypertensive	Labetalol
		5 α -Reductase inhibitor	Finasteride, dutasteride
		Antiarrhythmic	Amiodarone
		Anticholinergic	Oxybutynin, hyoscyamine
		Antidepressant, psychotropic	Tricyclics, heterocyclics, SSRIs, MAO inhibitors, benzodiazepines
		Antihypertensive	Clonidine, α -methyldopa
		Antihypertensive	Spiroonolactone
Infertility	Azoospermia Inhibited spermatogenesis, sperm motility Decreased sperm concentration Meiosis arrest Inhibited sperm protein synthesis Impaired motility Decreased sperm count Arrested spermatogenesis Decreased spermatogenesis	Antihypertensive	β -Blockers, hydrochlorothiazide
		Antipsychotic	Phenothiazines
Priapism	Failed smooth muscle contraction γ^* ? Increased testosterone Platelet activity ?	H ₂ blocker	Cimetidine, ranitidine, famotidine
		Antifungal	Ketoconazole
		5 α -Reductase inhibitor	Finasteride, dutasteride
		Chemotherapeutic	Sulfasalazine
		Antiinflammatory	Cimetidine
		H ₂ blocker	Gentamicin
		Antimicrobial	Nitrofurantoin
		Antimicrobial	Erythromycin
		Antimicrobial	Sulfa compounds
		Antimicrobial	Penicillins
Urinary obstruction, urinary retention	Anticholinergic α -Adrenergic agonist Increased external sphincter tone Bladder smooth muscle relaxation	Antimicrobial	Antiangrogens, prostaglandins
		Drug of abuse	Alcohol, marijuana, nicotine
		Vasoactive agent	Alprostadil, papaverine, phosphodiesterase inhibitors
		Antihypertensive	Labetalol
		Antipsychotic	Phenothiazines
		Endocrine	GnRH
		Anticoagulant	Heparin, warfarin
		Antidepressant	Trazodone
		Anticholinergic	Oxybutynin, hyoscyamine
		Antihistamine	Diphenhydramine, loratadine
Voiding dysfunction, incontinence	Acetylcholine α -Adrenergic antagonism Reduced outlet resistance Smooth muscle stimulation Striated muscle relaxants Increased urine volume	Antipsychotic	Phenothiazine
		Antidepressant	Tricyclics
		Decongestant	Pseudoephedrine, phenylephrine
		Amphetamine	Dextroamphetamine
		Narcotic	Morphine
		Dopaminergic	Carbidopa, levodopa
		Calcium channel blocker	Nifedipine
		Muscle relaxant	Diazepam
		Anticholinesterase	Neostigmine
		α -Antagonist	Prazosin, terazosin, doxazosin
Urolithiasis	Sulfa precipitate Triamterene precipitate Hypercalciuria Indinavir precipitate	Benzodiazepine	Diazepam
		Stimulant	Histamine, vasopressin
		Muscle relaxant	Baclofen
		Diuretic	Furosemide
		Sulfa compound	Acetylsulfamethoxazole, acetylsulfasoxazole, acetylsulfaguanidine, sulfadiazine
Diuretic	Triamterene		
Diuretic	Furosemide		
Protease inhibitor	Indinavir		

GnRH, Gonadotropin-releasing hormone; MAO, monoamine oxidase; NSAID, nonsteroidal antiinflammatory drug; SSRI, selective serotonin reuptake inhibitor. Data from Thomas A, Woodard C, Rovner ES, Wein AJ. Urologic complications of nonurologic medications. *Urol Clin North Am.* 2003;30:123-131 and Gerber GS, Brendler CB. Evaluation of the urologic patient. In Walsh PC, ed. *Campbell-Walsh urology*. 10th ed, vol 1. Philadelphia: Saunders; 2011.

later). Routine urinalysis lacks evidence of benefit, and guidelines recommend against routine urinalysis as part of adult or child preventive care, suggesting it only be done if clinically indicated (Hagan 2008; Stephens and Wilder, 2003; Wilkinson et al., 2013a, 2013b).

Although urinalysis can detect occult disease, most positive results will not yield this outcome; more patients would incur unnecessary or potentially dangerous medical evaluations than would benefit. Thus, the potential value is elusive, and there is the possibility of harm. It is important, however, not to confuse broad population screening recommendations with those specific to certain patients or problems. For example, microalbuminuria screening is routine in diabetes care (American Diabetes Association, 2014).

Physicians should be aware that there is a good chance of false-positive and false-negative results with dipstick tests. Thus, abnormal results are not necessarily indicative of disease and may need confirmatory testing (Gerber and Brendler, 2011; Simerville et al., 2005).

Specimen Preparation. A midstream clean-catch specimen is the recommended standard for urinalysis. Uncircumcised men should retract the foreskin before urinating. Urine should be examined immediately, if possible, and should be refrigerated if it will not be examined in 1 to 2 hours.

Inspection. Normal urine color varies from clear (dilute) to yellow to deep golden and cloudy. Many substances can cause urine color to appear abnormal (Table 40-1). Cloudy urine may be caused by infection (*pyuria*), but the most common cause is *phosphaturia*, in which phosphate crystals precipitate in alkaline urine. Microscopic analysis can differentiate between these two entities. A strong or

foul-smelling sample does not necessarily indicate infection. Urine odor may change because of dietary intake (e.g., asparagus), medications, illness, or concentration. Fecal odor suggests gastrointestinal-vesical fistula.

Dipstick Urinalysis

SPECIFIC GRAVITY. Urine specific gravity ranges from 1.001 to 1.035. It reflects the urine concentration and is a marker of hydration status. However, conditions affecting renal functions, such as chronic kidney disease (CKD) and syndrome of inappropriate antidiuretic hormone secretion (SIADH), alter specific gravity and its relation to hydration. The glomerular filtrate has a specific gravity of 1.010, and urine with this fixed specific gravity may indicate renal dysfunction.

PH. Average urinary pH is usually acidic, ranging from 5.5 to 6.5. It reflects the serum pH except in patients with *renal tubular acidosis* (RTA) (Simerville et al., 2005). These patients have alkaline urine because the kidneys cannot acidify urine. Whereas type 1 RTA will always have alkaline urine, urine in type 2 RTA may become acidic as the acidosis worsens. Urine infected with urease-producing organisms such as *Proteus* spp. becomes alkaline.

BLOOD. Dipstick urinalysis has a sensitivity of 91% to 100% and a specificity of 65% to 99% for microscopic hematuria (Grossfeld et al., 2001a). Myoglobin and hemoglobin can cause a false-positive dipstick reaction. Thus, heme-positive urine specimens require microscopic examination (Davis et al., 2012).

GLUCOSE. Glucose in the urine (*glycosuria*) occurs when the glucose concentration of the glomerular filtrate exceeds the proximal tubule's ability to resorb it. The dipstick only reacts to glucose. A finding in uncontrolled diabetes mellitus, glycosuria occurs when the serum glucose level exceeds 180 mg/dL.

KETONES. Urinary ketone bodies are a main feature of diabetic ketoacidosis. They may also be found in starvation states and pregnancy. Dipsticks detect acetoacetic acid. False-positive results may occur with very concentrated or acidic urine.

LEUKOCYTE ESTERASE. Leukocyte esterase is a substance produced by neutrophils that signifies possible pyuria. The likelihood a positive test result for leukocyte esterase indicates UTI improves if urinary nitrite is also positive (Simati et al., 2013). Urine contamination by vaginal cells is the most common reason for false-positive results. Patients with typical UTI symptoms, positive leukocyte esterase, and negative urine cultures should be evaluated for STIs (Graham and Galloway, 2001).

NITRITE. The finding of nitrites in the urine is 92% to 100% specific for a UTI (Simerville et al., 2005). However, many patients with UTIs will not be nitrite positive (i.e., low sensitivity). Gram-negative coliform organisms convert urinary nitrates to nitrite but not *Staphylococcus saprophyticus* or enterococci. The test loses accuracy with lower bacterial colony counts. The reagent is air sensitive, so a dipstick may yield false-positive results if strips in the container are not tightly sealed (Gallagher et al., 1990).

PROTEIN. Urine dipsticks are very sensitive and specific for albuminuria. The reagent color change roughly corresponds to the protein concentration in the sample (Table 40-2). Very dilute, alkaline, or nonalbumin proteinuria

Table 40-1 Factors Affecting Urine Color

Color	Causative Factor
Colorless	Very dilute urine; overhydration
Cloudy, milky	Phosphaturia; pyuria; chyluria
Red	Hematuria; hemoglobinuria, myoglobinuria; anthocyanin in beets and blackberries; chronic lead and mercury poisoning; phenolphthalein (in bowel evacuants); phenothiazines (e.g., prochlorperazine [Compazine]); rifampin
Orange	Dehydration; phenazopyridine (Pyridium); sulfasalazine (Azulfidine)
Green-blue	Biliverdin; indicanuria (tryptophan indole metabolites); amitriptyline (Elavil); indigo carmine; methylene blue; phenols (e.g., IV cimetidine [Tagamet]; IV promethazine [Phenergan]); resorcinol; triamterene (Dyrenium)
Brown	Urobilinogen; porphyria; aloe, fava beans, rhubarb; chloroquine, primaquine; furazolidone (Furoxone); metronidazole (Flagyl); nitrofurantoin (Furadantin)
Brown-black	Alkaptonuria (homogentisic acid); hemorrhage; melanin; tyrosinosis (hydroxyphenylpyruvic acid); cascara, senna (laxatives); methocarbamol (Robaxin); methyl dopa (Aldomet); sorbitol

IV, Intravenous.

Table 40-2 Dipstick Protein Findings

Dipstick Color	Estimated Corresponding Protein Level (mg/dL)
Yellow	Negative (no protein)
Yellow-green	Trace (10-20)
Green	1+ (30)
Dark green	2+ (100)
Green-blue	3+ (300)
Blue	4+ (>1000)

From Simerville JA, Maxted WC, Pahira JJ. Urinalysis: a comprehensive review. *Am Fam Physician*. 2005;71:1153-1162.

may cause false-negative results. Microalbuminuria screening usually requires a separate dipstick designed specifically for this purpose. A urine protein electrophoresis is needed to evaluate nonalbumin proteinuria, such as globulinuria or Bence Jones protein.

UROBILINOGEN. Urobilinogen is a breakdown product of conjugated bilirubin. There is normally a small amount present, but elevations indicate possible hemolysis or liver disease. Conjugated bilirubinuria is abnormal and signifies hepatic disease or biliary obstruction. Unconjugated bilirubin is not filtered by the glomerulus.

Urine Microscopy. To prepare a urine sample for microscopic analysis, centrifuge 10 mL of urine for 5 minutes at 2000 rpm. After centrifugation, pour off the supernatant and resuspend the remaining sample (0.5-1.0 mL). Place a drop of this sample on the slide and focus up to high power. Samples showing probable skin or vaginal contamination should be retested or a catheterized specimen obtained (Grossfeld et al., 2001a). Sediment counts should be estimated as the average number of elements viewed per high-power field (hpf).

RED BLOOD CELLS. Urine specific gravity may affect findings because red cells may lyse at values lower than 1.007 (Vaughan and Wyker, 1971). Whereas normal-appearing red blood cells (RBCs) suggest a lesion in the urinary tract, dysmorphic RBCs are probably of glomerular origin (Figure 40-1). RBC casts are typically found at the edges of the

glass coverslip and are highly suspicious for renal parenchymal disease.

WHITE BLOOD CELLS. Normal urine samples may show some white blood cells (WBCs) on high-power examination (Figure 40-2). For women, fewer than 5 WBCs/hpf is normal; for men, fewer than 2 WBCs/hpf is normal (Simerville et al., 2005). Values in excess of these limits constitute microscopic pyuria. Purulent, cloudy urine with WBCs too numerous to count describes gross pyuria.

White blood cells are inflammatory markers, so infection cannot be confirmed by their presence or ruled out by their absence. Common causes of sterile pyuria include STIs, kidney stones, prostatitis, and urinary tract neoplasms. In children, pyuria may occur during a febrile illness even if a UTI is not present (Graham and Galloway, 2001).

CASTS. Red blood cell casts signify a nephritic or vasculitic process. WBC casts are often considered pathognomonic for pyelonephritis, but they may be found in other types of nephritis. Granular and waxy casts signify renal parenchymal disease. Hyaline casts may be normal in concentrated specimens or a marker of renal infection or disease.

CRYSTALS. Various crystal morphologies may be seen in urine samples (Figure 40-3).

URINARY EPITHELIAL (UROTHELIAL) CELLS. Transitional epithelial cells are normally found in microscopic specimens. They are uniform in shape and have large, central nuclei. In contrast, squamous cells have irregular borders and small nuclei. Squamous cells indicate skin contamination.

BACTERIA. Bacteria may signify bacteruria, but in women, vaginal contamination is also likely. A urine Gram stain is also helpful for identifying bacterial characteristics in urine samples in which infection is suspected.

FUNGI. Yeast seen in urine specimens most likely indicates contamination from the skin or vagina. However, it may signify systemic *Candida* infection if found in a catheterized specimen (Graham and Galloway, 2001).

TRICHOMONADS. These motile organisms signify a common STI and may be seen in urine samples. Treatment with metronidazole (2 g as a single dose or 500 mg twice daily for 7 days) is effective. Patients should be evaluated for other STIs.

Crystals

Figure 40-3 Crystal types found in urine samples. **A**, Cystine. **B**, Calcium oxalate. **C**, Uric acid stones found in acidic urine. **D**, Triple-phosphate crystals found in alkaline specimens. (From Gerber GS, Brendler CB. Evaluation of the urologic patient. In Wein AJ, ed. *Campbell-Walsh urology*. 10th ed, vol 1. Philadelphia: Saunders; 2011:96.)

Urine Culture

Urine culture is the “gold standard” test for diagnosing UTIs. Many sources have emphasized the midstream clean-catch technique as necessary for preventing contamination, although the value of this practice is uncertain in adults (Lifshitz and Kramer, 2000). However, genital cleansing may be more important in children (Vaillancourt et al., 2007). Bladder aspiration and catheterization are invasive sampling techniques. Urine from a catheter bag should not be used for culture because bacterial contamination is typical.

More than one bacterial isolate on culture suggests contamination. Controversy exists regarding the threshold colony counts that define bacteruria consistent with infection. Although more than 10^5 colony-forming units per milliliter (CFU/mL) is a well-known cutoff, lower values are meaningful in certain patients. In patients with typical UTI symptoms, counts as low as 10^2 CFU/mL signify infection if *Escherichia coli* or other Enterobacteriaceae are isolated. A cutoff of 10^3 CFU/mL is appropriate in men with symptoms (Graham and Galloway, 2001).

Other Diagnostic Tests

Postvoid Residual Measurement. Postvoid residual measurement assesses the volume of urine in the bladder after voiding and can be performed in the office. One method is to have the patient void and then measure any residual urine by catheterization. Less than 50 mL of residual urine is normal, and 200 mL or greater is abnormal (Kobashi, 2011). Portable ultrasound units can also estimate bladder urine volume as well as postvoid residual urine. *Urodynamics* refers to a battery of tests examining micturition, which may include postvoid residual measurement as well as various tests of bladder and sphincter pressures.

Endoscopy. Urinary endoscopy (cystoscopy) provides visual diagnosis and the opportunity for intervention. Rigid or flexible endoscopic procedures are available. Common interventional techniques include stone retrieval, stent placement, tumor biopsy and resection, and laser

treatment. Risks include infection, bleeding, urethral damage, and bladder perforation.

IMAGING STUDIES

Key Points

- Ultrasound studies are ideal for evaluating renal parenchymal disease and testicular disorders.
- Computed tomography (CT) is a better choice for evaluating solid renal masses, renal infections, perirenal masses, and renal calculi.

Intravenous Urography

Once the standard method of upper urinary tract imaging, intravenous urography (IVU), also known as intravenous pyelography (IVP), has fallen out of favor for many indications in lieu of CT.

Ultrasonography

Ultrasonography has many applications for evaluating urinary tract disease. It is the method of choice for imaging renal cysts and the renal parenchyma as part of a renal disease workup. Ultrasonography is also the test of choice for evaluating scrotal and testicular disorders. It can usually differentiate masses such as hydrocele, inguinal hernia, and varicocele. Furthermore, regular and color Doppler ultrasonography are essential parts of evaluating acute scrotal pathology, such as epididymitis, orchitis, and testicular torsion.

Ultrasonography is almost 100% sensitive for testicular tumors (Dogra et al., 2003). However, it does not provide tissue diagnosis. Rather, ultrasonography helps define the nature of the suspected lesion, differentiating it from the many other conditions that might mimic an intratesticular tumor.

Computed Tomography

Computed tomography urography has replaced IVU as the test of choice for evaluating hematuria (Davis et al., 2012). It is a better choice for evaluating solid renal masses, perirenal masses, and renal infections (Grossfeld et al., 2001b). Noncontrast CT is the test of choice for adults in evaluating renal calculi (White, 2012). Other uses include CT angiography, trauma imaging, and cancer staging.

Other Techniques

Magnetic resonance imaging (MRI) is an option comparable with CT for detecting renal masses. MR urography is also available. MRI studies are more expensive than CT, however, and availability varies (Brehmer, 2002). Thus, this modality is often used when CT examination is equivocal or contraindicated. MRI is used for staging prostate cancers (Harisinghani et al., 2003).

Voiding cystourethrography (VCUG) uses contrast imaging of the bladder and urethra during urination. Contrast material is delivered via catheter, and the images are obtained while the patient voids. It is most often used to diagnose suspected vesicoureteral reflux (VUR). Nuclear

medicine studies may also be used to examine possible VUR, as well as renal function or suspected testicular torsion.

COMMON URINARY TRACT CONCERNS

Key Points

- Dysuria most often indicates UTI, vaginitis, or STI.
- Gross hematuria requires aggressive evaluation.
- Urine microscopy is required to diagnose hematuria. In adults, risk factors for malignancy should be assessed; isolated hematuria is most common in children.
- Hematuria of renal origin often has dysmorphic red cells. Hematuria of bladder origin should show normal RBCs.
- Nocturia is common in both genders and increases the risk of falling in older adults.
- The urine protein-to-creatinine (UPr/UCr) ratio correlates well with a 24-hour urine and is much easier to obtain.
- Proteinuria in children is most often orthostatic.

Dysuria

Urinary burning or pain most often represents UTI or vaginitis. It is common in middle-aged and sexually active women. In men, it is more likely to occur as they grow older (Brenmor and Sadovsky, 2002). Both voiding history and sexual history are essential. Questions regarding vaginal symptoms are important in women. Also, use of medications and personal hygiene products should be reviewed.

Dysuria significantly increases the chance that a patient has a UTI. However, there are many potential causes of dysuria (Table 40-3), and empiric treatment based on this symptom alone leads to unnecessary antibiotic use. Incorporating other symptoms increases the likelihood that a UTI is the cause (see Urinary Tract Infection) (Bent et al., 2002; McIsaac et al., 2002).

Flank Pain

Flank pain may be a presenting complaint indicating urinary tract disorder. It is typically not relieved by position changes and is colicky in nature. Nausea and vomiting may

Table 40-3 Differential Diagnosis of Dysuria

Calculi
Meatal stenosis
Medications
Neoplasm—bladder, benign prostate hyperplasia, prostate, penile, vulvovaginal
Prostatitis
Sexually transmitted infection— <i>Chlamydia</i> , gonorrhea, herpes simplex virus, <i>Mycoplasma</i> spp., <i>Trichomonas</i> spp.
Somatization
Trauma—foreign body, mechanical, masturbation, postcoital
Urethral syndrome
Urethritis—infectious, irritant, chemical, spondyloarthropathy
Urinary tract infection—cystitis, pyelonephritis, prostatitis
Vaginitis—allergic, atrophic, bacterial vaginosis, candidiasis, chemical

Modified from Seller RH. Urethral discharge and dysuria. In *Differential diagnosis of common complaints*. 3rd ed. Philadelphia: Saunders; 1996 and Brenmor JD, Sadovsky R. Evaluation of dysuria in adults. *Am Fam Physician*. 2002;65:1589-1596.

coincide. Obstruction (e.g., kidney stones) and inflammation (e.g., pyelonephritis) are the two most common causes. The location may help localize the underlying cause (Figure 40-4). Tumors are less likely because they are usually only symptomatic if they distend the renal capsule or obstruct the ureter.

Urinary Frequency

As a complaint, urinary frequency implies a deviation from a patient's normal urination pattern. Thus, it may either be truly abnormal or simply more than the patient's custom (but still normal). It may exist alone or in concert with other symptoms. For example, UTI often causes urinary frequency, urgency, and dysuria.

Adults typically urinate five to six times a day (Gerber and Brendler, 2011). Frequency usually represents an increased number of episodes with small volumes of urine as opposed to increased urine volumes, such as in polyuria. These factors help narrow the differential diagnosis (Table 40-4).

Hematuria

Hematuria is often an incidental finding on urinalysis, and evaluation depends on whether it is gross or microscopic and whether it occurs in adults, children, or adolescents. Most patients with hematuria do not have significant pathology, but this depends on the type of hematuria and underlying risk factors. One prospective study found that 61% of patients with hematuria had no finding after evaluation (Khadra et al., 2000). However, the malignancy rate in screening studies is 2.6%, suggesting the need for workup in patients demonstrating this finding (Davis et al., 2012).

Gross hematuria is blood in the urine visible to the patient or physician. Microscopic hematuria is the more common entity. Microscopic hematuria in adults is defined as 3 or more RBCs/hpf (Davis et al., 2012). In children, clear consensus is lacking, although more than 5 RBCs/hpf found in at least two weekly urine samples is considered abnormal (Dodge et al., 1976; Vehaskari et al., 1979). The reasons for the different definitions may reflect a lower evaluation

threshold in adults because of the larger spectrum of potential causes.

Dipstick urinalysis alone is insufficient for diagnosing hematuria because certain substances (e.g., myoglobin) and test characteristics (e.g., specificity) can cause false-positive results. Thus, microscopic analysis is necessary and inherent in the definition.

Hematuria in Adults

GROSS HEMATURIA. Gross hematuria is a common presenting symptom for patients with bladder or renal cancer (Yun et al., 2004). The sensitivity of gross hematuria for bladder cancer is 83%, and the positive predictive value (PPV) is 22% (Buntinx and Wauters, 1997). However, the studies generating these values were of low quality and based on referral populations. No studies are available on the likelihood that family medicine patients with this finding will have serious pathology. Pending this research, the approach to gross hematuria should remain aggressive (Khadra et al., 2000).

Confirmation of blood in the urine with dipstick and microscopy is needed in cases of red-tinted urine because certain substances can discolor the urine (see Table 40-1). However, visible clots are unlikely to have a mimic. History should focus on signs and symptoms of infection, trauma, and risk factors for urinary tract malignancy (see “Bladder Cancer”). Physical examination should assess the external genitalia and include a pelvic examination in women and a prostate examination in men. Urology consultation is appropriate except when an obviously benign (e.g., menses) or treatable cause is found. Even when a treatable cause is identified (e.g., renal calculi), close follow-up with repeat urinalysis is needed because gross hematuria is frequently a harbinger of serious urinary tract pathology (Khadra et al., 2000).

MICROSCOPIC HEMATURIA. *Asymptomatic hematuria* potentially signals serious urinary tract disease, although there are many causes, often benign. Hematuria may occur in 9% to 18% of normal subjects (Grossfeld et al., 2001a). Most studies evaluating and defining this problem were not performed in typical family medicine populations, are of

lower quality, or both. No prospective studies demonstrate an improved outcome from routine screening; as noted earlier, routine urinalysis is not recommended for adults. For the general population, finding asymptomatic microscopic hematuria carries a predictive value of only 0.5% (Brehmer, 2002). Thus, benefit from routine microhematuria screening is unlikely (Kryszczuk et al., 2004).

Family physicians encountering microhematuria should consider patient risk characteristics and systematic laboratory testing and imaging (Figure 40-5). The first step in approaching asymptomatic microscopic hematuria is to assess whether a benign cause such as menses, sexual activity, vigorous exercise, viral illness, or trauma is the explanation, as this may preclude further workup. However, repeat urinalysis is often needed to verify the hematuria has resolved. A caveat is a patient at risk for bladder cancer because intermittent hematuria can precede this finding, and more extensive follow-up may be warranted (Davis et al., 2012; Grossfeld et al., 2001b). Family physicians should be cautious not to misattribute certain causes as benign. For example, warfarin (Coumadin) could cause hematuria if the patient is excessively anticoagulated, but it should not cause hematuria within its goal international normalized ratio (INR) range. Hematuria in this setting is often a sign of urologic disease (Culclasure et al., 1994). Thus, patients taking anticoagulants should be evaluated if they develop hematuria (Davis et al., 2012).

If hematuria is consistently found, the next step is to risk stratify the patient based on history, physical, and baseline laboratory findings. Initial laboratory testing should include urinalysis, urine culture (if indicated), and renal function assessment. If UTI is present, patients should be reassessed at a later date as they would for a benign cause. High-risk patients are those at increased risk for urologic malignancy—men, age older than 35 years, tobacco use history, analgesic abuse, pelvic irradiation, occupational exposures (see **Bladder Cancer**), prior urologic disease, irritative voiding symptoms, history of UTIs, history of urologic disease or gross hematuria, chronic indwelling device, and cyclophosphamide use (Davis et al., 2012). Hematuria of renal origin may be associated with microscopic RBC casts or dysmorphic RBCs. Other findings may include proteinuria, elevated serum creatinine, or a physical finding such as hypertension or edema. These patients need evaluation for renal disease, including urine protein quantification. Some patients will have risk factors and findings for both renal and urologic disease or may already have a history of CKD, so simultaneous evaluations for both causes may be necessary.

The evaluation for microhematuria includes upper urinary tract imaging (CT urography), and cystoscopy. Cystoscopy is necessary to rule out bladder cancer confidently because no imaging study is adequate for evaluation. However, cystoscopy is optional in low-risk patients because it is unlikely to yield a definitive finding (Davis et al., 2012). Urine cytology is no longer recommended as part of the routine workup but may be used for patients with negative evaluation findings who have ongoing hematuria and risk factors. Urine tumor markers are not routinely recommended either (Davis et al., 2012).

A cause of hematuria is often not found even after a complete evaluation. Isolated hematuria is *asymptomatic*

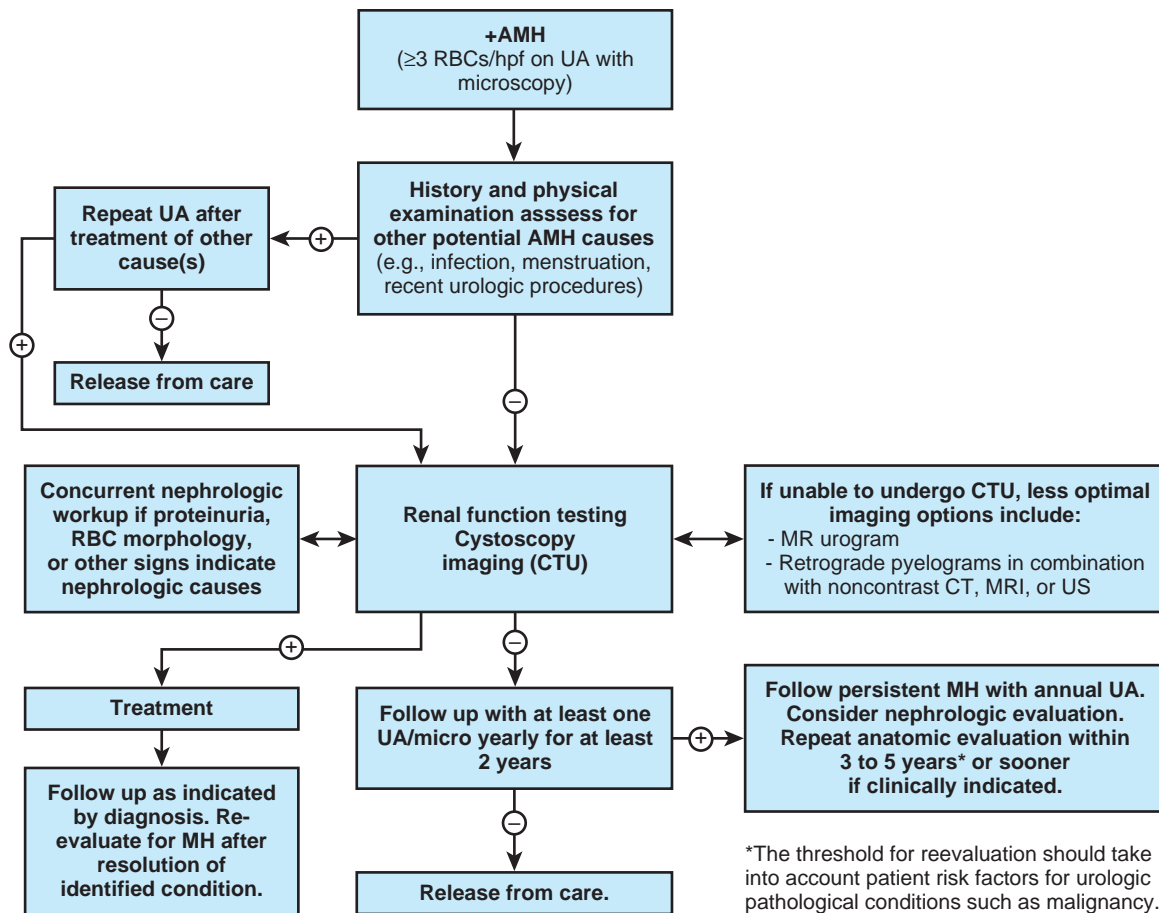

Figure 40-5 Diagnosis, evaluation, and follow-up of asymptomatic microscopic hematuria. AMH, Asymptomatic microscopic hematuria; CT, computed tomography; hpf, high-power field; MH, microscopic hematuria; MRI, magnetic resonance imaging; RBC, red blood cell; UA, urinalysis; US, ultrasonography. (Copyright ©2012 American Urological Association Education and Research, Inc.)

microscopic hematuria with a normal urologic evaluation and no signs of systemic disease or microscopic evidence of intrinsic renal disease (the definition slightly differs for children). The prognosis is good, although some studies indicate a high proportion of renal abnormalities (e.g., IgA nephropathy). Thus, surveillance for signs of renal disease is appropriate (Grossfeld et al., 2001b). Persons with negative evaluation findings can be followed with annual microscopic urinalysis. If results are normal for 2 years, they need no further testing because their risk approaches that of the general population. Those with ongoing hematuria need regular follow-up and may need a repeat urologic evaluation (Davis et al., 2012).

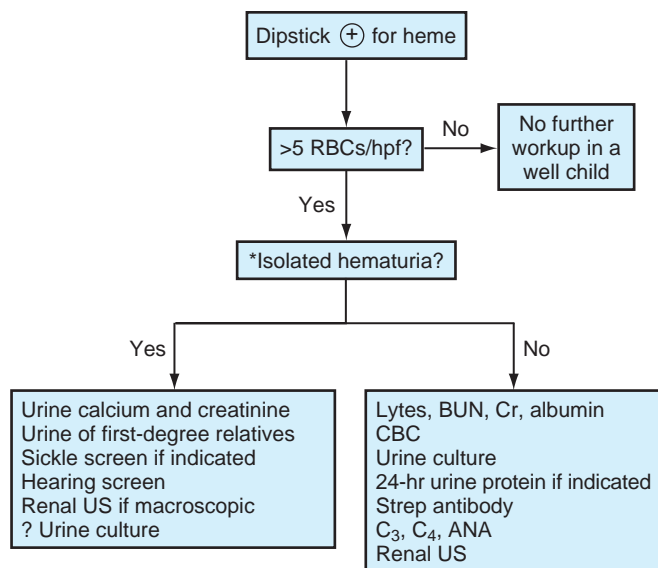

Evaluation and treatment of *symptomatic microscopic hematuria* is directed at the condition. However, family physicians should consider the underlying risk of urinary tract abnormalities when deciding on follow-up. For example, a patient with a symptomatic kidney stone may have microhematuria. Although this provides the most likely explanation for the bleeding, if the patient has a background risk for malignancy (e.g., smoking) or renal disease, repeat urinalysis is needed to ensure resolution.

Hematuria in Children and Adolescents. Hematuria is a relatively common finding in children, with an estimated

prevalence of 0.5% to 2% of asymptomatic school-age children (Dodge et al., 1976). Those with hematuria and proteinuria, particularly when associated with hypertension, edema, or urinary casts, need aggressive evaluation for underlying glomerular disease or uropathy. The vast majority of children with hematuria, however, present with isolated hematuria. This is typically detected on a random urine sample obtained in the context of a routine physical examination but may also present as asymptomatic gross hematuria. In children, the term *isolated* refers to the complete absence of symptoms, significant past medical or family history, physical examination findings, or other abnormalities on urinalysis. This distinction often separates children with benign processes from those with underlying pathology.

After the diagnosis of hematuria has been confirmed, a complete history obtained, and a physical examination performed, a staged evaluation should ensue (Figure 40-6). Significant underlying renal or urologic disease is highly unlikely in children with isolated microscopic hematuria (Bergstein et al., 2005). A more thorough evaluation is indicated for asymptomatic macroscopic hematuria.

The most common glomerular diseases associated with isolated hematuria are subclinical postinfectious glomerulonephritis, IgA nephropathy, and Alport syndrome. In the

*Negative history; normal physical exam findings; and absence of symptoms, HTN, pyuria, proteinuria, and cellular casts

absence of proteinuria or more advanced disease, there is no treatment given for these conditions. Yearly follow-up with blood pressure and urinalysis is indicated for all forms of persistent hematuria.

Hypercalciuria may or may not be associated with pain. The exact mechanism by which hypercalciuria causes hematuria is unproven but probably is secondary to crystaluria (Stapleton, 1994). Hypercalciuria is generally defined by a urinary calcium excretion higher than 4 mg/kg/day or a random UPr/UCr higher than 0.2. Higher excretion rates are expected in infants and toddlers. Patients with documented hypercalciuria should undergo renal ultrasonography to rule out nephrocalcinosis or significant stone disease. The treatment is to increase fluid intake and restrict dietary sodium (<3 g/day) while maintaining the recommended daily allowance of calcium (Escribano et al., 2014; Srivastava and Alon, 2005). This dietary intervention may lower the urine calcium concentration and ultimately result in resolution of the hematuria. A thiazide diuretic should be considered if there is evidence of nephrocalcinosis or nephrolithiasis.

Lower Urinary Tract Symptoms

Lower urinary tract symptoms (LUTS) are the symptoms traditionally associated with BPH. Many subcategories of LUTS exist, but the two most prominent are storage and voiding symptoms (Table 40-5). *Voiding* symptoms imply obstruction, but physical obstruction may not be responsible. In men with BPH, for example, detrusor overactivity, neurologic disorders, or age-related smooth muscle dysfunction may be the cause. Thus, LUTS should shift attention toward a larger symptom complex with many potential causes. This is particularly important when dealing with urinary tract disorders such as BPH, incontinence, and overactive bladder.

From Weiss JP, Blaivas JG. Nocturia. *J Urol*. 2000;163:5-12.

Nocturia

Nocturia describes waking at night to urinate. It is more common in older adults, but no population data define a normal range for any group; therefore, the complaint implies a deviation from a perceived norm. Furthermore, the primary complaint often centers on a sleep disturbance rather than on urination. It may represent frequent nocturnal urination or excessive nocturnal urine production (nocturnal polyuria). Although often thought of as a prostatic symptom, it is common in both men and women. The many secondary causes in addition to local causes include prostatic hyperplasia and bladder dysfunction (Table 40-6). In patients with prominent LUTS, the problem is compounded by urination difficulty. Furthermore, studies in older adults indicate that nocturia or LUTS increases the risk of falling (Parsons et al., 2009). Age-related variations in arginine vasopressin secretion may play a role in nocturnal polyuria (Weiss and Blaivas, 2000).

Treatment centers on the underlying cause, and a voiding diary may aid clinical decisions. Prostate hyperplasia or bladder dysfunction often receives first attention. Treating BPH may help, although BPH often does not result in true physical obstruction, and epidemiologic data have indicated

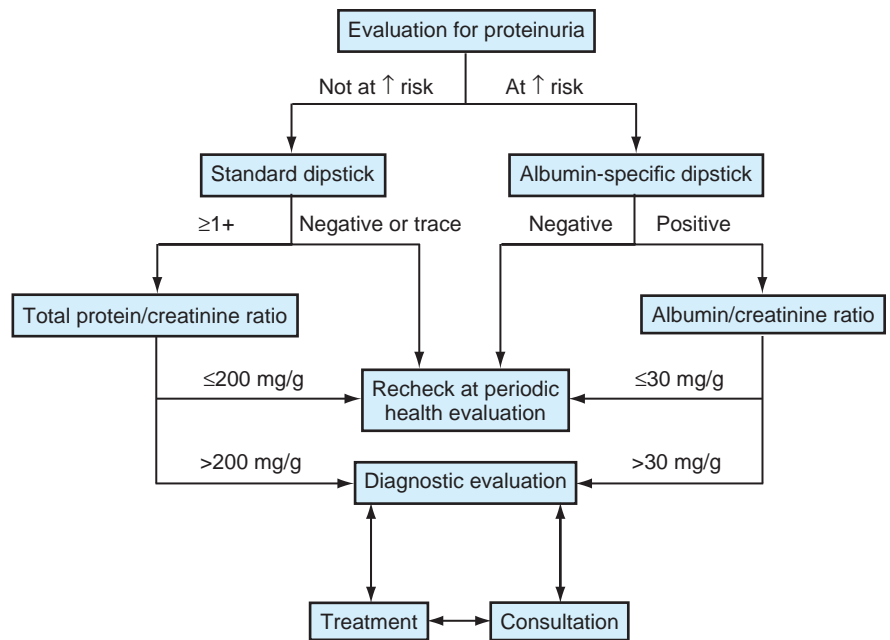

Figure 40-7 Approach to proteinuria in adults. (Modified from Levey AS, Coresh J, Balk E, et al. National Kidney Foundation practice guidelines for chronic kidney disease: evaluation, classification, and stratification. *Ann Intern Med.* 2003; 139:137-147, E148-E149. Redrawn from National Kidney Foundation/Kidney Disease Quality Initiative. See Web Resources.)

that nocturia is common in men without prostatic obstruction. Thus, family physicians should consider the contribution of nocturnal polyuria. For example, patients with chronic heart failure and leg edema may benefit from fluid restriction and napping with leg elevation during the day. Treating obstructive sleep apnea helps alleviate the increased urine production resulting from increased atrial natriuretic peptide production. Behavioral interventions include avoiding excess nighttime alcohol or fluid intake and afternoon napping. Adjusting diuretic doses so they are given earlier in the evening should negate medication effects during sleep (Weiss and Blaivas, 2000).

Proteinuria

The kidneys normally excrete a small amount of protein daily, usually glycoproteins. Only very small amounts of globulins, light-chain proteins, or albumin are released. Functional proteinuria may result from physiologic changes in glomerular filtration, as occurs with exercise (Venkat, 2004). However, consistent albuminuria implies glomerular or tubular dysfunction.

The urine dipstick is the most convenient measurement, but a more accurate test is the UPr/UCr ratio, obtained by dividing the random urine sample protein level by the urine creatinine level (both in milligrams per deciliter). This ratio has proven correlation with 24-hour excretion rates (Ginsberg et al., 1983). Thus, random urine samples are the best way to identify and follow proteinuria, and 24-hour collections are usually not needed (Levey et al., 2003) (Table 40-7). However, results from those with low or high levels of muscle mass may not correlate as well with 24-hour measurements (Venkat, 2004).

Proteinuria in Adults. Proteinuria is a marker of kidney disease in adults and may actually contribute to renal impairment. Patients with diabetes should be periodically tested for microalbuminuria. Others at risk for kidney disease, such as patients with hypertension, should also be tested.

Table 40-7 Proteinuria Values

Test	Protein Value
Dipstick	≥1+ if urine specific gravity ≤1.015 ≥2+ if urine specific gravity >1.015
UPr/UCr ratio	CHILDREN >0.5 (age 6 mo to 2 yr) >0.25 (>2 yr) ADULTS: >0.2
24-hour urine assay	CHILDREN >4 mg/m ² /hr >100 mg/m ² /day ADULTS 30-300 mg/24 hr—microalbuminuria >300 mg/24 hr—albuminuria >3.5 g/24 hr—nephritic-range proteinuria

UPr/UCr, Urine protein/creatinine.

Adults with proteinuria need their UPr/UCr ratios determined. Those with values outside the normal range should undergo an evaluation for CKD (see later). Patients with dipstick proteinuria but normal-range UPr/UCr values should be rechecked at periodic follow-ups (Figure 40-7).

Proteinuria in Children and Adolescents. Most proteinuria in children is transient when followed up with weekly urine sample testing. Persistent proteinuria found in at least two of three weekly urine samples warrants further evaluation to identify children who may have chronic renal disease.

Proteinuria in children may be classified as functional, isolated, or symptomatic. *Functional* proteinuria may occur with fever or exercise. *Isolated* proteinuria is defined by the absence of abnormal history, physical examination findings, symptoms, or other urinary abnormalities. The most common cause of this form is *benign orthostatic proteinuria*,

Table 40-8 Causes of Pathologic Proteinuria in Children

Glomerular disease	Minimal-change disease

defined by normal protein excretion overnight or in the supine position. The initial evaluation for isolated proteinuria involves obtaining a first-morning urine sample for protein and creatinine as well as a formal urinalysis for microscopy review (Hogg et al., 2000). The absence of morning proteinuria, as evidenced by normal UPr/UCr ratio, supports the diagnosis of benign orthostatic proteinuria. A more accurate assessment is a split 24-hour urine collection for protein. Benign orthostatic proteinuria may be transient or fixed and in either case has an excellent prognosis (Springberg et al., 1982). In contrast, *nonorthostatic* isolated proteinuria with a duration of 1 year or longer may represent significant renal pathology (Trachtman et al., 1994). Thus, these patients need yearly or twice-yearly clinical follow-up with assessment of blood pressure, renal function, serum albumin, urine microscopy, and urine protein.

Pathologic proteinuria, whether isolated or symptomatic, occurs in the setting of a variety of glomerular and tubulointerstitial diseases (Table 40-8). Some children may present with the *nephrotic syndrome* (proteinuria, hypoalbuminemia, edema). Depending on the degree of proteinuria and the results of the initial laboratory evaluation, a renal biopsy may be indicated (Figure 40-8).

Anatomic Disorders

Key Points

- Underlying urinary tract obstruction may cause prenatally identified hydronephrosis. These infants need close follow-up with ultrasonography in the first week of life.
- Hydroceles in infants often resolve by age 2 years. Hydroceles in adults may have a secondary cause.
- Peyronie disease is usually self-limited but may require urology consultation when treatment is considered.
- Testicular torsion is a medical emergency. Torsion of the appendix testis is less severe and can be managed with supportive care.

Anatomic urinary tract disorders involve various congenital and acquired abnormalities, most notably of the

Table 40-9 Selected Differential Diagnosis of Scrotal Masses with Physical Findings

Abnormality	Physical Finding
Epididymitis, orchitis	Tender mass
Hydrocele	Transilluminates
Inguinal hernia	Does not transilluminate
Testicular torsion	Pain and loss of cremasteric reflex
Torsion of the appendix testis	Blue dot sign
Trauma	Tender scrotum, edema, trauma history
Tumor	Solid mass
Spermatocele	Nontender cystic mass
Varicocele	Bag of worms appearance

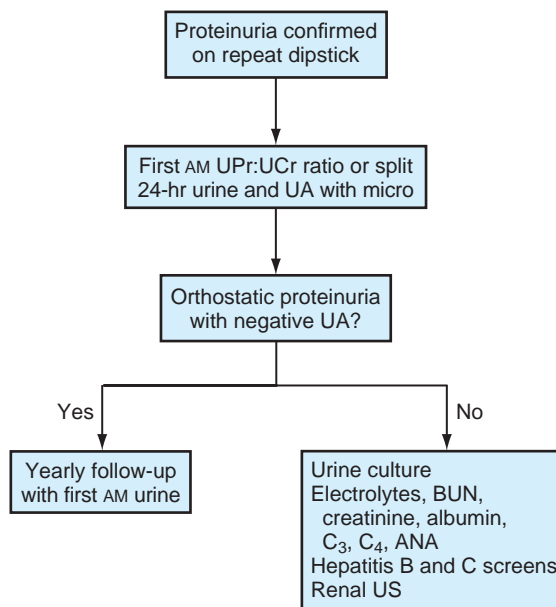

Figure 40-8 Approach to the child with proteinuria. ANA, Antinuclear antibody; BUN, blood urea nitrogen; UA, urinalysis; UPr:UCr, urine protein/urine creatinine.

external genitalia. Testicular disorders are seen more often than abnormalities of the penis, particularly undescended testes. Anatomic derangements of the bladder, ureter, and kidney are often only discovered incidentally or during an evaluation for UTIs, voiding problems, CKD, or pain possibly related to the urinary tract. For example, posterior urethral valves cause VUR and may contribute to recurrent UTIs (see “Urinary Tract Infections in Children”).

Scrotal masses are frequently encountered in family medicine. Anatomic causes of scrotal masses are not limited to the urinary tract, and neoplastic and infectious causes are also in the differential diagnosis (Table 40-9). Scrotal or testicular pain, the so-called acute scrotum, implies a more urgent or emergent cause (e.g., testicular). Because the history and physical examination may not be adequate to differentiate certain conditions (e.g., epididymo-orchitis from testicular torsion), adjunctive imaging such as ultrasonography is often used.

FETAL HYDRONEPHROSIS

With the pervasive use of fetal ultrasonography, hydronephrosis is more often diagnosed prenatally. A dilated renal

collecting system is often the only indication of a number of congenital uropathies (Ismaili et al., 2004). Although transient hydronephrosis is most common, two processes cause hydronephrosis: reverse urine flow (VUR) and impaired forward urine flow (obstruction) (Yamacake and Nguyen, 2013). VUR occurs as an isolated entity or can be associated with a more complicated uropathy, such as bladder outlet obstruction with VUR. Obstructive uropathy may occur at different sites along the urinary tract, most often the ureteropelvic junction.

Infants with fetal hydronephrosis need ultrasonography in the first week of life. If results are normal, repeat ultrasonography should be done in 4 weeks and 1 to 2 years (Yamacake and Nguyen, 2013). After the diagnosis is confirmed, evaluation includes a urinalysis, urine culture, basic metabolic panel (if bilateral), and a VCUG. If the VCUG results are normal, furosemide renography is needed to determine the presence and degree of obstruction.

HYDROCELE

Hydroceles are fluid accumulations in the tunica vaginalis and can result from a failure of the processus vaginalis to close during development, or secondary to epididymitis, orchitis, testicular torsion, trauma, or tumors (Barthold, 2011). Whereas hydroceles typically transilluminate, inguinal hernias do not. In young children, management is supportive, with the hydrocele often resolving by age 2 years. Hydroceles presenting beyond 2 years or those associated with inguinal hernias require surgical consultation. Also, some hydroceles are communicating; that is, fluid can pass from the peritoneal cavity into the hydrocele. These may change in size with activity or during the day and need surgical evaluation (Schneck and Bellinger, 2007). Hydroceles arising de novo in adults often have a secondary cause and require evaluation (Dogra et al., 2003).

HYPOSPADIAS

Hypospadias, in which the urethra opens on the underside of the penis, is infrequently seen (Figure 40-9). However, it is important that hypospadias is recognized early, preferably at the initial newborn examination. It can occur with or without chordee (curvature). Circumcision should be withheld and a urology consultation obtained. Hypospadias must be differentiated from ambiguous genitalia, which implies an intersex disorder. *Epispadias*, in which the meatus is located on the dorsal surface of the penis, is uncommon and is usually associated with extrophy of the bladder.

LABIAL ADHESIONS

Labial adhesions may be seen in young girls and may be partial or complete (fusion) and asymptomatic. However, labial adhesions can be associated with difficult or abnormal urination and may contribute to the development of UTIs. It is important to perform an external genital examination in a girl with her first UTI (Figure 40-10). Retrospective data and case series support topical estrogen cream to the affected areas, with gentle traction until the adhesions have separated (Bacon, 2002; Tebruegge et al., 2007). However, labial separation occurred more quickly

Figure 40-9 Hypospadias. (From Borer JG, Retik AB. Hypospadias. In Wein AJ, ed. *Campbell-Walsh urology*. 9th ed, vol IV. Philadelphia: Elsevier; 2007.)

Figure 40-10 Techniques for pediatric female genital examination. (From Canning DA, Nguyen MT. Evaluation of the pediatric urologic patient. In Wein AJ, ed. *Campbell-Walsh urology*. 9th ed, vol 4. Philadelphia: Elsevier; 2007.)

and with less recurrence in patients treated with betamethasone than in those treated with estrogen cream (Mayoglou et al., 2009).

PEYRONIE DISEASE

Peyronie disease is characterized by formation of fibrosis in the tunica albuginea, with resulting penile deformity and pain. Symptoms include painful erection, physical penile deformity (often curvature), palpable penile plaque

Figure 40-11 Paraphimosis. (From Kleigman R, Behrman RE, Jenson HB, et al. *Nelson textbook of pediatrics*. ed 18. Philadelphia: Saunders; 2007:2256.)

(fibrosis), and erectile dysfunction (ED). Pain is typically transient, most cases do not result in a deformity so severe that it impairs intercourse, and most patients do not require any treatment beyond reassurance and counseling. However, sexual history, counseling, and partner involvement are important because Peyronie disease can be disruptive to a relationship.

Urologic consultation should be considered before exploring treatment. Nonsurgical treatments are available and tend to focus on treatments with antiinflammatory or antioxidant properties, but overall supporting evidence is limited. Vitamin E and colchicine have uncertain efficacy. Pentoxifylline and phosphodiesterase-5 (PDE-5) inhibitors show promise. Intralesional verapamil is also an option. Steroid injection is not recommended. Surgery is an option in severe cases (Lewis and Munarriz, 2007; Shaw et al., 2013).

PHIMOSIS AND PARAPHIMOSIS

Phimosis (inability to retract foreskin over glans) and paraphimosis (inability to return retracted foreskin over glans) are possible complications seen in uncircumcised boys (Figure 40-11). About 50% of boys typically are able to retract their foreskins by 1 year of age and 80% by age 3 years (Anderson and Anderson, 1999). Low-potency topical corticosteroid therapy (0.05% betamethasone) combined with daily prepuce retraction appears effective for phimosis (Reddy et al., 2012; Zampieri et al., 2005).

Because vascular engorgement leads to necrosis of the glans, acute paraphimosis needs urgent medical attention. A dorsal slit procedure may be required if other reduction techniques are unsuccessful. Ice packs and plastic wrap may reduce the edema enough to allow manual reduction (Choe, 2000). Circumcision is generally indicated after the reduction and edema resolution. Methods of reduction

included manual, osmotic, puncture, and aspiration (Little and White, 2004).

SPERMATOCELES

Spermatoceles (epididymal cysts) are painless cysts filled with sperm and can be palpated distinct from the testis. They transilluminate, are generally of no consequence, and do not affect fertility.

TESTICULAR DISORDERS

Testicular Torsion

Although occasionally seen in newborn boys, testicular torsion is an acquired condition seen during puberty and is an emergency (Ringdahl and Teague, 2006). It usually presents with an abrupt onset of severe scrotal pain, at times waking the patient up in the early morning. Associated signs and symptoms include fever, nausea, vomiting, and abdominal pain. Intermittent testicular torsion has been described. On physical examination, the testis may lie in a more horizontal position, caused by a lack of normal attachment to the tunica vaginalis (“bell clapper” deformity), and demonstrate a loss of the cremasteric reflex. The diagnosis of testicular torsion can be made by physical examination or with the assistance of color Doppler ultrasonography; however, physical examination is unreliable for ruling torsion in or out (Schmitz and Safranek, 2009). Timeliness of the diagnosis is critical because testicular viability declines to 0% if detorsion occurs 24 hours after the onset of symptoms (Brenner and Ojo, 2004). Testicular torsion can occur in systemic illnesses, such as Henoch-Schönlein purpura, or can mimic the symptoms of other conditions, such as appendicitis or nephrolithiasis.

Torsion of the appendix testis presents similar to testicular torsion, although the symptoms are not as severe. The classic patient is a boy age 7 to 12 years. Palpation of the testis is normal except for a small, tender, palpable mass located on the superior or inferior pole. The cremasteric reflex is intact. The “blue dot” sign may be present and represents the compromised appendix testis as viewed through the scrotum. The diagnosis is generally made clinically, and treatment is supportive, including analgesia and scrotal elevation. It is not unusual for the pain to last 5 to 10 days, but chronic pain may occur and warrants urology consultation.

Undescended Testis

Undescended testis (testes) occurs in 2.7% to 5.9% of full-term male infants, decreasing to 1.2% to 1.8% by age 1 year (Pillai and Bassner, 1998); the incidence is higher in premature infants. An undescended testis must be differentiated from a *retractile* testis, which may occur as the cremasteric reflex is developed. As opposed to an undescended testis, a retractile testis can be manually coaxed into the scrotum. In general, the patient with truly undescended testes needs urology evaluation. Failure to respond to human chorionic gonadotropin (hCG) is an indication for orchiopexy, especially if the testes have not descended by the first birthday. This should be accomplished before the child is 6 years old (Job et al., 1982). Although it is uncertain that a contralateral normal testicle is at increased risk,

testicular examination should be taught to orchiopexy patients because of the increased risk of testicular cancer (Altman, 1967; Wood and Elder, 2009).

Varicoceles

A varicocele is a collection of dilated and tortuous veins surrounding the spermatic cord. It is most often asymptomatic and left sided. Varicoceles arise in adolescence and are estimated to occur in 10% to 15% of the male population (Schneck and Bellinger, 2007). Evidence that varicoceles cause infertility is limited, but they are found in 12% of men presenting with infertility, and in mature adolescents with varicoceles, 26% had abnormal semen analyses (Biyani et al., 2009; Brenner and Ojo, 2004). The “bag of worms” appearance on scrotal examination is the hallmark of this diagnosis. Inferior vena cava obstruction should be considered if the varicocele is right sided, of acute onset, or occurs in a prepubertal boy.

Functional Disorders

Key Points

- Patients with proteinuria and elevated UPr/UCr ratios should be evaluated for CKD. The serum creatinine level may not correlate with glomerular filtration rate (GFR); GFR estimates are adequate to diagnose kidney disease, and 24-hour urine testing is usually not needed.
- Patients with CKD need systemic management.
- Enuresis typically resolves with age. A bedwetting alarm is effective if treatment is needed.
- ED has many causes and is associated with cardiovascular disease.
- Pelvic floor muscle exercises are the first-line treatment for urinary incontinence.
- Anticholinergic drugs and tiroprium are effective treatments for urge incontinence.
- Anticholinergic drugs for an overactive bladder can be beneficial but often cause dry mouth.
- Men with recurrent kidney stones and idiopathic hypercalciuria should be on low-sodium, low-protein diets. Low-calcium diets do not reduce stone formation.
- Non-contrast-enhanced CT is the test of choice for diagnosing kidney stones.

CHRONIC KIDNEY DISEASE

Renal disease is a significant public health burden, with almost 20 million persons in the United States having CKD (Coresh et al., 2003). The National Kidney Foundation’s guidelines on the evaluation and management of CKD defines CKD as kidney damage or decreased kidney function for 3 months or longer (Levey et al., 2003).

Proteinuria is a clinical sign of kidney disease. Patients with proteinuria should be approached as described earlier. Patients with abnormal urinary protein values (e.g., UPr/UCr ratio) or other markers of kidney damage should be assessed for CKD (Johnson et al., 2004). The primary measure of kidney function is the GFR, and the stages of CKD are based on GFR (calculated by Cockcroft-Gault or

Table 40-10 Stages of Chronic Kidney Disease

Stage	Defining Features	GFR [†] (mL/min/1.73 m ²)
1	Kidney damage,* normal GFR	≥90
2	Kidney damage, mild decrease in GFR	60-89
3	Moderate decrease in GFR	30-59
4	Severe decrease in GFR	15-29
5	Kidney failure	<15

*Pathologic renal abnormalities; markers of damage: abnormal blood, urine, or imaging study results.

†Glomerular filtration rate (GFR) equations:

Cockcroft-Gault equation:

$$\text{CCr (mL/min)} = \frac{[(140 - \text{Age}) \times \text{Weight}] / 72 \times \text{SCr}}{(\times 0.85, \text{ if female})}$$

Abbreviated MDRD:

$$\text{GFR (mL/min/1.73m}^2\text{)} = 1.86 \times (\text{SCr})^{1.154} \times (\text{Age}) / (0.742 \text{ [if female]} \times 1.210 \text{ [if black]})$$

CCr, Creatinine clearance; MDRD, modification of diet in renal disease study equation; SCr, serum creatinine level (mg/dL).

Calculators for office use are available from the National Kidney Disease Education Program (NKDEP). http://www.nkdep.nih.gov/professionals/gfr_calculators/index.htm.

From Johnson CA, Levey AS, Coresh J, et al. Clinical practice guidelines for chronic kidney disease in adults. Part II. Glomerular filtration rate, proteinuria, and other markers. *Am Fam Physician*. 2004;70:1091-1097.

Table 40-11 Serum Creatinine Levels and Chronic Kidney Disease*

Age (yr)	Serum Creatinine (mg/dL) MDRD Study Equation					
	European American		African American		Cockcroft-Gault Equation	
	Men	Women	Men	Women	Men	Women
30	1.47	1.13	1.73	1.34	1.83	1.56
40	1.39	1.08	1.65	1.27	1.67	1.42
50	1.34	1.03	1.58	1.22	1.50	1.28
60	1.30	1.00	1.53	1.18	1.33	1.13
70	1.26	0.97	1.49	1.15	1.17	0.99
80	1.23	0.95	1.46	1.12	1.00	0.85

*These values correspond to a glomerular filtration rate of 60 mL/min/1.73 m².

MDRD, Modification of diet in renal disease.

Modified from Levey AS, Coresh J, Balk E, et al. National Kidney Foundation practice guidelines for chronic kidney disease: evaluation, classification, and stratification. *Ann Intern Med*. 2003;139:137-147, E148-E149.

modification of diet in renal disease [MDRD] equation) (Table 40-10). The MDRD equation performs as well or better than measured creatinine clearance (Levey et al., 1999). However, physicians should be aware that the values obtained by the equations may differ slightly, and the Cockcroft-Gault equation is the primary measure used when validating recommended medication dosing adjustments for creatinine clearance. Slightly elevated (or even “normal range”) serum creatinine levels may correlate with impaired GFR, depending on factors such as age or race (Table 40-11). Thus, the serum creatinine level alone is an inadequate clinical marker for a patient’s risk for, or the presence of, renal impairment (Levey et al., 2003).

Workup of persons identified as having CKD (by GFR) includes a complete urinalysis, renal ultrasonography, and determination of the serum creatinine and serum electrolyte levels and albumin-to-creatinine ratio. Patients should also be assessed for background risk factors that may worsen their disease. Particular emphasis should be placed on the most common problems—diabetes, hypertension, and tobacco use. Patients with class 1 CKD have evidence of renal disease (e.g., diabetes, proteinuria) but a normal GFR. Patients with type 2 diabetes and nephropathy clearly benefit from treatment with an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin receptor blocker (ARB). Furthermore, blood pressure control is critical for preventing nephropathy progression. ACE inhibitors have stronger evidence for treatment in patients with CKD without diabetes. ARBs are of uncertain benefit in this group. However, it is not clear if either drug is effective at reducing mortality rates (Clase, 2011; Sharma et al., 2011). The evidence is stronger for ARBs for preventing end-stage failure in patients with advanced nephropathy (Shlipak, 2009).

Management of patients with stage 1 or 2 CKD focuses on risk factors and preventing disease progression. Particular attention should be directed toward controlling diabetes and hypertension, if present. It is unclear if treating to certain albumin targets is helpful (Clase, 2011). CKD has numerous complications requiring regular assessment. In stage 3 CKD, family physicians should assess for anemia, neuropathy, nutrition, and disorders of bone metabolism. Patients with a GFR less than 30 should be referred to a nephrologist. Stage 4 patients should be proactively prepared for dialysis or transplantation. Patients in stage 5 should be monitored for uremia and dialysis initiated at that point (Levey et al., 2003).

CHRONIC NONBACTERIAL PROSTATITIS

The term *prostatitis* means prostate inflammation but often also implies infection (infectious causes are discussed later). However, prostatitis encompasses many different clinical entities (Table 40-12). Chronic nonbacterial prostatitis, also known as *chronic pelvic pain syndrome*, is poorly understood and better classified as a *functional* urinary tract disorder. Patients with chronic nonbacterial prostatitis can experience genital, ejaculatory, perineal, back, pelvic, or rectal pain; irritative voiding symptoms; and sexual dysfunction. Unlike those with category II prostatitis, however, patients with nonbacterial prostatitis do not experience recurrent UTIs (Stevermer and Easley, 2000). Physical examination results may be normal or reveal a tender prostate.

Chronic nonbacterial prostatitis negatively affects quality of life and is associated with depression, anxiety, and somatization (McNaughton-Collins, 2003). A potentially helpful clinical tool is the validated National Institutes of Health (NIH) Chronic Prostatitis Symptom Index, which can help define a patient's symptoms (McNaughton-Collins et al., 2007). Treatment is problematic because the underlying pathogenesis is uncertain and the evidence base poor. α -Adrenergic blockers are often initially considered because some data show reduced pain and improved quality of life. However, the evidence supporting this is inconsistent, so

Table 40-12 NIH and NIDDK Classification System for Prostatitis

Category	Name	Defining Characteristics
I	Acute bacterial prostatitis	Acute prostate infection
II	Chronic bacterial prostatitis	Recurrent prostate infection
IIIa	Chronic nonbacterial prostatitis— inflammatory chronic pelvic pain syndrome	No infection; WBCs evident in semen, prostatic secretions, or postprostate massage voided urine
IIIb	Chronic nonbacterial prostatitis— noninflammatory chronic pelvic pain syndrome	No infection; no WBCs in semen, prostatic secretions, or postprostate massage voided urine
IV	Asymptomatic inflammatory prostatitis	No subjective symptoms; WBCs in prostatic secretions or prostate tissue

WBC, White blood cell.

From McNaughton-Collins M, Joyce GF, et al. Prostatitis. In Litwin MS, Saigal CS, eds. *Urologic diseases in America*. US Department of Health and Human Services, Public Health Service, National Institutes of Health (NIH), National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). Washington, DC, US Government Printing Office, 2007; NIH Pub No 07-5512, p 13.

the benefit is uncertain (Le and Schaeffer, 2011). Routine antibiotic use is not beneficial (McNaughton-Collins et al., 2001). Patients with NIH category IIIa prostatitis can receive a trial of a fluoroquinolone antibiotic for 2 to 4 weeks or a prolonged course (4-6 weeks total) if they benefit. However, antibiotics in categories IIIb and IV prostatitis appear ineffective (Le and Schaeffer, 2011; Wagenlehner and Naber, 2003). Allopurinol, 5α -reductase inhibitors, antiinflammatory drugs, biofeedback, pentosan (Elmiron), pregabalin, prostate massage, quercetin, thermotherapy, and Sitz baths are alternatives of uncertain effectiveness (Aboumarzouk and Nelson, 2012; Le and Schaeffer, 2011; McNaughton-Collins and Wilt, 2002). As in other somatic syndromes, patients benefit from a supportive physician relationship focused on quality of life rather than cure.

ENURESIS

Nocturnal Enuresis

Enuresis is a common childhood complaint. Distinguishing *primary* enuresis (children who have never achieved a satisfactory period of nighttime dryness) from *secondary* enuresis (return of nighttime wetting after 6 months of nighttime dryness) is important; secondary enuresis indicates possible dysfunctional voiding or other pathologic condition. A child needs to be 5 years old to be considered enuretic, and children younger than 7 years may not exhibit the commitment necessary for treatment to be effective (Kiddoo, 2011). It is more common in boys and has a genetic tendency. The exact cause is unknown. Family background, life stressors, and psychological problems have not shown a causal relationship (Theidke, 2003). Enuresis typically resolves with age, although 1% of adults may have an average of 2 wet nights per week (Kiddoo, 2011).

History should focus on birth and development, family history, voiding and defecation history, signs of abnormal voiding, and parental response to the problem. A voiding diary may be helpful (Theidke, 2003). Evaluation with a urinalysis and an age-appropriate neurologic examination, including gait and anal reflex (wink), as well as close examination of the lumbosacral area, is mandatory to determine the need for further evaluation in a patient with primary nocturnal enuresis. If the history, physical examination, and urinalysis are normal, usually no further workup is indicated.

Interventions found to be beneficial for managing nocturnal enuresis include decreasing fluids at night, medications such as desmopressin and tricyclics, and conditioning therapy with nighttime bedwetting alarms with or without dry-bed training. Waking children age 4 to 5 years after 1.5 to 2 hours of sleep (“lifting”) may help reduce the number of wet nights (Caldwell et al., 2013; vanDommelen et al., 2009). A bedwetting alarm is the most effective treatment for nocturnal enuresis (Glazener et al., 2005b). Desmopressin and tricyclic medications are effective, but the effects are temporary, with a high relapse rate once discontinued (Glazener and Evans, 2002; Glazener et al., 2003; Kiddoo, 2011). Tricyclic medication side effects, such as anorexia, drowsiness, and cardiac arrhythmias, limit their use. Other medication options lack adequate evidence of efficacy (Deshpande et al., 2012). Complementary therapies and dry bed training alone have uncertain efficacy (Glazener et al., 2004; Huang et al., 2011; Kiddoo 2011). Because most children will be dry by 7 years old, reassurance may be most appropriate until that point (Kiddoo, 2011).

DYSFUNCTIONAL VOIDING

Dysfunctional voiding, a term used to describe impairments of micturition, encompasses a wide array of symptoms and can lead to significant morbidity. The typical patient is a school-age girl who may be enuretic or have recurrent UTIs. Parents will often give a history that the child “holds her urine” or demonstrates urgency with infrequent voiding. *Vincent’s curtsy* is a well-known posture assumed by these girls to help alleviate the pressure of a full bladder, which can result in a non-neurogenic neurogenic bladder. The dysfunctional voiding scoring system (DVSS) is a validated tool that can be used to diagnose and evaluate children with dysfunctional voiding (Farhat et al., 2000). Urodynamic studies, cystoscopy, and imaging studies are available in the workup of voiding dysfunction, if indicated by the history and physical examination. Treatment is designed to improve bladder tone by placing the patient on a timed voiding schedule.

ERECTILE DISORDERS

Erectile Dysfunction

Erectile dysfunction refers to “the inability to attain and/or maintain penile erection sufficient for satisfactory sexual performance” (NIH Consensus Development Panel on Impotence, 1993). Sexual function declines with age, and normal erectile function depends on a number of body systems, including cardiovascular, endocrine, muscular,

nervous, and psychological (Lue, 2000). Disorders in any of these can lead to ED, although many factors often are involved.

Risk factors include diabetes, cardiovascular diseases (e.g., hypertension, coronary heart disease, hyperlipidemia), lifestyle (e.g., alcohol, obesity, smoking), depression, neurologic disease or damage, pelvic or vascular surgery, and medications, and other endocrine and urologic disorders (Fink et al., 2002). Medications such as antidepressants and antihypertensives are often implicated, and medications play a role in as many as 25% of cases (McVary, 2007) (see eTable 40-1). Men with cardiovascular disease often experience ED before the onset of cardiac symptoms (Billups, 2005). This association suggests that ED and cardiovascular disease may be part of the same continuum for many men and that men with ED should undergo cardiac risk assessment (Gandaglia et al., 2014).

The assessment should include a general health history, with a particular focus on risk factors and psychosocial issues, such as substance use, libido, and partner relationship. Clinical survey tools such as the Sexual Health Inventory for Men (SHIM) can aid in diagnosis and treatment (Cappelleri and Rosen, 2005). Surgical and medication history is essential. The examination should focus on genitourinary, endocrine, and vascular function. Laboratory work includes urinalysis; blood count; and assessment of renal function and glucose, lipid, and serum testosterone levels. Hyperprolactinemia may cause ED, although this occurs in fewer than 2% of cases (Mikhail, 2005). Thus, determination of prolactin levels, along with free testosterone and luteinizing hormone levels, should be reserved for patients with signs or findings consistent with hypogonadism (e.g., low serum testosterone level) (Lue, 2000).

Alprostadil (intracavernosal, intraurethral), apomorphine, and PDE-5 inhibitors are effective ED treatments (Table 40-13) (Montague and Jarow, 2007). Potentially beneficial alternative therapies include yohimbine and Korean red ginseng, with ginseng having the stronger evidence base (Khera and Goldstein, 2011). Attention to lifestyle issues is important. For example, weight loss may improve sexual function in obese patients (Esposito et al., 2004). Discontinuing potentially causative medicines is an option, although the risks and benefits of this choice and its effect on other conditions must be considered. The advent of oral treatment with PDE-5 inhibitors has made these medications the drugs of first choice (Table 40-14). Cardiovascular disease is a concern with PDE-5 inhibitors because these patients may be taking nitrates or may experience cardiac symptoms from sexual exertion. The medicine itself does not cause ischemia. Furthermore, no increase in cardiovascular events or death was found in randomized trials (Fink et al., 2002). Patients with antidepressant-induced ED, primarily from selective serotonin reuptake inhibitors (SSRIs), may benefit from the addition of a PDE-5 inhibitor, a switch to a different antidepressant (e.g., bupropion), or a drug holiday (Rudkin et al., 2004; Sturpe et al., 2002). PDE-5 inhibitors may also be beneficial in patients with ED from diabetes or spinal cord injury.

One unintended consequence of widely publicized ED treatments is the negative emotions when these treatments fail, which they often do (Fink et al., 2002; Tomlinson and

Wright, 2004). Psychosexual counseling may be beneficial, although evidence is limited (Khera and Goldstein, 2011).

Premature Ejaculation

Although various definitions exist, premature ejaculation is “a male sexual dysfunction characterized by ejaculation always or nearly always occurs prior to or within about 1 minute of vaginal penetration; inability to delay ejaculation on all or nearly all vaginal penetrations; and negative personal consequences, such as distress, bother, frustration and/or the avoidance of sexual intimacy” (McMahon et al.,

2008). Sexual history, psychological history, and differentiation from ED are essential. Treatment should be tailored to the individual patient. Psychological interventions are options for willing patients, although the evidence base supporting this approach is poor (Melnik et al., 2011). No medicines are U.S. Food and Drug Administration (FDA) approved for this problem; however, exploiting side effects of SSRIs and topical anesthetics is an option (American Urological Association [AUA], 2004).

INCONTINENCE

Urinary incontinence is defined by the involuntary loss of urine. Many systems for classifying incontinence exist, but the most widely accepted divides the problem into stress, urge, and mixed incontinence (Abrams et al., 2010). *Stress* incontinence is the loss of urine with effort, exertion, or the Valsalva maneuver (e.g., coughing). *Urge* incontinence is urine leakage preceded by an urge to void. *Mixed* incontinence describes patients with symptoms from both categories. *Functional* incontinence can be used to describe patients who have incontinence with clear functional causes and who do not fit the previous categories (e.g., spinal cord injury, bedridden patient).

Urinary incontinence negatively affects quality of life through social isolation, depression, sexual dysfunction, and impaired activities of daily living (Scottish Intercollegiate Guidelines Network [SIGN], 2004). Women are more likely to experience incontinence at a younger age than men. Risk increases with age, increased weight, depression, hysterectomy, smoking, and childbirth (Melville et al., 2005; Onwude, 2009). Causes for men are not well defined but include prostate procedures. Women are less likely than men to seek medical advice for this problem (SIGN, 2004). In community-dwelling elderly persons, the rates may approach 35%, up to 60% in those at long-term care facilities (Griebing, 2009).

The evaluation should address bowel and bladder history, symptom characteristics, surgical history, and medication review. A voiding diary may be helpful in characterizing the

Table 40-13 Erectile Dysfunction Treatment Options

ATLPROSTADIL* Intracavernosal (Caverject, Edex)* Intraurethral (Muse)* Topical
APOMORPHINE (SUBLINGUAL)*
COGNITIVE-BEHAVIORAL THERAPY
GINSENG
PHOSPHODIESTERASE (TYPE 5) INHIBITORS Avanafil (Vivus) Sildenafil (Viagra)* Tadalafil (Cialis)* Vardenafil (Levitra)*
YOHIMBINE (YOCON, YOHIMEX, GENERIC)
PAPAVERINE* (ALONE OR MIXED WITH PHENTOLAMINE OR PHENTOLAMINE AND ALPROSTADIL)
PENILE PROSTHESIS SURGERY
PSYCHOSEXUAL COUNSELING
THERAPEUTIC LIFESTYLE CHANGES—SMOKING CESSATION, WEIGHT LOSS, LIMITED ALCOHOL CONSUMPTION
VACUUM DEVICE*

*These treatments have good evidence of benefit.
 †Harms may limit use. Alprostadil may cause penile pain.
 ‡Harms may limit use. Papaverine injections may alter liver function and cause penile bruising or fibrosis.
 Modified from Tharyan P, Gopalakrishnan G. Erectile dysfunction. *Clin Evid.* 2009;05:1803.

Table 40-14 Oral Phosphodiesterase Inhibitors for Erectile Dysfunction

Drug	Doses	Dosing	Side Effects, Precautions, Drug Contraindications
Avanafil (Vivus)	50, 100, 200 mg	100 mg/24 hr; 0.5 hr before intercourse; 50 mg if on α -blocker or CYP3A4	Common—headache, flushing, dyspepsia, nasal congestion, abnormal vision; serious—priapism, nonarteritic anterior ischemic optic neuropathy
Sildenafil (Viagra)	25, 50, 100 mg	50 mg (25 mg if >65 yr); 100 mg/24 hr; take 0.5-4 hr before intercourse	Caution if sexual activity or exertion risky because of existing cardiovascular disease; caution with potent CYP3A4 inhibitors; caution in renal, hepatic impairment; caution in anatomic penile deformity or risk for priapism; caution in older adults (>65 yr); caution with α -blockers*
Tadalafil (Cialis)	2.5, 5, 10, 20 mg	Daily use: 2.5 mg; may increase to 5 mg PRN use: 10 mg, 1 dose/24 hr; take before intercourse	Nitrates
Vardenafil (Levitra)	2.5, 5, 10, and 20 mg	10 mg (5 mg if >65 yr); 1 dose/24 hr; take 1 hour before intercourse	Avoid in patients with prolonged QT taking class IA or III antiarrhythmics

*Phosphodiesterase-5 (PDE-5) inhibitors should be used with caution in patients taking α -adrenergic blockers. This is no longer a contraindication based on labeling, but a number of precautions are based on potential for additive vasodilation in concomitant use:
 1. Patients should be on α -blocker therapy and stable before starting PDE-5 inhibitor.
 2. Patients who already have hemodynamic instability on α -blockers are at increased risk of additive vasodilatory effects.
 3. Use the lowest recommended dose to start.
 4. If starting α -blocker in a patient on a PDE-5 inhibitor, use the lowest dose of α -blocker.
 5. Other medications or volume status may also contribute to vasodilation and should be considered.

PRN, As needed.
 From *Physicians' desk reference*. 64th ed. Montvale, NJ: Thompson, 2010. <http://www.pdr.net>.

type of incontinence and possible overlap with syndromes such as overactive bladder. Genitourinary and neurologic examinations as well as urinalysis should be performed. A postvoid residual urine measurement is useful for men with obstructive symptoms and patients with voiding difficulty (SIGN, 2004). Urodynamic studies are of uncertain benefit. Available data suggest that these test do alter clinical approach but may not improve outcomes (Clement et al., 2013; Lemack, 2004). Urodynamics may be helpful if the cause of incontinence is uncertain (Lopez et al., 2002). Children who are thought to be incontinent—that is, those who cannot be categorized as simply enuretic or dysfunctional voiders—need more extensive evaluation.

Incontinence treatment should focus on improving quality of life. Stress and urge incontinence may be treated differently, depending on the underlying cause. Physical therapies, medications, alternative treatments, and surgery are options. Pelvic floor exercises are effective and a reasonable first choice for stress, urge, and mixed symptoms (Dumoulin et al., 2014). Available evidence suggests that bladder training is effective for urge incontinence (Teunissen et al., 2004; Wallace et al., 2004). Other options include biofeedback and electrical stimulation (Onwude, 2009). Evidence does not currently support acupuncture treatment (SIGN, 2004).

Medications include α -agonists, anticholinergics, β -agonists, estrogen, serotonin and norepinephrine reuptake inhibitors, and tricyclic antidepressants (TCAs). Oral estrogen replacement therapy should not be used because of the underlying cardiac and cancer risk, as well as the finding that it worsens incontinence (Cody et al., 2012; Hendrix et al., 2005). Topical vaginal estrogen appears effective; however, data on long-term use and effects after treatment cessation are limited or lacking. Thus, short-term use is likely most prudent at present (Cody et al., 2012).

For stress incontinence, some evidence has shown that α -agonists are more effective than placebo, but the only available form in the United States is pseudoephedrine, and side effects limit its use. TCAs are an option, but no randomized controlled trials (RCTs) have evaluated this use (SIGN, 2004). Duloxetine (Cymbalta) improves stress incontinence compared with placebo, but long-term data are lacking (Guay, 2005; Onwude, 2009). Anticholinergic drugs such as oxybutynin, tolterodine, fesoterodine, solifenacin, and darifenacin are effective for urge incontinence (Table 40-15). Trospium, a quaternary ammonium compound, is also effective (Athanasopoulos and Perimenis, 2009). Mirabegron is a newer option that works on β_3 -adrenergic receptors in the detrusor (Hersh and Salzman, 2013). Preventing incontinence would be ideal. Methods such as pelvic muscle exercises are often recommended for women after childbirth, and evidence supports this approach, which may also be beneficial before childbirth (Boyle et al., 2012). Episiotomy does not appear to reduce urinary incontinence in women (Hartmann et al., 2005).

INTERSTITIAL CYSTITIS AND BLADDER PAIN SYNDROME

Interstitial cystitis is a chronic, noninfectious bladder disorder predominantly diagnosed in women. Symptoms mimic those of a UTI (urgency, frequency) with the addition of

Table 40-15 Medications for Urinary Incontinence

Medication	Dosage
STRESS INCONTINENCE	
Duloxetine (Cymbalta)*	40 mg twice daily
Pseudoephedrine	30, 60 mg every 4-6 hr 120 mg SR daily
Estrogen*	Topical
URGE INCONTINENCE OR OVERACTIVE BLADDER	
Tolterodine (Detrol, Detrol LA)	1, 2 mg twice daily 2, 4 mg/day (LA)
Trospium (Sanctura, Sanctura XR)	20 mg twice daily 60 mg/day (XR)
Solifenacin (Vesicare)	5, 10 mg/day
Darifenacin (Enablex)	7.5, 15 mg/day

Modified from Athanasopoulos A, Perimenis P. Pharmacotherapy of urinary incontinence. *Int Urogynecol J Pelvic Floor Dysfunct.* 2009;20:475-482; *Physicians' desk reference.* 64th ed. Montvale, NJ: Thompson, 2010. <http://www.pdr.net>; and Hersh L, Salzman B. Clinical management of urinary incontinence in women. *Am Fam Physician.* 2013;87(9):634-640.

pelvic pain or pressure, dyspareunia, or both and varying with bladder filling. Although not associated with cellular change, epithelial inflammation and prolonged symptoms can lead to epithelial damage (Kahn et al., 2005). Two forms are identified: “classic” interstitial cystitis, demonstrating inflammatory bladder wall changes identifiable on cystoscopy, and *bladder pain syndrome*, defined by the symptoms of interstitial cystitis in the absence of any objective cystoscopic findings (Marinkovic et al., 2009).

The main impact of interstitial cystitis is on quality of life. Patients often express somatization and depression or anxiety; as with other somatic pain syndromes, its pathogenesis is unclear. The differential diagnosis includes other somatic syndromes such as fibromyalgia, irritable bowel, and chronic pelvic pain, as well as UTI, overactive bladder, uterine fibroids, and endometriosis. Interstitial cystitis should be considered in any patient presenting frequently with UTI symptoms. There may also be association with autoimmune disorders. Coexisting somatic syndromes are also common (Hanno et al., 2011).

Pentosan polysulfate sodium (Elmiron), 100 mg three times daily, is the only FDA-approved medication for interstitial cystitis. Adjunctive medications include antihistamines, TCAs, gabapentin, anticholinergics, and cyclosporine (Marinkovic et al., 2009). Urologic consultation should be considered. Physical therapy, counseling, and bladder training may help (Kahn et al., 2005). Pelvic floor muscle exercises are not recommended (Hanno et al., 2011). Many dietary avoidance recommendations have focused on acidic,

high-potassium foods and drinks with acid, caffeine, or alcohol. However, prospective data on dietary interventions are lacking, so such restrictions should be individualized to each patient.

OVERACTIVE BLADDER

Overactive bladder describes a clinical syndrome characterized by lower urinary tract voiding dysfunction. The International Continence Society has defined overactive bladder as “urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of UTI or other obvious pathology” (Haylen et al., 2010). The lack of specificity inherent in this definition creates potential for overlap with other urinary tract symptom complexes (e.g., LUTS) and diseases. The pathogenesis is uncertain, and urinary tract abnormalities that could cause symptoms should be ruled out. The primary dysfunction revolves around improper detrusor muscle activity and functional reductions in bladder volume. However, the definition does not exclude patients with the symptoms who do not have objective bladder hypercontractility. Furthermore, voluntary control of bladder contraction may be impaired so that the urge to void cannot be controlled (Herbison et al., 2003).

Neurologic conditions may contribute. For example, patients with multiple sclerosis, stroke, or diabetic neuropathy might manifest an overactive bladder. This might be better described as *neurogenic detrusor overactivity*, but patients without a cause or contributor might be described as having *idiopathic detrusor overactivity* (Herbison et al., 2003). Thus, overactive bladder is best viewed as a descriptive, symptom-driven complex rather than a disease.

Overactive bladder affects approximately 7% to 27% of men and 9% to 43% of women (Gormley et al., 2012). However, women are more likely to experience urge incontinence as a feature (Stewart et al., 2003). Patients may plan their days around issues such as restroom access or avoiding social settings because of incontinence. Patients may be reluctant to discuss these symptoms because of embarrassment, so family physicians may not detect the true impact of these symptoms without specific inquiry.

Physical and behavioral treatments, such as bladder training and pelvic floor exercises, are recommended as the initial approach because they are equal or superior to medications (Gormley et al., 2012). There have been no systematic reviews comparing these treatments, although incontinence data have suggested that physical therapies are a reasonable option. Many pharmacotherapy options are available for overactive bladder (see Table 40-15). Anticholinergic treatment can reduce leaking or likely voiding episodes, with dry mouth being a common side effect. A systematic review of anticholinergic medications versus placebo shows statistically significant effectiveness. However, the clinical significance is uncertain, with the exception of side effects, and long-term treatment effects are unknown (Herbison et al., 2003; Madhuvrata et al., 2012). There are small differences in effectiveness among medications, with extended-release products seeming to provide better efficacy with less dry mouth (Madhuvrata et al., 2012).

RENAL CALCULI

Adults

Approximately 9% of adults will have a kidney stone, and the chance of a recurrent stone is 50% (Parmar, 2004; Pearle et al., 2014; Teichman, 2004). Whites have the highest risk, particularly men. Family history increases the risk threefold and is present in 55% of recurrent stone formers (Teichman, 2004).

A classic history suggesting renal calculi is the abrupt onset of unilateral flank pain. It often radiates into the groin and may be accompanied by nausea and vomiting. Patients with kidney stones typically have great difficulty finding a comfortable position. On examination, there may be costo-vertebral angle or lower abdominal pain, and hematuria occurs in 90% of patients (Teichman, 2004). Patients may experience UTI symptoms such as dysuria, frequency, and urgency as the stone passes from the ureter into the bladder. However, patients with fever, microscopic signs of infection, or signs of systemic sepsis may have superimposed UTI. Complete obstruction and hydronephrosis can result in renal failure.

Helical non-contrast-enhanced CT is the test of choice for diagnosing renal calculi in adults (White, 2012). Renal ultrasonography may be helpful for children and pregnant women (Sheafor et al., 2000; White, 2012). Stones smaller than 5 mm are more likely to pass without intervention, and most do so within 6 weeks (Preminger et al., 2007; Teichman, 2004). Stones 5 mm to less than 10 mm also have a reasonable chance of passing spontaneously (47%) and observation with pain control is an option. Medical treatment with α -blockers should be considered to increase the chances of stone passage (Preminger et al., 2007; Tseng and Preminger, 2011). Stones 10 mm and greater likely require intervention (Preminger et al., 2007).

Treatment initially focuses on analgesia and relieving nausea and vomiting. Pain results from ureteral obstruction and renal capsular distention or hydronephrosis. Pain can be effectively managed with narcotic analgesics or nonsteroidal antiinflammatory drugs (diclofenac, indomethacin) (Tseng and Preminger, 2011). Ketorolac (Toradol) is more effective than meperidine (Demerol) and probably as effective as narcotics (Larkin et al., 1999; Teichman, 2004). α -Blockers such as terazosin or tamsulosin increase the likelihood of a stone passing (Tseng and Preminger, 2011).

Two thirds of stones pass spontaneously. Stones that have not passed within 4 weeks are unlikely to pass (Teichman, 2004). Urine straining is important because a captured stone can be analyzed for content (Pearle et al., 2014). Repeat imaging is needed when stone passage has not occurred or is uncertain.

It is debatable whether all patients should receive an evaluation for metabolic disorders after a first kidney stone. A reasonable workup includes an electrolyte panel, urinalysis, blood urea nitrogen, creatinine, calcium, parathyroid hormone (if calcium elevated), and stone analysis if possible. Calcium oxalate is found in 60% to 80% of stones (Parmar, 2004). Patients with recurrent stones need a more extensive evaluation, including urine culture and a 24-hour urine study to determine calcium, oxalate, uric

acid, citrate, phosphate, sodium, and creatinine levels (Teichman, 2004).

Proper hydration may help prevent recurrent stones, although this has not been tested in randomized trials. Patients should aim for urine output of 2.5 L/day (Bao and Wei, 2012; Pearle et al., 2014). Cost-effectiveness data suggest that dietary intervention is appropriate for first episodes (Lotan et al., 2004). Patients with recurrent stones need dietary intervention, a metabolic evaluation, and potassium citrate measurement. Hypercalciuria is an indication for prophylaxis with thiazide diuretics, which effectively reduce the recurrence of calcium oxalate stones. Calcium oxalate stone formers with low urinary citrate benefit from potassium citrate treatment (Pearle et al., 2014). Men with recurrent stones and idiopathic hypercalciuria will have fewer stones on a low-sodium, low-protein diet than men on a low-calcium diet (number needed to treat, 5.5 for 5 years). Low-calcium diets do not reduce stone formation (Borghi et al., 2002).

Patients with uric acid stones respond to urinary alkalization with potassium citrate (Pearle et al., 2014).

Children

Although usually considered an adult problem, children are not immune to urolithiasis. Older children present with typical symptoms, and younger children may have signs mimicking those of colic. About 15% of children presenting to the emergency department who were ultimately diagnosed with urolithiasis by CT did not have hematuria (Persaud et al., 2009). Metabolic disorders are often the cause of pediatric stones, most often hypercalciuria (Peitrow et al., 2002).

The mainstay of treatment is a high fluid intake. Urinary alkalization inhibits cystine and uric acid stones. For calcium-based stones, a diet low in sodium and oxalate and high in potassium is recommended. Excess intake of vitamins D and C is discouraged. Thiazide diuretics are also a treatment option. Gated and ungated shockwave lithotripsy has been successful treatment in children, with minimal morbidity (Shouman et al., 2009).

KEY TREATMENT

- ACE inhibitors and ARBs should be used for nephropathy prevention in diabetes (Shlipak, 2009) (SOR: A).
- Antibiotics are ineffective for chronic nonbacterial prostatitis (category IIIb, IV) (Le and Schaeffer, 2011) (SOR: A).
- Enuresis alarm helps manage nocturnal enuresis (Kiddoo, 2011) (SOR: A).
- Pelvic floor muscle exercises are used for urinary incontinence (Dumoulin et al., 2014) (SOR: B).
- Duloxetine is effective for stress incontinence (Onwude, 2009) (SOR: A).
- Anticholinergics (oxybutynin, tolterodine, solifenacin, darifenacin) and trospium are effective for urge incontinence (Madhuvrata et al., 2012) (SOR: A).
- PDE-5 inhibitors are used for ED (Khera and Goldstein, 2011) (SOR: A).
- Men with ED should be evaluated for cardiovascular disease (Gandagila et al., 2014) (SOR: B).

Infectious Disorders

Key Points

- *Neisseria gonorrhoeae* and *Chlamydia trachomatis* cause most cases of urethritis and often coexist.
- Identifying and treating asymptomatic bacteriuria is only important in pregnant women.
- Evaluate for urethritis, prostatitis, or both in men with UTI symptoms.
- Women with dysuria and frequency without vaginal symptoms have a 90% chance of UTI.
- Cranberry juice does not prevent UTIs
- The ideal evaluation of children with UTIs is controversial.

BALANITIS

Balanitis refers to inflammation of the glans penis (Figure 40-12). It may occur as a local infectious process, as part of a urethritis syndrome (e.g., Reiter syndrome), or as a skin disease (e.g., lichen sclerosis). In uncircumcised men, yeast balanitis may result from poor hygiene. Consideration should be given to dermatologic conditions and immunodeficiency (including diabetes) in circumcised men.

EPIDIDYMITIS

Epididymitis (epididymo-orchitis) often presents with testicular pain or swelling. It is usually unilateral, with a palpable, tender epididymis and possibly hydrocele. Risk factors include STI, insertive anal intercourse, invasive urinary tract procedures, and anatomic urinary tract disorders. Anatomic abnormalities are the most likely explanation in children. The differential diagnosis includes trauma, infarction, testicular cancer, and testicular torsion. Testicular cancer can be misdiagnosed as epididymitis. Thus, family physicians should emphasize close follow-up.

Chlamydia trachomatis and *N. gonorrhoeae* cause most cases in men younger than 35 years of age and usually

Figure 40-12 Circinate balanitis in a patient diagnosed with Reiter syndrome (arthritis, conjunctivitis, urethritis). (From the CDC Public Health Image Library image 5806. Courtesy Susan Lindsley and Dr. M. Rein.)

coexists with urethritis (Centers for Disease Control and Prevention [CDC], 2010). Other causative organisms include gram-negative enteric bacteria acquired during insertive anal intercourse. In men older than 35 years, causes include obstructive uropathy and invasive procedures (e.g., cystoscopy). Fungi and tuberculosis are other possible infectious causes and present as chronic epididymitis (CDC, 2010).

Treatment includes antibiotics, analgesia, and scrotal elevation. In patients in whom gonorrhea or chlamydia is the likely cause, ceftriaxone (single dose, 250 mg intramuscularly) and doxycycline (100 mg twice daily for 10 days) is the treatment of choice. In patients who are allergic to these or likely to have an enteric organism as the cause, 10 days of treatment with ofloxacin or levofloxacin is appropriate (CDC, 2010; del Rio, 2007).

PROSTATITIS

Prostatitis is a fairly common urinary tract disorder in men (Krieger et al., 2003) (see Table 40-12). Categories I (acute) and II (chronic) prostatitis are treated as infectious disorders. The four-glass method for diagnosing and localizing prostatitis is often recommended but has not been prospectively validated. A two-glass method, before and after prostate massage test, has good correlation with the four-glass method (Nickel, 2006; Sharp et al., 2010).

Acute Bacterial Prostatitis

Acute bacterial prostatitis should be suspected in men presenting with symptoms of UTI. Age and immunodeficiency contribute to men having UTIs, so prostatitis is more likely in otherwise healthy men with these symptoms (Lipsky, 1999). Patients may have UTI symptoms (e.g., dysuria, frequency, urgency) and typically systemic symptoms of acute illness, such as fever, chills, and myalgias. Local discomfort in the form of pelvic or back pain is also typical. Examination reveals a tender, boggy prostate. Most experts have recommended against prostate massage in acute prostatitis because it would be very uncomfortable and theoretically could disseminate the infection (Benway and Moon, 2008; Wagenlehner and Naber, 2003).

Abnormal urinalysis results showing nitrite and leukocyte esterase carry a 95% predictive value, but a negative test result does not rule out prostatitis. Urine and blood culture, blood count, and testing for STIs in at-risk patients are appropriate (Lipsky et al., 2010). Treatment is empiric pending the results. Depending on the degree of illness, patients may need an intravenous broad-spectrum penicillin or third-generation cephalosporin, possibly with an aminoglycoside, or a fluoroquinolone (Wagenlehner and Naber, 2003). Less severe cases can be managed with oral antibiotics. Fluoroquinolones are generally the choice, with options including trimethoprim-sulfamethoxazole (TMP-SMX) (Lipsky, 1999; Lipsky et al., 2010). An alternative when STI is likely is intramuscular (IM) ceftriaxone followed by oral doxycycline. Antibiotic therapy is typically 14 days, although some recommend 4 weeks because of concerns about antibiotics poorly penetrating prostatic tissue. Obstructive uropathy may result from prostatic enlargement; thus, assessment for this clinically or with postvoid

residual assessment should be considered (Benway and Moon, 2008).

Chronic Bacterial Prostatitis

Chronic bacterial prostatitis may manifest with irritative voiding symptoms, prostatitic obstruction, or recurrent UTIs (Lipsky, 1999). Patients may have microscopic pyuria but negative culture results. Other symptoms include hemospemia, penile discharge, and systemic symptoms.

Longer courses of antibiotics are necessary for treatment, although the ideal duration is uncertain. Generally, treatment is for a minimum of 4 weeks, with fluoroquinolones being the treatment of choice. If an atypical infection such as chlamydia is a consideration, then a macrolide is likely more effective (Perletti, 2013). α -Adrenergic blockers may provide benefit when added to antimicrobials, but this has not been assessed in RCTs (Le and Schaeffer, 2011). Patients with recurrent symptoms may need longer antibiotic courses, urologic consultation, or reconsideration of their diagnosis.

SEXUALLY TRANSMITTED INFECTIONS

Chancroid

Chancroid is caused by infection with *Haemophilus ducreyi*. A clinical syndrome of painful genital ulcers and adenopathy (the patient does not have syphilis; ulcers are herpes negative) allows for presumptive diagnosis (Figure 40-13). Many treatment options exist (Table 40-16).

Gonorrhea and Nongonococcal Urethritis

Urethritis may present as a urethral discharge or simply dysuria. Family physicians should suspect urethritis in patients with symptoms of UTI, pyuria, presence of leukocyte esterase, and negative urine culture results. *N. gonorrhoeae* and *C. trachomatis* are the most important causative organisms. Gonococcal urethritis is typically symptomatic. Chlamydia causes most cases of nongonococcal urethritis (CDC, 2010). Patients need to be tested for both organisms because co-infection is common (CDC, 2010). Various treatment options exist (see Table 40-16). Patients with gonorrhea should be treated with IM ceftriaxone plus oral treatment with either azithromycin or doxycycline. Fluoroquinolones are no longer recommended because of

Figure 40-13 Chancroid: penile lesions and inguinal adenopathy. (From the CDC Public Health Image Library image 4419. Courtesy Pledger.)

Table 40-16 Treatment for Selected Sexually Transmitted Infections*

STI	Medication	Dose	Route*	Duration
Chancroid	Azithromycin	1000 mg	PO	Single dose
	Ceftriaxone [†]	250 mg	IM	Single dose
	Ciprofloxacin	500 mg	PO	Twice daily for 3 days
	Erythromycin base	500 mg	PO	Three times daily for 7 days
Chlamydia	Azithromycin	1000 mg	PO	Single dose
	Doxycycline	100 mg	PO	Twice daily for 7 days
Gonorrhea	Ceftriaxone [†]	250 mg	IM	Single dose
	plus Azithromycin	1000 mg	PO	Single dose
	or Doxycycline	100 mg	PO	Twice daily for 7 days
Syphilis, primary	Penicillin	2.4 million U	IM	Single dose

*For full recommendations including treatment alternatives, see Centers for Disease Control and Prevention (CDC). Sexually transmitted disease treatment guidelines, 2010. *MMWR Recomm Rep.* 2010;59(No. RR-12):1-109. Available at www.cdc.gov.

[†]Cefixime 400 mg is optional if ceftriaxone is not available. However, patients need a test of cure 1 week after treatment.

IM, Intramuscular; PO, oral.

resistance rates (CDC, 2010; Del Rio et al., 2007). Furthermore, oral cephalosporins are no longer recommended as first-line treatment (Del Rio et al., 2012).

Herpes Genitalis

Herpes simplex virus type 2 (HSV-2) causes most genital herpes infections, although HSV-1 is increasingly a cause (CDC, 2010). An estimated 20% of those older than 12 years have it, and infection is often asymptomatic (U.S. Preventive Services Task Force [USPSTF], 2005). Symptoms, if present, may present as multiple, small, painful ulcers or vesicles (Figure 40-14). The causative virus is prognostically important, so confirmatory testing is recommended. Polymerase chain reaction testing is recommended, but a Tzanck preparation is not (CDC, 2010). Serologic tests for herpes IgG are available but do not differentiate acute from remote infection. Herpes IgM testing does not reliably differentiate HSV-1 from HSV-2 (CDC, 2010). The USPSTF recommends against routine screening for HSV in asymptomatic adults because there is no evidence that this decreases disease transmission or reduces morbidity (USPSTF, 2005). Antiviral medications can treat initial and

Table 40-17 Treatment Options for Genital Warts

Treatment	Dose or Form	Notes
Imiquimod	1%, 5% cream	5% more effective but greater skin irritation Unknown effectiveness in patients with HIV
Interferon	Topical	Expensive
Podophyllotoxin	Topical	Skin burning, bleeding
Bichloroacetic acid, trichloroacetic acid	Topical	Office application
Cryotherapy		Office treatment
Surgical excision, electrosurgical excision		Office treatment

Buck HW. Warts (genital). *Clin Evid (Online)*. 2010;2010:1602.

recurrent acute outbreaks and can be used as prophylaxis to prevent recurrent outbreaks (Hollier and Straub, 2011).

Human Papillomavirus

Human papillomavirus (HPV) may cause symptomatic genital warts, although most patients do not manifest them. HPV types 6 and 11 cause most visible warts (CDC, 2010). Certain HPV types are associated with genital squamous neoplasia. Placing an acetic acid solution on the plaque and looking for an acetowhite change is not a sensitive test (CDC, 2010). Untreated warts will regress, remain stable, or spread; treatment is primarily symptomatic (Table 40-17).

Syphilis

Primary *Treponema pallidum* infection manifests as a painless genital ulcer known as a *chancre* (Figure 40-15). The diagnosis combines nontreponemal screening tests (rapid plasma reagin, Venereal Disease Research Laboratories) with confirmatory treponemal-specific tests (fluorescent treponemal antibody absorption, *Treponema pallidum* passive particle agglutination, and immunoassays). *T. pallidum* is difficult to culture, so darkfield microscopy or fluorescent antibody testing of a tissue specimen provides definitive diagnosis. Primary syphilis is treated with a single dose of

Figure 40-15 Chancre of primary syphilis. (From CDC Public Health Image Library image 6803. Courtesy Dr. M. Rein.)

penicillin (2.4 million units IM in adults and 50,000 to 2.4 million U/kg IM in children) (CDC, 2010). Penicillin remains the primary treatment option for all populations, although there is limited evidence supporting alternatives such as doxycycline and tetracycline for penicillin-allergic patients (CDC, 2010).

URINARY TRACT INFECTIONS

Urinary tract infections are the most common urologic issue encountered by family physicians and one of the most common diagnoses overall (Stange et al., 1998). Most are uncomplicated lower UTIs, such as cystitis.

Asymptomatic Bacteriuria

Approximately 5% of reproductive-age women have asymptomatic bacteriuria (Bent et al., 2002). It is also common in older adults. This is important for understanding the community risk of UTI when evaluating a patient with UTI symptoms. However, although asymptomatic bacteriuria may conceptually place a patient at risk for UTI, identification and treatment do not appear to affect morbidity or mortality (Lin and Fajardo, 2008). Thus, bacteriuria screening is not recommended (USPSTF, 2008).

In contrast, pregnant women do benefit from screening. Testing with urine culture should be done in all pregnant women at 12 to 16 weeks of gestation (USPSTF, 2008). Urine culture is the best method because dipstick testing and microscopy are not accurate enough tests to predict this condition.

Uncomplicated Cystitis

Most UTIs manifest as acute uncomplicated bacterial cystitis, and women experience most of these episodes. *E. coli* causes up to 90% of cases, with the rest probably caused by *Staphylococcus saprophyticus*. Other causative organisms include *Proteus mirabilis*, enterococci, and *Klebsiella* spp. (Fihn, 2003). To have “uncomplicated cystitis,” women must have no underlying urinary tract abnormalities or immune compromise (Bent et al., 2002).

Dysuria, frequency, and urgency are the classic clinical triad. The condition most commonly mimicking UTI is vaginitis. Other conditions have been described (see “Dysuria”).

Table 40-18 Treatment Options for Acute Uncomplicated Urinary Tract Infections*

Medication	Dose	Regimen	Duration
Trimethoprim–sulfamethoxazole (Bactrim DS, Cotrim DS, Septra DS)	160/800 mg	Twice daily	3 days
Nitrofurantoin monohydrate macrocrystals (Macrobid)	100 mg	Twice daily	7 days
Ciprofloxacin (Cipro)	250 mg	Twice daily	3 days
Levofloxacin (Levaquin)	250 mg	Once daily	3 days
Norfloxacin (Noroxin)	400 mg	Twice daily	3 days
Ofloxacin (Floxin)	200 mg	Twice daily	3 days
Fosfomycin (Monurol)	3 g	Single dose	Single dose

* β -Lactams agents may be used as an alternative to quinolones, but amoxicillin or ampicillin should be avoided.

DS, Double strength.

Adapted from Gupta K, Hooton TM, Naber KG, et al. International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. *Clin Infect Dis*. 2011; 52(5): e103–e120 and Grabe M, Bjerklund-Johansen TE, Botto H, et al. *Guidelines on urological infections*. European Association of Urology; 2011.

Patients may also experience back or flank pain and suprapubic abdominal pain. Dipstick urinalysis may show leukocyte esterase or nitrite or may be heme positive. Microscopic analysis should assess for pyuria, hematuria, and bacteriuria. The gold standard for diagnosis is urine culture.

Women presenting with at least one UTI symptom have a 50% chance of having a UTI. The combination of dysuria and frequency without vaginal symptoms increases the chance to 90% (likelihood ratio, 24.6). Four symptoms significantly increase the chance of UTI—dysuria, frequency, hematuria, and back pain (Bent et al., 2002). Overall, no clinical symptom strongly indicates UTI. Nitrite-positive or leukocyte esterase-positive dipsticks are the most accurate tests but cannot rule out a UTI if negative (Medina-Bombardó and Jover-Palmer, 2011).

Antibiotics are the mainstay of treatment (Table 40-18). A shorter duration is as effective as longer therapy for most women, including older adult women (Lutters and Vogt, 2002; Milo et al., 2005). In the southeastern and southwestern United States, there is growing *E. coli* resistance to TMP-SMX, leading some to recommend that this should no longer be first-line treatment for UTIs. However, many women treated with TMP-SMX who have a resistant organism on culture achieve clinical cure (Fihn, 2003). Compared with quinolones' propensity for resistance, TMP-SMX is still a reasonable first choice for many patients, and family physicians should base treatment choices on documented local resistance patterns. If resistance to TMP-SMX exceeds 20%, an alternative treatment should be used (Gupta et al., 2011).

Complicated Infection

Complicated UTIs are characterized by signs and symptoms of upper tract (i.e., renal) involvement or by factors that predispose to upper tract involvement. UTIs with signs of

renal or systemic involvement are also called *pyelonephritis*. Most cases of pyelonephritis are caused by ascending bacterial infection from the bladder (Ramakrishnan and Scheid, 2005).

Symptoms include fever, flank pain, nausea, vomiting, and costovertebral angle tenderness. Findings such as pyuria are typical, and urine culture results are usually positive. WBC casts may be present on urine microscopy. Hospitalized patients with UTIs are best managed based on culture results. *E. coli* is the typical pathogen for uncomplicated outpatient UTIs and pyelonephritis. *E. coli* is still the most common isolate in hospitalized patients, but now to a lesser extent as *Enterococcus*, *Pseudomonas*, and *Staphylococcus* spp. have become more likely (Graham and Galloway, 2001; Scholes et al., 2005). Blood cultures do not necessarily change management (Ramakrishnan and Scheid, 2005). Imaging, such as renal ultrasonography, is sometimes recommended, but it also does not necessarily change management and thus can be used at clinical discretion (Nicolle, 2008).

Outpatients can be managed with an oral fluoroquinolone. Hospitalized patients should receive a fluoroquinolone, an aminoglycoside with or without ampicillin, or an extended-spectrum cephalosporin with or without an aminoglycoside. Patients with cultures showing gram-positive cocci should receive an aminopenicillin along with a β -lactamase inhibitor (Grabe, 2011). Treatment for 7 to 14 days is usually adequate; however, an optimum treatment course is unknown because randomized trials of antibiotic treatment are lacking (Neumann and Moore, 2011). Resistant bacteria and renal calculi are the most common causes of treatment failure (Ramakrishnan and Scheid, 2005).

Recurrent Infections

In healthy, nonpregnant women, recurrent UTI can be defined as three episodes in 1 year or two episodes in 6 months (Sen, 2008). Patients with urinary tract pathology or other conditions impacting urinary function (e.g., neurogenic bladder) may require consultation. Self-diagnosis has an 84% PPV in women with recurrent UTIs (Bent et al., 2002). Cultures are helpful in guiding antibiotic choice (Table 40-19). Prophylactic antibiotics are effective for the subset of women with recurrent symptomatic UTI, although

choice of patient and duration is uncertain. Because sexual activity is associated with developing UTIs, many physicians recommend that women void immediately after intercourse. However, the poor-quality study examining this practice found no significant effect (Beisel et al., 2002). Thus, no evidence supports recommending this practice to patients. In contrast, postcoital antibiotic prophylaxis reduces the incidence of cystitis (Sen, 2008). Furthermore, it may be as effective as continuous prophylaxis at reducing recurrence because women in one RCT comparing these methods showed no difference in UTI rates (Albert et al., 2004). In postmenopausal women, topical estrogen is often proposed, but this also lacks good supporting evidence (Sen, 2008).

Cranberry juice is promoted as a potential preventive treatment for recurrent UTI because of chemical effects inhibiting bacterial adherence to uroepithelial cells (Raz et al., 2004). However, meta-analysis revealed a lack of efficacy in preventing recurrent UTIs (Jepson, 2012).

Urinary Tract Infections in Children

An estimated 3% to 8% of girls and 1% to 2% of boys will have a UTI (Foxman, 2002; Hellstrom et al., 1991). *Pyelonephritis* is a clinical diagnosis and is the most common documented serious bacterial infection in febrile infants. *Cystitis* is common in school-age children and adolescents and, as a general rule, is not a condition of infants or pre-toilet-trained toddlers. Risk factors for UTI range from constipation and dysfunctional voiding to congenital uropathies. Presenting symptoms vary with age and site of infection and may be nonspecific in younger children. Pyelonephritis in infants, for example, may present with fever, irritability, vomiting, diarrhea, poor feeding, or failure to thrive. School-age children and adolescents may present with fever, vomiting, and flank pain. Symptoms of cystitis are more common after age 2 years and may include dysuria, frequency, urgency, and low-grade fever ($<38.3^{\circ}\text{C}$).

As with adults, the gold standard test in children is an appropriately obtained urine culture. In neonates and young infants, it is the ideal collection method. Either catheterization or a suprapubic aspiration is needed until the child is old enough to collect a midstream clean-catch specimen. Bag urine collections are unreliable and increase the number of ambiguous cultures (American Academy of Pediatrics [AAP], 2011; Schroeder et al., 2005). Many elements of the urinalysis have been viewed as tools for aiding diagnosis of UTI. Inadequate sensitivity and specificity continue to support use of urine culture (AAP, 2011). Furthermore, no RCTs have evaluated clinical empiric treatment versus awaiting culture results (Larcombe, 2010). However, pyuria (>5 WBCs/hpf) and a positive Gram stain result are helpful in making the decision to initiate early antibiotic therapy, pending culture results.

Treatment remains somewhat controversial, particularly the choice between parenteral and oral antibiotics in the setting of pyelonephritis. For children with pyelonephritis, therapeutic goals include treating or preventing systemic complications of bacteremia, preventing renal sequelae, and ameliorating acute symptoms. Historically, parenteral antibiotics have been the preferred option, particularly in younger children with pyelonephritis. This remains true for infants younger than 4 weeks, who should be hospitalized

Table 40-19 Selected Antibiotics for Uncomplicated Urinary Tract Infection Prophylaxis*

Drug	Pediatric Dose	Adult Dose*
Amoxicillin	10 mg/kg once daily	N/A
TMP-SMX	2 mg/kg once daily based on TMP	Single strength (80/400 mg), half-tablet at night or three times weekly
Trimethoprim	N/A	100 mg nightly
Nitrofurantoin	1-2 mg/kg once daily	50 or 100 mg nightly
Ciprofloxacin	N/A	125 mg/day
Norfloxacin	N/A	200 mg nightly

*Postcoital prophylaxis options: TMP-SMX, nitrofurantoin, fluoroquinolones. N/A, Not applicable; TMP-SMX, trimethoprim-sulfamethoxazole. Adult dosing adapted from Grabe et al., 2011.

and receive parenteral therapy. This is also true for older infants and children assessed at high risk because of a septic appearance, vomiting or inability to take oral fluids and medications, dehydration, or concerns regarding compliance. However, most children can be treated with oral antibiotics (AAP, 2011). The choice of parenteral antibiotic includes ampicillin in combination with gentamicin or cefotaxime for neonates and third-generation cephalosporin alone for older children. In these cases, transition to oral therapy follows when culture results and sensitivities are known and signs of systemic infection have resolved. Follow-up urine cultures to test for cure are unnecessary in patients with good clinical response, although advice regarding reevaluation for febrile illnesses should be provided (AAP, 2011). Prolonged parenteral therapy is indicated for septic infants. For children 1 month and older not assessed as high risk, it now appears that oral antibiotics are equally effective not only regarding course of illness but also in preventing renal scarring (Montini et al., 2007). Options for initial oral therapy include amoxicillin-clavulanic acid, TMP-SMX (>2 months), and cephalosporins. Because of the increasing incidence of UTI with ampicillin-resistant *E. coli*, amoxicillin is no longer the preferred initial choice. The recommended length of therapy is typically 7 to 10 days for an uncomplicated UTI (i.e., cystitis) and 10 to 14 days for pyelonephritis (AAP, 2011; Larcombe, 2010).

The most appropriate evaluation after a child's first UTI is controversial (Layton, 2003). Traditionally, children have undergone a complete evaluation for underlying urologic abnormalities that would increase the risk of further infections and renal scarring, including renal ultrasonography and VCUG. In 309 children younger than 24 months with their first febrile UTI, ultrasonography was of limited value because it did not change management, and other tests may be obviated by routine cultures for children with a febrile illness after a prior UTI (Hoberman et al., 2003). However, 29% of 390 children younger than age 5 years with a first-time febrile UTI had abnormal renal ultrasound findings (Huang et al., 2008). Therefore, renal and bladder ultrasonography is recommended (AAP, 2011).

The most common uropathy associated with pediatric UTI is VUR, occurring in 30% to 40% of cases. Reflux is diagnosed by VCUG and graded on a scale of 1 to 5, with grade 5 being the most severe. The degree of VUR is directly proportional to the incidence of renal scarring. In addition to the standard fluoroscopic VCUG, radionuclide cystography may be performed. This test has the advantage of less radiation exposure but is lacking in anatomic detail and is most often used for follow-up studies. The traditional approach to a patient with VUR has been prophylactic antibiotics, with surgical intervention reserved for complicated patients with breakthrough UTIs and evidence of renal injury (see Table 40-19). Deflux is a newer, less invasive procedure performed using cystoscopy and is proving to be highly effective in the treatment of reflux. However, the management of VUR is a rapidly evolving field and remains controversial. Evidence supporting prolonged antibiotic prophylaxis is weak because of a lack of properly designed RCTs (Williams and Craig, 2011). Also, evidence is lacking showing that surgical repair is superior to medical management for reducing negative outcomes in children with

moderate to severe VUR (Larcombe, 2010). The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study is a multicenter, randomized, double-blind prospective study currently in progress in the United States designed to assess the efficacy of prophylactic antibiotics in the treatment of grade 1 to 4 VUR in children age 2 months to 6 years. Initial findings show that children receiving prophylaxis have fewer UTIs but not reduced renal scarring (RIVUR Trial Investigators, 2014). Present guidelines do not recommend VCUG after the initial febrile UTI, but evaluation should be considered in recurrences, if there are findings on ultrasonography, or in special clinical situations (AAP, 2011). Renal scintigraphy (dimercaptosuccinic acid [DMSA] scan) has been recommended to help diagnose pyelonephritis. This is also controversial because false-negative results could lead to undertreating children with pyelonephritis. DMSA scanning has shown promise in predicting higher grades of reflux in older infants and children (Lee et al., 2009), but this has not been true in neonates (Siomou et al., 2009). DMSA scans are not recommended routinely in children with UTI (AAP, 2011).

The ultimate goal in the approach to patients with UTI is to prevent morbidity. Renal scarring may ultimately manifest as hypertension, proteinuria, or both. The incidence of renal scarring in patients with UTI is increased in children younger than 3 years, presence of VUR proportional to grade of reflux, recurrent UTI, and delayed or inadequate therapy.

KEY TREATMENT

- Continuous and postcoital antibiotics are equally effective for recurrent UTI (Sen, 2008) (SOR: A).
- IM ceftriaxone plus azithromycin or doxycycline is used for gonorrhea (CDC, 2010; Del Rio et al., 2012) (SOR: C).
- Fluoroquinolones should not be used to treat gonorrhea (CDC, 2010; Del Rio, 2007) (SOR: C).
- Screen for asymptomatic bacteruria in pregnant women at 12 to 16 weeks (USPSTF, 2008) (SOR: A).

Neoplastic Disorders

Key Points

- BPH is a finding in many, but not all, men experiencing LUTS. LUTS vary and may not correlate with prostate size.
- α -Adrenergic antagonists and 5 α -reductase inhibitors are effective for BPH and LUTS.
- Smoking is the top risk factor for bladder cancer, and hematuria is the most common presenting sign.
- Prostate cancer is the most common cancer in men and second most common cause of male cancer death.
- There is no prostate-specific antigen (PSA) value that is both sensitive and specific for prostate cancer.
- When ordering a PSA test, family physicians should discuss the risk, benefits, and uncertainties with patients so a shared decision can be made.
- The value of testicular self-examination is unknown.

BENIGN NEOPLASIA: BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia is a common problem for men. More than 50% of men older than 60 years have BPH, and this reaches 80% by 80 years of age (Dull et al., 2002; Thorpe and Neal, 2003). The exact pathogenesis of BPH is uncertain, but it is characterized by epithelial and stromal cell proliferation in the periurethral prostate tissue.

The LUTS syndrome (see earlier) overlaps with BPH because up to 30% of men have LUTS (Thorpe and Neal, 2003). The symptoms defining LUTS were once thought to be solely indicative of BPH. However, LUTS may arise from other disorders (e.g., detrusor dysfunction), and there is a lack of symptomatic correlation with prostate size. However, outflow obstruction from an enlarged prostate may contribute to the development of detrusor dysfunction and urinary retention, referred to as LUTS-BPH. More specifically, BPH refers to a histologic abnormality, and LUTS describes the symptom complex that may result (AUA, 2010).

The diagnosis focuses on patient history, rectal examination, and impact on quality of life. Symptoms can vary over time even without treatment; however, the course is typically progressive, and 1% to 2% of men with BPH experience acute urinary retention annually (McNicholas and Kirby, 2011). Various measures exist for measuring symptom severity. The most widely used and well validated is the International Prostate Symptom Score. This scoring system can discriminate the severity of symptoms and treatment response. However, it does not correlate with anatomic findings or objective measures of urinary flow (Barry and O'Leary, 1995). PSA values may increase with prostate hyperplasia, but the overlap with prostate cancer makes this of limited use in managing BPH (Barry, 2001).

Medical therapies have overtaken surgical as the most common treatments. α -Adrenergic blocking drugs improve urinary symptoms in BPH (McNicholas and Kirby, 2011; Wilt et al., 2008). α -Adrenergic antagonists block adrenoceptors in the prostate and bladder neck (Table 40-20). They may also induce prostate epithelial apoptosis (Thorpe and Neal, 2003). Side effects, particularly blood pressure effects, are important because these drugs will most often be used in older adults (Schulman, 2003). Furthermore, α -blockers carry labeling cautioning use around the time of cataract surgery (AUA, 2010; Bell, 2009).

Prostate tissue is androgen responsive throughout life. 5α -Reductase inhibitors inhibit the conversion of testosterone to dihydrotestosterone, leading to glandular atrophy and reduced prostate volume (20%-30%) (Thorpe and Neal, 2003). It takes many months for these medicines to become effective. Sexual side effects are the most prominent. These drugs also reduce PSA by up to 50%. Based on the Prostate Cancer Prevention Trial, family physicians should discuss potential benefits and harms of 5α -reductase inhibitors (see "Prostate Cancer") when using these medications for BPH and LUTS (Kramer et al., 2009). Given that these drugs address prostate size, they are not recommended for treating LUTS absent prostate enlargement (AUA, 2010).

Prostate enlargement can progress enough to obstruct the bladder outlet completely, leading to acute urinary retention. If this occurs, catheterization is warranted. The addition of an α -blocker may aid in voiding after the

Table 40-20 Pharmacotherapy for Benign Prostatic Hyperplasia

Drug	Dosage	Adverse Effects
α-ADRENERGIC BLOCKERS		
Alfuzosin (Uroxatral)	10 mg/day	Cardiovascular: dizziness, postural hypotension, syncope
Doxazosin (Cardura, generic)	1-8 mg/day	Ocular: warning for use around cataract surgery, intraoperative floppy iris syndrome
Terazosin (Hytrin, generic)	1-10 mg at bedtime	
Tamsulosin (Flomax)*†	0.4 mg/day	Sexual: ejaculatory dysfunction
Sildenafil (Rapaflo)	8 mg/day	Systemic: asthenia, drowsiness, fatigue, headache
5α-REDUCTASE INHIBITORS		
Dutasteride (Avodart)	0.5 mg/day	Sexual: impotence, decreased libido, ejaculatory dysfunction
Finasteride (Proscar)	5 mg/day	

* α -1 adrenoceptor selective.

†Hypotension risk is greatest during the first 8 weeks of treatment.

From Schulman CC. Lower urinary tract symptoms/benign prostatic hyperplasia: minimizing morbidity caused by treatment. *Urology*. 2003;62:24-33; Schwinn DA, Price DT, Narayan P. α -Adrenoceptor subtype selectivity and lower urinary tract symptoms. *Mayo Clin Proc*. 2004;79:1423-1434; Thorpe A, Neal D. Benign prostatic hyperplasia. *Lancet*. 2003;361:1359-1367; American Urological Association guideline: management of benign prostatic hyperplasia (BPH). *American Urological Association Education and Research, Inc*; 2010; and Bird ST, Delany JAC, Brophy JM, et al. Tamsulosin treatment for benign prostatic hyperplasia and risk of severe hypotension in men aged 40-85 years in the United States: risk window analyses using between and with patient methodology. *BMJ*. 2013;347:f6320.

catheter is removed (Thorpe and Neal, 2003). A randomized, double-blind trial of doxazosin and finasteride over 4 years showed that combining these two medications significantly slowed symptomatic progression and reduced the risk of urinary retention and invasive treatment. Treatment was safe, and the effect of combined treatment on symptom scores was greater than the effect of either agent alone (McConnell et al., 2003).

Given the commonality of BPH and LUTS, there is interest in alternative therapies. Saw palmetto extract (*Serenoa repens*) once held promise; however, high-quality evidence shows that it is not an effective treatment (Tacklind et al., 2012). β -Sitosterols may be effective, and pygeum (African plum, *Prunus africanus*) and rye grass pollen (cernilton) have uncertain efficacy (McNicholas and Kirby, 2011).

MALIGNANT NEOPLASIAS

With the exception of prostate cancer, urologic malignancy is relatively uncommon in the general population. After prostate cancer, which is the most common cancer diagnosed in men, the next most common cancers are bladder and kidney cancers (American Cancer Society [ACS], 2013). Testicular cancer is relatively common in young men compared with other cancers in that age group.

Bladder Cancer

Bladder cancer incidence increases with age and occurs four times more often in men than women. Its incidence in

white men is twofold higher than in African American men (ACS, 2013; National Cancer Institute [NCI], 2013a).

Cigarette smoking is the most prominent risk factor, increasing the risk four- to sevenfold. Aminobiphenyl is a cigarette carcinogen linked to bladder cancer. Smoking cessation decreases the risk, although it still remains twofold higher 10 years after cessation. Other risk factors include exposure to the aromatic amines used in the dye and rubber industry, benzidine production, paint, metal, and petroleum manufacturing. Medical risks include cyclophosphamide, radiation, and prolonged exposure to foreign bodies (e.g., catheter). Finally, aristolochic acid, found in certain weight loss supplements and traditional Chinese herbal compounds containing *Aristolochia fangchi*, may increase the risk. Banned in many Western countries, it is still available in the United States (NCI, 2013a).

Hematuria is the most common sign of bladder cancer (NCI, 2013a), and the diagnosis is most often made by direct bladder visualization (cystoscopy) and biopsy. However, the prevalence of bladder cancer is low, and most patients with hematuria do not have bladder tumors. Positive urine cytology results are essentially diagnostic, although false-negative results limit the usefulness of this approach alone. No imaging test can reliably detect bladder cancers.

The USPSTF (2011a) does not recommend for or against screening asymptomatic persons for bladder cancer because of insufficient evidence.

Penile Cancers

Penile cancers are rare, with 1570 new U.S. cases in 2013 (ACS, 2013). Penile cancers are most often squamous cell, and there may be a connection to HPV infection. As expected from this cell type, lesions may appear as a superficial plaque or ulcer. Biopsy or consultation is appropriate in the evaluation of a suspicious penile lesion.

Prostate Cancer

Prostate cancer is the most common cancer diagnosed in men and is the second most common cause of cancer death in men after lung cancer. The gap between the annual numbers of diagnoses (238,590) and deaths (29,720) is wide (ACS, 2013). Major risk factors include age, African American race, and family history. Most cases occur in men older than 65 years of age. African Americans have a 70% higher incidence than whites and experience a disproportionate share of prostate cancer deaths (ACS, 2013).

Dietary factors may play a role, including an elevated risk with proandrogenic effects of dietary fat and carcinogenic compounds in grilled meats and a reduced risk with antioxidants in vegetables (Nelson et al., 2003). Dietary antioxidants such as lycopene show epidemiologic links supporting a preventive effect, with possible mechanisms including androgen inhibition (Wertz et al., 2004). However, an RCT using vitamin E and selenium, alone or in combination, showed that vitamin E increases the risk of prostate cancer (Klein et al., 2011; Lippman et al., 2009). Furthermore, there is a lack of evidence to know whether lycopene provides preventive benefit (Ilic et al., 2011). Given these results and prior disappointing results of other antioxidant trials, clinicians should not recommend supplements for prostate cancer prevention.

Prostate cancer is most often indolent, with symptoms typically arising later in the disease course (Johansson et al., 2004). Physical examination is most often unrevealing. A firm nodule on DRE may indicate a tumor. However, DRE accuracy depends on the performing physician and is imprecise. An abnormal DRE predicts prostate cancer in 18% to 28% of cases (Schwartz et al., 2005). Furthermore, up to 25% of biopsy-detected cancers after an abnormal DRE occur on the side opposite the palpated nodule (McNaughton-Collins et al., 1997). Thus, although DRE may be a potentially useful examination in a symptomatic patient, it does not play a prominent role in general population prostate cancer screening.

Prostate-specific antigen is a glycoprotein produced by prostatic epithelial cells. Its level increases with prostate adenocarcinoma, hyperplasia, inflammation, procedures, ejaculation, and massage. However, clinical DRE should not affect the PSA level (Barry, 2001). The most widely accepted upper limit of normal for total PSA is 4.0 ng/mL. The Prostate Cancer Prevention Trial, using a biopsy standard, indicated that as PSA levels increase, sensitivity declines and specificity increases, and at no point is there a good balance between the two (Thompson et al., 2005). Thus, cancer appears ubiquitous—men with normal-range PSA levels may have prostate cancer; 15% of men with a PSA less than 4.0 ng/mL have cancer, 15% of which are high-grade tumors (Thompson et al., 2004). Furthermore, although some studies have concluded that a lower abnormal PSA cutoff level would detect more cancer (Punglia et al., 2003), these findings indicate that more men would have unnecessary biopsies. Thus, PSA testing suffers from both a high false-positive and a false-negative rate (Harvey et al., 2009). Emerging data suggest that less frequent testing and adjusting the cutoff point for further testing upward could be helpful (Hayes and Barry, 2014).

Tumors are most often diagnosed after biopsy for an abnormal screening result. The Gleason score grades cellular differentiation of the two most common patterns seen in a biopsy specimen. Scores range from 2 to 10, with higher scores indicating a more poorly differentiated tumor (Schwartz et al., 2005). The risk of prostate cancer death is higher with poorly differentiated cancer. Whereas men with low Gleason scores (2-4) have a low risk of death, those with higher scores (8-10) had a high probability of dying from prostate cancer within 10 years (Albertson et al., 2005).

Treatment options for patients with prostate cancer include watchful waiting, brachytherapy, external-beam radiation, prostatectomy, androgen ablation, and combinations of these options. High-grade tumors receive aggressive treatment, but the ideal treatment for intermediate-grade tumors (Gleason score of 5 to 7) is controversial. Low-grade tumors are candidates for watchful waiting. Treatment for localized disease, regardless of method, carries the risk of persistent negative effects on quality of life, such as sexual, urinary, and bowel dysfunction (Smith et al., 2009). An RCT of prostatectomy versus watchful waiting for low-grade tumors in Scandinavian men found little difference in outcomes during early follow-up, but at 15 years, the prostatectomy group had a lower risk of prostate cancer death and lower overall mortality (Bill-Axelsson et al., 2005, 2014; Holmberg et al.,

2002). The U.S Prostate Cancer Intervention Versus Observation Trial (PIVOT) found no improvements in all cause or prostate cancer–specific mortality at 12 years from prostatectomy versus observation in men with localized tumors (Wilt et al., 2012).

Men may be more comfortable with an aggressive approach to even localized prostate cancer and choose treatment accordingly (Xu et al., 2012). Because PSA testing will detect cancers early, patients may live longer with the disease but not actually live longer lives (lead-time bias). Also, some patients treated for PSA-detected cancer may not have aggressive tumors. Treating them may artificially elevate treatment success and survival rates (length-time bias). Thus, mortality rate reductions may reflect the success of screening, misattribution of cause of death, research bias, improved treatments, or changing disease patterns. The most significant challenge remains that there is no way to differentiate patients with aggressive disease from those with clinically unimportant disease using current screening tools. Until this is resolved, controversy surrounding prostate cancer screening will persist.

Two large, randomized screening trials, the Prostate, Lung, Colorectal, and Ovary (PLCO) trial and the European Randomized Study of Screening for Prostate Cancer (ERSPC), evaluated the impact of screening on mortality. ERSPC did not show an overall mortality benefit but did show a 20% relative reduction in prostate cancer death (absolute risk reduction, 0.07%); 1410 men would need to be screened and 48 prostate cancer cases treated to prevent one death in 10 years. Overdiagnosis of clinically insignificant prostate cancer was a problem (Chou et al., 2011; Schroder et al., 2009). In contrast, the PLCO trial found no differences in prostate cancer or all-cause mortality between the test and control groups (Andriole et al., 2009). A meta-analysis of prostate cancer screening failed to show a significant impact on prostate cancer mortality (Ilic et al., 2013).

Despite any clear evidence showing that screening saves lives, PSA testing remains common (Thompson et al., 2005). PSA testing is a well-known test, with men possibly believing that being screened is beneficial and responsible behavior (Chapple et al., 2002). Furthermore, the PSA test has accuracy problems, which makes reassuring patients with normal-range results difficult. As with any screening method, false-positive test results have potential for physical and psychological harm. Prostate biopsy carries procedural risks as well as the risk of discovering and treating a cancer that would not be significant in the patient's lifetime. Present data suggest that the number needed to screen to prevent possibly one prostate cancer death is 1000, and the potential for harm is significant. Furthermore, because of the inherent properties of the test, there will be significant overdiagnosis and overtreatment because of screening (Chou, 2011; USPSTF, 2012). However, some data suggest that men ages 55 to 69 years may be candidates for a risk-versus-benefit discussion, and this is reflected in certain guidelines (Hayes and Barry, 2014).

The controversies surrounding screening are reflected in the disparate prostate cancer screening guidelines (Table 40-21). The USPSTF recommends against PSA testing to detect prostate cancer for general population screening (USPSTF, 2012). Other bodies recommend

Table 40-21 Prostate Cancer Screening Recommendations

Organization	Recommendation
USPSTF (2012)	Recommends against screening with PSA (USPSTF D recommendation)
American Cancer Society (Wolf et al., 2010)	Recommends giving asymptomatic men with a 10-year life expectancy the opportunity to consider screening High-risk men before age 50 yr; average risk at 50 yr Recommends against testing without informed decision making and mass screening Screening uses PSA with or without DRE
American Academy of Family Physicians (2013)	Recommends against PSA screening
American Urological Association (Carter et al., 2013)	Recommends against screening men younger than age 40 yr No recommendation for screening average risk men 40-54 yr, men older than 70 yr, and men with less than a 10- to 15-yr life expectancy Recommends individualized screening decisions for high-risk men age 40-54 yr Recommends shared decision making for men age 55-69 yr; if PSA is performed, it should occur every 2 yr

DRE, Digital rectal examination; PSA, prostate-specific antigen.

different approaches. However, there is emerging consensus that mass PSA screening (by physicians, health fairs, and so on) should be avoided and that the decision to screen with PSA should not occur without an informed-consent discussion. The risks, benefits, and limitations should be discussed so that patients are fully informed and can incorporate their personal preferences into the screening decision.

Although older men have a higher prostate cancer risk, competing causes of death and the low chance of progression make screening men with less than 10 years in remaining life expectancy of little benefit (Fisher, 2002; Ilic et al., 2013).

Preventing prostate cancer with prophylactic measures has been suggested. The Prostate Cancer Prevention Trial showed that finasteride significantly reduced cancer compared with placebo in an RCT (absolute risk reduction, 6% at 7 years). However, patients taking finasteride had an increased risk of high-grade cancer (Thompson et al., 2003). The American Society for Clinical Oncology (ASCO) and AUA joint guideline previously recommended that clinicians consider discussing the risks and benefits of 5 α -reductase inhibitors for men as chemoprevention. However, using these drugs for chemoprevention is not FDA approved, and the recommendation has been revised to reflect this (ASCO/AUA, 2012). Clinicians with patients taking 5 α -reductase inhibitors should consider the impact on PSA values, and how PSA screening is interpreted must also be considered (Kramer et al., 2009).

Renal Cancers

Renal cancers are twice as common in men as in women; more than 40,000 cases are diagnosed annually in men (ACS, 2013). Risk factors are less well understood than for other urologic cancers. Heavy tobacco use (>20 packs/year)

is a risk factor in men, and severe obesity is a risk in both genders. Risks from occupational or medication exposure are less certain (Dhote et al., 2004).

The diagnosis of renal cancer is often incidental to an imaging study (e.g., ultrasonography) obtained for another reason. Hematuria is also a clinical sign that may lead to the diagnosis. Localized renal cell cancers have a favorable outlook (91% at 5 years); however, overall survival rates (40% at 5 years) are not as encouraging as in other urologic cancers (ACS, 2013; Dhote et al., 2004; NCI, 2013b).

Testicular Cancer

Approximately 7900 men were diagnosed with testicular cancer in 2013 (ACS, 2013). It is unusual in that it occurs mostly in young men (15-35 years) and is the most common cancer in this group. Orchiopexy in children with cryptorchidism does not necessarily prevent cancer, so these patients should be followed closely (NCI, 2013c).

Most testicular tumors are initially discovered by patients. Typical presentations include painless testicular lumps or scrotal pain, edema, or hardness. Symptoms can mimic those of epididymitis, and tumor should be in the differential diagnosis of this condition (Kinkade, 1999). Ultrasonography is the initial study of choice for suspected testicular masses. Most tumors are germ cell neoplasms. Thus, serum tumor markers (β -hCG, lactate dehydrogenase, α -fetoprotein) are important in the diagnosis, prognosis, and monitoring aspects of care (NCI, 2013d). However, normal values do not rule out cancer in patients with a mass, and they are not appropriate as screening tools, so they should not be used to decide whether a confirmed mass is cancerous (Kinkade, 1999). Patients are typically followed for many years for treatment failure or recurrence, and family physicians play an important role in ensuring that patients participate adequately with follow-up.

Testicular self-examination or clinical examination might detect cancer at an earlier stage but is highly unlikely to have a significant impact on testicular cancer mortality because survival rates are already so high. Thus, the USPSTF does not recommend testicular cancer screening in the general population (USPSTF, 2011b).

Wilms Tumor

Wilms tumor presents in childhood as an abdominal mass. It is a rare cancer, with approximately 500 cases annually. Wilms tumor has good cure potential, with survival rates greater than 90% at 4 years (NCI, 2013e).

KEY TREATMENT

- Use of 5 α -reductase inhibitors is effective for BPH (AUA, 2010; Kramer et al., 2009; Thorpe and Neal, 2003) (SOR: A).
- α -Adrenergic blockers are also used to treat BPH (AUA, 2010; Wilt et al., 2000) (SOR: A).
- 5 α -Reductase medications are not FDA approved for prostate cancer prevention (SOR: C).
- Surgical treatments may be needed for BPH (SOR: A).

CHAPTER OUTLINE

Neurologic Examination, 997

Neurologic Conditions, 999

Family physicians regularly encounter and manage a range of neurologic conditions. Many are fairly common in certain age groups, such as febrile seizures in children and Alzheimer dementia in older adults. Other conditions, such as dysautonomia, are less common but present first to primary care physicians. This chapter discusses the neurologic disorders that family physicians are most likely to encounter, with guidelines for assessment and management.

Neurologic Examination

The neurologic examination begins with information obtained from the neurologic history, which is similar to a general medical history. The chief complaint is determined by asking open-ended questions. Analysis of the chief complaint should include the following:

- Date of onset
- Character and severity
- Location and extension
- Time relationship (acute, subacute, or chronic)
- Associated complaints
- Aggravating and alleviating factors
- Previous treatment and effects

Knowing the sequence of the events and their progression is helpful in localizing the lesion and developing a differential diagnosis. A brief neurologic review of systems should include questions about headaches, visual changes, weakness, sensory changes, gait disturbances, and bowel and bladder function. The past medical history, social history, and family history are reviewed as well.

Much of the initial neurologic examination, including cranial nerve (CN) testing, carotid artery auscultation, and reflex and sensory assessment, can be conducted with the patient seated in a chair, on the bed, or on the examination table. Superficial reflexes, tests for meningeal irritability, and rectal examination are performed with the patient lying down. Gait, strength, and coordination can subsequently be evaluated with the patient standing. Traditionally, the neurologic examination is divided into five major areas: mental status, CNs, motor system, sensory system, and reflexes.

MENTAL STATUS EXAMINATION

The mental status examination assesses appearance and behavior (including level of consciousness), speech and language, mood, thoughts and perceptions, and cognition.

Speech abnormalities can interfere with the initial history. Abnormalities of speech include hearing deficits, aphasia (problems with understanding, thought, and word finding), and dysarthria (problems with articulation). *Aphasia* results from damage to the dominant hemisphere. *Wernicke* aphasia refers to poor comprehension, with fluent but often meaningless speech. In *Broca* aphasia, comprehension is preserved, but speech is nonfluent. Repetition, naming, reading, and writing are impaired in Wernicke and Broca aphasia. With *conductive* aphasia, there is a loss of repetition but preserved comprehension. Reading comprehension is thus relatively preserved, but reading aloud and writing are impaired. *Dysarthria* refers to difficulties with the production of speech caused by injury to the vocal cords, larynx, palate, tongue, or facial muscles. It is also seen with extrapyramidal or cerebellar lesions. Cognitive function is often assessed by tools such as the Mini-Mental State Examination, a simple, quick screening test for cognitive function. Errors in copying several simple drawings can be indicative of organic brain damage, particularly in those with dementia or parietal lobe damage.

CRANIAL NERVE EXAMINATION

The CN examination usually evaluates all CNs, with the exception of CN I. CN I testing is generally reserved for patients with complaints of loss of smell or a closed-head injury. Smell can be decreased or lost in degenerative diseases, such as Parkinson or Alzheimer disease.

Cranial Nerve II (Optic Nerve)

The principal function of the optic nerve is vision. Testing of the optic nerve includes assessment of visual acuity and visual fields, funduscopic examination, and pupillary light reflex. Visual acuity is assessed in each eye individually. Visual fields are evaluated by confrontation. When performing the funduscopic examination, look for papilledema, hemorrhages, cholesterol emboli, and atrophy. Atrophy is characterized by a small, pale disc. Pupillary function assesses CNs II and III as well as sympathetic activity. The direct and consensual responses require CNs II and III to work correctly. If CN II is damaged, an afferent pupillary defect is often present. If the optic nerve is damaged, the light reflex is sluggish.

Cranial Nerves III (Oculomotor), IV (Trochlear), and VI (Abducens)

The principal functions of these nerves include ocular rotation, eyelid elevation (III), and pupillary constriction. CN III

innervates the medial, inferior, and superior rectus muscles; the inferior oblique, which allows inward and upward gaze; and the levator palpebrae superioris muscle, which raises the upper eyelid. It also innervates the pupillary constrictor muscle. CN IV innervates the superior oblique muscle, which causes the eye to look inward and down. CN VI innervates the lateral rectus muscle.

To test ocular rotation, the patient should first be examined by looking straight ahead to note any imbalances between the eyes. Next, ocular rotation of each eye is tested separately. First, abduction is tested with the patient following the examiner's finger horizontally; this tests the lateral rectus muscle. The patient then looks laterally and upward to test the superior rectus and downward to test the inferior rectus. Adduction of the eye tests the medial rectus muscle. With the eye adducted, the patient looks up to test the inferior oblique and downward to test the superior oblique.

The pupils should be observed for symmetry. Most unequal pupils (anisocoria) are congenital and not clinically significant. The light reflex, direct and consensual, is checked by shining a bright light directly into the pupil. The response to light should be brisk.

Cranial Nerve V (Trigeminal)

The principal functions of the trigeminal nerve include control of the muscles of mastication and sensation in the face; anterior half of the scalp; and mucous membranes of the mouth, nose, and sinuses. The nerve also mediates the afferent arc of the corneal reflex. The three sensory divisions are ophthalmic, maxillary, and mandibular. Each division is tested by light touch, pinprick, and temperature. The motor division of CN V can be assessed by palpating the jaw as the patient bites down. CN V is the afferent limb of the corneal reflex, and CN VII is the efferent limb. This reflex is tested by lightly touching the cornea with a wisp of cotton; the reflex, integrated through the pons, results in brisk, bilateral eye closure.

Cranial Nerve VII (Facial)

The principal functions of the facial nerve are control of the muscles of facial expression and provision of taste for the anterior two thirds of the tongue. It also innervates the lacrimal, sublingual, and submaxillary glands. To test the facial nerve, the patient is asked to smile, close the eyes tightly, and wrinkle the forehead. Taste is tested on each side separately using bitter and sweet substances.

Cranial Nerve VIII (Vestibulocochlear Nerve)

The principal functions of the vestibulocochlear nerve are hearing and vestibular function. Hearing is tested one ear at a time. Testing of hearing can be done by comparing each side with a finger rub, watch tick, or vibration of a tuning fork. The Rinne test compares bone conduction with air conduction on both sides. A tuning fork is placed on the mastoid process to assess bone conduction and then in front of the ear to assess air conduction. Air conduction should be louder than bone conduction. The Weber test evaluates middle ear conduction. A vibrating tuning fork is placed on the forehead. With normal hearing, there should be equal sound in both ears. Sound lateralized to one side indicates a conductive loss on that side or a neural loss on the opposite side. Vestibular function is not routinely tested.

Cranial Nerve IX (Glossopharyngeal)

The principal function of CN IX is to supply sensation to the pharynx and tonsillar fossa and taste to the posterior third of the tongue. Clinical testing is done by eliciting a gag reflex. It should be done on both sides of the pharynx.

Cranial Nerve X (Vagus)

The principal functions of the vagus nerve are motor control to the pharynx, palate, and larynx and parasympathetic innervation of the thoracic and abdominal viscera. Motor control is tested by observing for symmetric elevation of the palate. The uvula should not deviate. Vocal cord paralysis can present with hoarseness or dysphonia and can occur with injury to the recurrent laryngeal branch.

Cranial Nerve XI (Spinal Accessory)

The principal functions of this nerve are to allow turning of the head and assist in shrugging of the shoulders. It innervates the sternocleidomastoid and upper trapezius. Strength is tested by shrugging the shoulders and turning the head to both sides against resistance.

Cranial Nerve XII (Hypoglossal)

The principal function of the hypoglossal nerve is innervation of intrinsic muscles of the tongue. To test this nerve, ask the patient to protrude the tongue. It should be midline. If not, it protrudes to the paretic side. Also, observe for atrophy or fasciculations of the tongue.

MOTOR EXAMINATION

The motor examination includes assessment of body position, strength, tone, involuntary movements, coordination, and gait. Strength is graded as follows:

- 5—Normal
- 4—Weak but can overcome gravity plus some additional resistance
- 3—Can overcome gravity but not additional resistance
- 2—Can move joint but cannot overcome the force of gravity
- 1—Muscle contracts but with little or no joint movement
- 0—No muscle contraction

Muscle tone is tested by passively flexing and extending the arm or wrist. Abnormal responses include spasticity, rigidity, and flaccidity. *Spasticity* refers to increased muscle resistance when the muscle is passively stretched. This is seen with lesions to the cortical spinal tract. *Rigidity* or *cogwheeling* is observed with extrapyramidal lesions and Parkinson disease. *Flaccid* refers to the absence of muscle tone.

Muscular weakness can result from upper motor neuron (UMN) lesions, lower motor neuron (LMN) lesions, muscle disease, neuromuscular junction disorders, or functional weakness. Whereas UMN disease is characterized by increased tone and reflexes, LMN disease presents with wasting, fasciculations, decreased tone, and absent reflexes. With neuromuscular junction disorders, the patient complains of fatigable weakness but has normal or decreased tone and normal reflexes. A patient with functional weakness has normal tone, normal reflexes without wasting, and erratic power. The motor examination also includes

observation for any abnormal movements, including tremors, choreiform movements, myoclonus, and dystonia.

Gait should be examined even if assistance is needed. Assessment includes stride length, arm swing, posture, and turning, starting, and stopping. Watch for specific gait abnormalities, such as *hemiplegia*, which is seen with unilateral UMN damage; *spasticity*, in which both legs have UMN lesions; *steppage*, in which there is footdrop; *waddling*, caused by weakness of the trunk and pelvic girdle; and *parkinsonism*, characterized by a stooped posture, short steps, and flexed arms with decreased arm swing.

Balance is maintained by the cerebellum, proprioceptive system, basal ganglia, and vestibular system. The Romberg sign is tested with the patient standing with the feet together and then with eyes closed. If the patient falls with eyes closed, the test result is considered positive. A positive test result indicates proprioceptive loss, which can be from a peripheral cause or a posterior column lesion. The result of the Romberg test can be positive with cerebellar or vestibular disease. Postural stability can be checked by gently pushing the patient while the feet are together.

Coordination can be tested with simple tests. For the finger-to-nose test, ask the patient to extend the arm, touch the tip of the nose, and then touch the examiner's index finger. This is repeated after the examiner has moved the index finger several times. The heel-knee-shin test is performed by asking the supine patient to slide one heel smoothly down the opposite leg from the knee to the shin. Two other tests of coordination are finger tapping and rapidly alternating hand movements. Injury to the cerebellar hemisphere impairs smooth coordination of limb movements on the same side of the body. With cerebellar lesions, these tests will be inaccurate, will have increased amplitude, and will be initiated more slowly.

SENSORY EXAMINATION

The sensory examination requires an alert and cooperative patient. Sensory testing includes light touch, pinprick, proprioception, and vibration. Start by testing for light touch using a wisp of cotton or tissue on the major dermatomes of the extremities and trunk (Figure 41-1). Observe for dermatomal losses or a distal-to-proximal gradient. The same areas are then tested for superficial pain with a pin. Temperature is mediated by the same pathway as pain, so any deficits of pain sensation should have a corresponding deficit in temperature sensation. Vibration is tested by placing a 128-cycles/sec tuning fork on the bony prominences of the extremities and asking the patient to identify when it stops vibrating. Comparisons are made side to side. If there is a question of myelopathy, a vibration level may be noted as the tuning fork is moved up the spinous processes. Position is best tested using the great toe and distal phalanx of the thumb or another finger. The digit is grasped on the sides and moved up and down. Even a very slight movement of a finger should be detected. Proprioception, vibration, and light touch are functions of the dorsal column, and pain, temperature, crude touch, and pressure are functions of the spinothalamic tract.

Stereognosis, graphesthesia, and touch localization are integrated cortical sensations and are difficult to test if primary sensations are impaired. To test *stereognosis*, several small familiar objects are placed in the patient's hand, and

Table 41-1 Nerve Root Innervations and Main Reflexes

Root	Movement	Reflex
C5	Shoulder abduction, elbow flexion	Biceps
C6	Elbow flexion	Supinator
C7	Finger extension, elbow extension	Triceps
C8	Finger flexors	Finger
T1	Small muscles of hand	None
L1, L2	Hip flexion	None
L3, L4	Knee extension	Knee
L5	Extension of great toe	None
S1	Hip extension, knee flexion, plantar flexion	Ankle

C, Cervical; T, thoracic; L, lumbar; S, sacral.

the patient is asked to identify them. To test *graphesthesia*, the examiner writes numbers on the patient's palm and asks the patient to identify them.

REFLEXES

The reflex examination includes the deep tendon reflexes (DTRs) and the pathologic reflexes. In testing the DTRs, it is important to look for symmetry. DTRs are graded using the following scale:

- 0—Absent
- 1—Present but diminished
- 2—Normal
- 3—Normal but brisker than average
- 4—Increased and pathologic, with one or more beats of clonus

The DTRs assist with localization of a lesion because these reflexes are integrated at different levels of the spinal cord. DTRs help in distinguishing whether a lesion is a UMN lesion with pathologic hyperreflexia or possibly an LMN lesion with hyporeflexia. Table 41-1 summarizes the most important reflexes and their nerve root innervations.

The Babinski sign, or extensor toe sign, is tested by stroking the sole of the foot with a sharp object. A normal response is toe flexion. A pathologic response is extension of the great toe and flaring of the other toes. A positive response is always abnormal in patients older than 3 years and is a sign of pyramidal tract disorder.

Neurologic Conditions

HEADACHES

Key Points

- More than 90% of men and women will have at least one headache each year.
- If there is a history typical of a particular primary headache with a normal examination, neuroimaging and electroencephalography (EEG) are not necessary.
- Prophylactic treatment of migraine headaches is recommended when they occur with increasing frequency and there appears to be a potential overuse of acute therapies.
- Giant cell or temporal arteritis is a serious headache to consider in older adults and can be associated with blindness.

Levels of principal dermatomes

- C5 Clavicles
- C5, 6 Lateral sides of upper limbs
- C8, T1 Medial sides of upper limbs
- C6 Thumb
- C6, 7, 8 Hand
- C8 Ring and little fingers
- T4 Level of nipples

- T10 Level of umbilicus
- L1 Inguinal or groin regions
- L1, 2, 3, 4 Anterior and inner surfaces of lower limbs
- L4, 5, S1 Foot
- L4 Medial side of great toe
- L5, S1, 2 Lateral and posterior surfaces of lower limbs
- S1 Lateral margin of foot and little toe
- S2, 3, 4 Perineum

Figure 41-1 Dermatomes. (Reused with permission from Netter FH. *Atlas of human anatomy*. 6th ed. Philadelphia: Saunders; 2014.)

Headaches are a common problem encountered by family physicians. More than 90% of men and women will have at least one headache each year, and as many as 4.5 million Americans will experience recurrent headaches. The International Headache Society established a system for the classification of headaches to assist in diagnosis and treatment with a standard of care for family physicians. Migraine with aura, migraine without aura, tension, and cluster headaches constitute most primary headaches. Secondary headaches are symptoms of organic disease (Sarchielli, 2004). The initial evaluation of a patient with headache requires a complete history and physical examination with the following information:

- Age at onset
- Location, frequency, and duration
- Intensity and character
- Associated symptoms
- Triggering and ameliorating factors
- Medications
- Associated physical and neurologic symptoms
- Impact on work and family
- Psychological symptoms
- History of head trauma
- Previous imaging results
- Family history

Features of the history that should warn of an ominous cause for headache include the following:

- Sudden onset of headache or headache that reaches maximal intensity within seconds or minutes of onset
- Worst (or first) headache ever
- Late onset of new headache (after age 50 years)
- Headache associated with fever, rash, or a stiff neck
- Progressively worsening headache
- Headache associated with neurologic signs and symptoms other than aura
- Headache associated with mental status changes
- Headache associated with papilledema
- Headache with exertion, sexual activity, coughing, or sneezing

The physical examination of a patient first presenting for evaluation of headache should include vital signs; cardiac examination; cervical spine examination, including nuchal rigidity; and ophthalmologic examination, including the optic fundi, pupils, and visual fields. The neurologic examination should include an assessment of cognitive function, motor function, reflexes, plantar response, CNs, coordination, and gait.

If there is a history typical of a particular primary headache with a normal examination, neuroimaging and EEG are not necessary. A lumbar puncture (LP) after neuroimaging is recommended only if there is suspicion of subarachnoid hemorrhage, infection, or idiopathic intracranial hypertension (pseudotumor cerebri). Routine EEG is not indicated but may be useful in evaluating patients with associated mental status or consciousness changes, a history of head injury, or a history of syncope.

Migraine

Migraine headaches include migraine without aura, migraine with aura, and other migrainous disorders. Women

have migraines three times as often as men, and 90% of those with migraines have a positive family history. Migraines can begin in childhood, and as many as 4% to 10% of school-age children have migraines. The International Headache Society has developed diagnostic criteria for these types of headaches (Sarchielli, 2004). To establish a diagnosis of *migraine without aura*, there must have been at least five attacks fulfilling the following criteria:

1. Headache attacks lasting 4 to 72 hours
2. Headache with at least two of the following characteristics:
 - a. Unilateral location
 - b. Pulsating quality
 - c. Moderate or severe intensity (inhibits or prohibits daily activities or causes avoidance of routine)
 - d. Aggravated by physical activity such as walking or climbing
3. During the headache, at least one of the following occurs:
 - a. Nausea and vomiting
 - b. Photophobia and phonophobia

Migraine with aura has comparable diagnostic criteria but includes an aura. *Auras* can be visual, sensory, motor, or speech auras. Visual changes include parallel zigzag lines and are often associated with scotomatous defects. Sensory deficits can involve an ipsilateral arm or periorbital numbness or tingling. The tongue may be involved in some patients. The sensation has a marching characteristic. Motor deficits can be similar to sensory in that the deficits spread from one area to another. Speech problems may manifest as a mild dysphasia.

Other migraine types include basilar-type migraine, retinal migraine, status migrainosus, and migrainous infarction. *Basilar-type migraine* aura symptoms are referable to the brainstem or bilateral hemispheres, including dysarthria, vertigo, tinnitus, diplopia, and bilateral paresthesias. Reversible monocular, positive or negative visual disturbances associated with migraine are characteristic of *retinal migraine*. A diagnosis of *status migrainosus* requires an ongoing migraine of at least 72 hours in duration. Neuroimaging evidence of a cerebral infarct associated with a migraine is indicative of *migrainous infarction*.

Treatment. Migraine headache management includes acute analgesia, pharmacologic prophylaxis, and non-pharmacologic management. Factors to consider before starting prophylactic medications include frequency, severity, and lack of response or contraindications to analgesic medications. Nonpharmacologic management includes identification and avoidance of triggering factors, stress management, regular sleep and exercise, and physical therapy. Factors that can aggravate or trigger migraines include alcohol, oral contraceptives, hormonal replacement, caffeine or caffeine withdrawal, stress, changes in weather, strong scents, foods (nitrates, dairy products, chocolate, aged cheese), and fasting or missing meals.

The goal of pharmacologic treatment is to reduce the patient's disability and maintain an acceptable quality of life. The choice of abortive drug therapy depends on the severity of the patient's symptoms. A plan can be developed with the patient to use some medications for mild to

Table 41-2 Symptomatic Migraine Medications

Drug Name	Dose Range	Adverse Effects
Acetaminophen, 325 mg; isometheptene, 65 mg; and dichloralphenazone, 100 mg (Midrin)	2 capsules at onset, then qh PRN; max 5 caps/12 hr	Liver toxicity, dizziness
Lidocaine 4% aqueous solution for nasal spray (Xylocaine)	0.5 mL to nostrils; may repeat after 15 min	None known
Ergotamine, 1 mg with caffeine, 100-mg oral tablets (Cafergot)	2 tablets; then 1 every 30 min four times PRN; max 6 tabs/attack or 10 tabs/wk	Nausea, vasoconstriction, fetal harm
PARENTERAL AGENTS		
Dihydroergotamine, 1 mg/mL (DHE 45)	1 mg IV, IM, or SC qh, maximum, 2 mg IV, 3 mg IM or SC	Nausea, vasoconstriction
Dihydroergotamine, 0.5 mg/mL (Migranal)	0.5 mg spray in each nostril; may repeat in 15 min	
Ketorolac (Toradol)	15-30 mg IM or IV q6h	GI upset, renal toxicity
SELECTIVE SEROTONIN (5-HT) AGONISTS		
Sumatriptan (Imitrex) Autoinjector	6 mg qh PRN Maximum, 12 mg/day	Chest and neck discomfort
Nasal spray	5 to 20 mg q2h PRN Maximum, 40 mg/day	
Tablet	25-100 mg q2h PRN Maximum, 200 mg/day	
Naratriptan (Amerge)	1 to 2.5 mg q4h PRN Maximum, 5 mg/day	
Rizatriptan (Maxalt)	5 to 10 mg q2h PRN Maximum, 30 mg/day	
Tabs	1.25 to 2.5 mg q2h PRN Maximum, 10 mg/day	
Orally disintegrating tabs (ZMT)	2.5 mg q2h PRN Maximum, 10 mg/day	
Nasal Spray	5 mg (1 spray) in one nostril q2h PRN Maximum, 10 mg/day	
Zolmitriptan (Zomig)	2.5 to 5 mg q2h PRN Maximum, 10 mg/day	
Eletriptan (Relpax)	20 to 40 mg q2h PRN Maximum, 80 mg/day	
Frovatriptan (Frova)	2.5 mg q2h PRN Maximum, 7.5 mg/day	
Almotriptan (Axert)	6.25 to 12.5 mg q2h PRN Maximum, 25 mg/day	
Sumatriptan 85 mg and naproxen sodium 500 mg (Treximet)	1 tablet q2h PRN Maximum, 2 tablets/day	

5-HT, 5-Hydroxytryptamine; GI, gastrointestinal; IM, intramuscular; IV, intravenous; qh, every hour; q2h, every 2 hours; PRN, as needed; SC, subcutaneous.

moderate attacks and other medications for more severe attacks. For mild attacks, combination medicines, such as aspirin, acetaminophen, and caffeine (Excedrin or generic equivalent), are effective. For more severe headaches, the triptans are the drugs of choice (the triptans are not indicated for basilar migraines or hemiplegic migraines) (Polizzotto, 2002).

Dihydroergotamine (DHE) and other ergotamine compounds are useful. Aqueous lidocaine applied intranasally is another option. Briefly, 0.5 mL of a 4% aqueous solution of lidocaine is slowly dripped into one nostril with the patient supine and the head hyperextended 45 degrees and rotated 30 degrees toward the side affected by the headache (Maizels et al., 1996). Antiemetics, such as metoclopramide or chlorpromazine, can be used in conjunction with most abortive medications (Table 41-2).

Prophylactic treatment of migraine is recommended when headaches occur with increasing frequency and the patient may be overusing acute therapies. The daily use of symptomatic medications, including acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs), can cause liver and kidney injury. Also, regular use of certain medications (e.g., propoxyphene, butalbital, ergotamines, triptans) can result in habituation or rebound headaches. Preventive treatment is also recommended for patients who have fre-

quent attacks, often four or more, throughout the month or when headaches are so severe that acute treatment is no longer completely effective. The overall goal of preventive treatment is to reduce the frequency and severity of migraine attacks. Prophylactic agents include β -adrenergic blockers, calcium channel blockers, selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and anticonvulsant medications (Table 41-3). β -Blockers such as propranolol have proven efficacy in this role (Polizzotto, 2002). For patients requesting alternative therapies, there is level B evidence for the effectiveness of petasites (purified extract from the butterbur plant), 75 mg twice a day for migraine prophylaxis (Lipton et al., 2004; Schapowal, 2002).

Tension-Type Headaches

Tension-type headaches can be episodic or chronic. There is a slight female preponderance, and the prevalence may be directly related to socioeconomic status. Chronic tension headaches can sometimes develop in migraine patients and are frequently associated with overuse of analgesics. The International Headache Society has further subdivided tension-type headaches into those with and without *pericranial tenderness* (Sarchielli, 2004). Headaches can be classified by cause, such as temporomandibular joint

Table 41-3 Preventive Antimigraine Therapy

Type of Drug	Dose Range	Adverse Effects
β-ADRENERGIC BLOCKERS		
Propranolol (Inderal)	40-240 mg/day	Bronchospasm, bradycardia, hypotension, fatigue, depression
Timolol (Blocadren)	10-60 mg/day	Bronchospasm, bradycardia, hypotension, fatigue, depression
CALCIUM CHANNEL BLOCKERS		
Verapamil (Calan)	240-480 mg/day	Hypotension, constipation, edema
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline (Elavil)	10-100 mg/day	Sedation, dry mouth, weight gain, tremor, cardiac arrhythmias, difficulty voiding
Nortriptyline (Pamelor)	10-150 mg/day	Sedation, dry mouth, weight gain, tremor, cardiac arrhythmias, difficulty voiding
ANTICONVULSANTS		
Divalproex sodium (Depakote)	250-1000 mg/day	Nausea, fatigue, weight gain, hair loss, tremor, liver toxicity, fetal harm
Gabapentin (Neurontin)	100-3600 mg/day	Fatigue
Topiramate (Topamax)	25-200 mg/day	Fatigue, paresthesias, weight loss, memory loss, nephrolithiasis
Cyproheptadine	4-16 mg/day	Drowsiness, dizziness, constipation, urinary retention
BOTANICALS		
Petasites extract (Butterbur)	75 mg BID	Potential allergic reaction to the plant

BID, Twice a day.

dysfunction, psychosocial stress, and analgesic overuse. Tension-type headaches require a comprehensive assessment to determine whether any comorbid conditions exacerbate the headache. The diagnostic criteria for episodic tension-type headaches include at least 10 previous headache episodes fulfilling the following criteria:

- Headaches lasting for 30 minutes to 7 days, with at least two of the following pain characteristics:
 - Pressing or tightening (nonpulsating) quality
 - Mild or moderate intensity
 - Bilateral location
 - No aggravation by walking, climbing stairs, or similar routine physical activity
- Both of the following:
 - No nausea or vomiting
 - Photophobia and phonophobia—both absent or only one present

Frequently, the initial symptoms of a tension headache are described as a bandlike, squeezing, or tight pressure sensation. It is generally diffuse, often concentrated in the occipital region or in the temples. This can also be associated with depression or anxiety and aggravated by stress. No neurologic abnormalities should be noted in the history or physical examination.

A chronic tension headache requires that the pain be present for 15 days a month for more than 3 months. The

other criteria are the same as those for episodic tension-type headaches.

The treatment for tension-type headaches is generally difficult. There is always the concern of analgesic abuse. Amitriptyline is frequently a reasonable drug choice, 10 to 100 mg/day. Muscle relaxants can be helpful as a short-term intervention when the pain extends into the shoulder trapezius muscles. In addition to therapeutic options, it is beneficial to use relaxation therapy, physical therapy, and stress management programs. Improvement of posture, stretching exercises, and even traction can be beneficial. On occasion, relief can be obtained with injections or occipital nerve blocks.

Medications can be used for abortive treatment and can include NSAIDs and analgesics with caffeine. The choice of medication depends on the severity and frequency of the headaches. Care needs to be used when prescribing butalbital-containing compounds because their addiction potential is high. In addition, there is always the problem of analgesic overuse, which could lead to the development of chronic daily headaches.

Cluster Headaches

Cluster headaches are less common than migraines, and almost 80% of patients are male. Cluster headaches present with unilateral pain. Attacks may last 15 to 180 minutes and can occur every other day to up to eight times daily. The cycle may last for 4 to 12 weeks. These headaches frequently are triggered by alcohol, with some nausea. They tend to occur at a similar time during the day or night. The pain is frequently in the orbital or periorbital region. It is an extremely sharp, continuous, incapacitating pain. The criteria for diagnosis include at least five attacks with the following elements:

- Severe unilateral orbital or supraorbital pain lasting 15 to 180 minutes
- Headache associated with at least one of the following ipsilateral signs in addition to the headache:
 - Conjunctival infection
 - Lacrimation
 - Nasal congestion
 - Miosis or ptosis
 - Eye edema
 - Forehead and facial sweating
 - Sense of restlessness or agitation
- Frequency from every other day to eight times a day

Cluster headaches are unusual in that they may come at certain intervals throughout the year. Headaches may last for a few weeks and then disappear or can become chronic and persist throughout the year.

Medications for the treatment of cluster headaches include some of the same drugs used for abortive treatment for migraines, including DHE, ergotamines, intranasal 4% aqueous lidocaine solution, and triptans. The nasal and injectable forms have a more rapid onset of action than the oral preparations. Cluster headaches are also unusual in that they may respond to oxygen. Inhaled 100% oxygen can relieve an attack within 10 to 15 minutes.

For headaches that are intense, do not respond to abortive treatment, or require excessive use of abortive treatment, prophylaxis is recommended. Divalproex (Depakote) can be used for the treatment of the chronic cluster

headache. Dosages range up to 1000 mg/day in divided doses. A pulse dose of steroids can also be effective, as can verapamil.

Medication Overuse Headaches

Individuals with headaches can begin to experience daily or almost daily headaches when medication doses are excessive or too frequent. Rebound can occur with opioids, acetaminophen, aspirin, analgesic–codeine or analgesic–barbiturate combinations, NSAIDs, ergotamines, and triptans. Characteristics of rebound headaches include a diffuse, bilateral, almost daily headache, often aggravated by mild physical or mental exertion. The headache is frequently present on waking and can be associated with restlessness, nausea, forgetfulness, and depression. Tolerance develops to abortive medications, and there is a decreased responsiveness to preventive medications.

Treatment of rebound headaches can be difficult. The causative medications must be identified, and there may be some psychological as well as physical dependence. The key to treatment is to discontinue the overused medication and thus break the cycle. Stopping the medication may result in withdrawal symptoms and an initial period of increased headaches, with subsequent improvement. Although there is no significant difference in outcomes at 1 year with inpatient versus outpatient treatment, hospitalization to stop the medication should be considered for barbiturates, opioids, and benzodiazepines. Specific limits need to be set for the use of analgesics, ergotamines, and triptans to reduce the likelihood of rebound headaches.

Miscellaneous Headaches

Episodic and chronic *paroxysmal hemicrania* is an unusual headache that tends to occur in women. The attacks are short, and the pain is similar to that of a cluster headache. These headaches respond to indomethacin, with a maximum of 150 mg/day in divided doses (off-label usage).

Posttraumatic headaches can follow a head injury, with presentation similar to that of migraine headache. No clear correlation appears to exist between intensity of the head trauma and development of headache. These headaches may be associated with dizziness and impaired concentration. Treatment is difficult, but many of the migraine compounds are effective.

Trigeminal neuralgia is described as a piercing, sudden, severe pain that can last for seconds to minutes in the area of the cheek or jaw and can be aggravated by chewing or talking. Treatment options include carbamazepine, oxcarbazepine, baclofen, and gabapentin. Surgical intervention is an option when medical treatment fails.

Headaches in Older Adults

A serious headache that presents in the older adult population is *giant cell arteritis*, or temporal arteritis. The pain can be bimodal or unilateral; is moderate to severe in intensity; is diffuse, not always throbbing; and persists throughout the day and often worsens at night. This headache is often associated with systemic complaints (e.g., weight loss, joint tenderness) and can be aggravated with jaw movement. It is important to treat giant cell arteritis because it can be associated with blindness. The Westergren erythrocyte sedimentation rate (ESR) is frequently elevated. If

temporal arteritis is suspected, a diagnostic temporal artery biopsy is performed. It is important not to delay treatment while waiting for the biopsy. Steroid treatment can be initiated up to 2 weeks before the biopsy without compromising the results. A patient with a headache of giant cell arteritis requires high doses of prednisone, usually for several months or longer.

Ophthalmic zoster is another type of head pain in older adults. The pain is described as a burning, constant, piercing, shocklike pain. It follows the distribution of the trigeminal nerve. This is a difficult headache to treat, but it responds well to anticonvulsants, particularly carbamazepine and gabapentin.

Glaucoma can cause a migrainelike headache, with severe pain around the affected eye.

STROKE

Key Points

- Strokes usually occur without warning, and fewer than 20% of cerebrovascular accidents (CVAs) are preceded by a warning transient ischemic attack (TIA).
- Stroke risk factors include hypertension, smoking, atrial fibrillation, internal carotid artery stenosis, and diabetes.
- The time-related cellular death in areas of hypoperfusion requires reperfusing the ischemic penumbra.
- Both dipyridamole (plus aspirin) and clopidogrel are reasonable first-line antiplatelet agents for secondary stroke prevention.
- During the first day after an ischemic stroke, most patients with elevated blood pressure (BP) should not be treated unless the systolic blood pressure (SBP) is consistently higher than 220 mm Hg or the diastolic blood pressure (DBP) is consistently higher than 120 mm Hg.

Stroke is the fourth leading cause of death in the United States and the leading cause of significant disability in adults. Until the past few years, stroke was the third leading cause of death, but efforts to increase adherence to risk factor modification as well as more extensive use of acute stroke treatments have reduced the number of deaths from stroke. The role of primary care in management of risk factors is paramount. Among women, stroke remains the third leading cause of death in the United States, however. Worldwide, stroke is the second leading cause of death, and in some countries, such as China, Japan, and Brazil, stroke is the leading cause of death.

About 750,000 new cases of stroke occur each year. Despite a decline in the stroke death rate, the absolute number of strokes in the United States continues to rise. This continued annual increase is the result of a rise in the mean age of the population. Current projections predict a 20% overall increase in stroke prevalence from 2012 to 2030. The mortality rate for CVA is about 15%, and only slightly less than one third of patients who have a stroke regain normal cerebral function. Furthermore, the recurrence rate for patients who survive a stroke is about 10% per year. Thus, stroke remains a major public health problem

in the United States (Benavente and Hart, 1999; Hart and Benavente, 1999).

Stroke is defined as the sudden onset of neurologic dysfunction caused by focal central nervous system (CNS) infarction, which involves brain, spinal cord, or retinal cell death caused by ischemia. Evidence for the cell death can be determined by imaging, pathological data, or clinical presentation. A TIA is similarly characterized by the rapid onset of neurologic dysfunction but without permanent infarction. Previously, time-based definitions of stroke and TIA were used but are thought to be inadequate to reflect current understanding of the clinicopathological processes involved in cerebrovascular disease. Whereas strokes may be of ischemic or hemorrhagic origin, TIAs are generally ischemic events. Statistically, most patients have ischemic rather than hemorrhagic strokes. About two thirds of ischemic strokes are caused by thrombosis, and slightly less than one third are caused by embolus. *Ischemic* strokes result from many causes, including intracranial atherosclerosis; cervical carotid artery stenosis; and occlusive disease of the small, penetrating arteries, leading to lacunar infarcts. *Hemorrhagic* strokes are generally related to intracranial or subarachnoid hemorrhage, with intracranial hemorrhages being more common. No specific cause is identified in as many as 30% of patients with stroke; patients with cryptogenic stroke are often younger.

Strokes usually occur without warning, and fewer than 20% are preceded by a warning TIA. Patients with a previous TIA or CVA have a 4.5% to 6.6% annual risk for subsequent stroke. The risk for stroke after a retinal TIA (amaurosis fugax) is much lower than that after a hemispheric TIA.

Risk Factors

Hypertension. Patients with a SBP higher than 160 mm Hg or a diastolic DBP higher than 95 mm Hg have a fourfold increased risk of stroke compared with the general population. Decreasing DBP by as little as 5 mm Hg reduces the relative risk of strokes by 43%, and a decrease of 10 mm Hg results in a 50% relative risk reduction. Treatment of older adults with isolated SBP elevations higher than 160 mm Hg reduces their risk of stroke and is usually well tolerated if approached carefully.

Smoking. Cigarette smoking is an independent risk factor for stroke. The risk of stroke is almost twice as high for smokers, and the relative risk of subarachnoid hemorrhage is almost three times as high as for the general population. Patients who smoke should be encouraged to quit. It is also reasonable to avoid passive exposure to environmental tobacco smoke.

Atrial Fibrillation. Clinical trials continue to demonstrate the benefits of warfarin for primary and secondary stroke prevention among high-risk patients with nonvalvular atrial fibrillation. The stroke risk in patients with atrial fibrillation is reduced by about two thirds when they are treated with warfarin adjusted to achieve a target international normalized ratio (INR) of 2 or 3. Novel oral anticoagulants have become available and include dabigatran, rivaroxaban, and apixaban. These agents tend to have favorable safety profiles and do not require ongoing
