Surgery is often performed for CHL. Myringotomy with or without tube insertion corrects hearing loss in cases of OME. The procedure is performed under brief general anesthesia in children or under local anesthesia for most adults. A tympanoplasty is performed for tympanic membrane perforations and to reconstruct ossicles with a prosthesis. A stapedectomy with placement of a prosthesis is often a successful option in patients with otosclerosis.

Cochlear implantation is indicated for profound SNHL in patients who do not benefit from conventional hearing aids.

The procedure is indicated for adults and children as young as 12 months old.

A variety of styles of hearing aids are used to rehabilitate hearing loss in patients with SNHL and CHL. The simplest (and least expensive) are larger, behind-the-ear aids with analog amplification of sound. The most complex (and most expensive) are completely-in-the-canal aids with programmable digital amplification. Several other types of aids fall between these two extremes. A certified audiologist, under the supervision of an otorhinolaryngologist, assists the patient with proper selection of an appropriate hearing aid.

KEY TREATMENT

- Treatment of acute episodes of Meniere disease involves vestibular suppressants and antiemetics, and maintenance therapy consists of reduction in sodium chloride and the use of a diuretic (SOR: A) (Thirlwall and Kundu, 2006).
- A patient with Meniere disease who fails conservative treatment is likely to have improvement of vertigo with intratympanic gentamicin treatment (SOR: B).
- Patients with BPPV should be treated with an otoconia repositioning maneuver (SOR: B) (Herdman, 2013).
- Ciprofloxacin–dexamethasone 0.1% for acute otitis externa is more effective against *P. aeruginosa* (most common isolate) than neomycin–polymixin B–hydrocortisone (SOR: A) (Dohar et al., 2009).
- Successful treatment of auricular hematoma is incision and drainage with dental rolls sutured to the anterior and posterior auricle (SOR: B) (Jones and Mahendran, 2008).
- In AOM, severity, laterality, and age of the patient determine whether to use antibiotics or close follow-up (SOR: B).
- Severe AOM is defined as moderate to severe otalgia and fever greater than 39°C (102.2°F) and should be treated with antibiotics.
- Second- and third-generation cephalosporins may be used to treat AOM in penicillin-allergic patients or in those who have received amoxicillin in the previous 30 days (SOR: A) (Pichichero and Casey, 2007).
- Antihistamines, decongestants, antibiotics, and corticosteroids are not recommended for routine management of OME (SOR: A) (van Zon et al., 2012).
- Tympanostomy tube insertion reduces recurrence frequency and total recurrence time in recurrent AOM (SOR: A) (Cheong and Hussain, 2012).

Facial Nerve Paralysis

Key Points

- Bell palsy is the most common cause of facial paralysis
- Lyme disease is often overlooked as a cause of facial paralysis.
- Audiometry is recommended in facial paralysis because of the proximity of the facial nerve to cranial nerves VII and VIII.

Table 18-10 Causes of Facial Paralysis in Order of Occurrence

Cause	Percentage	Characteristics
Idiopathic (Bell palsy)	60-85	Acute onset; viral prodrome (60% of cases)
Trauma	20-50	Acute-onset paralysis or paresis of previously functioning nerve
Herpes zoster	10-15	Ramsay Hunt syndrome with cranial nerve VII involvement, vestibular(vertigo), cochlear (hearing loss)
Tumor	10-15	Slow progression to complete paralysis
Birth	10-15	Part of congenital syndrome or birth trauma at delivery
Infection	4	Mastoiditis, otitis media, direct cranial nerve VII infection, Lyme disease
Brain lesion (central nervous system)	<10	Supranuclear or in brainstem

From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:131.

Facial paralysis occurs for various reasons. Possible causes are listed in Table 18-10. The eponym “Bell palsy” is reserved for cases of idiopathic facial paralysis. It has been shown, however, that many, if not most, cases of idiopathic facial paralysis are actually caused by reactivation of latent herpesvirus living in the facial nerve or geniculate ganglion.

Although the most common cause of facial paralysis is indeed Bell palsy, it is incumbent to rule out *other* potentially serious causes of facial paralysis before making this *diagnosis of exclusion*. Initially, a complete history and physical examination are required, including otologic and neurologic evaluation. The patient should be questioned regarding history of recurrent cold sores, which suggest herpetic involvement. Recent travel (especially camping) should be noted because Lyme disease is an often overlooked cause of facial paralysis. Involvement of facial nerves is a concern in patients with a history of chronic otitis media or cholesteatoma. Other symptoms should be noted. Otalgia is common with Bell palsy and does not always imply that the ear is involved. Of course, questions regarding risk factors for cerebrovascular disease or previous CVA should be obtained.

Evaluation of facial nerve function requires careful attention and comparison between the two sides of the face. The patient should be evaluated at rest and with voluntary movement. The patient should be asked to wrinkle the nose, raise the eyebrows, squeeze the eyes shut, and purse the lips to assess all branches of the facial nerve. The facial skin should be assessed because a rash can indicate *herpes zoster oticus* (Ramsay Hunt syndrome). The eyes should be inspected to rule out exposure keratitis from lack of eye closure and dryness. If keratitis is suspected, ophthalmologic consultation should be obtained to prevent loss of vision. A complete neurologic examination must be done. If other neurologic deficits are found, neurology consultation is indicated. Lesions in the auditory canal should raise suspicion of herpes zoster oticus or malignancy of the external auditory canal with facial nerve involvement.

Otitis externa and facial weakness can represent malignant otitis externa, especially if the patient has diabetes or is immunocompromised. Signs of otitis media imply involvement of the facial nerve as it courses through the middle ear. The parotid gland and the rest of the neck should be checked to rule out a parotid salivary gland mass that involves the facial nerve. Any of these associated ear findings should prompt ENT consultation because early intervention can improve outcome. Audiometry is recommended in the evaluation of facial paralysis because of the proximity of cranial nerves VII and VIII in the temporal bone.

In cases in which no identifiable cause is found, the diagnosis of Bell palsy is made (although this diagnosis is not certain until a facial or acoustic neuroma has been ruled out either with return of facial function or with MRI scan). In the past, Bell palsy was treated expectantly because the cause was not clear, making treatment difficult. Evidence now indicates that most Bell palsy cases are secondary to a reactivation of the herpes simplex virus (HSV) in the geniculate ganglion, causing neural edema and neurapraxia. On the basis of this research, treatment with antivirals and steroids are thought to improve outcomes. If no contraindications to steroids exist, prednisone (1 mg/kg, up to a maximum of 60 mg/day, over 7 days with a taper) is reasonable. In addition to steroids, an oral antiviral with activity against the herpesvirus is given (200 mg acyclovir [Zovirax] five times daily or valacyclovir [Valtrex] 500 mg twice daily for 7-10 days). Of the utmost importance is protection of the eye. Moisturizing eyedrops and nightly lubrication should be prescribed. Any signs of irritation should prompt an ophthalmology evaluation.

If the facial weakness is secondary to Ramsay Hunt syndrome, treatment is similar to that of Bell palsy, but the clinical course and expected outcomes differ. This syndrome is caused by herpes zoster (rather than herpes simplex) involvement of the facial (geniculate), vestibulocochlear, or trigeminal ganglia. The infection causes pain and eventually vesicular eruptions around the auricle and external ear canal. Vesicles may appear only in the pharynx or hard palate in some cases. Facial weakness and at times dense paralysis are common. Hearing loss, tinnitus, and persistent vertigo also occur in 20% to 30% of patients (Adour, 1994). As with Bell palsy, prompt initiation of oral steroids and acyclovir should begin when the diagnosis is suspected. This therapy can lessen vertigo and improve recovery of facial nerve function, although outcomes are not as favorable as for Bell palsy. Some patients struggle with persistent facial weakness, pain, and hearing loss (Robillard et al., 1988).

In cases of facial paralysis associated with otitis externa or otitis media, treatment differs. If malignant otitis externa is suspected, the patient requires hospital admission, control of diabetes, and infectious diseases and ENT consultation. IV antibiotics and sometimes surgical debridement are required. CNS complications are possible.

Facial weakness in the setting of AOM requires treatment with a broad-spectrum antibiotic covering the usual pathogens of otitis media. In addition, a myringotomy with or without tube insertion is thought to hasten resolution and improve outcomes by allowing decompression of the infection. This also allows a culture to be done and antibiotic sensitivities determined. If facial weakness occurs in the

setting of chronic otitis media or known cholesteatoma, topical and systemic antistaphylococcal and antipseudomonas antibiotics should be started and an urgent ENT consultation obtained in hopes of preventing permanent facial paralysis and further complications.

Expected outcome for true Bell palsy is full return of function in 80% of patients. The remaining 20% have variable recovery. If recovery is incomplete, MRI is indicated to rule out neoplastic process (most likely a facial neuroma) that could mimic Bell palsy. Patients with diabetes mellitus have a higher incidence of Bell palsy and often have a poorer outcome. Permanent facial weakness is also more common after herpes zoster oticus. Outcomes of facial paralysis secondary to the other causes discussed are variable and depend on the severity of the pathology, the patient's general state of health, and the response to treatment.

In patients who have poor return of facial function, rehabilitation is necessary. The most important goal is protection of the eye followed by improved cosmesis. Ophthalmologic and ENT involvement is continued (Almeida et al., 2009).

KEY TREATMENT

- In Bell palsy, steroids are highly likely to increase the probability of recovery of nerve function (SOR: A) (Gronseth and Paduga, 2012).
- The addition of antivirals to steroids in the treatment of Bell palsy increases modestly (<7%) the functional recovery of the facial nerve (SOR: A) (Gronseth and Paduga, 2012).

The Nose and Paranasal Sinuses

Key Points

- Cigarette smoking and environmental allergies are important contributing factors to chronic nasal problems.
- Excessive use of decongestant nasal sprays can lead to rebound swelling and worsened nasal symptoms.
- A CT scan of the sinuses is not recommended to diagnose uncomplicated acute sinusitis in adults or children. CT should be considered when the diagnosis is uncertain, treatment has failed, or a complication or neoplasia is suspected. MRI is useful in evaluation of sinus tumors.
- Adenoid hypertrophy is a common cause of nasal symptoms in children but in an adult can indicate a lymphoproliferative disorder or HIV infection.
- A nasal foreign body should be suspected in a child who presents with recent unilateral nasal obstruction, rhinorrhea, and odor.
- Nasal polyps can be seen with asthma, cystic fibrosis, and rarely neoplasia. Nasal polyps always deserve further investigation.
- Unlike adults, children with sinusitis rarely complain of facial pain.
- The diagnosis of acute bacterial sinusitis should be considered when typical upper respiratory infection (URI) symptoms last longer than 10 days or symptoms worsen or fever occurs.

- Empiric antibiotic treatment for adult or pediatric acute sinusitis should provide coverage for the most common pathogens, *Pneumococcus* spp., *H. influenza*, and *M. catarrhalis*.
- Chronic and recurrent sinusitis leads to significant decrease in quality of life and can rarely lead to life-threatening complications.
- Sinonasal tumors often present with symptoms similar to sinusitis.
- An undiagnosed nasal septal hematoma can cause cartilage destruction and lead to disfigurement. Prompt diagnosis and treatment can prevent this.

HISTORY

Signs and symptoms of most nasal and sinus disorders include nasal congestion, rhinorrhea, bleeding, facial pressure, halitosis or pain, headache, cough, otalgia, facial or periorbital swelling, altered (diminished, absent, or distorted) sense of smell, or postnasal drainage. Initial evaluation of the patient with nasal complaints begins with a complete history, with specific questions directed at the timing and chronicity of the symptoms and modifying factors. The patient should be questioned specifically about previous nasal trauma.

Patients should be asked about prescription and over-the-counter (OTC) nasal, sinus, and allergy medications. Many patients try OTC remedies before seeking medical advice. Excessive use of decongestant nasal sprays can exacerbate and even cause nasal obstruction secondary to *rhinitis medicamentosa* and rebound nasal congestion. The patient should also be questioned about previous nasal surgery. Rarely, the patient admits to unorthodox self-treatment that may be significant (e.g., peroxide irrigation, overzealous nasal cleaning). This can explain continued symptoms and may indicate an underlying problem. The underlying problem may be true nasal pathology or rarely may be obsessive-compulsive disorder manifesting as repeated nasal cleaning.

Information about the patient's medical history and social history is also necessary. Knowledge of the patient's work environment may be relevant. Exposure to chemicals or fumes can cause nasal symptoms. Woodworkers are known to have a higher incidence of sinonasal carcinoma. A history of environmental allergies or immune dysfunction is relevant. Many medical conditions (e.g., asthma, autoimmune disorders) are associated with sinonasal dysfunction. Hypertension will limit the use of decongestants for treatment or predispose to epistaxis. A history of migraine is noteworthy because migraine headaches can be confused with sinus pain. Some prescriptions can exacerbate or even cause nasal dysfunction, especially medications that can lead to excessive nasal dryness (antihistamines, diuretics, antidepressants). Drug allergies should be noted. Previous nasal surgery, if done, may not have been successful or may even have led to increased problems. Cigarette smoking and excessive use of alcohol and caffeine have negative effects on mucociliary function that can lead to congestion. A history of nasal or facial trauma is important. Previous or current use of intranasal cocaine can lead to significant pathology and symptomatology.

PHYSICAL EXAMINATION

See [eAppendix 18-2](#) online.

RADIOGRAPHY

Plain radiographs are often ordered in cases of facial trauma, especially isolated nasal trauma. The radiographs can be complementary to the physical examination.

Plain radiographs of the sinuses are still useful in certain circumstances. Plain sinus radiographs are reasonably accurate in assessing the maxillary and frontal sinuses in cases of *acute* sinusitis. Complete opacification or an air-fluid level in one of these sinuses usually indicates acute sinusitis. However, the relatively low sensitivity and specificity of plain radiographs, especially in evaluating the ethmoid sinuses, have limited their usefulness.

Computed tomography has become an invaluable diagnostic tool for evaluating chronic nasal and sinus problems and has essentially supplanted the use of plain sinus radiographs. CT of the sinuses allows unparalleled imaging of the complicated anatomy of the nose and paranasal sinuses. It has also increased understanding of the pathophysiology of sinusitis. CT scanning can show areas of mild mucosal thickening in the sinuses (indicating chronic sinusitis), complete opacification (seen in acute sinusitis, polyps, or sinus tumors), bone erosion, or abscess formation in adjacent critical structures such as the orbit or brain ([Figure 18-6](#)). CT can show whether the *ostiomeatal complex* (the “bottleneck” of normal sinus drainage) is patent or obstructed and shows the myriad nasal and sinus normal variants, some of which predispose to sinonasal pathology.

Figure 18-6 Coronal computed tomography scan showing complete opacification of the right maxillary and ethmoid sinuses with partial opacification of the left maxillary and ethmoid sinuses. Arrow indicates ostiomeatal complex.

18-2 *Nose and Paranasal Sinuses: Physical Examination*

Examination of patients with nasal complaints should include a complete assessment of the face, oral cavity, oropharynx, nasopharynx, ears, lungs, nose, and sinuses. On initial inspection, it should be noted whether the patient prefers to breathe with the mouth open or closed. The face should be inspected for any visible asymmetry resulting from previous trauma or that can be associated with nasal and sinus tumors or polyps. The periorbital region should be inspected for swelling or erythema. The area over the maxillary and frontal sinuses should be palpated and percussed to elicit tenderness, and the external nasal skin should be inspected.

The oral cavity and oropharynx should be examined for evidence of mass effect, ulceration, or postnasal drainage. In children, the size and appearance of the tonsils should be noted. The nasopharynx can be inspected indirectly with a small dental mirror to look for drainage or masses and to evaluate the adenoid size.

Examination of the ears might show coexisting otitis media with effusion that indicates sinus disease, adenoidal hypertrophy, or a nasopharyngeal mass. Auscultation of the lungs is performed because chronic sinusitis and pulmonary disease coexist in certain patient populations (chronic obstructive pulmonary, asthma, cystic fibrosis, Wegener granulomatosis, immotile cilia syndrome). The neck should be palpated because sinus and nasopharyngeal neoplasms are often associated with cervical lymphadenopathy.

Intranasal examination is best done with a bright headlight and a nasal speculum. An otoscope with a large tip suffices and is often preferable in children. If a rigid or flexible endoscope is available, endoscopic examination of the nose provides optimum visualization of the entire nasal cavity but requires experience to perform properly. The appearance of the nasal mucosa should be inspected; healthy mucosa appears pink and moist. The quality of any rhinorrhea, if present, should be noted. The position of the nasal septum should be evaluated. Although most people have mild, asymptomatic septal deviation, moderate to severe septal deflections can cause nasal obstruction.

The inferior turbinates are easily seen low in the nasal cavity. They are sometimes mistaken for a mass or a polyp, especially if there is asymmetry between the right and left sides. The normal nasal cycle often causes the inferior turbinates to be of different size. Looking superiorly in the nasal cavity allows visualization of the middle turbinate.

This is a critical structure because normal drainage of most mucus produced in the sinuses (~1 qt/day) converges on an area called the *ostiomeatal complex* or *ostiomeatal unit* (OMC or OMU), which empties into the *middle meatus*, the space under the middle turbinate. The superior turbinate is not visible without endoscopy. Inspection should be made for any abnormal lesions, ulcerations, recent bleeding, or (in children) foreign bodies. If significant rhinorrhea, nasal congestion, or septal deviation does not allow adequate inspection of the nasal cavity, ear, nose, and throat evaluation is necessary for a complete examination.

Nasal Obstruction

Physical examination should include a complete examination of the face, oral cavity, pharynx, and internal and external nose. The patients should be observed (while unaware) for signs of mouth breathing while at rest. This is especially important in children whose predominant symptom of nasal obstruction might be mouth breathing. Inspection should be made for stigmata of allergic rhinitis, which include circles under the eyes (“allergic shiners”) or a crease on the bridge of the nose secondary to the allergic salute. Children with long-standing nasal obstruction (often from adenoid hypertrophy) often have a classic appearance of open-mouth posture, periorbital edema, and narrow face, the *adenoid facies*. Previous nasal trauma may be evidenced by obvious external nasal deformity. The oral cavity and pharynx should be inspected for enlargement of the tonsils, which often coexists with adenoid hypertrophy. Thick drainage along the posterior oropharyngeal wall can indicate coexistent sinusitis. The palate should be examined for distortion or ulceration from a neoplasm arising in the sinuses or the nasal cavity. An attempt may be made to visualize the nasopharynx indirectly with a headlight and dental mirror.

Examination of the nasal cavity is done systematically. The nasal septum is inspected for evidence of significant septal deviation. The size of the inferior turbinates is assessed. The presence and quality of any rhinorrhea is noted. The presence or absence of polyps or other intranasal masses must be confirmed. Several diagnoses are listed in [eTable 18-8](#).

eTable 18-8 Differential Diagnosis of Nasal Stuffiness Based on Incidence, Age, and Gender

Incidence	Children (0-10 yr)	Adolescents (11-19 yr)	Adults (≥20 yr)
Common	Infection, viral Infection, bacterial Allergy Adenoid hypertrophy (young > old)	Infection, viral Infection, bacterial Allergy Nasoseptal deformities (M > F) Vasomotor rhinitis	Infection, viral Infection, bacterial Allergy Nasoseptal deformities (M > F) Rhinitis medicamentosa Environmental and occupational irritants (M > F)
Uncommon	Nasoseptal deformities Chronic sinusitis (bacterial) Septal hematoma Septal abscess Foreign body	Rhinitis medicamentosa Chronic sinusitis (bacterial) Septal hematoma Septal abscess Infectious mononucleosis Antrochoanal polyp (F > M)	Atrophic rhinitis Chronic sinusitis (bacterial) Metabolic or endocrine disorder Septal perforation Hypothyroidism Antrochoanal polyp (F > M) Diabetes mellitus Menses, pregnancy
Rare	Atrophic rhinitis Choanal atresia Cystic fibrosis Dysgammaglobulinemia Neoplasm	Atrophic rhinitis Angiofibroma (boys) Fibrous dysplasia (M > F) Rhinolith Tornwaldt bursa	Malignant neoplasm Granuloma of pregnancy Midline lethal granulomatosis (Wegener granulomatosis) Rhinolith Paget's disease

F, Female; M, male.

Modified from May M, West JW. The "stuffy" nose. *Otolaryngol Clin North Am.* 1973;6:665.

Computed tomography of the sinuses should be ordered when the diagnosis of chronic sinusitis is suspected, medical treatment of sinusitis has failed and surgery is being contemplated, a complication of sinusitis is suspected, or a nasal or sinus mass is suspected. CT is not required as a confirmatory test in the treatment of uncomplicated acute sinusitis except in certain circumstances. The scan is helpful, however, in cases of *recurrent acute sinusitis* or when the diagnosis is not certain. Obtaining a scan during a patient's presumed infection allows the diagnosis to be confirmed or ruled out. Although some abnormalities require further treatment occasionally, the scan identifies abnormalities or variations of normal anatomy that require no intervention. Mucus retention cysts, for example, are seen in up to 20% of the population and are typically asymptomatic. Unless they are large or infection is suspected (the patient complains of pain in the vicinity of the cyst), treatment is not required. Recently, low radiation, cone-beam scanners have become common in ENT offices. This technology allows relatively inexpensive "point-of-care" imaging at a fraction of the radiation exposure and cost of helical CT scans.

Magnetic resonance imaging is not particularly helpful in evaluating sinusitis and has two main limitations in evaluating inflammatory sinus conditions. First, MRI often tends to be too sensitive, showing mucosal thickening that is often clinically insignificant. Second, MRI fails to show bony anatomy, which is critical in diagnosis and surgical planning in chronic sinusitis. MRI is useful in evaluating suspected sinonasal tumors and fungal infections of the sinuses. The limitations of MRI and its relatively high cost compared with CT do not justify its routine use in evaluating chronic sinusitis. If incidental sinusitis is noted on an MR image and the degree of sinusitis is severe, is asymmetric, or the patient is symptomatic, ENT referral or treatment is indicated.

CLINICAL PROBLEMS

Complaints related to the nose and sinuses are among the most common seen in a family medicine practice. Acute rhinitis (the common cold), allergic rhinitis, and sinusitis comprise the vast majority of these complaints and, taken together, result in an enormous socioeconomic impact in terms of missed workdays and schooldays and pharmaceutical costs. Nasal and sinus conditions can result in significant reduction in quality of life and can, rarely, be debilitating or even life threatening.

Epistaxis

See also the earlier section, "Emergencies." Epistaxis can be caused by trauma, dry weather, hypertension, bleeding dyscrasias, anticoagulation therapy, and intranasal tumors. Adolescent boys with recurrent epistaxis and nasal obstruction might have juvenile nasopharyngeal angiofibroma. Intranasal hemangioma can affect any age group. Epistaxis typically responds to conservative treatment, including nasal hydration with saline mist, nasal ointment, environmental humidification, avoidance of digital trauma, and control of hypertension if present. If bleeding continues to be a problem, the patient should be referred to an ENT consultant for a complete evaluation of the nasal cavities and

possible cautery. Screening blood studies for coagulopathy or imaging may be necessary.

Nasal Obstruction

The sensation of unilateral or bilateral nasal obstruction is relatively common and can range from mildly annoying to extremely frustrating to the patient. Nasal obstruction may be associated with other symptoms such as rhinorrhea, lost or altered sense of smell, or facial discomfort. Nasal obstruction may result from pathology of the nasal cavity or nasopharynx. (eTable 18-8 online summarizes the most common causes, associated signs and symptoms, and treatment for nasal obstruction.)

Physical Examination. See eAppendix 18-3 online.

Treatment. Successful treatment of nasal obstruction depends on making a correct diagnosis. After the diagnosis has been established, a treatment plan should be developed. If the nasal obstruction is secondary to one of the various types of rhinitis, it is treated medically. This includes nasal steroids, antihistamines, leukotriene inhibitors, mucolytics, oral decongestants, topical decongestants, and nasal saline. These medications may be used alone or in various combinations. The choice of medications is determined by the severity of symptoms and the patient's medical history, response to treatment, and wishes. Oral steroids can be used in select severe cases but are associated with potential significant side effects. Nasal decongestant sprays are very effective for treating severe nasal congestion but should be used sparingly and never for longer than 3 days to prevent rebound nasal obstruction (rhinitis medicamentosa). Allergy testing is done when allergies are suspected and the standard regimen is largely ineffective. Antibiotics are administered if a bacterial infection is suspected (acute rhinosinusitis).

Adenoid Hypertrophy

Adenoid hypertrophy is common in children. If identified in an adult, adenoid hypertrophy could indicate a lymphoproliferative disorder or HIV infection. The patient may present with nasal symptoms or symptoms of eustachian tube dysfunction. In the pediatric population, adenoid hypertrophy causes chronic or recurrent nasal obstruction, rhinorrhea, snoring, cough, or otitis media. The diagnosis is usually clinical but can be confirmed with lateral neck radiography. If symptoms are severe or persistent, adenoidectomy should be considered. Improvement in properly selected patients is usually significant, although well-controlled studies demonstrating efficacy are few (Aardweg, 2010).

Foreign Body

A nasal foreign body should be suspected in a child with or without a history of previous nasal problems who presents with recent unilateral nasal obstruction, rhinorrhea, and odor. The nasal foreign body might not be visible secondary to the presence of mucosal edema, mucus, or pus.

If the foreign body is identified, removal may be attempted in a cooperative child. If removal is not possible or the diagnosis is uncertain, ENT consultation should be obtained. The ENT evaluation may be done in the office setting or in the OR, depending again on patient cooperation and degree

18-3 *Nasal Obstruction: Physical Examination*

A wide variety of disorders may be found in the oral cavity and pharynx. Information is obtained from a thorough history and systematic physical examination of this area.

Problems in the oral cavity are usually dental in nature, and all physicians should be able to describe abnormalities accurately in consultation with dental colleagues. Children have 20 deciduous teeth, and adults have 32 permanent teeth. The teeth are numbered beginning with the upper right third molar (tooth number 1). The upper left third molar is number 16, the left mandibular third molar is number 17, and the right mandibular third molar is number 32. Adults have four upper and four lower midline incisors and a canine tooth flanking the incisors (four total). The premolars are lateral to the canines (four total). If the “wisdom teeth” are present, adults have four upper molars per side and four lower molars per side (16 total). The appearance of the teeth should be noted and dental evaluation requested if necessary.

Particular attention is paid to mucosal appearance. All mucosa should be inspected. The color and contour should be pink, smooth, and moist. The presence of mucosal ulceration or mass is noteworthy. Mucosal abnormalities may be conditions that are congenital, infectious, autoimmune, traumatic, neoplastic, toxic, or irritative (cigarettes, oral tobacco). They may also be secondary to immune deficiency (HIV/AIDS), systemic inflammatory disorders, or nutritional deficiencies. Proper identification of these allows prompt diagnosis and treatment.

The tongue consists of papillae that cover most of the dorsal surface and include fungiform, filiform, and

circumvallate papillae. The circumvallate papillae are a V-shaped group of papillae located between the anterior two thirds and the posterior one third of the tongue. These papillae may be mistaken for an abnormality by the patient or even the physician. The foramen cecum is a pit located midline at the junction between the anterior two thirds and the posterior third of the tongue and represents the location of initial descent of the embryologic thyroid into the neck. The lingual tonsil lies at the base of the tongue and is a fairly common location for infection (lingual tonsillitis) as well as neoplasia (base of tongue cancer). The base of the tongue should be palpated if concern for neoplasia exists.

The two pairs of major salivary ducts should be inspected. Wharton ducts drain saliva from the submandibular glands. They lie in the floor of mouth, just lateral to the lingual frenulum. Stenson ducts supply saliva from the parotid glands. They open into the buccal mucosa adjacent to the upper first molars. Each of these glands should be palpated. In cases of suspected sialoadenitis, the quality of the saliva should be inspected as the glands are massaged. If infection is present, purulence may be seen coming through the papilla of the duct of the affected gland.

The palatine tonsils should be inspected. They are part of the oropharynx. Their size, appearance, and symmetry should be noted. The size of the tonsils is graded on a scale of 1 to 4. A “1” tonsil is quite small, barely visible, “4” tonsils touch in the middle (kissing tonsils), and “2” and “3” tonsils are mildly and moderately hypertrophic. Asymmetric tonsils require further investigation because this is a concern for malignancy, especially in adults.

of suspicion. The nasal cavity is suctioned, decongested, and anesthetized with topical lidocaine. Endoscopy may be done. If the foreign body is seen, removal is undertaken.

If the child is old enough, asking him or her to blow the nose after decongestion might remove the foreign body or at least move it anteriorly. Removal can be difficult, and experience helps. Problems that can hinder removal include bleeding that obscures visibility. The foreign body can also be inadvertently pushed posteriorly. Softer foreign bodies, such as food matter and tissue paper, can disintegrate, requiring piecemeal removal.

A headlight and bivalve nasal speculum are recommended. Suction should be available. A small alligator or bayonet forceps is sometimes used but may simply push the foreign body posteriorly. In many cases, a useful instrument is a small, ball-tipped, right-angle probe, actually an otologic surgical instrument called an “attic hook.” This can be gently passed posterior to the foreign body, turned 90 degrees, and then used to pull the foreign body anteriorly and out of the nose.

After the foreign body is removed, the nasal cavity should be reinspected for retained, more distal foreign bodies. The other nasal cavity and ears should also be inspected because the child may have introduced foreign bodies into multiple orifices. Retained foreign bodies for years have been described. If the foreign body might be a disc battery, emergent removal is necessary to prevent significant tissue injury. Antibiotics are recommended if there is evidence of obvious infection or complete removal is not certain and reexamination is planned.

Nasal Vestibulitis

A low-grade infection of the anterior nasal vestibule will cause chronic irritation, crusting, and sometimes bleeding. The examination typically shows mild erythema, cracking, and yellow crusting just inside the nostril, but it may also appear fairly normal. The cause is usually *S. aureus* infection but may be fungal. Herpetic infections are typically more severe and not as protracted. Treatment is with OTC topical antibiotic ointment (without neomycin because of possible sensitivity) and avoidance of irritating the area. If symptoms continue, methicillin-resistant *S. aureus* (MRSA) infection is possible and should respond to mupirocin ointment. Sometimes an oral antibiotic may be necessary. Obtaining a culture may be helpful. Continued symptoms require ENT consultation to evaluate for other possible causes, including chronic sinusitis, anatomic problems such as deviated nasal septum, or even a neoplastic etiology.

Choanal Atresia

Choanal atresia is a common cause of nasal obstruction in children but can also be seen in adults. If bilateral, it manifests shortly after birth as an airway emergency because neonates are “obligate nasal breathers” and cannot tolerate nasal obstruction. Typically, they oxygenate well while crying but become cyanotic when crying stops and they cannot feed. This condition requires urgent ENT consultation. The airway is stabilized and the atresia repaired shortly thereafter. If unilateral, the atresia can go undiagnosed until later in childhood or even adulthood. The patient will report a lifelong history of nasal obstruction and

rhinorrhea. Diagnosis is made with endoscopy and CT. Treatment is surgical.

Nasal Polyps

Nasal polyps are the result of nasal mucosal inflammation and edema. On examination, nasal polyps are usually silver-gray in color and may be translucent. If there is associated infection, polyps can appear erythematous or may be obscured by mucus. Polyps cause significant and sometimes complete nasal obstruction but are painless and insensate. Nasal polyps predispose the patient to sinusitis and often cause anosmia.

The exact cause of nasal polyps is unclear. Polyps are often associated with chronic sinusitis, reactive airway disease, and less often with environmental allergies. In children, the presence of polyps should prompt testing for cystic fibrosis. Nasal polyps always require investigation because sinonasal tumor or fungal involvement is possible, especially if the polyps are unilateral. If polyps are identified, further evaluation includes allergy and asthma testing and CT scan. Medical treatment is initially offered but is often inadequate. Initial treatment includes topical steroids, allergy treatment, and treatment of sinusitis. In many patients, endoscopic sinus surgery (ESS) is an important adjunct to medical treatment and results in significant improvement in symptoms. Polyps almost always recur after removal without continued medical treatment. Appropriate postoperative treatment can dramatically slow, and sometimes halt, the rate of polyp regrowth. Symptom improvement after polyp removal with sinus surgery is usually dramatic.

Deviated Septum

Most patients have some degree of asymptomatic septal deviation, but in some patients, it is severe enough to cause symptoms of obstruction. Septal deviation is usually the result of previous nasal trauma. The trauma might have seemed relatively minor at the time or might have resulted in a nasal fracture. Deviated septum may be congenital. Physical examination clearly demonstrates an anterior septal deviation. If more posterior, nasal endoscopy or CT may be necessary to make the diagnosis. Any patient complaining of persistent nasal obstruction deserves further evaluation, especially if the cause is not immediately evident. Symptomatic septal deviation is readily treatable with outpatient surgery.

Septoplasty is done through an intranasal incision, allowing deviated portions of cartilage and bone to be replaced to the midline or removed, resulting in a symmetrically patent nasal airway. Septoplasty is often combined with a turbinate reduction procedure. The procedures are usually well tolerated. Postoperative pain, formerly a greater problem, usually resulted from the need for nasal packing and removal. Newer devices such as soft-silicone (Silastic) splints now cause much less postoperative discomfort than traditional packing.

In pediatric patients, septoplasty is not usually recommended because of concern about disrupting nasal and facial growth, although this risk appears to be low. Chronic mouth-breathing can also negatively affect facial growth, so for this reason, “limited” septoplasty may be considered in pediatric patients with severe or congenital deviation.

Hypertrophied Turbinates

Inferior turbinate hypertrophy is relatively common in adults and children. This usually occurs with chronic inflammation, usually resulting from allergy or rhinosinusitis. Turbinate hypertrophy usually responds to medical treatment addressing the primary problem. If the turbinates remain significantly hypertrophied despite medical treatment, turbinate reduction is offered, using cautery, radiofrequency treatment, fracture, excision, laser treatment, or cryotherapy. Submucosal resection of a portion of the conchal bone and reactive stromal tissue seems to provide the greatest improvement. It is important to preserve functional turbinate tissue. The turbinates are reactive structures that allow the nose to filter, warm, and humidify inspired air. Overly aggressive removal of turbinate tissue can leave the nasal cavity too vacuous, leading to nasal sicca, discomfort, bleeding, and infection. This is referred to as the “empty nose syndrome.” Because this condition is very difficult to treat, avoidance with conservative surgery is paramount.

Rhinitis

Acute Viral Rhinitis, the Common Cold, and Upper Respiratory Infection. The symptoms of “the common cold” are well known to all. Many viruses are known to be pathogenic to the upper respiratory tract, the most common being rhinovirus. The infection typically causes damage to the respiratory epithelium, leading to symptoms of sore throat, cough, low-grade fever, malaise, rhinorrhea, ear fullness, hoarseness, and nasal congestion. Symptom control is the patient’s primary concern, and there are myriad OTC medications available to control cough, nasal congestion, and rhinorrhea. These include oral and topical decongestants, saline mist or irrigations, cough suppressants or mucolytics, and analgesics and antipyretics. Topical decongestants are very effective treatment for nasal congestion but must be stopped after 3 days of use to prevent rebound swelling (“rhinitis medicamentosa”). Saline mist and saline irrigations are useful for thinning and washing away thick nasal secretions. Unless a bacterial infection is suspected, antibiotics are not indicated to treat an uncomplicated URI.

Although many treatments are available for viral URI, few have been well studied. The Cochrane Collaboration has made specific statements on the following treatments for URIs (The Cochrane Collaboration. Published by John Wiley & Sons, Ltd):

- Vitamin C with regular supplementation has been shown to reduce the severity and duration of the common cold. It is recommended that patients try vitamin C to see if it is helpful on an individual basis. Further studies are necessary.
- Antihistamine–decongestant–analgesic combinations have “some general benefit” in adults and older children.
- Intranasal ipratropium bromide spray appears to be effective in decreasing rhinorrhea with little effect on nasal congestion with tolerable side effects.
- Zinc lozenges at 75 mg/day or more administered within 24 hours of onset of symptoms reduces the duration of

common cold symptoms, although there is heterogeneity of the data. Zinc has a bad taste and can cause nausea. The effect of prophylactic use of zinc is less clear.

- Current evidence does not support the use of oral corticosteroids in the treatment of URI.
- Routine use of antibiotics is contraindicated in the treatment of the common cold in children and adults.
- There is a lack of evidence supporting the use of vaccines for the common cold.
- Garlic supplementation has not been proven effective in the treatment of URI.

The main concern of primary care physicians is to help patients with symptom relief and to determine which patients need more close follow-up or treatment. As a result of temporary mucociliary dysfunction, impaired local immunity, and epithelial damage from a viral URI, the patient’s infection can progress to AOM, bacterial pharyngitis, bronchitis or pneumonia, or acute bacterial rhinosinusitis (ABRS). Further evaluation is necessary if clinical suspicion of any of these exists. The determination of when a cold has progressed to bacterial sinusitis can be especially challenging and frustrating to both the patient and the clinician. It is estimated that 1% to 2% of colds will progress to bacterial sinusitis. A reasonable guide to make this determination is persistence of symptoms past 10 to 14 days or significant worsening of symptoms earlier (Figure 18-7). Preexisting medical conditions and the patient’s smoking history should also be considered. There must be a balance of listening to the patient’s concerns and recommending appropriate symptomatic treatment but not prescribing unnecessary treatment such as antibiotics or oral steroids, which can be counterproductive or even dangerous.

Allergic Rhinitis. See Chapter 19, Allergy.

Vasomotor Rhinitis and Idiopathic Rhinitis. When a cause for rhinitis cannot be made, the diagnosis of vasomotor or idiopathic rhinitis may be given. The primary symptoms are a feeling of nasal congestion and rhinorrhea. Table 18-11 lists some of the conditions that are included in the category of vasomotor rhinitis. Allergy skin test results in patients with vasomotor rhinorrhea are negative, with less than 25% eosinophils present on a nasal swab. These patients do not fully respond to topical or systemic corticosteroids. The condition suggests hyperactivity of parasympathetic tone, blockage of sympathetic tone with vasodilation of submucosal venous sinusoids, and excessive seromucous secretions from the mucous glands. A good analogy to vasomotor rhinorrhea is functional bowel disease. Treatment is with systemic decongestants and antihistamines or topical anticholinergic agents such as ipratropium bromide (Atrovent 0.06% nasal spray). Because of the persistence of symptoms, patients should be warned about excessive use of OTC nasal sprays, which can lead to rhinitis medicamentosa.

Rhinitis Medicamentosa. The prolonged use of topical decongestants for the nose can itself induce nasal stuffiness. The condition is caused by *rebound swelling* after dissipation of the decongestive effect of the nasal spray. Increasing the dose of the spray is the patient’s response to the rebound

Figure 18-7 Time course of symptoms during an upper respiratory (viral) illness. ABS, Acute bacterial sinusitis; URI, upper respiratory infection. (From McCoul ED. Upper respiratory infections. American Rhinologic Society, 2011. http://care.american-rhinologic.org/upper_respiratory_infections.)

Table 18-11 Conditions Included Under Vasomotor Rhinitis

Drug-induced rhinitis (reserpine, nonselective β -blockers, antidepressants, oral contraceptives)
Irritant rhinitis (smoke, gases)
Temperature- and humidity-induced rhinitis
Emotion- and stress-induced rhinitis
Hormonal rhinitis (pregnancy, premenstrual, hypothyroidism)
Idiopathic rhinitis

swelling, and the vicious cycle is difficult to break without education and medical help.

To treat rhinitis medicamentosa, the patient must stop using the topical decongestant to allow recovery of the damaged nasal mucosa. To relieve the subsequent rebound mucosal swelling, topical and oral corticosteroids are recommended. The length of time needed to successfully treat rhinitis medicamentosa varies depending on the duration the patient has used nasal decongestants. It takes at least 2 weeks to reverse the edema and histamine sensitivity. Other forms of treatment include systemic antihistamines or decongestants, corticosteroid injection into the inferior turbinate, and nocturnal sedation. Many patients begin using these sprays because of underlying pathology such as deviated septum, turbinate hypertrophy, or chronic sinusitis. Surgery may be helpful in these cases. Graf and colleagues (1995) achieved a 100% success rate at the end of 6 weeks of nasal corticosteroid therapy and avoidance of nasal decongestants. It takes time and patience to educate the patient about rhinitis medicamentosa, and both are essential for the treatment to be successful.

Atrophic Rhinitis. Elderly patients are more prone to develop atrophic rhinitis, which leads to nasal congestion, crusting, and foul odor. Although the Cochrane Collaboration found insufficient evidence for any consistently effective treatment for atrophic rhinitis, improvement can be seen

with moisturizing the nose with saline nose sprays (combinations of saline, aloe vera, oils) or saline irrigations with culture-directed topical antibiotics (Mirshra et al., 2012).

Atrophic rhinitis can also result from previous nasal surgery (referred to as “empty nose syndrome”), use of cocaine, and autoimmune or systemic inflammatory disorders (e.g., lupus, Wegener granulomatosis). In the case of a systemic disease, appropriate medical treatment of that condition will often help the associated nasal symptoms. If the cause of the patient’s atrophic rhinitis is unclear, further workup, including biopsy, is indicated.

Sinusitis and Rhinosinusitis

Symptoms of rhinitis and sinusitis are often very similar and even difficult to differentiate in many cases. Sinusitis implies inflammation of the mucosa of one or more of the paranasal sinuses. This usually coexists with rhinitis and is actually more accurately referred to as *rhinosinusitis*. Studies have shown that CT scans of patients with uncomplicated viral URIs have mucosal thickening and opacification of the sinuses. For this reason, most URIs are technically considered *viral rhinosinusitis*. In most cases, these changes resolve with time and symptomatic treatment. The terms *rhinosinusitis* or *sinusitis* are typically used when a bacterial infection of the sinuses is suspected. About 2% of viral URIs will progress to bacterial rhinosinusitis. An estimated 20 million cases of bacterial sinusitis occur in the United States annually, accounting for 9% and 21% of all pediatric and adult antibiotic annual prescriptions, respectively (Anon et al., 2004).

Inflammatory conditions of the paranasal sinuses cause significant socioeconomic impact annually secondary to considerable medical expense and missed workdays. Chronic sinusitis can be quite debilitating. Studies have shown that quality-of-life scores of patients with chronic sinusitis are often similar to those of other, more severe conditions (congestive heart failure, chronic obstructive pulmonary disease). Chronic sinusitis can also exacerbate coexisting medical conditions, most notably reactive airway disease.

Sinusitis represents one of the most common disorders requiring antibiotic treatment in adults. The challenge to the clinician in evaluating a patient with possible sinusitis is to differentiate viral URI, allergic rhinitis, and even a migraine headache, which do not require antibiotics, from bacterial sinusitis, which does respond to antibiotic treatment. There still seems to be a public perception that antibiotics hasten recovery from the common cold. Some physicians prescribe antibiotics in these situations, not wanting to disappoint the patient and seeing no significant risk. In fact, evidence suggests that there is a greater likelihood of *harming rather than benefiting* the patient with inappropriate use of antibiotics (Scott and Orzano, 2001). The emergence of bacteria highly resistant to broad-spectrum antibiotics has forced the medical community to modify its behavior regarding the treatment of URIs. More recently, there is concern that antibiotics may harm the patient's own protective "microbiome." For these reasons, antibiotics should not be prescribed unless a bacterial infection is certain or at least probable. The patient should be educated about the rationale for this.

The underlying cause of most cases of sinusitis is mucociliary dysfunction and sinus obstruction. The maxillary sinuses, anterior ethmoid sinuses, and frontal sinuses all drain through small ostia that converge into a small channel called the *ostiomeatal unit*, which then empties into the middle meatus beneath the middle turbinate. Obstruction at the ostiomeatal unit leads to obstruction of these sinuses and secondary infection. The posterior ethmoid sinuses and sphenoid sinuses are usually affected later. Sinusitis most often follows a viral URI or an episode of allergic rhinitis. Mucosal edema, impaired local immunity, and ciliary dysfunction lead to impaired sinus drainage and mucus stasis followed by bacterial infection.

Sinusitis is classified into *acute* (symptoms up to 3 weeks), *subacute* (symptoms from 3 to 6 weeks), and *chronic* (symptoms longer than 6 weeks) cases. Cases of acute sinusitis that clear completely only to develop again quickly are referred to as *recurrent acute sinusitis*. Although the types of sinusitis share many characteristics, there are several critical differences in pathogenesis and treatment.

The most important risk factor for the development of sinusitis is rhinitis (e.g., viral, allergic). Other risk factors include anatomic abnormalities (abnormality within the sinuses, septal deviation, choanal atresia, foreign body, adenoid hypertrophy), nasal polyps (which can also occur secondary to chronic sinusitis), conditions of local or systemic immunodeficiency, cystic fibrosis, primary ciliary dysfunction (Kartagener syndrome), secondary ciliary dysfunction (cigarette smoking, nasal decongestant abuse, cocaine abuse), gastroesophageal reflux disease (GERD), systemic inflammatory conditions (sarcoidosis, Wegener granulomatosis), dental disease, and nasal or sinus tumors. Any of these conditions can mimic or cause rhinosinusitis. Further workup or referral is indicated if a patient continues to struggle with nasal or sinus symptoms despite medical therapy.

The diagnosis of sinusitis is initially clinical. Imaging and cultures are not initially indicated unless symptoms are severe or become chronic or if a complication is suspected (Reider, 2003). A CT scan may also be helpful when the diagnosis of acute sinusitis has been made multiple times

but is still not certain. In 1996, the Task Force on Rhinosinusitis sponsored by the American Academy of Otolaryngology–Head and Neck Surgery developed diagnostic criteria for sinusitis. The signs and symptoms of sinusitis are divided into major and minor. *Major* signs and symptoms include facial pain and pressure, nasal congestion and obstruction, nasal discharge, discolored posterior discharge, anosmia or hyposmia, fever (acute only), and purulence on intranasal examination. *Minor* signs and symptoms include headache, otalgia or ear pressure, halitosis, dental pain, cough, and fever (nonacute) and in children, fatigue and irritability. The diagnosis of sinusitis is *probable* if the patient has two or more major factors or one major and two or more minor factors. A *suggestive* history is indicated by the presence of one major factor or two minor factors.

Microbiology of sinusitis varies according to its chronicity. Acute sinusitis is most often *initially* viral. If symptoms persist, the likelihood of bacterial infection increases. The bacteria most often involved in acute sinusitis are *Pneumococcus* spp., *H. influenzae*, and *M. catarrhalis*, with β -lactamase production common in all these. Chronic sinusitis is caused by the same bacteria as in acute sinusitis, but anaerobic bacteria, *Pseudomonas* spp., and staphylococci become involved more often. The incidence of antibiotic-resistant bacteria, including MRSA and multidrug-resistant *Pneumococcus* spp., seems to be increasing. Polymicrobial infections are not uncommon.

Sinusitis can also be caused by fungi. *Invasive* fungal sinusitis (caused most often by *Aspergillus* or *Mucor* spp.) can be seen in patients with impaired immune function and poorly controlled diabetes. It is life threatening even with aggressive medical and surgical treatment. Much more common is a more indolent fungally mediated sinusitis. *Allergic fungal sinusitis* is seen in patients with normal immune function. This is often seen in association with nasal polyps and is thought to be the result of an aberrant immune response to the fungus rather than a true infection. Patients do not always have type I hypersensitivity to fungi. Secondary bacterial infection is often associated with this problem.

Rarer causes of sinusitis are secondary to mycobacterial or parasitic infection.

Complications of Sinusitis. Most cases of sinusitis would resolve with or without medical treatment. Sinusitis is usually treated, however, to avoid potential complications and hasten recovery. The proximity of the paranasal sinuses to the orbits and brain potentially allows infection to spread to these locations. Orbital and CNS involvement of sinusitis can lead to loss of vision and can be life threatening and therefore requires early recognition and treatment. Table 18-12 lists the potential complications of sinusitis and treatment recommendations. A high degree of clinical suspicion is required in cases of possible complicated sinusitis, especially in young children. Patients with a recent URI who present with periorbital erythema, vision change, increasing or severe headache, high fever, or altered mental status require *urgent evaluation* and treatment. Ophthalmologic, infectious disease, and ENT consultations are obtained in cases of orbital complication. Periorbital and orbital cellulitis usually can be managed with IV antibiotics.

Table 18-12 Complications of Sinusitis

Complication	Physical Findings	Treatment
Periorbital cellulitis	Periorbital erythema, edema	Antibiotics: PO or IV
Orbital cellulitis	Erythema, edema, proptosis ± vision loss	IV antibiotics, close observation
Orbital abscess	Erythema, edema, proptosis ± vision loss	IV antibiotics + drainage, FESS
Cavernous sinus thrombosis	Erythema, edema, proptosis + vision loss	IV antibiotics + FESS
Meningitis	Headache, altered mental status, nuchal rigidity, fever	IV antibiotics ± FESS
Intracranial abscess	Headache, altered mental status, high fever	IV antibiotics + drainage, FESS
Mucocele or pyocele	Facial swelling ± fever ± pain	Drainage

FESS, Functional endoscopic sinus surgery; IV, intravenous; PO, oral.

The more severe orbital complications, however, usually require drainage procedures in combination with IV antibiotics. Surgical drainage also allows cultures to be obtained. Recovery from orbital complications is usually complete with prompt and aggressive treatment. Permanent vision impairment can occur even after appropriate treatment.

The CNS complications require neurosurgical, ENT, and infectious disease consultation. High-dose IV antibiotics are administered. Surgical drainage of the sinuses is sometimes recommended to treat the nidus of the infection and identify the exact pathogen. Recovery from CNS complications is more variable and depends on the patient's age and medical history, severity of the infection, and response to treatment.

Although not always complicated infections, sphenoid and frontal sinusitis deserve special mention because of their proximity to adjacent, critical structures. In some cases, drainage of the frontal sinuses is compromised. Chronic and recurrent frontal sinusitis can lead to both intracranial and ophthalmologic complications if untreated. Large *mucoceles* or *mucoepitheliocetes* or frontal bone osteomyelitis can also occur, causing disfigurement and diplopia. These conditions usually require surgical drainage. Similarly, sphenoid sinusitis can rarely be aggressive. The carotid artery and optic nerves traverse the lateral walls of the sphenoid sinuses. The sphenoid sinus occupies a space inferior and anterior to the cranial vault. Acute or long-standing sphenoid sinusitis can progress to CNS or eye complications or both. If frontal or sphenoid sinus involvement is noted on CT scan, ENT evaluation is usually indicated.

Medical Treatment of Acute Sinusitis. Treatment of acute sinusitis is almost always medical. Medical treatment of sinusitis is intended to restore normal mucociliary function, eradicate infection, and improve patient symptoms. Treatment to restore mucociliary function is critical and is as important as antibiotic treatment. Improved mucociliary function allows the patient's local immunity to function better and often leads to resolution of the infection.

The patient's medical history must be considered. Patients with poorly controlled hypertension or coronary artery disease may not tolerate decongestants. In acute cases of sinusitis, mucociliary function can be improved by a combination of medications, including oral or topical decongestants (topically for less than 3 days), mucolytics (guaifenesin), and nasal saline mist or irrigations. Nasal saline irrigations are available OTC or can be homemade. Both 0.9% isotonic saline and hypertonic saline irrigations are extremely beneficial. Although nasal steroids are *not indicated* for acute sinusitis, they have been shown to decrease symptoms and hasten recovery in patients. Antihistamines are usually not helpful unless there is a strong allergic component, and they can actually be counterproductive by increasing mucus viscosity and mucosal dryness. Oral steroids are usually not indicated in acute sinusitis, but they may be helpful in select patients.

Antibiotics are typically prescribed when acute bacterial sinusitis is suspected. Even an appropriate course of antibiotics can lead to significant side effects or complications. According to Cochrane Collaboration recommendations for treatment of acute sinusitis, antibiotics provide a minor improvement in simple, acute (uncomplicated) sinus infections. However, eight of 10 patients improve without antibiotics within 2 weeks. The Cochrane Collaboration states, "The potential benefit of antibiotics in the treatment of clinically diagnosed acute rhinosinusitis needs to be seen in the context of a high prevalence of adverse events. Taking into account antibiotic resistance and the very low incidence of serious complications, we conclude that there is no place for antibiotics for the patient with clinically diagnosed, uncomplicated acute rhinosinusitis." This leaves the clinician the task of using good judgment regarding when to prescribe antibiotics. With proper counseling, some patients may choose to avoid antibiotics. These patients need close follow-up.

A rapid assay to detect specific pathogens in acute sinusitis may be available in the future, but antibiotics are empirically chosen based on the expected pathogens and local antibiotic resistance patterns. The high incidence of β -lactamase-producing strains of *H. influenzae* and *M. catarrhalis* and the penicillin-resistant pneumococci must be considered. More prudent use of antibiotics seems to have resulted in a plateau of the emergence of antibiotic resistance of these pathogens. The incidence of MRSA seems to be increasing, especially in chronic sinusitis.

Many antibiotics are indicated for the treatment of ABRS. In addition, some antibiotics do not have Food and Drug Administration (FDA) approval for treatment of sinusitis but are still appropriately used.

Anon et al. (2004) made the following comprehensive recommendations regarding the treatment of acute rhinosinusitis:

1. A bacterial infection should be suspected if symptoms of a viral URI do not improve after 10 days or if symptoms worsen after 5 to 7 days.
2. Antibiotic resistance is common. Specifically, intermediate resistance of *S. pneumoniae* to penicillin is 15%, and complete resistance is estimated at 25%. Resistance of *S. pneumoniae* and *H. influenzae* to trimethoprim-sulfamethoxazole (TMP-SMX) is common, as is

resistance of *S. pneumoniae* macrolides. β -Lactamase production of *H. influenzae* and *M. catarrhalis* is 30% and 100%, respectively.

3. Selection of an antibiotic should be based on severity of symptoms, whether the patient has received an antibiotic in the past 4 to 6 weeks, and the response to current antibiotic therapy after 72 hours. Mild symptoms include rhinorrhea and fatigue. Moderate symptoms include congestion, low-grade fever, and facial pain.
4. The widespread use of fluoroquinolones for mild sinusitis may promote resistance to this class of antibiotics.
5. Antibiotic choices for adults with mild disease and no recent antibiotics include amoxicillin (1.75-4 g/day, with or without clavulanate), cefpodoxime proxetil, cefuroxime axetil, or cefdinir. TMP-SMX, doxycycline, azithromycin, erythromycin, and clarithromycin may be considered in penicillin-allergic patients, but the failure rate may be as high as 20% to 25%. Failure of therapy should prompt reevaluation of the patient or a switch in therapy.
6. Antibiotic choices for adults with moderate disease or with mild disease who have received recent antibiotics include amoxicillin-clavulanate (4 g/day) or a respiratory fluoroquinolone (levofloxacin or moxifloxacin). Ceftriaxone (1-2 g parenterally for 5 days) or combination therapy for gram-positive and gram-negative bacteria may also be considered. Failure of therapy should prompt reevaluation of the patient, CT scan, endoscopy with culture, or a switch in therapy.
7. Antibiotic choices for children with mild disease and no recent antibiotics include amoxicillin (90 mg/kg/day, with or without clavulanate), cefpodoxime proxetil, cefuroxime axetil, or cefdinir. TMP-SMX, doxycycline, azithromycin, erythromycin, and clarithromycin may be considered in penicillin-allergic patients (especially immediate type I hypersensitivity), but the failure rate may be as high as 20% to 25%. If the patient has a true type I hypersensitivity to β -lactams, desensitization, sinus culture, CT scan, or other intervention may be necessary. Less severe reaction may allow use of another β -lactam antibiotic. Failure of therapy should prompt reevaluation of the patient or a switch in therapy.
8. Antibiotic choices for children with moderate disease or with mild disease who recently received antibiotics include amoxicillin-clavulanate (90 mg/kg/day). Cefpodoxime proxetil, cefuroxime axetil, or cefdinir may be used if there is a nonsevere penicillin allergy (rash). Cefdinir is preferred because of high patient acceptance. Ceftriaxone (50 mg/kg/day parenterally for 5 days) or combination therapy for gram-positive and gram-negative bacteria may also be considered. Failure of therapy should prompt reevaluation of the patient, CT scan, endoscopy with culture, or a switch in therapy.

As recurrence or severity of the infection increases, broader spectrum antibiotics are indicated. Macrolides, fluoroquinolones, augmented penicillins, and cephalosporins are useful in these cases. Culture-directed antibiotic treatment may be indicated in more refractory cases. Obtaining a culture usually requires an ENT referral because simply swabbing the nasal cavity is not reliable.

Cultures can be obtained from an endoscopically guided middle meatus swab. Maxillary sinus aspiration can also be done but is more invasive and not much more accurate than a middle meatal culture. DNA swabs allowing for rapid identification of pathogens and resistance may be available in the near future. Adjunctive treatment to help improve mucociliary function becomes more important as recurrence increases.

TREATMENT

KEY TREATMENT

The American Academy of Otolaryngology-Head and Neck Surgery produced a consensus statement of Clinical Practice Guidelines for Treatment of Presumed Sinusitis (Rosenfeld et al., 2007). The following summary guidelines are for acute viral sinusitis (VRS), presumed ABRS, and chronic rhinosinusitis (CRS). The key symptoms of sinusitis were rhinorrhea, nasal obstruction, and facial pressure or pain.

Strongly Recommended Treatment

The quality of data supporting the benefits of treatment outweighing the potential harm is strong (Grades A, B):

- Clinicians should attempt to differentiate between viral and bacterial sinusitis.
- The level of pain should be assessed when treating ABRS.

Recommended Treatment

The benefits of treatment outweigh the risks, but the data are not as strong (grades B, C):

- Imaging studies are not recommended for cases of uncomplicated VRS.
- If a decision is made to treat ARS, amoxicillin should be used as first-line therapy if the patient does not have a penicillin allergy.
- If the condition worsens or fails to improve in 7 days, antibiotics should be started or changed.
- The clinician should attempt to differentiate CRS from recurrent ARS.
- The clinician should assess the patient with CRS or recurrent ARS for conditions or anatomic abnormalities that would predispose the patient to these conditions.
- The clinician should obtain a CT scan when evaluating a patient with recurrent ARS or CRS.
- The patient should be educated on control measures for ARS and CRS.

Optional Treatment

There is only weak evidence that the benefit of treatment outweighs the risk (grade D):

- Symptom relief should be offered when treating VRS.
- Symptom relief should be offered when treating ARS.
- Observation without use of antibiotics may be done in cases of uncomplicated ARS with temperature less than 101°F (<38.3°C).
- Diagnostic nasal endoscopy should be used in the evaluation of recurrent ARS or CRS.
- Testing should be done for allergy and immune system dysfunction in patients with recurrent ARS or CRS. (SOR: B).

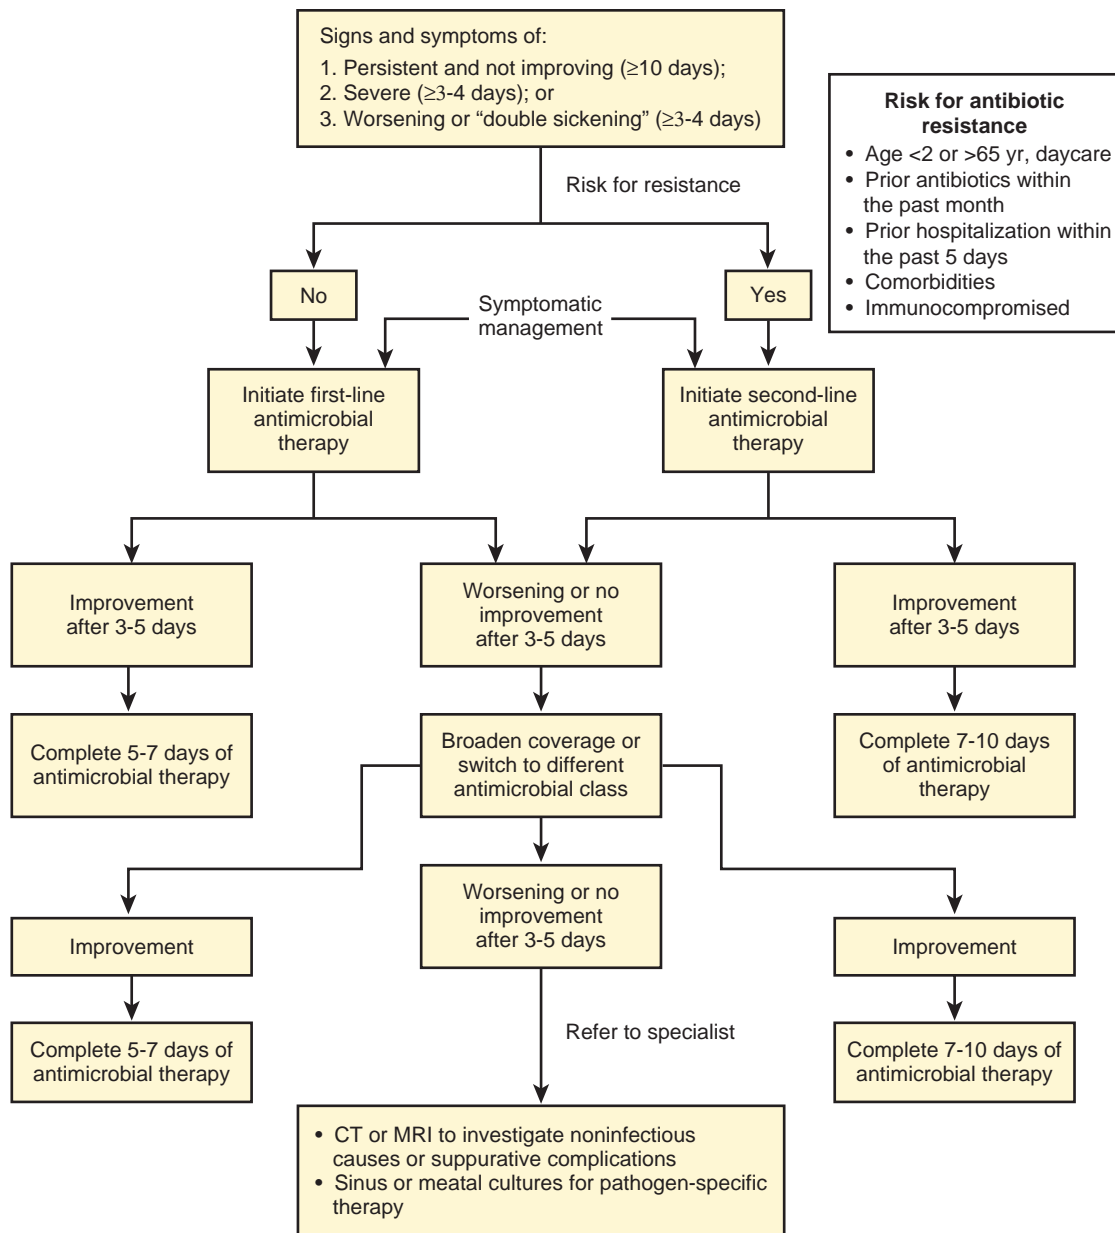

Figure 18-8 Algorithm for the management of acute bacterial rhinosinusitis. CT, Computed tomography; MRI, magnetic resonance imaging. (Reprinted with permission from Chow AW, Benninger MS, Brook I, et al. IDSA clinical practice guideline for acute bacterial rhinosinusitis in children and adults. *Clin Infect Dis.* 2012;54(8):e72-e112.)

In 2012, The Infectious Disease Society of America (IDSA) published a practice guideline for the treatment of ABRs in adults and children. The multidisciplinary panel addressed several issues in the management of ABRs, including (1) the difficulty of accurately differentiating bacterial from viral acute rhinosinusitis, leading to inappropriate antimicrobial therapy; (2) lack of consensus regarding the use of empiric antimicrobial therapy for ABRs; (3) changing bacterial isolates and antimicrobial susceptibility profiles associated with ABRs; and (4) impact of the conjugated vaccines for *S. pneumoniae* and the emergence of non-vaccine serotypes associated with ABRs. A useful algorithm for subsequent management based on risk assessment for

antimicrobial resistance and evolution of clinical responses was offered (Figure 18-8).

Medical Treatment of Chronic Sinusitis. Medical treatment of CRS is based on the same principles as for acute sinusitis: improvement of mucociliary function and eradication of bacteria. Treatment of chronic sinusitis requires more aggressive therapy, with potential side effects. If chronic sinusitis is suspected, CT scan of the paranasal sinus should be ordered to confirm the diagnosis before further treatment is initiated. This contrasts with acute sinusitis, for which CT is not necessary before treatment. In addition to confirming the diagnosis and severity of the

infections, CT can identify abnormalities that can predict a poorer response to medical treatment. This includes a posterior septal deviation, polyps, allergic fungal sinusitis, and various sinus abnormalities. The scan may also arouse suspicion of sinonasal mass or tumor, which would require earlier ENT evaluation.

It is noteworthy that there are *no* medications with FDA indications for treatment of chronic sinusitis. Despite this, several medical options are effective in improving symptoms in patients with CRS. Nasal saline irrigations for the symptoms of CRS are effective and well tolerated. Although minor side effects are common, the beneficial effect of saline appears to outweigh these drawbacks for the majority of patients. The use of topical saline could be included as a treatment adjunct for the symptoms of CRS. Additionally, a Cochrane Collaboration review in 2011 concluded that the topical nasal steroids were likely beneficial in the treatment of CRS, and the adverse affects were mild (Snidvongs et al., 2011).

Topical and systemic steroids can be used to improve drainage in cases of chronic sinusitis by decreasing mucosal inflammation, edema, and mucus production. Most topical nasal steroids must be used daily for several weeks to have significant benefit. Although oral steroids significantly improve symptoms, the effects may be short lived, and the potential side effects must be considered. Patients with known allergies should be treated. It should be remembered, however, that antihistamines cause mucosal drying and mucus stasis. Other allergy and asthma medications such as leukotriene inhibitors and IgE antagonists can also benefit coexisting sinusitis.

Although it is common to use antibiotics, the efficacy in treating chronic sinusitis has not been validated in controlled studies in adults. Two consensus statements do report that antibiotic treatment is likely beneficial in adults but not in children (Duiker, 2004; grade B). Because of the apparent benefit, antibiotics are typically used to treat chronic sinusitis in adults. An antibiotic with activity against staphylococci, as well as the more typical pathogens (with predicted antibiotic resistance), must be chosen. In cases of nasal polyps, an antibiotic with antipseudomonal activity may be necessary. Although no antibiotics have FDA indications for “chronic sinusitis,” appropriate choices include macrolides, broader spectrum cephalosporins, fluoroquinolones, and augmented penicillin. “Older” antibiotics, such as TMP-SMX, clindamycin, doxycycline, and linezolid, may be quite useful in documented staphylococcal infections. Also, the addition of rifampin may be useful in treating documented staphylococcal infections. ENT evaluation, including diagnostic nasal endoscopy, will allow for a swab and culture of the middle meatus. Middle meatal culture has been shown to be a reliable substitute to an invasive maxillary puncture and aspiration. Typically, longer courses of antibiotics are used (3-6 weeks) to treat chronic sinusitis. Few controlled studies are available to support this, and side effects may be significant. An oral probiotic should be considered because it may offer gastrointestinal (GI) protection.

In the past, studies demonstrated successful treatment of patients with CRS using systemic, topical antifungals, or both. This was based on a theory that environmental fungi

incited an intense immune response in predisposed patients. The lack of further studies supporting this theory has led the Cochrane Collaboration to recommend against the routine use of antifungals in the treatment of CRS. There are selected cases in which this treatment should be considered.

Otolaryngologists have begun to use a variety of medications topically to treat chronic sinusitis. Some of this is off-label use or compounded (usually antibiotics and steroids). The vast number of topical medications for the treatment of nasal and sinus conditions (and the paucity of well-controlled comparison studies) makes it very difficult to make recommendations about which treatment to use. In general, topical medications are appealing because the medication is deposited where the pathology exists and not subjected to GI breakdown and metabolism. Side effects and complications are rare, and many of these medications are indicated in children (some as young as 2 years old). For any topical medication to be effective, it must be able to reach the nasal epithelium. If pathology such as deviated nasal septum or polyps exists, this must be addressed. FDA indications for most of these sprays are for allergic rhinitis but also have efficacy for nonallergic causes of rhinitis.

Failure of Medical Treatment of Sinusitis. When medical treatment of recurrent acute sinusitis or chronic sinusitis is not successful, further evaluation and treatment are indicated. An ENT consultation should be obtained for patients unresponsive to medical treatment of chronic sinusitis. The risk factors listed previously should be considered and modified if possible. Allergy and immune system testing should be arranged. Pulmonary evaluation may be helpful if the patient has poorly controlled reactive airway disease.

If CT has not been done, a scan of the sinuses should be ordered to evaluate the anatomy of the sinuses. If CT has already been done and symptoms have changed or significant time has elapsed since the first scan, a repeat scan may be helpful. Before repeating the scan, ENT consultation should be considered because the consultant might have a preference for the type of scan ordered. A standard sinus CT scan often contains only coronal views; more detailed scans may be necessary for surgical planning. Low-radiation sinus scanners are now in many ENT offices, and these are typically much less expensive than a hospital scan.

The CT scan will show any evidence of chronic mucosal edema of the sinuses or even complete opacification. Partial or complete bilateral sinus opacification is typically seen in cases of long-standing chronic sinusitis or polyposis. Unilateral opacification or bony erosion is more worrisome for neoplastic disease or fungal sinusitis. The size of the turbinates and position of the nasal septum can also be assessed. In cases of medical failure or intolerance to continued aggressive medical treatment, surgery should be considered. ESS or *functional* ESS (FESS) has become the mainstay of surgical intervention for chronic sinusitis. Although earlier external surgical techniques are still occasionally indicated, FESS has the advantage of leaving no external scars and specifically addresses the critical area within the sinuses: the ostiomeatal unit. The procedure is

typically done under general anesthesia but can also be done under local anesthesia. Success rates of greater than 90% are expected and have been reported in many studies. Some patients experience relapse of their condition, especially if they had nasal polyps. Revision surgery is offered in these cases and is usually quite successful.

Successful sinus surgery often results in fewer and less severe infections and improved response to future medical treatment. The procedure is often done with septoplasty and turbinate surgery and is well tolerated. Advancements in minimally invasive surgical techniques have allowed preservation of more normal tissue and less surgical morbidity. Nasal packing is often not necessary. When used, resorbable packs are typically applied, obviating the need and discomfort of pack removal. Potential complications of ESS include bleeding, scarring leading to further sinus blockage, loss of smell, and rare orbital and CNS injury. For this reason, surgery is undertaken only after appropriate medical treatment and careful patient consideration.

According to Cochrane Collaboration recommendations for CRS, FESS as currently practiced is a safe procedure. The limited evidence suggests that FESS has not been demonstrated to confer additional benefit to that obtained by medical treatment (with or without sinus irrigation) in CRS. It is important to note that FESS should be viewed as an adjunct to medical therapy and not as a stand-alone procedure in most cases. After surgery, the sinuses should be much more receptive to topical therapy, including saline, steroid, or antibiotic rinses. The open sinus cavities also allow for direct endoscopic culture and more tailored antibiotic treatment. With this in mind, FESS has been shown to be a viable treatment option for patients who fail medical treatment. More randomized controlled trials comparing FESS with medical and other treatments are required, with long-term follow-up.

Advances in medical and surgical treatment deserve mention. Newer allergy and asthma medications (leukotriene inhibitors and IgE antagonists) show promise in the future treatment of chronic sinusitis. New antibiotics continue to be released to treat antibiotic-resistant bacteria. Compounding pharmacies have made available topical antibiotic and antifungal formulations that are quite effective in some patients. Topical treatment is appealing because it delivers extremely high concentrations of medication to the target area, minimizing systemic side effects and, theoretically, development of resistance. Topical treatment seems more effective in patients with sinus surgery that created open sinuses, allowing antibiotic delivery. Research into the genetics of sinusitis continues and should lead to further advances in treatment.

Surgical advances include improved power surgical debriders that spare normal mucosa, have more efficient surgery, and reduce blood loss. Packing materials have improved and often are resorbable or impregnated with medication. Image-guided surgery has become more common. Balloon techniques allow dilation of the sinus ostia without tissue removal but do not treat the ethmoid sinuses, which are most commonly involved. Balloon dilation can be done in the office on selected patients. Although not a substitute for an experienced surgeon, these advances often allow more focused and possibly safer surgery.

Pediatric Sinusitis. Although the sinuses are not completely developed until adolescence, children can still develop sinusitis, usually involving the ethmoid and maxillary sinuses. Young children can have 5 to 10 episodes of acute rhinitis (viral URI) in a year. The usual symptoms of a URI lasting longer than 2 weeks can indicate development of bacterial sinusitis. Other symptoms indicating sinusitis in children include nighttime cough and foul breath. Children rarely complain of facial pain, which is common in adults.

Diagnoses other than sinusitis should also be considered in children with prolonged URI-type symptoms. Previously undiagnosed choanal atresia or stenosis can be present. Unilateral or bilateral nasal foreign bodies can also cause these symptoms. Environmental allergies should be considered, as should immunodeficiency, GERD, ciliary dyskinesia, and cystic fibrosis. Many children with asthma also have coexisting sinusitis, which can complicate asthma management. Recurrent sinusitis can cause or worsen asthma exacerbations.

Chronic adenoid hypertrophy or chronic adenoiditis can mimic sinusitis in children. Adenoid hypertrophy can also cause sinusitis secondary to nasal obstruction, mucus stasis, and subsequent infection. This can occur with or without the presence of tonsil hypertrophy. Adenoid hypertrophy can lead to facial changes caused by chronic mouth breathing. Children with long-standing nasal obstruction tend to have elongated, narrow faces with open-mouth breathing, the “adenoid facies.” Differentiating chronic adenoiditis from sinusitis can be difficult because the symptoms may be identical, and the disorders often coexist.

According to Cochrane Collaboration recommendations, limited evidence suggests that *intranasal corticosteroids* may significantly improve nasal obstruction symptoms in children with moderate to severe adenoidal hypertrophy. This improvement may be associated with a reduction of adenoid size.

Medical treatment of pediatric acute sinusitis is similar to that for adults: decongestants, nasal saline irrigations or mist, and antibiotics (Duiker, 2004). The pathogens are similar to those of adults: pneumococci, *H. influenzae*, and *M. catarrhalis*. Coexisting problems (e.g., allergies) should be controlled. Diligence on the part of the parents is required because children might not tolerate nasal saline sprays willingly. If compliance is ensured, medical treatment should result in improvement in the vast majority of patients.

Children who fail medical therapy should be referred to an otorhinolaryngologist. Often, adenoidectomy, sometimes combined with a turbinate reduction procedure, is recommended. In properly selected patients, this procedure has a high success rate in greatly improving symptoms. For children unresponsive to medical treatment and adenoidectomy, a CT scan should be obtained. If significant sinusitis exists, the child likely has chronic sinusitis. Medical treatment should be reattempted because it might be more effective after the obstructing adenoids have been removed. If not previously done, the child should be screened for allergies, immune deficiency, and cystic fibrosis.

The efficacy of antibiotics in the treatment of pediatric chronic sinusitis has not been validated. Unlike adults with

chronic sinusitis who likely benefit from longer courses of antibiotics, evidence-based research indicates that this is not the case for children (Duiker, 2004).

If symptoms persist, ESS is considered. The surgery targets the ostiomeatal unit in hope of improving sinus drainage and aeration. A ciliary biopsy may also be done to evaluate for ciliary dyskinesia. Cultures should also be obtained to tailor postoperative antibiotics. In properly selected patients, sinus surgery has an extremely high success rate. Although rare, significant risks, including bleeding and orbital and intracranial injury, must be considered. Surgery may be especially beneficial in children with coexisting pulmonary disease (asthma or cystic fibrosis).

Sinonasal Tumors

Intranasal and sinus tumors often manifest with symptoms identical to those of more benign sinonasal conditions. Nasal obstruction, facial pressure or pain, and bloody rhinorrhea are common symptoms of a neoplastic process within the nasal cavity or sinuses. Because these symptoms are also common with sinusitis, a high index of suspicion is required, and diagnosis is often delayed.

Tumors of the external nose are usually related to prolonged exposure to the sun. Basal cell carcinoma and squamous cell carcinoma (SCC) are most common (see Chapter 33). Intranasal tumors can be benign or malignant. The most common growth within the nasal cavity is *benign squamous papilloma*, caused by human papillomavirus (HPV). This typically appears as an exophytic lesion within the nose, often at a junction between squamous and respiratory epithelium, and causes irritation and bleeding. Treatment consists of simple excision, and recurrence is uncommon. Malignant degeneration is extremely unlikely.

A much more aggressive papillary lesion is an *inverted papilloma*. These tumors often manifest as unilateral polyps and can cause symptoms of nasal obstruction, bleeding, and sinusitis. These lesions require excision because they can be locally destructive, and malignant degeneration can occur. Endoscopic excision is usually possible, although external approaches are sometimes required.

The *juvenile nasopharyngeal angiofibroma* is a tumor that occurs exclusively in adolescent boys. The tumor is located within the nasopharynx but typically causes nasal symptoms. Patients present with nasal obstruction and recurrent epistaxis. Because nosebleeds and nasal obstruction are both common problems, a high index of suspicion is required to make a timely diagnosis. These tumors can be extremely aggressive, and surgical excision is required. Recurrences are possible, and radiation therapy is recommended for some patients.

Malignant tumors of the nose and sinuses include SCC, adenocarcinoma, adenoid cystic carcinoma, hemangiopericytoma, osteosarcoma, and malignant melanoma. Again, early symptoms are similar to those of sinusitis, which often results in a delayed diagnosis. The prognosis ranges from extremely good to extremely poor, depending on tumor type and stage. Orbital and intracranial extension often occurs. Both regional and distant metastases result in poorer prognosis. Aggressive treatment is required and involves combined treatment with surgery and radiation, sometimes with chemotherapy.

KEY TREATMENT

- Nasal saline sprays or irrigations are a very effective treatment for both rhinitis and sinusitis (SOR: B).
- Nasal steroids sprays are an important treatment for chronic sinusitis (SOR: B).
- Treatment to restore mucociliary function in sinusitis is likely as important as antimicrobial therapy (SOR: C).

Oral Cavity and Pharynx

Key Points

- The IDSA now recommends the rapid antigen test alone to confirm the presence of group A β -hemolytic streptococcal (GABHS) pharyngitis in adults.
- Back-up throat cultures for those with a negative rapid antigen detection test (RADT) are not necessary in adults because of the low incidence of GABHS and low risk for rheumatic fever. Antistreptococcal antibody titers are not recommended to diagnose acute GABHS because they indicate past infection.
- Whereas motor disorders of the esophagus are more likely to cause difficulty swallowing liquids, mechanical obstruction produces dysphagia with both solids and liquids.
- From 23% to 60% of patients presenting with a globus sensation have GERD.
- Snoring is the most common symptom of obstructive sleep apnea (OSA) and is more common in men than women.

PHYSICAL EXAMINATION AND RADIOGRAPHY

See eAppendix 18-4 online.

ACUTE PHARYNGITIS AND TONSILLITIS

Viral agents cause the majority of sore throats. Even when exudates are present, fewer than 15% of children and 10% of adults have documented GABHS as the cause. In children younger than 3 years, the predominance of a viral cause is even higher than in school-age children.

Pharyngitis caused by GABHS (*Streptococcus pyogenes*) has its peak incidence in late winter and early spring. The incubation phase is 2 to 5 days and leads to sudden onset of sore throat, painful swallowing, fever, and chills. Less frequent symptoms include headache, abdominal pain, and nausea. On physical examination, a purulent white exudate is often seen on the tonsils, and the anterior cervical nodes are tender and enlarged. There is sometimes a scarlet fever rash (a diffuse, erythematous, macular, rough rash that tends to coalesce) and soft palate petechiae. Scarlet fever is the result of exotoxin-producing strains of GABHS. Pastia lines are caused by prominence of the rash in the flexor creases of the antecubital space or axilla. A strawberry tongue is another sign of GABHS.

A throat culture is the “gold standard” for diagnosing GABHS infection. A 5% sheep blood agar plate is used to plate the throat swab and can be read in 24 hours (sensitivity, 96%). Serologic tests (antistreptolysin O [ASO] titer) are

18-4 *Oral Cavity and Pharynx: Radiography*

Imaging of the oral cavity and oral pharynx can greatly aid in the examination of these areas in certain circumstances. Plain radiography or computed tomography (CT) scanning of the mandible can aid in delineating fractures, infections, cysts, and tumors. A panoramic radiograph is particularly useful in evaluating bony abnormalities of the mandible. CT and magnetic resonance imaging (MRI) scans are useful in evaluating tumors of the oral cavity and oropharynx. Not only do these scans help by differentiating solid, cystic, and vascular lesions, but they also can distinguish the depth of the lesion and its relationship to important neurovascular structures.

Imaging is also extremely useful for masses with extension into the submental and sublingual space. CT or MRI can help determine whether the lesion is inflammatory (Ludwig angina), cystic (plunging ranula), vascular (hemangioma), or neoplastic (squamous cell carcinoma or salivary gland tumor). Enhanced CT scanning is particularly helpful in the diagnosis of peritonsillar abscess and in differentiating this condition from peritonsillar cellulitis. The scan sometimes shows poorly circumscribed “phlegmonous” changes that represent *early* abscess formation. This knowledge helps in formulating appropriate treatment for these patients.

accurate but not practical to use in diagnosing an acute infection because of the time involved in obtaining results and the fact that an elevated titer could just indicate a past infection. RADTs or optical immunoassays (OIAs) are the most popular tests for detection of GABHS. Although most manufacturers claim 95% to 97% true negatives (specificity), clinical trials suggest a lower figure of 90%. True positives (sensitivity) are claimed to be 90% to 95%, but again, clinical trials show closer to 60% to 80% sensitivity (Shulman et al., 2012).

Scoring systems based on features of sore throat have been developed. The McIsaac Decision Rule is a modification of the Centor criteria for diagnosing GABHS (McIsaac et al., 2000). McIsaac allots points to specific criteria. One point is given for each of the following criteria: temperature higher than 38°C, no cough, tender anterior cervical adenopathy, tonsillar swelling or exudates, and age 3 to 14 years. No points are given for age 15 to 44 years, and -1 point is taken away for age older than 45 years. The number of points provides a predictive percent of the probability of having GABHS. A score of 0 means 2% to 3% of patients have GABHS; 1 point, a 4% to 6% incidence; 2 points, a 10% to 12% incidence; 3 points, a 27% to 28% incidence; and 4 points, a 38% to 63% incidence of GABHS. When the score is less than 2, no treatment is recommended. When the score is 2 or 3, cultures or OIAs are recommended. When the score is 4 or 5, treatment is the best option. The IDSA now recommends the use of the rapid antigen test alone to confirm the presence of GABHS in adults (Bisno et al., 2002).

A study comparing five management strategies (no treatment or testing, empiric treatment with penicillin, throat culture, OIA with culture if results negative, OIA alone) found empiric therapy the least cost effective and culture the most cost-effective strategy when the GABHS prevalence was 10%. OIA alone was as effective as OIA followed by throat culture when the OIA result was negative (Neuner et al., 2003). After a test result is positive, treatment with penicillin or a cephalosporin is recommended because there has been no incidence of in vitro resistance to these drugs.

Treatment for GABHS is penicillin VK, 250 mg two or three times daily in children and 500 mg twice daily in adolescents and adults for 10 days. Intramuscular penicillin G benzathine, 600,000 U for a child weighing less than 60 lb (27 kg) or 1.2 million U for patients weighing more than 60 lb, can be used if compliance is a problem or if the child cannot swallow or is vomiting. Mixing the benzathine penicillin with 300,000 U of procaine penicillin alleviates some of the discomfort. Penicillin-allergic patients can use erythromycin, 40 mg/kg in two or four divided doses daily for 10 days. In recurrent disease, cephalexin, 12.5 mg/kg or 500 mg twice daily for 10 days, can be prescribed. Alternative antibiotics include cefpodoxime (Vantin), cefprozil (Cefzil), cefuroxime axetil (Ceftin), cefixime (Suprax), ceftibuten (Cedax), azithromycin (Zithromax), clarithromycin (Biaxin), and amoxicillin-clavulanic acid (Augmentin). Cephalosporins appear to be superior to penicillin in terms of bacterial eradication and clinical cure (Pichichero and Brixner, 2006).

After treatment, 15% of throat cultures remain positive for GABHS. This is considered a carrier state. One effective way to eliminate the carrier state is to use clindamycin (Cleocin), 20 mg/kg/day in three divided doses (maximum,

450 mg/day) for 10 days (Tanzet et al., 1998). Contagiousness to others is inversely proportional to the length of time that GABHS is carried. Culturing contacts is indicated only when the contact is symptomatic. Pets have been considered a reservoir for GABHS, but some evidence casts doubt on this supposition (Wilson et al., 1995).

Although antimicrobial treatment is believed to decrease the suppurative (peritonsillar abscess) and immunologic (acute rheumatic fever, acute glomerulonephritis [AGN]) sequelae of GABHS infection, much is not known. *Acute rheumatic fever* had become rare until 1986, when its incidence increased; any explanation is mere speculation. Good evidence indicates that antimicrobial treatment shortens the symptomatic period of GABHS and plays a part in preventing acute rheumatic fever. However, acute rheumatic fever can still occur in the presence of appropriately diagnosed and treated cases of GABHS pharyngitis and even in the absence of a symptomatic infection.

Only specific serotypes of GABHS (12, 49, 55, 57, Red Lake strain) cause AGN because of an antigen-antibody deposition on the kidney glomerular membrane. When a patient does have GABHS infection caused by one of these strains, only 15% develop AGN. Edema, hypertension, and rusty urine are the hallmarks of AGN and occur 10 days after the infection. Prompt treatment of GABHS pharyngitis with penicillin does not appear to prevent AGN. Treatment is symptomatic to control the blood pressure and edema.

The indications for tonsillectomy after GABHS infections are six episodes within 1 year or three to four episodes within each of 2 years (Pichichero, 2004). The severity of the infections and the total number of missed workdays or schooldays should also be taken into account when considering tonsillectomy. Sleep-disordered breathing is another indication for tonsillectomy and runs the gamut from snoring to sleep apnea.

Viral causes of pharyngitis include rhinovirus (20% of all pharyngitis) and coronavirus, adenovirus, and parainfluenza virus (5% of all pharyngitis) (Middleton, 1996). Coxsackievirus A can cause 1- to 2-mm red-ringed vesicles on the tonsils, uvula, and soft palate and is known as *herpangina*. Coxsackievirus A16 is the major cause of hand, foot, and mouth disease, a 1-week illness with 4- to 8-mm ulcers on the tongue and buccal mucosa and vesicles on the palms and soles. The incubation time for this illness is 4 to 6 days.

A type of pharyngitis similar to coxsackievirus A16 pharyngitis is caused by HSV. Painful, shallow, red-bordered ulcers develop on the soft palate, gums, lips, or buccal mucosa and cause fever, pain, and lymphadenopathy. Acyclovir (Zovirax), 200 mg five times daily for 5 days; famciclovir (Famvir), 125 mg twice daily for 5 days; or valacyclovir (Valtrex), 500 mg twice daily for 5 days, can be used in severe cases of herpes stomatitis and lessen the duration of symptoms and viral shedding.

Epstein-Barr virus (EBV) as a cause of pharyngitis can mimic GABHS infection. It can also occur concurrently with GABHS infection. Studies have shown the two infections occurring together in 2% to 33% of cases. Prodromal symptoms to severe sore throat include malaise, anorexia, chills, and headache. Fatigue, lymphadenopathy, and hepatosplenomegaly can follow in 5 to 14 days. Pharyngitis with tonsillar hypertrophy and a membranous white tonsillar exudate lasts 5 to 10 days. Lymphadenopathy and

hepatosplenomegaly can persist for 3 to 6 weeks. Contact sports should be avoided for 6 weeks because of the possibility of splenic rupture. Complications that occur in fewer than 2% of patients with EBV infection include thrombocytopenia, hemolytic anemia, Guillain-Barré syndrome, Bell palsy, transverse myelitis, and aseptic meningitis. Hepatitis can be seen in 20% to 50% of patients with EBV infection.

The diagnosis is made on clinical grounds, supported by positive antibody test results. A CBC shows atypical lymphocytes, and a monospot test is positive in 95% of cases of infectious mononucleosis (Middleton, 1996). Steroids (and rarely urgent tonsillectomy) are indicated when the tonsillar hypertrophy causes pharyngeal obstruction or when other life-threatening complications occur. Amoxicillin should be avoided because it often causes a rash in patients with infectious mononucleosis.

When the symptoms point to infectious mononucleosis but the monospot test or EBV titer result is negative, the patient may be infected with cytomegalovirus (CMV). The illness lasts 2 to 6 weeks and is characterized in older patients by a higher fever and greater malaise but milder pharyngitis than with infectious mononucleosis. A CMV-specific immunoglobulin M (IgM) antibody test is the best means of diagnosing this infection. In immunocompromised patients, ganciclovir (Cytovene) or foscarnet (Foscavir) can control the infection. Bacterial causes of pharyngitis other than GABHS are shown in Table 18-13.

KEY TREATMENT

- Although current treatment guidelines recommend oral penicillin V or intramuscular penicillin G benzathine as drugs of choice for GABHS, strong evidence supports cephalosporins as a first choice for this infection (SOR: A) (Casey and Pichichero, 2007).
- In countries with low rates of rheumatic fever, 3 to 6 days of oral cephalosporins to treat GABHS has comparable efficacy to the usual 10-day oral penicillin regimen (SOR: A) (Altamimi et al., 2009).
- Once-daily amoxicillin (750 mg to 1 g) for 10 days is as good as twice-daily or three-times-daily dosing (SOR: A) (Lennon et al., 2008).

ABNORMALITIES OF THE ORAL REGION

(eTable 18-9)

Swallowing Disorders

Patients who experience difficulty swallowing solids or liquids have *dysphagia*. About 7% of Americans experience dysphagia in their lifetimes, and 30% to 40% of nursing home residents have swallowing disorders. Whereas motor disorders of the esophagus are more likely to cause difficulty in swallowing liquid, mechanical obstruction causes dysphagia with both solids and liquids.

Pharyngeal muscle weakness or CNS disease can lead to difficulty beginning the act of swallowing. The proximal third of the esophagus is composed of striated or voluntary muscles, the middle third is a combination of striated and smooth muscles, and the distal third is entirely smooth muscle tissue. The two sphincters involved in swallowing are the upper and lower esophageal sphincters (UES and LES).

Food sticking in the throat is known as *oropharyngeal dysphagia*, and 80% of the cases are the result of neuromuscular disease (see eTable 18-10 online for causes) (Trate et al., 1996). An inability to move solids from the esophagus to the stomach is referred to as *esophageal dysphagia*, which is more common than oropharyngeal dysphagia (see eTable 18-11 online for causes). The history is extremely important in determining the cause of the dysphagia. If dysphagia is associated with chest pain, especially difficulty swallowing cold liquids, diffuse esophageal spasm is the most likely diagnosis.

A constant sensation of a lump in the throat is known as *globus hystericus* and is not necessarily associated with the act of swallowing. This diagnosis can be made only by ruling out anatomic or motor abnormalities of the pharynx, larynx, or esophagus. From 23% to 60% of patients presenting with a globus sensation have GERD as the origin (Ahuja et al., 1999). eTable 18-12 online lists head and neck symptoms related to GERD versus gastroesophageal symptoms.

If the food bolus sticks in the distal esophagus, a stricture, malignancy, or ring is most likely the cause. Achalasia or degeneration of the nerve cell bodies of the myenteric plexus leads to esophageal dilation and food retention associated with increased tone of the LES.

Motor disorders of the esophagus cause progression of dysphagia over months to years. A carcinoma should be suspected when there is a rapid progression of dysphagia for solids in an older person with anorexia and weight loss; a history of smoking and alcohol use makes this diagnosis more likely. Medication-induced esophagitis is characterized by acute retrosternal pain exacerbated by swallowing. The most common medications associated with this syndrome are the tetracyclines (doxycycline, minocycline), potassium chloride pills, iron preparations, quinidine and its derivatives, aspirin, and nonsteroidal antiinflammatory drugs.

Another mechanical reason for dysphagia is an *esophageal web*, a thin diaphragm most often in the proximal esophagus. When associated with iron-deficiency anemia, the condition is known as *Plummer-Vinson syndrome*. *Pulsion diverticula* are usually seen at the level of the cricopharyngeal muscle and occur predominantly in men older than

eTable 18-9 Some Disorders of the Oral Regions by Predominant Site of Involvement

Disorder	Description	Disorder	Description
NONSPECIFIC		Verrucous carcinoma	Slow growing, exophytic, usually well differentiated, at site of snuff application, metastasis unusual, occurring late
Acute herpetic gingivostomatitis	Widespread ulcerating vesicular lesions	White spongy nevus	Thick, white folds over most of buccal mucosa except gingivae; benign
Behçet syndrome	Multiple oral ulcers similar to those of aphthous stomatitis	PALATE	
Cicatricial pemphigoid	Bullae that rupture quickly, leaving ulcers; ocular lesions that develop after oral lesions	Infectious mononucleosis	Petechiae at junction of hard and soft palates
Condyloma acuminatum	Sexually transmitted wart forming cauliflower-like clumps	Kaposi sarcoma	Painless, red to purple macules progressing to painful papules
Dyskeratosis	Occurs with erythroplakia, leukoplakia (with patch on mucous membrane that does not rub off), and mixed red-and-white lesions; precancerous	Necrotizing sialometaplasia	Large, rapidly developing ulcer, often painless; appears grossly malignant; heals spontaneously in 1-3 mo
Erythema multiforme	Multiple bullae that rupture quickly, leaving hemorrhagic ulcers; includes Stevens-Johnson syndrome	Papillary inflammatory hyperplasia	Red spongy tissue, followed by fibrous tissue folds; benign
Hemangioma	Purple to dark-red lesions, similar to port-wine stain; benign	Pipe smoker's palate (nicotine stomatitis)	Red punctate areas at ducts of minor salivary glands, often with severe, usually benign, leukoplakia
Hereditary hemorrhagic telangiectasia	Localized dilated blood vessels	Secondary herpes simplex	Small papules quickly coalescing into series of ulcers
Lichen planus	Lacy pattern (Wickham striae) sometimes erosive; can become malignant	Torus palatinus	Overgrowth of bone in midline; benign
Lymphangioma	Localized swelling or discoloration; benign	Wegener granulomatosis	Lethal midline granuloma with bone destruction, sequestration, and perforation
Mucocele (mucous retention cyst)	Soft nodule; if superficial, covered by thin epithelium; bluish	TONGUE AND FLOOR OF MOUTH	
Noma	Small vesicle or ulcer that rapidly enlarges and becomes necrotic	Ankyloglossia	Tongue unable to protrude
Pemphigoid	Small, yellow or hemorrhagic, tense bullae; can last several days before rupture	Benign lymphoepithelial cyst	Yellowish nodule on ventral part of tongue or anterior floor of mouth
Peutz-Jeghers syndrome	Brownish black melanin spots with gastrointestinal polyposis	Benign migratory glossitis (geographic tongue, erythema migrans)	Changing patterns of hyperkeratosis and erythema on dorsum and edges; desquamated filiform papillae in irregular circinate pattern, often with inflamed center and white or yellow border
Recurrent aphthous stomatitis (canker sores)	Small, painful ulcers or large, painful scarring ulcers	Dermoid cyst	Swollen floor of mouth
Syphilis	Chancre,* mucous patch, gumma	Enlargement of tongue	Localized or generalized, depending on how many teeth are missing; adjacent teeth may indent tongue
LIPS		Fissured (scrotal) tongue	Deep furrows in lateral and dorsal areas
Actinic atrophy	Thin, atrophic mucosa with erosive area; predisposes to neoplasia	Glossitis	Red, painful tongue; often secondary to another condition, allergic, or idiopathic
Angioedema	Acute swelling	Hairy tongue	Dark, elongated filiform papillae
Angular cheilitis (cheilosis)	Fissuring of corners of mouth, often with maceration	Linea alba	Thin white line on edge of tongue, usually bilateral
Cheilitis glandularis	Enlarged, nodular labial glands with inflamed, dilated secretory ducts; sometimes everted, hypertrophic lips	Lingual thyroid nodule	Smooth nodular mass of thyroid tissue follicles on far posterior dorsum of tongue, usually at midline
Cheilitis granulomatosa	Diffusely swollen lips, primarily lower lip	Ludwig angina	Can compromise airway by forcing tongue superiorly and posteriorly
Cracking exfoliative cheilitis	Chronic desquamation of superficial mucosal cells	Median rhomboid glossitis	Red (usually) patch in midline of tongue, without papillae
Keratoacanthoma	Benign, locally destructive epithelial tumor resembling squamous cell carcinoma; regresses spontaneously in about 5 months	Neurilemoma	Persistent swelling, sometimes at site of previous trauma

*Red papule rapidly developing into a painless ulcer with a serosanguinous crust.

Continued on following page

eTable 18-9 Causes of Esophageal Dysphagia (Continued)

Disorder	Description	Disorder	Description
Secondary herpes simplex (cold sores)	Short-lived vesicle followed by small, painful ulcer at vermilion border	Pernicious anemia	Smooth pale tongue, often with glossodynia or glossopyrosis
Verruca vulgaris (wart)	Pebbly surface	Ranula	Large mucocele penetrating mylohyoid muscle; can plunge deep into neck; swollen floor of mouth
BUCCAL MUCOSA		Thyroglossal duct cyst	Midline swelling that moves upward when tongue protrudes
Aspirin burn	Painful white area; when wiped off, exposes inflamed area	Tuberculosis	Ulcers on dorsum of tongue, cervical adenopathy
Fordyce granules	Cream-colored macules, about 1 mm in diameter; benign	SALIVARY GLANDS	
Hand, foot, and mouth disease	Small, ulcerated vesicles	Benign lymphoepithelial lesion (Mikulicz disease)	Unilateral or bilateral enlargement of salivary glands; often with dry mouth and eyes
Herpangina	Vesicles in posterior of mouth	Sialadenitis	Swelling, often painful; benign
Irritation fibroma	Smooth-surfaced, dome-shaped sessile	Sialolithiasis	Swelling (e.g., floor of mouth) that increases at mealtime or after eating a pickle
Koplik spots	Tiny, grayish white macules with red margins near orifice of parotid duct	Sjögren syndrome	See text section on salivary glands
Linea alba	Thin white line, typically bilateral, on level of occlusal plane; benign	Xerostomia	Dry mouth
Smokeless tobacco lesion	White or gray, corrugated; usually behind lower lip; tends toward malignancy

50 years. Regurgitation of food and liquid immediately after swallowing is the hallmark of this condition, with large diverticula that can cause almost complete obstruction. A *Zenker diverticulum* originates from the posterior aspect of the esophagus and is bounded superiorly by the cricopharyngeal muscle and inferiorly by the inferior pharyngeal muscle. Treatment is usually surgical.

Dysphagia in the pediatric population is often secondary to tonsillar hypertrophy or an esophageal foreign body. Diagnostic studies include a barium esophagram with views of the pharynx, esophagus, and stomach. To detect rings and early strictures, a barium-coated tablet or marshmallow can reveal the site of narrowing. When there is radiographic evidence of a lesion, esophagogastroscopy is indicated.

If no abnormality is found, esophageal manometry should be performed. The goal of esophageal manometry is to assess the characteristics of esophageal contractions and to define the LES and the UES and their response to swallowing. Only about 50% of patients show a definitive abnormality with this test. Provocative testing with manometry involves infusion of edrophonium, esophageal balloon dilation, or acid perfusion into the esophagus. Recording esophageal pH in an ambulatory setting can indicate if acid reflux episodes are present at the same time as the patient's symptoms.

The management of swallowing difficulties is directed toward the specific cause involved. [eTable 18-13](#) lists the treatments for the various causes of dysphagia.

Snoring and Obstructive Sleep Apnea

Snoring is extremely prevalent but is also the most common symptom of OSA. OSA occurs when the upper airway collapses during sleep, leading to obstruction, hypoventilation, and hypoxemia. OSA has been associated with development or exacerbation of hypertension, coronary artery disease, pulmonary hypertension, poor concentration, impotence, obesity, depression, and increased risk of motor vehicle crashes. It is a potentially serious medical condition that can be overlooked if not specifically sought.

Men have OSA more than women, and children can also be affected. Adults with OSA are often overweight or stocky. They are told that they snore loudly, and episodes of respiratory obstruction or gasping might be witnessed by a family member. Symptoms of OSA include loud snoring, daytime fatigue, morning headache (secondary to hypoxemia), restless sleeping habits, and frequent catnaps (often unintentionally, sometimes while driving).

Physical examination should be performed with attention to the patient's body habitus. The oral cavity should be inspected for tonsillar hypertrophy and evidence of excess soft palate tissue. The size and position of the tongue should be noted. The nose should be inspected for nasal obstruction. The size and position of the mandible and its relationship to the neck should be evaluated.

Strong suspicion of sleep apnea should be confirmed with an overnight sleep study or polysomnogram. The sleep study measures intensity of snoring, presence of apnea or hypopnea (partial apnea), oxygen saturation, sleep efficiency, and cardiac rhythm. The data are compiled and analyzed by a sleep specialist. A numeric value of the total number of apneas and hypopneas is derived, called

the apnea-hypopnea index or *respiratory distress index* (RDI). An RDI of less than 5 is considered normal. An RDI greater than 5 with or without oxygen desaturation indicates sleep apnea. Some patients are found to have normal RDI values but have snoring with disrupted sleep. This condition has been described as "upper airway resistance syndrome."

Treatment. Treatment for OSA is either nonsurgical or surgical. Nonsurgical methods are always attempted first and include weight loss and assisted nighttime ventilation by continuous positive airway pressure (CPAP). CPAP essentially splints the collapsed airway open with positive pressure, given as the patient initiates inhalation. It is generally well tolerated, safe, and extremely effective in compliant patients. Unfortunately, some patients either do not tolerate CPAP or choose not to use it. Surgery is a potential option in these patients.

Numerous surgical procedures exist for the treatment of OSA. The gold standard is tracheotomy, which bypasses the upper airway obstruction and is almost always successful in eliminating sleep apnea. Obviously, most patients do not see this as an appealing solution. For patients with severe OSA and morbid obesity, however, a tracheotomy can give extremely satisfying results. More popular procedures have been devised to try to eliminate (rather than bypass) the upper airway anatomic obstruction. Uvulopalatopharyngoplasty is used most often and entails removal of redundant oropharyngeal tissue, including the tonsils, the uvula, and a strip of soft palate. Its success depends on the severity of the OSA and the patient's anatomy. Other procedures use laser or radiofrequency tissue ablation to eliminate excess pharyngeal tissue. If nasal obstruction exists, it is corrected. In severe cases, procedures directed at the tongue base and facial skeleton have been effective in properly selected patients.

The Larynx

Key Points

- Most cases of acute stridor are secondary to inflammatory disorders such as croup, epiglottitis, and tracheitis.
- Parainfluenza virus is the most common cause of croup.
- Neoplasia must be considered in adults with voice or swallowing complaints.
- Visualization of the laryngopharynx is required to evaluate any patient with persistent or severe stridor or with voice or throat symptoms.
- Laryngomalacia is the most common cause of chronic stridor in neonates.
- Vocal cord nodules are always bilateral; polyps and cysts are usually unilateral.
- It is essential to elicit smoking and alcohol histories in patients with voice complaints because of the association with cancer.
- Although often idiopathic or iatrogenic, vocal cord paralysis requires thorough investigation.
- Vocal cord dysfunction is often misdiagnosed as asthma.

eTable 18-13 Treatment of Dysphagia

Cause	Treatment
Carcinoma of distal third of esophagus with no metastases	Surgery
Carcinoma of middle third of esophagus	Surgery and radiation therapy, chemotherapy, or both
Carcinoma of proximal third of esophagus	Radiation therapy
Benign strictures and rings <13 mm in diameter	Dilation with Hurst or Maloney mercury bougies
Neuromuscular disease, reflux esophagitis with inflammation, or scleroderma	Chronic antireflux medication, PPIs, or H ₂ blockers and elevating head of bed
Achalasia	Botulinum toxin, pneumatic dilation of LES, sphincterotomy (Heller procedure)
Diffuse esophageal spasm	Medications (anticholinergics, calcium channel blockers, nitrates, hydralazine)

LES, Lower esophageal sphincter; PPI, proton pump inhibitor.

INITIAL EVALUATION

Hoarseness, stridor, foreign body (globus) sensation, and dysphagia are all symptoms of laryngeal or hypopharyngeal pathology. When a patient presents with any of these persistent symptoms, a complete past medical and social history is essential. In addition, if hoarseness has persisted, laryngoscopy is indicated. Laryngoscopy can be performed indirectly using a mirror. If the hypopharynx and larynx are not adequately visualized with the mirror because of an excessive gag reflex, direct flexible fiberoptic laryngoscopy can be performed. A topical vasoconstrictor (e.g., 0.5% ephedrine) with a topical anesthetic (e.g., topical lidocaine) can be applied in the nose to improve patient comfort; however, this is not always necessary. The flexible fiberoptic nasopharyngoscope is then passed through the pharynx to visualize the larynx.

RADIOGRAPHY

Indications for imaging the larynx include evaluation of laryngeal tumors and traumatic laryngeal injuries. CT or MRI is performed to evaluate depth of invasion with tumors. CT is the preferred method for imaging malignant and non-malignant disease, although MRI has certain indications. Traumatic injuries are best evaluated by CT scan. The modalities to assess stridor are directed by the history and physical examination. Available imaging techniques include chest radiography (posteroanterior [PA] and lateral radiographs), neck radiography (PA and lateral radiographs), and fluoroscopy. Contrast esophagography may be necessary to evaluate for vascular anomalies that can cause airway and esophageal compression or to rule out tracheoesophageal fistulas.

SPECIAL STUDIES

Airway fluoroscopy is useful for evaluating pediatric stridor. Fluoroscopy provides a dynamic picture of the entire airway from the nasopharynx to the carina. This facilitates the identification of obstructive lesions or foreign bodies during both phases of respiration.

A more specialized examination called video laryngeal stroboscopy (VLS) is performed by a speech-language pathologist. This technique allows highly detailed views of the larynx and evaluation of the gross movement of the vocal cords and their vibratory motion. VLS is an excellent modality to photodocument lesions of the laryngopharynx. VLS is also helpful to voice therapists in identifying and following patients with voice disorders, including hoarseness and paradoxical vocal cord dysfunction (see later discussion).

Finally, direct laryngoscopy using a rigid laryngoscope can be performed, usually in the OR. Indications include the need for further evaluation and biopsy of pathology of the larynx.

LARYNGITIS

Laryngitis is the most common cause of acute hoarseness. It is secondary to diffuse swelling of the larynx. Viral infections are the most common cause and are often associated

with other upper respiratory tract symptoms. Treatment is conservative, and recommendations include relative voice rest and avoidance of inhalational substances such as cigarette smoke or other irritating substances. Humidification may be helpful. Symptoms from viral laryngitis usually improve within days. Consider other causes if symptoms persist. A Cochrane review concluded that the risks of antibiotics outweigh the benefits in treatment (Revez & Cardona, 2013).

Fungal infections can also localize to the larynx. Of these, *Candida albicans* is the most common and is found in immunocompromised patients; patients using inhaled steroids; and those using long-term, broad-spectrum antibiotics. Characteristic findings on examination include a diffuse reddened mucosa covered by white patches. Topical treatment includes nystatin, miconazole, or clotrimazole; systemic therapy includes fluconazole or ketoconazole. Other uncommon infectious causes of laryngitis include tuberculosis and syphilis.

STRIDOR

Stridor is noisy breathing. Stridor is a symptom, not a definitive diagnosis. It results from turbulent airflow and some degree of airway obstruction, usually at the level of the laryngopharynx or trachea. Stridor can affect both adults and children, but children present special diagnostic and therapeutic challenges because the antecedent history may be limited, physical examination is more challenging, and their small airways are more susceptible to critical obstruction. Because of the small airway diameter in infants and children, even small and subtle abnormalities can cause stridor and obstruct the airway.

It is helpful to localize stridor in the respiratory cycle. In general, whereas *inspiratory* stridor typically is caused by an obstruction at or above the level of the true vocal cords, *expiratory* stridor is usually localized to the more distal tracheobronchial tree. Biphase stridor is usually caused by an obstruction at the true vocal cords, typically at the immediate subglottic level.

The medical history provides valuable information in the evaluation of stridor. In the pediatric population, a history should include questions about cyanosis, feeding difficulty, failure to gain weight, and retractions. Time of onset of stridor, birth history, prematurity, and need for immediate intubation at birth may help to identify the cause of stridor. A past medical history of smoking or ethanol abuse in an adult patient should raise the suspicion of a neoplastic process. Factors that tend to exacerbate the stridor are noted. These include change of intensity of stridor when in different positions, when crying, and when feeding. Previous intubation or laryngotracheal trauma can lead to acquired subglottic or tracheal stenosis. The presence of fever and a history of acute onset may be significant for an infectious process, including epiglottitis, croup, or tracheitis. New-onset stridor or increased stridor may portend impending airway distress, which would require more immediate workup, close monitoring, and possibly the need to stabilize the airway.

The severity of the obstruction and the need for intervention are sometimes difficult to determine. A child with a partially obstructed airway can have stridor but may not

appear to be in respiratory distress. Intervention might or might not be needed. Examination should include documentation of stridor in the phase of respiration and whether suprasternal or intercostal retractions are present. The patency of the nose, oral cavity, and oropharynx should be noted. Large tonsils and adenoids can contribute to obstruction of the airway. The neck should be palpated for any masses that can cause extrinsic compression. Significant obstruction can cause signs of tachycardia, tachypnea, confusion, restlessness, or obtundation. Visualization of the larynx is paramount. Flexible fiberoptic laryngoscopy is the most useful modality in the workup of stridor. This usually requires an ENT consultation. It is easily performed in infants and adults.

There are many causes of stridor in the adult and pediatric population. The differential diagnosis includes lesions affecting various parts of the airway (see [eTable 18-14](#) online). Pediatric patients are more likely to have congenital causes of stridor, but any age group may have stridor secondary to trauma; inflammation; neoplasia, polyps, or papillomas; and foreign bodies. Common congenital anomalies include laryngomalacia, true vocal cord paralysis, subglottic stenosis, laryngeal webs and clefts, subglottic hemangiomas, anomalous great vessels, and complete tracheal rings. Most cases of acute stridor are caused by inflammatory disorders, including croup, epiglottitis, and tracheitis. Chronic causes of stridor are more likely to be congenital, neoplastic, or from airway stenosis.

The most common cause of acute stridor in the pediatric population is *croup* (laryngotracheobronchitis). The parainfluenza virus is the most common cause and affects primarily the subglottic area but can also affect other portions of the laryngotracheal complex. Stridor can be inspiratory or biphasic and is often associated with a barking cough. Radiographs usually show the typical subglottic narrowing caused by edema. The typical age group is 6 months to 2 years, but the condition can be seen in children up to 5 years. The infection and inflammation are usually self-limiting, and conservative management is recommended. Evidence supports the routine use of corticosteroids in most children with croup ([Husby et al., 1993](#)). Intervention at an earlier phase of the illness reduces the severity of symptoms and the rates of return to a health care practitioner for additional medical attention, ED visits, and hospital admissions. Many children respond to a single oral dose of dexamethasone. For those who do not tolerate the oral preparation, nebulized budesonide or intramuscular dexamethasone is a reasonable alternative.

According to Cochrane Collaboration recommendations regarding glucocorticoids for croup, dexamethasone and budesonide are effective in relieving the symptoms of croup as early as 6 hours after treatment. Fewer return visits and (re)admissions are required, and hospital stay is shortened. Dexamethasone is also effective in patients with mild croup ([Russell et al., 2011](#)).

Severe cases of croup can manifest with significant respiratory distress or even obstruction. Therapy in these patients requires hospitalization (ICU in some cases); treatment includes corticosteroids, supplemental oxygen, fluids, humidification, nebulized racemic epinephrine aerosols, heliox, and occasionally intubation. A Cochrane review concluded benefit of symptoms at 30 minutes with

nebulized epinephrine ([Bjornson et al., 2013](#)). Complications from croup include airway obstruction, pneumonia, pulmonary edema, and cardiac failure.

Laryngomalacia is the most common cause of chronic stridor in neonates and is characterized by high-pitched inspiratory stridor that can be intensified with agitation, feeding, and placement in the supine position. The disorder is caused by immaturity of the laryngeal cartilages and is typically seen on examination as an omega-shaped epiglottis and floppy aryepiglottic folds that partially obstruct the laryngeal inlet on inspiration. The key to the diagnosis lies in the history and typical findings on flexible fiberoptic laryngoscopy. Airway fluoroscopy provides a dynamic evaluation of the laryngotracheal complex and often shows a component of tracheomalacia as well (laryngotracheomalacia). Treatment is rarely needed because the problem is self-limiting and resolves by 18 months of age. Gastroesophageal reflux is extremely common because the increased pressure gradient needed for adequate ventilation causes an increase in acid reflux into the esophagus. This exacerbates the condition by causing a component of reflux laryngitis. Rarely, failure to thrive because of feeding problems, cor pulmonale, or persistent desaturations while asleep can indicate the need for surgical intervention to improve the airway. Even if uncomplicated laryngomalacia is suspected, ENT evaluation is still recommended to confirm the diagnosis.

True *vocal cord paralysis* is another common cause of congenital stridor and usually occurs at birth to 2 months of age. In newborns, the cause is usually injury to the vagus nerve sustained at birth, or it can be secondary to CNS abnormalities. Unilateral paralysis is more common than bilateral paralysis. The diagnosis is confirmed by flexible fiberoptic laryngoscopy. Workup also includes barium swallow, neck and chest radiography, and cardiology consultation to rule out a cardiothoracic cause of vagal paralysis. Treatment is rarely necessary because most patients improve or compensate adequately with the opposite vocal cord. On the other hand, bilateral vocal cord paralysis manifests with a high-pitched stridor and upper airway obstruction. MRI of the brain should be included in the workup to rule out hydrocephalus and Arnold-Chiari malformation. Emergent airway intervention by intubation or tracheotomy might be necessary.

Adults may also be affected by vocal cord paralysis, either unilateral or bilateral. Possible etiologies include neoplastic processes, traumatic injuries to the recurrent laryngeal nerve, or idiopathic causes. If the cause is known (e.g., occurring after cervical surgery resulting in recurrent laryngeal nerve injury), further workup may not be recommended. If the cause is not clear, imaging of the brain, neck, and chest is ordered to rule out a compressive lesion affecting the recurrent laryngeal nerve.

Recurrent respiratory papillomatosis occurs in all ages but is more common in children. It is the most common benign tumor of the airway and is usually found on the true vocal cords and supraglottic and subglottic areas. The causative agent is HPV, typically subtypes 6 and 11. In juvenile onset cases, the virus is thought to be acquired through the birth canal. Adult cases are thought to be sexually transmitted. Symptoms usually begin with hoarseness or aphonia and progress to stridor and dyspnea at a later stage of disease.

eTable 18-14 Causes of Stridor

Nose	Oral Cavity or Oropharynx
Nasal aperture stenosis	Ludwig angina
Choanal atresia (unilateral or bilateral)	Tonsil hypertrophy or acute tonsillitis
Nasal polyposis	Peritonsillar abscess
Neoplasia	Parapharyngeal abscess
	Macroglossia
	Retrognathia
	Neoplasia
Larynx	Trachea
Laryngomalacia	Neoplasia
Bilateral vocal cord paralysis	Subglottic stenosis
Papilloma	Vascular anomalies
Laryngotracheobronchitis (croup)	Hemangioma
Epiglottitis	Complete tracheal rings
Papilloma	Tracheoesophageal fistula
Neoplasia	Tracheitis
	Tracheomalacia
	Enlarged thyroid
	Foreign body
	Neoplasia

The disease can progress to complete airway obstruction and eventually death. There is no cure, but some patients eventually go into remission. Treatment includes endoscopic debulking with various lasers or laryngeal shaver, but recurrence and multiple procedures are common. Intralesional cidofovir is often used for recalcitrant cases, but adequate studies are lacking (Chadha, 2012). Intralesional bevacizumab is a promising new treatment. Hopefully, the HPV vaccination program will lead to a reduced incidence of respiratory papillomatosis.

Subglottic tracheal stenosis is caused by cicatricial scarring of the subglottic trachea and can be congenital or acquired. This area is often affected because the cricoid cartilage is the only complete ring in the trachea and is the narrowest segment in the airway. Acquired subglottic stenosis is most frequently a result of long-term intubation, with traumatic injury to the subglottic segment causing pressure necrosis and subsequent scarring. It may be idiopathic. Subglottic stenosis can occur in adults or children. Patients with severely stenotic segments causing significant respiratory symptoms usually require surgical intervention that includes splitting the subglottis with short-term stents, use of cartilage grafts, or placement of long-term stents.

Although many of the etiologies previously listed may also cause stridor in the adult population; most often an adult who presents with stridor will have this symptom secondary to subglottic tracheal stenosis, inflammation or edema of the larynx, neoplasia, or vocal cord paralysis. The workup is tailored to the history and endoscopic findings. In general, treatment of stridor depends on the etiology. The critical issue is stabilizing the airway in hopes of preventing catastrophe. Some conditions may respond to medical treatment, but any patient with stridor should be treated as having an impending airway obstruction until proved otherwise. ICU observation may be required, with personnel available to stabilize the airway by intubation or tracheotomy. ENT consultation is recommended for further evaluation and more definitive treatment.

LARYNGEAL TRAUMA

Injury to the airway is an important cause of death in patients with head and neck trauma. Laryngeal trauma must be recognized early to avoid catastrophic sequelae. Securing the airway is the most important initial step in the management of these injuries to preserve life. The most preventable factor in morbidity and mortality is likely a delay in diagnosis. Less severe laryngeal injuries may initially go undiagnosed, but major injuries can lead to early death.

Blunt trauma is a common cause of death in motor vehicle crashes. The mechanism of blunt laryngeal trauma is typically caused by a hyperextension of the neck (i.e., against the dashboard) with compression and fixation of the larynx against the cervical spine, which leads to fracture or comminution of cartilage with associated soft tissue injury. Laryngotracheal disruption can occur from “clothesline” injury, which can occur with motorcycle and snowmobile accidents.

Penetrating trauma is becoming more common with an increase in civilian violence. Knife and gunshot wounds are the most common cause of death in homicide cases. Other

traumatized structures in the neck can include the great vessels, the esophagus, and the cervical spine.

Signs of laryngotracheal trauma include tenderness over the larynx, anterior neck contusion, subcutaneous emphysema, palpable fractures or crepitus, loss of thyroid prominence, tracheal deviation, and hemoptysis. Symptoms include hoarseness, shortness of breath, inability to tolerate the supine position, and dysphagia.

Examination should include flexible fiberoptic laryngoscopy in every patient, if possible, to evaluate the anatomy and function of the larynx. Diagnostic imaging includes cervical spine films, chest radiographs, and CT scan. Unless physical examination and flexible fiberoptic laryngoscopy are normal, CT should be done in most cases. The decision to take a patient to the OR is based on history, physical examination, flexible fiberoptic laryngoscopy, and CT scanning.

As with any trauma patient, management of the airway is of primary importance. Some controversy still exists on the optimal management of the airway. Most authors recommend awake local tracheotomy as the safest and least traumatic method of securing the airway in an adult patient with laryngeal trauma. Some reports recount the disastrous outcome of a lost airway after attempted oral or nasal intubation in patients with laryngeal trauma. However, many still advocate intubation as the initial method of securing the airway. Emergency cricothyroidotomy can be performed if time does not permit a formal tracheotomy.

HOARSENESS

All patients who present with hoarseness should be questioned about the history, the duration, and the progression of symptoms. Hoarseness may be categorized as chronic or acute. Acute hoarseness is rarely secondary to a malignant process. Acute hoarseness usually results from vocal abuse, laryngitis, or smoking. Malignancy should be considered in patients with chronic hoarseness, but the differential also includes GERD, polyps, nodules, neurologic disorders, papillomas, and functional voice disorders (see [eTable 18-15](#) online).

Other symptoms can coexist with hoarseness. Cough can be secondary to irritation of the vocal cords from acute or chronic inflammation but can also indicate cancer of the larynx or lung. Dysphagia or odynophagia can be present from disorders of the pharynx and esophagus. Hemoptysis with hoarseness should be considered secondary to a malignancy until proved otherwise. A history of smoking and vocal abuse is an important consideration. Clear visualization of the larynx by indirect or direct laryngoscopy is absolutely necessary for all patients who present with hoarseness that does not resolve on its own or with medical therapy. This can require referral to an otorhinolaryngologist unless the family physician has training and experience in the procedures.

An unusual cause of voice problems is *spasmodic dysphonia* (or laryngeal dystonia). The exact cause is unknown but is thought to be a CNS condition classified under “focal dystonias.” It typically causes a harsh staccato voice but may cause breathiness. Spasmodic dystonia responds poorly to voice therapy but has been shown to respond very well

eTable 18-15 Common Causes of Hoarseness

Condition	Cause
ACUTE	
Acute laryngitis	Viral or bacterial
Vocal cord hemorrhage	Vocal abuse or misuse
Postnasal drip	Sinusitis or allergies
Gastroesophageal reflux	Gastric acid
Neck trauma	Blunt or penetrating trauma
Intubation granuloma	Short or long periods of intubation
Psychiatric problems	Conversion disorder, hysterical aphonia
CHRONIC	
Chronic laryngitis	Viral, bacterial, or smoking
Malignancy	Squamous cell carcinoma, thyroid cancer
Vocal cord nodules	Vocal cord abuse or misuse
Vocal cord polyps	Vocal cord abuse or misuse, smoking, allergies
Papillomas	Recurrent respiratory papillomatosis
Vocal cord paralysis	Cancer, trauma, stroke, degenerative disease

to botulinum toxin injections into the larynx, which is done endoscopically or externally. The treatment weakens the muscles and lessens the symptoms for several months. Repeat injections are usually done, and response to treatment can decrease over time.

VOCAL CORD PARALYSIS

Vocal cord paralysis can manifest itself as hoarseness. However, many patients are able to maintain a relatively normal voice because of compensation from the opposite vocal cord. Patients can present with shortness of breath while conversing, cough when swallowing, aspiration, or recurrent pneumonia. They may complain of the inability to hold a breath while exerting against a closed glottis (Valsalva maneuver). Visualization of the larynx by indirect or flexible fiberoptic nasolaryngoscopy usually reveals an immobile, sluggish vocal cord in a paramedian position.

Paralysis can result from peripheral (recurrent laryngeal or vagus) nerve involvement or a CNS disorder (e.g., CVA). Approximately 90% of vocal cord paralysees result from dysfunction of the peripheral nerve. Most causes of paralysis are found after a careful history and physical examination (see eTable 18-16 online). Because of the course of the recurrent laryngeal nerve around the arch of the aorta on the left and around the subclavian artery on the right, imaging, typically with CT, includes the skull base to mediastinum to evaluate the entire extent of the nerve. VLS is very useful and often yields further diagnostic and prognostic information.

Surgical trauma from thyroidectomy, carotid artery surgery, or transcervical spine procedures is the most common cause of unilateral vocal cord paralysis. Idiopathic or a presumed viral etiology is another common cause. Neoplastic processes, including thyroid, lung, and esophageal cancers, must always be ruled out as a cause of either compression or invasion. Skull base tumors and mediastinal lesions are less common causes of paralysis. Careful palpation of the neck to rule out masses and evaluation of other cranial nerves help identify these problems.

Bilateral vocal cord paralysis typically manifests with significant respiratory distress caused by obstruction of the glottis from bilateral medialization of vocal cords. Many of these patients need emergent establishment of the airway by intubation or tracheotomy. Causes of bilateral vocal cord paralysis include thyroid or cervical spine surgery or CNS disorders. Hydrocephalus or an Arnold-Chiari malformation can cause bilateral paralysis via brainstem herniation with stretching of the vagus nerves. Treatment in these circumstances is aimed at stabilizing the airway and treating the underlying problem, with the paralyzed cord usually returning to normal function after a few months.

Numerous surgical techniques can improve vocalization. Endoscopic injection of autologous, allogenic, or alloplastic substances can provide temporary and even permanent improvement by medializing the weak vocal cord so that the mobile vocal cord can make contact. Open surgical approaches can also be performed for permanent unilateral paralysis, with excellent results. Medialization of the vocal cord with the use of alloplastic materials is now common. Surgical options to correct permanent bilateral vocal cord paralysis include removal of a portion of the arytenoids or

Figure 18-9 Intraoperative photograph of true vocal cords with nodules in 25-year-old teacher.

vocal cords to open the airway; permanent tracheotomy is a last resort.

VOCAL CORD NODULES

Vocal cord nodules result from long-term vocal overuse or abuse. Nodules are typically seen as symmetric raised areas at the anterior aspect of each vocal cord. These occur more often in women, boys, lecturers, coaches, and professional singers. The most common symptom is hoarseness and a persistent raspy voice. Smoking, allergies, and GERD tend to aggravate the condition and can prevent healing.

Nodules are always bilateral and classically occur at the junction of the anterior third and posterior two thirds of the vocal cords (Figure 18-9). Nodules must be distinguished from polyps, which are smooth and often unilateral, and granulomas, which tend to be located more posteriorly on the vocal cord. Treatment is initially conservative. The patient is referred for voice therapy, which consists of counseling, vocal reeducation, relative voice rest, and psychotherapeutic rehabilitation. Most patients respond after several sessions of voice therapy, but satisfactory improvement can take up to 12 to 18 months. Measures to control acid reflux and avoidance of irritating substances such as cigarette smoke are also routinely recommended. Surgery is reserved for rare patients who do not respond to voice therapy and consists of endoscopic removal. Postoperative voice therapy and acid reflux control are always indicated after surgical removal of nodules.

REFLUX LARYNGITIS

Reflux laryngitis, also known as *laryngopharyngeal reflux* (LPR), is a relatively common condition. Many patients do not have the classic symptoms of GERD, including heartburn, and the correct diagnosis is often initially overlooked. Constant throat clearing may be the only presenting symptom. Other manifestations include a feeling of a lump

eTable 18-16 Causes of Vocal Cord Paralysis

Neoplasm	CAUSING NERVE COMPRESSION

	Other

in the throat with a choking sensation (*globus pharyngeus*), odynophagia, dysphagia, chronic cough, and hoarseness. The patient may also complain of postnasal drainage. Spicy foods, fats, caffeine, chocolate, beer, milk, and orange juice are known to exacerbate the condition by lowering LES pressure. Several medications increase reflux of acid into the esophagus, such as β -blockers, calcium channel blockers, diazepam, and progesterone. Obesity and sleep apnea also predispose the patient to GERD and reflux laryngitis.

A careful history and examination allow the diagnosis to be made. Findings on indirect or flexible fiberoptic laryngoscopy are nonspecific and include edema, erythema, and redundancy of the mucosa around the arytenoids and post-cricoid area. Occasionally, small granulomas are present posteriorly near the vocal processes of the arytenoids. Studies that help confirm the diagnosis of GERD include barium swallow, pH probe, esophageal manometry, and esophagoscopy. Gastroenterology consultation may be necessary.

Often the diagnosis of reflux laryngitis cannot be confirmed or excluded without a trial of empiric therapy. The treatment for reflux laryngitis consists of diet and lifestyle modifications and acid-reducing medications. Diet modification includes avoidance of foods and substances known to increase acid reflux. Lifestyle modifications include avoidance of eating near bedtime, elevation of the head of the bed 6 to 10 inches (15-25 cm), weight loss, and avoidance of tight-fitting clothing. Medical therapy usually begins with a trial of H₂ blockers or preferably daily dosing of proton pump inhibitors (PPIs). Refractory or severe cases usually respond well to twice-daily PPI therapy. Although most patients respond to treatment, resolution of symptoms can take several months after initiating proper treatment. It is critical that visualization of the larynx be obtained early if the patient's symptoms persist to rule out more serious pathology such as neoplasia.

CANCER OF THE LARYNX

Squamous cell carcinoma is by far the most common malignancy of the larynx. Laryngeal cancer accounts for 1% to 4% of all malignancies detected every year. The peak age group is between 60 and 65 years old, and it is more prevalent in men than in women (8:1), although the incidence in women is rising. Malignancies of the larynx are most common in smokers and alcohol abusers. When both these factors are present, the risk of developing cancer becomes 50% greater than the additive risk of each. Only 2% to 5% of laryngeal cancer patients have no history of smoking. Thus, it is extremely important to elicit smoking and alcohol histories in patients with head and neck complaints.

Hoarseness can be a very early symptom, making most cancers of the larynx curable because they are detected early. For this reason, hoarseness should never be simply attributed to "laryngitis" without proper evaluation. Other symptoms, including sore throat and referred otalgia, can exist without hoarseness. These patients are often treated incorrectly with antibiotics for an extended period, and referral is delayed, thereby increasing morbidity and mortality.

Detection of cancer requires visualization of the larynx. Indirect or direct laryngoscopy usually shows a discrete,

well-circumscribed exophytic lesion in the endolarynx, most frequently on one of the true vocal cords. A critical concern is potential airway obstruction in bulky tumors; emergent airway intervention is fairly common. The neck should be palpated to evaluate for cervical lymphadenopathy. Metastasis to the lungs or brain is also possible.

Several modalities of treatment exist for laryngeal cancer. Carcinoma in situ and leukoplakia can be treated with laser vaporization. Stage I carcinoma is treated with external-beam radiation or partial laryngectomy techniques. Stage II carcinoma may be treated with radiation therapy, partial laryngectomy, or total laryngectomy. Stage III disease may be treated with single or combined modality treatments. Single modality treatment includes radiation or surgery. Combined modality includes chemoradiation or surgery and radiation. Stage IV treatment includes total laryngectomy with radiation or chemoradiation with or without total laryngectomy. Specific treatment depends on the location and extent of the tumor. Radiation and chemoradiation are often used in organ-sparing protocols to preserve function. Speech restoration is still possible after total laryngectomy with a tracheoesophageal prosthesis. Neck dissection is required in patients with cervical metastases. Stage I glottic carcinoma has a 90% 5-year survival with treatment because a tumor on the vocal cord presents early as hoarseness and the vocal fold has less lymphatics to allow tumor to metastasis. Unfortunately, tumors at other laryngeal locations often cause symptoms only when large or when regional metastases develop. Therefore, the prognosis of these tumors is much worse.

KEY TREATMENT

The American Academy of Otolaryngology–Head and Neck Surgery produced a consensus statement of clinical practice guidelines for hoarseness (dysphonia).

Strongly Recommended Treatment

The quality of data supporting the benefits of treatment outweighing the potential harm is strong (grades A, B):

- Clinicians should not routinely prescribe oral antibiotics to treat hoarseness.
- Voice therapy should be employed for patients with hoarseness that affects voice-related quality of life.

Recommended Treatment

The benefits of treatment outweigh the risks, but the data are not as strong (grades B, C):

- Hoarseness should be diagnosed in a patient with an altered quality of voice.
- Patients with hoarseness should be assessed with history or physical examination with attention to previous factors or treatments that may have affected the recurrent laryngeal nerve or larynx. This may include neck or chest surgery or radiation therapy, endotracheal intubation, tobacco use, or occupational vocal overuse.
- The clinician may perform laryngoscopy (or refer) if hoarseness persists at a maximum of 3 months or sooner if suspicion of serious illness is high. A general rule of thumb is to refer for laryngoscopy after 3 weeks as this is the time frame that a viral laryngitis should have resolved.

- CT or MRI should not be performed until the larynx has been visualized (these tests may not be necessary).
- Antireflux medications should not be prescribed in the absence of other signs or symptoms of reflux.
- Clinicians should not routinely prescribe oral corticosteroids to treat hoarseness.
- Laryngoscopy should be performed before recommending voice therapy.
- Clinicians should advocate for surgery as an option in cases of suspected malignancy, soft tissue lesion, or glottic insufficiency.
- Patients should be referred for possible treatment with botulinum toxin in cases of spasmodic dysphonia.

Optional Treatment

There is only weak evidence that the benefit of treatment outweighs the risk (grade D):

- The clinician may perform laryngoscopy (or refer) at any time after diagnosis of hoarseness.
- Antireflux medications may be prescribed in patients with hoarseness if there are signs of chronic laryngitis with laryngoscopy.
- Patients with hoarseness should be educated on control and prevention methods (SOR: A; B).

The Neck

Key Points

- Knowledge of anatomy is critical in the diagnosis of a neck mass.
- In the pediatric population, a neck mass is by far most commonly infectious or inflammatory.
- In adults, a neck mass is neoplastic until proven otherwise.
- Imaging may be necessary in the evaluation and can include CT with contrast, ultrasonography, or MRI.
- Tissue sampling in the form of fine needle biopsy or excisional biopsy may be necessary when the examination and imaging are not diagnostic.
- Avoid core biopsy and incisional biopsy in cases of suspected neoplasm other than lymphoma as to avoid seeding tumor into surrounding tissue.

PHYSICAL EXAMINATION

See [eAppendix 18-5](#) online.

NECK MASSES

Proper evaluation of a neck mass includes obtaining a complete history and performing a thorough examination of the neck and all mucosal surfaces. Knowledge of anatomy is critical in narrowing the differential diagnosis because the list of possible diagnoses for a neck mass is extensive. History should include duration; growth rate; and associated symptoms such as pain, sore throat, voice change, dysphagia, fever, weight loss, night sweats, and otalgia. Aspects of the social history, such as tobacco use or exposure, alcohol use, ill contacts, and recent travel, should be

obtained. The clinician should ascertain characteristics of the mass on examination, such as whether the mass is soft, firm, mobile, fixed, pulsatile, fluctuant, tender, or overlying skin change. Imaging options include CT with contrast, MRI with contrast, and ultrasonography, which may assist in the diagnosis and help define the extent of a lesion. Tissue sampling is often necessary to determine the etiology of a neck mass. Usually a fine-needle biopsy is recommended as the first-line option for biopsy. This test is sometimes necessary to obtain under image guidance. Excisional biopsy is performed when needle biopsy is inconclusive or if further pathologic assessment is necessary. Core needle biopsy and incisional biopsy should be avoided when there is a concern for neoplasm other than lymphoma to avoid seeding surrounding tissue with neoplastic cells. Classification includes congenital, inflammatory, and neoplastic disorders. In general, pediatric neck masses are usually inflammatory followed by congenital lesions. Neoplasia occurs less often in pediatric patients. In adults, neoplasia is by far the most common entity, with inflammatory causes less common and congenital masses rare.

Congenital Neck Masses

Congenital neck masses are common in children but can occur in any age group. These are the most common cause of noninflammatory neck masses in the pediatric population. Classifying these into midline or lateral location helps in the workup because congenital neck masses occur in consistent anatomic sites (see [eTable 18-17](#) online).

Midline Neck Masses

Thyroglossal duct cysts are the most common anterior midline neck masses in children. They are remnants of the descending tract of the thyroid gland from the foramen cecum at the base of the tongue to its normal position in the lower neck. Cysts or fistulas can occur anywhere along this tract and can intermittently become infected. Physical examination usually reveals a 2- to 4-cm mass in the anterior neck that moves with swallowing and elevates with tongue protrusion ([Figure 18-10](#)). Treatment is surgical excision of the cyst and the tract, including the midhyoid bone, to the base of the tongue (Sistrunk procedure). There have been reports of neoplastic transformation of these cysts. Recurrence is possible.

Dermoid cysts typically develop along midline embryonic fusion planes and are composed of ectodermal and mesodermal embryonic remnants. Their usual location in the neck is in the submental area. They are also found along the dorsum of the nose. Dermoid cysts tend not to move with swallowing or elevate with tongue protrusion, unlike thyroglossal duct cysts. Treatment is surgical excision.

Ranulas are cystic lesions that are usually present in the floor of the mouth. They can become “plunging” and extend through muscle planes into the upper midneck area. Plunging ranulas are thought to occur from mucus extravasation from a blocked salivary duct. Physical examination of a plunging ranula reveals a cystic mass in the submental area with or without a cystic mass in the floor of the mouth.

Lateral Neck Masses

Branchial cleft cysts are common congenital abnormalities found in the lateral neck area and are caused by failure of

18-5 *Neck: Physical Examination*

Examination of the neck is an important part of the routine ear, nose, and throat examination. Of utmost importance is identifying abnormal masses. Several normal anatomic structures are present and can be confused for masses in some cases. These structures include low-lying submandibular glands, calcified carotid arteries, and transverse

cervical processes. Masses in the neck can be secondary to enlargement of lymph nodes, thyroid masses, salivary gland masses, or a variety of other abnormalities. Any questionable neck mass should be referred to a head and neck surgeon if resolution does not occur promptly after appropriate therapy.

eTable 18-17 Differential Diagnosis of Neck Masses

Congenital	MIDLINE
	Dermoid cyst Thyroglossal duct cyst Ranula (plunging)
Inflammatory	LATERAL
	Branchial cleft cyst Lymphangioma (cystic hygroma)

	BENIGN
	Epidermoid inclusion cyst Fibroma Lipoma Neurofibroma Paraganglioma Schwannoma (neurilemoma) Sebaceous cyst
	MALIGNANT
	Lymphoma Metastatic squamous cell carcinoma Neurofibrosarcoma Rhabdomyosarcoma Salivary carcinoma Thyroid carcinoma

Figure 18-10 Photograph of 9-year-old child with midline neck mass (arrow) near the hyoid bone. Swallowing produced movement in the mass. Surgical excision with pathologic evaluation demonstrated a thyroglossal duct cyst.

obliteration of the embryonic branchial clefts during development. Abnormalities can also manifest as sinus tracts or fistulas in the skin. These can become intermittently infected, especially after URIs.

Second branchial cleft abnormalities are by far the most common. These usually manifest as masses anterior to the sternocleidomastoid muscle with or without a fistulous opening. The sinus tract passes between the external and internal carotid arteries and ends in the tonsillar fossa. Treatment is complete surgical excision of the cyst and sinus tract after control of infection with appropriate antibiotics. First branchial cleft cysts are less common and manifest as a duplication abnormality of the external auditory canal (type I) or as an infected mass near the angle of the mandible with a sinus tract passing superiorly through the parotid salivary gland (type II).

Lymphangiomas (cystic hygromas) are congenital lymphatic masses often found in the neck. They usually manifest during the first year of life and often enlarge after a URI. They can also increase in size after hemorrhage into the cystic cavities. Lymphangiomas form from a failure of complete development and subsequent obstruction of the lymphatic system. They are most frequently found as an asymptomatic mass in the posterior triangle of the neck but can also be found anteriorly, causing airway or swallowing problems. Physical examination reveals a nontender, fluctuant, soft, spongy mass without discrete margins. Surgery is the mainstay treatment for lymphangiomas, although other modalities of treatment include intralesional injection sclerotherapy and systemic interferon.

Hemangiomas are the most common congenital malformations. Most are cutaneous, but they can also be found in deep tissues. The most common deep location in the head and neck is the masseter muscle. Hemangiomas are characterized by appearance at or after birth followed by a rapid proliferative phase at 6 to 18 months of age. The

Figure 18-11 Intraoperative photograph of a large lipoma of the left upper neck.

lesion then reaches a plateau phase followed by a slow, involutional phase over 6 to 8 years. Even large, uncomplicated lesions left untreated usually undergo almost complete resolution. Conservative management is almost always recommended.

Certain locations, including the nasal tip, lips, and eyelids, can cause severe functional or cosmetic deformities, and referral for removal may be appropriate. Massive lesions can cause high-output heart failure or a consumptive coagulopathy (Kasabach-Merritt syndrome); others can become ulcerated, infected, or hemorrhagic. Treatment of hemangiomas includes surgical excision, pulsed-dye laser therapy, β -blockers, interferon- α -2ab and -2b, and corticosteroids.

Neoplastic Neck Masses

Benign lesions in the head and neck include *lipomas* and *fibromas* and require no treatment unless they cause significant functional or cosmetic deformity (Figure 18-11).

All neck masses in adults should be presumed to be malignant until proved otherwise. The most common malignant neck mass in adults is metastatic SCC. Primary tumors are usually found in the upper aerodigestive tract or skin and metastasize to cervical lymph nodes according to identifiable lymphatic drainage patterns. Smoking and alcohol abuse are major etiologic factors. However, base of tongue and tonsil SCCs related to HPV subtypes 16 and 18 are becoming more common. Careful examination of all mucosal surfaces of the head and neck is crucial to identify the primary tumor site. Endoscopy with biopsies is the first step in the diagnosis. Treatment may include any combination of surgical resection of the primary site neck dissection, radiation, and chemotherapy, depending on the location and extent of the primary tumor and the extent of cervical metastasis. HPV-related SCC has high cure rates in contrast to tobacco-related carcinoma and is often treated with chemoradiation.

Lymphomas are one of the most common malignancies of the neck in children but can occur at any age. Patients can present with lymphadenopathy associated with constitutional symptoms (night sweats, fever, weight loss),

hilar adenopathy, or hepatosplenomegaly. Diagnosis is confirmed by excisional biopsy. Most head and neck lymphomas are treated with a combination of radiation and chemotherapy.

Rhabdomyosarcoma is a common childhood neoplasm with peak incidence at age 5 years. Early symptoms include a painless, enlarging mass or symptoms related to obstruction by tumor. Approximately 35% of rhabdomyosarcomas manifest in the head, neck, and orbit. Embryonal rhabdomyosarcoma and botryoid sarcoma (a variety of embryonal rhabdomyosarcoma) are most common in the head and neck, accounting for 75% of cases. Other forms include alveolar and pleomorphic. Diagnosis is made by excisional biopsy, and treatment is multimodal, including surgery, radiation, and chemotherapy.

Carotid body tumors are paragangliomas that arise from the adventitia of the common carotid bifurcation. They are thought to arise from derivatives of neural crest cells and are members of the diffuse neuroendocrine system. They can be associated with other tumors of similar origin, including medullary thyroid carcinoma, parathyroid adenoma, and pheochromocytoma, in up to 7% of cases. Familial incidence is 8% to 10%, and inheritance is autosomal dominant. A high incidence of bilateral carotid body tumors occurs in familial paraganglioma syndromes, and 1% to 3% of these tumors actively secrete substances such as catecholamines or serotonin. Symptoms of catecholamine secretion include headache, perspiration, palpitations, pallor, and nausea. Screening for blood and urinary catecholamines should be performed to rule out a secreting tumor or pheochromocytoma. Symptoms of serotonin secretion are carcinoid syndrome, including diarrhea, flushing, severe headaches, and hypertension.

Other tumors of the head and neck arise from neurogenic tissue. These include schwannomas, neurofibromas, neurofibrosarcomas, and neuroblastomas. These tumors can manifest with associated cranial nerve deficits. Treatment is surgical excision.

Inflammatory Neck Masses

Whereas *reactive lymph nodes* from a viral infection should be treated expectantly, bacterial infections such as streptococcal tonsillitis or pharyngitis should be treated with appropriate antibiotics. Infectious mononucleosis is an important cause of extensive cervical lymphadenitis. An association with tonsillopharyngitis, fever, and malaise should raise suspicions. Monospot or EBV serology can be obtained for diagnosis. In general, a CBC with differential and ESR or CRP can aid in determining if lymph node enlargement is inflammatory. In some cases, inflamed lymph nodes can suppurate and become abscessed, requiring incision and drainage. Masses thought to be reactive lymph nodes not responding to conservative management (antibiotics) after approximately 4 to 6 weeks often need referral for further evaluation to obtain a definitive diagnosis.

Cervical lymphadenitis can be caused by *atypical mycobacteria*, which may appear as a subcutaneous abscess with erythematous overlying skin (Figure 18-12). Treatment includes excisional biopsy and appropriate antibiotics according to culture sensitivities. Incisional drainage is contraindicated and can cause chronic fistulization.

Figure 18-12 Photograph showing cervical adenitis with overlying skin erythema in a young child. Cultures revealed atypical mycobacteria.

Cat-scratch disease is another pediatric infection that can manifest with lymphadenopathy. Most patients recount exposure to a cat, and many have a cutaneous lesion representing an inoculation site. The diagnosis is made by serologic testing for *Bartonella henselae*. The disease is self-limited.

Tuberculous cervical lymphadenitis (scrofula), caused by *Mycobacterium tuberculosis*, can manifest with bilateral lower lymph node enlargement. It is usually associated with pulmonary involvement, and treatment is with a multidrug regimen. Nodes not responding to treatment should be excised.

Patients infected with *human immunodeficiency virus* (HIV) can present with asymptomatic lymph node enlargement. Persistent lymphadenopathy in AIDS patients is common, and most are followed if the nodes remain stable. Because of the higher incidence of non-Hodgkin lymphoma and Kaposi sarcoma in these patients, any suspicious neck masses with other constitutional symptoms should be referred for biopsy and tissue diagnosis. Fine-needle aspiration biopsy is appropriate, with indeterminate cytology requiring open excisional biopsy. Other possible causes of neck lymphadenopathy in immunocompromised patients include histoplasmosis, tuberculosis, atypical mycobacterial infections, and toxoplasmosis.

Sarcoidosis is a granulomatous disease that causes cervical lymphadenopathy and may be the presenting sign in 10% to 15% of cases. This disorder typically affects the African American population. Other findings include fever, sinusitis, parotid swelling, and hilar adenopathy on chest radiographs. Diagnosis is classically made by tissue biopsy showing noncaseating granulomas. A high angiotensin-converting enzyme level is common but not diagnostic.

Other studies include cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) to rule out other granulomatous diseases, purified protein derivative and acid-fast bacillus stains to rule out tuberculosis, and Venereal Disease Research Laboratory and RPR tests to exclude syphilis.

Sebaceous cysts and epidermal inclusion cysts are also common and usually need to be excised because of the high incidence of recurrent infection.

DISORDERS OF THE SALIVARY GLANDS

The salivary glands consist of the paired parotid, submandibular, and sublingual glands and the minor salivary glands. Disorders of the salivary glands can be categorized into inflammatory, metabolic, and neoplastic problems (see eTable 18-18 online). The history and physical examination facilitate differentiation among these categories.

Inflammatory Disorders

Acute sialoadenitis is a common cause of painful enlargement of the parotid and submandibular glands. The organism is usually *S. aureus*, but it can also be caused by *S. pneumoniae* and other bacteria. The infection is secondary to salivary stasis caused by decreased production (dehydration, poor oral hygiene) or intrinsic or extrinsic obstruction (stones, strictures, masses). Patients present with exquisite tenderness over the gland, fever, and sometimes skin erythema. Purulence can be expressed from the duct with manual massage of the gland. Treatment includes anti-staphylococcal antibiotics, adequate hydration, massage of the gland, sialogogues, and warm compresses. Abscess can occur and requires incision and drainage.

Mumps is a relatively common cause of painful unilateral or bilateral parotid gland enlargement in children. It is caused by a paramyxovirus, and the diagnosis is confirmed by elevation of antibodies to the S and V virus antigens or by isolation of the virus in the urine. The incubation period is 2 to 3 weeks, and infection lasts 7 to 10 days. Treatment is conservative, with close follow-up to observe for possible complications such as pancreatitis, meningitis, orchitis, and hearing loss.

Sialolithiasis is a cause of intermittent salivary gland enlargement and is usually associated with eating. Most calculi occur in the submandibular duct, and most are radiopaque. Calculi arising in the parotid duct are less common and tend to be radiolucent. Symptoms include recurrent, unilateral, tender salivary enlargement that subsides within 24 to 48 hours. Physical examination usually reveals a palpable stone in the duct of the gland. Sialography is successfully diagnostic if a calculus is not palpable. CT scan and ultrasonography are also effective in identifying calculi. Treatment depends on the location of the obstruction. Calculi near the terminal orifice are easily removed transorally. Symptomatic calculi located near the hilum of the gland usually require excision of the gland. Sialoendoscopy is a novel method often used successfully to remove sialoliths.

Patients with HIV infection can present with enlargement of salivary glands. Glands can become infiltrated with benign lymphoid tissue or *lymphoepithelial cysts*. The cystic lesions often occur in the tail of the parotid gland, and

aspiration can provide temporary relief of symptoms. These patients are treated conservatively because cysts tend to recur after excision or aspiration procedures. The differential diagnosis of salivary gland enlargement in HIV-infected patients includes non-Hodgkin lymphoma and Kaposi sarcoma. Fine-needle aspiration or excisional biopsy of suspicious masses is performed for diagnosis of malignancy.

Included in the differential diagnosis of inflammatory lesions of the major salivary glands are tuberculosis, cat-scratch disease, CMV infection, and first branchial arch cysts and sinuses.

Autoimmune Disorders

Sjögren's syndrome is characterized by xerostomia (dry mouth) with or without parotid gland enlargement. Chronic inflammatory cells and lymphocytes infiltrate the glands, leading to fibrosis and atrophy of the parenchyma. Xerophthalmia suggests involvement of the lacrimal gland and causes a gritty or painful sensation of the eye. Primary Sjögren syndrome involves the exocrine glands, only without association with other connective tissue disorders. Secondary Sjögren syndrome is often associated with rheumatoid arthritis and other autoimmune disorders.

The SS-A and SS-B autoantibodies are positive in most cases of primary Sjögren syndrome. Other useful laboratory tests include rheumatoid factor, antinuclear antibody, thyroid globulin antibody, and thyroid antimicrosomal antibody titers. Lip biopsy can confirm the diagnosis of Sjögren syndrome, and referral to a rheumatologist is appropriate. Treatment includes proper oral hygiene, mouth rinses, and medications that stimulate salivary flow. Steroids are useful for severe cases.

Other causes of xerostomia include surgery and irradiation of the head and neck. Several common classes of medications can cause mouth dryness as a side effect. These include antihistamines, analgesics, anticonvulsants, antidepressants, and antihypertensives. Systemic disorders that can be associated with xerostomia include dehydration, diabetes, anemia, and overall debilitation.

Neoplastic Disorders

Most salivary gland neoplasms arise in the parotid gland, and most are benign. Approximately 80% of parotid gland tumors are benign, with *pleomorphic adenoma* (mixed tumor) being the most common in adults. *Hemangiomas* are the most common benign tumor in children, but malignancy in children is more likely than in adults when a solid mass is found in the salivary gland. Other benign tumors include Warthin tumors (papillary cystadenoma lymphomatosum) and oncocytomas. The most common malignancy in adults and children is *mucoepidermoid carcinoma*. Other malignancies include adenoid cystic carcinoma, malignant mixed tumor, and SCC. Treatment of salivary gland neoplasms is surgical excision.

THYROID MASSES

Careful examination for thyroid abnormalities should be performed on each patient in routine office visits. *Thyroid nodules* occur in about 5% to 10% of the population; of these, approximately 10% are malignant. The differential

diagnosis of thyroid masses is presented in [Table 18-14](#). Risk factors for malignancy include exposure to radiation and family history of medullary carcinoma. Factors that increase the possibility of carcinoma include hoarseness; age younger than 20 years or older than 45 years; male gender; presence of a firm, hard nodule; and vocal cord paralysis.

The most common disorder in patients who present with a thyroid nodule is *nontoxic multinodular goiter*. The presence of multiple nodules is helpful in diagnosis, but only one dominant nodule may be apparent on physical examination. Nontoxic multinodular goiter may be endemic in iodine-deficient areas or sporadic. Nodularity is thought to be secondary to repeated episodes of deficiency of thyroid hormone, causing increased levels of thyroid-stimulating hormone (TSH), which results in hyperplasia of the gland. Symptomatic compression on the trachea or esophagus can occur. Surgery is reserved for functional problems caused by compression or to rule out malignancy. Chest radiography and CT are helpful in evaluating substernal extension of goiter ([Figure 18-13](#)).

Graves disease is an autoimmune disease that causes diffuse thyroid enlargement, hyperthyroidism, infiltrative ophthalmopathy, and myxedema. It is the most common

cause of hyperthyroidism and is more common in women age 20 to 50 years. Treatment modalities include antithyroid medications, radioactive iodine ablation, or surgical excision when medical treatment fails.

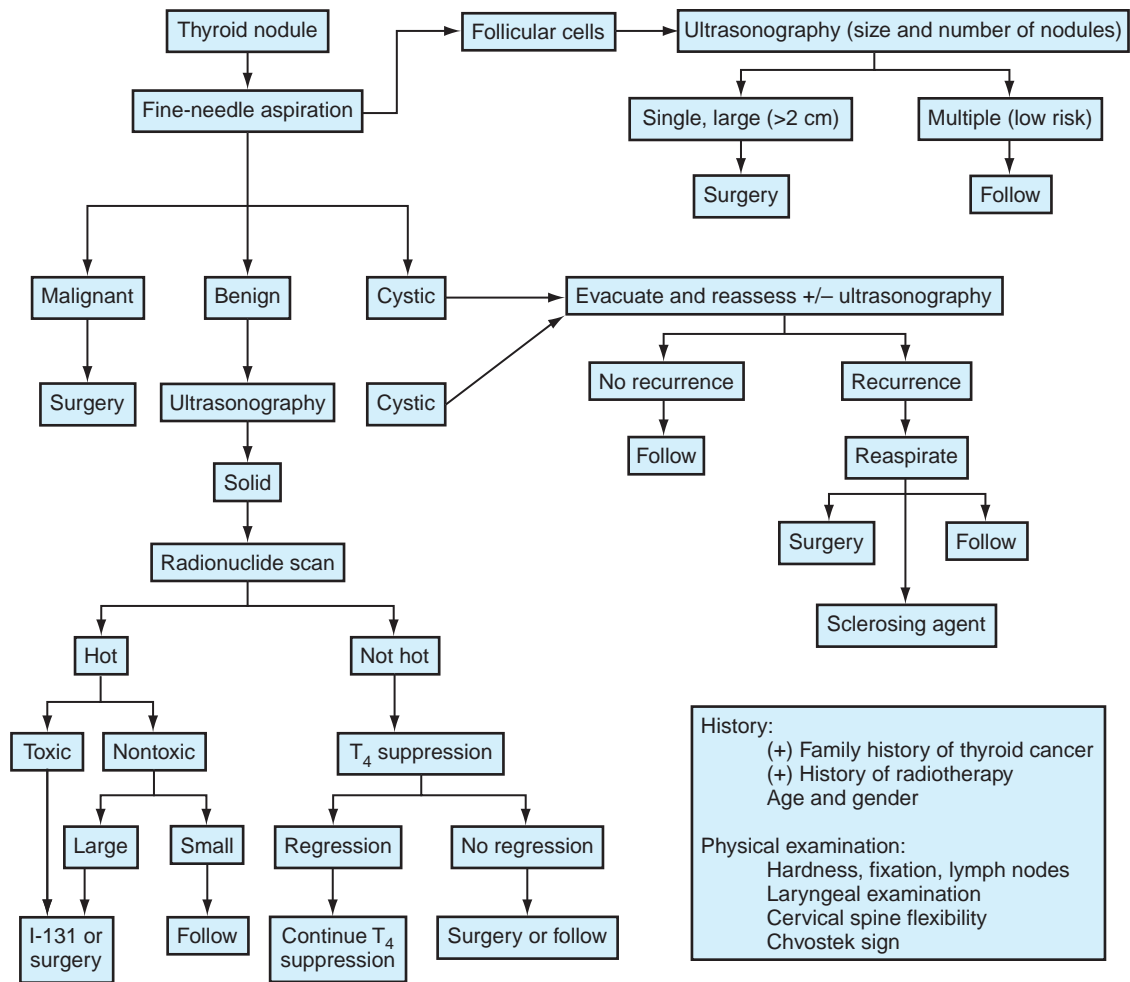

Thyroiditis can cause nodular enlargement of the thyroid gland. Subacute thyroiditis may be a cause of intermittent hyperthyroidism from the release of stored thyroid hormone. Chronic lymphocytic (Hashimoto) thyroiditis can cause diffuse nodular enlargement of the thyroid. Measurement of antithyroid microsomal antibodies is helpful but not specific for this disorder. Fibrous (Riedel) thyroiditis is a rare cause of thyroid enlargement, and distinction from neoplasia can be difficult.

Neoplasms of the thyroid are classified as malignant or benign tumors. Follicular adenoma is the most common benign tumor. Malignancies include papillary (65%), follicular (20%), medullary (5%), and anaplastic (10%) carcinomas. Medullary carcinoma is associated with an elevated calcitonin level, with pheochromocytoma and parathyroid hyperplasia in multiple endocrine neoplasia (MEN) IIA, and with pheochromocytoma, mucosal neuromas, ganglioneuromatosis, and marfanoid body habitus in MEN IIB. Measurement of urinary catecholamines, vanillylmandelic acid, and metanephrine levels is necessary to aid in the diagnosis of pheochromocytoma, which must be treated before surgery for medullary thyroid carcinoma. Hypercalcemia is diagnosed by measuring serum calcium levels.

Initial evaluation of a suspected or palpable nodule includes a thyroid ultrasound and TSH level. If the TSH level is low, a radioiodine scan is obtained. If the nodule corresponds to an area of increased uptake, a biopsy is not necessary because almost all “hot” nodules are benign. Ultrasonography will define the number and size of nodules and identify characteristics suggesting malignancy.

Fine-needle aspiration biopsy (FNAB) is indicated for nodules larger than 1 cm or with suspicious ultrasound or examination features. Ultrasound guidance may be used to improve the diagnostic yield for difficult-to-palpate nodules (see [eFigure 18-9](#)). FNAB is highly accurate. Results are reported as benign, indeterminate or unsatisfactory, suspicious for follicular cancer, suspicious for cancer, or malignant. Benign nodules should be followed with serial examination and ultrasonography. Repeat FNAB is indicated with a significant size change. An indeterminate diagnosis may represent a follicular lesion. Follicular neoplasms are not distinguishable as benign or malignant because fine-needle aspiration fails to identify the critical factor of vascular or capsular invasion. Therefore, a thyroid lobectomy may be necessary for diagnosis. Alternatively, a radioiodine scan may be obtained and surgery performed if the nodule is “cold.” Indeterminate aspirates should undergo repeat FNAB. A malignant diagnosis often requires a total thyroidectomy with central compartment lymphadenectomy. Postoperative radioactive iodine is often given. Risks of thyroid surgery include recurrent laryngeal injury and hypoparathyroidism.

The prognosis for patients with papillary thyroid carcinoma is excellent, especially for younger patients. The prognosis is good for those with medullary and follicular carcinoma and universally poor for those with anaplastic carcinoma ([Cooper et al., 2006](#)).

KEY TREATMENT

- The Sistrunk procedure (removal of the central portion of the hyoid) leads to less than 5% recurrence rate of thyroglossal duct cysts (SOR: A).
- Chemoradiation offers greater than 90% 5-year survival rate for HPV-related oropharyngeal SCC with neck metastasis (SOR: A).
- Ultrasonography and TSH are recommended in the evaluation of a suspected thyroid nodule (SOR: A).
- If needle biopsy cytology is suspicious or diagnostic for papillary thyroid carcinoma, surgery is recommended (SOR: A).

Allergy

VIVIAN HERNANDEZ-TRUJILLO, ELLY RILEY, and CHAD RUDNICK

CHAPTER OUTLINE

Allergic Rhinitis, 351
Nonallergic Rhinitis, 354
Allergy in the Eye, 354

Asthma, 355
Anaphylaxis, 360

An allergic patient differs from a nonallergic patient in several ways (Table 19-1). The cause is unknown, but these abnormalities clearly are associated with abnormal cytokine production (Table 19-2). The result of these abnormalities is that allergic persons have diseases such as allergic rhinitis and allergic asthma.

It must always be remembered, however, that these diseases are defined by their *phenotype*, and for each allergic disease, there is an almost identical phenotypic expression unrelated to allergy, such as allergic and nonallergic (intrinsic) asthma, allergic and nonallergic rhinitis, and IgE-mediated and non-IgE-mediated anaphylactic events. Thus, when approaching the patient, the physician must always consider the mechanism of production of the symptoms because subtle differences may exist in treatment between allergic and nonallergic forms of disease, often with significant differences in prognosis.

The most important aspect of establishing the diagnosis of each of these illnesses is the history. The distinction between the allergic and nonallergic forms can only be conclusively determined by allergy testing. The most sensitive and least expensive (per test) means of assessing the presence of allergy is the allergy skin test. In vitro testing is often helpful, however, as a screening procedure.

The other important phenomenon to recognize is that the major allergic diseases (allergic rhinitis, allergic asthma, and anaphylaxis) are all increasing in incidence. The cause is unknown, but several hypotheses have been proposed. The *hygiene hypothesis* postulates that the rise in allergic disease is related to infection control in infants and children (e.g., through vaccination) and improved public health (e.g., through hygienic measures). Another hypothesis is that the allergic response is the same response used to defend against parasites. With a reduction in parasitic disease in more technically developed countries, a population has arisen that is free from exposure to parasites but still maintains a vigorous antiparasitic immune response that is aberrantly directed against the normally harmless organic substances such as pollen, animal dander, and food. Regardless of the mechanism, the burden of allergic disease in developed countries has increased rapidly since the 1970s.

Allergic Rhinitis

Key Points

- Symptoms of allergic rhinitis include allergic shiners, allergic salute, pale nasal mucosa, loss of taste or smell, nasal speech, eustachian tube dysfunction, and disrupted sleep.
- Ophthalmologist referral should be provided to prevent cornea complications.
- Treatment of acute rhinitis includes environmental control, medications, and immunotherapy.
- Use environmental controls such as air conditioning with change of filters, high-efficiency particulate air (HEPA) filters, and masks with microfoam filters for dust allergy.
- Wash linens in hot water using impermeable encasings for pillows and mattresses.
- Avoid fans and cool-mist vaporizers and remove carpets.
- Oral second-generation antihistamines provide less sedation than previous drugs.
- Medications include intranasal steroids, topical antihistamines, and leukotriene modifiers.
- Immunotherapy is directed at specific allergens with possible resolution of allergy.

Allergic rhinitis is a symptom complex caused by airborne antigens. After initial sensitization, exposure to airborne antigens causes activation of allergen-specific T cells, which activate and increase other factors, leading to production of allergen-specific IgE (Rosenwasser, 2011). It occurs as *seasonal rhinitis* (hay fever) when pollens are in high concentration in the air. When it is intermittent or continuous without seasonal variation, it is termed *perennial allergic rhinitis* (Orban et al., 2009). Often occurring in families with an allergic history, perennial allergic rhinitis and mixed perennial and seasonal rhinitis were found to be twice as common as seasonal allergic rhinitis (Skoner, 2001).

Table 19-1 Abnormalities Described in Allergic Patients

Predisposition to manufacture large amounts of IgE directed against formerly harmless substances (e.g., pollen and food)
Abnormalities in the autonomic nervous system
Hyporesponsive β -adrenergic system
Hyperresponsive α -adrenergic system
Hyperactive cholinergic responses in the airways
Hyperreleasability of mast cells and basophils

Table 19-2 Cytokine Production Abnormalities and Effects in Allergic Patients

Cytokine	Effects
Increased production of IL-4	Enhanced IgE production
Increased production of IL-13	Enhanced IgE production
Increased production of IL-5	Enhanced eosinophil activity and prolongation of the life of eosinophils
Increased production of IL-9	Bronchial hyperreactivity

Ig, Immunoglobulin; IL, interleukin.

MANIFESTATIONS

In seasonal allergic rhinitis, exposure is followed by complaints of paroxysmal sneezing, a watery nasal discharge with congestion, and nasal pruritus. Conjunctival and pharyngeal itching often occurs. Less specific symptoms are postnasal drainage or fullness or aching in the frontal areas.

The patient might exhibit an *allergic salute*, an upward thrust of the palm against the nares to relieve itching and open the nasal airways and a gaping expression from mouth breathing. *Allergic shiners* or Dennie lines are wrinkles beneath the lower eyelid. Speech can have a nasal quality. In children, nasal irritation can result in nose picking and recurrent epistaxis. Sleep disruption is often associated with nasal obstruction and mouth breathing. Patients might have sleep apnea–like symptoms, including restless sleep, snoring, or nighttime coughing, associated with postnasal mucus drainage and mild hoarseness. The nasal mucosa is typically moist, with enlarged, pale turbinates and serous discharge. Because the sense of smell is impaired, appetite may be decreased. Maxillomandibular alignment problems (overbite or underbite) result from chronic symptoms.

In perennial allergic rhinitis, nasal congestion, itching, obstruction, and frequent sniffing may be associated with a loss of sense of taste or smell, with decreased hearing and a popping sensation in the ears. A lower sneezing threshold often occurs with altered autonomic reflexes in perennial allergic rhinitis. Paroxysms of sneezing and rhinorrhea can result from changes in ambient temperature, odors from perfume, tobacco smoke, irritants, alcohol, and exposure to small quantities of antigen. Exercise reverses nasal congestion temporarily, from minutes to hours.

The turbinates are usually swollen and edematous and may be mistaken for nasal polyps, which are pearl-gray gelatinous masses and unusual in uncomplicated allergic rhinitis. Below the turbinates, the floor of the nostril is often prominent as a result of mucosal edema. One third to half of children with allergic rhinitis have eustachian tube obstruction and resultant serous otitis. Otoscopy reveals a

retracted or bulging tympanic membrane, impaired mobility, or fluid level. In patients with intact tympanic membranes, tympanometry to measure middle ear pressures provides an indirect measure of eustachian tube function (Lazo-Saenz et al., 2005). The edematous nasal mucosa can obstruct the ostia, resulting in congestion or sinusitis with pressure symptoms or headache that is particularly notable with bending forward. Up to one third of patients have a lower respiratory tract component, including exercise-induced and mild persistent asthma.

DIAGNOSIS

A seasonal history or an association with an inhaled allergen is helpful. It is often difficult to associate specific allergens with perennial rhinitis, although late-evening or early-morning symptoms may be seen with dust allergy. Occasionally, improvement of symptoms with a change in environment, such as a vacation, indicates the presence of environmental allergens. A nasal smear, stained with Hansel's stain to identify eosinophils, can support a diagnosis of nasal allergy, but it is not itself diagnostic. An elevated peripheral eosinophil count may be helpful; however, marked allergic symptoms can occur in the absence of blood eosinophilia.

Along with clinical history, the diagnosis of allergic rhinitis can be supported by skin prick testing. This involves passing a fine needle through a drop of allergen extract and into the skin. Positive results are indicated by the wheal response with wheal diameters ≥ 3 mm considered positive. Surrounding erythema may be present, but its appearance or size is not indicative of a positive or negative test result (Bousquet et al., 2012). Skin prick testing is more sensitive than specific IgE assays for identifying sensitization to inhalant allergens and confirming clinical allergy. IgE assays with defined quantifiable threshold levels can also predict positive respiratory responses after allergen exposure (Bernstein et al., 2008).

TREATMENT

Nonspecific Measures

Removing known allergens is of prime importance because it can eliminate symptoms. When exposure is unavoidable, environmental control should reduce symptoms and prevent exacerbations. The patient or the family must assume responsibility for environmental control, so an understanding of the allergens to which the patient is sensitized is helpful. Commonly, inhaled allergens can lead to allergic rhinitis, allergic conjunctivitis, and asthma. Allergenic pollens come from trees, grasses, and weeds (Platts-Mills, 2003; Shiekh et al., 2004). Pollens from flowering plants are insect borne and are not important allergens. Pollen prevalence is usually determined by gravity slides, which sample pollen fallout without regard to wind direction, speed, and turbulence, so that daily reports of pollen prevalence often do not reflect the true concentration in the air or individual exposure.

Inhaled fungal allergens in fungus-sensitive subjects can produce seasonal symptoms during situations that promote fungal growth, such as humid and rainy weather and exposure to hay, mulch, commercial peat moss, and compost. Indoors, areas of spore formation can be identified

at sites of water condensation such as shower curtains, window moldings, and damp basements. In addition, cool-mist vaporizers can serve as sources of fungal contamination.

A prime role for the patient and family is controlling house dust. House dust is a heterogeneous mixture of bacteria, fibrous matter of plant and animal origin, human epidermis, food remnants, fungi, insect debris, and animal dander and contains one major source of antigen: dust mites. Mites are ubiquitous in households and are most prevalent in bedding, mattresses, carpeting, and upholstered furniture, particularly where warmth and humidity are high. Air conditioners and dehumidifiers are useful for these patients. HEPA filters are effective in removing dust and animal dander. Fans should not be used so that these lightweight particles can settle. Minimizing clutter and removing carpets are also effective measures. Linens should be washed in hot water (130°F or 55°C). Impermeable cases can be used for pillows and mattresses. The use of a mask over the nose and mouth with replaceable microfoam filters significantly reduces the effects of temporary exposure to inhaled allergens such as dust or pollens.

Animal allergens are derived from dried saliva on shed cat fur, rodent urine, and epidermal material from farm animals. The allergic respiratory reactions produced by animal allergens are species specific. Finished furs and wools are not allergenic. Feathers are often nonallergenic when fresh, and they produce allergic symptoms only after degradation. A careful history to identify environmental allergens is important for advising avoidance and treatment.

Control of Symptoms

Antihistamines are effective for symptomatic control of allergic rhinitis, whether it is seasonal or perennial (Bousquet et al., 2008; Brozek et al., 2010; Simons and Adkis, 2009; Wallace et al., 2008; SOR: A). For optimal results, antihistamines should be used before exposure to the known allergen. Complete control might not be achieved when patients use antihistamines only sporadically. During the implicated season, around-the-clock administration provides maximal symptomatic relief. Because compliance is always an issue, the new second-generation antihistamines offer a convenient dosing regimen because the half-lives of these medications are longer (see eTable 19-1 online). These groups of drugs, with specific binding properties, allow little to no penetration into the central nervous system (CNS), greatly reducing their side effects, primarily sedation. The second-generation antihistamines also have antiinflammatory effects.

Fexofenadine (Allegra), an analog of terfenadine, is safe and effective. Through its effects on T cells, fexofenadine can decrease airway inflammation. Loratadine (Claritin) is available as a once-daily product (Gelfand et al., 2002). It provides safe and effective control of most symptoms of allergic rhinitis if taken regularly. Desloratadine (Clarinex), also a once-daily medication, is a metabolite of loratadine. In murine models, desloratadine inhibits bronchial hyperresponsiveness and airway inflammation (Bryce et al., 2003). Cetirizine (Zyrtec), a metabolite of hydroxyzine, is available in once-daily dosing. Cetirizine has antiinflammatory properties and may be effective in patients with allergic rhinitis and reactive airway disease. Cetirizine's chemical properties, however, allow greater CNS penetration, and

sedation is its chief side effect (16% vs. 4% for fexofenadine and loratadine). Levocetirizine (Xyzal), also a once-daily medication, is a metabolite of cetirizine. Less sedation is associated with it than cetirizine.

Herbal medications have been used with effectiveness in treating perennial and seasonal allergic rhinitis. Butterbur (32 mg daily) was effective in treating seasonal allergic rhinitis when compared with cetirizine (10 mg daily) in 125 patients. After 2 weeks, patients treated with butterbur had improved vitality, general health, and physical activity as well as less sedation (Schapowal, 2002; SOR: A).

Second-generation antihistamines are available in combination with α -adrenergic decongestants and might be more effective in this form than antihistamines alone. α -Adrenergic drugs are also effective applied topically. Topical vasoconstrictors (sprays and drops) are best restricted to temporary use, such as when taking an airplane trip or during a severe flare-up of symptoms. Unfortunately, the side effect profile increases in these combinations. Intranasal antihistamines have the most rapid onset of action and are as effective as oral second-generation antihistamines in the treatment of seasonal allergic rhinitis (SOR: A). Azelastine (Astelin, Astepro), available in a nasal spray formulation, decreases nasal airway resistance and is an effective treatment for rhinitis. Olopatadine (Patanase) is another topical antihistamine with effectiveness against symptoms of rhinitis. Leukotriene receptor antagonists, such as montelukast (Singulair), are also effective for the treatment of perennial and seasonal allergic rhinitis (Wallace et al., 2008).

Topical intranasal glucocorticoids—beclomethasone, fluticasone, mometasone, triamcinolone, flunisolide, ciclesonide, and budesonide—are the most effective medication in the treatment of allergic rhinitis (Wallace et al., 2008; SOR: A). Their effectiveness is directly related to proper and daily use, posing problems with patient compliance. Side effects are related primarily to nasal dryness and epistaxis, which may improve when using saline as a moisturizer. The therapeutic effects are generally not immediate, and some patients must take these medications for 1 to 3 weeks before they achieve maximum benefit.

When symptoms are severe and not responsive to trials of topical therapy, oral glucocorticoid therapy can be used as a last resort and only for limited duration. The rationale for glucocorticoid therapy for allergic rhinitis is that the condition, although mediated by immunoglobulin E (IgE), has a dual component: the immediate phase of edema and hypersecretion and a late inflammatory phase (Castro-Rodriguez et al., 2005; Ciprandi et al., 2005). This dual reaction occurs in asthma as well.

Specific Immunotherapy

When skin tests identify sensitivity to an unavoidable inhalant allergen, immunotherapy may be indicated for treating allergic rhinitis. Its efficacy has been shown to be 80% for controlling pollen symptoms and 60% for controlling mold and house dust symptoms. Immunotherapy is therefore more effective in seasonal allergic rhinitis than perennial allergic rhinitis. When considering immunotherapy, the ease of control of other therapies should be weighed against the frequency and severity of symptoms as well as the possibility of complete resolution of allergy with immunotherapy (Cox, et al., 2011).

eTable 19-1 Second-Generation Oral Antihistamines for Treatment of Allergic Rhinitis

Drug (Brand)	Formulation	Dosing Frequency	Age of Patient
Cetirizine* (Zyrtec)	5 mg/5 mL syrup	qd	6 mo
	5-mg, 10-mg chewable tablet	qd	
	10-mg tablet	qd	
Desloratadine (Clarinx)	2.5 mg/5 mL syrup	qd	6 mo
	5-mg tablet	qd	
Fexofenadine* (Allegra)	30-mg, 60-mg tablets	Twice daily	6 yr
	180-mg tablet	qd	
Levocetirizine (Xyzal)	2.5 mg/5 mL syrup	qd	6 mo
	5-mg tablet	qd	
Loratadine* (Claritin)	5 mg/5 mL syrup	qd	2 yr
	10-mg reditablet	qd	

*Available as an over-the-counter generic drug.
qd, Once daily,

KEY TREATMENT

- Oral antihistamines, including fexofenadine, cetirizine, loratadine, levocetirizine, and desloratadine, improve symptoms (e.g., runny nose, nasal pruritus, sneezing, and quality of life) in patients with seasonal allergic rhinitis compared with placebo (SOR: A).
- Herbal medications have been used with effectiveness in treating perennial and seasonal allergic rhinitis (SOR: A).
- Inhaled corticosteroids were more effective than oral antihistamines in treating most nasal symptoms of seasonal allergic rhinitis, including nasal congestion, runny nose, pruritus, and sneezing (SOR: A).
- Immunotherapy is effective against allergic rhinitis and can prevent the development of asthma in children (SOR: A).

Nonallergic Rhinitis**Key Points**

- Symptoms of nonallergic rhinitis include chronic nasal obstruction and eosinophils on nasal smear, in the absence of allergy.
- Topical glucocorticoid steroid therapy is useful in treatment of nonallergic rhinitis with eosinophilia (NARES).
- Aggravating factors include physical changes or irritants for vasomotor rhinitis.
- Ipratropium bromide is best for controlling symptoms of vasomotor rhinitis.

Some patients with perennial rhinitis are not atopic by history or skin testing. Chronic nasal obstruction is the predominant symptom, and the condition may be associated with sinus disease and nasal polyps. Although there is no evidence of allergy by skin testing, numerous eosinophils are present, and the diagnosis is readily made by examining the nasal secretions for eosinophils and eosinophilic cationic protein (Kramer et al., 2004). The condition is also called NARES. A substantial number of patients have chronic rhinitis with rhinorrhea, postnasal drainage, and chronic or intermittent nasal obstruction. Symptoms are aggravated by many physical or irritant factors, such as cold air, odors, and smoke. Skin test results are negative, and no eosinophils are present in the tissue or secretions.

Topical glucocorticoid therapy is much more effective than antihistamines or decongestants for NARES. As with patients with asthma, patients with associated sinus disease and nasal polyps are at risk for adverse reactions to aspirin and nonsteroidal antiinflammatory drugs (NSAIDs). Patients with NARES are also at risk for obstructive sleep apnea (Wallace et al., 2008). Ipratropium bromide (0.03%) spray solution, fluticasone, and azelastine nasal sprays have all been shown to be effective treatments. Some patients benefit from antihistamine–decongestant combinations. The regular use of buffered saline lavage can also provide satisfactory symptomatic relief.

Allergy in the Eye**Key Points**

- Symptoms of eye allergy include pruritus, erythema, and lacrimation.
- Treatment includes oral antihistamines plus topical medications such as mast cell stabilizers or H₁ blockers.

Allergic conjunctivitis is the usual ocular reaction to airborne allergens. As in other forms of allergic inflammation, the mast cell plays a key role. Itching is the first symptom and may be associated with lacrimation. Dilation of the conjunctival blood vessels produces a “red” eye. Transudation of fluid through vessel walls results in edema of the conjunctiva, and exuded cells with increased glandular mucus secretions result in ocular discharge. In most atopic patients, conjunctivitis and allergic rhinitis occur together, but some patients are bothered only by eye symptoms. In contrast to other forms of conjunctivitis, the secretions contain eosinophils.

Vernal conjunctivitis is so called because of its occurrence in spring and summer. It is characterized by a bilateral recurrent inflammation of the conjunctiva. Vernal conjunctivitis typically occurs between ages 5 and 20 years. It often spontaneously resolves in 10 years. More than 50% of children with vernal conjunctivitis also have an atopic disorder such as allergic rhinitis, eczema, or asthma. Signs and symptoms include acute itching, tearing, photophobia, and excess mucus production.

The topical conjunctival appearance establishes the diagnosis, which is confirmed by cytologic smears showing numerous eosinophils. In the tarsal (palpebral) form, there are flat-top cobblestone papillae; in the limbal form, there may be gelatinous hypertrophy and limbal papillary hypertrophy often associated with white dots (Trantas dots). Although vernal conjunctivitis is usually self-limiting, corneal complications can occur, and ophthalmology consultation should be obtained (Bozkurt, et al., 2009). Although conjunctivitis is typically seasonal and common in atopic patients, no allergens have been identified as causal or aggravating factors.

The usual therapy for allergic conjunctivitis is an oral antihistamine with a topical medication (see eTable 19-2 online). Cromolyn (Opticrom) and lodoxamide 0.1% (Alomide) are mast cell stabilizers. Topical H₁ histamine blockers are also effective for treating allergic conjunctivitis. Ophthalmic histamine blocker solutions include emedastine (Emadine) and levocabastine (Livostin). Azelastine (Optivar), epinastine (Elestat), ketotifen (Zaditor, Claritin Eye, Zyrtec Itchy Eye), and olopatadine (Patanol, Pataday) are dual-acting drugs, preventing mast cell release and exerting antihistamine activity as well. Ketorolac (Acular) is an NSAID. Regular daily use is necessary to obtain maximum positive results with all topical agents. In severe cases and in vernal conjunctivitis, a soluble steroid such as fluorometholone ophthalmic solution (0.1%) is effective. The dose should be titrated to the minimum required to control symptoms. Use should be intermittent because glucocorticoids can lead to the development of cataracts,

eTable 19-2 Ophthalmic Solutions Useful in the Treatment of Allergic Conjunctivitis

Drug (Brand)	Formulation	Dosage
MAST CELL STABILIZERS		
Cromolyn (Opticrom)	4%	1-2 gtt OU every 4-6 hr daily
Lodoxamide (Alomide)	0.1%	1 gtt OU qid
H₁ Histamine Blockers		
Emedastine (Emadine)	0.05%	1 gtt OU qid
Levocabastine (Livostin)	0.5 mg/mL	1 gtt OU bid
COMBINATION STABILIZERS/BLOCKERS		
Ketotifen (Zaditor)	0.025%	1 gtt OU bid 8-12 hr apart
(Zyrtec Itchy Eye)	0.025%	1 gtt OU bid 8-12 hr apart
(Claritin Eye)	0.025%	1 gtt OU bid 8-12 hr apart
Epinastine (Elestat)	0.05%	1 gtt OU bid
Olopatadine (Patanol)	0.1%	1 gtt OU bid 6-8 hr apart
(Pataday)	0.2%	1 gtt OU qd
Azelastine (Optivar)	0.05%	1 gtt OU bid
NONSTEROIDAL ANTIINFLAMMATORY DRUGS		
Ketorolac (Acular)	0.5%	1 gtt OU qid

bid, Twice daily; *gtt*, drops; *OU*, each eye; *qd*, once daily; *qid*, four times daily.

potentiate a secondary bacterial infection or a herpes simplex keratitis, and increase intraocular pressure. Steroid eyedrops should always be used under supervision by an ophthalmologist.

Asthma

Key Points

- The diagnosis is based on presence of reversible airway obstruction, airway inflammation, and increased airway responsiveness to a variety of stimuli.
- Identification and avoidance of allergens or triggers are essential.
- Control of rhinitis symptoms is often necessary to improve the control of asthma.
- An action plan is needed to aid the patient in identifying a possible exacerbation.
- Therapy is based on presence of certain clinical features, as well as spirometric values.

The definition of asthma has undergone many changes over the years, but three elements are key to the diagnosis: reversible airway obstruction, airway inflammation, and increased airway responsiveness to a variety of stimuli. Physicians must remember that not all wheezing is asthma, and not all asthma has wheezing. Asthma is a chronic inflammatory disorder of the airways in which many different cells play a role. In patients with asthma, this inflammation causes breathlessness, chest tightness, recurrent episodes of wheezing, and cough, particularly at night. These symptoms are usually associated with variable airflow limitation that is partly reversible with treatment or sometimes spontaneously. This inflammation causes an associated increase in airway responsiveness to a variety of stimuli (Busse et al., 2007). Data from the Centers for Disease Control and Prevention (CDC) have shown an increase in the prevalence of asthma in the United States from 1980 to 2010. However, there has been no increase in mortality and hospitalization rates since 1997, and the number of asthma deaths has declined steadily since 2001 (cdc.gov/asthma).

DIAGNOSIS

Because of the lack of any specific symptom or sign to define asthma by history or physical examination, some patients are mistakenly thought to have asthma. Numerous other diseases must be considered in the differential diagnosis of asthma (Table 19-3; eBox 19-1 and eBox 19-2). Although parental history of asthma is present in half of children with asthma, the positive predictive value of this history ranges from 11% to 37% (Burke et al., 2003). The diagnosis of asthma should occur in three stages. First, suggestive symptoms referable to the chest with precipitating factors should raise the possibility of asthma. Second, further testing should be performed to confirm the diagnosis. Third, the patient should have symptomatic improvement with the appropriate asthma therapy (see

Table 19-3 Differential Diagnosis of Asthma

Infants and Children	Adults
Allergic rhinosinusitis	ACE inhibitor–induced cough
Cystic fibrosis	COPD
Foreign body	Congestive heart failure
GERD	Eosinophilic pulmonary infiltration
Heart disease	GERD
Paradoxical vocal cord motion	Mechanical obstruction of the airway
Tumor	Paradoxical vocal cord motion
Viral bronchiolitis	Pulmonary embolism

ACE, Angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; GERD, gastroesophageal reflux disease.

Table 19-4 Factors That Can Precipitate Asthma

Environmental allergens such as pollen, molds, house dust mites, cockroach excreta, and animal danders
Environmental changes or climate change
Exercise
Exposure to irritants (e.g., tobacco smoke), strong odors, and air pollutants
Exposure to medication: salicylates, NSAIDs, or β -blockers
Exposure to occupational chemicals or allergens
Exposure to some food additives
GERD
Menses
Pregnancy
Sinusitis
Strong emotional feelings
Viral respiratory infections

GERD, Gastroesophageal reflux disease; NSAID, nonsteroidal antiinflammatory drug.

“Classification”). When all the stages have been performed and meet the criteria, the diagnosis of asthma can be made.

Precipitating Factors

All patients suspected of having asthma should be questioned about early warning signs and precipitating factors. Early warning signs of an attack include symptoms such as cough, a scratchy throat, and nasal stuffiness, especially if an attack follows an upper respiratory tract infection. Many other precipitating factors can provoke asthma symptoms or an acute attack (Table 19-4). Identification of these precipitating factors can help patients manage their asthma by learning their early warning signs and avoiding any exposure that triggers an exacerbation. These symptoms and identification of triggers are the first stages of diagnosis of asthma.

Confirmatory Testing

Pulmonary function testing is the “gold standard” for the diagnosis and management of asthma and is the second stage in the diagnosis of asthma. The only exclusion for obtaining pulmonary function tests should be the lack of an ability to perform the testing, most often determined by the patient’s age (usually <4 years).

Spirometry is the most useful test in the diagnosis of asthma. Spirometry includes measuring the forced expiratory volume of air in 1 second (FEV₁) and forced vital capacity (FVC), the amount of air one can expel during

eBox 19-1 Exercise-Induced Bronchospasm

Exercise-induced bronchospasm is a bronchospastic event that usually occurs during or minutes after vigorous activity. The peak of the bronchospasm occurs 5 to 10 minutes after stopping the activity and usually resolves by 30 minutes. The goal of management is to allow patients to participate in any activity they choose without being hindered by asthma symptoms.

β_2 -Agonists used shortly before exercise help prevent exercise-induced bronchospasm in more than 80% of patients. Cromolyn or nedocromil taken shortly before exercise are acceptable options but should be considered alternatives. If symptoms are not controlled with these options, long-term controller medications such as an inhaled corticosteroid or leukotriene modifier may be considered. A warm-up period before exercise can benefit patients who can tolerate continuous exercise with minimal symptoms (Busse et al., 2007).

eBox 19-2 Paradoxical Vocal Cord Motion

Paradoxical vocal cord motion is defined by an inappropriate adduction of the true vocal cords on inspiration and adduction on expiration. The functional airway obstruction results in marked inspiratory stridor and wheezing, and the symptoms are similar to those of asthma. Often misdiagnosed as refractory asthma, paradoxical vocal cord motion appears to be psychogenic and occurs most often in young women with a history of prior psychiatric illnesses (e.g., depression, personality disorder, posttraumatic stress disorder, sexual abuse, generalized anxiety). The diagnosis is made by direct laryngoscopy with visualization of the cords throughout the respiratory cycle. Treatment is difficult because there are no published studies on the efficacy of psychodynamic therapy or pharmacologic treatment.

Table 19-5 Severity of Any Spirometric Abnormality Based on FEV₁

Degree of Severity	FEV ₁ (% Predicted)
Mild	>70
Moderate	60-69
Moderately severe	50-59
Severe	35-49
Very severe	<35

FEV₁, Forced expiratory volume in 1 second.

From Brusaco V, Crapo R, Viegi G. Interpretative strategies for lung function tests. *Eur Respir J*. 2005;26:948-968. American Thoracic Society.

forced expiration. FEV₁ is the most important value for the assessment of airflow obstruction. It declines in direct and linear proportion of worsening airway obstruction and increases with successful treatment of airway obstruction. Degrees of airway obstruction are defined according to the percentage of predicted FEV₁ achieved by the patient (Table 19-5) (Brusaco et al., 2005).

Administration of a bronchodilator such as albuterol is indicated when performing spirometry. Improvement of FEV₁ by 12% or 200 mL after administering a bronchodilator suggests significant reversibility of the airway obstruction. Another useful value is the FEV₁/FVC ratio. A reduced ratio below the fifth percentile of the predicted value suggests obstructive airway disease. A reduced FVC with a normal or increased FEV₁/FVC ratio (>5% of predicted value) suggests a restrictive pattern of lung disease (Brusaco et al., 2005). Additional testing by bronchoprovocation may be considered if one suspects a patient has asthma but spirometry testing results are normal. The only absolute contraindications to methacholine bronchoprovocation testing are severely reduced airflow (FEV₁ <50%), acute coronary syndrome or stroke in the past 3 months, uncontrolled hypertension, or known aortic aneurysm.

PEAK-FLOW MONITORING

The home use of peak-flow meters is helpful in the self-management of asthma but not in the diagnosis. The National Asthma Education and Prevention Program (Brusaco et al., 2005) recommends daily monitoring for patients with moderate to severe persistent asthma; for those with severe exacerbation history; and for patients who have poor perception of their worsening asthma, including children. There is no evidence that peak-flow monitoring improves patient outcomes over self-monitoring of symptoms. However, if a practitioner provides a peak-flow meter, the patient should be properly instructed in its use (Busse et al., 2007). The patient should establish a baseline peak flow in the absence of asthma symptoms. Three zones on the meter are then set—green, yellow, and red. The green zone is 80% to 100% of the patient's "personal best" and reassures the patient to continue the current regimen. The yellow zone is 50% to 80% of personal best and should signal the patient to change the measurement plan according to the clinician. The red zone is less than 50% of the personal best and should signal the patient to

seek medical attention. The use of the peak-flow meter can help give some patients objective findings of the severity of their asthma.

TREATMENT

Classification

Asthma is classified into four categories based on subjective symptoms of frequency and severity and objective measurements of pulmonary function (Figures 19-1 and 19-2). Classification is initially based on the highest step at which any feature occurs, realizing that clinical features for individual patients can overlap. An individual patient's classification can and should change over time so the patient can move to a lower classification with adequate therapy.

The goal of asthma therapy is to maintain control of asthma with the least amount of medication and the least risk for adverse side effects. Obtaining control of asthma can be difficult to define for the patient and the clinician. Several keys to the definition of controlled asthma are prevention of troublesome symptoms (cough or wheezing), maintenance of normal pulmonary function, maintenance of normal activity levels, prevention of recurrent exacerbations, and meeting patients' and families' expectations of asthma care.

Classification of asthma is the last stage in the diagnosis of asthma. Patients with asthma should respond to traditional treatment based on the stage of asthma. The National Heart, Lung and Blood Institute (NHLBI) provides the current clinical guidelines (Figures 19-3 and 19-4) (Busse et al., 2007). The physician should keep the following points in mind when using the NHLBI guidelines:

1. The stepwise approach is intended to assist, not replace, the clinical decision making required to meet individual patient needs.
2. Classify severity; assign the patient to the most severe step in which any feature occurs.
3. Gain control as quickly as possible (a course of short systemic corticosteroids may be required); then step down to the least medication necessary to maintain control.
4. Minimize the use of short-acting inhaled β_2 -agonists. Overreliance (e.g., use of short-acting inhaled β_2 -agonist every day, increasing use or lack of expected effect, or use of approximately one canister a month even if not using it every day) indicates inadequate control of asthma and the need to initiate or intensify long-term-control therapy.
5. Provide parent education on asthma management and controlling environmental factors that make asthma worse at all points of care (e.g., allergens, irritants).
6. Consultation with an asthma specialist is recommended for patients with moderate or severe persistent asthma. Consider consultation for patients with mild persistent asthma.

Management of Asthma in Children

More than half of children with asthma develop symptoms before their fifth birthday. However, diagnosis can be difficult because there are no reliable tests for children at this age, and diagnosis must rely solely on clinical presentation.

Components of severity		Classifying Asthma Severity and Initiating Therapy in Children							
		Intermittent		Persistent					
				Mild		Moderate		Severe	
		Ages 0-4 yr	Ages 5-11 yr	Ages 0-4 yr	Ages 5-11 yr	Ages 0-4 yr	Ages 5-11 yr	Ages 0-4 yr	Ages 5-11 yr
Impairment	Symptoms	≤2 d/wk		>2 d/wk but not daily		Daily		Throughout the day	
	Nighttime awakenings	0	≤2x/ mo	1-2x/ mo	3-4x/ mo	3-4x/ mo	>1x/wk but not nightly	>1x/ wk	Often 7x/wk
	Short-acting β ₂ -agonist use for symptom control	≤2 d/wk		>2 d/wk but not daily		Daily		Several times per day	
	Interference with normal activity	None		Minor limitation		Some limitation		Extremely limited	
	Lung function • FEV ₁ (predicted) or peak flow (personal best) • FEV ₁ /FVC	N/A	Normal FEV ₁ between exacerbations >80% >85%	N/A	>80% >80%	N/A	60%-80% 75%-80%	N/A	<60% <75%
Risk	Exacerbations requiring oral systemic corticosteroids (consider severity and interval since last exacerbation)	0-1/yr (see notes)		≥2 exacerbations in 6 months requiring oral systemic corticosteroids or ≥4 wheezing episodes/1 yr lasting >1 d AND risk factors for persistent asthma	≥2x/yr (see notes)				
					Relative annual risk may be related to FEV ₁				
Recommended step for initiating therapy (See “Stepwise Approach for Managing Asthma” for treatment steps.) The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.		Step 1 (for both age groups)		Step 2 (for both age groups)		Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option and consider short course of oral systemic corticosteroids	Step 3 and consider short course of oral systemic corticosteroids	Step 3: medium-dose ICS option OR step 4 and consider short course of oral systemic corticosteroids
In 2-6 wk, depending on severity, evaluate level of asthma control that is achieved. • Children 0-4 yr old: If no clear benefit is observed in 4-6 wk, stop treatment and consider alternative diagnoses or adjusting therapy. • Children 5-11 yr old: Adjust therapy accordingly.									

Figure 19-1 Classifying asthma severity and initiating therapy in children. FEV₁, Forced expiratory volume of air in 1 second; FVC, forced vital capacity; ICS, inhaled corticosteroid; N/A, not applicable. (From Busse WW, Boushey HA, Camargo CA, et al. *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

Among children younger than 5 years, the most common cause of asthma symptoms is a viral upper respiratory tract infection. Based on expert opinion, daily long-term control therapy should be initiated in young children who consistently require symptomatic treatment more than twice per week and those who experience severe exacerbations that occur less than 6 weeks apart. Therapy is recommended for children who had more than four episodes of wheezing in the past year that lasted more than 1 day and affected sleep and who have a positive asthma predictive index (Busse et al., 2007). A positive asthma predictive index is at least three episodes of wheezing in a years' time during the first 3 years of life and either one of two major risk factors

(parental history of asthma or physician diagnosis of atopic dermatitis) or two of three minor risk factors (wheezing apart from colds, peripheral blood eosinophilia higher than 4%, or evidence of sensitization of foods) (Castro-Rodriguez, 2011). Therapy may be given by metered-dose inhalers with a spacer; evidence suggests they are as good as or better than nebulizers for children with asthma (SOR: A) (Hsu et al., 2004).

Management of Asthma Exacerbation

Asthma exacerbations consist of episodes of progressively worsening shortness of breath, cough, wheezing, or chest tightness. These exacerbations are characterized by

Components of severity		Classification of Asthma Severity ≥12 years of age			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment Normal FEV ₁ /FVC: 8-19 yr 85% 20-39 yr 80% 40-59 yr 75% 60-80 yr 70%	Symptoms	≤2 d/wk	>2 d/wk but not daily	Daily	Throughout the day
	Nighttime awakenings	≤2x/mo	3-4x/mo	>1x/wk but not nightly	Often 7x/wk
	Short-acting β ₂ -agonist use for symptom control (not prevention of EIB)	≤2 d/wk	>2 d/wk but not daily and not more than 1x on any day	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	<ul style="list-style-type: none"> • Normal FEV₁ between exacerbations • FEV₁ >80% predicted • FEV₁/FVC normal 	<ul style="list-style-type: none"> • FEV₁ >80% predicted • FEV₁/FVC normal 	<ul style="list-style-type: none"> • FEV₁ >60% but <80% predicted • FEV₁/FVC reduced 5% 	<ul style="list-style-type: none"> • FEV₁ <60% predicted • FEV₁/FVC reduced 5%
Risk	Exacerbations requiring oral systemic corticosteroids	0-1/yr (see note)	≥2/yr (see note) →		
		← Consider severity and interval since last exacerbation. → Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV ₁ .			
Recommended step for initiating therapy (See "Stepwise Approach for Managing Asthma" for treatment steps.)		Step 1	Step 2	Step 3 and consider short course of oral systemic corticosteroids	Step 4 or 5
In 2-6 wk, evaluate level of asthma control that is achieved and adjust therapy accordingly.					

Figure 19-2 Classification of asthma severity. *EIB*, Exercise-induced bronchospasm; *FEV₁*, forced expiratory volume of air in 1 second; *FVC*, forced vital capacity. (From Busse WW, Boushey HA, Camargo CA, et al. *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

decreases in FVC and FEV₁. Peak-flow monitoring can help grade the severity of an exacerbation. Early treatment is the best strategy for effective treatment of asthma exacerbations. Patients should receive a written action plan to guide self-management of exacerbation, especially patients with persistent asthma or any history of a severe exacerbation. Patients should be able to recognize the early indicators of an exacerbation, such as a decline in peak expiratory flow rate (PEFR). There should be prompt communication between the clinician and patient during any abrupt worsening of asthma, as well as availability of a short course of systemic corticosteroids even before this communication takes place. The goals of treating an exacerbation are correction of any significant hypoxemia, rapid reversal of air-flow obstruction, and reduction of the likelihood of recurrence of severe airflow obstruction by intensifying therapy.

The NHLBI expert panel recommends increasing the frequency of inhaled β₂-agonists and initiating or increasing oral corticosteroid treatment. The panel does not recommend drinking large volumes of liquids or breathing warm, moist air. They also discourage the use of over-the-counter products such as antihistamines, cold remedies, or bronchodilators. For patients who present to emergency departments (EDs), the clinician should obtain a brief targeted history as well as objective data such as peak-flow measurement and pulse oximetry. Clinicians should be aware of risk factors for asthma-related deaths: previous intubation or intensive care unit admission for asthma, two or more hospitalizations, or more than three ED visits in the past year; use of more than two canisters of short-acting β₂-agonist per month; low socioeconomic status; illicit drug use; major psychosocial problems; and comorbidities such as cardiovascular or chronic lung disease.

		Step up if needed (first check inhaler technique, adherence, environmental control, and comorbid conditions)						
		Assess control						
		Step down if possible (and asthma is well controlled at least 3 months)						
		Step 1	Step 2	Step 3	Step 4	Step 5	Step 6	
Children 0-4 yr of age		Intermittent asthma	Persistent asthma: daily medication Consult with asthma specialist if step 3 care or higher is required. Consider consultation at step 2.

	Each step: Patient education, environmental control, and management of comorbidities							
		Steps 2-4: Consider subcutaneous allergen immunotherapy for patients who have persistent, allergic asthma.						
		Quick-relief medication	<ul style="list-style-type: none"> SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to three treatments at 20-minute intervals as needed. Short course of oral systemic corticosteroids may be needed. <p>Caution: Increasing use of SABA or use >2 d a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step up treatment.</p>					

Figure 19-3 Step therapy for children with asthma. *EIB*, Exercise-induced bronchospasm; *ICS*, inhaled corticosteroid; *LABA*, long-acting β-agonist; *LTRA*, leukotriene receptor antagonist; *PRN*, as needed; *q*, every; *SABA*, short-acting β-agonist. (From Busse WW, Boushey HA, Camargo CA, et al. *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

Chest radiographs should be obtained only in patients suspected of having a more complicated process such as pneumothorax, pneumonia, or congestive heart failure. Treatment of exacerbations in the ED should include nebulizer therapy with short-acting β₂-agonists and nebulized anticholinergics such as ipratropium bromide (SOR: A)

(Busse et al., 2007). However, the NHLBI does not recommend continued use of nebulized anticholinergics during hospitalization. In general, patients should be discharged if their FEV₁ or PEFr has returned to greater than 70% of their predicted personal best and they are in no respiratory distress.

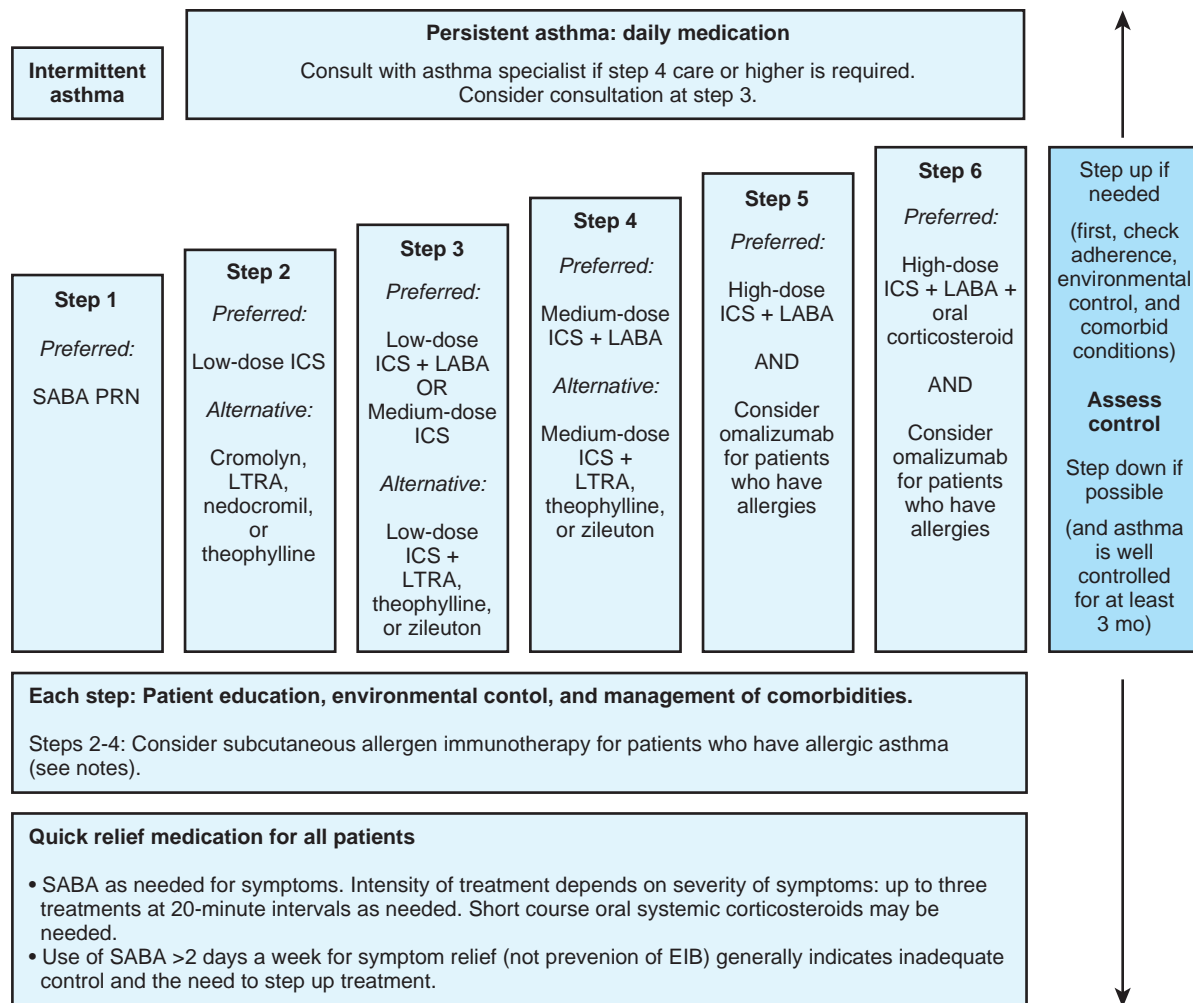

Figure 19-4 Step therapy for adults with asthma. *EIB*, Exercise-induced bronchospasm; *ICS*, inhaled corticosteroid; *LABA*, long-acting β -agonist; *LTRA*, leukotriene receptor antagonist; *PRN*, as needed; *SABA*, short-acting β -agonist. (From Busse WW, Boushey HA, Camargo CA, et al. *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, Expert Panel Report 3. NIH Pub No 08-5846, October 2007.)

KEY TREATMENT

- Pulmonary function testing is the “gold standard” for the diagnosis and management of asthma and should be performed in all patients older than 4 years of age (SOR: C).
- Minimize the use of short-acting inhaled β_2 -agonists for asthma patients (SOR: C).
- Short-acting inhaled β_2 -agonists should be used less than twice a week for asthma, or step therapy should be increased (SOR: C).
- Inhaled corticosteroids are the preferred therapy for all patients with persistent asthma (SOR: A).
- Asthma exacerbations should be treated with oral corticosteroids (SOR: A).
- Nebulized ipratropium can be used for asthma exacerbation in the ED setting but should not be used in the inpatient setting (SOR: A).

Anaphylaxis

Key Points

- Anaphylaxis is a severe allergic reaction that can result in death.
- Increasing numbers of patients with anaphylaxis are reported.
- Identification of the signs and symptoms is necessary to prevent mortality.
- Diagnostic testing can aid the clinician in identifying the allergen responsible.
- Physicians should have intramuscular (IM) epinephrine readily accessible at all times for these patients.

Table 19-6 Signs and Symptoms of Anaphylaxis and Frequency of Occurrence

Signs and Symptoms	Frequency (%)
CUTANEOUS	90
Urticaria and angioedema	85-90
Flushing	45-55
Pruritus without rash	2-5
RESPIRATORY	40-60
Upper airway angioedema	60-60
Dyspnea, wheeze	45-50
Rhinitis	15-20
ABDOMINAL	
Nausea, vomiting, diarrhea, cramping abdominal pain	25-30
MISCELLANEOUS	
Dizziness, syncope, hypotension	30-35
Headache	5-8
Substernal pain	4-6
Seizure	1-2

Anaphylaxis has been traditionally defined as an acute, systemic, immediate hypersensitivity reaction produced by IgE-mediated degranulation of mast cells and basophils (Lieberman, 2006). The term *anaphylactoid* has referred to a clinically similar event not mediated by IgE-induced mast cell and basophil degranulation. An alternative classification by the World Allergy Organization (Johansson et al., 2004) eliminates the term *anaphylactoid* and refers to all events as *anaphylactic*, subdividing them into immunologic and nonimmunologic episodes. Immunologic episodes are then further subdivided into those caused by IgE-mediated mast cell and basophil degranulation and those resulting from other immunologic processes. An example of a non-IgE immunologically mediated event is a transfusion reaction. An example of a nonimmunologic event is a reaction to the administration of radiocontrast media (RCM) that can directly degranulate mast cells and basophils without intervening IgE. In the case of anaphylaxis to RCM, patients should be premedicated with steroids and antihistamines if its use is clinically indicated (Lieberman, 2009; Lieberman et al., 2010; eTable 19-3 online).

MANIFESTATIONS

Almost all patients with anaphylaxis express cutaneous symptoms, the most common of which are urticaria and angioedema. However, anaphylactic events can occur without any cutaneous manifestation. The most common cause is probably the rapid onset of hypotension and shock, which diverts blood flow from the skin. Anaphylaxis can clearly be the cause of syncope without any other manifestation and therefore must be considered as a cause of any syncopal episode. Table 19-6 lists signs and symptoms of anaphylaxis and their frequency (Sampson et al., 2005).

Criteria have been established for the diagnosis of anaphylaxis (Table 19-7) (Sampson et al., 2005). Anaphylaxis usually requires at least two-system involvement; in most

Table 19-7 Diagnosis of Anaphylaxis*

<i>and</i>
Airway compromise (e.g., dyspnea, wheeze or bronchospasm, stridor, reduced lung functions)
<i>or</i>
Reduced blood pressure or associated symptoms (e.g., hypotonia, syncope)
Two or more of the following after exposure to known allergen for that patient (minutes to hours):
History of severe allergic reaction
Skin or mucosal tissue involvement (e.g., hives, generalized itch or flush, swollen lips, tongue, uvula)
Airway compromise (e.g., dyspnea, wheeze/bronchospasm, stridor, reduced lung function)
Reduced blood pressure or associated symptoms (e.g., hypotonia, syncope)
In suspected food allergy: gastrointestinal symptoms (e.g., cramping abdominal pain, vomiting)
Hypotension after exposure to known allergen for that patient (minutes to hours)
Infants and children: low systolic blood pressure (age specific)
Adults: systolic blood pressure less than 100 mm Hg

**Caution:* These criteria describe classic cases of anaphylaxis. Other presentations can also indicate anaphylaxis. Physicians must remember the potential for false-positive symptoms or signs resulting from panic, vasovagal episodes, and other causes.

cases, the skin is involved, and respiratory, vascular, or gastrointestinal symptoms accompany skin involvement. Patients with gastrointestinal anaphylaxis are often misdiagnosed. Single-system involvement (usually the skin) may be sufficient when this symptom appears after exposure to a known allergen (e.g., a person known to be allergic to shellfish who develops urticaria within 30 minutes of shellfish ingestion); the diagnosis of anaphylaxis can be made without two-system involvement. This concept is important because rapid administration of epinephrine in such a patient might prevent further manifestations. The earlier the symptoms are recognized, the more likely the patient will respond to the epinephrine. The risk of death exists in patients who either do not receive epinephrine or epinephrine is not administered promptly during an anaphylactic reaction (Simons et al., 2011; Simons et al., 2013).

The differential diagnosis and most common causes of anaphylaxis are shown in Tables 19-8 and 19-9. The most frequent cause of anaphylaxis is foods, and the next most common is drugs. The most common food to cause anaphylaxis in adults is shellfish. In infants, cow's milk is the most common food allergen; in older children, peanuts are the most common offenders. As many as 50% of cases of anaphylaxis occur without a known cause despite intense investigative efforts (Webb et al., 2004). Recently, delayed anaphylaxis to a carbohydrate in red meat (α -1,3-galactose) has been reported (Simons et al., 2011). Laboratory testing can be useful to establish a diagnosis of anaphylaxis and to rule out other causes of symptoms caused by conditions that mimic anaphylaxis (Table 19-10). The most common test to confirm a diagnosis of anaphylaxis is serum tryptase, with high specificity but low sensitivity.

Table 19-8 Differential Diagnosis of Anaphylaxis

Anaphylaxis
Vasodepressor and vasovagal reactions
Other forms of shock
Hemorrhagic
Hypoglycemic
Cardiogenic
Endotoxic
Flushing syndromes
Carcinoid
Red man syndrome caused by vancomycin
Postmenopausal
Alcohol induced
Vasointestinal peptide and other vasoactive peptide–secreting gastrointestinal tumors
Nonorganic diseases such as panic attacks

Table 19-9 Most Common Causes of Anaphylaxis

Foods	Shellfish Peanuts Tree nuts Fish
Drugs	Antibiotics (especially β -lactams) NSAIDs
Physical	Exercise Cold Heat Sunlight Idiopathic

NSAID, nonsteroidal antiinflammatory drug.

TREATMENT

Special equipment is necessary to deal with anaphylactic events that occur in the office (Table 19-11). An algorithm for the management of the acute episode is shown in Figure 19-5.

On suspicion that an anaphylactic event has occurred, therapy should be initiated immediately (Table 19-12). The airway, circulation, and level of consciousness should immediately be assessed. Oxygen should be started and the patient placed in the recumbent position with the feet elevated. The recumbent position is important because death has been associated with the upright position. The upright position allows decreased venous return to the heart, resulting in pulseless ventricular contractions and arrhythmias.

Simultaneous with assessment, epinephrine should be administered (Working Group of the Resuscitation Council, 2008). IM injection in the lateral thigh gives a more rapid peak level than subcutaneous or deltoid IM injection; therefore, the lateral thigh is the preferred site of injection. For adults, the dose is 0.2 to 0.5 mL of a 1 : 1000 aqueous epinephrine preparation. For children, the dose is 0.01 mg/kg to a maximum of 0.3 mg. A more precise dosage regimen has been recommended by the Resuscitation Council of the United Kingdom (Table 19-13). If symptoms do not improve, this dose can be readministered at 5-minute intervals (or more frequently if the physician deems necessary). After several injections, if there is no response, an intravenous (IV) infusion of epinephrine may be considered. An infusion

Table 19-10 Tests Used to Confirm a Diagnosis of Anaphylaxis

Test	Comment
TESTS USED TO RULE IN ANAPHYLAXIS	
Serum tryptase	Peaks at 60-90 minutes after onset of symptoms. May be elevated up to 6 hours. Ideal time to obtain blood is 1-2 hours after symptoms begin.
Plasma histamine	Begins to rise 5 to 10 minutes after onset of symptoms but remains elevated only up to 60 minutes.
24-hour urinary N-methylhistamine	May be assayed in urine for up to 24 hours after initiation of histamine metabolite symptoms.
TESTS USED TO RULE OUT OTHER CONDITIONS	
Serum serotonin	Rules out carcinoid
Urinary 5-hydroxyindoleacetic acid	Rules out carcinoid
Serum vasointestinal hormonal polypeptide panel*	Rules out vasoactive polypeptide–secreting gastrointestinal tumor or medullary carcinoma of thyroid
Plasma-free metanephrine and urinary vanillylmandelic acid	Rules out paradoxical response to pheochromocytoma

*For example, pancreastatin, pancreatic hormone, vasointestinal polypeptide, and substance P.

Table 19-11 Equipment and Medication for Therapy of Anaphylaxis in the Office

PRIMARY

Epinephrine solution (aqueous) 1 : 1000 (1-mL ampules and multidose vials)
Epinephrine solution (aqueous) 1 : 10,000 (commercially available preloaded in a syringe)
Tourniquet
1-mL and 5-mL disposable syringes
Oxygen tank and mask or nasal prongs
Diphenhydramine injectable
Ranitidine or cimetidine injectable
Injectable corticosteroids
Ambu bag, oral airway, laryngoscope, endotracheal tube, no. 12 needle
IV setup with large-bore catheter
IV fluids: 2000 mL of crystalloid solution, 1000 mL of hydroxyethyl starch
Aerosol β -II bronchodilator and compressor nebulizer
Glucagon
Electrocardiogram
Normal saline: 10-mL vial for epinephrine dilution

SUPPORTING

Dopamine
Suction apparatus
Sodium bicarbonate
Aminophylline
Atropine
IV setup with needles, tape, and tubing
Nonlatex gloves

OPTIONAL

Defibrillator
Calcium gluconate
Neuroleptic agents for seizures
Lidocaine

IV, Intravenous.

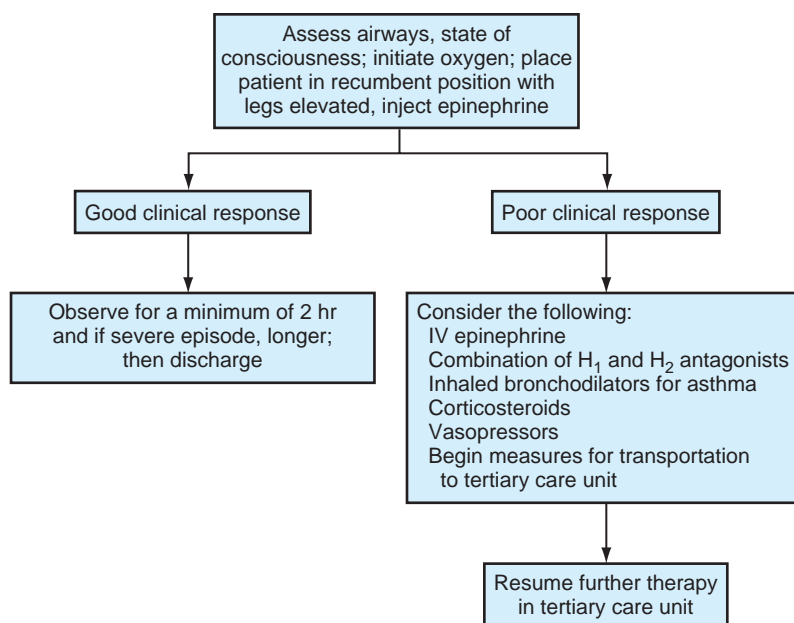

Figure 19-5 Algorithm for managing an episode of anaphylaxis. *IV*, Intravenous.

Table 19-12 Therapy for Anaphylaxis

Immediate Action	Treatment
Assessment	Epinephrine
Check airway and secure if needed	Supine position, legs elevated
Rapid assessment of level of consciousness	Oxygen
Vital signs	Tourniquet proximal to injection site
DEPENDENT ON EVALUATION	HOSPITAL MANAGEMENT
Start peripheral IV fluids	MAST
H ₁ and H ₂ antagonist	Continued therapy with above agents and management of complications
Vasopressors	
Corticosteroids	
Aminophylline	
Glucagon	
Atropine	
Electrocardiographic monitoring	
Transfer to hospital	

IV, Intravenous; *MAST*, medical antishock trousers.

can be prepared by adding 1 mg (1 mL of 1:1000 dilution of epinephrine) to 250 mL of D5W, yielding a concentration of 4.0 µg/mL. This solution is infused at a rate of 1 to 4 µg/min (15-60 drops/min with microdrop apparatus), increasing to a maximum of 10.0 µg/min for adults and adolescents. For children, the dose is 0.01 mg/kg (0.1 mL/kg of 1:10,000 solution up to 10 µg/min); the maximum recommended dose is 0.3 mg.

Epinephrine is mandated and is the drug of choice for anaphylaxis. Other drugs include H₁ and H₂ antagonists; a combination of both is more effective than an H₁ antagonist alone for vascular manifestations. Antihistamines, however, should only be considered as part of treatment after epinephrine has been administered. Diphenhydramine, 25 to 50 mg for adults and 1 mg/kg for children, can be given by slow IV infusion. Ranitidine can be administered in a dose of 1 mg/kg in adults and 12.5 to 50 mg in children, infused over 10 to 15 minutes. No controlled studies have demonstrated efficacy of corticosteroids, but they should help in prolonged reactions. Although there is no established dose,

Table 19-13 Dosing Recommendations for Intramuscular Epinephrine in Anaphylaxis*

ADULTS

0.5 mg (0.5 mL of 1:1000 concentration)

CHILDREN

Age > 12 yr: 0.5 mg (0.5 mL of 1:1000 concentration)

or

0.3 mg (0.3 mL of 1:1000 concentration) if child is small or prepubertal

6-12 yr: 0.3 mg (0.3 mL using a 1:1000 concentration)[†]

6 mo to 6 yr: 0.15 mg (0.15 mL of 1:1000 concentration)

Age < 6 mo: 0.15 mg (0.15 mL of 1:1000 concentration)

*Dosing in pediatrics depends on weight of child, not age. In the office/hospital setting, 0.5 mg of 1:1000 concentration is recommended dose in adults. Current autoinjector devices for patient use come in 2 doses: 0.15 mg is the lower dose and 0.3 mg is the higher dose.

[†]If the child is small, use the 0.01 mg/kg dose.

the suggested dose equivalent is 1 to 2 mg/kg of methylprednisolone every 6 hours.

For persistent hypotension, fluids or other vasopressors (or both) should be administered. For adults with persistent hypotension, 1 to 2 L of normal saline can be administered at rates of 5 to 10 mg/kg in the first 5 minutes. After resolution of symptoms, patients should be observed because biphasic reactions can occur in up to 23% of cases (Scranton et al., 2009). The observation period should range from 6 to 24 hours, depending on the severity of the reaction (Tole and Lieberman, 2007).

Patients who have experienced episodes of anaphylaxis and who are at further risk of future events (e.g., insect sting hypersensitivity, food allergy) should have a prescription for an epinephrine autoinjector and should be instructed in its use. Medical alert bracelets can benefit these patients. In addition, such patients should not take, if at all possible, drugs that might increase the severity of any future event or interfere with the use of epinephrine to treat such an event (eTable 19-3 online).

eTable 19-3 Drugs That Can Worsen or Complicate Therapy in Anaphylaxis

Drug Class	Effect
β -Blockers	Can worsen hypotension or wheeze and simultaneously decrease the β -adrenergic response to epinephrine as well as accentuate its α -adrenergic response.
ACE inhibitors	ACE metabolizes kinins that are activated during anaphylactic events; therefore, an ACE inhibitor can worsen episodes.
ACE blockers	Although there is no clear-cut admonition regarding ACE blockers, theoretically they can have an effect similar to an ACE inhibitor.
MAO inhibitors	Interfere with catabolism of epinephrine and thus complicate calculation of correct dose of these drug inhibitors.
TCA	Prevent catecholamine reuptake and therefore can accentuate effect of a dose of epinephrine, thus complicating calculation of a proper dose.

ACE, Angiotensin-converting enzyme; MAO, monoamine oxidase; TCA, tricyclic antidepressant.

KEY TREATMENT

- Epinephrine should be the first medication used in the treatment of anaphylaxis (SOR: A).
- Patients should be placed in supine position and oxygen administered, if needed (SOR: A).
- Treatment with IV fluids, antihistamines (both H₁ and H₂), and corticosteroids should be considered only after epinephrine administration (SOR: A).
- Glucagon or atropine should be considered in anaphylaxis recalcitrant to treatment (SOR: A).

Key Points

- The United States ranks 31th in infant mortality.
- The causes of infant mortality are preterm birth, birth defects, sudden infant death syndrome, respiratory distress syndrome, and maternal pregnancy complications.

The American Academy of Family Physicians (AAFP) describes the specialty of family practice as the enhanced expression of general medical practice that is uniquely defined within the context of the family. Providing care across the continuum of the family life cycle, the family physician provides care to the pregnant woman as part of the full expression of the field. The family physician incorporates a comprehensive approach to maternity care that includes the assessment and management of psychosocial and biomedical risk factors. The family physician provides care to patients with low-risk pregnancies and equips them to birth their children without unnecessary interventions.

The family physician brings a unique approach to the management of the pregnant woman, who is often a healthy individual undergoing a natural process. This approach is patient centered, prevention oriented, educational, and noninterventional. Nationwide, approximately 29.6% of all family physicians provide routine obstetric services as part of their hospital care (AAFP, 2011). This number has been steadily declining, with regional variations reflecting the needs of the population and local attitudes (AAFP, 1998). The majority of family physicians do not desire to practice obstetrics because of lifestyle issues, increasing costs of malpractice insurance, and difficulty obtaining hospital privileges. However, the family physician may be asked to counsel or care for the pregnant woman even if not part of daily practice. It becomes incumbent on the individual practitioner to have a fundamental

knowledge and appreciation of the field of obstetrics, including the obstetric emergency. Given that the family physician may be the sole provider of obstetric services, particularly in rural or underserved areas, the need to maintain the knowledge and skills to treat the problems and emergencies unique to obstetrics becomes increasingly important. The Advanced Life Support in Obstetrics (ALSO) course developed in 1990 effectively incorporates the techniques of other established life support courses as it applies to obstetric care.

For the successful practice of obstetrics, it is imperative for the family physician to practice in concert with an obstetric specialist. A collaborative relationship among obstetricians; family physicians; and in some cases, nurse midwives is essential for provision of consistent, high-quality care to pregnant women. Access to reliable consultation and suitable referral facilities for complicated patients will optimize patient care and outcomes.

The integration of prenatal care into the clinical practice of the family physician not only reflects the full scope of the field but also provides a continuous infusion of pediatric patients into the practice. It serves as a model for the training of medical students and residents interested in the practice of obstetric care in the context of family practice.

This chapter provides an overview of the field of obstetrics, which includes prenatal, intrapartum, and postpartum care of the pregnant woman. An evidence-based approach to areas of controversy and empiric practice is used while addressing the unique needs of family physicians, emphasizing their contribution and role in the research and development of the obstetrics literature.

Woman and Child Health

The health of a nation is often reflected in the health of its mothers and newborns. The World Health Organization (WHO) often uses a nation's maternity and neonatal

morbidity and mortality statistics as a proxy for the health status of its population. It is an important summary reflecting social, political, health care delivery, and medical outcomes in a geographic area. The United States, despite its economic wealth and medical resources, consistently ranks poorly in such measures as maternal and infant mortality rates (IMRs).

The most recent data available (2008) in the United States record that 28,059 infants died before reaching their first birthdays, an IMR of 6.6 per 1000 live births. Despite a decline from an IMR 6.9 in 2005 and an historical low rate, the United States still ranks 31st, after such countries as Japan, the Scandinavian countries, and Canada, as ranked by the Organization for Economic Cooperation and Development (OECD), as shown in Table 20-1. This number reflects in part the continuing disparities in health access and delivery for U.S. citizens.

The causes of infant death are multiple, with birth defects being the leading cause, with a 2008 rate of 20.1% of the infant deaths in the first year of life. Preterm birth (birth at <37 completed weeks of gestation) or low birth weight (LBW) is the second leading cause of infant mortality in the United States. Preterm birth rates differ by race in the United States; the rates were highest for black infants (13.3) followed by Native Americans (8.4), whites (5.7), and Asians (4.8). This persistent disparity contributes to the relative high IMR in the United States compared with similarly developed countries. Other causes of infant mortality include sudden infant death syndrome, respiratory distress syndrome, and maternal pregnancy complications. The top 10 causes of infant mortality account for nearly 70% of the total (Figure 20-1). Despite gains in the overall IMR, the rates of preterm birth, birth defects, and LBW remain relatively constant. This indicates a need for further health initiatives to address the health needs of pregnant women and unborn fetuses.

Preconception Counseling

Key Points

- Preconception care is an integral part of prenatal care and permits health promotion and early identification of risk factors that can then be treated before pregnancy.
- Folic acid supplementation should be started before conception, if possible, or immediately on diagnosis of pregnancy.

Ideally, women should plan pregnancy and discuss this plan with their physicians. Often, however, this option is not considered. It becomes the task of the physician to anticipate the potential and discuss preparation for pregnancy just as for methods of birth control. Primary care physicians are in the best position to anticipate the need for this counseling, being most aware of ongoing medical problems and social concerns of the women in their care. Indeed, the practice of preconception care has been formally recommended since at least 1989 (*Caring for Our Future, 1989*). However, we believe that preconception care, in particular

U.S. 2008 data from Ariadi M, Minino MPH, Sherry L, et al. *National Vital Statics Reports: deaths: final data for 2008*. Hyattsville, MD: National Center for Health Statistics 59(10), December 7, 2011.

education, should begin at the time a woman reaches reproductive age, not only when she announces the desire to become pregnant.

The preconception period is an ideal time for education and counseling regarding cessation of cigarette, alcohol, or drug use. Often, the incentive of a healthier pregnancy is sufficient impetus for a change in behavior. Although many women are able to cease cigarette, alcohol, or drug use during pregnancy, the majority resume use after delivery or breastfeeding. This is an opportune time for the family physician to reinforce further health-conscious behavior. Tobacco is a known carcinogen that can harm developing

Figure 20-1 Six leading causes of U.S. infant deaths, 2008. (Data from Ariadi M, Minino MPH, Sherry L, et al. *National Vital Statistics Reports: Deaths: Final Data for 2008*. Hyattsville, MD: National Center for Health Statistics 59(10), December 7, 2011.)

fetuses. Women who quit smoking before pregnancy or in early pregnancy significantly reduce the risk of adverse outcomes, including preterm birth, LBW, and infant mortality. However, smoking cessation therapies also carry risks in pregnant women. Using nicotine replacement therapies during the early stages of pregnancy may increase the risk of birth defects, according to a study of 77,000 pregnant Danish women (Morales-Suárez-Varela et al., 2006).

Other pharmacologic aids have not been tested for safety and effectiveness in treating tobacco dependence in pregnant women. Therefore, pregnant smokers should be offered intensive person-to-person interventions that exceed minimal advice to quit, such as behavioral support and problem solving, counseling, and referral to support organizations (Fiore et al., 2008).

The preconception use of folic acid supplementation was formally recommended by the U.S. Centers for Disease Control and Prevention (CDC) in 1991 and later by others (American Academy of Pediatrics, Committee on Genetics, 1999). Evidence supports a reduction in neural tube defects by 50% when folic acid stores are replenished before pregnancy (Milunsky et al., 1989). It is now recommended that all reproductive-age women take 0.4 mg of folic acid daily (CDC, 1992). This is easily accomplished by prescribing prenatal vitamins before pregnancy as well as throughout gestation. Alternately, over-the-counter (OTC) vitamins can also be used because many now contain this higher amount of folic acid. For couples with one or more children with a neural tube defect or a family history, there should be a referral for specific counseling. From 2 to 4 mg of folic acid daily is recommended for these women at least 1 month before pregnancy and during the first 3 months of pregnancy.

Many genetic disorders are now amenable to prenatal diagnosis through direct analysis of the underlying mutations, analysis of their protein products, or abnormal metabolites. Genetic counseling should include a systematic assessment of the family history of both parents. This can be done through a targeted questionnaire or formal genetic counseling by a genetic counselor or geneticist (Table 20-2). The family physician should be aware of the ethnic makeup of the practice and be especially familiar with disorders in these groups (Table 20-3). When targeted screening reveals an area of potential concern, formal

Table 20-2 Genetic Screening and Teratology Counseling

1. Will you be 35 years old or older at the time of your baby's birth?
2. What medications—prescribed, herbal, or over the counter—have you taken since your last menstrual period?
3. How much alcohol, cigarettes, or street drugs have you used since your last menstrual period?
4. Have you had miscarriages or stillbirths? How many?
5. Do you have any metabolic disorders (e.g., diabetes or phenylketonuria)?
6. Have you been ill or had any infections since your last menstrual period?
7. What are the ethnic backgrounds of you and the baby's father? Are you related in any way?
8. Do you, the baby's father, or anyone in either of your families have:
 - a. Neural tube defects (meningomyelocele, spina bifida, or anencephaly)?
 - b. Congenital heart defects?
 - c. Down syndrome?
 - d. Tay-Sachs disease (Jewish, Cajun, or French Canadian)?
 - e. Sickle cell disease or trait (African American)?
 - f. Thalassemia (mean corpuscular volume <80 fL/red cell) (Italian, Mediterranean, Asian, or African American)?
 - g. Muscular dystrophy?
 - h. Cystic fibrosis?
 - i. Huntington's chorea?
 - j. Fragile X, mental retardation, or autism?
 - k. Other chromosomal or inherited disorders or birth defects?

genetic counseling should be obtained. With advances in discovery of the genetic basis for many diseases, the list of disorders amenable to prenatal diagnosis grows daily.

KEY TREATMENT

- Folic acid supplementation is 0.4 mg for women without risk factors and up to 4 mg for those with risk factors (USPTE, 2009) (SOR: A).

Nutrition

There are sufficient data to confirm that poor nutrition during the prenatal period is associated with adverse pregnancy outcomes, specifically *fetal growth restriction* (FGR)

Table 20-3 Genetic Screening and Teratology Counseling and Risk

Ethnic Group	Higher Risk	Carrier Frequency
White	Cystic fibrosis	1 in 25
African American	Sickle cell disease	1 in 12
	β -Thalassemia	
Southeast Asian	α -Thalassemia	1 in 20
Mediterranean (Italian, Greek)	β -Thalassemia	1 in 25
Ashkenazi Jewish	Tay-Sachs disease	1 in 30
	Gaucher disease type 1	1 in 12

and preterm delivery. Specific nutritional guidelines have been developed based on a woman's prepregnancy weight or, more specifically, her body mass index (BMI) (Table 20-4). Caloric intake of an extra 300 kcal/day is sufficient for adequate maternal weight gain and fetal growth.

The practice of prenatal supplementation of vitamins and minerals is widespread, although many nutritionists believe it is unnecessary. Only the following two supplements are recommended in an adequately nourished woman with a singleton pregnancy:

1. Iron, 30 mg/day, in the second and third trimester to meet the fetal demands for erythropoiesis
2. Folic acid, 400 μ g/day, in the preconception period and during the first trimester for prevention of birth defects

However, because many U.S. women do not consume adequate vitamins and minerals (Block and Adams, 1993) and specific assessment of nutritional intake is often difficult, supplements are now widely used. Recommended daily allowances for pregnant women have been established and continue to be reevaluated (Table 20-5). Care must be taken to avoid toxicity of the fat-soluble vitamins, in particular vitamin A (retinol), because more is not necessarily better. Daily doses of retinol greater than 10,000 IU, approximately 3000 retinol equivalents, have been associated with birth defects (American College of Obstetrics and Gynecologists, 2008; Rothman et al., 1995). Women who do not consume sufficient milk products may benefit from calcium supplementation. This can easily be accomplished by prescribing an antacid that is made of calcium

Table 20-5 Recommended Dietary Allowances for Women

carbonate, most easily taken in chewable form. This will not only replenish calcium stores but also treat reflux esophagitis, which often occurs in the latter half of pregnancy.

Recent data suggest that supplementation with omega-3 fatty acids, specifically docosahexaenoic acid (DHA) plus eicosapentaenoic acid (EPA), may be beneficial (Dunstan et al., 2008). Both DHA and EPA may be beneficial for fetal brain development and are found in large amounts in wild fish. However, increased fish intake in pregnancy is not recommended because of the risk of increased mercury ingestion. Therefore, supplementation is required. Large, well-controlled studies are needed before recommendation in pregnancy, but supplementation may be considered on an individual basis. The U.S. Food and Drug Administration has formally warned women of childbearing age, pregnant and lactating women, and young children to avoid eating swordfish, shark, king mackerel, and tilefish and to consume no more than one 6-oz can of albacore tuna per week. In all pregnant women, nutritional risk factors should be addressed, including low starting BMI, prior LBW infants, adolescence, religious and cultural dietary restrictions, medical illnesses requiring dietary manipulation, substance abuse, and eating disorders (Kolasa and Weismiller, 1995). Certain woman may benefit from formal dietary counseling from a dietician or nutritionist.

KEY TREATMENT

- Iron (30 mg/day) is recommended in the second and third trimesters (SOR: A).
- Folic acid (400 µg/day) is recommended in the preconception period and the first trimester (SOR: A).

Medical Risk Assessment

The preconception period is the ideal time to assess and counsel the prospective pregnant woman regarding medical disorders or risks she may encounter during the pregnancy. Of medical problems that have substantial impact on the fetus, hypertensive disorders and diabetes are among the most common.

Hypertension may have many effects on the pregnancy depending on the degree of abnormality. Fetal effects range from none to increased miscarriage, FGR, abruptio placentae, and fetal death. Underlying blood pressure (BP) disorders should be treated appropriately before pregnancy. Some hypertensive, reproductive-age women are treated with angiotensin-converting enzyme (ACE) inhibitors. This class of therapeutics can cause significant risk to the developing fetus. These medications should be stopped and alternate medications started if needed. Women with preexisting hypertension should be referred for concurrent care with a physician experienced in managing hypertension in pregnancy.

Diabetes can also have many effects on a developing fetus. The preconception control of the maternal metabolism, reflected as normal blood glucose values before and after meals and normal hemoglobin A_{1c}, has been shown to decrease the incidence of diabetes-associated embryopathy to almost that of a nondiabetic pregnant woman (Mills et al., 1988). Women with preexisting diabetes should be referred for specialized care if pregnancy is contemplated.

Less attention is directed to emotional and psychiatric disorders. Pregnancy may be a stressor that precipitates an acute event or worsens ongoing anxiety or depression. This is more likely in the postpartum period.

KEY TREATMENT

- Preconception care is an integral part of prenatal care and permits health promotion and early identification of risk factors that can then be treated before pregnancy, such as diabetes or hypertension (SOR: A).
- Women with preexisting diabetes should be referred for specialized care if pregnancy is contemplated (SOR: C).

Routine Prenatal Care

In most Western countries, women attend between 7 and 11 prenatal visits, although recent data suggest that a reduced number of antenatal visits could be introduced into clinical practice without adverse effect to the mother and child (Carroli et al., 2001). Obstetric care provided by obstetricians, family physicians, and midwives has been found to be equally effective; however, patients were slightly more

satisfied by the care provided by midwives and family physicians (Villar et al., 2004). Prenatal care services typically include screening and treatment for medical conditions and identification and interventions for behavioral risk factors associated with poor birth outcomes (e.g., smoking, poor nutrition).

One of the most important goals of prenatal care is recognizing which women have high-risk pregnancies and triaging these women to appropriate care (Kontopoulos and Vintzileos, 2004). It is important to identify the women at risk for adverse outcomes and refer them to appropriate specialty care. Adequate prenatal care has been shown to increase the chances that a woman has a healthy pregnancy and baby.

FIRST PRENATAL VISIT

The first prenatal visit is one of the most important, particularly if the woman has not had preconception care (Table 20-6). The first prenatal visit should occur shortly after the woman discovers she might be pregnant and should be viewed as a continuation of preconception counseling. Home pregnancy test kits have a sensitivity and specificity of at least 95%; many can detect pregnancy by the fifth menstrual week. The most important aspects of the first prenatal visit include education, risk assessment, appropriate laboratory testing, and establishment of gestational age.

Education is an important component of prenatal care, particularly for women who are pregnant for the first time. The frequency of prenatal visits should be explained, with information about the physiologic changes that occur during pregnancy. Preparation for the birthing process is a key theme around which to discuss care issues and choices such as breastfeeding. Structured educational programs to promote breastfeeding have unclear effectiveness. Pregnant women should be counseled about the risks of possible teratogens, including smoking, alcohol, drug use, and exposure to medications, prescriptions, OTC drugs, and herbal remedies. Good hand washing is always encouraged because this is one of the best ways to avoid community-acquired infectious diseases. Appropriate immunizations such as influenza and novel influenza A (H1N1) virus should be offered. Common exposures such as workplace conditions and use of hot tubs and saunas should be explored. Exercise should also be encouraged if there is no obstetric contraindication (ACOG, 1994) (Table 20-7). Intercourse during pregnancy should be actively addressed because some women are reluctant to discuss this topic even with their physicians. Sexual activity can generally continue during pregnancy except for few situations, such as placenta previa and preterm labor. Counseling regarding sexually transmitted diseases (STDs) and their avoidance should occur. Nutrition should be individualized, with an estimate of desirable weight gain given to the pregnant woman.

The estimated date of delivery (EDD) should be calculated by accurate determination of the last menstrual period (LMP). The first day of the LMP is a good clinical sign from which to calculate the EDD, remembering that it must be adjusted for cycles shorter or longer than 28 days. The EDD can be calculated by Nagele's rule, that is, subtracting 3 months and adding 7 days to the first day of the LMP. The

EDD should then be extended by the number of days longer than a 28-day cycle or shortened by the number of days shorter. This approach should be considered if there is uncertainty about the LMP.

The physical examination during the first prenatal visit should include careful assessment of uterine size. If there is a discrepancy between menstrual age and uterine size, ultrasonography should be considered early in the pregnancy to resolve the issue of dating. Recent evidence suggests that early ultrasonography provides more accurate dating, which is important for timing screening tests and interventions and for optimal management of complications such as postterm pregnancies (Neilson, 2004). Late ultrasonography, after 24 weeks, is not as sensitive for confirming gestational age. Additionally, any irregular bleeding or abdominal pain should prompt the practitioner to obtain ultrasonographic confirmation of viability of the pregnancy as well as its normal intrauterine location.

Table 20-7 Recommendations for Exercise in Pregnancy

1. Established exercise routines can be continued with mild to moderate intensity.
2. High-intensity or high-impact routines should be avoided or reduced.
3. The supine position should be avoided in the second and third trimesters.
4. Hyperthermia should be avoided.
5. Weight-bearing exercise should minimize strain because joints are more lax.
6. Routines should be designed to minimize the risk of maternal trauma (falling).
7. Adequate nutritional intake to compensate for pregnancy should be assured.
8. Resumption of prepregnancy routines in the postpartum period should be gradual.

A history and directed physical examination should be performed to detect conditions associated with increased maternal and perinatal morbidity and mortality. The first prenatal examination provides an opportunity for cervical cancer screening with a Papanicolaou (Pap) test in women who have not been screened recently. However, Pap tests performed in pregnant women may be less reliable. Risk factors should then identify other testing that might be done at this time, including blood glucose, sickle cell screening, Tay-Sachs screening, and surveillance for other infectious diseases.

Routine fetal heart auscultation; urinalysis; and assessment of maternal weight, BP, and fundal height generally are recommended, although the supportive evidence varies (Kirkham et al., 2005). Women should be offered ABO and Rh blood typing and screening for anemia during the first prenatal visit. Genetic counseling and testing should be offered to couples with a family history of genetic disorders, a previously affected fetus or child, or a history of recurrent miscarriage. All women should be offered prenatal serum marker screening for neural tube defects and aneuploidy. Women at increased risk for aneuploidy should be offered amniocentesis or chorionic villus sampling (CVS). Counseling about the limitations and risks of these tests, as well as their psychologic implications, is necessary. Folic acid supplementation beginning in the preconception period and early pregnancy reduces the incidence of neural tube defects. Laboratory testing during the first prenatal visit consists of assessment of hemoglobin and hematocrit to identify anemia, blood D(Rh) type, serologic tests for syphilis and rubella immunity, hepatitis B, and urinalysis. Testing for human immunodeficiency virus (HIV) infection should be offered and highly recommended because perinatal transmission can be decreased with appropriate medical intervention. During the pelvic examination, a Pap smear (if indicated) as well as cultures for *Neisseria gonorrhoeae* and *Chlamydia* should be taken.

FOLLOW-UP PRENATAL VISITS

According to the report of the Expert Panel on Prenatal Care (Rosen et al., 1991), low-risk primigravid women should have at least 10 prenatal visits; low-risk multiparous women should have at least eight visits. Again, however,

data suggest that antenatal visits could be reduced without adverse effect to the mother and child (Carroli et al., 2001). Women with psychosocial issues or pregnancy complications should be seen more frequently. In the first two trimesters, prenatal visits may be 5 to 6 weeks apart if no problems have been ascertained. The frequency of visits should increase after 30 weeks, with weekly visits after 37 weeks. Specific recommendations are noted in Table 20-8. Routine visits for low-risk women should be scheduled at times that recommended laboratory testing could be accomplished. Prenatal screening for chromosomal abnormalities is available in the first trimester between 10 weeks, 2 days and 13 weeks, 6 days. Structural defects of the fetus (in particular neural tube defects) and karyotypic abnormalities in the form of α -fetoprotein (AFP)-based tests (quad screen; see later discussion) can be obtained at 16 to 18 weeks. Screening for gestational diabetes (GDM) is

recommended at 26 to 28 weeks of gestation, as well as screening for anemia with a hemoglobin or hematocrit. Antibody screening, Rh₀(D) immune globulin (RhoGAM) prophylaxis for D-negative mothers, and repeat testing for infectious diseases for at-risk mothers are recommended at this time.

Group B streptococcus (GBS) is the leading cause of early-onset neonatal sepsis in the United States. At 35 to 37 weeks' gestation, rectocervical cultures for GBS should be obtained in all pregnant women. The CDC recently updated its guideline for the prevention of early-onset neonatal GBS disease (2010). If cultures are positive or the patient tests positive for GBS bacteremia, antibiotic prophylaxis during labor is indicated. For women without a penicillin allergy, penicillin (5 million units; then 2.5 million units intravenously [IV] every 4 hours) is administered during labor. Ampicillin (2 g IV initial dose; then 1 g IV every 4 hours until delivery) is an acceptable alternative. If there is a penicillin allergy, sensitivities to clindamycin and erythromycin should be obtained. If the GBS is sensitive to both antibiotics, clindamycin can be used. If the GBS is resistant to either clindamycin or erythromycin or if time does not permit testing, women with a serious penicillin allergy should receive vancomycin. Women with a minimal reaction from penicillin (e.g., rash) should receive a first-generation cephalosporin such as cefazolin IV during labor (American College of Obstetricians and Gynecologists [ACOG], 2002a; CDC, 2009; Schrag et al., 2002; Verani et al., 2010). A patient with a severe allergy is defined as one with a history of developing angioedema, anaphylaxis, urticaria, or respiratory distress after receiving penicillin or a cephalosporin. Women with GBS bacteremia or a prior child affected with GBS sepsis should be treated during labor without screening cultures. Intrapartum antibiotic prophylaxis is not indicated if an elective cesarean delivery is planned and there is no labor or rupture of membranes.

KEY TREATMENT

- Universal screening at 35 to 37 weeks of gestation and intrapartum treatment of colonized women are the most effective approaches in reducing GBS sepsis of the newborn (ACOG, 2011) (SOR: A).

The clinical components of routine prenatal visits are controversial. Most guidelines recommend routine assessment with fundal height and maternal weight and BP measurements, fetal heart auscultation, urine testing for protein and glucose, and questions about fetal movement. The assessment of uterine growth and size should be performed at every prenatal visit. Documentation of fetal heart tones is also recommended with each prenatal visit. Before 12 weeks' gestation, the size of the uterus is estimated by bimanual pelvic examination. The ability to assess the presence of fetal heart tones using Doppler ultrasonography before 12 weeks is variable. After 12 weeks and before 20 weeks, adequate uterine growth is assessed by location of the uterine fundus in the lower abdomen (Figure 20-2). Fetal heart tones should be reliably heard during this period. At 20 weeks of gestation, most women have a palpable fundus at the umbilicus. After 20 weeks, fundal height is measured using the distance from the top of the symphysis

Figure 20-2 Fundal growth at various weeks of gestation.

pubis to top of the fundus. The number of completed weeks of gestation should equal this measurement in centimeters (± 2 cm). This measurement should be performed as accurately as possible. The most common reasons for inconsistency between menstrual age and fundal height is an inaccurate menstrual-age assignment and inaccurate measurements caused by maternal obesity. Larger-than-expected fundal height may also be caused by multiple gestation, uterine fibroids, polyhydramnios, or a large-for-gestational-age (LGA) fetus. Smaller-than-expected fundal height should warrant an exploration for etiologies such as oligohydramnios, FGR, and fetal demise.

By 30 weeks' gestation, the fetus is large enough that it can be palpated through the maternal abdomen. The position of the fetus should be documented at this and subsequent visits. This is easily done in most women by Leopold's maneuvers (Figure 20-3). The first maneuver involves palpation of the uterine fundus to identify the fetal part that is there. The palpating hands then glide downward laterally to perform the second maneuver, location of the fetal back. In the third maneuver, the hands are cupped around the presenting part at the level of the symphysis pubis to determine the presenting part as well as its degree of descent into the pelvis. If the presenting part is cephalic, the fourth maneuver will determine its degree of flexion. The examiner now turns 180 degrees to face the mother's legs, and the cephalic prominence is palpated. Another aid in ascertaining the position of the fetal back is the location of the fetal heart tones by Doppler sonography or auscultation. These sounds are best heard through the fetal back; in the left lower uterus in left occiput anterior, transverse, and posterior positions of the fetal head; and in the right lower uterus in right occiput positions. The evidence supporting the previous practices is variable but continues as the standard of care (Kirkham et al., 2005).

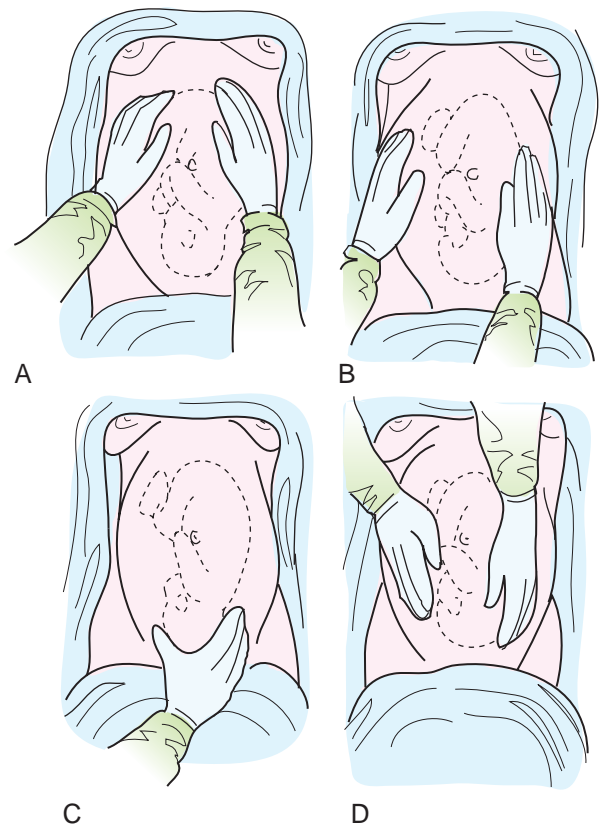

Figure 20-3 Leopold's maneuvers for determination of fetal position. **A**, First maneuver: palpation of the uterine fundus to identify the fetal part. **B**, Second maneuver: location of the fetal back. **C**, Third maneuver: cupped hands to determine the presenting part and station. **D**, Fourth maneuver: palpation of the cephalic prominence to determine the degree of flexion.

By the end of gestation, the practitioner as well as the woman should know the presentation of the fetus. This avoids emergent management when she presents in labor with a nonvertex presentation. Internal digital cervical examination can also verify presentation of the fetus and may be done when needed. Unless indicated, however, routine cervical examination to determine cervical readiness for labor need not be done until 41 weeks' gestation.

Prenatal Screening and Diagnostic Testing

Prenatal screening for fetal abnormalities should be offered to all pregnant women. If specific risk factors for fetal abnormalities are identified in the mother, appropriate counseling and specific diagnostic testing should be offered (CVS or amniocentesis). The most common reason to offer prenatal genetic diagnosis is advanced maternal age (maternal age at birth of 35 years or older); a somewhat linear increase in nondisjunction in meiosis increases the risk of a liveborn infant with aneuploidy (abnormal chromo-

†Not used for neural tube defect screening.

hCG, Human chorionic gonadotropin.

some number), most commonly Down syndrome, as well as an increased risk of first trimester miscarriage or fetal abnormalities.

Low-risk women can be offered screening for genetic abnormalities of the fetus by biochemical testing in the first or second trimester and ultrasound nuchal translucency screening (first trimester) and targeted ultrasound evaluation of fetal anatomy, best done at 18 to 20 weeks' gestation. Traditionally, biochemical testing was used for screening. Measurement of certain chemicals found in the mother's blood is predictive of fetal abnormality. The quadruple screen is a maternal blood test in which one maternal sample drawn at 15 to 20 weeks (but most sensitive at 16 to 18 weeks) is assayed for AFP, estriols, and β subunit of human chorionic gonadotropin (hCG). Normal ranges vary for each gestational week. Maternal serum α -fetoprotein (MSAFP) elevations can result from open neural tube defects such as spina bifida or anencephaly, when the protein leaks from the fetal tissue into the amniotic fluid through the amniochorion and into the maternal system. A lower-than-expected MSAFP suggests Down syndrome. The addition of β subunit of hCG and estriols has improved sensitivity for the detection of chromosomal abnormalities (Table 20-9). This test should be offered to all pregnant women with appropriate counseling regarding sensitivity and specificity. Women with abnormal test results should be referred for targeted ultrasonography and possible amniocentesis.

First trimester ultrasound and biochemical screening are now available for clinical use in all women. Specifically, the "first trimester screen" is performed between 10 weeks, 2 days and 13 weeks, 6 days of gestation. Testing involves an ultrasound measurement of the nuchal translucency (lymphatic fluid at fetal neck) (Figure 20-4) and laboratory measurement of pregnancy-associated plasma protein A (PAPP-A) and β subunit of hCG. The first trimester screen has about 85% sensitivity for Down syndrome detection at a 4% false-positive rate. Several tests are also available that combine a first trimester screen with a second trimester screen for even higher sensitivity. Physicians should become familiar with the sensitivity, specificity, and availability of the test most suitable for their practices.

Figure 20-4 Transabdominal ultrasound assessment of nuchal translucency (NT). The measurement in this figure is normal. An increased measure (>3 mm) is associated with an increased risk of chromosomal abnormalities, complex congenital heart disease, and other genetic syndromes.

Newly developed cell-free fetal DNA (cffDNA) in maternal blood screening tests have improved the sensitivity of aneuploidy screening while having a very low false-positive rate (Chiu et al., 2011). For example, these tests detect Down syndrome with 99% sensitivity and trisomy 18 with 98% sensitivity. The basis of these tests, which can be performed any time after 10 weeks of gestation, is determination of the relative quantity of cffDNA fragments in the maternal blood, which are thought to be derived from placental cell apoptosis. The relative quantities of cell-free fragments from each chromosome can predict a trisomy or monosomy for a particular chromosome. Cell-free fetal DNA based screening is recommended for women with advanced maternal age, a history of aneuploidy, an abnormal finding on fetal ultrasonography, or an abnormal serum biochemical based screening test result. This testing modality is currently being studied for use in low-risk women and is expected to replace biochemical-based screening in the future.

Any abnormality in cffDNA in maternal blood testing should be confirmed by CVS or amniocentesis.

EVIDENCE-BASED SUMMARY

- First trimester screening between 10 weeks, 2 days and 13 weeks, 6 days of gestation using both nuchal translucency measurement and biochemical markers is an effective screening test for Down syndrome in the general population (SOR: A).
- Women found to have increased risk of aneuploidy with first trimester screening should be offered genetic counseling and the option of CVS or second trimester amniocentesis (SOR: A).
- Cell-free fetal DNA screening in maternal blood is a newly developed screening test with high sensitivity and low false positive rate which is currently available for high risk women. Any abnormality should be confirmed with more definitive testing, CVS, or amniocentesis (SOR: A) (Wilson et al., 2013).

Prenatal Diagnostic Tests

AMNIOCENTESIS

Genetic amniocentesis is typically performed at 15 to 20 weeks of gestation but can also be done any time after 20 menstrual weeks. After ultrasound examination of the fetus and placenta, an area of skin overlying a pocket of amniotic fluid is cleaned with iodine solution. With ultrasound guidance throughout the procedure, a 22-gauge spinal needle is used to remove 20 mL of amniotic fluid. Special care is taken to avoid the fetus, the umbilical cord, and the large placental vessels. In experienced hands, the pregnancy loss rate attributed to the procedure is about one in 300. The entire testing time for a chromosomal analysis is about 10 to 12 days. Alternately, the supernatant may be assayed for metabolites to diagnose other disorders that run in the family if identified on counseling. Earlier amniocentesis (at 11 to 13 weeks) has been successfully performed but is not recommended any longer because of the recent initial reports regarding a slightly higher rate of clubfoot in these newborns.

CHORIONIC VILLUS SAMPLING

In CVS, another technique for obtaining fetal tissue for genetic evaluation, the chorionic villi, or placental cells, are aspirated. With ultrasound guidance, CVS can be performed at 10 to 13 menstrual weeks transabdominally with a spinal needle or transvaginally with a catheter designed and approved for this purpose. Chromosomal analysis of the villous cells can be completed in 7 days. Thus, the advantage to CVS is the early gestational time of the procedure and availability of the results. The procedure-related fetal loss rate is approximately one in 125 tests (Jackson et al., 1992).

EVIDENCE-BASED SUMMARY

- Early amniocentesis performed before 14 completed weeks of gestation is not considered a safe alternative to second trimester amniocentesis or CVS (SOR: A).

- CVS should *not* be performed before 10 completed weeks of gestation (SOR: B).
- CVS should always be performed under direct ultrasound control (SOR: B).
- Third trimester amniocentesis does not appear to be associated with significant risk of complications leading to emergency delivery (SOR: B).

Drug and Chemical Exposures in Pregnancy

Pregnant women frequently ask about the effect of drug and other chemical exposures on the unborn infant, whether environmental, OTC, or prescription. Many of these are everyday exposures at the workplace, in the community, or as a result of medical treatment and management. The consequences can range from the most innocuous to actually jeopardizing the pregnancy. The physician should be prepared to answer these pregnancy-related questions and advise their patients appropriately.

The consequences of a chemical exposure may be related to the nature of the agent and the timing, dose, and duration of the exposure. The effect can range from minor morphologic abnormalities and growth deficiency to severe malformation and loss of the pregnancy. Thalidomide has obvious effects on the fetus, causing one third of fetuses to have limb reduction defects. Furthermore, the effect of a drug may be subtle or delayed (Welch et al., 1993). Diethylstilbestrol (DES) is associated with the development of uterine structural abnormalities and clear cell carcinoma of the vagina in daughters whose mothers took this medication.

Much of the knowledge about chemical exposures and effects on reproduction and fetal development comes from research on experimental animals. This poses great uncertainty given genetic variability and species-specific responses. Given these limitations, the health care provider must carefully weigh the evidence before using a drug. To help practitioners classify a drug for use, the U.S. FDA developed a risk factors index. The abbreviated definitions of these categories are as follows:

- **Category A:** Controlled studies in women fail to demonstrate a risk to the fetus.
- **Category B:** Animal reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women, or animal reproduction studies have shown adverse effect that was not confirmed in controlled human studies.
- **Category C:** Studies in animals have revealed adverse effects on the fetus, and there are no controlled studies in women. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
- **Category D:** There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable.
- **Category X:** Studies in animals or humans have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience. The drug is contraindicated in women who are or who may become pregnant.

Table 20-10 Drugs and Exposures in Pregnancy

Agent	Recommendation	Comments
Antihistamines	Acceptable	Most are category B
Decongestants	Acceptable	Pseudoephedrine preferred
Cough medication with guaifenesin	Acceptable	—
Acetaminophen	Acceptable	Preferred analgesic and antipyretic
Aspirin	Avoid	Increases risk of bleeding; no benefit in preeclampsia; may be prescribed in low doses for specific conditions
NSAIDs	Avoid	Premature closure of ductus arteriosus
Cephalosporins	Acceptable	—
Sulfonamides	Avoid in third trimester	Kernicterus in newborn
Tetracyclines	Avoid	Discoloration of teeth
ACE inhibitors	Avoid	Stillborn, renal abnormalities, renal failure in newborn
Immunizations	Avoid live, attenuated viruses	Measles, mumps, rubella
Allergy shots	Acceptable	Alteration in maintenance dose may be necessary

ACE, Angiotensin-converting enzyme; NSAID, nonsteroidal antiinflammatory drug.

Modified from Hueston WJ, Eolers GM, King DE, McGlaughlin VG. Common questions patients ask during pregnancy. *Am Fam Physician*. 1995;51:1465-1470.

This classification is an oversimplification, and the individual practitioner will need to weigh the available data in the management of the pregnant woman. Few absolutes are possible in the field of human teratology; however, current recommendations for common drug categories in pregnancy are summarized in [Table 20-10](#) ([Briggs et al., 1994](#)). It is important to emphasize that it is difficult to demonstrate an actual cause-and-effect relationship between a specific drug and an adverse pregnancy outcome. At no time, however, should a drug be considered safe because no data exist.

Infections in Pregnancy

Although a woman is subject to many of the same infections during pregnancy as when not pregnant, specific infectious diseases have implications on fetal development and complications of pregnancy, such as premature labor and premature rupture of membranes. Certain infections in pregnancy can be teratogenic to the fetus, particularly if infections occur in the first trimester. These agents have been given the acronym of TORCH for toxoplasmosis, other (e.g., syphilis), rubella, cytomegalovirus (CMV), and herpesvirus. Although not teratogenic, HIV may be transmitted to the fetus and may be lethal in the child.

TOXOPLASMOSIS

The causative agent of toxoplasmosis is *Toxoplasma gondii*, a parasite that usually infects rodents. Based on serologic studies, approximately one third of reproductive-age women have had toxoplasmosis. In the United States, maternal infection is thought to occur in about 0.5%. Congenital toxoplasmosis can only occur when active infection occurs during pregnancy. Recognizable damage to newborns is estimated to occur in about one in 10,000 births; the incidence of infected but asymptomatic newborns is unknown. Maternal infections that occur in the first trimester are more likely to cause abortion and significant fetal damage. Infections later in pregnancy tend to be asymptomatic at birth.

A pregnant woman can contract toxoplasmosis by eating raw meat containing the cysts of the organism or by fecal-oral transmission of the oocytes from an infected cat. Cats that are fed cooked or canned food are most often not infectious. Those that obtain rodents from the wild are more at risk. Pregnant women should avoid changing cat litter and handling cats, particularly cats allowed to roam outdoors. Maternal toxoplasmosis may be asymptomatic or may present as a mononucleosis-like syndrome. Congenital disease ranges from overwhelming, including seizures, microcephaly or hydrocephaly, chorioretinitis, hepatosplenomegaly, jaundice, microphthalmia, and cataracts, to less symptomatic, which usually involves chorioretinitis. Prenatal ultrasonography or postnatal brain scan can also show intracranial calcifications. The placenta should be examined pathologically for cysts of *T. gondii* ([Beazley and Egerman, 1998](#)).

The diagnosis of toxoplasmosis is serologic, looking for immunoglobulin G (IgG) and IgM by enzyme-linked immunosorbent assay (ELISA). Some assays have a high level of false-positive results. Laboratories well versed in performing these serologic tests should be used. Pyrimethamine and sulfadiazine can treat women who acquire the infection prenatally. Effectiveness of treatment protocols for prevention of congenital infection appears variable ([Wallon et al., 1999](#)). Screening of all pregnant women is not recommended at this time.

SYPHILIS

Syphilis is a treatable infection caused by *Treponema pallidum*, a motile spirochete. In pregnant women, infection is most often sexually transmitted. The infection is described in four stages: primary, secondary, latent, and tertiary or late. It is rare to see pregnant women with tertiary or late syphilis ([Sheffield and Wendel, 1999](#)).

Pregnancy has little effect on the course of syphilis, but syphilis has a substantial effect on pregnancy and the fetus. Stages with spirochetemia are the most deleterious for the fetus. This is most often seen in late primary syphilis and in secondary syphilis. An increase in miscarriage, hydrops fetalis, stillborn, and preterm delivery of an infected fetus can be seen. Penicillin is the only antibiotic currently recommended for syphilis treatment in pregnancy because of its safety, efficacy, and transplacental passage to treat the fetus ([CDC, 1999](#)). Penicillin-allergic women should undergo desensitization first. Whenever treatment

adequacy is questioned in pregnancy, repeat therapy should occur because congenital syphilis is a preventable disorder. All women with syphilis should be carefully evaluated for other STDs, in particular HIV, because the treatment and surveillance is different in co-infection and the possibility of neurosyphilis must be carefully evaluated.

RUBELLA

Congenital rubella was first recognized in 1941, when after a rubella epidemic, a large number of children born to infected mothers were noted to have cataracts. Immunization against the rubella virus in the United States, Canada, and many European countries has decreased maternal rubella and thus congenital rubella. In the United States, only a few cases of congenital rubella are reported per year. Attention is now directed at its eradication in developing countries (Banatvala, 1998).

Although maternal infection can be subclinical, it usually presents 14 to 21 days after exposure with a maculopapular rash that begins on the face and spreads to the neck, trunk, arms, and legs. It is associated with lymphadenopathy, malaise, arthralgias, and petechiae. There is no therapy other than supportive. Pregnant women found not to have immunity to rubella should be instructed to avoid individuals who have viral illnesses. Suspected infection should be documented by specific rubella IgG and IgM measurement or by viral culture of the mother.

Maternal rubella acquired in the first trimester of pregnancy has a high risk of conferring damage to the developing fetus, and documented cases should be counseled and pregnancy interruption offered. In congenital rubella syndrome, many abnormalities can be found, such as cataracts, chorioretinitis, microphthalmia, congenital heart disease, myocarditis, microcephaly, deafness, mental retardation, and bone lesions, as well as signs of systemic infection (pneumonitis, hepatosplenomegaly, hepatitis, thrombocytopenia) (Stamos and Rowley, 1994).

CYTOMEGALOVIRUS

Two percent of pregnant women develop primary CMV infection, obtained by direct contact or respiratory aerosol from an infected individual. They are most often asymptomatic or have mild generalized symptoms such as fatigue, malaise, fever, lymphadenopathy, and pharyngitis. Approximately 50% of fetuses whose mothers seroconvert during pregnancy will develop CMV infection, but only 10% to 15% of these fetuses will have damage from the infection. Hearing loss is the most common manifestation.

Fetal infection and damage are more likely in the first and second trimesters. Although hearing loss is the most common presentation, congenital CMV can also present with microcephaly or hydrocephalus, microphthalmia, mental retardation, and brain calcifications. Overwhelming fetal infection at birth, known as cytomegalic inclusion disease, is uncommon, is most often caused by maternal primary infection late in gestation, and is often fatal.

Recurrent CMV infection in pregnancy can also cause infection of the fetus but rarely fetal damage (Stagno, 1982). Thus, documented immunity to CMV with serologic studies performed before a pregnancy can be reassuring to

women at risk of exposure, such as child care providers or health care workers. General screening for CMV in pregnancy is not recommended at present. Suspected CMV infection should be documented by serology or cultures of the cervix, amniotic fluid, or maternal urine.

HERPESVIRUS

Herpes simplex virus type 2 (HSV-2) is the causative agent in most cases of genital herpes, with a few cases caused by HSV-1, which most often causes oropharyngeal herpes. Primary infection is most deleterious for both mother and fetus and can present as fever, malaise, inguinal lymphadenopathy, and urinary retention. At 2 to 10 days after exposure, vesicles containing numerous viral particles painfully erupt on the cervix, vagina, perineum, or rectum; ulcerate; and remain open for 1 to 3 weeks. Herpetic lesions in recurrent disease last a shorter period and are most often not associated with systemic symptoms.

Fetuses are most susceptible to herpesvirus infection and damage during viremia, which most often occurs in primary herpes. At that time, herpes-specific maternal IgG is not adequate for transplacental passage and protection of the fetus from serious disease. The fetus may also acquire a herpetic infection from delivery through an infected vaginal canal. If this occurs during a primary episode, the risk of congenital infection is about 50%; if during a recurrent infection, the risk is less than 8%. Congenital herpes may be localized to skin, eyes, and oral cavity and may involve the central nervous system (CNS). Congenital infection may be disseminated and is often fatal or entirely asymptomatic (Riley, 1998).

Various surveillance protocols have been attempted to decrease perinatal transmission at delivery. At present, at labor and delivery, a careful evaluation of the genital tract for ulcers is performed. If any active lesions are found, the baby is delivered by cesarean section (Roberts et al., 1995). Prenatal use of acyclovir is controversial, but it has been used with informed consent in pregnant women with systemic disease or frequent episodes of recurrent disease.

HUMAN IMMUNODEFICIENCY VIRUS

Human immunodeficiency virus is a retrovirus transmitted through infected secretions, most often sexually. The most serious consequence of HIV infection in pregnancy is transmission to the fetus, resulting in the birth of an HIV-congenitally infected newborn. Maternal HIV is not teratogenic or associated with increased fetal loss (except end-stage disease). The goal in pregnancy is identification of HIV disease and prevention of perinatal transmission. At-risk women include those with hemophilia, IV drug users, prostitutes, and female partners of infected men. Although most often seen in urban areas, HIV infection in women is rising throughout the United States.

Screening for HIV is recommended and should be offered to all pregnant women. At-risk women should be screened more than once during the pregnancy. Testing for IgG antibody with ELISA is the basis of screening for an HIV infection. Western blot or another, more specific test confirms all positive test results. If a pregnant woman is found to have HIV infection, specific counseling should be given, which is

often best done in a center familiar with treatment and management. Specific therapy should be instituted to prevent perinatal transmission.

Zidovudine administration in HIV-infected pregnant women from 14 to 34 weeks' gestation decreased perinatal HIV transmission from 25.5% to 8.3% (Connor et al., 1994). Presently, highly active retroviral therapy (HART) or combination anti-retroviral therapy, which includes zidovudine, is recommended for HIV-infected pregnant women. HIV-infected pregnant women should be referred for consultation to a center with experience in management of HIV in pregnancy. In the intrapartum period, women who have any detectable viral load should receive at least 4 hours of IV zidovudine before delivery, specifically 2 mg/kg body weight IV over 1 hour, then 1 mg/kg/hr until delivery. IV zidovudine is no longer required for HIV-infected women receiving combination antiretroviral regimens who have an HIV viral load of less than 400 copies/mL.

Zidovudine is given to newborns (2 mg/kg orally every 6 hours for 6 weeks). This therapeutic regimen is currently used in pregnancy. However, combination therapy, including reverse-transcriptase inhibitors, is recommended by some experts (Rose, 1998).

Pregnant women on zidovudine therapy must be followed for bone marrow suppression and liver toxicity on a monthly basis. Although long-term studies are not available, the drug appears safe for the fetus. The quantity of viral load (HIV-1 RNA) in the mother appears to be a significant risk factor to fetal infection (Mofenson et al., 1999). The mode of delivery is controversial, with many experts recommending cesarean section to those women with high viral load. During vaginal delivery, artificial rupture of membranes and placement of a scalp electrode onto the fetal head are contraindicated. Amniocentesis and breastfeeding are also contraindicated in HIV-infected women.

EVIDENCE-BASED SUMMARY

- Pregnant women should be offered screening for HIV infection early in pregnancy because appropriate antenatal interventions can reduce maternal-to-child transmission (SOR: A).
- Women diagnosed as HIV positive during pregnancy should be informed that interventions such as antiretroviral therapy, cesarean section, and avoidance of breastfeeding can reduce the risk of mother-to child HIV transmission (SOR: A).
- Amniocentesis and breastfeeding are contraindicated in HIV-infected pregnant patients (SOR: A).

INFLUENZA AND NOVEL INFLUENZA A (H1N1) VIRUS

The influenza virus poses a particular threat to the pregnant patient. The majority of pregnant women with novel influenza A (H1N1) or the regular seasonal influenza virus infection present with typical acute upper respiratory, influenza-like illness (e.g., cough, sore throat, rhinorrhea), and fever. Other symptoms can include body aches, headache, fatigue, vomiting, and diarrhea. Most pregnant women have an uncomplicated disease course. However,

pregnant women appear to be at higher risk for severe complications from influenza infection, and for some, illness might progress rapidly and be complicated by secondary bacterial infections, including pneumonia and evidence of fetal distress. Case reports of adverse pregnancy outcomes and maternal deaths have been associated with severe illness and death. Ideally, pregnant women who have suspected novel influenza A (H1N1) virus infection should be tested for influenza, although commercially available rapid-testing kits have limited sensitivity.

Treatment should not be delayed pending results of testing or withheld in the absence of testing. Antiviral treatment is most effective when started as early as possible after the onset of symptoms (i.e., within first 2 days). The highest priority is to treat pregnant women with influenza-like symptoms as soon as possible. The currently novel influenza A (H1N1) virus is sensitive to the neuraminidase inhibitor antiviral medications zanamivir (Relenza) and oseltamivir (Tamiflu). Pregnancy should not be considered a contraindication to oseltamivir or zanamivir use. Because pregnant women may be at higher risk, the benefits of treatment or chemoprophylaxis with oseltamivir or zanamivir outweigh the theoretic risks of antiviral use. The Advisory Committee on Immunization Practices recommends that H1N1 monovalent flu and the seasonal flu vaccine be given to all pregnant women at any time during pregnancy. The ACOG and AAFP also recommend routine vaccination of all pregnant women. The nasal spray vaccine is not approved for use by pregnant women. Pregnant women should not receive nasal spray vaccine for either seasonal flu or H1N1 flu.

KEY TREATMENT

- Pregnant women with confirmed, probable, or suspected novel influenza A (H1N1) infection should receive antiviral therapy with oseltamivir (Tamiflu) (CDC, 2009) (SOR: C).

IMMUNIZATIONS IN PREGNANCY

Tetanus, Diphtheria, and Pertussis (Tdap) and Tetanus and Diphtheria (Td)

Health-care personnel should administer a dose of Tdap during each pregnancy irrespective of the patient's prior history of receiving Tdap (CDC, 2013). To maximize the maternal antibody response and passive antibody transfer to the infant, optimal timing for Tdap administration is between 27 and 36 weeks of gestation, although Tdap may be given at any time during pregnancy.

The risk to a developing fetus from vaccination of the mother during pregnancy is theoretical. Immunizations that are not live, attenuated virus are not contraindicated in pregnancy. No evidence exists of risk to the fetus from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. Live vaccines administered to a pregnant woman pose a theoretical risk to the fetus; therefore, live, attenuated virus and live bacterial vaccines generally are contraindicated during pregnancy. The measles, mumps, and rubella (MMR) are the most common vaccines with live attenuated viruses and should be

Table 20-11 General Recommendation for Use of Vaccines in Pregnant Women

Vaccine	Recommendation	Comments
Hepatitis A	Recommended if otherwise indicated	Recommended if another high-risk condition or other indication is present.
Hepatitis B	Recommended if otherwise indicated	Available vaccines contain noninfectious HBsAg and should cause no risk of infection to the fetus.
Human papillomavirus	Not recommended	If a woman is found to be pregnant after initiating the vaccination series, the remainder of the three-dose series should be delayed until completion of pregnancy.
Influenza (inactivated)	Recommended	Routine influenza vaccination is recommended for all women who are or will be pregnant (in any trimester) during influenza season.
Influenza (LAIV)	Contraindicated	
MCV4 (MenACWY)	May be used if otherwise indicated	
MMR	Contraindicated	Women should be counseled to avoid becoming pregnant for 28 days after vaccination with measles or mumps vaccines or MMR or other rubella-containing vaccines.
PCV13	Inadequate data for recommendation	ACIP has not published pregnancy recommendations for PCV13 at this time.
Polio	May be used if needed	
PPSV23	Inadequate data for recommendation	
Rabies	May be used if otherwise indicated	
Td	Should be used if otherwise indicated	
Tdap	Recommended	Administer a dose of Tdap during each pregnancy irrespective of the patient's history of receiving Tdap.
Varicella	Contraindicated	Nonpregnant women who are vaccinated should avoid becoming pregnant for 1 month after each injection.
Zoster	Contraindicated	Women should avoid becoming pregnant for 4 weeks after zoster vaccination. If a pregnant woman is vaccinated or becomes pregnant within 1 month of vaccination, she should be counseled about potential effects on the fetus.

ACIP, Advisory Committee on Immunization Practices; MCV4, meningococcal conjugate vaccine; MMR, measles, mumps, and rubella; PCV13, pneumococcal conjugate vaccine; PPSV23, pneumococcal polysaccharide vaccine; Td, tetanus and diphtheria, and pertussis; Tdap, tetanus, diphtheria, and pertussis.

Adapted from Centers for Disease Control and Prevention. General Recommendation on immunization: recommendations of the Advisory Committee on Immunization Practices (ACIP). *MMWR*. 2011;60(2):26.

avoided during pregnancy, although assessment of risks to the fetus has not been documented as a significant risk. The benefits of vaccinating pregnant women usually outweigh the potential risks when the likelihood of disease exposure is high, when infection would pose a risk to the mother or fetus, and when the vaccine is unlikely to cause harm (CDC, 2011). A clear example of the benefits of vaccination is the new recommendations to administer a dose of Tdap during each pregnancy, irrespective of the patient's immunization history. Optimally administered between 27 weeks and 36 weeks, this is done to minimize the significant burden of pertussis disease in the vulnerable newborn (CDC, 2011). Please see Table 20-11 for a more complete list.

Medical Disorders in Pregnancy

Many medical disorders can be seen in pregnant women; few are incompatible with pregnancy. In the management and care of a pregnant woman with a medical illness, it is important to understand the normal physiology of pregnancy and the effect of the disorder on the pregnancy and vice versa. Common medical problems in pregnancy include anemia, asthma, hypertension, diabetes, and pyelonephritis. Women with moderate to severe preexisting medical illness should be referred for evaluation to a physician experienced in managing the disorder in pregnancy.

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) is the leading cause of maternal death in the United States. Pregnancy increases the risk of VTE four to fivefold over that of the nonpregnant state. The risk is further increased if there is a personal or family history of thrombosis or thrombophilia. The two manifestations of VTE are deep vein thrombosis (DVT) and pulmonary embolus (PE). Although most reports suggest that VTE can occur at any trimester in pregnancy, some studies suggest that VTE is more common during the first half of pregnancy. The sequelae of DVT and PE include complications such as pulmonary hypertension, post-thrombotic syndrome, and venous insufficiency. Studies in this area suggest that the anatomic distribution of DVT in pregnant women differs from that for nonpregnant patients. Left-sided DVT is more common in pregnancy, and furthermore, it appears that proximal DVT is restricted to the femoral or iliac veins, where they are more likely to embolize and are also more common (Chan, 2010). This can occur without involvement of the calf vasculature.

The symptoms of DVT are nonspecific as in the nonpregnant state and can include unilateral leg pain and swelling. The Homan sign (unilateral pain with dorsiflexion) is neither sensitive nor specific in the diagnosis of this disorder. PE disease more often presents in the postpartum period and after a cesarean section. The signs and symptoms of a PE are equally nonspecific and include shortness of breath,

chest pain, and even cardiopulmonary collapse. Both disorders require a high level of suspicion on the part of the clinician.

Diagnostic testing can be equally challenging in the pregnancy state. D-Dimer testing, which is routinely used in the clinic setting for risk stratification, progressively increases during pregnancy, and there are no universally accepted values for pregnancy. However, a low D-dimer with a low clinical suspicion has a high negative predictive value. The current initial test of choice in the evaluation of VTE is compression ultrasonography (CUS) of the lower extremity veins. However, if the CUS study is equivocal, if Doppler testing results are abnormal, or if suspicion of pelvic DVT is high, further evaluation with magnetic resonance imaging (MRI) is recommended. MRI has been shown to have 97% sensitivity and 95% specificity for pelvic DVT in nonpregnant patients. The spiral computed tomography pulmonary angiography (CT-PA) is the recommended study for the evaluation of PE in pregnancy, particularly in the presence of known pulmonary disease or abnormal chest radiography findings (Michiels, 2000). In a pregnant patient with no known pulmonary disease and normal chest radiograph findings, ventilation/perfusion (V/Q) scanning is an acceptable alternative if a spiral CT is not available.

Anticoagulation at a therapeutic dose is indicated when either DVT or PE is diagnosed. Anticoagulation options include low-molecular-weight heparins (LMWHs), unfractionated heparin (UFH), and warfarin. Warfarin is a known teratogen and its use should be restricted to the postpartum period. Warfarin is safe during breastfeeding. LMWHs have replaced UFH as the first-choice medications for VTE treatment and prophylaxis in pregnancy. Compared with UFH, LMWHs have lower rates of adverse effects, including heparin-induced thrombocytopenia, symptomatic osteoporosis, bleeding, and allergic reactions.

ANEMIA

Iron-deficiency anemia during pregnancy has been associated with an increased risk of LBW, preterm delivery, and perinatal death. Normal physiologic changes in intravascular volume cause a physiologic anemia of pregnancy. However, severe anemia with maternal hemoglobin (Hb) levels less than 6 g/dL has been associated with abnormal fetal oxygenation, resulting in nonreassuring fetal heart rate (FHR) pattern, reduced amniotic fluid volume, fetal cerebral vasodilatation, and fetal death. In normal singleton pregnancy, blood volume increases approximately 36%, plasma volume 47%, and red blood cell (RBC) mass 17%, causing a relative hemodilution throughout pregnancy, but most pronounced after 28 weeks' gestation. Thus, Hb, hematocrit (Hct), and RBC count will be lower than normal, but RBC indices, specifically the mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC), remain normal. Iron, iron-binding capacity, and ferritin remain unchanged. Hb less than 15 mg/dL and Hct less than 33% are generally considered nonphysiologic anemia in pregnancy.

The most common nonphysiologic anemia encountered in pregnancy is iron deficiency. *Iron-deficiency anemia* is suspected when the RBC indices are low and there are

microcytic, hypochromic RBCs on the peripheral blood smear. This anemia is confirmed by a low serum iron concentration, high total iron binding capacity, and low ferritin. Risk factors for iron-deficiency anemia in otherwise healthy women include poor nutrition, menstrual loss, and short interconceptual period. Reproductive-age women have low-normal to abnormal iron stores for this reason. Iron requirements in pregnancy put an increased demand on maternal iron stores because iron is actively transported across the placenta to the fetus regardless of maternal stores. Iron supplementation decreases the prevalence of maternal anemia at delivery, and without iron supplementation in pregnancy, many women will become iron deficient. The recommendation is 30 mg of elemental iron in the form of simple salts such as ferrous sulfate, gluconate, or fumarate. Iron-deficiency anemia should be treated with 60 to 120 mg of elemental iron in two or three divided doses daily, which can cause gastric irritation and constipation. More frequent administration has not been shown to improve absorption. Because iron demands in pregnancy are highest after 20 weeks' gestation, depending on the degree of anemia, full-dose iron therapy can be delayed until that time, when pregnancy-associated nausea and vomiting should have subsided. Dietary modifications or stool softeners may be required when pregnant women take large doses of iron.

The failure to respond to appropriate iron therapy should prompt further investigation and may suggest an incorrect diagnosis, coexisting disease, malabsorption (sometimes caused by enteric-coated tablets or concomitant antacids), patient noncompliance, or ongoing blood loss. Hypochromic, microcytic RBCs with an MCV of less than 80 femtoliters suggest thalassemia. Hemoglobin electrophoresis should also be performed when evaluating hypochromic, microcytic anemia. Iron-deficiency anemia and β -thalassemia can coexist. Megaloblastic anemia from folic acid deficiency is unlikely in the pregnant woman because many reproductive-age women take at least 400 μ g of folic acid daily. Any other anemia may occur in pregnancy. Its diagnosis and therapy should be prompt to ensure a healthy outcome for the fetus. Hereditary anemias have the additional implication of possible inheritance by the fetus that should be addressed with the pregnant woman.

EVIDENCE-BASED SUMMARY

- Iron supplementation decreases the prevalence of maternal anemia at delivery (SOR: A).
- Iron-deficiency anemia during pregnancy has been associated with an increased risk of LBW, preterm delivery, and perinatal mortality (SOR: B).
- Severe anemia with maternal hemoglobin levels less than 6 g/dL has been associated with abnormal fetal oxygenation; thus, maternal transfusion should be considered for fetal indications (SOR: B).

ASTHMA

Asthma is caused by reversible airway obstruction from bronchial smooth muscle contraction, excessive secretions, and edema in response to various stimuli, most often

Table 20-12 Pulmonary Function Changes in Pregnancy

Parameter	Nonpregnant Value	Pregnant Value
Tidal volume (V_T) (amount of air moved in one respiratory cycle)	450 mL	600 mL
Respiratory rate (breaths/min)	16-18	Same
Minute ventilation (volume of air moved/min)	7.2 L	9.6 L
Forced expiratory volume in 1 second (FEV ₁)	80%-85% of VC	Same
Peak expiratory flow rate (PEFR)	380-550 L/min	Same
Forced vital capacity (FVC) (largest amount of air that can be exhaled after maximum filling of lungs)	3.5 L	Same
Residual volume (RV) (amount of air left in lungs after maximum expiration)	1000 mL	800 mL

Modified from Cugell DW, Frank NR, Gaensler EA, Badger TL. Pulmonary function in pregnancy. I. Serial observations in normal women. *Am Rev Tuberc*, 1953;67:568.

Table 20-13 Normal Arterial Blood Gas Values in Pregnancy

	pH	Pco ₂ (mm Hg)	Po ₂ (mm Hg)
Normal	7.40	35-40	75-100
Pregnancy	7.45	27-32	90-108

infectious or allergic. Airway obstruction is most severe in expiration, making breathing difficult and fatiguing. Asthma is a chronic illness with acute exacerbations.

Approximately 4% of pregnant women will have asthma with severity varying from mild to life threatening. One third of pregnant patients with asthma will experience exacerbations of their disease (Stenius-Aarnaila et al., 1988). Women with severe asthma are more likely to have disease exacerbation while pregnant. Additionally, moderate to severe asthma can have a significant effect on pregnancy, including an increase in preterm labor, LBW, perinatal death, and preeclampsia.

In normal pregnancy, progesterone causes an increase in tidal volume and thus minute ventilation to make more oxygen available for the fetus (Table 20-12). These changes result in a mild respiratory alkalosis that should be taken into account when interpreting blood gas values (Table 20-13).

Evaluation and management of acute asthma should include objective assessment of maternal lung function and fetal well-being, avoidance or control of environmental precipitating factors, pharmacologic therapy, and patient education (Clark, 1993). The best respiratory parameter to measure for assessment of the degree of obstruction in asthmatic patients is forced expiratory volume in 1 second (FEV₁) (see Table 20-12). This requires formal pulmonary function testing, so it is not a practical tool for monitoring. However, this value can be estimated by measuring the peak expiratory flow rate (PEFR) using an inexpensive portable peak-flow meter. Women with moderate to severe asthma should monitor their PEFR several times daily while pregnant. Normal PEFR for pregnant as well as

Table 20-14 Classification of Hypertensive Disorders in Pregnancy

Chronic hypertension
Preeclampsia or eclampsia
Preeclampsia superimposed on chronic hypertension
Gestational hypertension
Transient hypertension of pregnancy if preeclampsia is not present at delivery and blood pressure returns to normal by 12 weeks postpartum
Chronic hypertension if the elevation persists

nonpregnant women is 380 to 550 L/min. PEFR can be used to diagnose an exacerbation early, as well as for evaluation of therapy.

Pharmacologic therapy in pregnant patients with asthma is similar to that in nonpregnant women. The main goal of therapy is to maintain adequate oxygenation for the mother and fetus. The arterial oxygen partial pressure (PaO₂) should be kept above 60 mm Hg and oxygen saturation (SO₂) at least 95%. In acute exacerbations during pregnancy, the clinician should have a lower threshold for hospital admission and intubation. Women in the late second trimester and the third trimester should also have fetal monitoring.

Ultrasonography to detect FGR of the fetus in patients with moderate to severe asthma is warranted. If FGR is diagnosed, antenatal testing should be performed. During labor and delivery, the F-series prostaglandins (PGs), in particular prostaglandin F₂α (Hemabate), should be avoided because they stimulate bronchial smooth muscle to constrict. Instead, PGE₂ (Prostin E₂), which causes bronchodilation, should be used.

CHRONIC HYPERTENSION

Historically, there have been many classifications of hypertension in pregnancy with no apparent consensus. In this chapter, we use the now-accepted classification as developed by the National Institutes of Health (Report of the National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy). Hypertension during pregnancy is categorized as (1) preeclampsia or eclampsia, (2) gestational hypertension, (3) chronic hypertension, or (4) preeclampsia superimposed on chronic hypertension (Table 20-14). These categories identify different disorders that at times overlap but with different epidemiologic characteristics, pathophysiology, and risks for the mother and baby. Pregnancy-induced hypertensive disorder is an older, less specific term no longer in general use.

Preexisting hypertension often complicates pregnancy. A diagnosis of chronic hypertension is made when hypertension precedes pregnancy or is diagnosed before 20 weeks of gestation. In normal pregnancy, arterial BP and peripheral vascular resistance (PVR) decrease shortly after implantation of the conception. Normal first trimester and early second trimester BP ranges from 92 to 114 mm Hg systolic, 46 to 66 mm Hg diastolic sitting, 103 to 123 mm Hg systolic, 47 to 67 mm Hg diastolic supine. At 28 to 30 weeks' gestation, BP in normal pregnant women increases to near prepregnancy range. It is generally accepted that BP greater

than 130/80 mm Hg at any time during pregnancy is abnormal.

Fetal effects of chronic or essential hypertension depend on severity of hypertension and range from none to FGR, fetal distress, abruptio placentae, prematurity, and fetal death (Haddad and Sibai, 1999). Women with preexisting hypertension have approximately a 20% chance of developing superimposed preeclampsia. The maternal and fetal morbidity and mortality rates are higher in chronic hypertension with superimposed preeclampsia than in each disorder alone.

Most women with chronic hypertension present at their first prenatal visit with the diagnosis. As many as one third of pregnant women with essential hypertension become normotensive in the first half of pregnancy. Often, their antihypertensive medications can be discontinued and only restarted when elevations recur, typically after 28 weeks. Controversy exists as to whether medical treatment of essential hypertension in pregnancy improves fetal outcome or decreases the risk of superimposed preeclampsia. However, maternal complications can occur when diastolic BP is persistently elevated. Thus, it is generally accepted that therapy to decrease maternal BP be instituted or modified to keep maternal diastolic BP lower than 100 to 105 mm Hg. A profound drop in maternal BP over a short period should be avoided to prevent decreased cardiac output to the placenta and fetus.

α -Methyldopa (Aldomet), a central-acting, α -adrenergic, false neurotransmitter, and labetalol, an α - and β -blocker, are the two most commonly used drugs for treatment of chronic hypertension in pregnancy. The initial starting dose for methyldopa is 250 mg every 8 hours. This dose can be increased to 2 g/day if needed. The initial starting dose of labetalol is 200 mg orally, twice a day, for a maximum 800 mg three times a day.

If adequate control cannot be obtained, a second drug, most often nifedipine or hydralazine, can be added. ACE inhibitors and diuretics for BP control are contraindicated in pregnancy (Witlin and Sibai, 1998).

Obstetric management includes baseline laboratory studies early in pregnancy that will later help in diagnosis of superimposed preeclampsia. Specifically, in addition to routine prenatal testing, this includes renal function studies, liver enzymes, platelets, uric acid, and 24-hour urine test for protein and creatinine clearance. If chronic hypertension is a new diagnosis, pheochromocytoma should be ruled out by catecholamine levels in serum or 24-hour urine (Keely, 1998). Early ultrasonography to confirm dating and intermittently to evaluate fetal growth will aid in the diagnosis of FGR. Women with moderate to severe hypertension benefit from more frequent prenatal visits as well as home BP monitoring. Antenatal testing should be performed at least for women with superimposed preeclampsia or FGR. Preterm delivery may occur.

KEY TREATMENT

- Monotherapy with α -methyldopa (Aldomet), a central-acting α -adrenergic, false neurotransmitter, or labetalol, an α - and β -blocking agent, is the treatment of choice of chronic hypertension in pregnancy (SOR: C).

GESTATIONAL DIABETES

Gestational diabetes, or diabetes diagnosed in pregnancy, affects 3% to 5% of pregnant women. Pregnancy is a state of increasing insulin resistance predominantly caused by placentally produced hormones, in particular human placental lactogen, which increases with placental mass and gestational age. Although most women can compensate, a small subset of pregnant women cannot. Early impairment of glucose metabolism may have no maternal signs or symptoms but can have fetal effects that include macrosomia, fetal distress, and fetal demise.

Screening for GDM by a glucose challenge is recommended at 26 to 28 weeks of gestation. There is little evidence supporting earlier screening. The USPSTF recommends screening for gestational diabetes mellitus (GDM) in asymptomatic pregnant women after 24 weeks of gestation (B recommendation). The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for GDM in asymptomatic pregnant women before 24 weeks of gestation (I statement). Discussions should include information about the uncertainty of benefits and harms as well as the frequency of positive screening test results. Women who are obese, older than 25 years of age, have a family history of type 2 diabetes or GDM, or are members of certain ethnic groups (i.e., Hispanics, Native Americans, Asians, and African Americans) are at increased risk for GDM.

The initial screening test is performed in a nonfasting state. The pregnant woman is asked to drink a mixture containing 50 g of glucose; 1 hour later, a plasma glucose level is performed. If the result is 140 mg/dL or greater, the more definitive 100-g 3-hour glucose challenge is performed. The pregnant woman should have at least 3 days of adequate carbohydrate intake, fast the night before the test, and receive 100 g of glucose. Venous blood glucose is determined fasting and at 1, 2, and 3 hours after the glucose challenge. Two abnormal values make the diagnosis of GDM (Table 20-15). Different studies have various thresholds for making the diagnosis, and clinicians should review their institutional norms (Carpenter and Coustan, 1982) (Table 20-16). Women at high risk for GDM, such as those with glucosuria, prior GDM, obesity, or a strong family history, should be screened earlier in pregnancy. If the test result is negative, testing should be repeated in the latter half of pregnancy. The evidence supporting this practice is variable.

Table 20-15 Screening for Gestational Diabetes*

Test	Abnormal Glucose Level (mg/dL)
50-g glucose, 1-hr challenge	≥ 140
100-g glucose, 3-hr challenge*	
Fasting	≥ 105
1 hour	≥ 190
2 hour	≥ 165
3 hour	≥ 145

†Carpenter MW, Coustan DR. Criteria for screening tests for gestational diabetes. *Am J Obstet Gynecol*. 1982;144:768-773.

Initial therapies of GDM are diet and, if not contraindicated in the pregnancy, exercise in the form of walking, as well as support from diabetes educators and nutritionists and increased surveillance in prenatal care. The daily recommendation is 30 to 35 kcal/kg lean body weight. If fasting blood sugar cannot be maintained below 105 and 2-hour postprandial blood sugars below 120 mg/dL, insulin therapy is begun. Hemoglobin A_{1c} can be performed every 4 to 6 weeks but will not be elevated unless there is fasting hyperglycemia. At least weekly, evaluation of blood sugar is recommended because insulin resistance increases with advancing gestation. Ultrasonography to assess fetal size should be performed every 4 to 6 weeks. Women requiring insulin should have antenatal testing in the third trimester. Good blood sugar control is also important to decrease the incidence of metabolic newborn complications such as hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia.

The family physician should remember that women who have had GDM have a 30% to 60% chance of developing type 2 diabetes mellitus in their lifetimes (O'Sullivan, 1979). Postpartum and yearly glucose tolerance testing is recommended in these women. Weight loss and exercise have been shown to decrease their risk.

EVIDENCE-BASED SUMMARY

- The USPSTF recommends screening for gestational diabetes mellitus (GDM) in asymptomatic pregnant women after 24 weeks of gestation (SOR: B).
- The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for GDM in asymptomatic pregnant women before 24 weeks of gestation (I statement).

PYELONEPHRITIS

Asymptomatic bacteriuria can be found in 3% to 5% of pregnant women and up to 10% of those with sickle cell trait. Asymptomatic bacteriuria is most often caused by *Escherichia coli*. Antibiotic therapy is similar to that in the nonpregnant state. Cephalosporins, ampicillin, and nitrofurantoin (Macrochantin) are frequently used medications that are safe in pregnancy. It appears best to treat asymptomatic bacteriuria in pregnancy for 5 to 7 days. If they are untreated, 30% of women with asymptomatic bacteriuria will progress to pyelonephritis. Hormonal and anatomic changes of pregnancy causing hydronephrosis and

hydronephrosis are responsible for the higher incidence of pyelonephritis in the pregnant woman. A urinary pathogen count of at least 100,000 colonies/mL is considered significant, although pyelonephritis also occurs at counts as low as 20,000 to 50,000 colonies/mL (Cunningham and Lucas, 1994). Periodic cultures for screening should be performed in women with sickle cell trait, recurrent urinary tract infection, recurrent asymptomatic bacteriuria, or urine dipstick suggesting bacterial growth (e.g., positive nitrite).

Pyelonephritis in pregnancy requires hospitalization because of frequently associated dehydration, nausea, vomiting, and premature labor, as well as the uncommon but serious risk of endotoxic shock and endotoxin damage of alveolocapillary membranes leading to pulmonary edema and a clinical picture of adult respiratory distress syndrome (Gurman et al., 1990). Pregnant women with pyelonephritis require hospitalization for aggressive hydration and parenteral antibiotics. Antibiotic treatment is similar to those of other adult regimens. IV antibiotic therapy with a cephalosporin or an extended-spectrum penicillin until symptoms improve and the fever has completely resolved is usually sufficient for initial therapy. Because 25% of patients with mild acute pyelonephritis who are pregnant have a recurrence, these patients should have monthly urine cultures or antimicrobial suppression with oral nitrofurantoin (Macrochantin), 100 mg/day, until 4 to 6 weeks postpartum. Fluoroquinolones should be avoided because of concerns about their teratogenic effects on the fetus. Oral antibiotics are then prescribed for 7 to 10 additional days. For seriously ill women, the addition of an aminoglycoside at the onset of therapy may be warranted until sensitivities of the offending organism are available. Renal function as well as peak and trough aminoglycoside levels should be followed.

Complications of Early Pregnancy

ECTOPIC PREGNANCY

An ectopic pregnancy occurs when the fertilized ovum implants on any tissue other than the endometrial lining of the uterus. Overall, 95% of all ectopic pregnancies are tubal, 1.5% abdominal, 0.5% ovarian, and 0.03% cervical (Breen, 1970). A *heterotopic pregnancy* is a coexisting intrauterine and extrauterine pregnancy. Historically, there is an increasing incidence reported in the literature to a current rate of about one in 4000 pregnancies. This increased rate is thought to be associated with the use of ovarian stimulation and with assisted reproductive technologies. Ectopic pregnancies are responsible for more than 10% of all maternal deaths in the United States (Koonin et al., 1997).

The rate of ectopic pregnancy in women with known history of pelvic inflammatory disease (PID) is six to 10 times higher than in women with no history of PID. PID usually results from invasion by either gonorrhea or Chlamydia from the cervix into the uterus and tubes. The infection in these tissues causes an intense inflammatory reaction. Bacteria, white blood cells, and other fluids fill the tubes as the body combats the infection. During the healing process, however, the delicate tubal mucosa is permanently scarred. The fimbriated end of the fallopian tube as well as the lumen may become partially or completely blocked with

scar tissue. If PID is treated very early and aggressively with IV antibiotics, the tubal damage might be minimized and fertility preserved. Other conditions associated with ectopic pregnancies include progesterin-bearing intrauterine devices (IUDs), previous tubal surgery, and tubal ligation.

Diagnosis

A common clinical presentation of a woman with an ectopic pregnancy is the classic triad of amenorrhea, abdominal pain, and irregular vaginal bleeding. All women with these symptoms should be evaluated for possible ectopic gestation.

Serum quantitative hCG is often used to help identify those women with ectopic pregnancies. An isolated hCG level is not of much use unless it is above the threshold where one should visualize an intrauterine pregnancy with ultrasound. This threshold may vary depending on type of hCG assay used and the sonographic technique (Peisner and Timor-Tritsch, 1990). Two hCG levels drawn 48 hours apart are more informative. The general rule is a doubling of values in 48 hours. However, one must be careful to give pregnancies with a slow hCG rise every chance possible because they may turn out to be normal. A plateauing of hCG is consistent with an ectopic gestation or abnormal intrauterine pregnancy; ultrasonography can be used to differentiate the two.

Serum progesterone levels are of some value in making the diagnosis of ectopic pregnancy (Stovall et al., 1989). A progesterone level less than 15 ng/mL is seen in 81% of ectopic, 93% of abnormal intrauterine, and 11% of normal intrauterine pregnancies. Fewer than 2% of ectopic pregnancies and fewer than about 4% of abnormal intrauterine pregnancies will have progesterone levels of 25 ng/mL or greater. Therefore, a single progesterone value less than 15 ng/mL is probably an abnormal pregnancy and should prompt further evaluation. A single value greater than 25 ng/mL probably indicates a normal pregnancy.

Ultrasound

Key Point

- Routine screening ultrasonography in low-risk pregnancies is not associated with a decrease in perinatal death, birth weight, or preterm birth (Bernard et al., 1993).

With high-resolution vaginal sonography, a normal singleton pregnancy can be seen by 5.5 to 6 weeks of pregnancy (1.5 to 2 weeks after the missed period). By this time, the quantitative hCG level has reached the *discriminatory zone*, or the level above which a gestational sac is always visualized. The discriminatory zone may vary from institution to institution because of differences in equipment and assays, but ranges from 800 to 1000 IU/L (Second International Standard) or 1000 to 2000 IU/L (First International Reference Preparation) (Nyberg et al., 1985; Peisner and Timor-Tritsch, 1990).

As many as 20% to 30% of ectopic gestations have no detectable sonographic abnormality (Figure 20-5, A). The typical ultrasound findings for ectopic pregnancy are a

unilateral mass, fluid in the cul de sac, and no evidence of intrauterine pregnancy (Figure 20-5, B and C). Conclusive diagnosis of an ectopic gestation by sonography can only be made if a fetus or fetal cardiac motion is seen outside the uterus. With vaginal ultrasonography, this only occurs in about 20% of ectopic pregnancies.

Management

Treatment for ectopic pregnancy can be medical or surgical. Methotrexate, a folate antagonist, is often used in the medical management of ectopic gestation. It inhibits the rapidly growing trophoblast cells of the early placenta. Several treatment protocols are accepted (Buster and Pisarska, 1999). Most side effects seen with low-dose methotrexate therapy are mild and transient. Resolution of the ectopic state has been reported in about 70% to 95% of cases treated, depending somewhat on selection criteria.

The surgical approaches for ectopic pregnancy include laparoscopy for both confirmation and treatment and occasionally, laparotomy. The procedure of choice is salpingostomy, reserving salpingectomy for women not wanting future fertility.

SPONTANEOUS ABORTION

First trimester miscarriage is a common event. All women with clinically recognized pregnancies have approximately a 15% chance of spontaneous pregnancy loss in the first 3 months of pregnancy (Evans and Beischer, 1970). The risk is lower for younger women and higher for older mothers. Because women can present with symptoms of spontaneous miscarriage even before they are aware of pregnancy, all family physicians should be well versed in its assessment and management.

There are many causes of spontaneous pregnancy loss in the first trimester; sporadic chromosomal aneuploidy accounts for about 60%. The remaining 40% have various etiologies, including chronic maternal illness (e.g., diabetes, connective tissue disorder), uterine structural malformations, certain infections, inadequate progesterone production, and possibly other less-well-understood causes such as immunologic “rejection” and environmental factors.

Diagnosis

First trimester miscarriage can be further defined according to the stage of pregnancy loss and associated symptoms.

Threatened abortion is diagnosed when the pregnant woman presents with vaginal bleeding, lower back discomfort, or midline pelvic cramping. On examination, the cervical os is closed, and the pregnancy is viable (by Doppler ultrasonography). About 25% of women will have some degree of bleeding in the first trimester, about half of whom will miscarry. The remaining women may have a slightly higher risk of perinatal complications, such as preterm labor and FGR. The risk of congenital malformations is not increased.

Inevitable abortion occurs when there is profuse bleeding requiring surgical intervention or overt rupture of membranes. Although the cervical os may be initially closed and tissue has not passed, the miscarriage is inevitable.

Incomplete abortion is diagnosed when products of conception have passed the level of the cervical os. The woman

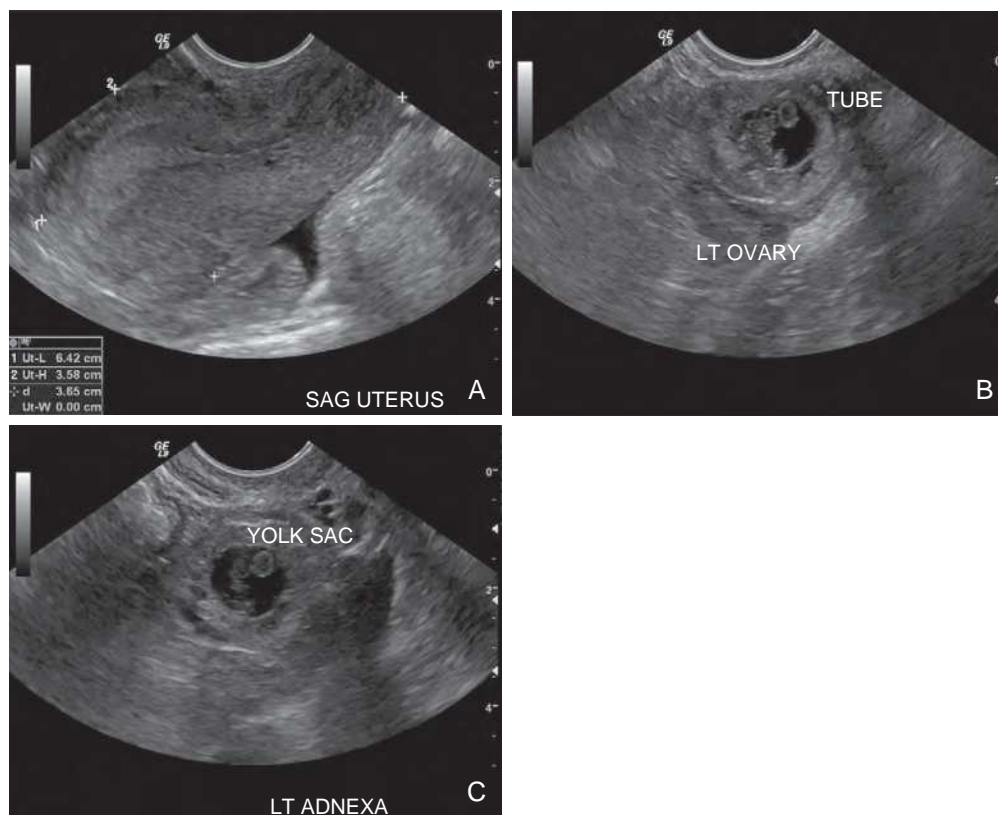

Figure 20-5 **A**, First trimester scan for ectopic pregnancy. The uterus is small and empty, suspicious for an ectopic pregnancy. This could also be a very early intrauterine pregnancy that is too early to be seen by transvaginal scan. However, further ultrasound assessment makes the diagnosis. **B**, Cross-section of the left fallopian tube shows an early pregnancy with a yolk sac (fetal heart motion was also seen). The left ovary is separate from the tube and pregnancy. **C**, Same tubal pregnancy with a normal-appearing yolk sac.

often has heavy vaginal bleeding, midline cramping, and an open cervical os.

Complete abortion occurs when all the gestational products have passed. This is ascertained by examination of the passed products of conception, pelvic ultrasonography to ascertain emptiness of the uterus, and at times retrospectively with falling quantitative hCG levels.

“Missed abortion” is a poor term still in use to describe retention of a nonviable pregnancy for longer than 4 weeks. Ultrasound scans of these women provide a more specific and usually earlier diagnosis, such as an empty sac or an embryonic gestation or fetal demise.

Septic abortion is diagnosed when there is infection of the uterus and products of conception. This occurs most often with incomplete abortions. Fever, uterine tenderness, foul discharge, and leukocytosis should aid the practitioner in making this diagnosis.

Recurrent spontaneous abortion is reserved for women who have had three or more first trimester losses. This diagnosis should prompt further evaluation for etiology.

Management

The goal of management of early miscarriage is assurance of complete emptying of the uterus in the least traumatic manner, avoidance of excessive blood loss, prevention of infection, and administration of adequate emotional support. Women with threatened abortions are reassured somewhat that the loss is neither imminent nor inevitable.

Bed rest is encouraged, but no evidence supports its value in prevention of miscarriage.

When there is profuse bleeding or sepsis, women with inevitable, incomplete, or septic abortions require prompt surgical treatment in the form of dilation and curettage (D&C), or in some, curettage alone. IV antibiotics should be used when appropriate. Rarely, blood transfusion is required. Certain women may benefit from oral antibiotics and methylergonovine (Methergine) on discharge.

When the diagnosis is missed abortion or incomplete abortion without hemorrhage or infection, the choice is surgical intervention versus natural spontaneous completion of the miscarriage. In well-selected women, no convincing evidence suggests one method is preferable. Many practitioners give these patients the option of D&C or spontaneous resolution. D&C has risks of anesthesia, cervical trauma, uterine scarring, and perforation; spontaneous resolution has risks of infection and hemorrhage. If products of conception for karyotype analysis are required for the evaluation of recurrent losses, the surgical approach is more successful in producing uncontaminated tissue for culture.

Women who are Rh(D) negative and at less than 13 weeks' gestation should receive 50 µg of D immune globulin intramuscularly (IM) when the abortion is diagnosed to prevent sensitization. If they are beyond 13 weeks' gestation, 300 µg is used. This treatment can be omitted if the father is known to be D negative as well. Iron therapy should

Figure 20-6 Hydatidiform mole (complete mole) at 12 weeks of gestation (transabdominal scan); the ultrasound shows a distended endometrial cavity containing numerous anechoic cysts of various sizes. No fetus is seen.

be given to women when heavy bleeding occurs or is anticipated.

MOLAR PREGNANCY

A molar pregnancy, or *hydatidiform mole*, is uncommon. A *gestational trophoblastic disease* (GTD), it occurs predominantly in older women. In the United States, molar pregnancy occurs in about one in 1800 pregnancies (Grimes, 1984). Molar pregnancy can be classified as complete or incomplete, which are two distinct entities etiologically and pathologically. A *complete* or hydatidiform mole has no fetal components, consists entirely of hydropic placental villi, is frequently associated with medical complications, and has a 15% to 20% risk of GTD (Jones, 1987) (Figure 20-6). In an *incomplete* mole, a fetus, usually abnormal, is often present. The placenta may be hydropic or small, and there is a 5% to 10% risk of GTD.

A hydatidiform mole is most often diagnosed in the first trimester because of symptoms of excessive nausea and vomiting, vaginal bleeding, uterine size larger than expected, and sonographic findings of no fetus but a large placenta with numerous small cysts. These findings should prompt quantitative hCG evaluation, which is often elevated. Evacuation of the uterus with careful attention to levels of hCG postevacuation is important to detect GTD, usually an invasive mole and occasionally choriocarcinoma. Pregnancy is avoided for 1 year after a complete mole.

An incomplete mole is most often diagnosed in the second trimester and occasionally the third trimester. There may be an abnormal placenta, fetal growth and structural abnormalities, or signs and symptoms of preeclampsia.

Complications of Late Pregnancy

PRETERM LABOR

Preterm labor is defined as uterine contractions occurring before 37 weeks of gestation that cause cervical change.

Table 20-17 Risk Factors for Preterm Labor

Low socioeconomic status
Uterine anomalies
African American ethnic group
Uterine leiomyoma
Poor nutritional state
Bacterial vaginosis
Low maternal weight (<50 kg)
Multiple gestation
Poor pregnancy weight gain
Bacteriuria or urinary tract infection
Prior preterm labor
Placenta previa or abruptio
Cocaine use
Polyhydramnios
Nicotine use
Poor prenatal care

Cervical change can be diagnosed if an initial examination reveals a cervix that is at least 2 cm dilated or 80% effaced or if interval cervical examinations document progression of effacement or dilation. Preterm contractions without cervical advancement can also occur; these do not require intervention. The distinction may be difficult, in particular at the onset of contractions.

Certain women are at higher risk of developing preterm labor (Table 20-17). These women should be assessed more frequently in the prenatal period and instructed on signs and symptoms of premature labor. Although many tests to identify women at risk of preterm labor have been proposed and evaluated, only ultrasonography for cervical length and fetal fibronectin have been shown to be effective (ACOG, 2001; Iams et al., 1996). A short cervix by transvaginal ultrasonography and positive cervicovaginal fetal fibronectin test is predictive of an increased risk of preterm delivery in the index pregnancy.

Assessment of patients thought to be in premature labor involves monitoring for premature contractions as well as FHR while they are in the right or left lateral recumbent position. Complete history and physical examination should be performed to find any treatable causes of premature labor as well as any contraindications to tocolytic therapy. Urinalysis and culture are obtained and antibiotic therapy instituted if the urinalysis is suspicious. If there is a possibility of rupture of membranes, a sterile speculum examination of the cervix should be performed and vaginal fluid for nitrazine and ferning obtained. Cultures for GBS, *Chlamydia*, and possibly herpesvirus and *N. gonorrhoeae* are often performed in this setting. If there is no historical or physical evidence of rupture of membranes, digital examination of the cervix with careful assessment of consistency as well as dilation and effacement is performed. Chorioamnionitis should be ruled out by assessing the degree of uterine tenderness, leukocytosis, maternal fever, and fetal well-being.

In a woman at 22 to 35 weeks' gestation, before digital examination, assessment of the presence of fetal fibronectin can be determined. *Fetal fibronectin* is released from the interface of the chorion and decidua in women likely to deliver preterm. Fetal fibronectin can be determined in 1 hour by most hospital laboratories and is used predominantly for its high negative predictive value. Thus, if the

fetal fibronectin result is negative, the woman will likely not deliver for at least 7 to 10 days; if positive, closer surveillance or treatment is warranted.

Management

Hydration appears to decrease the frequency of preterm contractions, but it does not decrease the rate of preterm birth. Intermittent digital cervical examinations should be performed either to confirm the diagnosis of preterm labor or to monitor progression. The frequency of these examinations has not been established and should be based on the clinical situation. However, a digital examination should always be performed at discharge to assess any cervical change.

If preterm delivery is a possibility, antibiotic prophylaxis for GBS should be administered (ACOG, 2002a). Betamethasone is also recommended, 12 mg IM every 24 hours for two doses, to accelerate fetal lung maturity in patients between 24 and 34 weeks of gestation (Liggins and Howie, 1972).

If a diagnosis of preterm labor is made and contractions do not subside with bed rest and hydration, pharmacologic therapy is considered. Contraindications to stopping labor include chorioamnionitis, abruptio placentae, heavy vaginal bleeding, severe or chronic hypertension, and fetal demise. Although many tocolytic drugs are available, terbutaline and magnesium sulfate are used often.

Historically, terbutaline has been administered subcutaneously in an effort to prolong pregnancy; however, the FDA is now warning the public that *injectable* terbutaline should not be used in pregnant women for prevention or prolonged treatment (beyond 48-72 hours) of preterm labor in either the hospital or outpatient setting because of the potential for serious maternal heart problems and death. Through β -1 receptors, β -agonists increase heart rate and thus stroke volume, increase fat breakdown, drive intravascular potassium into cells, and decrease gastrointestinal motility. Through β -2 receptors, bronchial and uterine smooth muscle relaxation and glycogenolysis occurs. Women taking β -adrenergic agonists experience tachycardia, jitteriness, and occasionally nausea and vomiting. A maternal heart rate of 120 beats/min or greater is a contraindication for further dosing, and the interval or quantity may need modification. Although it may be clinically deemed appropriate based on the health care professional's judgment to administer terbutaline by injection in urgent individual obstetrical situations in a hospital setting, the prolonged use of this drug is discouraged to prevent recurrent preterm labor. FHR elevations can also be seen. Oral or injectable terbutaline should not be used in the outpatient setting.

Intravenous magnesium sulfate therapy can also be used for preterm labor. There is no clear-cut greater efficacy of one tocolytic versus another. Magnesium sulfate relaxes uterine smooth muscle by competitive inhibition of the action of calcium. The dose should be adjusted so that contractions are decreased or abolished but maternal toxicity is not reached. This can be done by frequent examination of deep tendon reflexes, which should be present but depressed. Complete loss of deep tendon reflexes can herald further toxicity, and dosing should be decreased. Plasma magnesium levels can also be performed and should be

kept between 5 and 8 mg/dL. Because it is excreted predominantly by the kidneys, the plasma magnesium level is influenced by urine output as well as infusion rate. Calcium gluconate should be readily available in case of magnesium toxicity. Women receiving IV magnesium experience warmth, flushing, and poor muscle tone; some develop diplopia, nausea, and vomiting. The majority of these side effects occur with the loading dose. Magnesium sulfate therapy is typically used for 24 hours and then discontinued. Long-term tocolytic therapy has not been shown to be efficacious.

EVIDENCE-BASED SUMMARY

- There are no clear "first-line" tocolytic drugs to manage preterm labor; clinical circumstances and physician preferences should dictate treatment (SOR: A).
- Antibiotics do not appear to prolong gestation and should be reserved for GBS prophylaxis in patients in whom delivery is imminent (SOR: A).
- Neither maintenance treatment with tocolytic drugs nor repeated acute tocolysis improves perinatal outcome; neither should be undertaken as a general practice (SOR: A).
- Tocolytic drugs may prolong pregnancy for 2 to 7 days, which may allow for administration of steroids to improve fetal lung maturity and consideration of maternal transport to a tertiary care facility (SOR: A).
- Cervical ultrasound examination and fetal fibronectin testing have good negative predictive value; thus, either approach or both combined may be helpful in determining which patients do not need tocolysis (SOR: B).
- Amniocentesis may be used in women in preterm labor to assess fetal lung maturity and intraamniotic infection (SOR: B).
- Bed rest, hydration, and pelvic rest do not appear to improve the rate of preterm birth and should not be routinely recommended (SOR: B).

INTRAUTERINE GROWTH RESTRICTION

Fetuses with FGR are those that fall below the 10th percentile for weight for a given gestational age. FGR occurs when a fetus does not meet its growth potential (Vandenbosche and Kirchner, 1998). Some below-10th-percentile fetuses are not growth restricted but constitutionally small, have reached their growth potential, and are healthy. Often, it is difficult to differentiate the two states.

Although mild growth abnormalities are generally tolerated well by the fetus, more severe growth abnormalities can be associated with poor outcome, including fetal distress, fetal demise, and postnatal developmental abnormalities (Botero and Lifshitz, 1999). Growth-restricted fetuses should be identified so that appropriate management can be instituted to ensure the best outcome. Factors that influence fetal growth can be divided into the following three categories:

1. Maternal factors affecting nutrient availability to the fetus, such as poor nutrition and cigarette smoking (Chomitz et al., 1995)

2. Maternal factors influencing placental growth and function, such as maternal hypertension, diabetes with vascular involvement, and connective tissue disorders
3. Fetal factors interfering with adequate utilization of nutrients despite their availability, such as fetal infection or a genetic disorder

Growth restriction has also been described as asymmetric and symmetric. *Asymmetric* or “head-sparing” FGR occurs because of fetal autoregulation of blood flow. The initial response to a lack of adequate delivery of oxygen and nutrients to the fetus results in shunting of blood flow to important organs such as the brain and adrenal glands. Muscle and other viscera such as the kidneys are somewhat underperfused, resulting in a smaller body than head, smaller muscle mass, and oligohydramnios caused by underperfusion of the fetal kidneys and decreased fetal urine output. If inadequate delivery of oxygen and nutrients is early, persistent, or profound, all organs and tissues of the body will be affected, and *symmetric* FGR ensues. FGR from fetal infection or genetic disorder is often symmetric as well because all of the tissues of the body are often affected.

Diagnosis

The physician can suspect FGR based on lack of appropriate growth of the uterine fundus. Poor fundal growth with or without risk factors for FGR should prompt ultrasound evaluation. Women at risk for FGR should have early sonography to confirm their estimated day of delivery to aid in diagnosis. For example, a woman at 30 weeks' gestation has her first ultrasound examination for possible FGR. The fetus is found to be 27 weeks by all parameters measured. It would be difficult to decide if the fetus is symmetrically growth restricted or just due 3 weeks later. Overall, ultrasonography for diagnosis of FGR is 80% to 90% sensitive, depending on the measurements used. The abdominal circumference, a soft tissue measurement, is the first routinely measured parameter to fall behind normal growth in FGR. Estimation of fetal weight, calculated using the abdominal circumference, can be plotted on fetal growth curves to evaluate its percentile for a specific gestational age.

Management

The only treatment modality thought to be of benefit for FGR is bed rest in a lateral recumbent position. This position prevents vena caval compression by the gravid uterus and allows maximal venous return to the heart, maximizing cardiac output and uteroplacental perfusion. Certain fetuses with growth restriction caused by significant maternal illness may benefit from improvement of the maternal condition. Antenatal testing is recommended for FGR fetuses. If antenatal testing results are abnormal or persistent oligohydramnios is present, delivery may be warranted before term. Otherwise, these fetuses are delivered at 38 to 40 weeks of gestation, depending on the degree of growth restriction.

PREECLAMPSIA

Preeclampsia is one of the most common causes of perinatal morbidity and mortality. The etiology for preeclampsia remains unknown. However, placental dysfunction may

initiate systemic vasospasm, ischemia, and thrombosis that eventually damage maternal organs and cause placental infarction, FGR, and death. Preeclampsia complicates 5% to 10% of all pregnancies. It occurs at both extremes of reproductive age but is greatest in women younger than 20 years of age. Risk factors for preeclampsia include extremes of maternal age, nulliparity, African American race, multiple gestation, molar pregnancy, preexisting medical conditions (hypertension, diabetes, renal disease, connective tissue disorders, vascular disease), and prior or family history of preeclampsia or eclampsia.

The disorder is typically suspected in the presence of hypertension and proteinuria in the pregnant woman without history of preexisting chronic hypertension. Edema is no longer considered a reliable clinical sign and is often seen after the 20th week of gestation without signs of a hypertensive disorder. Historically, mild preeclampsia was diagnosed with a systolic BP rise of 30 mm Hg or diastolic BP rise of 15 mm Hg. Consensus statements now describe mild preeclampsia as an absolute reading of 140/90 mm Hg or greater in a pregnant woman with proteinuria greater than 0.3 g in a 24-hour urine collection. Again, nondependent edema is no longer considered a diagnostic criterion. Severe preeclampsia consists of a systolic BP greater than 160 mm Hg or diastolic BP greater than 110 mm Hg complicated by significant proteinuria (>5.0 g/day) and evidence of end-organ damage. Signs and symptoms indicating severe preeclampsia include headache, visual disturbances, confusion, right upper quadrant (RUQ) or epigastric pain, impaired liver function, proteinuria, oliguria (<500 mL/24 hr), pulmonary edema, microangiopathic hemolytic anemia, thrombocytopenia, oligohydramnios, and FGR.

Pregnant women with hypertension documented before pregnancy may develop preeclampsia. Chronic hypertension with superimposed preeclampsia is responsible for 15% to 30% of hypertensive disease in pregnancy. Treatment for mild preeclampsia involves bed rest and surveillance to assess development of complications. Delivery is carefully delayed until fetal maturity, development of severe preeclampsia, or other complications occur. In most cases, treatment of severe preeclampsia is delivery.

During labor and delivery, women with preeclampsia should receive IV magnesium sulfate for seizure prophylaxis, with a loading dose of 4 g infused over 15 to 20 minutes, then continuous infusion at 2 g/hr, similar to the preterm-labor magnesium therapy protocol (Table 20-18). BP should be carefully evaluated and treated with IV hydralazine if levels are persistently above 110 mm Hg diastolic. Women with severe preeclampsia should generally deliver within 24 hours. Postpartum therapy with magnesium sulfate is recommended for 12 to 24 hours depending on the degree of severity.

HELLP SYNDROME

If unrecognized, preeclampsia can progress to a syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). This is another complication in seemingly stable patients. The HELLP syndrome is noted in 5% to 10% of patients with preeclamptic symptoms. Such patients often present with RUQ and epigastric pain and a

Table 20-18 Magnesium Sulfate Protocol for Preterm Labor

Continuous electronic fetal and contraction monitoring
Patient in lateral recumbent position
Nothing by mouth initially; then clear liquids if muscle tone adequate to prevent aspiration
Intravenous fluids begun with lactated Ringer 5% dextrose solution
Four g (range, 2-6 g) of $MgSO_4 \cdot 7H_2O$ in 500 mL of 5% dextrose administered over 15 minutes as loading dose
Continuous infusion of 1 to 3 g/hr of $MgSO_4 \cdot 7H_2O$ after initial load
Calcium gluconate readily available
Accurate intake and output
Frequent assessment of deep tendon reflexes
Frequent examination of lungs for early signs of pulmonary edema
Plasma magnesium levels monitored as clinically indicated
Continue protocol for 24 hours; change to oral β -adrenergic agent if needed

peripheral blood smear consistent with a microangiopathic hemolytic anemia. There may be decrements in the platelet count and increments in the transaminase (aspartate aminotransferase, alanine aminotransferase) and lactic acid dehydrogenase enzymes. This is a life-threatening emergency that requires prompt delivery of the baby.

ECLAMPSIA

Another serious complication of preeclampsia is development of seizures or coma. This is known as eclampsia. Eclampsia occurs in approximately 0.2% of pregnancies and terminates one in 1000 pregnancies. The seizures and mental status changes of eclampsia are thought to result from hypertensive encephalopathy. The perinatal mortality rate is 2.0% to 8.6% (Sibai et al., 1981). The maternal mortality rate is less than 2%, with intracranial hemorrhage the major cause.

GESTATIONAL HYPERTENSION

Gestational hypertension is defined as systolic BP of 140 mm Hg or greater or a diastolic BP of 90 mm Hg or greater in the absence of proteinuria in a previously normotensive pregnant woman at or after 20 weeks of gestation. Gestational hypertension is considered severe with sustained elevations in systolic BP of 160 or diastolic of 110 mm Hg or greater. Women with BP greater than 140/90 mm Hg without proteinuria or end-organ damage may ultimately develop preeclampsia. These initially normotensive women usually become hypertensive late in pregnancy, during labor, or within 24 hours postpartum and note a return to normal BP within 10 days postpartum. If preeclampsia does not develop, the diagnosis of gestational hypertension is made. The diagnosis of gestational hypertension is a temporary one and should be used during pregnancy only in women who do not meet criteria for preeclampsia or chronic hypertension.

ABRUPTIO PLACENTAE

Abruptio placentae (placental abruption) refers to separation of a normally located placenta before the birth of the fetus. This event occurs in 1 in 129 births. Severe

abruption results in a fetal mortality rate of 0.2%. Bleeding into the decidua basalis leads to separation of the placenta. Hematoma formation further separates the placenta from the uterine wall and compresses these structures, compromising the blood supply to the fetus, leading to increased intrauterine pressure, uterine tenderness, frequent uterine contractions, fetal distress, and demise. The severity of fetal distress correlates with the degree of placental separation.

When the abruption is extensive, retroplacental blood may penetrate the thickness of the uterine wall into the peritoneal cavity because of increased intrauterine pressure. This phenomenon is called “couvelaire uterus.” The myometrium becomes weakened and rarely may rupture, leading immediately to a life-threatening obstetric emergency. In near-complete or complete abruption, fetal death is inevitable unless immediate delivery by cesarean section is performed. Abruptio placentae received renewed awareness with the causal relationship to cocaine (Kline et al., 1997).

Abruptio placentae is a clinical diagnosis. Painful vaginal bleeding in the third trimester is the hallmark. Because ultrasonography for this disorder has a high false-negative rate, this complication is diagnosed primarily on the findings of vaginal bleeding, abdominal pain, uterine tenderness, uterine contractions, and fetal distress. In one prospective study, almost 80% of patients with abruptio placentae presented with vaginal bleeding, 66% with uterine or back pain, and 60% with fetal distress (Hurd et al., 1983). Other evidence of abruptio placentae can include idiopathic preterm labor, uterine hypertonicity, and fetal demise. The monitoring of uterine contractions may reveal a high baseline pressure with concurrent contractions often 1 to 2 minutes apart.

Etiology

From 40% to 50% of women with abruptio placentae have underlying hypertension. Maternal trauma is the cause in 1.5% to 9.4%. The remainder can be associated with excessive alcohol consumption, cocaine use, sudden decompression of the uterus (as in delivery of a first twin), retroplacental bleeding from needle puncture after amniocentesis, and possibly tobacco use. In a small group, no underlying association is found; abnormalities of uterine blood vessels and decidua likely exist in this idiopathic group.

Management

The management of abruptio placentae is primarily supportive and entails both aggressive hydration and monitoring of maternal and fetal well-being, with the expeditious delivery of the fetus if indicated (Turner, 1994). Maternal and fetal death may result from hemorrhage and coagulopathy. Coagulation studies should be performed to look for disseminated intravascular coagulation (DIC). Packed RBCs should be typed and held. If the fetus appears viable but compromised, urgent cesarean delivery should be considered. Recommended laboratory testing includes complete blood count (CBC) with platelets, prothrombin and partial thromboplastin time, fibrinogen, fibrin degradation products, D-dimer, blood type, and Kleihauer-Betke acid elution. D(Rh)-negative mothers benefit from administration of D immune globulin (Pearlman et al., 1990).

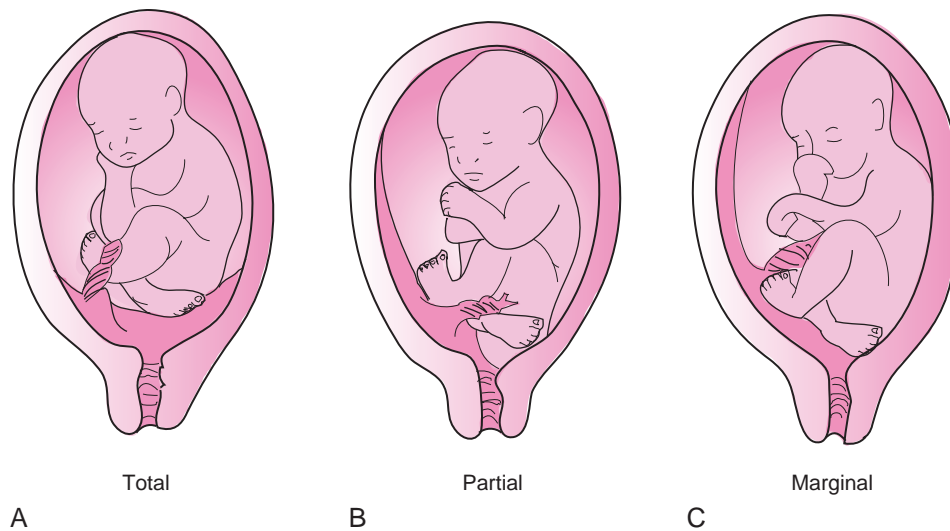

Figure 20-7 Various types of placenta previa. **A**, The cervical os is completely covered by the placenta. **B**, The cervical os is partially covered by the placenta. **C**, The placenta extends to the edge of the cervical os.

PLACENTA PREVIA

Placenta previa is a life-threatening condition that presents in three forms (Figure 20-7). When the cervical os is completely covered with placenta, it is classified as a *complete* or *total* placenta previa. *Partial* placenta previa occurs when the placenta covers a portion of the cervical os. A *marginal* placenta previa is one that extends just to the edge of the cervix. Placental implantation in the lower uterine segment is termed *low-lying placenta*. The incidence of placenta previa is about 1 in 200 to 250 pregnancies and is associated with potentially serious consequences from hemorrhage, separation of the placenta, or emergency cesarean delivery (Iyasu et al., 1993).

Placenta previa is usually diagnosed when the patient complains of painless vaginal bleeding in the third trimester. A smaller number of patients present with excessive bleeding in labor. Usually the initial bleeding is not profuse enough to be fatal and spontaneously ceases, only to recur later. The average first bleed occurs at 27 to 32 weeks of gestation. Women with a centrally implanted placenta previa tend to have earlier episodes of bleeding, which are more severe. Another suspicious aspect of the history includes an abnormal lie, in particular transverse or breech presentation.

Risk Factors

There are a few predisposing factors for placenta previa. They include advanced maternal age, increased parity, uterine abnormalities, multiple gestation, tobacco abuse, prior placenta previa, and previous uterine surgery.

Ultrasonography

Transabdominal ultrasonography is a simple, precise, and safe method to visualize the placenta. It has an accuracy of 93% to 98% (Bowie et al., 1978). False-positive results can result from focal uterine contractions or bladder distention. The accurate assessment of placental position can also be difficult with a placenta implanted on the posterior uterine wall. In a patient whose placental edge is not well visualized

and is not actively bleeding, the transvaginal approach may be used (Laing, 1981). The bladder should be empty, and initially the vaginal transducer should be inserted into the vagina to visualize the cervix. After the closed cervix is visualized, deeper insertion of the probe aids in visualization of the placenta. The use of the vaginal approach is safe and accurate in diagnosis of a placenta previa (Figure 20-8).

During routine second trimester ultrasonography, placenta previa is frequently diagnosed. Typically, at 16 weeks' gestation, the placenta occupies 25% to 50% of the uterine surface area. As the third trimester approaches, growth of the lower uterine segment outflanks growth of the placenta, allowing apparent "migration" of the placenta (placental migration) away from the cervical os. For this reason, although 5% of pregnancies are diagnosed with complete previa by second trimester ultrasonography, 90% of these resolve by term (Rizos et al., 1979). When second trimester ultrasonography suggests a placenta previa, transvaginal ultrasonography can be helpful in making a more accurate diagnosis before term.

VASA PREVIA

Vasa previa is a rarely reported condition in which fetal blood vessels unsupported by the umbilical cord or placental tissue traverse the fetal membranes below the presenting part, covering the cervical os. It almost always coexists with a velamentous insertion of the umbilical cord. Vasa previa leads to fetal exsanguination from tearing of the large-caliber fetal vessels when the membranes rupture spontaneously or artificially. This event has an associated fetal mortality rate of 33% to 100% (Bright and Becker, 1991).

When pulsatile vessels are palpated preceding the fetal vertex during digital examination, vasa previa should be considered along with cord presentation. Vasa previa must be included in the differential diagnosis of all cases of third trimester bleeding. The blood that is lost can be tested for the presence of fetal hemoglobin, but often there is insufficient time to accomplish this. Vasa previa is often a retrospective diagnosis made after emergent cesarean delivery

Figure 20-8 **A**, Complete placenta previa from transabdominal midline sagittal scan. The anterior wall implanted placenta covers the cervix completely. **B**, Complete placenta previa from transvaginal scan. The endocervical canal is measured in the image with (+). Note that the placenta covers the entire endocervical canal. **C**, Marginal placenta previa. The anterior uterine wall-implanted placenta covers just to the internal cervical os.

for fetal distress. Fetal mortality and morbidity from vasa previa may be reduced if there are a high index of suspicion, reliable method of diagnosis, and prompt surgical intervention (Messer et al., 1987).

PLACENTA ACCRETA, INCRETA, AND PERCRETA

These three conditions are forms of abnormal placental attachment in which the trophoblasts invade beyond the normal location into the uterine muscle to varying degrees. Abnormal blood supply to the inner lining of the uterus and prior trauma to both the endometrium and myometrium (the muscle layer) appear to alter lower uterine physiology and influence placental implantation. The most common risk factor is a previous cesarean delivery or prior uterine surgery.

The risk of maternal death is 3%. In cases of bladder involvement with a placenta percreta, the risk of maternal death increases to 20%. The leading immediate causes of death are uterine bleeding and DIC. Placenta accreta, increta, or percreta is often the etiology of retained placenta (Breen et al., 1997). During manual extraction, the placenta fragments without complete separation, resulting in uncontrolled hemorrhage.

The major factor affecting outcome is the degree of placental invasion. A minimally invasive placenta (accreta) can often be removed manually or by curettage. Invasion deeper in the myometrium (increta) or through the myometrium (percreta) more often requires hysterectomy. The increased rate of cesarean deliveries is making abnormalities of placental attachment more frequent, particularly if the placenta is attached in the area of the prior uterine incision.

Multiple Gestation

At least 1 in 80 births is a twin gestation. With assisted reproductive technologies, this rate has now increased to almost 1 in 50 to 60. Approximately two thirds to three quarters of twins are dizygotic.

Twin gestation presents unique challenges. Monozygotic twins have twice the anomaly rate of dizygotic twins or singletons. Women with twin gestations are more likely to miscarry early in gestation and more likely to deliver prematurely. Half of mothers of twins experience premature labor. Bed rest is often recommended after 5 months of gestation to aid in preterm labor prevention. Education regarding associated signs and symptoms is important in this group. The average gestational age of delivery for a twin gestation is 36 menstrual weeks.

Women with twin gestations are also at higher risk for chronic hypertension, pyelonephritis, GDM, and placenta previa. They should take supplemental iron, particularly in the latter trimesters, even if they are not iron deficient. Growth discordance can also occur, from twin–twin transfusion syndrome or more often simply from different placental implantation and different accessibility to nutrients. Serial ultrasound studies for growth approximately every 6 weeks is recommended. Twin fetuses with growth discordance should have antenatal testing.

The majority of twins will present both head first, cephalic–cephalic (Figure 20-9, A), or first one cephalic and second one breech (cephalic–breech; Figure 20-9, B). Any other combination can be seen, although cephalic–transverse (Figure 20-9, C) and breech–cephalic are the most likely in this remaining group. When well into the

Figure 20-9 Three common twin presentations: cephalic–cephalic (A), cephalic–breech (B), and cephalic–transverse (C).

third trimester, the first presenting fetus most often stays in its position; the second fetus often changes position, occasionally even during early labor. Twins who are cephalic–cephalic can be delivered vaginally. Those who are cephalic–breech and cephalic–transverse can also be attempted vaginally by skilled operators in carefully chosen women. When the first fetus is presenting other than cephalic, delivery is often best accomplished by cesarean section. Breastfeeding has been successful in many women with twins and should be encouraged.

Antepartum Fetal Surveillance

The three most common methods used to evaluate fetal well-being in utero are the nonstress test (NST), contraction stress test (CST), and biophysical profile (BPP) (Babbitt, 1996). Vibroacoustic stimulation and fetal movement counts are also useful adjunctive tools in the evaluation of fetal well-being.

The indications for antepartum fetal surveillance are multiple and reflect conditions that are associated with increased fetal morbidity and mortality (Smith-Levitin et al., 1997). Conditions that lead to fetal hypoxia, uteroplacental insufficiency, and death are all indications for increased fetal surveillance. There are no absolute protocols for increased fetal surveillance, but there are certain accepted practices for given maternal–fetal risks. For example, weekly antenatal testing beginning in the 32nd week of gestation is often performed in women with low to moderate risk (e.g., GDM, chronic hypertension, mild preeclampsia). For women with a higher risk of an abnormal outcome, earlier and more frequent antenatal testing is indicated, requiring an individualized approach.

NONSTRESS TEST

Most often the NST is used as the primary tool in antepartum fetal surveillance. It has been used to document second and third trimester fetal well-being for the past 40 years. It serves as a surrogate measure of the developing fetal autonomic nervous system and the adequacy of the uteroplacental function (Myrick and Harper, 1996).

The NST is more specific than sensitive and thus a better indicator of fetal health than fetal illness. The test itself is

read as reactive or nonreactive and may be repeated at intervals as a screen for high-risk maternal conditions. A reactive or reassuring NST is defined as one with at least two accelerations above a baseline FHR of 15 beats/min for 15 seconds in a 20-minute period. If a reactive pattern is not present at the end of the first 20 minutes, attempts may be made to arouse the fetus. Fetal rest periods, reportedly 30 to 40 minutes in duration, must be excluded for the fetus to demonstrate a reactive NST. Because fetuses can have normal sleep cycles lasting up to 40 minutes, NST might require more than 1 hour to complete if it is initially nonreactive. It is important to differentiate whether a nonreactive tracing truly represents a compromised fetus versus a temporary behavioral state (Knuppel et al., 1982).

The absence of fetal accelerations with the exclusion of a fetal sleep state denotes a nonreactive test. There are no contraindications to the NST as a primary screening tool, and it is easily reproducible, relatively inexpensive, and acceptable to most patients. Maternal narcotics, extreme prematurity, and fetal cardiac or CNS anomalies may also be responsible for a nonreactive NST. A nonreactive NST does not indicate fetal jeopardy but should be viewed as an indication for further evaluation. This evaluation may take the form of a BPP or CST.

BIOPHYSICAL PROFILE

The BPP is an ultrasound assessment of fetal well-being. It was originally designed to mimic the Apgar score for postnatal assessment. The BPP is technically more difficult to perform and interpret but provides a greater degree of certainty of fetal well-being. During a 30-minute examination, certain behavioral patterns associated with a healthy fetus are documented. The test is scored with five components, each worth 2 points (Table 20-19). Indicators such as amniotic fluid volume, fetal breathing, FHR, movement, and tone are evaluated. A score of 8 or 10 is reassuring; a score of 6 is suspicious and indicates a need for further evaluation; and a score of 4 or less is ominous, indicating the need for immediate intervention. A low score may also reflect the fetus's behavioral state during the test, such as normal sleep or sedation from maternal use of narcotics or CNS depressants. However, a decreasing score has been well correlated with a poor outcome and with increasing degrees of fetal acidemia.

Table 20-19 Components of the Biophysical Profile*

Parameter	Normal (Score = 2)	Abnormal (Score = 0)
Nonstress test	Two or more accelerations of at least 15 beats/min above baseline for at least 15 sec	Less than two accelerations of sufficient height and duration
Amniotic fluid volume	At least one amniotic fluid pocket is $\geq 2 \times 2$ cm in perpendicular plane	No 2×2 -cm pockets or AFI < 5.0
Fetal breathing movements	Sustained fetal breathing for at least 30 sec	< 30 seconds of fetal breathing
Fetal body movements	At least three limb or gross body movements	Less than three limb or body movements
Fetal tone	Extremities in flexion at rest and at least one episode of extension of extremity or spine with return to flexion	Extension at rest or no return to flexion after movement

*Scoring of the latter four components is done sonographically in 30-minute observation period. A total score of 8 to 10 is reassuring, a score of 6 is suspicious, and a score of 4 or less is ominous.

AFI, Amniotic fluid index (sum of largest vertical pocket in each of four quadrants of uterus).

Modified from Norman LA, Karp LE. Biophysical profile for antepartum fetal assessment. *Am J Fam Physician*. 1986;34:83-89.

MODIFIED BIOPHYSICAL PROFILE

The modified BPP consists of the NST and the amniotic fluid index. It has proved to be an excellent means of fetal surveillance and identifies a group of patients at increased risk for poor perinatal outcome and small-for-gestational-age (SGA) infants. It has proved to be as effective as a full BPP in assessing fetal well-being.

CONTRACTION STRESS TEST

With the increasing popularity of the NST, the CST, also known as the *oxytocin challenge test* (OCT), is most often used as a supplementary tool in fetal surveillance. The CST is more cumbersome to perform, is difficult to interpret, and has several contraindications. This test is used to assess the reserve of the marginally compromised fetus when subjected to the stress of several uterine contractions (Collea and Hollis, 1982; Lagrew, 1995). The goal of the CST or OCT is to achieve three contractions in a 10-minute period through oxytocin infusion or nipple stimulation and look for late decelerations.

The CST result is considered to be negative if no late decelerations are noted. A negative (normal) CST result is a good indication of adequate fetal well-being as judged by fetal distress in labor, Apgar scores, and absence of meconium. The CST result is considered positive if late decelerations accompany 50% or more of contractions. A positive CST result is predictive of fetal compromise and distress in labor in up to 80% of cases and in specific clinical situations indicates need for delivery of the fetus. The presence of fewer decelerations indicates a suspicious study. The latter two conditions mandate need for further evaluation. Contraindications to a CST include risk of preterm labor, placenta previa, classic uterine scar or full-thickness scar from previous uterine surgery, incompetent cervix, and multiple gestation (Babbitt, 1996).

VIBROACOUSTIC STIMULATION

Vibroacoustic stimulation is an artificial burst of noise produced by a handheld battery-powered artificial larynx (Birnholtz and Benacerraf, 1983). This device is portable and easy to apply to the maternal abdomen and provides a stimulation that combines both sound and vibration. The goal is to alter the fetal behavioral state, waken a sleeping

fetus, and provoke accelerations in the heart rate. Use of this device is associated with a significant increase in the number of reactive NSTs and a significant decrease in overall testing time. The use of vibroacoustic stimulation in achieving FHR accelerations has been found to be equally predictive of a favorable fetal outcome as spontaneously generated FHR accelerations (Smith et al., 1986).

Normal Labor and Delivery

Labor, whether preterm or term, is defined as the presence of sufficient uterine contractions in frequency, intensity, and duration to bring about effacement and dilation of the cervix. Control of normal labor is complex and, despite advances in medical science, poorly understood. Evidence supports PG involvement, in particular PGE₂ and PGF₂α, as well as other mediators (Ulmsten, 1997).

Before the onset of labor, the fetal head may descend into the pelvis, and the height of the fundus will diminish. This lightening may occur acutely and may be very obvious to the pregnant woman, or it may occur over several weeks. An increase in pelvic pressure is experienced at this time. *False labor*, or irregular, short contractions that occur often before true labor, may in fact aid in cervical effacement and shortening of the cervical canal that begins as funneling at the internal cervical os. With impending true labor, cervical effacement and early dilation may allow the passage of a blood-tinged mucous, termed “bloody show.” Most women go into true labor within 3 days of a bloody show. Bleeding described as “heavy as the beginning of a menstrual period” may be pathologic, and the pregnant woman should be evaluated for placenta previa, abruptio placentae, and other causes of vaginal bleeding.

Contractions of active labor most often occur every 2 to 3 minutes, last about 1 minute, and have a mean of 40 mm Hg in intensity. However, some women successfully deliver babies with less frequent and intense uterine contractions. Frequent contractions of 1 to 2 minutes apart may be a sign of the increased intrauterine pressure associated with abruptio placentae. Adequate relaxation between contractions is imperative to allow oxygenated blood to enter the intravillous spaces and transfer to the fetal compartment. During the course of labor, uterine contractions cause cervical effacement and then dilation to a full 10 cm

Figure 20-10 Composite curves of normal and abnormal labor progress. (From Scherger J, Levitt C, Acheson L: Teaching family-centered perinatal care in family medicine. Part 2. *Fam Med*. 1992;24:369.)

Stage	Onset	Completion
First (latent and active phases)	Active labor	Complete dilation
Second	Complete dilation	Delivery of baby
Third	Delivery of baby	Delivery of placenta
Fourth*	Delivery of placenta	Contracted uterus

*Not always considered a stage.

to allow passage of the fetal head, the largest diameter of the fetus to pass through the birth canal.

PROGRESS OF LABOR

The degree and rate of cervical dilation measures the progress of labor. Labor can be divided into stages that are somewhat predictable in nulliparous and multiparous women (Table 20-20 and Figure 20-10). The first stage of the labor course can be subdivided into the latent phase and the active phase.

First Stage of Labor

Latent Phase

The latent phase of the first stage of labor is variable in length but is usually less than 20 hours for a nullipara and 14 hours for a multipara. Little cervical dilation is seen, but cervical preparation for labor occurs with changes in consistency caused by changes in collagen and connective tissue. An increase in effacement as well as the anterior positioning of the cervix is also noted. Conduction anesthesia given in this phase may prolong or arrest progress. In normal pregnant women, latent phase labor is best experienced at home. Clear liquids instead of heavy meals are encouraged during this time. Instructions for coming to the hospital include vaginal bleeding similar to a period, rupture of membranes, painful contractions at least 3 to 4 minutes apart, and decreased fetal movement. A subset of women may have a prolonged latent phase that can be treated with morphine in a hospital setting. Often this treatment accelerates transition to the active phase.

Active Phase

The active phase of the first stage of labor is the segment of rapid dilation, the progress of which is not affected by

sedation or conduction anesthesia. This phase usually occurs at about 4 to 5 cm of cervical dilation. In general, nulliparous women dilate at least 1.2 cm/hr and multiparous 1.5 cm/hr (Friedman, 1978). Progress of the active phase depends on the strength and frequency of uterine contractions; size, position, and attitude of the fetal head; and the size and shape of the bony pelvis. Because of the different diameters of the pelvic inlet, midplane, and outlet, the fetal head must turn at different times of descent to negotiate the bony structure. Flexion of the fetal head during this process is crucial because this diminishes its anteroposterior diameter and permits easier descent. The cardinal movements of the fetal head during labor include engagement, descent, flexion, internal rotation, extension, external rotation, and expulsion.

Either continuous electronic fetal monitoring (EFM) or intermittent auscultation can be used to monitor the fetus in the active phase of labor (ACOG, 1995a). Instead of continuous EFM in this phase, in low-risk mothers with normal labor, the fetal heart may be auscultated after a contraction and recorded every 30 minutes; the frequency should be increased to every 15 minutes in higher risk labors. FHR decelerations should prompt even more frequent auscultation or continuous EFM. Auscultation rather than continuous EFM will allow mobility during labor, which may improve maternal comfort. IV fluids in a normal gravida can be reserved for women with long labor who become dehydrated despite oral liquids, those who require conduction anesthesia or large doses of pain medication, and those in whom complications develop or are suspected.

Second Stage of Labor

The second stage of labor involves maternal expulsive forces during uterine contractions to aid in the descent and ultimate delivery of the fetus. Instead of continuous monitoring, the fetal heart should be auscultated and recorded every 15 minutes in normal, low-risk pregnancies and every 10 minutes in higher risk pregnancies. The second stage of labor averages 20 minutes for multiparas and 50 minutes for nulliparas. Although pushing for longer than 2 hours without an epidural or 3 hours with an epidural in a nullipara should alert the practitioner to possible cephalopelvic disproportion (CPD), pushing can continue longer in cases of adequate FHR and continued progress in descent.

Third Stage of Labor

The third stage of labor begins with the delivery of the baby. Appropriate equipment for resuscitation should be available. Maternal pushing with contractions will cause the fetal head to bulge the perineal tissues with increasing pressure to distend the opening of the vaginal canal and allow the fetal head to deliver. It is only when the head is stretching these tissues should the decision for episiotomy be made. The fetal head delivers with extension, after which the practitioner suction the fetal mouth, pharynx, and nose. If meconium is present, wall suction to a DeLee trap is used for suctioning, and the fetus is not stimulated to breathe before a laryngoscope is used to assess the presence of meconium below the cords. After delivery of the fetal head and suctioning are complete, the neck of the fetus is explored for nuchal cords, which are preferably reduced if possible.

If too tight to reduce, the cord must be clamped and then cut. The anterior shoulder of the fetus is then delivered with gentle downward traction but predominantly with maternal expulsive forces to avoid excessive pulling on the fetal neck, which can be associated with brachial plexus injury. Hyperflexion of the legs at the hip joint will allow the anterior shoulder to deliver more easily. After delivery of the anterior shoulder, the posterior shoulder is delivered usually quite easily with gentle upward traction. Excessive maternal efforts at this point can cause perineal lacerations. Thus, the mother is instructed to push hard for the delivery of the anterior shoulder and gently for the posterior shoulder. After the shoulders are delivered, the remainder of the body escapes easily. The baby can then be placed on the mother's abdomen where warm towels await. The timing of clamping of the cord is controversial. As long as the baby is kept on the maternal abdomen, excessive blood shifts through an unclamped cord will usually not occur. The cord can then be clamped. Cord blood is obtained, as well as cord pH if desired.

The placenta should then be allowed to separate spontaneously. During this time, inspection of the vaginal canal and cervix for tears can be started, but adequate inspection for lacerations should be done after delivery of the placenta. Signs of placental separation include lengthening of the cord, a gush of blood, and a change in the contour of the uterine fundus. Separation of the placenta from the maternal decidua is most likely from shearing forces as the now-smaller uterus contracts. After separation, uterine contractions decrease the size of the implantation site to arrest bleeding from this area. Maternal expulsive forces may be required to deliver the placenta along with gentle traction on the cord. Uterine massage and immediate breastfeeding will aid in maintaining a contractile state of the uterus and decrease uterine atony. In some cases, oxytocin may be required to maintain uterine contractility. After separation of the placenta, the episiotomy (if cut) and any lacerations should be repaired.

Fourth Stage of Labor

Some consider the first hour after delivery of the placenta the fourth stage of labor. Risk of uterine atony is highest during this period. The patient should be watched carefully for excessive vaginal bleeding, an enlarging boggy fundus, and hypotension. Massage of the uterine fundus most often is sufficient to return it to a contracted state and stop bleeding. Oxytocin may be added to the IV fluids in doses of 20 or 40 units/L of fluid and the IV rate increased, or if no IV fluid is needed, 20 units of oxytocin can be given IM. Alternatively, methylergonovine (Methergine), 0.2 mg, can be given IM every 20 minutes if the mother is not hypertensive. Finally, if there is no resolution to bleeding, 250 µg of PGF₂α (Hemabate) can be given IM every 15 to 20 minutes as needed for up to three doses. Misoprostol is a PG that is now widely used despite its "off-label" indication that has demonstrated to increase uterine tone and decrease bleeding in the postpartum period. It can be administered via the oral, sublingual, vaginal, and rectal routes in doses ranging from 200 to 1000 µg. It has no known contraindication but should be used with caution in cardiovascular disease and is associated with nausea, vomiting, pyrexia, and diarrhea in high doses.

Table 20-21 Bishop Pelvic Scoring for Elective Induction of Labor

Score	Dilation	Effacement (%)	Station	Position	Consistency
0	Closed	0-30	-3		
1	1-2 cm	40-50	-2	Posterior	Firm
2	3-4 cm	60-70	-1, 0	Midposition	Moderately firm
3	5+ cm	80+	+1, +2	Anterior	Soft

The Bishop score generally follows this scale:

Modifiers

A point is added to the score for each of the following:

- Preeclampsia
- Each prior vaginal delivery

A point is subtracted from the score for:

- Postdates pregnancy
- Nulliparity
- Premature or prolonged rupture of membranes
- Interpretation

Indications for Cervical Ripening with Prostaglandins

1. Bishop score <5
2. Membranes intact
3. No regular contractions

Indications for Labor Induction with Pitocin

1. Bishop score \geq 5
2. Rupture of membranes

Cesarean Rates	First-Time Mothers (%)	Women with Past Vaginal Deliveries (%)
Scores of 0-3	45	7.7
Scores of 4-6	10	3.9
Scores of 7-10	1.4	0.9

Points for each parameter are added. A score of 9 or greater is favorable for induction.

Modified from Bishop EH. Pelvic scoring for elective induction. *Obstet Gynecol.* 1964;24:266.

INDUCTION OF LABOR

Physicians have turned to induction of labor as a means of preventing complications from conditions such as prolonged rupture of membranes, fetal demise in utero or severe preeclampsia, or a postterm pregnancy. For example, postterm delivery beyond 42 weeks' gestation poses risks to both mothers and babies, including increased perinatal death, increased cesarean deliveries, perineal injuries from macrosomia, and labor dystocias (Gülmezoglu et al., 2006). The onset of labor can be stimulated in different ways. Less interventional approaches, such as stripping of the amniotic membranes, may be effective but not predictable and thus may not be sufficient in women who need prompt delivery. Stripping of the membranes requires the cervix to be dilated sufficiently to introduce the examining finger. Potential risks include rupture of membranes, infection, and bleeding. However, this technique appears safe particularly for gravidas approaching postdates (El-Torkey and Grant, 1992).

In most cases, the pharmacologic induction of pregnancy should be reserved for a medical or obstetric indication, such as hypertension, diabetes, premature rupture of membranes, postdates, fetal demise, and FGR. Logistic and psychosocial factors, such as distance from the hospital and rapid labors, are also indications. Absolute contraindications for induction of labor are similar to those for spontaneous labor and vaginal delivery. Before an induction, accurate dating and if necessary, fetal maturity should be confirmed. Gestational age of at least 39 weeks should

be confirmed by early positive pregnancy test, early ultrasonography, or early fetal heart tone auscultation. In some cases, fetal lung maturity studies from amniotic fluid may be required.

Successful induction is mainly a factor of parity and cervical readiness at the time of induction. A scoring system developed by Bishop in 1964 to assess the cervix has become popular (Table 20-21). A Bishop score of 9 or greater is favorable for induction. Women with low scores benefit from cervical ripening with PGs before induction.

Prostaglandin E₂ is now approved by the FDA for cervical ripening. Dinoprostone (Prepidil) is 0.5 mg of modified PGE₂ in 2.5 mL of gel that is placed intracervically and repeated once in 6 to 12 hours if the Bishop score does not change appreciably. Intracervical dinoprostone may or may not cause uterine contractions. Its effect on cervical consistency appears unrelated to the number of contractions. Alternately, dinoprostone (Cervidil) may be given intravaginally as a slow-release, 12-hour vaginal insert that may be removed if uterine hyperstimulation occurs. Previous cesarean section is not a contraindication for use. If spontaneous labor does not ensue, an oxytocin infusion may then be used.

Misoprostol (Cytotec), a synthetic PGE₁ FDA approved for prevention of gastric ulcers, has been used off label for cervical ripening and labor induction. Several protocols have been developed. It is a potent uterotonic agent that may be associated with an increased incidence of uterine rupture. Misoprostol is best not used in women with prior cesarean section or uterine surgery.

Oxytocin has been available for labor induction for 40 years. Administered appropriately, it is as safe as spontaneous labor. Many protocols are available for IV oxytocin infusion for induction of labor, from low-dose constant infusion (Mercer et al., 1990) to higher dose incremental infusion (Muller et al., 1992; Satin et al., 1994). Steady-state levels after IV infusion occur about 40 minutes after the start of infusion. Starting doses range from 0.5 to 2 mU/min with incremental increases of 1 to 2 mU/min every 30 to 60 minutes (ACOG, 1995b). The goal is to achieve two to four uterine contractions in 10 minutes. All protocols share certain precautions. Continuous FHR and uterine contraction monitoring is mandatory. Hyperstimulation can occur even after a stable infusion rate has been established. Often, contraction intensity and frequency will increase spontaneously after the pregnant woman reaches the active phase or if the amniotic membranes rupture, necessitating a decrease in the oxytocin infusion rate. Hyperstimulation associated with FHR decelerations requires discontinuing or lowering of the infusion until recovery. Prolonged use of high doses of oxytocin can cause water intoxication because of its biochemical similarity to antidiuretic hormone.

Amniotomy alone or in conjunction with oxytocin has been shown to decrease the length of labor. In some cases, amniotomy alone can stimulate normal labor, omitting the need for oxytocin. The risks of early amniotomy include cord prolapse and chorioamnionitis. In clinical practice, the decision between induction and expectant management should include favorability of the cervix, maternal parity, and complicating medical or obstetric issues, as well as patient or physician convenience and preferences.

EVIDENCE-BASED SUMMARY

- Patients should be counseled that walking during labor does not enhance or improve progress in labor and that it is not harmful (SOR: A).
- Continuous support during labor from caregivers should be encouraged because it is beneficial for women and their newborns (SOR: A).
- Active management of labor may shorten labor in nulliparous women, although it has not consistently been shown to reduce the rate of cesarean delivery (SOR: B).
- Amniotomy may be used to enhance progress in active labor but may increase the risk of maternal fever (SOR: B).
- Intrauterine pressure catheters may be helpful in the management of dystocia in select patients, such as obese women (SOR: C).
- Women with twin gestations may undergo augmentation of labor (SOR: C).

KEY TREATMENT

- PGE analogs are effective for cervical ripening and inducing labor (SOR: A).
- Low- or high-dose oxytocin regimens are appropriate for women in whom induction of labor is indicated (SOR: A).
- Before 28 weeks' gestation, vaginal misoprostol appears to be the most efficient method of labor induction regardless of Bishop score, although high-dose oxytocin infusion is also acceptable (SOR: A).

- Approximately 25 µg of misoprostol should be considered as the initial dose for cervical ripening and labor induction; the frequency of administration should be no more than every 3 to 6 hours (SOR: A).
- Intravaginal PGE₂ for induction of labor in women with premature rupture of membranes appears to be safe and effective (SOR: A).
- The use of misoprostol in women with prior cesarean delivery or major uterine surgery has been associated with an increase in uterine rupture and therefore should be avoided in the third trimester (SOR: A).
- Misoprostol (50 µg every 6 hours) to induce labor may be appropriate in some situations, although higher doses are associated with an increased risk of complications, including uterine tachysystole with FHR decelerations (SOR: B).

Abnormalities of Labor and Delivery

DYSFUNCTIONAL LABOR

A dysfunctional pattern of labor is defined as a deviation from the norm for the different phases of labor described earlier (see Figure 20-10). In the latent phase of the first stage of labor, a prolonged or protracted course can be seen. In the active phase of the first stage of labor, both a protracted course and an arrested course can be seen (O'Brien and Cephalo, 1991). The disorders for each of these phases are examined separately.

PROLONGED LATENT PHASE

The latent phase of the first stage of labor is variable in length but usually less than 20 hours for a nullipara and 14 hours for a multipara. It is defined by the onset of regular contractions and is terminated by the onset of the active phase. The rate of dilation is usually 0.6 cm/hr or less. This phase is considered prolonged if it falls outside these parameters. The possible etiologies include an unripe cervix, false labor, sedation, and uterine inertia. The management of this condition is primarily conservative unless there is an expeditious need to deliver the fetus. This includes rest, observation, and possibly oxytocin augmentation. Maternal rest can be induced by a therapeutic dose of morphine to provide a respite from the stresses of early labor and to promote sleep. The vast majority of these patients will declare themselves and either progress into labor or cease contractions, and then the diagnosis of false labor can be made. Amniotomy should be avoided in this phase because it increases the risk for chorioamnionitis. A prolonged latent phase in itself is not an indication for cesarean section.

PROTRACTED ACTIVE PHASE

The active phase of labor is defined as dilation of the cervix occurring at a rate of at least 1.2 cm/hr for nulliparous women and 1.5 cm/hr for multiparous women. A slower rate of dilation is known as protracted active phase or *primary dysfunctional labor*. The etiologies of a protracted active phase include fetal malposition (e.g., occiput

posterior), relative CPD, inadequate uterine contractions, and anesthesia. Historically, debate has surrounded its management. The current trend is active management with oxytocin to optimize uterine contractions. A protracted active phase is a frequent predecessor of secondary arrest of cervical dilation and is associated with an increased risk of operative delivery.

SECONDARY ARREST OF CERVICAL DILATION

The cessation of cervical dilation for 2 hours with a history of previously normal dilation is termed *secondary arrest*. The management of this condition varies considerably; however, an initial assessment and examination of the patient (including vaginal) are probably warranted to document cervical dilation, fetal station, presentation, and position. Placement of an intrauterine monitor should be considered to assess the adequacy of uterine contractions. Alternative measures include ambulation, amniotomy, and oxytocin augmentation if the uterine contractions are judged inadequate. There is a high association with CPD, and a significant number of these patients will need operative delivery.

ABNORMALITIES OF THE SECOND STAGE OF LABOR

The second stage of labor is defined as the interval between the complete dilation of the cervix to the delivery of the infant. As with previous stages of labor, abnormalities in this stage include a protracted rate or a complete “arrest of descent,” or the more common term *failure of descent*, used to describe an unchanged station. The evaluation of descent disorders should include maternal and fetal well-being, adequacy of contractions, obstructive etiologies (e.g., distended bladder), and cephalopelvic relationships. Other mitigating factors include maternal exhaustion, ineffective pushing, conduction anesthesia, and perineal resistance. There is also a high incidence of CPD with this condition and an increased risk of operative deliveries.

A *protracted descent* is more difficult to gauge but is defined by a rate of less than 1 cm/hr in nullipara women and less than 2 cm/hr in multiparous women. This diagnosis should prompt an evaluation for such causes as CPD, macrosomia, and inadequate pushing.

SHOULDER DYSTOCIA

Shoulder dystocia is defined as the impaction of the anterior shoulder against the pubic symphysis after the delivery of the head and occurs when the breadth of the shoulder is greater than the biparietal diameter of the head (Figure 20-11). It is a life-threatening event associated with significant morbidity and mortality that needs to be recognized early and managed promptly. The overall incidence of shoulder dystocia is 0.3% to 1% but increases to 5% to 7% for newborns with macrosomia (birth weight >4500 g). Although a number of factors are associated with its occurrence, their predictive values are low, making it incumbent on the practitioner to be ever vigilant.

Several maternal and fetal complications are associated with shoulder dystocia (Carlan et al., 1991). Maternal

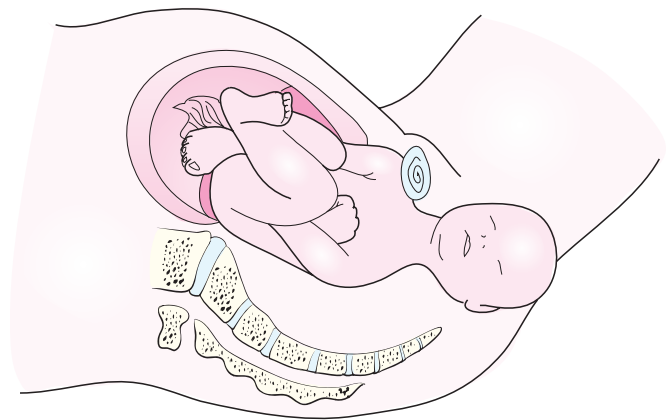

Figure 20-11 Shoulder dystocia. Impaction of the anterior shoulder against the pubic symphysis.

complications are usually a consequence of soft tissue damage. The attempt to deliver the baby can result in an extension of an episiotomy to a fourth-degree laceration, with disruption of the anal sphincter and rectal mucosa. Other complications include hemorrhage secondary to uterine atony, vaginal lacerations, and, rarely, uterine rupture.

Fetal complications tend to be more profound. Brachial plexus injury can occur. Most resolve within 6 months with adequate physical therapy. However, the injury may persist as a source of lingering disability. Erb palsy is the most common brachial plexus injury and involves the fifth and sixth cervical roots. Klumpke palsy involves injury to the eighth cervical root and the first thoracic fibers. Clavicular fracture may occur spontaneously or intentionally and may rarely result in damage to the underlying tissue. Prolonged fetal hypoxia secondary to a delay in the delivery can result in severe neurologic damage and even death.

Conditions that predispose to development of shoulder dystocia are related to either a macrosomic fetus or a contracted pelvis. Importantly, however, approximately half of all shoulder dystocias occur with normal-weight fetuses and are unanticipated. Predisposing conditions include prepregnancy weight of greater than 180 lb, excessive maternal weight gain, a history of diabetes or abnormal glucose tolerance, advanced maternal age, or a postterm pregnancy.

The key to management of this condition is anticipation and preparation. Warning signs include a prolonged second stage of labor or use of a vacuum or forceps. When shoulder dystocia becomes apparent, a number of maneuvers can be used to disimpact the shoulder (Figure 20-12). The McRoberts maneuver is a time-honored and proven technique that is ideal in initial management (Gherman et al., 1997). It involves the flexion of the maternal thighs onto the abdomen, which increases the inlet diameter, straightens the lumbosacral lordosis, and removes the sacral prominence as a possible obstruction to delivery. This procedure is often done with suprapubic pressure to dislodge the offending shoulder from behind the maternal pubic symphysis. In contrast to suprapubic pressure, fundal pressure, which often serves to exacerbate the condition, should not be exerted. Other measures include the Woods

Figure 20-12 Shoulder dystocia. Release of the anterior shoulder from behind the pubic symphysis.

screw maneuver, an attempt to apply pressure to the back of the posterior shoulder to rotate the fetus, free the anterior shoulder, and attempt delivery obliquely. Alternately, delivery of the posterior arm can be attempted. Finally, as a measure of last resort, the Zavanelli maneuver, the cephalic replacement of the fetus followed by cesarean delivery, can be attempted.

Electronic Fetal Monitoring

Electronic fetal monitoring, developed at Yale University in the 1960s, was introduced into clinical practice in the early 1970s as an indirect measure of fetal oxygenation. EFM allowed the early detection of abnormal FHR patterns potentially associated with hypoxia and metabolic acidosis. Use of EFM has quickly become the standard of care for the management of high-risk pregnancies and a standard practice for low-risk pregnancies. In 2002, the National Center for Health Statistics estimated that approximately 85% of women in labor had EFM. When used, EFM is predictive of a good outcome but not accurate or predictive of a bad outcome. In other words the false-positive rate of EFM is high for predicting adverse fetal outcomes. Recognizing the limitations of this technology, the [ACOG \(2005\)](#) concurred that EFM appears to have no inherent benefit over auscultation properly performed in low-risk women. Furthermore, the [USPSTF \(1996\)](#) could not recommend its routine use for the management of low-risk deliveries.

The use of EFM is associated with an increase in the rate of surgical interventions (vacuum, forceps, cesarean delivery), increased cost, and possibly increased legal risk; however, it is not associated with a decrease in the incidence of cerebral palsy. If the monitoring is done internally, there is increased risk of uterine perforation and scalp abscess in the neonate.

The multiple reasons for EFM may be subdivided into maternal and fetal indications ([Table 20-22](#)). EFM is indicated mainly for the monitoring of high-risk patients in labor, as well as for abnormalities in structured intermittent auscultation and when inadequate staffing is available to maintain the protocol for intermittent auscultation.

Table 20-22 Indications for Electronic Fetal Monitoring

Maternal	Fetal
Hypertension	Premature rupture of membranes
Insulin-dependent diabetes	Abnormal presentation
Asthma	Prematurity
Other maternal diseases	Postdates pregnancy
Advanced maternal age	Oxytocin use
Epidural analgesia	Intrauterine growth restriction
Absence of prenatal care	Meconium
Multiple gestations	

INTERPRETATION OF FETAL HEART RATE RECORDINGS

A systematic approach in evaluation of FHR recordings is recommended to optimize interpretation. Studies have demonstrated poor reliability and consistency among various expert interpreters even in controlled settings. The initial recommendations in 1997 by a [National Institute of Child Health and Human Development \(NICHD\)](#) work group have been revised and updated by a 2008 work group cosponsored by the Society for Maternal-Fetal Medicine, in part to simplify and standardize FHR interpretation ([ACOG, 2009](#); [Macones et al., 2008](#)). Five features of the FHR that need to be assessed are baseline, variability, accelerations, decelerations and their subclassifications, and corresponding contractions. As of 2008, FHR recordings can be considered as belonging to one of three categories: normal (NICHD category I), indeterminate (category II), and abnormal (category III). *Normal* tracings are associated with a normal pH and fetal well-being, and current management should continue. *Indeterminate* tracings and *abnormal* tracings suggest the need for further evaluation and possible intervention. This evaluation may include vaginal examination, checking maternal vital signs, giving oxygen, changing maternal position, administering fluids, scalp stimulation, and determination of scalp pH measurement. An NICHD category II tracing represents a significant fraction of those encountered in clinical care and includes all tracings that do not belong in categories I and III. An abnormal (NICHD III) tracing usually indicates the need for the previous measures and consideration of expedited delivery.

Baseline Fetal Heart Rate

Normal baseline FHR ranges from 110 to 160 beats/min. A baseline change is interpreted as one that persists for 10 minutes or more and occurs between or in the absence of contractions. An FHR of less than 110 beats/min is considered *bradycardia*. FHR is a function of the autonomic nervous system. Whereas the vagus nerve provides an inhibitory affect, the sympathetic nervous system provides an excitatory influence. As the gestation advances, the vagal system gains dominance, resulting in a gradual decrease in the baseline. Stressful events such as hypoxia, uterine contractions, and head compression evoke a baroreceptor reflex, with resulting peripheral vasoconstriction and hypertension causing bradycardia. Stimulation of peripheral nerve receptors can cause acceleration of FHR ([Figure 20-13](#)). An FHR baseline greater than 160 beats/min is defined as *tachycardia*. This is seen with certain

Figure 20-13 Accelerations of the fetal heart rate above a baseline rate of 130 to 140 beats/min. Good variability is present.

maternal and fetal conditions, such as chorioamnionitis, maternal fever, and fetal tachyarrhythmias.

Variability of Fetal Heart Rate

The baseline FHR fluctuates constantly under normal conditions, described as its *variability*. This variability is often a good indicator of a healthy nervous system. Variability is the oscillation of the FHR around the baseline with amplitude of 6 to 25 beats/min. Variability reflects vagal efferent impulses only. Uncomplicated loss of variability is often caused by fetal quiescence (sleep state), CNS depressants (e.g., diazepam, morphine, magnesium sulfate), or parasympatholytic agents (e.g., atropine). The uncomplicated loss of variability is associated with no risk or minimal risk of acidosis and low Apgar scores. The presence of decreased variability in combination with late or severe variable deceleration is an ominous finding. Clinically, variability is one of the most important indicators of fetal well-being, and the majority of babies with good variability do well regardless of the presence of decelerations.

Recent guidelines do not recommend the use of or differentiation between short-term and long-term variability in the assessment of fetal well-being (NICHD, 2008). In the assessment of variability, the following categories are now recommended, reflecting the amplitude of the FHR tracing around the baseline (Figure 20-14):

- **Absent:** Amplitude range is undetectable.
- **Minimal:** Amplitude range is detectable, but 5 beats/min or less.
- **Moderate:** Amplitude is 6 to 25 beats/min.
- **Marked:** Amplitude range is greater than 25 beats/min.

Bradycardia

Bradycardia is defined as FHR less than 110 beats/min for at least 10 minutes. *Mild* bradycardia ranges between 100

and 110 beats/min. Mild bradycardia with normal variability is not associated with fetal acidosis and is considered reassuring. *Moderate* bradycardia of 80 to 100 beats/min is considered a nonreassuring pattern. Bradycardia less than 80 beats/min is considered ominous and is often a terminal event (Figure 20-15). There are numerous etiologies for fetal bradycardia (Table 20-23).

Tachycardia

Fetal tachycardia is defined as a baseline FHR of greater than 160 beats/min for at least 10 minutes. *Mild* tachycardia is a FHR of 160 to 180 beats/min; in *severe* tachycardia, the FHR is greater than 180 beats/min. Fetal tachycardia greater than 200 beats/min is usually caused by fetal tachyarrhythmia or rarely a congenital anomaly and seldom results from fetal hypoxia. There are numerous etiologies of fetal tachycardia (Table 20-24).

Accelerations

Accelerations are transitory increases in FHR associated with fetal movement, scalp or acoustic stimulation, and uterine contractions. Accelerations are considered reassuring and are associated with fetal well-being. Accelerations form the basis of a reactive NST, defined as the presence of two or more accelerations of 15 beats/min above baseline for at least 15 seconds (see Figure 20-13).

Early Decelerations

Early decelerations are caused by a vagal response to fetal head compression resulting in a slowing of FHR. These decelerations have a smooth, uniform shape that is a mirror image of the corresponding contraction. They begin with the onset of a contraction, nadir at the peak of the contraction, and promptly return to baseline. Early decelerations are considered reassuring and are associated with a good outcome.

Variable Decelerations

Variable decelerations are characterized by an acute fall in FHR with a rapid down slope and a variable recovery. These have variable shapes, at times described as being “v,” “u,” or “w” (Figure 20-16). They also have a variable relationship with contractions. Variable decelerations may be classified according to their depth and duration as *mild* when the depth is greater than 80 beats/min and duration less than 30 seconds. Variable decelerations are considered *moderate* when the depth is 70 to 80 beats/min and duration is 30 to 60 seconds. Variable decelerations are *severe* when the depth is less than 70 beats/min and duration longer than 60 seconds.

Variable decelerations are the most commonly encountered pattern, occurring in 50% to 80% of all deliveries. They are almost always caused by umbilical cord compression. Variable decelerations are noted to be common with nuchal cord, a short or prolapsed cord, or when the membranes have been ruptured. Segments of FHR accelerations just before and after the variable deceleration (shoulders) indicate a healthy response.

Late Decelerations

Late decelerations are consistent with NICHD category III, abnormal FHR tracing, and are associated with uteroplacental insufficiency. These are provoked by uterine contractions and are associated with decrease in uterine blood flow or placental dysfunction. A late deceleration is a symmetric, gradual fall in FHR beginning at or after the contraction peak, with a slow return to baseline only after the contraction has passed (Figure 20-17). Postdate gestation, preeclampsia, chronic hypertension, and diabetes mellitus are among the many causes of placental dysfunction. The management of late decelerations include turning the patient on her side to physiologically increase cardiac output and uterine blood flow, administering IV fluids to correct hypotension, discontinuing oxytocin infusion, and administering oxygen.

Sinusoidal Patterns

Sinusoidal patterns are rare but particularly ominous, belong to the NICHD category III, and are associated with a high rate of fetal morbidity and mortality.

Figure 20-17 Late deceleration of fetal heart rate.

Sinusoidal patterns are characterized by a smooth, undulating, sine-wave pattern of 2 to 5 cycles/min and amplitude of 5 to 15 beats/min, with a notable absence of variability (Figure 20-18). They occur with fetal anemia or severe hypoxia and need to be differentiated from a “pseudosinusoidal” pattern, which is a benign, uniform variability pattern with the preservation of beat-to-beat variability. Sinusoidal patterns are often ominous but are occasionally seen after the administration of narcotics to the mother.

CONTRACTIONS

Contractions are classified as *normal* (no more than five contractions in a 10-minute period) or *tachysystole* (more than five contractions in a 10-minute period, averaged over a 30-minute window). The term *hyperstimulation* is no longer accepted and should be discontinued. Tachysystole is qualified by the presence or absence of decelerations, and it applies to both spontaneous and stimulated labor.

EVIDENCE-BASED SUMMARY

- The false-positive rate of EFM for predicting adverse outcomes is high (SOR: A).
- The use of EFM is associated with an increase in the rate of surgical interventions (SOR: A).
- Compared with structured intermittent auscultation, continuous EFM shows no difference in overall neonatal mortality (SOR: A).
- Continuous EFM reduces neonatal seizure rates (SOR: A).
- Fetal pulse oximetry has not shown a reduction in cesarean delivery rates (SOR: A).
- The use of EFM does not result in a reduction of cerebral palsy rates (SOR: A).
- The labor of women with high-risk conditions should be monitored continuously (SOR: B).
- Reinterpretation of the FHR tracing, especially knowing the neonatal outcome, is not reliable (SOR: B).
- The use of fetal pulse oximetry in clinical practice cannot be supported at this time (SOR: B) (East et al., 2007).

Figure 20-18 Sinusoidal fetal heart rate pattern.

Vaginal Birth after Cesarean Section

A trial of vaginal birth after a previous cesarean delivery (VBAC) is an accepted method of delivery for most women with a prior low-transverse cesarean delivery. Factors that increase morbidity in VBAC should be understood so that practical decisions can be made regarding the best route of delivery for each patient. The [ACOG \(2004\)](#) suggests the following criteria for selection of appropriate candidates: one previous cesarean delivery, adequate pelvis, no uterine scars, and immediate availability of both a physician to perform an emergency cesarean delivery and facilities and anesthesia to support an immediate cesarean delivery. Use of PG cervical ripening is discouraged in these women because of the small increased risk of uterine rupture associated with these medications when used with a scarred uterus.

The [AAFP \(2005\)](#) reviewed a trial of labor after cesarean (TOLAC) and compared TOLAC with elective repeat cesarean section (ERCS) and formulated the following recommendations:

- Most women with one previous cesarean delivery with a low-transverse incision are candidates for VBAC and should be counseled about VBAC and offered a trial of labor; epidural anesthesia may be used for VBAC (SOR: A).
- Women with a vertical incision within the lower uterine segment that does not extend into the fundus are candidates for VBAC (limited or inconsistent scientific evidence; SOR: B).
- The use of PGs for cervical ripening or induction of labor in most women with a previous cesarean delivery should be discouraged. Because uterine rupture may be catastrophic, VBAC should be attempted in institutions equipped to respond to emergencies with physicians immediately available to provide emergency care. After thorough counseling that weighs the individual benefits

and risks of VBAC, the ultimate decision to attempt this procedure or undergo a repeat cesarean delivery should be made by the patient and her physician. This discussion should be documented in the medical record. VBAC is contraindicated in women with a previous classic uterine incision or extensive transfundal uterine surgery (primarily consensus and expert opinion; SOR: C).

After careful patient selection, preparation, and management, seven or eight of 10 women with uterine scars deliver vaginally. The strongest predictor of the safety of VBAC is the location of the previous uterine scar. Safety of TOLAC in women with history of one cervical low-transverse cesarean has been documented. Rupture of these incisions is low at 0.5% ([Pridjian, 1992](#)). Information is insufficient to determine whether TOLAC is safe for VBAC candidates with two or more prior low-transverse cesarean sections, previous low-vertical incision, multiple gestation, breech presentation, or suspected macrosomia.

Oxytocin use and epidural anesthesia are not contraindicated in women attempting VBAC, although they should be used cautiously in this setting. An internal uterine pressure monitor is recommended when labor is enhanced or induced medically. The most common signs and symptoms of uterine rupture are fetal decelerations and distress, heavy vaginal bleeding, decreasing station or complete loss of the presenting part, loss of contraction intensity as documented by internal pressure monitor, uterine or pelvic pain in between contractions, and bloody urine.

Women who are most likely to have a successful VBAC are younger than 40 years old, have had one prior cesarean delivery, undergo spontaneous labor, have a baby weighing no more than 4000 g, and had a prior cesarean section that was not for failure to progress or CPD in the active phase of labor. Based on the available data, the overall outcomes from TOLAC and ERCS are so similar that the two birthing methods appear medically equivalent. As a consequence, women's preferences for the method of delivery must be

explored and respected throughout pregnancy and during the delivery process. Women should be encouraged to undergo a TOLAC, but they should also have the opportunity to weigh the potential harms and benefits of TOLAC versus ERCS. A decision to have a cesarean delivery should be supported.

EVIDENCE-BASED SUMMARY

- Most women with one previous cesarean delivery with a low-transverse incision are candidates for VBAC and should be counseled about VBAC and offered a trial of labor (SOR: A).
- Epidural anesthesia may be used for VBAC (SOR: A).
- Women with a vertical incision within the lower uterine segment that does not extend into the fundus are candidates for VBAC (SOR: B).
- The use of misoprostol in women with prior cesarean delivery or major uterine surgery has been associated with an increase in uterine rupture and therefore should be avoided in the third trimester (SOR: A).
- After thorough counseling about benefits and risks of VBAC, the decision to attempt this procedure or undergo a repeat cesarean delivery should be made by the patient and her physician (SOR: C).
- VBAC is contraindicated in women with a previous classic uterine incision or extensive transfundal uterine surgery (SOR: C).

Intrapartum Procedures

OBSTETRIC ANESTHESIA

At present, many pregnant women are choosing to receive analgesia to relieve the pain of childbirth through several methods. More than 50% of women in labor are reported to choose intrapartum epidural analgesia at many U.S. institutions. This probably reflects changing societal expectations and increasing participation in the birth process on the part of both anesthesiologists and certified registered nurse anesthetists.

Pain during the first stage of labor is attributable to uterine contractions and cervical dilation. Afferent impulses from the cervix and uterus are transmitted to the spinal cord via the tenth thoracic to first lumbar (T10-L1) segments. Pain is conducted along the paracervical and inferior hypogastric plexus. During the second stage, pain also occurs from distention and stretching of pelvic structures and the perineum. Second-stage pain is principally somatic in nature and is transmitted through the spinal second to fourth sacral (S2-S4) segments.

Therapeutic modalities to manage the pain of childbirth include systemic narcotics, local anesthesia, and psychological methods (Howell, 2000). Systemic narcotics used to manage pain during labor include meperidine (Demerol, 25 mg IM or IV) and nalbuphine (Nubain, 10 mg IV). Narcotics should be avoided at or near delivery because they can cause nausea, vomiting, decreased gastric motility, and respiratory depression and can interfere with the mother's ability to concentrate and cooperate. Fetal effects include

respiratory and CNS depression and temperature instability. Naloxone (0.01 mg/kg) can be administered to depressed newborn as an IV bolus for counteracting the effect of narcotics.

A pudendal block provides analgesia to the vaginal introitus and perineum. Usually done in the second stage of labor, 5 mL of 1% lidocaine is injected into the pudendal canal, the location of the pudendal nerves and vessels. Care is taken to aspirate for blood before instilling the anesthetic solution. It takes approximately 10 minutes for anesthesia to establish. Infection at the injection site, intravascular injection, and maternal overdose are the major potential complications.

Neuraxial or epidural analgesia is popular among both physicians and patients (Vincent and Chestnut, 1998). The anesthesiologist's goal for epidural analgesia during the first stage of labor is to provide segmental sensory anesthesia of the T10 to L1 dermatomes. The dose of anesthetic necessary to achieve effective labor analgesia will depend on the intensity and location of the patient's pain. These in turn depend on the amount and rate of cervical dilation; the strength, frequency, and duration of uterine contractions; and the position of the fetal head at the time epidural analgesia is placed. Typically, bupivacaine (Marcaine) or ropivacaine (Naropin), with or without a small dose of a lipid-soluble opioid such as fentanyl (Sublimaze) or sufentanil (Sufenta), establishes effective analgesia with minimal motor block. Maintenance of epidural analgesia may be achieved with intermittent bolus injections, continuous infusion, or patient-controlled dosing frequency.

Although epidural analgesia provides superior pain relief during labor, much controversy surrounds its drawbacks. These include the increased duration of labor, increased need for oxytocin augmentation, and increased rate of cesarean section for failure to progress. The most common complications, however, are maternal hypotension and headache from inadvertent puncture of the dura.

Contraindications to epidural analgesia include patient refusal, active maternal hemorrhage, maternal septicemia or untreated febrile illness, infection at or near needle insertion site, and maternal coagulopathy.

Psychological methods of pain relief include Lamaze, natural-childbirth methods, acupuncture, biofeedback, and self-hypnosis. These techniques are useful in decreasing maternal anxiety and may reduce the amount of analgesia needed.

EPISIOTOMY

An episiotomy is a surgical incision in the perineum to enlarge the introitus at delivery. Episiotomy is one of the most common medical procedures performed in the United States. There are two types of episiotomies (Figure 20-19). The midline or *median* episiotomy is the most common in the United States. It involves an incision from the posterior aspect of the vagina downward, directly toward the anus, approximately half the length of the perineum. The *mediolateral* episiotomy is a diagonal incision toward either side of the midline that is done to prevent tearing into the rectum. The mediolateral incision may serve to decrease the incidence of third- and fourth-degree extensions but is more difficult to repair and is associated with more blood

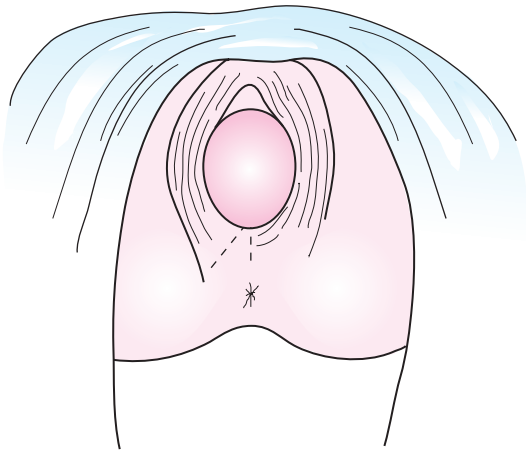

Figure 20-19 Crowning fetal head distending the perineal tissues. Broken lines depict the location of the incision for a midline (median) or mediolateral episiotomy.

Table 20-25 Categories of Perineal and Vaginal Lacerations

First degree	Confined to the superficial skin or mucosa; repair usually not required unless extensive or bleeding
Second degree	Involves the mucosa and deeper tissues of the vagina and perineum
Third degree	Involves the anal sphincter
Fourth degree	Involves the rectal mucosa and usually transects the anal sphincter

loss, pain, slow healing, and dyspareunia. It is performed when the fetal head is crowning 3 to 4 cm. An average incision extends 5 to 6 cm into the vagina. Lacerations and extensions of episiotomies are described according to the extent of tissue involvement (Table 20-25).

Historically, episiotomies were performed for a number of indications. These include the substitution of an anticipated ragged spontaneous laceration for a more controlled straight surgical incision, reduction in the second stage of a labor, and reduction in subsequent pelvic relaxation and trauma to pelvic musculature.

The literature since 1980 does not substantiate the alleged benefits of episiotomy (Argentine Episiotomy Trial Collaborative Group, 1993), as supported by more recent review by the Agency for Healthcare Research and Quality (Viswanathan et al., 2005). The reputed long- and short-term benefits have not been substantiated. Episiotomy is used in approximately one third of vaginal deliveries to hasten birth and prevent tearing of the perineum during delivery, but in fact it fails to accomplish any of the other maternal or fetal benefits traditionally ascribed to it (Klein, 1995). Episiotomies fail to prevent perineal damage, pelvic floor relaxation, reduction of the second stage of labor, and protection of the newborn from either intracranial hemorrhage or intrapartum asphyxia (Klein, 1995). Also, episiotomy does not protect women against urinary or fecal incontinence, pelvic organ prolapse, or difficulties in sexual function in the first 3 months to 5 years after delivery. Furthermore, in primigravid women, episiotomy appears to be causally associated with third- and fourth-degree lacerations.

In summary, episiotomy is an unproven, controversial surgical procedure best restricted to specific fetal and maternal indications. Most data do not support its routine application, making its use a decision best left to the individual physician and patient (Sleep et al., 1984).

The repair of an episiotomy should be approached with standard surgical principles. After appropriate positioning of the patient and with adequate lighting, the practitioner should determine the extent of the wound. Efforts should be made to assess the adequacy of the anesthesia. Sites of uncontrolled bleeding should be identified and hemostasis ensured. In the repair, the practitioner should aim to use the least amount of suture material possible and achieve wound approximation without dead space. Several techniques of repair are accepted. Typically, an anchoring, hemostatic stitch of an absorbable or delayed-absorbable material such as 2-0 chromic catgut or polyglycolic acid is placed at the apex of the vaginal incision, and the vaginal mucosa is approximated in a continuous interlocking fashion to the hymenal ring (Figure 20-20, A). Polyglycolic acid sutures may be superior to chromium catgut for episiotomy suturing. Compared with surgical repair using catgut or chromic suture, repair using 3-0 polyglactin 910 (Vicryl) suture results in decreased wound dehiscence and less postpartum perineal pain. This suture can then be tied or brought through to repair the deep layer of the perineum (Figure 20-20, B). The deep perineal tissues are then approximated with interrupted or continuous stitches in the muscle and fascia. Finally, the skin is approximated with a subcuticular stitch, knotted, and buried inside the vagina above the hymenal ring (Figure 20-20, C).

DIAGNOSTIC ULTRASONOGRAPHY

Ultrasonographic examination with the appropriate indication is a skill that enhances the diagnostic and therapeutic capabilities of family physicians who practice obstetrics. Even physicians who do not deliver babies are faced with clinical questions for which diagnostic ultrasonography is indicated. Studies do not support the routine use of ultrasonography in low-risk prenatal care; however, societal expectations and the relative ease of access to this technology have made it an established aspect of obstetric care. The Radius study group evaluated the use of screening ultrasonography in 15,151 low-risk pregnancies and found no difference in perinatal mortality, birth weight, or preterm birth. The study did not evaluate its use in high-risk pregnancy (Bernard et al., 1993).

Obstetric ultrasonography has numerous indications and benefits in prenatal care (Table 20-26). Benefits include estimation of fetal age through biometry (accurate to within 1 week before 20 weeks, ± 2 weeks at 20-28 weeks, and ± 4 weeks after 28 weeks). In the hands of an experienced ultrasonographer, the gestational sac size or the crown-rump length has proved a reliable measure of gestational age (Figure 20-21). Again, early ultrasonography may provide more accurate dating, which is important for timing screening tests and interventions and for optimal management of complications such as postterm pregnancies (Neilson, 2004). Prenatal diagnosis and evaluation of fetal anomalies, growth anomalies (e.g., size vs. date discrepancies), fetal assessment (e.g., BPP, confirmation of

fetal demise), maternal factors (e.g., diagnosis of ectopic pregnancy), and uterine anomalies are other indications and benefits.

The overuse or recreational use of ultrasound technology may pose a medical-legal risk, particularly in the hands of an inexperienced provider.

OPERATIVE VAGINAL DELIVERIES

Safe reduction of the rate of primary cesarean deliveries can be achieved by adjustments on how we manage labor and the threshold for intervention. For example, it may be necessary to revisit the definition of labor dystocia because recent data show that contemporary labor progresses at a

Figure 20-21 The crown–rump length (CRL) is denoted by crosses. Care should be taken to view the entire fetus in the midsagittal plane so as not to undermeasure. Conversely, the yolk sac is not a part of the CRL, so its inclusion will falsely increase the measurement.

rate that is substantially slower than what was historically taught. Additionally, improved and standardized FHR interpretation and management may have an effect. Increasing women's access to nonmedical interventions during labor, such as continuous labor and delivery support, also has been shown to reduce cesarean birth rates. External cephalic version for breech presentation and a trial of labor for women with twin gestations when the first twin is in cephalic presentation are other of several examples of interventions that can contribute to the safe lowering of the primary cesarean delivery rate.

Indications for operative vaginal delivery in a low-risk mother are nonreassuring FHR, maternal exhaustion, and prolonged second stage, which is generally 3 hours for a nulliparous woman and 2 hours for a parous woman.

Essential for safe operative vaginal delivery is optimal readiness. The laboring woman should understand the reasons why operative delivery has been chosen, with documentation in the chart. She should then be placed in a position in which her legs are maximally open, preferably in stirrups, with the perineum at the edge of the bed. Usual washing and draping are performed. The bladder is emptied. Adequate anesthesia makes placement of instruments easier and improves maternal cooperation. Pudendal block is often adequate for procedures when the fetal head is at the outlet. However, conduction anesthesia is often used. The cervix should be completely dilated and the membranes ruptured. Station, position, and attitude of the fetal head should be known. The fetal head should be engaged. Palpation, maternal sensation, or contraction monitoring can help identify the timing of contractions. Facilities for cesarean section should be available. Decision to use forceps or vacuum is based on operator skill; availability of instruments; and fetal-maternal considerations, including pelvic shape and size, fetal head position, and availability of anesthesia.

FORCEPS DELIVERY

Currently, forceps deliveries are divided into outlet, low, mid, and high forceps, determined by the station of the fetal head. In an *outlet* forceps delivery, the fetal head has reached the pelvic floor and is seen at the introitus without separating the labia. The fetal head may be right, left, or straight occiput anterior or posterior, and delivery is accomplished without rotation of greater than 45 degrees. A *low* forceps delivery is one in which the fetal head is at least +2 cm (on a 0 to +5 cm scale of station) but not on the pelvic floor. Rotation may be greater than or less than 45 degrees. A *mid* forceps delivery occurs when the head is engaged but less than +2 cm station. A *high* forceps delivery, when the fetal head is unengaged, is no longer performed in modern obstetrics.

The choice of forceps to use is based on the operator's training and the type of forceps delivery. Typically, Simpson (or Simpson-DeLee) or Elliot forceps are used for low and outlet deliveries. After requirements for operative vaginal deliveries are met, the operator faces the maternal perineum with forceps held in the position desired. The left blade is generally placed first. The operator's right hand is fitted between the fetal head and the left vaginal side wall, and the left blade is placed by holding the handle at 12 o'clock and rotating counterclockwise as the blade slips between the fetal head and the operator's right hand. After adequate placement, the majority of the blade is no longer visible. In a similar fashion, the operator's left hand then aids in placement of the right blade. When properly placed, the handles should come together easily. Appropriate placement is then ascertained. The sagittal suture should be equidistant from both blades and perpendicular to the shanks, with the posterior fontanelle exactly between the two blades. The posterior fontanelle should be palpable about 1 fingerbreadth above the interdigitated shanks. Failure to apply the forceps symmetrically will increase risk of injury and failure of the technique.

Holding the handles together with moderate pressure, the operator rotates the fetal head if needed so that the

Figure 20-22 Outlet forceps delivery. The direction of traction is first downward so that the fetal head negotiates the pubic symphysis and then upward to deliver in extension.

occiput is directly anterior or posterior (sagittal suture is perpendicular to the floor). This rotation should be done during uterine muscle relaxation just before a contraction. A mild degree of flexion of the fetal head during rotation will make rotation easier. With a contraction and additional expulsive forces from the mother, the operator applies traction. Traction direction should be guided by the maternal pelvis. Initial traction is downward (toward the floor) until the fetal head clears the symphysis pubis. Then traction is directed more upward as the fetal head delivers with extension (Figure 20-22). Although in some cases early episiotomy is beneficial to forceps delivery, most often episiotomy should be cut if needed when the fetal head is bulging the perineal tissues. In many cases, removal of the forceps at this time will preclude the need for episiotomy. Removal of the forceps before delivery of the head should be in the opposite direction and order of placement. Maternal expulsive forces during a contraction can then often deliver the remainder of the fetal head. The vagina and cervix should be carefully inspected for lacerations.

VACUUM EXTRACTION

Vacuum extractors currently in widespread use in the United States are those with a soft cup made of silicone or plastic. They are smaller and more flexible than the classic Malstrom metal cup. Vacuum can be easily applied. Although these cups tend to dislodge somewhat more frequently than the Malstrom metal cup, less scalp trauma is noted with their use. Often, vacuum delivery can be performed with little to no anesthesia. However, requirements of operative vaginal delivery still apply. For the best results, the vacuum cup should be placed over the sagittal suture about 3 cm from the posterior fontanelle. This can be difficult in fetal heads descending with asynclitism (lateral deflection). After placement of the cup, an examining finger is used to ascertain that no cervical, vaginal, or perineal tissue is trapped in the cup. With a contraction, after adequate vacuum is generated, downward and then upward traction should be applied to the fetal head (Figure 20-23). The fetal head should be allowed to rotate if needed during descent. Forceful rotation of the fetal head using the suction

Figure 20-23 Vacuum extraction with J-shaped direction of traction, similar to forceps delivery.

cup is generally not recommended because of the increased risk of scalp injury. Removal of the cup is easily accomplished after suction is discontinued. The cervix and vagina should be examined carefully for lacerations.

The Puerperium

The postpartum period, or puerperium, is the time during which the mother's altered anatomy, physiology, and biochemistry return to the nonpregnant state. This process has its onset at the third stage of labor and is completed 6 weeks after delivery. These changes are normal and should not be confused with a pathologic condition. The woman undergoes physiologic and emotional changes that need to be monitored by her primary care physician.

Within the first 24 hours, the mother's pulse rate drops, and her temperature may be slightly elevated. Generally, the white blood cell count increases during labor, with a marked leukocytosis (to 20,000/ μ L) occurring in the first 24 hours postpartum. The vaginal discharge is grossly bloody (lochia rubra) for the first 3 or 4 days. During the next few to 10 days, the lochia becomes more serous and pinkish brown and decreases in amount (lochia serosa). Finally, 7 to 10 days postpartum, the lochia becomes pale yellow–white and decreases even more in volume. Urine output temporarily increases and might contain protein and sugar, reflecting a maternal diuresis. This loss of fluid with the accompanying decrease in intravascular volume artificially elevates the hematocrit for a few days. The uterus involutes progressively; after 5 to 7 days, it should be firm and nontender, extending midway between the symphysis and umbilicus. By 2 weeks, the uterus should no longer be palpable abdominally. Contractions of the involuting uterus are often painful and can require analgesics. Care should be exercised in choice of analgesia so as not to interfere with the maternal–infant bond or breastfeeding.

The mother is observed for 1 hour after completing the third stage of labor and given periodic uterine massage to make sure that the uterus contracts and remains contracted, preventing excess bleeding. If desired, breastfeeding can be initiated at this stage to promote uterine contraction, minimize bleeding, and promote involution of the uterus. If the uterus does not remain contracted with massage alone, oxytocin can be administered, either 10

units IM or dilute oxytocin with IV drip (10 or 30 U/1000 mL of IV fluid) at 125 to 200 mL/hr for 1 to 2 hours. Recent trends in the active management of labor encourage the administration of oxytocin before delivery of the placenta. This has been found to promote the delivery of the placenta and decrease the incidence of uterine atony and postpartum hemorrhage (PPH) (Prendiville et al., 2000). If general anesthesia was used for operative delivery, the mother is monitored (preferably in a recovery room or a labor, delivery, recovery, and postpartum room); oxygen and blood are tested for compatibility, and IV fluids must be readily available after delivery.

After the first 24 hours, postpartum recovery is rapid. A regular diet after a normal vaginal delivery can be offered as soon as the patient requests food. Full ambulation is encouraged as soon as possible. Showers can be encouraged, but vaginal douching is prohibited during the early postpartum period. Discomfort from an episiotomy can be relieved with hot sitz baths several times a day and analgesia. Drugs may be offered for pain as necessary but should be limited in breastfeeding mothers because most drugs are secreted in breast milk. Meperidine (Demerol) is not the preferred analgesic for use in breastfeeding women because of the long half-life of its metabolite in infants. Repeated exposure to analgesics, especially meperidine, can result in drug accumulation and toxic effects in young or compromised infants because of their underdeveloped hepatic conjugation.

Bladder care is important. Urine retention, bladder overdistention, and catheterization should be avoided if possible. Rapid diuresis can occur, especially when oxytocin is discontinued. The woman must be encouraged to void and must be monitored to prevent asymptomatic bladder overfilling. The woman should be encouraged to defecate before leaving the hospital, although with early discharge, women often leave before a bowel movement has occurred. Laxatives may be needed for constipation. If a bowel movement has not occurred within 3 days, a mild cathartic may be given. Hemorrhoids can be minimized by maintaining an appropriate diet and good bowel function and can be treated with warm sitz baths. Regional anesthesia (spinal or epidural) delays ambulation and can delay spontaneous urination. Catheterization is recommended if significant urine output is not achieved by 12 hours and a distended bladder is apparent.

A CBC should be performed before discharge to verify that the woman is not significantly anemic. Women who have been determined to be seronegative should be immunized against rubella on the day of discharge. If the woman has Rh-negative blood, is not sensitized, and has an infant with Rh-positive blood, she should be given Rh₀D immune globulin 300 μ g within 72 hours of delivery to prevent sensitization.

Rh(D) blood typing and antibody testing are strongly recommended for all pregnant women during their first visit for pregnancy-related care. The USPSTF found good evidence that Rh(D) blood typing, anti-Rh(D) antibody testing, and intervention with Rh(D) immunoglobulin are appropriate, prevent maternal sensitization, and improve outcomes for newborns. The USPSTF found good evidence that Rh(D) blood typing, anti-Rh(D) antibody testing, and intervention with Rh(D) immunoglobulin, as appropriate, prevents maternal sensitization and improves outcomes for

newborns. The benefits substantially outweigh any potential harms (USPSTF, 1996).

The breasts might become painfully engorged during early lactation, when the amount of milk is beginning to increase. If the mother is not going to breastfeed, lactation can be suppressed by firmly supporting the breasts because gravity stimulates the letdown reflex and encourages milk flow. Many mothers find that tight binding of the breasts and restriction of oral fluid intake followed by firm support are effective, with symptoms lasting only 3 to 5 days.

The postpartum period can be complicated by the “baby blues,” a common, self-limited mood disorder. This is characterized by mild depressive symptoms, tearfulness (often for no discernible reason), anxiety, irritability, mood lability, increased sensitivity, and fatigue. The “blues” typically peak 4 to 5 days after delivery, can last hours to days, and usually resolve by the 10th postnatal day.

The “blues” is distinct from postpartum major depression, which occurs in approximately 10% of childbearing women (O’Hara et al., 1990). It can begin from 24 hours to several months after delivery. Its onset can be abrupt and symptoms severe, and it can be associated with a lack of interest in the infant, suicidal or homicidal thoughts, hallucinations, or psychotic behavior. True psychosis probably reflects the exacerbation of preexisting mental illness in response to the physical and psychological stress of pregnancy and delivery. Psychotherapy or pharmacotherapy is indicated, alone or in combination. Selective serotonin reuptake inhibitors may be associated with congenital heart anomalies and should be used with caution in pregnancy. All women should be routinely assessed during the antenatal period for a history of depression.

Prevention of pregnancy for several months to allow complete recovery is in the woman’s best interest. *Rubella immunization mandates a delay of 3 months before a woman becomes pregnant.* Therefore, although intercourse may be resumed as soon as desired and comfortable, contraception is required because pregnancy is possible. Oral contraceptives may be started at discharge. A low-dose estrogen or progesterone-only preparation is desirable. A diaphragm should be fitted only after complete involution of the uterus at 6 to 8 weeks; meanwhile, foams, jellies, and condoms may be used. In mothers who are not breastfeeding, earliest ovulation usually occurs about 4 weeks postpartum, 2 weeks before the first menses. However, conception has been reported as early as 2 weeks postpartum, so ovulation can occur earlier. Breastfeeding mothers tend to ovulate and then menstruate, usually at 10 to 12 weeks postpartum. The duration of anovulation is influenced by the frequency of breastfeeding, the duration of feedings, and the proportions of supplemental feeding.

Postpartum Hemorrhage

Traditionally, PPH was defined as blood loss greater than 500 mL in a vaginal delivery and greater than 1000 mL in a cesarean delivery. However, studies have revealed that an uncomplicated delivery often results in blood loss of more than 500 mL without any compromise of the mother’s condition (Pritchard et al., 1962). Clinically, these findings led some authors to adopt a broader definition for PPH. Any bleeding that results in signs and symptoms of

hemodynamic instability or bleeding that could result in hemodynamic instability if untreated is considered PPH. The loss of these amounts within 24 hours of delivery is termed *early* or *primary* PPH, and such losses are termed *late* or *secondary* PPH if they occur 24 hours after delivery or later. This section focuses primarily on early PPH.

The most common causes of PPH are uterine atony and lacerations of the vagina and cervix. Other causes include retained placental fragments, lower genital tract lacerations, uterine rupture or inversion, placenta accreta, and hereditary coagulopathy. Causes of late PPH (24 hours to 6 weeks after delivery) include infection, placental site subinvolvement, retained placental fragments, and hereditary coagulopathy (ACOG, 1998a).

Risk factors for uterine atony include uterine overdistention secondary to hydramnios, multiple gestation, use of oxytocin, fetal macrosomia, high parity, rapid or prolonged labor, intraamniotic infection, and use of uterine-relaxing agents (Combs et al., 1991). Uterine rupture occurs in approximately one in 2000 deliveries. Previous uterine surgery is a significant risk factor for uterine rupture, placenta accreta, and PPH. Other risk factors include obstructed labor, multiple gestations, abnormal fetal lie, and high parity.

Risk factors for hemorrhage at the time of cesarean delivery include preeclampsia, disorders of active labor, a history of previous hemorrhage, obesity, use of general anesthesia, and intraamniotic infection.

Adequate intravascular access should be obtained in women who have significant risk factors for PPH. Active management of the third stage of labor has been shown to decrease the incidence of PPH. Early administration of oxytocin, early cord cutting and clamping, and controlled cord traction have been shown to decrease PPH by two thirds (Soriano et al., 1996).

In the event of hemorrhage, supplemental oxygen should be administered to enhance cellular oxygen delivery. Heart rate and BP should be monitored closely. Initial laboratory evaluation includes a CBC with platelet concentration. Blood type and crossmatch should be performed if not previously obtained. Fibrinogen, fibrin split products, prothrombin time, and partial thromboplastin time should be measured (ACOG, 1998a).

Excessive vaginal bleeding after placental delivery should prompt vigorous fundal massage while the patient is rapidly given 10 to 30 units of oxytocin in 1 L of IV fluid. If the fundus does not become firm, uterine atony is the presumed (and most common) diagnosis. Uterine atony should be initially managed by bimanual uterine massage and compression in addition to the oxytocin. If IV or IM oxytocin proves ineffective, other uterotonic agents, such as methylergonovine and PG derivatives (15-methyl PGF₂α), may be used as second-line treatment (ACOG, 1998a). Methylergonovine may be administered at 0.2 mg IM every 2 to 4 hours. Methylergonovine can cause cramping, headache, and dizziness. This agent is contraindicated in hypertensive disease states because it induces vasoconstriction, which can lead to severe hypertension.

15-Methyl PGF₂α (Hemabate), may be given in a dose of 0.25 mg IM every 15 to 90 minutes (no more than eight doses). PGF₂α may also be given by intramyometrial injection at cesarean delivery or transabdominally after vaginal delivery. PGE₂ can cause vasodilation and

exacerbation of hypotension; therefore, 15-methyl PGF₂α is preferred. Because oxygen desaturation has been reported with use of PGF₂α, patients should be monitored by pulse oximetry.

Continuing hemorrhage in a patient with a firm uterine fundus can indicate a hidden vaginal or cervical laceration. This type of injury is usually easy to identify and repair with adequate lighting, exposure, and assistance. If no laceration is present and the fundus is firm, the uterus requires gentle but thorough manual exploration for retained placenta, which should be removed. Uterine rupture is occasionally evident and requires immediate surgery.

An occult uterine inversion might also be discovered on vaginal examination, or it can manifest frankly. Uterine inversion is somewhat more common in primiparas and has no clear association with the mismanagement of labor. Because uterine inversion can quickly lead to shock, the physician should order brisk IV hydration and grasp the uterus in the palm, with the thumb anterior. The uterus is then firmly pushed back up into the abdominal cavity and held in place for several minutes (Brar et al., 1989). Magnesium sulfate, 0.25 mg IV, has been reported to assist in the repositioning of the uterus (Catanzarite et al., 1986).

If uterine and vaginal exploration is nondiagnostic, uterine inversion is excluded, and the fundus is firm, rarer causes of hemorrhage should be considered. Puerperal hematomas typically cause a vulvar or vaginal mass, and an occult retroperitoneal hematoma can manifest with severe abdominal pain and shock after delivery. The diagnosis is confirmed on laparotomy. Visible hematomas smaller than 4 cm and not expanding may be managed with ice packs and observation. Larger or expanding hematomas must be incised, irrigated, and packed, and any obvious bleeding vessels must be ligated. If venipuncture sites are oozing, coagulopathy should be considered.

Surgical intervention is undertaken for direct indications, such as uterine curettage for suspected retained placental tissue or for hemostasis if medical therapy fails. The most common indications for emergency hysterectomy include uterine atony, placenta accreta, uterine rupture, and the extension of a low-transverse uterine incision.

KEY TREATMENT

- Uterotonic agents should be the first-line treatment for PPH caused by uterine atony (SOR: C).
- Management of PPH may vary greatly among patients, depending on the etiology and available treatment options, and often a multidisciplinary approach is required (SOR: C).
- When uterotonics fail after vaginal delivery, exploratory laparotomy is the next step (SOR: C).
- In the presence of conditions known to be associated with placenta accreta, the obstetric care provider must have a high clinical suspicion and take appropriate precautions (SOR: C).

Care of the Newborn

SHERIN E. WESLEY, ERIN ALLEN, and HEATHER BARTSCH

CHAPTER OUTLINE

Care at Delivery, 411

Care in the Newborn Nursery, 416

Care at the Primary Care Office, 425

Parental Education and Anticipatory Guidance, 426

The birth of a child is an exciting and, at times, overwhelming experience for parents. Family physicians are in a unique position because they have the opportunity to care for both the expectant mother and the newborn. They are able to provide anticipatory guidance to the mother early in the pregnancy and continued support after delivery of the newborn. They are familiar with the details of the mother's pregnancy and delivery as well as the family environment that the newborn will enter. The physician will have established rapport with the expectant parents, which will be useful when giving advice in the care of the newborn. In a world where health care is increasingly fragmented, parents will be relieved to know their doctor can provide comprehensive and integrated medical care to all family members.

Care at Delivery

Key Points

- For most infants, the transition to the extrauterine environment involves little resuscitation. Infants who are premature, born via cesarean section, or have congenital anomalies may have difficulty transitioning and have increased resuscitation needs.
- Airway, breathing, and circulation are the key principles of neonatal resuscitation.
- A term, vigorous infant is one who is breathing and crying at birth with a strong respiratory effort, has a heart rate greater than 100 beats/min, and has good muscle tone.
- Fetal and maternal factors can predict a high-risk delivery where a practitioner trained in neonatal care and resuscitation should be present.
- Intramuscular vitamin K is administered to all newborns at birth to prevent hemorrhagic disease of the newborn.
- Erythromycin 0.5% ophthalmic ointment is applied to the eyes of all newborns to prevent gonococcal ophthalmia neonatorum.
- If a two-vessel umbilical cord is detected after birth, the infant should be carefully examined for syndromic features and anatomic abnormalities.

PHYSIOLOGIC TRANSITION

At birth, a newborn undergoes a rapid physiologic transition to the extrauterine environment. This transition is a complex interaction among multiple organ systems, including the cardiovascular, pulmonary, neurologic, and endocrine systems.

The placenta is responsible for oxygenation of fetal blood. The fetal circulation acts in parallel through three shunts: the ductus venosus, the ductus arteriosus, and the foramen ovale. [Figure 21-1](#) illustrates the fetal circulation. The umbilical vein returns oxygenated blood from the placenta to the liver of the fetus. A portion of the blood from the umbilical vein is shunted directly to the inferior vena cava away from the liver via the ductus venosus. From the inferior vena cava, oxygenated blood flows into the right atrium. Because the pressure in the right atrium is greater, most of this blood is shunted through the foramen ovale into the left atrium to be distributed to the brain and coronary arteries via the aorta. Blood returns from the head by way of the superior vena cava to the right atrium. It flows into the pulmonary artery from the right ventricle, and via the ductus arteriosus, most of this blood reenters the descending aorta, where it is distributed to the body and lower extremities. Deoxygenated blood containing waste products and carbon dioxide then leaves the fetus via the umbilical arteries to be disposed of by the mother.

As the neonate takes his or her first breath at delivery, pulmonary vascular resistance falls, pulmonary blood flow increases, and the oxygen saturation of the blood increases. Clearance of fetal lung fluid and surfactant production is important for the expansion of the lungs. Surfactant production, which begins at 24 to 28 weeks of gestation, decreases surface tension in the alveoli and allows for lung expansion. The mechanism and timing of the clearance of fetal lung fluid is not entirely understood. Previously, mechanical forces such as vaginal squeeze and Starling's forces were hypothesized to be the major factors in clearing fetal lung fluid ([Jain et al., 2006](#)). Studies have shown that clearance of fetal lung fluid is also dependent on termination of the chloride-mediated channels that secrete fluid and activation of the basal Na-K⁺ ATPase channels on type II cells of airway epithelium to resorb fluid ([Jain et al., 2006](#)). Elevated levels of cortisol, thyroid hormones, and

Figure 21-1 Prenatal and postnatal circulation. (Used with permission from Florin T, Ludwig S, Aronson PL, Werner HC, eds. *Netter's pediatrics*. Philadelphia: Elsevier; 2011.)

catecholamines in the fetus and neonate also play a role in clearing fluid from the lungs (Hillman et al., 2012; Jain et al, 2006; Liggins, 1994). In addition, initiation of continuous breathing by activation of the respiratory center in the brainstem is critical to survival of the neonate.

With the cutting of the umbilical cord, the peripheral vascular resistance of the neonate increases, and without a blood supply, the ductus venosus closes functionally within minutes after birth and structurally within the first week of life. As pulmonary vascular resistance decreases secondary to the expansion of the lungs and oxygenation of blood, the pulmonary blood flow to the left atria increases, which in turn increases left atrial blood pressure. Because the left atrial pressure now exceeds that of the right atria, the foramen ovale closes. The ductus arteriosus constricts after birth secondary to increased oxygen saturation of the blood as well as in response to decreased blood flow. With the closure of the fetal cardiac shunts, the circulation functions like that of an adult.

For a full term, normal newborn, this transition occurs rapidly with little resuscitation required aside from standard drying, stimulation, and clearance of the airway.

Preterm infants, infants with congenital anomalies of the heart or lungs, infants of mothers with diabetes, and infants born via cesarean section may struggle with the transition to the extrauterine environment and have increased resuscitation needs.

RESUSCITATION OF THE NEONATE

After delivery, evaluating the neonate's airway, breathing, and circulation will allow the practitioner to determine the resuscitation needs of the newborn. At every delivery, a staff member trained in the resuscitation of neonates should be designated to care for the neonate. Supporting staff members, who will aid in resuscitating the neonate, should also be trained. The American Heart Association (AHA) and American Academy of Pediatrics (AAP) offer a course in the resuscitation of neonates called the Neonatal Resuscitation Program (NRP). The algorithm in Figure 21-2 provides a brief summary of the steps needed to resuscitate a neonate, but it does not replace taking the course and becoming certified in neonatal resuscitation. Resuscitation equipment should be easily accessible, and if

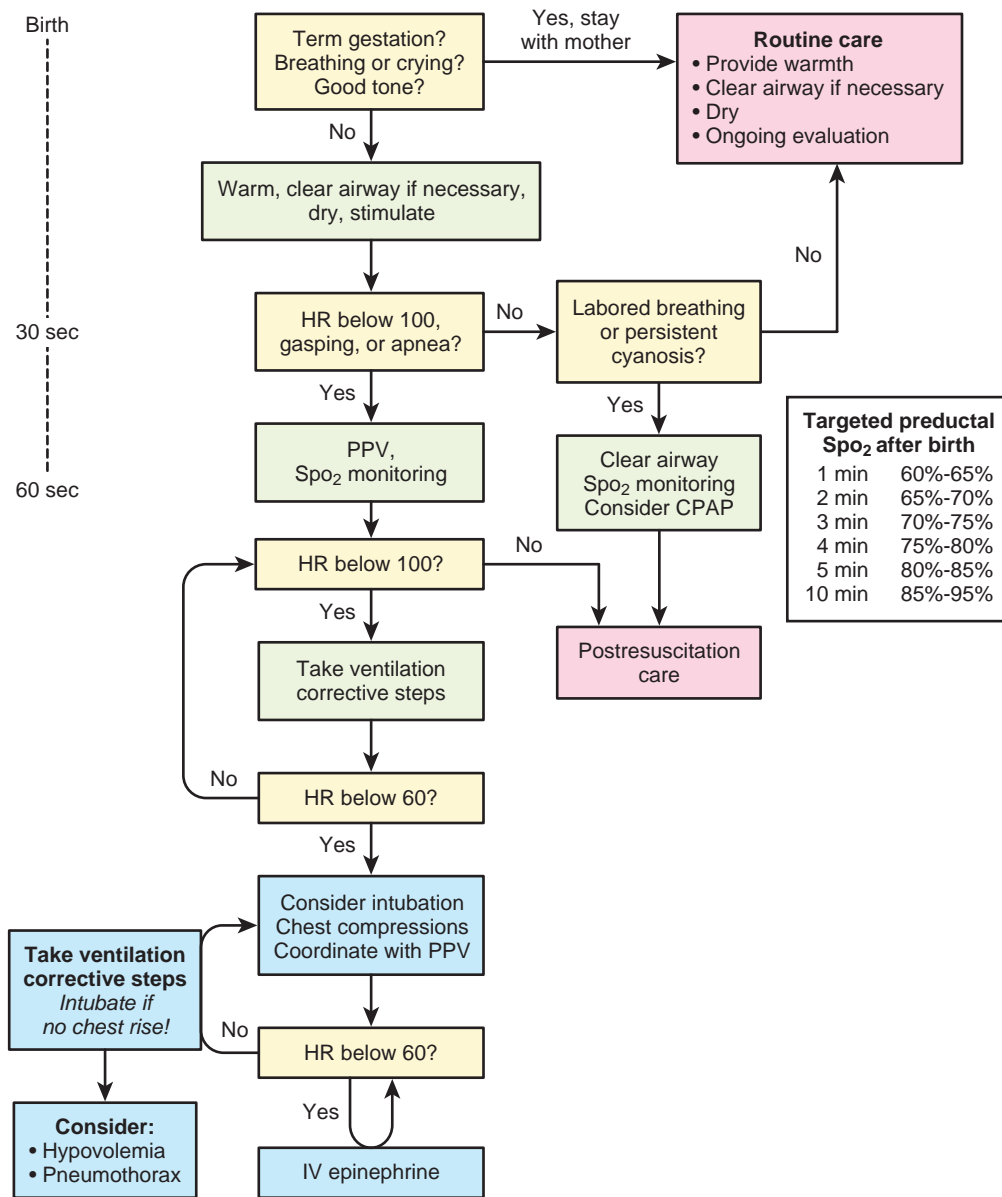

Figure 21-2 Algorithm for neonatal resuscitation. (Used with permission from Kattwinkel J, Perlman JM, Aziz K, et al; American Heart Association. Neonatal resuscitation: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Pediatrics*. 2010;126:e1400-e1413. American Academy of Pediatrics. 2010.)

a neonate is at high risk for complications, the equipment should be assembled and tested before delivery (Table 21-1).

ASSESSMENT OF THE NEONATE

A term infant with clear amniotic fluid who is vigorous (breathing or crying at birth with a strong respiratory effort, heart rate greater than 100 beats/min, and good muscle tone) can be returned to the mother after being dried for skin-to-skin contact and to breastfeed. Breast-feeding should start as soon as possible after birth, preferably within the first hour after delivery.

If the infant is not breathing or crying, the infant is placed under a warmer on his or her back with the neck slightly extended. This position facilitates air entry by aligning the posterior pharynx, larynx, and trachea (Kattwinkel,

2011). Next, the airway is cleared using bulb suction or a large-bore suction catheter. Simultaneously, the newborn is dried. The act of drying and suctioning also provides stimulation to the infant. Additional techniques for providing tactile stimulation include using the fingers to flick the soles of the feet and rubbing the newborn’s back, trunk or extremities gently with the hand. Heart rate, respiratory rate, and color of the newborn are then assessed, and the resuscitation algorithm is followed as outlined in Figure 21-2.

NEONATE WITH MECONIUM-STAINED FLUID

Infants with meconium-stained fluid who are not vigorous (poor muscle tone, heart rate less than 100 beats/min, and poor respiratory effort) should be temporarily intubated

Table 21-1 Neonatal Resuscitation Supplies and Equipment for Delivery of a Term Infant

Suction equipment	Bulb syringe Mechanical suction and tubing Suction catheters 8-Fr feeding tube and 20-mL syringe Meconium aspirator
Bag and mask equipment	Neonatal resuscitation bag with a pressure-release valve or pressure manometer Face masks, newborn and premature sizes Oxygen source with flow meter and tubing
Medications and supplies to be immediately available if necessary	Epinephrine 1:10,000 Isotonic crystalloid for volume expansion Sodium bicarbonate 4.2% Naloxone hydrochloride (0.4 mg/mL) Dextrose 10% Normal saline for flushes Umbilical vessel catheterization supplies Syringes and needles
Miscellaneous	Gloves and appropriate personal protection Radiant warmer or other heat source Firm, padded resuscitation surface Clock Warmed linens and dry blankets Stethoscope Oropharyngeal airways
Intubation equipment	Laryngoscope with straight blades, no. 1 Extra bulbs and batteries for laryngoscope Endotracheal (ET) tubes, sizes 2.5, 3.0, 3.5, and 4.0 mm Materials to secure ET tube in place CO ₂ detector

Modified from Kattwinkel J, ed. *Textbook of neonatal resuscitation*. 6th ed. Elk Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2011.

with an endotracheal tube and meconium should be aspirated from the airway if present. If an infant with meconium-stained fluid is vigorous, the mouth and nose should be cleared of meconium using bulb suction or a large-bore catheter. The infant can then be dried and returned to the mother for bonding and breastfeeding.

HIGH RISK DELIVERIES

Fetal and maternal factors can predict a high-risk delivery. Fetal factors include prematurity, gestational age greater than 42 weeks, multiple gestations, meconium-stained fluid, nonreassuring fetal heart tones, abnormal presentation (e.g., breech), and congenital anomalies. Maternal factors include diabetes, hypertension, substance abuse, advanced maternal age, placental anomalies, and chorioamnionitis (Kattwinkel, 2011). A team of health care providers who are trained in neonatal resuscitation and competent in resuscitating and stabilizing a neonate should be present at high-risk deliveries. If a high-risk delivery is anticipated, transfer to a hospital with a perinatal center is recommended before delivery.

THE APGAR SCORE

The Apgar score, devised by Virginia Apgar in 1952, is a tool that provides a standard method to assess the physical condition of newborns immediately after birth. It can also be used to assess an infant's response to resuscitation. The

Table 21-2 The Apgar Score*

Sign	Score*		
	0	1	2
Heart rate	Absent	<100 beats/min	≥100 beats/min
Respirations	Absent	Irregular and slow	Strong breaths, crying
Muscle tone	Limp	Some flexion	Good flexion, active motion
Reflex irritability to tactile stimulation	No response	Grimace	Cough, sneeze, cry,
Color	Blue or pale	Blue extremities, pink body	Completely pink

*The infant's Apgar score should be assessed at 1 and 5 minutes. A score of 7 to 10 is considered normal. A score of less than 7 should be repeated at 5-minute intervals up to 20 minutes while resuscitation efforts continue. Resuscitation of the neonate should not be interrupted to assign the Apgar score.

Modified from Kattwinkel J, ed. *Textbook of neonatal resuscitation*. 6th ed. Grove Village, IL: American Academy of Pediatrics and American Heart Association; 2011.

heart rate, respiratory effort, muscle tone, response to stimuli, and color are assessed at 1 and 5 minutes. Zero to two points are awarded in each category (Table 21-2). A score of 7 to 10 is considered normal. A score of less than 7 should be repeated at 5-minute intervals up to 20 minutes (AAP, 2006). Assessment of the newborn's airway, breathing, and circulation should not be delayed for calculation of the Apgar score. The Apgar score can be affected by gestational age, maternal medications, neurologic and cardiorespiratory conditions, trauma, infection, and ongoing resuscitation efforts (Freeman et al., 1988). A low Apgar score (0-3) has not been shown to predict neurologic outcome nor can a low score be used to determine if a hypoxic event occurred in utero (AAP, 2006). Some evidence suggests that a score of 0 to 3 at 5 minutes may correlate with neonatal death (Casey et al., 2001).

ASSESSMENT OF GROWTH PARAMETERS AND GESTATIONAL AGE

The length, weight, and head circumference of the infant should be measured and plotted on growth charts. The infant is then characterized as large, small, or appropriate for gestational age based on these measurements. The length, weight, and head circumference of appropriate for gestational age infants (AGA) fall between the 10th and 90th percentiles for age. Infants with growth parameters less than the 10th percentile for age are classified as small for gestational age (SGA) and may have complications after birth, including temperature instability and hypoglycemia. Large-for-gestational-age (LGA) infants whose growth parameters are greater than the 90th percentile for age are often born to mothers with uncontrolled diabetes, and these infants are also at risk for hypoglycemia after birth.

Gestational age is assessed using the new Ballard score. In the new Ballard score (Figure 21-3), the neuromuscular

NEUROMUSCULAR MATURITY

	-1	0	1	2	3	4	5
Posture							
Square window (wrist)	>90°	90°	60°	45°	30°	0°

PHYSICAL MATURITY

Skin	Sticky; friable; transparent	Gelatinous; red; translucent	Smooth; pink; visible veins	Superficial peeling and/or rash; few veins	Cracking; pale areas; rare veins	Parchment; deep cracking; no vessels	Leathery; cracked; wrinkled
Lanugo	None	Sparse	Abundant	Thinning	Bald areas	Mostly bald	
Plantar surface	Heel-toe 40-50 mm: -1 <40 mm: -2	>50 mm; no crease	Faint red marks	Anterior transverse crease only	Creases ant. 2/3	Creases over entire sole	
Breast	Imperceptible	Barely perceptible	Flat areola; no bud	Stippled areola; 1-2 mm bud	Raised areola; 3-4 mm bud	Full areola; 5-10 mm bud	
Eye/ear	Lids fused loosely: -1 tightly: -2	Lids open; pinna flat; stays folded	Sl. curved pinna; soft; slow recoil	Well-curved pinna; soft but ready recoil	Formed & firm; instant recoil	Thick cartilage; ear stuff	
Genitals male	Scrotum flat; smooth	Scrotum empty; faint rugae	Testes in upper canal; rare rugae	Testes descending; few rugae	Testes down; good rugae	Testes pendulous; deep rugae	
Genitals female	Clitoris prominent; labia flat	Prominent clitoris; small labia minora	Prominent clitoris; enlarging minora	Majora & minora equally prominent	Majora large; minora small	Majora covers clitoris & minora	

Figure 21-3 Maturation assessment of gestational age using the new Ballard score. See Table 21-3 for a description of the new Ballard examination technique. (From Ballard JL, Khoury JC, Wedig K, et al. New Ballard score, expanded to include extremely premature infants. *J Pediatr.* 1991;119:417-423.)

and physical maturity of the neonate is evaluated. The scores for each are summed, and a table is used to determine the gestational age based on the score. Table 21-3 explains the examination for the new Ballard score in detail. If there is a discrepancy of greater than 1 week between the gestational age by dates versus the gestational age by exam, the earlier gestational age should be used. A head-to-toe examination of the neonate should be performed within 24 hours of delivery. Detailed information on this examination is provided in the next section, “Care in the Newborn Nursery.”

ROUTINE CARE AT DELIVERY

After delivery, the umbilical cord is clamped and cut. The timing of cord clamping after delivery is not standardized. Current evidence is insufficient to support early (within 15-20 seconds after birth) versus delayed (30-60 seconds after birth) clamping in term infants (American College of Obstetricians and Gynecologists [ACOG], 2012). The number of arteries and veins in the umbilical cord should be counted after the cord is clamped. The umbilical cord normally contains two arteries and one vein. A single

Table 21-3 Examination for the New Ballard Score

Neuromuscular maturity	<p><i>Posture:</i> Assign score when infant is relaxed and quiet.</p> <p><i>Square window:</i> Measure the angle of the wrist in flexion between the hypothenar eminence and the forearm.</p> <p><i>Arm recoil:</i> Score the position of the arm after flexing the forearms for 5 seconds, fully extending the arm and releasing quickly.</p> <p><i>Popliteal angle:</i> Measure the angle of the popliteal fossil with the hip fully flexed and the knee extended with gentle pressure.</p> <p><i>Scarf sign:</i> Maneuver arm over opposite shoulder keeping scapulae on the examination table.</p> <p><i>Heel to ear:</i> Keeping the pelvis on the examination table and without forcing the leg, move the infant's foot toward the head.</p>
Physical maturity	<p><i>Skin:</i> With increasing gestational age, the skin becomes thicker, tougher, and less transparent.</p> <p><i>Lanugo:</i> Describe the fine, downy lanugo hair as seen over the infant's back and scapulae.</p> <p><i>Plantar surface of foot:</i> Measure from the tip of great toe to the back of the heel.</p> <p><i>Breast tissue:</i> Describe nipple size, stage of development, and amount of breast tissue.</p> <p><i>Eyes and ears:</i> Loosely fused eyelids open with gentle traction; the pinna in a term infant is well formed and quickly recoils after bending.</p> <p><i>Genitalia:</i> Describe the development of the external genitalia.</p>

Modified from Tureen PJ, Deacon J, Hernandez JA, et al. *Assessment and care of the well newborn*. 2nd ed. Philadelphia: Saunders; 2005.

umbilical artery typically is an isolated finding; however, it has been associated with chromosomal and anatomic abnormalities (Granese et al., 2007). If a two-vessel cord is detected with a prenatal ultrasonography, the heart and kidneys should also be imaged (Dagklis et al., 2010; Pursutte and Hobbins, 1995). If anomalies are present, the mother should be offered fetal karyotype analysis. If a two-vessel cord is detected after delivery, the infant should be carefully examined for syndromic features and anatomic abnormalities.

Additional measures taken at birth to care for the newborn include administration of vitamin K and prophylactic ocular topical medication. At birth, newborn infants are given 0.5 to 1.0 mg of vitamin K intramuscularly to prevent early and late hemorrhagic disease of the newborn. All infants are born vitamin K deficient (Zipursky, 1999). Additional factors that place newborns at risk for hemorrhagic disease include lower stores of vitamin K in the liver, low levels of vitamin K in breast milk, and the short half-life of vitamin K (Loughnan et al., 1996). Intramuscular vitamin K has been shown to be more effective at preventing late hemorrhagic disease than oral administration of vitamin K (Zipursky, 1999).

To prevent gonococcal ophthalmia neonatorum, erythromycin 0.5% ophthalmic ointment is routinely applied to both eyes of all newborns. Gonococcal ophthalmia neonatorum can result in corneal scarring, ocular perforation, and blindness. Gonococcal ophthalmia neonatorum develops in 28% of infants born to women infected with gonorrhea (U.S. Preventive Services Task Force [USPSTF], 2012). Silver nitrate 1.0% solution and tetracycline 1.0% ointment can also be used but are no longer available in the United States. Prophylaxis should be applied within the first 24 hours of life.

KEY TREATMENT

- Intramuscular vitamin K administered to all newborns at birth prevents hemorrhagic disease of the newborn (Zipursky, 1999) (SOR: A).
- Erythromycin 0.5% ophthalmic ointment applied to the eyes of all newborns prevents gonococcal ophthalmia neonatorum (USPSTF, 2012) (SOR: A).

Care in the Newborn Nursery

INITIAL NEWBORN EVALUATION AND COMMON PHYSICAL EXAMINATION FINDINGS

Key Points

- A complete head-to-toe examination of the newborn should be completed within the first 24 hours of life to identify any potential physical abnormalities or medical problems.
- Periodic breathing is a normal finding in the newborn, characterized by an irregular breathing pattern.
- Grunting may be present during the first hour of life as fetal lung fluid is cleared, but persistent evidence of respiratory distress requires further evaluation.
- Soft systolic murmurs may be present in the first 24 hours of life because of delayed closure of the ductus arteriosus or peripheral pulmonary stenosis.
- Molding and overriding sutures are common findings in newborns because of the compression of the head through the birth canal.
- Milky, white, or blood-tinged vaginal discharge is common in the first few weeks of life because of withdrawal of maternal hormones.
- The hips should be carefully examined with the Ortolani and Barlow maneuvers for signs of dislocation.
- Benign skin lesions are common and require appropriate education and reassurance of the parent.

Within the first 24 hours of life, a complete history and physical examination of the infant should be completed. The newborn history should review all components of the pregnancy, labor, and delivery. Gathering a complete maternal history, including a review of the mother's medical problems; past obstetric history; medications, drug, alcohol, or tobacco use during pregnancy; and prenatal serologies is important. Delivery complications and neonatal resuscitation measures should also be noted. The examination is best performed if the infant is quietly resting and should begin with an assessment of the infant's general appearance followed by auscultation of the heart and lungs. The examination should then proceed from head to toe in a systematic

Table 21-4 Vital Signs in the First Days of Life

Vital Sign	Normal Value
Heart rate	100-180 beats/min
Respiratory rate	24-60 beats/min
Systolic blood pressure	65-90 mm Hg
Diastolic blood pressure	50-70 mm Hg
Temperature	<100.4°F (38.0°C) and >96.8°F (36.0°C)

Data from Gunn VL, Nechyba C. *The Harriet Lane handbook*. 16th ed. St Louis: Mosby; 2002; Rudolph AM, Kamei RK, Sagan P. *Rudolph's fundamentals of pediatrics*. 2nd ed. Norwalk, CT: Appleton & Lange; 1998.

fashion. The following sections describe how to perform each portion of the physical examination in an infant as well as normal and abnormal findings that may be present in the examination.

General Appearance

The examination should begin with a general assessment of the infant's respiratory effort, position, level of activity, and color. A healthy infant should breathe comfortably with no respiratory distress. *Periodic breathing* is characterized by an irregular breathing pattern consisting of rapid breaths intermixed with short pauses lasting 5 to 10 seconds and is considered a normal finding in newborns. A normal newborn rests with his or her extremities flexed and should appear pink. A bluish discoloration of the hands and feet, known as *acrocyanosis*, is common. Central cyanosis, pallor, jaundice, or a ruddy complexion signals underlying medical problems. [Table 21-4](#) lists normal vital signs for a term infant. An infant's weight, length, and head circumference should also be reviewed and plotted on standard growth charts.

Head and Face

Examination of the head should include observation of the head shape and size and palpation of the anterior and posterior fontanels and cranial sutures. The anterior fontanel is located at the juncture of the metopic, sagittal, and coronal sutures, and the posterior fontanel is located at the juncture of the sagittal and lambdoid sutures. Both fontanels should be soft and flat when palpated. A bulging or tense fontanel in an otherwise calm neonate may be an indication of raised intracranial pressure and should be further evaluated. The anterior fontanel size is typically 4 to 6 cm in diameter, and the posterior fontanel is usually smaller than 1 cm in diameter ([Bickley, 2012](#)). Large fontanels are often associated with congenital hypothyroidism. Molding and overriding sutures are common findings in newborns caused by the compression of the head through the birth canal. Asymmetry caused by molding is temporary and should resolve in the first few days of life. Persistent asymmetry, however, should be further evaluated for craniosynostosis. Delivery can also cause extracranial complications such as caput succedaneum and cephalohematoma. *Caput succedaneum*, an area of edema on the scalp, is present at birth, crosses suture lines, and resolves within days ([Figure 21-4](#)). A *cephalohematoma* develops from bleeding in the subperiosteal space, is not evident until a few hours of age, does not cross suture lines, and can take weeks or months to resolve ([Figure 21-5](#)).

Figure 21-4 Caput succedaneum in a newborn infant. (Used with permission from Brozanski BS, Riley MM, Bogen DL. Neonatology. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of pediatric physical diagnosis*. 6th ed. Philadelphia: Elsevier; 2012:45-77.)

Figure 21-5 Cephalohematoma of the right parietal bone. (Used with permission from Carlo WA. Nervous system disorders. In Kliegman RM, Stanton BF, St. Geme JW, et al, eds. *Nelson textbook of pediatrics*. 19th ed. Philadelphia: Elsevier; 2011:565-574.

The face should be examined for symmetry. Asymmetry may be attributable to facial palsies from birth trauma or congenital abnormalities. Transient skin lesions may be present on the face from delivery, especially if forceps were used.

Eyes

The eyes should initially be inspected to evaluate for spacing and symmetry and normal extraocular movement. Intermittent crossing of the eyes is a normal finding in the first few months of life. The pupils should be evaluated for

symmetry and the presence of a *red reflex* bilaterally. A white reflex may be a sign of retinoblastoma, cataract, or retinal detachment and requires a referral to an ophthalmologist for further evaluation. The sclera, iris, and conjunctiva of both eyes should also be examined. Subconjunctival hemorrhages may be present from trauma experienced during birth. *Congenital nasal lacrimal duct obstruction* may present shortly after birth. Symptoms include persistent tearing and collection of debris on the eyelashes. In most infants, symptoms resolve by 6 months of age with gentle massage to the area and watchful waiting (*Pediatric Eye Disease Investigator Group, 2012; Takahashi et al., 2010*). Discharge from nasal lacrimal duct obstructions needs to be differentiated from purulent discharge caused by neonatal conjunctival infections, which require urgent medical attention. Because newborns keep their eyes closed most of the time, examining the eyes may be difficult. Holding the infant upright while slowly rotating him or her in a darkened room may stimulate eye opening.

Ears, Nose, and Throat

Ears should be evaluated for position and appearance. Malpositioned, rotated, or poorly formed ears can be a sign of underlying medical problems. The ear canal should be inspected for patency. Visualization of the tympanic membrane is difficult because of the small size of the canal and presence of vernix obscuring the tympanic membrane. Hearing can be assessed by monitoring for startling and blinking in response to a sudden noise.

The shape of the nose should be inspected, and patency of the nares should be verified. Obstructed nares may be due to anatomic problems such as choanal atresia, which can be tested by attempting to pass a small feeding tube or suction catheter through each nare.

The mouth should be both inspected and palpated for abnormalities. Small white retention cysts may be present on the gums, known as *Bohn nodules*, or the hard palate, known as *Epstein pearls*, and resolve within a few months (*Figure 21-6*). Occasionally, natal teeth are noted. They are typically an isolated finding but may be associated with other congenital abnormalities. The palate should be palpated to ensure it is intact and that no submucosal clefts are present. *Ankyloglossia* occurs if the frenulum is short and limits protrusion of the tongue. Most infants with ankyloglossia experience no symptoms. Some infants may have difficulty breastfeeding and future articulation problems

and therefore may benefit from surgical intervention (*Buryk et al., 2011; Lalakea and Messner, 2003*).

Chest and Lungs

The chest wall should be inspected for abnormalities in symmetry and structure. Gynecomastia may be present in male and female infants because of the effects of maternal estrogen and can be accompanied by a white, milky discharge referred to as “witch’s milk.” The clavicles should be palpated for smoothness and symmetry. An asymmetric Moro response, crepitus, or tenderness with palpation may be signs of a clavicle fracture. Infants who present with shoulder dystocia are at risk of clavicle fracture during delivery.

The lung examination is best performed if the newborn is quietly resting. Before auscultation, the infant’s respiratory effort should be observed for signs of respiratory distress, including tachypnea, nasal flaring, grunting, or retractions. Tachypnea is defined as a respiratory rate greater than 60 breaths/min. Auscultation should then be performed to assess for quality of breath sounds and accessory noises. Grunting without tachypnea or other symptoms of respiratory distress may be present during the first hour of life as fetal lung fluid is cleared from the lungs. Persistent grunting or retractions are signs of respiratory distress and require further evaluation.

The most common cause of tachypnea in the newborn is *transient tachypnea of the newborn (TTN)*, which occurs from delayed clearing of fetal lung fluid. The most prominent symptom of TTN is tachypnea, but retractions, grunting, and cyanosis may also be present. Infants with TTN should be closely monitored and may need respiratory support with oxygen. Symptoms typically resolve by 12 to 24 hours but may persist for up to 72 hours.

Cardiovascular

Before auscultation, capillary refill should be noted, and the point of maximal impulse (PMI) of the heart should be palpated. Auscultation of the heart is best done along the left sternal border and should reveal clear, regular first and second heart sounds. Dextrocardia may be diagnosed by the presence of heart sounds or the PMI in the right chest. Murmurs are common in the first 24 hours of life. They are often caused by delayed closure of the *ductus arteriosus* or *peripheral pulmonary stenosis* and are considered transient and benign. Murmurs that are harsh, pansystolic, grade III/IV or greater in intensity, and associated with abnormal

Figure 21-6 **A**, Epstein pearls located along the midpalatine raphe. **B**, Bohn nodules located on the alveolar ridges. (Used with permission from Martin B, Baumhandt H, D’Alesio A, et al. Oral disorders. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of pediatric physical diagnosis*. 6th ed. Philadelphia: Elsevier; 2012:775-802.)

second heart sounds require further evaluation. Femoral pulses should be palpated to assess for adequate perfusion. Absent or asymmetric femoral pulses may indicate the presence of coarctation of the aorta.

Abdomen

The abdomen in a normal newborn is soft, symmetric, and slightly protuberant. A scaphoid abdomen or distended abdomen requires further investigation. *Diastasis recti* or an *umbilical hernia* may be present. Both can be closely monitored for spontaneous resolution. Most umbilical hernias resolve by 1 year of age, and nearly all resolve by 5 years of age unless a large defect is present (Katz, 2001; Kelly and Ponsky, 2013; Snyder, 2007). The umbilical cord should be dry and clamped. Erythema of the skin surrounding the umbilicus or a foul-smelling discharge may indicate omphalitis or an infection of the umbilicus.

The abdomen should be auscultated for the presence of bowel sounds in all quadrants. The abdomen should then be palpated to assess the liver, spleen, and kidneys. The liver edge can be palpated 1 to 2 cm below the right costal margin and should be smooth. A spleen tip may be present. Palpation of additional masses requires further evaluation.

Genitalia

In female newborns, the labia majora, labia minora, clitoris, urethral orifice, and vaginal opening should be inspected. The labia majora should be opened to ensure that they are completely separate from each other, and the vaginal opening should be inspected for imperforate hymen. Vaginal or hymenal tags may be present. *Milky, white, or blood-tinged vaginal discharge* is common in the first few weeks of life because of withdrawal of maternal hormones.

In male newborns, the penis, urethral opening, scrotum, and testes should be examined. The length of the penis should be evaluated by measuring the stretched penis. The mean length of a full term infant's penis is 3.5 cm (Feldman and Smith, 1975). The urethral meatus should be midline and central on the glans. Ventral placement of the urethra is known as *hypospadias*, and dorsal placement is known as *epispadias* (Figure 21-7). Circumcision should not be performed in infants with an abnormally placed urethral meatus. The scrotum should be palpated for the presence of both testes. *Hydroceles* and *inguinal hernias* are common scrotal masses in newborns (Figure 21-8). Hydroceles are caused by a fluid collection around the testes and resolve spontaneously by 1 year of age. They can be differentiated from inguinal hernias on examination because they are not reducible and can be transilluminated. Inguinal hernias should be referred for surgical correction.

Back and Spine

The spine should be inspected and palpated for signs of a neural tube defect, including soft tissue masses, sacral cleft or dimple, tuft of hair, or skin abnormalities (e.g., hemangioma). *Sacral dimples* are very common, and those with an intact base typically do not warrant further imaging. Dimples that occur more than 2.5 cm from the anus, are deep and large, are associated with skin abnormalities, or that do not have an intact base should be further evaluated with a spinal ultrasound (Zywick et al., 2011).

Figure 21-9 Physical examination maneuvers for developmental dysplasia of the hip.

Hips

The hips should be carefully examined for signs of dislocation. Dislocation may be present in infants with *developmental dysplasia of the hips (DDH)*. The Ortolani and Barlow maneuvers should be used to assess hip stability (Figure 21-9). The *Ortolani maneuver* tests for the presence of a posteriorly dislocated hip and is performed by abducting the hips while firmly pressing on the greater trochanter of each femur. The test is result positive if a "clunk" is palpated as the femoral head moves back into place. The *Barlow maneuver* tests for subluxation of an intact but unstable hip by pressing down on flexed and adducted hips while applying pressure to the greater trochanter. A positive Barlow sign occurs if the head of the femur is felt slipping posteriorly out of the acetabulum. Risk factors for DDH include female gender, breech presentation, and family history. All infants should be evaluated by physical examination for DDH at well-child visits until they are walking. Newborns with a positive examination should be referred to an orthopedic specialist. If the examination is equivocally positive, the infant should be reexamined at the 2-week visit. Infants with a breech presentation but normal physical examination and female infants with a positive family history of DDH should receive a screening hip ultrasonography at 6 weeks of age (Committee on Quality Improvement, 2000; Shipman et al., 2006).

Neurologic

The neurologic examination of the infant includes assessment of the infant's general state, tone, posture, and primitive reflexes. The infant's level of alertness should be documented. Tone should be assessed by monitoring a newborn's posture at rest and testing his or her resistance to passive movements. Tone varies depending on gestational

age. A full-term infant should have strong flexion and symmetric movement of all extremities. Hypotonic infants are limp and lie in a frog-legged position with their arms flexed and hands positioned near the ears. Hypertonic infants may have spasticity or rigid movements. All newborns should exhibit innate reflexes called *primitive reflexes* that develop during gestation and are present at birth (Table 21-5). Asymmetry of movements, localized neurologic findings, or failure to elicit primitive reflexes are indicators of neurologic disease.

Brachial plexus injuries may occur because of pulling on the arm during delivery. These injuries result from stretching or tearing the nerve or hemorrhage within the nerve. *Erb's palsy* is an upper brachial plexus injury (C5-C6) that leads to adduction and internal rotation of the shoulder and pronation of the forearm. *Klumpke's palsy* is a lower plexus injury (C7-C8 and T1) that leads to isolated hand paralysis. Both conditions typically resolve within 1 to 3 months and leave no lasting neurologic deficit.

Skin

During the newborn period, common benign rashes may develop that often require education and reassurance to the parent. The skin of newborns is thinner and has less hair and sweat and sebaceous gland production. These benign lesions are typically self-limited to the newborn period (Treadwell, 1997).

Erythema toxicum neonatorum (ETN) is a common benign skin lesion occurring in 31% to 72% of full-term infants (Figure 21-10) (Treadwell, 1997). ETN is characterized by multiple erythematous macules and papules that rapidly progress to pustules on an erythematous base. The lesions are distributed over the trunk and proximal extremities, sparing the palms and soles. They typically first appear

Table 21-5 Primitive Neurologic Reflexes in Newborns

Primitive Reflex	Maneuver	Ages present
Stepping reflex	Hold the infant in a vertical position with the feet in contact with a flat surface. The infant will make alternating stepping movements.	Birth to 1-2 months
Galant reflex	Stroke the paravertebral region of the back from the shoulder to the buttocks. The infant's trunk will move to the side of stimulation.	Birth to 2 months
Asymmetric tonic neck reflex	Turn the infant's head to one side. The upper and lower extremities on that side will extend while the contralateral extremities will flex.	Birth to 2-4 months
Rooting reflex	Stroke the skin near the mouth of the newborn. The newborn will open his or her mouth and turn toward the direction of stimulation.	Birth to 3-4 months
Palmar and plantar grasp reflex	Press against the palmar or plantar surface. The infant will curl his or her fingers or his or her toes around the examiner's finger.	Birth to 3-4 months
Moro reflex	Hold the newborn in a supine position and abruptly lower his or her body. The infant's arms abduct and extend and the hands open followed by immediate flexion of the arms and closure of the fists.	Birth to 4-6 months

Figure 21-10 Erythema toxicum neonatorum. (Used with permission from Cohen BA, Davis HW, Gehris RP. *Dermatology*. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of pediatric physical diagnosis*. 6th ed. Philadelphia: Elsevier; 2012:299-368.)

within 24 to 48 hours of life and resolve within 5 to 7 days. Most physicians are able to diagnose ETN from its clinical appearance, but it can be confirmed by microscopic examination. A Wright-stained smear of the contents of a pustule will demonstrate a predominance of eosinophils. ETN resolves spontaneously without intervention or treatment.

Transient neonatal pustular melanosis (TNPM) is another benign skin lesion seen less commonly than ETN (Figure

Figure 21-11 Transient neonatal pustular melanosis. (Used with permission from Muniz AE. *Neonatal skin disorders*. In Baren JM, Rothrock SG, Brennan JA, Brown L, eds. *Pediatric emergency medicine*. Philadelphia: Elsevier; 2008:345-349.)

21-11). It mostly affects full-term infants with darker skin pigmentation but can be seen in all races. TNPM is characterized by three different lesions that occur at various stages. Initially, small superficial white pustules erupt on a nonerythematous base and may be present at birth. These pustules later unroof to reveal well-circumscribed erythematous macules with a surrounding collarette of scale that may persist for weeks to months. Last, hyperpigmented macules occur and gradually fade over several weeks to months. TNPM can also be confirmed by microscopic examination of a Wright-stained smear, which will show a predominance of neutrophils. TNPM also resolves without treatment.

Neonatal acne occurs in approximately 20% of infants and does not appear to run in families (Figure 21-12) (Treadwell, 1997). The neonate can have multiple papules and pustules distributed primarily on the forehead, cheeks, and upper chest. It is thought to be exacerbated by stimulation of sebaceous glands by maternal and endogenous androgens. Neonatal acne usually starts around 2 or 3 weeks of life. In most cases, no additional treatment is needed because these lesions usually resolve spontaneously within 4 to 6 months

Figure 21-12 Neonatal acne. (Used with permission from Burch JM, Aeling JL. Acne and acneiform eruptions. In Fitzpatrick JE, Morelli JG, eds. *Dermatology secrets plus*. 4th ed. Philadelphia: Elsevier; 2011:148-155.)

without scarring. Affected newborns do not appear to have a greater risk of acne in adolescence, which can be reassuring to parents.

Infantile acne is different from neonatal acne in that it presents at 3 to 4 months of age. The presentation is often more severe and consists of typical acneiform lesions, including comedones, inflammatory papules, pustules, and occasionally nodules on the face. Infantile acne also results from hyperplasia of sebaceous glands secondary to androgenic stimulation and is more common in boys (Treadwell, 1997). If lesions are severe and cause scarring, treatment by a specialist may be required. Otherwise, infantile acne usually resolves spontaneously by 1 year of life.

Milia are also benign skin lesions consisting of white pinpoint papules that are usually scattered on the nose and cheeks (Figure 21-13) (Zitelli et al., 2007). These epithelial-lined papules are caused by retention of keratin and sebaceous material in the pilosebaceous follicles. These lesions also resolve in the first few weeks of life without any treatment. In fact, parents should be educated to not attempt to denude these lesions because that may lead to scarring.

Miliaria is a common finding in newborns, especially in warm climates (Figure 21-14). It is caused by an accumulation of sweat beneath eccrine sweat ducts that are obstructed by keratin. A common form of this is *miliaria rubra* or “heat rash” or “prickly heat.” Groups of erythematous papules and pustules erupt over the face, upper trunk, and the folds of the neck when the obstructed sweat leaks into the dermis and causes a localized inflammatory response. *Miliaria* is another self-limited rash that requires no specific treatment. Lesions usually resolve rapidly when the infant is placed in a cooler environment. Parents should be advised to take measures that reduce sweating, such as using light, loose clothing and cool water baths.

Congenital dermal melanocytosis, also called Mongolian spot, is the most frequently encountered benign pigmented lesion in newborns (Figure 21-15). There is a significant racial disparity in the prevalence of these benign lesions, with Asian neonates having the highest prevalence at greater than 85% (Treadwell, 1997). Congenital dermal melanocytosis typically appears as a blue-grey pigmented,

Figure 21-13 Milia. (Used with permission from Cohen BA, Davis HW, Gehris RP. *Dermatology*. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of pediatric physical diagnosis*. 6th ed. Philadelphia: Elsevier; 2012:299-368.)

Figure 21-14 Miliaria rubra. (Used with permission from Cohen BA. *Pediatric dermatology*. 4th ed. Philadelphia: Elsevier; 2013:14-67.)

flat patch with irregular borders. The diameter of the lesion may be as large as 10 cm or more. The most common location is the sacral-gluteal region, but these lesions can appear anywhere on the body. Congenital dermal melanocytosis usually fades during the first or second year of life and most resolve completely by 7 to 10 years of age without any intervention or treatment (Treadwell, 1997). Although the distinctive clinical appearance of these blue-grey patches is usually diagnostic, there are reports of false accusations of child abuse when these lesions are misinterpreted as bruises (Cohen, 1987). Therefore, it is important to document the presence of these benign lesions on the newborn record and to educate the parents of the benign, self-limited nature of these lesions.

SCREENING

Key Points

- Routine glucose screening is not recommended in healthy term infants.
- Physiologic jaundice is the most common cause of hyperbilirubinemia and typically resolves in the first week of life.
- A total bilirubin should be obtained and plotted on the phototherapy nomogram before discharge from the hospital.
- Pulse oximetry screening is becoming an increasingly common practice to screen for congenital heart disease.
- Universal hearing screen is recommended for all infants before discharge.

Glucose

Routine glucose screening is not recommended in healthy term infants after a normal pregnancy and delivery. Blood glucose levels should be measured in infants at risk of developing hypoglycemia and those displaying symptoms of hypoglycemia. Risk factors include infants who are SGA, LGA, born to mothers with diabetes, or late preterm infants (34-36 $\frac{1}{2}$ weeks' gestation). Infants with clinical symptoms of hypoglycemia should be immediately screened with a blood glucose level. Clinical symptoms of hypoglycemia

are nonspecific and include jitteriness, decreased tone, irritability or lethargy, tachypnea, apnea, bradycardia, cyanosis, poor feeding, hypothermia, seizures, or weak cry. Hypoglycemia itself can be a sign of more serious medical problems, such as sepsis or inborn errors of metabolism.

The definition of hypoglycemia is controversial. A 2011 AAP report recommends using 45 mg/dL as a target; however, each hospital system may define hypoglycemia differently (AAP, 2011). Bedside glucose testing can be used as a rapid screening method. Because these measures are less accurate than laboratory testing, abnormal blood glucose concentrations should be confirmed by laboratory testing, but confirmation should not delay treatment.

Management of hypoglycemia should be tailored to the needs of the infant depending on the presence or absence of signs of hypoglycemia (AAP and ACOG, 2012). Infants at risk of developing hypoglycemia should be encouraged to feed in the first hour of life, and the initial blood glucose level should be obtained 30 minutes after feeding. Screening should continue every 2 to 3 hours for the first 12 to 24 hours of life or until the infant is feeding well and blood glucose levels are normal. Intravenous (IV) glucose should be initiated in symptomatic infants or infants with severe hypoglycemia. Asymptomatic infants with hypoglycemia should be fed breast milk or formula and have a glucose level repeated in 1 hour. If the blood glucose level has not increased at that time, IV glucose is recommended.

Bilirubin

PredischARGE bilirubin screening is recommended to prevent acute bilirubin encephalopathy or kernicterus because jaundice is a common finding in newborns. Kernicterus occurs when toxic levels of bilirubin cross the blood-brain barrier, leading to devastating and permanent neurologic defects. Jaundice results from increased levels of conjugated (direct) or unconjugated (indirect) bilirubin in the blood (Table 21-6). In most infants, jaundice is secondary to unconjugated hyperbilirubinemia, which occurs because of increased production of bilirubin, decreased clearance of bilirubin, or increased enterohepatic circulation. The most common cause of unconjugated hyperbilirubinemia in infants is physiologic jaundice (Kliegman et al., 2007). *Physiologic jaundice* is a result of increased turnover of red blood cells; transient deficiency of the enzyme UDP glucuronosyltransferase (UGT), which is responsible for bilirubin clearance in the liver; and increased enterohepatic circulation. Physiologic jaundice typically resolves in the first week of life without need for intervention. In infants with persistent or severe jaundice (jaundice in the first 24 hours of life or total bilirubin level greater than the 95th percentile), a direct and total bilirubin level should be measured to differentiate between conjugated and unconjugated hyperbilirubinemia, and the infant should be further evaluated for pathologic causes of jaundice.

Bilirubin screening identifies infants at risk of developing severe levels of hyperbilirubinemia (Subcommittee on Hyperbilirubinemia, 2004). Major risk factors include predischARGE total bilirubin level in the high-risk zone, jaundice in first 24 hours of life, blood group incompatibility, gestational age of 35 to 36 weeks, sibling requiring phototherapy, cephalohematoma or bruising, exclusive breastfeeding and excessive weight loss, and East Asian race. A

Table 21-6 Causes of Hyperbilirubinemia in Newborns

Conjugated hyperbilirubinemia	Sepsis
	Infection (toxoplasmosis, cytomegalovirus, rubella, herpes, syphilis)
	Paucity of bile ducts
	Disorders of bile acid metabolism
	Severe hemolytic disease
	Biliary atresia
	Giant cell hepatitis
	Choledochal cyst
	Cystic fibrosis
	Galactosemia
	α_1 -Antitrypsin deficiency
	Tyrosinemia
	Unconjugated hyperbilirubinemia
■ Isoimmune-mediated hemolysis (ABO blood group incompatibility, Rh incompatibility)	
■ Inherited red blood cell membrane defects (spherocytosis, elliptocytosis)	
■ Erythrocyte enzyme defects (glucose-6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency)	
■ Sepsis	
■ Polycythemia	
■ Extravascular hemorrhage (cephalohematoma, extensive bruising)	
Decreased bilirubin clearance	
■ Crigler-Najjar syndrome	
■ Gilbert syndrome	
■ Infant of mother with diabetes	
■ Congenital hypothyroidism	
Increased enterohepatic circulation	
■ Physiologic jaundice	
■ Breast milk jaundice	
■ Functional or anatomical obstruction	

total bilirubin level should be obtained before discharge and plotted on the phototherapy nomogram (Figure 21-16). Treatment with phototherapy is initiated when the total bilirubin level exceeds the threshold level on the phototherapy nomogram based on the infant's age in hours and risk level (see Figure 21-16). The infant's risk level is determined by the presence or absence of the following risk factors: isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin less than 3.0 g/dL. BiliTool is an excellent online resource that can be used to assist in assessing need for phototherapy (<http://www.bilitool.org>).

While receiving phototherapy, infants may continue to breastfeed but may require supplementation with expressed breast milk or formula if weight loss is excessive (greater than 12% of birth weight) or intake is inadequate. Hydration with IV fluids is reserved for infants with significant hypovolemia and does not need to be initiated in all infants. Phototherapy should be discontinued when total bilirubin levels decrease to safe levels. Total bilirubin levels should be reassessed 18 to 24 hours after discontinuing phototherapy to ensure that levels have not rebounded.

In infants whose bilirubin levels do not indicate need for treatment before discharge, the need for and timing of repeat evaluation depends on the zone in which the total bilirubin level falls and the age of the infant (Figure 21-17). Timing of follow-up is important, and a follow-up

Figure 21-16 Phototherapy nomogram for infants of 35 or more weeks' gestation. Risk factors include isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin less than 3.0 g/dL. (From AAP Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297-316.)

Figure 21-17 Nomogram for designation of risk of hyperbilirubinemia in well newborns. The serum total bilirubin level should be obtained before discharge. The zone in which the value falls predicts the likelihood of subsequent bilirubin level exceeding the 95th percentile (high-risk zone) and should determine the timing of follow-up. (From AAP Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297-316.)

appointment should be secured with the infant's primary care provider before discharge.

Critical Congenital Heart Disease

Screening for critical congenital heart disease with pulse oximetry is becoming an increasingly common practice. Pulse oximetry can detect mild levels of hypoxemia in infants with congenital heart disease who do not have obvious examination findings, such as a murmur or cyanosis (Thangaratinam et al., 2012). Screening is directed at identifying hypoplastic left heart syndrome, pulmonary atresia, tetralogy of Fallot, total anomalous pulmonary venous return, transposition of the great arteries, tricuspid atresia, and truncus arteriosus. Screening should be done

after 24 hours of life by placing a pulse oximetry probe on the right hand and either foot. A positive screening test result meets the following criteria: (1) SaO₂ less than 90% in either extremity, (2) SaO₂ less than 95% in both upper and lower extremities on three measurements with each measurement separated by 1 hour, or (3) SaO₂ difference of greater than 3% between the upper and lower extremities (Mahle et al., 2012). Positive screening warrants referral to the specialist for an echocardiogram.

Newborn Screen

The goal of newborn screening programs is to detect disease before the onset of symptoms to initiate early treatment and prevent complications. Newborn screening programs test for various congenital disorders, including metabolic disorders, endocrinopathies, hemoglobinopathies, cystic fibrosis, and immunodeficiencies. They are mandated by law and are implemented at the state level. Blood specimens should be collected between 24 and 48 hours of life via heel prick (AAP and ACOG, 2012). Some states mandate that a repeat specimen be obtained at 10 to 14 days of life to reduce the chance of missed diagnosis.

Hearing

Universal hearing screening is recommended for all infants. Hearing impairment occurs in approximately one to three per 1000 live births and has a significant impact on a child's language and social development and academic performance (USPTF, 2008). The USPTF recommends that all infants be screened before 1 month of age. Infants who fail a screening test should receive audiologic assessment by 3 months of age, and infants diagnosed with hearing loss should receive intervention by 6 months of age. Otoacoustic emissions (OAEs) and auditory brainstem response (ABR) are both appropriate screening tests. In OAEs, a microphone placed near the infant's ear produces stimulus noises and detects sound waves produced from the infant's cochlea. In ABR screening, electrodes placed on the forehead, neck, and mastoid measure waveforms generated by the auditory brainstem response to stimuli. The ABR must be completed when the infant is asleep. OAEs are most often used because they are quick, easy to administer, inexpensive, and can be performed when the infant is awake or asleep. Many hospitals use a two-step approach to screening. OAEs are administered first followed by an ABR if the infant fails the first test. Infants who fail hearing screening should be referred to a pediatric audiologist for further evaluation.

DISCHARGE FROM THE NEWBORN NURSERY

Discharge home optimally occurs when the newborn has been observed for a long enough period of time to identify medical problems and when the family is able and prepared to care for the newborn at home. If either the mother or the newborn requires a longer stay, all efforts should be made to keep the newborn and mother together to promote bonding if possible. Before discharge, the infant should have normal and stable vital signs for at least 12 hours, including a normal temperature in an open crib (Committee on Fetus and Newborn, 2004). The infant should have urinated and passed stool at least once and fed successfully twice. Feeding should be observed to document that the infant is able to

coordinate sucking, swallowing, and breathing and has an appropriate latch if breastfeeding. Parents of the newborn should be given appropriate anticipatory guidance (covered in the section, "Care at the Primary Care Office") to confidently provide adequate care. Most mother–newborn dyads meet discharge criteria after 48 hours of care. All infants should have follow-up scheduled with a medical home within 2 to 3 days after discharge.

Care at the Primary Care Office

Key Points

- The infant should be assessed for appropriate weight gain, voiding and stooling patterns, and jaundice at the initial visit in the primary care office.
- The AAP recommends the prompt assessment of a breastfed infant with greater than a 7% loss from birth weight.
- A normal newborn should pass urine and meconium stool within the first 24 hours of life.
- It is important to reassure parents that there may be occasional variations in the color and consistency of the stools.
- Breastfed infants may develop breast milk jaundice or physiologic jaundice that persists past the first week of life.

ASSESSMENT AND EVALUATION

A newborn will visit his or her physician in the first year of life more than at any other time. The schedule usually starts with the newborn examination at the time of delivery and then transitions to the first visit in the primary care office. This occurs as early as 3 to 5 days of life. At this initial visit in the primary care office, the provider will perform a similar comprehensive newborn examination as outlined earlier in this chapter. The physician should also evaluate the infant for weight gain or loss, difficulty with feeding, abnormal voiding or stooling patterns, and jaundice. Infants should have a second ambulatory visit at 2 to 3 weeks of age so the physician can monitor weight gain and provide additional support and encouragement to the mother during this critical period (Wenner Van Vleet, 2012).

Growth

The initial assessment of the newborn in the office includes a measurement of the weight, length, and fronto-occipital circumference (FOC). These measurements are plotted on the growth curve. Weight loss is normal after delivery, and the expected loss is 5% to 7% of birth weight (Paul et al., 2006). Term, healthy infants usually stop losing weight by 5 days of life and typically regain their birth weight by 2 weeks of age. After breastfeeding or formula feeding is well established, infants should gain 15 to 30 g/day. Excessive weight loss is a loss of greater than 10% of the birth weight. Weight loss beyond this normal expected amount may be an indication of poor intake that requires medical attention and intervention. The AAP recommends prompt assessment of a breastfed infant if there is

more than a 7% loss from birth weight ([Section on Breastfeeding, 2012](#)).

The physician should also get a detailed history of the voiding and stooling pattern. Voiding increases from one void in the first 24 hours to two or three in the second 24 hours, four to six during the third and fourth day, and six to eight on day 5 and thereafter.

Infants who are successfully feeding from the breast or bottle should pass a meconium stool in the first 48 hours of life and then have transitional stools within approximately 3 days of birth. After day 4 or 5, the majority of infants have three or more stools per day, which is often timed with feeding episodes. After the dark, thick meconium stool passes, normal infant stool will turn yellow-green, soft, and almost runny with seedlike particles ([Wenner Van Vleet, 2012](#)).

It is important to reassure the parents that there may be occasional variations in the color and consistency of the stools. The gastrocolic reflex of newborns is a physiologic reflex controlling the motility, or peristalsis, of the gastrointestinal tract. It involves an increase in motility of the colon in response to stretch in the stomach. This can be used to explain the increased frequency of stools, especially in breastfed infants. By 1 month of age, it is normal for some infants to have less frequent stools. Some infants may only have one bowel movement per week. If the infant is feeding well, making appropriate urine-filled diapers, and producing soft stools, the parents need to be reassured that this stooling pattern may still be within normal limits.

In breastfed infants, stool may appear green and frothy. This occurs in infants of mothers who produce copious milk and switch the infant from one breast to the other before most of the hind milk is completely extracted from the first breast. The high fat content in the hind milk usually slows gut motility enough that the majority of milk lactose digestion occurs in the small intestine. If the infant does not completely empty one breast, he or she will have less hind milk to slow motility, and high concentrations of lactose will reach the large bowel. This in turn causes excess gas and frothy stool production by the bacterial flora in the large intestine. Mothers should be advised to allow the infant to finish nursing on one breast before switching to the other even if the child does not take the second breast ([Section on Breastfeeding, 2012](#)).

Hyperbilirubinemia

An important component of the early follow-up visit is to reassess the infant for jaundice because hyperbilirubinemia is the most common cause of readmission to the hospital ([Paul et al., 2006](#)). Physicians should use their clinical judgment to determine if the infant requires a serum or transcutaneous bilirubin measurement. Need for treatment should again be based on the phototherapy nomogram (see [Figure 21-16](#)). Infants requiring treatment with phototherapy will likely require readmission to the hospital.

Breastfed infants may develop *breast milk jaundice* or physiologic jaundice that persists past the first week of life. Breast milk jaundice is a mild unconjugated hyperbilirubinemia caused by a factor in breast milk that promotes increased intestinal absorption of bilirubin. Infants with jaundice past the first week of life should be evaluated with a total and direct bilirubin level to ensure that pathologic

causes of jaundice are not present. After the diagnosis of breast milk jaundice has been established, the infant can be closely monitored to ensure the concentration of bilirubin is not increasing to a level requiring phototherapy. These infants can continue to receive breast milk until the jaundice resolves.

Parental Education and Anticipatory Guidance

Key Points

- Breastfeeding should be recommended for all infants, unless contraindicated, and is most successful if initiated within the first few hours of life.
- Supplements of water, glucose water, or formula should not be given to breastfed infants unless medically indicated.
- All breastfed infants should receive vitamin D drops daily during the first 2 months of life.
- The umbilical cord should be kept clean and dry without the repeated use of antiseptic agents.
- Infants should be placed in a supine position on a firm sleeping surface to reduce the risk of sudden infant death syndrome (SIDS).
- AAP car seat recommendations, updated in 2011, include the use of a rear-facing car seat until the child is 2 years of age.
- The Edinburg Postnatal Depression Scale is a useful and validated tool to screen for postpartum depression.

BREASTFEEDING

Successful breastfeeding requires support and education for both parents during pregnancy, throughout the postpartum hospitalization, and during the early newborn period. Immediately after delivery, the mother should be encouraged to make skin-to-skin contact with her newborn. At that time, it is important to support the mother in holding the infant in a comfortable position at the breast and in establishing a good latch ([Figure 21-18](#)). The mother should be encouraged to feed her newborn on demand and whenever the infant shows early signs of hunger, such as mouthing, rooting, or increased alertness or physical activity. During the initiation of breastfeeding, infants typically feed every 2 to 3 hours, or 8 to 12 times in a 24-hour period ([AAP Committee on Nutrition, 2009](#)). Mothers should be encouraged to offer both breasts at each feeding, but the first breast offered should be alternated so that both breasts receive equal stimulation and draining. Milk production is established in the first 2 to 4 days of life during which time the infant receives colostrum. On day 3 to 5 of life, milk production will dramatically increase. Mothers should be reassured that milk production is based on the demand of the infant and that formula supplementation is not necessary unless there is a medical indication. Similarly, water, glucose water, or other fluids should not be given to a newborn. Breastfed infants should be closely followed after hospital discharge to ensure weight gain is adequate and to provide support to the mother as breastfeeding is being

Figure 21-18 **A**, An appropriate latch for breastfeeding is characterized by a wide-open mouth, everted lips, and a high position on the mother's areola. **B**, An inadequate latch is characterized by a partially closed mouth with the lips near the base of the mother's nipple and little of the mother's areola in the infant's mouth. (Used with permission from Brozanski BS, Riley MM, Bogen DL. Neonatology. In Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of pediatric physical diagnosis*. 6th ed. Philadelphia: Elsevier; 2012:45-77. Courtesy Susan Costanza, RN, IBCLC, Rochester General Hospital, Rochester, NY.)

established. Using a lactation consultant or trained obstetric nurse to establish breastfeeding can provide comfort and confidence to the mother, as well as evaluation of the infant's position, latch, suck, and swallow while feeding.

Parents should be made aware that exclusive breastfeeding is sufficient to support optimal growth and development for the first 6 months of life ([Section on Breastfeeding, 2012](#)). Continued breastfeeding with complementary foods should be encouraged for at least the first year of life and beyond as long as it is beneficial and desired by the mother and child. Complementary foods rich in iron should be introduced gradually beginning around 6 months of age. During the first 6 months of age, water and juice are not recommended because it offers no nutritional benefit to the infant ([Gartner et al., 2005](#)).

Although human milk contains small amounts of vitamin D, it is not enough to prevent hypovitaminosis D or rickets. All breastfed infants should receive 200 IU of oral vitamin D drops daily during the first 2 months of life ([AAP Committee on Nutrition, 2009](#)). Vitamin D should be continued in breastfed infants until the daily consumption of vitamin D–fortified formula or milk is at least 500 mL (about 16 oz) per day. Supplementary fluoride should not be provided during the first 6 months of life. From 6 months to 3 years of age, the decision whether to provide fluoride supplementation should be made on the basis of whether there is adequate fluoride concentration in the water supply.

Many mothers experience problems while breastfeeding, including concern for decreased supply, nipple problems, engorgement, plugged ducts, and mastitis. In most women, milk supply can be augmented by increasing breast

stimulation through increased feeding time or pumping. Adequate rest, hydration, and nutrition are also important to ensure an adequate milk supply. Nipple pain commonly occurs in the immediate postpartum period, and cracked or blistered nipples often develop from incorrect breastfeeding technique. The infant–mother dyad should be observed while breastfeeding to ensure that a proper latch is being achieved. Nipple injury can be treated with cool or warm compresses, hydrogel pads, antibiotic ointments or other barrier ointments (e.g., lanolin), and mild analgesics. Nipple shields may also be used to assist with pain during feeding. Engorgement occurs when more milk than needed is produced. Engorgement typically resolves over time, but symptoms may be managed with warm or cold compresses, mild analgesics, and application of cool green cabbage leaves. Manual expression or pumping may be necessary to provide relief from pain. Plugged ducts present as painful lumps and may progress to infection or mastitis. Mothers should be encouraged to frequently feed or pump to help drain the plugged area. Breastfeeding should not be stopped as cessation will worsen the problem. Applying warm compresses and massage to the area may facilitate removal of the blockage ([AAP and ACOG, 2012](#)).

Physicians should recommend breastfeeding or expressed breast milk for all infants in whom human milk is not specifically contraindicated. There are few true contraindications to breastfeeding. These include (1) maternal infection with HIV, human T-cell lymphotropic virus, herpetic breast lesions, or active tuberculosis; (2) maternal substance abuse; and (3) newborns with galactosemia who require a non-lactose-based formula. Most maternal

medications are compatible with breastfeeding, but medications should be reviewed for potential contraindications before use (see [LactMed](#) in [Web Resources](#)) ([AAP and ACOG, 2012](#)).

UMBILICAL CORD CARE

In the hospital, aseptic care of the cord involves clamping and cutting of the umbilical cord. These measures have been incorporated as part of routine care to minimize the risk of omphalitis. In a meta-analysis of trials conducted in hospital settings, there was no reported difference in the risk of omphalitis between routine dry cord care and the addition of any antiseptic topical agent, including triple dye, alcohol, chlorhexidine, salicylic sugar powder, or green clay powder ([Imdad et al., 2013](#)). Anticipatory guidance to parents should include the importance of keeping the cord clean and dry.

Cord separation normally occurs within the first few weeks of life. Umbilical cord separation is initiated by thrombosis and contraction of the umbilical vessels followed by phagocyte-mediated tissue breakdown and epithelialization of the cord stump ([Imdad et al., 2013](#)). Stump colonization by bacteria acquired from the maternal genital tract or the environment can potentially cause umbilical infections, and it is imperative to keep the cord clean and dry. Until the cord has separated, physicians should advise parents to sponge bathe the infant rather than submersing his or her body in a tub of water. Keeping the diaper folded below the cord and exposing the cord to air may help to keep the area dry. Cleaning the cord too often and using rubbing alcohol may prevent normal leukocyte adhesion from occurring. There is a large variation in the time of normal cord separation; therefore, delayed cord separation does not have a specific definition. In general, any cord that persists after 4 to 6 weeks probably represents delayed cord separation. Delayed cord separation can be associated with an underlying immunodeficiency, infection, or urachal abnormality. Neutrophil function should be evaluated in infants with delayed cord separation and signs of umbilical infection because infants with leukocyte adhesion defects often present with these findings ([Imdad et al., 2013](#)).

SLEEP SAFETY

The AAP released its recommendation in 1992 that infants be placed for sleep in a nonprone position. Since the release of this recommendation, there has been a major decrease in the incidence of SIDS, but this decline has plateaued in recent years. In addition to prone sleeping, several other causes of sudden unexpected infant death (SUID) were published in the AAP's latest statement on SIDS issued in 2005 ([Task Force on Sudden Infant Death Syndrome, 2011](#)). Many of these risk factors are also modifiable, such as soft sleep surfaces, loose bedding, secondhand smoke exposure, overheating the infant, and bed sharing. It has become increasingly important to address these other causes of sleep-related infant death. The AAP expanded its recommendations from focusing only on SIDS to ensuring that parents always provide a safe sleep environment that can reduce the risk of all sleep-related infant deaths, including SIDS. Although the side position is safer than the prone

position, it still remains a risk for SIDS and should not be recommended. Supine positioning is preferred and still highly recommended. Physicians should also recommend that parents use a firm sleep surface such as crib mattress covered by a fitted sheet. A bassinet or portable crib or play yard that conforms to the safety standards of the [Consumer Product Safety Commission](#) can also be recommended. The infant should sleep in an area free of dangling cords, electric wires, and window-covering cords because they might present a strangulation risk. Sitting devices, such as car safety seats, strollers, swings, infant carriers, and infant slings, are not recommended for routine sleep in the hospital or at home. Soft objects, such as pillows, stuffed animals, and large blankets, should be kept out of the area where an infant is sleeping. The AAP does not recommend bumper pads or similar products that attach to crib slats or sides because there is no reliable evidence that these products prevent injury in young infants ([Task Force on Sudden Infant Death Syndrome, 2011](#)). In addition, these products do pose a risk for potential suffocation, entrapment, and strangulation. Parents should be advised that they can reduce the infant's risk of SIDS by not smoking when pregnant and not smoking in the home or around the infant. It is also important that the sleep clothing for an infant is light and does not promote overheating.

Since the Back to Sleep National Campaign recommendations, there has been an increase in cranial asymmetry and positional plagiocephaly. It is very important that anticipatory guidance regarding "tummy time" be given to parents as early as the 2-week well-child examination and repeated at subsequent visits ([Task Force on Sudden Infant Death Syndrome, 2011](#)).

CAR SEAT

In March 2011, the AAP released its revised Child Passenger Safety recommendations. The statement increased the minimum age that children should remain rear facing in infant and convertible seats from 1 to 2 years of age. Young children should ride in car safety seats with a harness until at least age 4 years, and school-aged children should ride in belt positioning booster seats until at least age 8 years or until the seat belt fits correctly, as described by the AAP and National Highway Traffic Safety Administration. The policy also included a change that children should remain in the rear seat of the car until 13 years of age ([Committee on Injury, Violence and Poison Prevention, 2011](#)). Physicians should review these new recommendations with the parents at every visit and remind them that a car seat should never be placed in the front seat of a car with a passenger side air bag. In addition, a car seat that has been involved in a motor vehicle accident should never be reused ([Lincoln, 2005](#)).

BATHING

Bathing an infant can eventually be a fun time for both the infant and parent; however, initially it can be a very daunting experience. Accidental drowning causes more than 600 deaths annually among children younger than 5 years of age. Bathtubs are one of the leading sites for such drowning for children younger than 2 years of age according to the Consumer Products Safety Commission Report (2011).

Physicians should remind parents that an infant should never be left alone in the bathtub and always advise the parent to have all of the supplies prepared before starting the bath. Parents should ensure that the temperature of the water in the home is set no hotter than 120°F to avoid burns (Simon et al., 2003).

An infant does not need to be bathed daily because frequent bathing may promote drying of the infant's skin. However, physicians should remind parents that it is important that parents wash or clean the diaper area thoroughly with each diaper change. Physicians should also advise parents to use fragrant-free, hypoallergenic products that are intended for infants when bathing and when applying lotions or cream (AAP, 2009).

FEVER AND SIGNS OF ILLNESS

Anticipatory guidance given to the parents of an infant should always include the discussion of fever and how to appropriately and accurately take a temperature. The AAP no longer recommends the use of glass mercury thermometers because of the potential for these thermometers to break and lead to inhalation toxicity. The AAP does recommend the use of digital thermometers. If the infant feels warm to touch, parents are advised to take the temperature with a clean thermometer. Feeling the skin is a subjective measure and may be highly inaccurate. The rectal temperature is the most accurate and preferred method in infants. If parents are not familiar or are not comfortable with this technique, then suggest taking an axillary temperature. Physicians should advise parents to avoid pacifier thermometers and forehead strips that gauge temperature. Fever in an infant is a rectal temperature of 100.4°F or 38°C or higher. Parents should be informed that if an infant younger than 3 months of age were to develop a fever, the physician should be immediately notified. Current guidelines recommend that physicians take a cautious approach to neonates (0-28 days) and young infants (29-90 days) with fever because of the risk and potentially adverse consequences of an unrecognized or untreated serious bacterial infection (Ishimine, 2006). Approximately 12% of febrile neonates may have a serious bacterial illness, and group B streptococcus is a common pathogen in this age group. The current guidelines suggest that all neonates with a rectal temperature greater than or equal to 100.4°F or 38°C have blood, urine, and cerebrospinal fluid cultures performed regardless of the infant's clinical appearance. In addition, chest radiography may be added to this workup if the neonate is also having evidence of respiratory distress (Lissauer, 2011).

POSTPARTUM DEPRESSION

After giving birth, most women and their friends and families expect the postpartum period to be a very pleasant period with the arrival of a healthy newborn. The reality, though, is that many women will experience mood disturbances that may be acute or chronic in nature. *Postpartum blues* refers to a transient condition characterized by mild and rapid mood changes. About 40% to 80% of postpartum women develop these mood changes, which may include

extremes of elation, sadness, irritability, anxiety, insomnia, forgetfulness, tearfulness, and even crying spells. This usually occurs within 2 to 3 days of delivery and resolves within 2 weeks of delivery (Cox et al., 1987). *Postpartum depression*, on the other hand, refers to a diagnosis of depressed mood or loss of interests that is present most of the day, occurs almost every day, and lasts for at least 2 weeks at a time.

It is imperative that physicians caring for newborns inquire about the mental health of the postpartum mother. The Edinburgh Postnatal Depression Scale (EPDS) is a 10-item self-report questionnaire designed specifically for the detection of depression in the postpartum period. It has been validated and is available in more than 12 different languages (Cox et al., 1987). Responses are scored 0, 1, 2, or 3, with a maximum score of 30. Mothers who score above 13 are likely to have a depressive illness of varying severity (Cox et al., 1987). When scoring the EPDS, the physician must also pay particular attention to question number 10 regarding a mother's intention to harm herself. Regardless of the total EPDS score, if the answer to this question is not zero, the test result is considered abnormal. The EPDS score should not override clinical judgment and should not prevent the physician from engaging the mother in a conversation about how she feels and determining what level of support she has. A mother identified as having postpartum blues or depression should be offered support, counseling, and a referral to a specialist.

Discipline, 436
Nutrition, 436
Behavior and Neurodevelopment, 439
Guidelines for Clinical Assessment, 441
Immunizations, 445

Children are distinguished from people in other age groups by physical growth and developmental changes that are ongoing, normative, and expected. These changes usually proceed in an orderly progression that allows for individual variation. The family physician must be familiar with the range of normal physical and developmental changes that occur in the process of providing health supervision to children.

Growth is a dynamic process in which increasing cell size and number in various tissues result in a physical increase in the size of the body as a whole. Simultaneously, development occurs as tissues differentiate in form and mature in function, reflecting the person's genetic heritage and environmental interaction. Nutritional, family, emotional, sociocultural, and community influences as well as physical factors play a role in shaping the child's psychological and physiological development (Vaughan and Litt, 1992). The child responds emotionally to a particular stimulus in an apparently innate and characteristic style that reflects his or her temperament.

Knowledge of normal as well as abnormal patterns of growth and development enables the physician to assist the child in maximizing his or her fullest potential. Growth in height and weight is a sensitive reflection of a child's general health. Deviations from normal can reflect the presence of physical illness or a disturbance in the child's environment. Table 22-1 lists some significant causes of growth abnormalities.

Care of Children in Family Medicine

Family physicians have the opportunity to provide family-centered pediatric care in the context of the child's family and community. The office should be "child friendly" and child safe, with at least one room equipped to evaluate children's physical growth. Blood pressure (BP) cuffs should be available to measure children's BP, at least from age 36 months and older. Electrical outlets and cords should be secured, and potentially hazardous chemicals and biohazard bins stored either out of reach or under lock and key from curious young toddlers. Guidelines for the frequency of "well-child" or "well-teen" visits are available from the American Academy of Pediatrics (AAP) *Bright Futures*:

Guidelines for Health Supervision of Infants, Children, and Adolescents (Hagan et al., 2008).

Initial history for a new infant or child includes the birth history, nutritional history (e.g., breastfed vs. bottle fed), developmental milestones achieved, immunization record, and environmental history (e.g., do parents smoke?). Later, the physician or staff will also perform anticipatory guidance, including injury prevention and the need to immunize against vaccine-preventable diseases.

Observation of the parent-child interaction informs the physician about the relationship between parent(s) and the child, especially with infants and young children. A parent sitting in a chair reading a magazine while her young infant teeters on an examination table engenders more concern than a parent who is standing next to the child or has him in her lap. Observation of the child's appearance, alertness, muscle tone, state of hydration, and respiratory status also raise or lower the index of concern about a child. Whereas the cardiorespiratory examination is often done best if the child is sitting or lying on a parent's lap, examination of the abdomen, genitalia, and hips is generally done on the examination table. The HEENT (head, eyes, ears, nose, and throat) examination is often done last because it is the most likely to provoke discomfort.

Blood Pressure Monitoring

Hypertension has become increasingly common in children and adolescents. Since 1988, the prevalence of high BP has increased, especially for certain populations, such as Mexican Americans and blacks (Din-Dzietham et al., 2007). The rising rate of obesity, particularly truncal obesity, at least partly accounts for this. Because of potential end-organ damage and cardiovascular risk in adulthood, auscultatory monitoring of BP is recommended during health care visits for all children 3 years and older and for younger children with certain high-risk features (Table 22-2). Automatic devices may be needed to measure BP in young infants. Elevated BP should be confirmed on repeat visits. The guidelines define *hypertension* as average systolic or diastolic BP of 95% or higher for gender, age, and height on three or more occasions. *Prehypertension* is defined as values of 90% or greater and less than 95%. For

Table 22-1 Significant Causes of Growth Abnormalities in Children**Short Stature**

Familial	Constitutional growth delay Familial (genetic) short stature
Genetic	Down syndrome Noonan syndrome Russell Silver syndrome Skeletal dysplasia (dwarfism) Turner's syndrome Virilizing congenital adrenal hyperplasia (tall child, short adult)
Systemic disorders	AIDS Asthma (poorly controlled) Cancer, caused by poor nutrition, chemotherapy, or radiotherapy Celiac disease Chronic heart failure Congenital heart disease Cushing's syndrome Cystic fibrosis Diabetes mellitus (poorly controlled) Endocrine disease Gastrointestinal disease Growth hormone deficiency, congenital or acquired Heart disease Hypopituitarism Hypothyroidism Immunologic diseases Inflammatory bowel disease (Crohn's disease) Malabsorption syndromes Pulmonary disease Renal disease, chronic renal failure, renal tubular acidosis Severe combined immunodeficiency
Environmental	Malnutrition Psychosocial deprivation Toxin or drug exposure (e.g., lead)

Tall Stature*

Familial	Constitutional acceleration of growth Familial tall stature
Genetic	Beckwith-Wiedemann syndrome Cerebral gigantism (Soto's syndrome) Homocystinuria Marfan syndrome
Systemic disorders	Endocrine disease Pituitary gigantism (acromegaly) Thyrotoxicosis

*Data from Bell J. Tall stature. In Finberg L, ed. *Saunders manual of pediatric practice*. Philadelphia: Saunders; 1998:728-730.

adolescents, BP greater than or equal to 120/80 mm Hg but less than 95% is defined as prehypertensive. Because of the inclusion of a diverse population, these guidelines and tables appear applicable to all ethnic groups (see eTable 22-1 and eTable 22-2 online or at www.nhlbi.nih.gov/files/docs/guidelines/child_tbl.pdf).

The approach to confirmed hypertension in children should be individualized and should consider variables such as comorbidities and family history. In overweight or obese children, the possibility of metabolic syndrome should be investigated. Lifestyle changes, including diet and exercise, may be sufficient for overweight children with stage 1 hypertension (BP at 95% to 99% plus 5 mm Hg). Children with stage 2 hypertension (BP >99% plus 5 mm Hg) and those with end-organ damage likely require medical therapy

Table 22-2 Indications for Blood Pressure Measurement in Children Younger Than 3 Years Old

History of prematurity, very low birth weight, or other neonatal complication requiring intensive care
Congenital heart disease (repaired or nonrepaired)
Recurrent urinary tract infections, hematuria, or proteinuria
Known renal disease or urologic malformations
Family history of congenital renal disease
Solid-organ transplant
Malignancy or bone marrow transplant
Treatment with drugs known to raise blood pressure
Other systemic illnesses associated with hypertension (e.g., neurofibromatosis, tuberous sclerosis)
Evidence of elevated intracranial pressure

Data from National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents: The Fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents. *Pediatrics*. 2004;114:555-576.

(National High Blood Pressure Education Program Working Group, 2004).

Measuring Physical Parameters of Growth

Key Points

- Measure height and weight at all well-child visits.
- Measure head circumference in children up to 24 months of age and BP in children 3 years and older.
- Plot measurements on National Center for Health Statistics (NCHS) growth charts to demonstrate normal growth.
- Investigate significant deviations if the child's growth crosses multiple percentile lines on the growth chart.

Weight, length, and head circumference are the most useful routine measurements in infants. Total body length in children up to age 2 years is obtained most accurately by placing them in the recumbent position and measuring from the crown to the heel. The child's head is placed perpendicular to the surface touching a fixed plate, the hips and knees are fully extended, and the soles of the feet are placed against a sliding board. Older children should have their shoeless standing height measured with a stadiometer with their heels and back touching the wall. Regardless of age, the head should be positioned so that the outer canthus of the eye is aligned with the external auditory canal and perpendicular to the measuring surface (Halac and Zimmerman, 2004). Children should ideally be weighed on the same scale at each visit. Infants should preferably be weighed nude; older children may wear light clothing but not shoes. Height and weight are then plotted on age- and gender-appropriate growth charts developed by the NCHS (see eFigure 22-1) or downloaded from http://www.cdc.gov/growthcharts/clinical_charts.htm.

Body mass index (BMI) is a reliable indicator of body fatness for most children and teenagers that is age and gender specific. A BMI less than the 5th percentile for age is *underweight*, from the 5th to 85th percentiles is *healthy*

weight, from the 85th up to 95th percentiles is *overweight*, and the 95th percentile or greater is considered *obese* (Centers for Disease Control and Prevention [CDC], 2009). BMI charts are also available from the same website.

Head circumference reflects the growth of the cranium and its contents. It should be determined and recorded at all routine physical examinations during the first 2 years of life. This also may be done as part of the initial examination at any age. A nonstretchable measuring tape (usually paper or flexible plastic) is used to obtain the greatest circumference encompassing the occipital, parietal, and frontal prominences. A small head circumference (microcephaly) may be familial; caused by craniosynostosis, congenital viral infections, fetal drug syndromes, or underlying structural abnormalities; or secondary to trauma, infection, or dysmorphic syndromes. A large head circumference (macrocephaly) most often is caused by hydrocephalus, but it may be familial, caused by intracranial bleeding or masses or thickening of the skull, or associated with fragile X syndrome and other conditions (Green, 1986).

PROPER USE AND INTERPRETATION OF GROWTH CHARTS

The growth charts shown in eFigure 22-1 online were revised by NCHS (2000) from surveys of generally well-nourished children representing a cross-section of ethnic and economic groups in the United States. These graphs provide a normal range of weight and length or height for a given chronologic age. Recumbent length is recorded on the chart for children from birth to 36 months, and standing height is recorded on the chart for children from 2 to 18 years. Premature infants should have their chronologic age adjusted according to their degree of prematurity up to age 2 years because most catch-up growth is complete by this time. Although a height or weight above the 95th percentile or below the fifth percentile should alert the physician to a possible problem, these can represent the outer fringe of the normal range.

Linear growth in infants has been shown to occur in incremental bursts rather than continuously (Lampl et al., 1992). A growth curve constructed by a series of heights and weights taken over time allows the physician to compare current growth with the child's previous pattern. The *linear growth velocity*, or rate of gain in height, decreases from 25 cm/yr during the first year of life to a prepubertal rate of 5 to 6 cm/yr by age 6 or 7 years (Miller and Zimmerman, 2004). The rate accelerates during puberty. A child whose growth curve parallels the normal curve regardless of the child's absolute percentile has a normal rate of growth for that particular child. In comparison, a child whose height or weight crosses multiple percentile lines or whose linear growth rate drops below 4 cm/yr requires further evaluation for nutritional, psychosocial, or organic problems that could impede or accelerate growth (Lipsky and Horner, 1988). Children with familial short stature have normal length and weight at birth, but their growth percentiles decline within the first 2 to 3 years of life as they reach their genetic potential (Halac and Zimmerman, 2004).

Although careful measuring and plotting of growth parameters is the most accurate method by which to follow a child's physical growth, approximate growth guidelines

Table 22-3 Approximate Growth Guidelines for Children

Age	Length or Height (ht)	Weight (wt)
Newborn	50 cm (20 in) average	3.4 kg (7.5 lb) average
Newborn to 3 mo	—	1 kg/mo (1 oz/day) average weight gain
3-12 mo	—	Wt (kg) = [Age (mo) + 9] ÷ 2 Wt (lb) = Age (mo) + 11*
12 months	75 cm (30 in) average	Triples birth weight
12-24 mo	Increases by >10 cm/yr	0.25 kg/mo
>5 yr	>5 cm (2 in)/yr until adolescent growth spurt	2.3 kg (5 lb)/yr until adolescent growth spurt
2-12 yr	Ht (cm) = [Age (yr) × 6] + 77 Ht (in) = [Age (yr) × 2.5] + 30* (e.g., 4-year-old child = 40 in)	Ages 1-6 yr: Wt (kg) = [Age (yr) × 2] + 8 Wt (lb) = [Age (yr) × 5] + 17* Ages 7-12 yr: Wt (kg) = [Age (yr) × 7 - 5] ÷ 2 Wt (lb) = Age (yr) × 7 + 5*
Puberty	8-14 cm/yr

Ht, Height; wt, weight.

are helpful to the physician in remembering and forming an overall impression of the child's progress (Table 22-3).

FAMILIAL SHORT STATURE AND CONSTITUTIONAL GROWTH DELAY

Each child has a different rate of maturation, or what Boas termed "tempo of growth" (Tanner, 1986). Persons with *short stature* are more than 2 standard deviations (SD) below the mean in height and constitute approximately 2.5% of children (Miller and Zimmerman, 2004). If a child's growth falls outside the range of normal, it is useful to obtain a bone-age radiograph, usually of the left hand and wrist, and compare it with age-specific standards. Children must be at least 2 years of age to reliably identify epiphyseal ossification centers. Table 22-4 lists some causes of retarded or accelerated bone age. Calculation of mean predicted adult height is also useful in determining whether a child is fulfilling her or his genetic potential. The mean predicted adult height is calculated as follows (Rogol, 2004):

$$\begin{aligned} \text{Boys mean height} &= \\ &[\text{Father's height} + (\text{Mother's height} + 13 \text{ cm})] / 2 \\ \text{Girl's mean height} &= \\ &[(\text{Father's height} - 13 \text{ cm}) + \text{Mother's height}] / 2 \end{aligned}$$

Children and adolescents of short stature whose bone age is delayed relative to their chronologic age have more growth potential than do children with a skeletal age appropriate for their chronologic age. If an organic cause of short stature has been excluded, children with delayed bone age are likely to have *constitutional growth delay*. The majority of these children are boys who were of normal length and weight at birth. Their growth rate decelerates during the first 2 years of life and subsequently returns to normal.

The children then follow a lower percentile on the growth curve until the onset of their pubertal growth spurt and development, which often occurs later than their peers. There is usually a family history of delayed growth and development (Bareille and Standhope, 1998). The bone age of these children equals their height age, which is the age at which their height plots on the 50th percentile of the growth chart.

Children with familial short stature usually have parents or close relatives who are short. They often have normal birth weight and length, but their growth rate declines during the first 2 to 3 years of life. Their growth curve subsequently parallels the normal curve but falls below the fifth percentile (Bareille et al., 1998). Their bone age is

approximately equal to their chronologic age but less than their height age. These children usually enter puberty at the appropriate age. The U.S. Food and Drug Administration (FDA) has approved the use of recombinant growth hormone for the treatment of idiopathic short stature. This can result in an increase of predicted height of more than 7 cm (Miller and Zimmerman, 2004). Because of potential side effects and the high cost, treatment should be undertaken in consultation with a specialist in pediatric growth disorders.

PUBERTAL GROWTH AND DEVELOPMENT

All children grow at a different tempo, with some maturing earlier than others and some later. This difference is most apparent during puberty. The NCHS growth charts now extend to age 20 years. Tanner and Davies (1985) took the earlier NCHS data and constructed height and weight velocity curves for American boys and girls that account for those groups who mature earlier and later. These charts also allow for notation of the various stages of puberty described by Tanner (1986) (Table 22-5).

The onset of puberty generally occurs at age 9 in American girls, with the peak height velocity occurring at age 11.5 years (range, 9.7 to 13.5 years for early to late maturers). American boys have onset of puberty at age 11 and peak height velocity at 13.5 years (range, 11.7-15.3 years) (Tanner and Davies, 1985). Because boys have two additional years of prepubertal growth and a peak height velocity greater than that of girls, their ultimate height is usually taller. Head, hands, and feet are first to reach their adult size followed by leg length, trunk length (which accounts for much of the spurt), and body breadth. Pubertal boys develop greater shoulder breadth than do pubertal girls, who develop wider hips. Adolescents can be reassured that their bodies eventually will become more proportionate with their hands and feet. Boys ultimately gain greater muscle size and strength than do girls while losing limb fat. This results from their increased secretion of testosterone.

Table 22-4 Causes of Short Stature and Relationship to Bone Age and Growth Rate

Bone age less than chronologic age	Growth Rate Normal or Slightly Decreased
	Constitutional growth delay
	Growth Rate Decreased
	Endocrine disorders
	Cushing's syndrome
	Growth hormone deficiency
	Chronic systemic disease
	Crohn's disease
	Heart failure
	Renal failure
Severe malnutrition	
Severe psychosocial deprivation	
Bone age equals chronologic age	Growth Rate Normal or Slightly Decreased
	Familial short stature
	Skeletal dysplasias
	Rickets
	Growth Rate Decreased
Chromosomal disorders	
Down syndrome	
Turner's syndrome	
Bone age greater than chronologic age	Growth Rate Initially Increased But Short Adult
	Congenital adrenal hyperplasia
	Exogenous androgenic steroids
	Precocious puberty

Table 22-5 Sexual Maturity Stages in Boys and Girls

Stage	Male Genitalia	Pubic Hair	Female Breasts
1	Preadolescent: testes, scrotum, and penis are childlike in size	None; may be vellus hair, as over abdomen	Preadolescent: elevation of papilla only
2	Slight enlargement of scrotum with reddening of skin; little or no enlargement of penis	Sparse growth of long, slightly pigmented, downy hair, straight or slightly curled, primarily at base of penis or along labia	Breast bud stage; breast and papilla form a small mound; areolar diameter enlarges
3	Further enlargement of scrotum; penis enlarges, mainly in length	Hair considerably darker, coarser, and more curled; spreads sparsely over junction of pubes	Further enlargement of breasts and areola with no separation of their contours
4	Further enlargement and darkening of scrotum; penis enlarges, especially in breadth; glans develops	Adult-type hair that does not extend onto thighs, covering a smaller area than in adults	Areola and papilla project to form a secondary mound above the contour of the breast; stage 4 development of the areolar mound does not occur in 10% of girls and is slight in 20%; when present, it may persist well into adulthood
5	Adult in size and shape	Adult in quantity and type with extension onto thighs but not up linea alba	Mature female; papilla projects and areola recesses to general contour of breast
6	—	Spreads up linea alba (80% of men, 10% of women)	—

Modified from Tanner JM. Normal growth and techniques of growth assessment. *Clin Endocrinol Metab.* 1986;15:436.

which also increases red blood cell mass and hemoglobin (Tanner, 1986).

The adolescent growth spurt in skeletal and body dimensions is associated closely with the development of the reproductive system. Although the onset and rate of maturation vary according to the individual, the sequence is usually the same within genders (Figures 22-1 and 22-2). Girls who demonstrate signs of puberty before 7 to 8 years of age and boys who show signs before 9 years should be evaluated for *precocious puberty*. Conversely, girls who do not show signs of puberty by age 13 years and boys by age 14 years should be evaluated for *pubertal delay* (Plotnick, 1999).

The first sign of puberty in boys is an increase in growth of the testes and scrotum, with reddening and wrinkling of the scrotal skin. Pubic hair appears within 6 months followed by phallic enlargement in 12 to 18 months and peak height velocity 2 to 2.5 years after testicular enlargement (Copeland, 1986). Axillary hair usually appears 2 years after the beginning of pubic hair growth (stage 4 pubic hair), but there is considerable variability. Some boys may have enlargement of the breasts midway through adolescence. After the attainment of peak height velocity, boys develop mature spermatozoa, full facial hair, and voice change. However, breaking of the voice is a late and often gradual process.

In girls, the breast buds are the first sign of puberty, and the pubertal growth spurt typically occurs concurrently, peaking at stage 3 breast and pubic hair. The uterus and vagina develop simultaneously with the breasts, but

menarche usually does not occur until stage 4 breast and pubic hair. Although the peak height velocity has been passed, girls may grow an average of 6 cm more after menarche. Early cycles may be irregular and anovulatory, but early sterility should never be presupposed (Tanner, 1986).

Screening Healthy Children

Key Points

- All newborns should have a hearing screen within the first month of life.
- Examine eyes at all well care visits; screen vision beginning at age 3 years.
- Provide anticipatory guidance regarding discipline starting at 15 months of age.

Preventive care services for children often include screening for health conditions in which early detection and early treatment can prevent or ameliorate more serious disease in the future. Screening tests should detect most persons with the condition (*sensitivity*) while excluding most persons who do not have the condition (*specificity*) in a cost-effective manner. In an inner-city Medicaid population, high continuity of care in infancy was associated with improved screening for anemia, lead, and tuberculosis (TB) (Flores et al., 2008).

HEARING AND VISION SCREENING

Early detection and intervention for hearing and vision deficits are important for maximal long-term functioning. Without appropriate opportunities to learn language, children with significant hearing deficits fall behind peers in terms of communication, cognition, reading, and social-emotional development, with long-term effects on educational attainment and adult employment (AAP Joint Committee on Infant Hearing, 2007). All infants should be screened for hearing loss by 1 month of age, regardless of risk factors. Those who do not pass the screening should have a complete audiologic evaluation by 3 months of age, and those with confirmed hearing loss should receive appropriate treatment by 6 months to ensure optimal outcome. Regardless of the outcome of newborn screening, ongoing surveillance of hearing status is recommended. Developmental delays and other risk factors (Table 22-6), particularly in language, as well as the presence of parental concern about hearing, should prompt referral for a complete audiologic evaluation, even if the newborn screening results were normal and there are no risk factors for hearing impairment (Hagan et al., 2008). Gradations of hearing loss are presented in Table 22-7.

Eyesight evaluation is a recommended part of routine health maintenance examinations in children beginning in the newborn period. In young children (<3 years), the evaluation, besides the actual eye examination, is somewhat subjective and based on parental history. Children with risk factors, such as prematurity, family history of retinoblastoma or glaucoma, or significant developmental delays or neurologic difficulties, should be referred to an experienced pediatric ophthalmologist. The U.S. Preventive Services

Table 22-6 Risk Factors for Delayed Onset of Hearing Loss in Young Children

Caregiver concern regarding hearing, speech, language, or developmental delay
Family history of permanent childhood hearing loss
Neonatal intensive care longer than 5 days
In utero infections (e.g., cytomegalovirus)
Craniofacial anomalies (e.g., ear pits, ear canal defects)
Syndromes known to be associated with hearing loss (e.g., neurofibromatosis)
Neurodegenerative disorders (e.g., Friedreich ataxia)
Postnatal infections (e.g., meningitis)
Head trauma (e.g., basal skull/temporal bone fracture)
Chemotherapy

Modified from Hagan JF, Shaw JS, Duncan PM, eds. *Bright futures: guidelines for health supervision of infants, children, and adolescents*. 3rd ed. Elk Grove Village, IL: American Academy of Pediatrics; 2008:232.

Table 22-7 Hearing Loss Scale

Hearing Impairment	Hearing Threshold (dB)
None	10-25
Mild	26-40
Moderate	41-55
Moderate to severe	56-70
Severe	71-90
Profound	>91

Task Force (USPSTF) recommends vision screening for all children at least once between the ages of 3 and 5 years, especially to detect amblyopia or its risk factors (e.g., strabismus), which occurs in 2% to 4% of preschool children (USPSTF, 2011, grade B evidence). Testing of children at this age may use standardized systems such as the Allen Cards, which have easily recognized pictures. Normal visual acuity is in the 20/30 to 20/40 range for children 3 to 4 years old but increases to 20/20 by early school age. Eye-specific screening should be attempted in an effort to detect amblyopia (more than one line difference on the chart) (SOR: B). The suspicion of amblyopia or strabismus requires further evaluation to prevent long-term visual loss. Routine screening should be done at least through early school age, at puberty, and whenever there are other signs, such as squinting or complaints of inability to see the board at school (Hagan et al., 2008).

SCREENING FOR IRON-DEFICIENCY ANEMIA

The USPSTF (2006) currently has found insufficient evidence to recommend for or against routine screening of asymptomatic infants age 6 to 12 months for iron-deficiency anemia (IDA). Hemoglobin determines red blood cell mass and the presence of anemia but is neither sensitive nor specific. Serum ferritin is more sensitive and may be used as a confirmatory test for iron deficiency as long as inflammation is absent (Baker et al., 2010). True iron deficiency is much more common than IDA. In addition, there is evidence that even children with severe anemia who are treated with iron supplementation continue to demonstrate behavioral and developmental deficits 10 years afterward (Lozoff et al., 2000). Nevertheless, the AAP Committee on Nutrition recommends universal screening for anemia at about 1 year of age. This should include an assessment of risk factors, including history of prematurity or low birth weight, exclusive breastfeeding beyond 4 months of age without supplemental iron, or weaning to whole milk or foods that are low in iron. If these risk factors are present, selective screening can be done at any age (Baker et al., 2010).

SCREENING FOR LEAD TOXICITY

Because lead is neurotoxic and affects both intellectual and behavioral function, the CDC defines a blood lead level (BLL) of 5 µg/dL or greater as a high BLL (CDC, 2013). This is based on the 97.5th percentile in the 2007 to 2010 National Health and Nutrition Examination Survey (NHANES), which demonstrated that the percentage of children with BLLs of 5 µg/dL or higher was 2.6% overall for children age 1 to 5 years, with 5.6% in black, non-Hispanic; 2.6% in Mexican American; and 2.4% in white non-Hispanic children. However, approximately 7% to 40% of immigrant and refugee children, especially from the Near East, Africa, Asia, and Central American or Caribbean countries, have high BLLs. Therefore, these children 6 months to 16 years old should be screened for lead within 30 to 90 days of arrival in the United States (CDC, 2013). Screening for IDA should also be done because this is a significant risk factor for elevated BLL. Targeted screening of specific groups of children may be recommended by state mandate or third-party

payers (e.g., Medicaid). Specific state information can be obtained at <http://www.cdc.gov/nceh/lead>. Children considered at risk who require screening include (1) those suspected by a parent or health care provider to be at risk for exposure; (2) those with a sibling or frequent playmate with an elevated BLL; (3) those with a parent or caregiver who works professionally or recreationally with lead; (4) those with a household member who uses traditional folk or ethnic remedies or cosmetics; or (5) those designated at increased risk for lead exposure by the health department because of local risk factors for lead exposure, such as residing in a high-risk zip code (Wengrovitz and Brown, 2009).

SCREENING FOR TUBERCULOSIS

In 2007, there were approximately 10 million cases of new and recurrent TB and 1.8 million deaths worldwide, with the highest rates occurring in low-income countries (Marais et al., 2009). The incidence of active TB is much lower in the United States, but an estimated 10 to 15 million persons have *latent tuberculosis infection* (LTBI). Six groups considered at high risk are children, foreign-born persons, HIV-infected persons, homeless persons, detainees and prisoners in correctional facilities, and close contacts of infectious persons (CDC, 2005). Targeted rather than universal testing of children for TB is now recommended. Risk factors for LTBI include (1) previous positive tuberculin skin test result, (2) birth in foreign country with high prevalence of TB (e.g., China, India, Mexico, Philippine Islands, Vietnam, certain African countries), (3) nontourist travel to a high-prevalence country for more than 1 week, (4) contact with a TB-infected person, and (5) presence in the household of another person with LTBI (CDC, 2005). The Mantoux TB skin test is recommended for children because its correlation with results of interferon- γ release assays is often discordant in children (Connell et al., 2008).

Discipline

Parents frequently ask their primary care physicians about discipline. Discipline should be a priority topic for anticipatory guidance when the child is 15 months and 18 months (Hagan et al., 2008). Effective discipline requires three essential components: (1) a positive, loving relationship between the parent(s) and child; (2) positive reinforcement strategies to increase desired behaviors; and (3) punishment or removal of reinforcement to reduce or eliminate undesired behaviors. Although often confused with punishment, discipline actually means to *teach*. All children benefit from guidance and structure, and most children require occasional discipline. The best discipline is consistent and considers the child's developmental level as well as the child's point of view. Effective strategies include environmental modifications (e.g., childproofing the house), distraction, redirection, giving appropriate choices, and time-outs. Although many parents spank (Regalado et al., 2004), corporal punishment is controversial and has potential long-term negative effects (Smith, 2006). Other methods of discipline are more effective over time and should be used. Some families may require more intensive assistance,

and clinicians should be aware of local resources for teaching parents.

Nutrition

Key Points

- Breast milk is the recommended food for infants and the standard to which infant formulas are compared.
- Give vitamin D supplements to all breastfed infants and those taking less than 1 L of vitamin D–fortified milk or formula per day.
- Begin iron-fortified cereal for infants older than 4 to 6 months or low-birth-weight (LBW) infants older than 2 weeks.
- Obtain a fasting lipid profile in children with a family history of dyslipidemia; premature atherosclerotic vascular disease; or personal risk factors such as overweight, hypertension, smoking, and diabetes mellitus.

INFANCY THROUGH ADOLESCENCE

Proper physical growth and appropriate cognitive development depend on adequate nutrition. Infants and young children with severe IDA were found to have significantly lower verbal and full-scale IQ scores and lower achievement test scores in arithmetic and writing than infants without iron deficiency, even 10 years after treatment (Lozoff et al., 2000). An increase in behavioral problems was also reported, although this could not be directly linked to the preceding iron deficiency. In NHANES III (1988-1994), 7.2% of 12- to 16-year-old girls had iron deficiency, but only 1.5% demonstrated anemia (Halterman et al., 2001). Adolescent iron-deficient girls scored significantly lower math scores compared with non-iron-deficient girls. Vitamin D deficiency and insufficiency in children and adolescents has been reported worldwide, including in North America (Wagner and Greer, 2008). Mealtimes also represent times for social interaction within the family unit, whether it is the bonding of mother and child during breastfeeding or discussion of the day's events during dinnertime.

Although malnutrition is still a problem in the United States, *inappropriate nutrition*, especially calorie-nutrient imbalance leading to overweight and obesity, has become commonplace. Recent NHANES studies demonstrate that the prevalence of overweight (BMI $\geq 95\%$) in girls 2 to 19 years old increased from 13.8% in 1999 to 2000 to 16% in 2003 to 2004, and the prevalence of overweight in boys 2 to 19 years old increased from 14% to 18.2% (Ogden et al., 2006). Increased pediatric BMI is associated with high BP, sleep apnea, asthma, polycystic ovarian syndrome, type 2 diabetes, gastroesophageal reflux, and orthopedic problems (Benson et al., 2009). A nationwide survey of more than 6000 children and adolescents found that at least 30% consumed "fast food" on a typical day. These children consumed more total fat, total carbohydrate, and added sugars and sugar-sweetened beverages, less milk, and fewer fruits

Table 22-8 Comparison of Common Milks and Infant Formulas

Milk or Formula	kcal/ 30 mL	Protein (g/dL)	CHO (g/dL)	CHO Type	Fat (g/dL)	Iron (mg/L)	Comments
Human milk	20	1.0	6.9	Lactose (primary), glucose, oligosaccharides	4.4	<0.1	Small flocculent curd is easily digestible, and iron is absorbed.
Whole cow's milk	19	3.3	4.7	Lactose	3.7	Trace	Curd is less easy to digest. Can cause intestinal blood loss. Do not use before age 12 mo.
Evaporated whole milk	43	6.9	10.0	Lactose	7.6	Trace	Curd is softer, smaller, and may be less allergenic. Dilute and add dextrose to make 20 kcal/oz formula.
Prepared formula, cow's milk based	20	1.4-1.7	6.9-7.5	Lactose	3.4-3.8	4.7-12.2*	AAP recommends only iron-fortified formulas.
Prepared formula, soy based	20	1.7-1.8	6.8-7.4	Corn syrup, corn syrup solids, sucrose, corn maltodextrin	3.4-3.7	12-12.2	May use if lactase-deficient vegetarian, galactosemic, or allergic to cow's milk. [†]

*Iron-fortified formula; [†]However, cross-reactivity with cow's milk protein sometimes occurs.

AAP, American Academy of Pediatrics; CHO, carbohydrate.

Modified and compiled from Kleinman RE, ed. *Pediatric nutrition handbook*. 6th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2008:1250-1265.

and nonstarchy vegetables than children who did not eat fast food (Bowman et al., 2004). The odds of having a BMI of 85th percentile or higher was more than four times that for 10- to 15-year-old children viewing more than 5 hours of television per day compared with those watching for 0 to 2 hours (Gortmaker et al., 1996). A survey of low-income preschool children in New York State found that children with TV sets in their bedrooms watched 4.6 hours per week more TV and videos than those without bedroom TVs. In this group, the prevalence of child overweight (BMI >85%) was associated with an odds ratio of 1.06 for each additional hour per day of TV or videos viewed (Dennison et al., 2002). Frequent television viewing can lead to decreased activity, excessive snacking on high-calorie junk foods, and subsequent obesity (Dietz and Gortmaker, 1985). In contrast, dieting in pursuit of the media's representation of the ideal woman can lead to eating disorders, such as bulimia or anorexia. The CDC has proposed 24 strategies to prevent obesity in the United States, including increasing the availability of healthier food and beverage choices, restricting the availability of less healthy foods and beverages in public service areas, and increasing the amount of physical activity in schools (Khan et al., 2009).

INFANTS AND TODDLERS

Infants require approximately 120 kcal/kg/day to meet basal metabolic requirements and the energy demands of growth and activity during the first 6 months of life. LBW newborns may require 130 to 150 cal/kg/day for catch-up growth. Weight gain should be 25 to 30 g/day during the first 3 months of life, decrease to 15 to 20 g/day between 3 and 6 months of age, and decrease to 10 to 15 g/day between 6 and 12 months (AAP, 2009). Energy requirements are increased by greater physical activity, stress imposed by disease processes (e.g., cystic fibrosis), or symptoms (e.g., fever). Fever can increase the fluid requirements of infants younger than 6 months beyond the usual 130 to 190 mL/kg/day (Barnes and Curran, 1996).

The composition of human milk varies by time, day, and maternal nutrition and from woman to woman. Infant formulas contain about 50% more protein than human milk and, similar to breast milk, provide 40% to 50% of energy as fat (Table 22-8). Beginning at 2 years of age, fat calories should decrease to approximately 30% of total energy consumption, with less than 10% of calories from saturated fat, and dietary cholesterol less than 300 mg/day (AAP, 2009).

The ideal food for full-term infants during the first 12 months of life is human milk. Oliver Wendell Holmes once noted, "A pair of substantial mammary glands has the advantage over the two hemispheres of the most learned professor's brain in the art of compounding a nutritious fluid for infants" (Cone, 1979, p. 138). Human milk is fresh, readily available at the proper temperature, and generally free of contaminating bacteria. Its acid-resistant whey proteins include secretory immunoglobulin A (sIgA); α -lactalbumin; and lactoferrin, a whey protein that transports iron and inhibits the growth of a range of organisms in the intestine. The protein in human milk consists predominantly of whey proteins that are of higher nutritional quality and digested and absorbed more easily than cow's milk proteins (AAP, 2009).

Commercial cow's milk and soy-based formulas must contain higher levels of protein to compensate for their lower quality (see Table 22-8). However, they are quite acceptable for mothers who are unable to nurse their infants or for parents who wish to bottle feed their children. Soy formulas are recommended for infants with hereditary lactase deficiency or galactosemia and may be tried in infants intolerant to cow's milk, but soy formula should not be used in preterm infants. Because some infants allergic to cow's milk protein will develop an allergy to soy protein, it is advisable to use an extensively hydrolyzed protein formula in cases of true milk allergy or malabsorption. These are lactose free and may contain medium-chain triglycerides to improve fat absorption (AAP, 2009).

Human breast milk or iron-fortified infant formula is recommended for the first 12 months of life. Cow's milk is not

suitable for infants because the higher intake of protein, sodium, potassium, and chloride increases renal solute load. In addition, the lower concentrations of iron, zinc, essential fatty acids, vitamin E, and other micronutrients can result in deficiencies. Significant intestinal blood loss can occur in infants younger than 12 months of age receiving cow's milk. Very-low-fat milks lack adequate calories for growth despite promoting excessive volume ingestion. Breastfed full-term infants seldom develop IDA before 4 to 6 months of age because the iron present in breast milk is well absorbed. Iron-fortified infant cereal or meats are then good sources of the 1 mg/kg/day of elemental iron required by full-term infants. All preterm or LBW infants should receive at least 2 mg/kg/day of elemental iron from 2 weeks until 12 months of age (AAP, 2009). Parents should be warned that iron is toxic in excessive amounts, and appropriate precautions should be taken.

Children 6 months to 3 years old who do not drink fluoridated water or other beverages may be given 0.25 mg/day of supplemental fluoride. Human milk contains only small amounts of biologically active vitamin D, and rickets has been reported in breastfed infants, infants with darker skin pigmentation, and even older children with minimal exposure to sunlight. Consequently, all breastfed infants, partially breastfed infants, nonbreastfed infants, and older children ingesting less than 1000 mL/day of vitamin D–fortified formula or milk should receive 400 IU/day of supplemental vitamin D daily beginning within the first few days of life until the infant or child is ingesting 1000 mL/day of vitamin D–fortified formula or milk (AAP, 2009). Higher doses of vitamin D may be required in children with chronic fat malabsorption. Vitamin B₁₂ supplementation should be given to breastfed infants whose mothers are strict vegetarians.

Both the World Health Organization and AAP promote exclusive breastfeeding for the first 6 months of life. However, safe, nutritious solid foods may be introduced between 4 and 6 months of age when the infant is developmentally ready. The order of introduction of solid foods is generally not critical; however, single-ingredient foods should be tried for 1 week at a time to observe for possible allergic reactions before introducing another food or mixtures of foods. Single-grain infant cereals such as rice (which lacks gluten) are usually well tolerated and provide a source of fortified iron. Homemade infant foods should not have added salt or sugar. Honey is associated with infant botulism and should not be given to infants younger than 1 year. Teething biscuits or finely chopped foods may be given by 8 to 10 months of age. However, foods such as popcorn, nuts, and rounded candies should not be offered to infants or toddlers because of the risks of choking, aspiration, and even death. Potentially hazardous foods such as hot dogs and grapes must be cut into small pieces, and the caregiver should always be present during mealtimes. Children should be weaned from the bottle to a cup by 12 to 15 months of age and bedtime bottles discouraged because they are associated with dental caries (AAP, 2009).

A toddler's food intake may be quite variable from day to day or even meal to meal. Because young children cannot choose a well-balanced diet, parents must provide nutritious, safe, developmentally appropriate foods at regular meals and snacks. Children should sit in a designated area

for mealtimes, without distractions such as television (AAP, 2009). Small portions of food should be offered to preschool children, allowing the child to determine how much he or she will eat and offering more as necessary. Excessive portion sizes can contribute to obesity later in life. Guidelines about types and quantities of foods from the basic food groups are available from the U.S. Department of Agriculture's Choose My Plate website (<http://www.choosemyplate.gov>), which provides recommendations on the amount of grain products, vegetables, fruits, and milk products based on the person's age, gender, and activity level.

Parents should be counseled that toddlers and preschool children are often picky eaters but generally grow well despite this. Parents need to guide children in their selection of food by offering a variety of nutritious items such as fruits and vegetables, keeping in mind that it can require eight to 10 exposures to a new food before a child accepts it (AAP, 2009). Mealtimes should not turn into a battleground because forcing a child to clean the plate can lead to specific food dislikes or promote obesity in later life. Snacking or eating while watching television should be discouraged, and physical activity should be encouraged.

Healthy children eating a varied diet usually do not require a multivitamin supplement. Children who do not eat dairy products, meat, or eggs require supplemental vitamin B₁₂ and are at risk for vitamin D deficiency, especially if they lack adequate sunlight exposure or have darkly pigmented skin. Children following strict vegetarian diets often have low intakes of iron and calcium that can require supplementation. They often have a low intake of zinc that may be obtained from zinc-fortified infant and adult cereals. The recommended fiber intake is 19 g/day for children 1 to 3 years old and 25 g/day for those 4 to 8 years old. Excessive fiber consumption may decrease the intake of energy-dense foods and inhibit the absorption of some minerals (AAP, 2009).

Children with malabsorption or hemolytic anemia can require additional folic acid. Parents who insist on using a vitamin supplement without any obvious deficiency on the part of the child should be counseled to use a preparation that does not exceed the dietary reference intakes established by the Institute of Medicine and the National Academy of Sciences. In particular, vitamins A and D can produce toxicity if given in excessive doses.

ADOLESCENTS

Adolescents are at greater risk than other age groups for nutritional deficiencies because they may skip meals, snack more, eat more fast foods, and follow fad diets for reasons ranging from weight loss to cultural differentiation. Teenage boys and girls often replace milk and juice with soft drinks, coffee, tea, and alcoholic beverages, thereby lowering their intake of calcium as well as vitamins A and C. Adolescents' iron intake may be lower than required for their rapid increases in lean body mass and hemoglobin mass in addition to menstrual blood loss in girls. Zinc is also required for growth and sexual maturation. Most teenagers do not ingest the recommended 1300 mg of calcium daily (AAP, 2009).

Energy requirements vary greatly in teenagers, depending on their gender, activity, and stage of adolescence.

Sedentary adolescent girls require 1600 to 1800 cal/day and sedentary boys 1800 to 2200 kcal/day. As much as 200 kcal/day may be added for moderate physical activity and 200 to 400 kcal/day added for those who are very active (Daniels and Greer, 2008). Healthy pregnant women of normal BMI should tailor their prenatal diet to achieve a total weight gain of 11.5 to 16 kg (26-35 lb), or an additional 300 kcal/day during the second and third trimesters. Additional protein requirements are about 15 and 27 g/day during the second and third trimesters, respectively. Most require some form of iron supplementation, about 30 mg/day during the second and third trimesters. Because zinc deficiency has potential teratogenic effects, pregnant adolescents should receive about 13 mg/day of zinc supplementation along with 1 mg/day of copper supplementation. All women of childbearing potential should take 400 to 600 µg of folic acid supplement per day in addition to 400 µg of dietary folate to decrease the risk of giving birth to children with neural tube defects. Pregnant women also require 1300 mg/day of calcium in their diets (AAP, 2009).

Cholesterol Recommendations

Universal screening for hypercholesterolemia in children is not currently recommended. A fasting lipid profile should be obtained in children who have a family history of dyslipidemia or premature (men ≤ 55 years, women ≤ 65 years) coronary heart disease or peripheral vascular or cerebrovascular disease. Children for whom the family history is not known or who have other risk factors such as overweight (BMI $\geq 85\%$ and $< 95\%$), obesity (BMI $\geq 95\%$), hypertension (BP $\geq 95\%$), cigarette smoking, or diabetes mellitus should also be screened. This screening should be done between 3 and 10 years of age. The National Cholesterol Education Program guidelines indicate that a total cholesterol less than 170 mg/dL is acceptable, 170 to 199 mg/dL is borderline, and 200 mg/dL or greater is high. Similarly, a low-density lipoprotein (LDL) level less than 110 mg/dL is acceptable, 110 to 129 mg/dL is borderline, and higher than 130 mg/dL is elevated (Daniels and Greer, 2008). The American Heart Association has designated triglyceride levels greater than 150 mg/dL and high-density lipoprotein (HDL) level less than 35 mg/dL as abnormal. If initial lipid values are within acceptable levels, retesting should be done in 3 to 5 years.

It is recommended that all healthy children older than 2 years follow a diet in which a wide variety of foods provide adequate caloric intake to achieve proper growth and development as well as desirable weight. Total fat and saturated fat intake should be no more than 30% and 10%, respectively, of total calories; dietary cholesterol should be less than 300 mg/day. Children who are overweight or obese and have a high triglyceride or low HDL level should be counseled regarding proper diet and increased physical activity. Children at especially high risk based on familial hyperlipidemias or premature cardiovascular disease may undertake a diet restricting saturated fat to 7% of total calories and cholesterol to 200 mg/day (Daniels and Greer, 2008). Children 10 years and older may be considered for pharmacologic therapy with LDL of 190 mg/dL or higher without additional risk factors, 160 mg/dL or greater with a family history of early heart disease or two or more other

risk factors, or 130 mg/dL or higher if diabetes mellitus is present (AAP, 2009).

KEY TREATMENT

- Ensure vitamin D intake of at least 400 IU/day, either by diet or supplementation (Wagner and Greer, 2008) (SOR: A).
- Children 2 years and older should follow a diet with less than 30% of calories from total fat and 10% from saturated fat (Daniels and Greer, 2008) (SOR: B).
- Communities should improve the availability of affordable healthier food and beverage choices and restrict the availability of less healthy choices in public service areas by decreasing the cost of healthy foods and increasing the cost of less healthy foods (Khan et al., 2009) (SOR: B).

Behavior and Neurodevelopment

Key Points

- Development is a product of factors intrinsic and extrinsic to the child.
- Basic knowledge of child development enables clinicians to guide and educate families.
- Development proceeds in a basic sequence.
- Delays in one area of development may affect another.
- In preterm infants, correct for prematurity until age 2 years.

One of the rewards of providing primary care for a child is sharing with the family in the development of cognitive, motor, social, and language skills. Clinicians need to understand the theoretic framework on which the scientific understanding of child development is based to individualize the approach to the unique needs and concerns of each family. Physicians should develop strategies for clinically assessing child development and managing identified developmental abnormalities.

THEORIES OF DEVELOPMENT

Child development was widely studied in the 20th century. A general understanding of the common theories can enrich the clinician's relationship with young patients. Most researchers in child development believe that developmental outcomes are a product of intrinsic child factors, including genetic potential and temperament, and extrinsic environmental factors, such as intrauterine, infectious, traumatic, chemical, and sociocultural factors (Vaughan and Litt, 1992). The relative weights of each of these factors vary considerably among persons, thus frustrating the attempts of researchers to develop a formula for predicting developmental outcome for any individual person.

A clinician who is familiar with the key elements of theoretic models can develop expertise in applying them appropriately to meet the needs of countless clinical scenarios. For example, a physician might use Erikson's theory

Table 22-9 Summary of Developmental Theories of Child Development

Theory (Proponents)	Key Features	Potential Clinical Applications
Normative approach: development as maturation (Gesell)	Behavior depends on neurologic and physical maturation. Universal progression of developmental sequence. Minimal role of environment and temperament.	Basis for age norms for developmental milestones typically used in clinical setting.
Psychosexual and psychoanalytic theory: development as resolution of conflict (Freud, Erikson)	Emotional life exerts a strong influence on development and behavior. Unconscious conflicts between biologic drive and social expectations continuously shape behavior and self-concept. Parents exert primary influence on child, affecting behavior into adulthood. Mastery of major developmental tasks at different stages is required for emotional growth.	Interpersonal relationships, especially with primary caregivers, influence present and future adjustment, functioning, and self-concept. Importance of “bonding.”
Behaviorism and social learning: development as learning (Pavlov, Skinner, Bandura)	Behavior, but not its underlying influences and motives, can be studied and changed. Environmental stimuli are the major forces shaping development and behavior. Environmental stimuli act as positive and negative reinforcements to existing behavior.	Children imitate what they see, so environmental models are important to learning (e.g., influences of media). Basis for behavioral management approaches.
Constructivist views: development as cognitive change (Piaget)	Cognitive development depends on both nature and nurture. Child uses physical and mental abilities to observe and act on the environment. Observation and action advance cognitive development. Child’s mental processing develops with age, influencing how child perceives and interacts with the world.	Children possess an innate drive to learn. Play is the medium by which children learn and develop. Parents can be guided in choosing appropriate playthings and settings to allow their children to learn.
Ecologic system: development as cultural and ecologic adaptation (Bronfenbrenner)	A set of interrelated systems (e.g., family, school, community, health services) influences development. These systems exert reciprocal influence on one another. Development is determined by interactions of child and family.	Children’s needs must be considered in context of the family and the environment.

of psychosocial stages to explain to a vexed parent of a 2-year-old child that the child’s constant temper tantrums represent a normal expression of the child’s need to exert autonomy over the environment. In the next room, the physician might refer to Piaget’s concept of concrete operational thought to explain why a 10-year-old child might not be capable of considering remote consequences of present actions (e.g., “If I don’t study for my science test, I might not meet my goal of becoming an astronaut”).

Features of the most widely accepted developmental theories are found in many pediatric references (Dixon and Stein, 2000). A summary of the salient features of each theory and potential clinical applications is presented in Table 22-9.

Erikson’s psychosocial stages theory is particularly relevant (Table 22-10). According to his theory, at each discrete life stage, persons are confronted with a crisis requiring integration of personal needs with sociocultural demands. Successful integration of needs and development indicates normal adaptation. A practitioner who is familiar with these stages can counsel families about the emotional needs of children at different ages and explain the appropriateness of challenging but normal childhood behavior.

The concept of temperament is also clinically relevant for primary care. *Temperament* is a set of consistent, inborn characteristics that influence how people interact with and learn from their environments (Thomas et al., 1968). A person’s temperament characteristics are innate to his or her personality. Three basic temperament profiles based on nine separate infant characteristics are outlined in Table 22-11. These are broad generalizations, and not all infants fit easily into one of these three categories.

Each family’s personal value system influences their reaction to a child of a particular temperament. For

Table 22-10 Using Erikson’s Psychosocial Stages to Guide Development

Psychosocial Stage	Guidance
Basic trust and mistrust (0-2 yr; infancy)	Parent can provide consistent nurturing to aid development of attitude of trust.
Autonomy vs. shame and doubt (2-4 yr)	Parent should allow safe exploration of environment and encourage decision making.
Initiative vs. guilt (5-7 yr)	Limits on child should be for protection of child, family, and society and not random or condemning.
Industry vs. inferiority (8-12 yr)	Caregiver must work with the school to ensure that child is achieving to his or her abilities and feeling a sense of competence vs. inferiority.
Identity vs. role confusion (13-17 yr)	Selection of career goals; establishment of relationships with the gender of attraction; independence from family should be encouraged by caregiver; failures to adapt in previous stages make this stage more difficult.
Intimacy vs. isolation (18-22 yr)	Need to make personal and occupational commitment.

example, a highly competitive, athletically oriented family may view high-energy, high-intensity characteristics more positively than a family who values studiousness. Qualities such as introversion or extroversion are often based on characteristics of temperament and are not modified readily by the environment. In a family in which “goodness of fit” between individual members’ temperaments does not exist, knowledge of the inborn nature of temperament can

Table 22-11 Temperament Characteristics and Profiles

Feature	Description
Characteristics	
Activity	Frequency and speed of involvement
Rhythmicity	Regularity of physiologic functions (e.g., hunger, sleep, elimination)
Approach and withdrawal	Immediate reaction of child to new stimuli
Adaptability	Degree of ease or difficulty with which child adjusts to new stimuli
Intensity	Energy level of responses, without regard to positive or negative quality of the response
Mood	Predominance of pleasant and friendly versus unfriendly behavior during waking
Attention span and persistence	Length of time the child will engage in a single activity with or without interruption
Distractibility	Degree of ease with which extraneous stimuli interfere with child's task performance
Sensory threshold	Amount of external stimulation required to evoke a response
Profiles	
Easy (40% of children)	Regularity of biologic functions; positive approach responses to new stimuli; high adaptability to change; mild to moderately intense mood that is predominantly positive
Difficult (10% of children)	Irregularity of biologic functions; negative withdrawal responses to new stimuli; no or slow adaptability to change; intense expressions of mood that are predominantly negative
Slow to warm up (15% of children)	Negative responses of mild intensity to new stimuli, with slow adaptability with repeated contact; mild intensity of reactions

Modified from Chess S, Thomas A. Dynamics of individual behavior development. In Levine MD, Carey WB, Crocker AC, eds. *Developmental-behavioral pediatrics*. Philadelphia: Saunders; 1992:86.

help the family accept a child's unique characteristics. Anticipatory guidance can then focus on achieving a better relationship between family and child.

Guidelines for Clinical Assessment

Although individual children develop at their own rate, with great variability in the normal range, general rules for neurodevelopmental maturation can serve as guidelines to help practitioners formulate a developmental trajectory for each child (Sturner and Howard, 1997). The developmental trajectory can be envisioned as an individualized growth chart of anticipated developmental progress based on normal neurodevelopmental milestones and moderated by child, parent, and environmental factors such as temperament, parental mental health, and exposure to lead.

Development usually is categorized into the domains of language, fine motor, gross motor, personal-social, and

cognitive. Delays can occur in one or any combination of these domains. For example, a child with intellectual disability is likely to have delays in multiple domains, although gross motor skills may be fairly well preserved. Conversely, a child with cerebral palsy may have normal or near-normal cognitive development with significant delays in gross and fine motor function. Many of the neurodevelopmental rules of thumb address the relationships among these domains.

Children acquire developmental tasks in a predictable sequence. For example, children typically do not learn to walk until they have mastered crawling and then standing. Although most children are able to crawl by 9 months of age and walk by 14.5 months, even severely delayed children follow the sequence of crawl, stand, and walk (Milani-Comparetti and Gidoni, 1967). This predictable sequence is dictated by building on previously learned skills, as well as by maturation of the central nervous system (CNS) (Springate, 1981). Before a critical stage in the maturation of the CNS, certain skills cannot be learned regardless of the intellectual potential or will of the child or parent. For example, because CNS control of the external anal sphincter is incomplete before 18 to 24 months of age, it is impossible to toilet train even the most precocious toddler before this age.

Responses to stimuli proceed from generalized, symmetric, whole-body reflexes to discrete, cortically controlled, voluntary actions. Newborn reflexes can be thought of in terms of their role in survival of the individual; an example is the rooting reflex, which helps the newborn seek out nutrition. Voluntary movements develop as the child learns to control the environment.

Development proceeds in head-to-toe (cephalocaudal) and proximal-to-distal directions. Therefore, an infant bears weight on the arms before bearing weight on the legs. As proximal-to-distal progression occurs, the infant becomes more precise in fine tuning the smaller muscles involved in reaching, grasping, and manipulating an object with his or her hand. Vocalization skills follow this pattern as well. A newborn infant vocalizes with "grunts" originating in the chest. As proximal-to-distal maturation develops, vocalizations originate more distally in the larynx (cooing), glottis (guttural syllables, "ga"), tongue ("da"), and lips ("ba").

Delays in one developmental domain can impair development in another domain. For example, an 18-month-old infant with motor impairments secondary to spina bifida lacks the freedom to explore the environment to learn how two pieces of furniture are oriented in space. Likewise, delays in one developmental domain can impair the practitioner's ability to evaluate skills in other domains. A 4-year-old toddler with cerebral palsy might understand the concept of sorting by shape but lack the motor control to manipulate the shapes to pass a standardized test.

An outline of salient features of development in each domain based on age is presented in Table 22-12. This guide to normal development should be considered by the physician along with past history, parental concerns, clinical observations, and developmental screening in the ongoing surveillance of child development. Until chronologic age 2 years, the development of a premature infant should be judged on corrected age (i.e., the chronologic age minus the number of weeks premature).

Table 22-12 Developmental Milestones in Young Children

Age	Gross Motor	Fine Motor and Reflex Motor	Social, Adaptive, and Cognitive	Language
Neonate	Flexed attitude, turns head side to side when prone without lifting, head sags if unsupported, body sags on ventral suspension	<i>Reflex:</i> moro symmetric, grasp reflex, stepping reflex, suck reflex, placing reflex	Fixates on face or light, moves in cadence with sound	Alerts to voice
1 mo	Extends legs more, holds chin up briefly when prone, head lag persists	<i>Reflex:</i> persistence of neonatal reflexes, tonic neck posture	Watches person, visually tracks to midline, begins to smile, body moves in cadence with voice	Throaty noises, range of cries to signal hunger, pain
2 mo	Raises head from prone position, sustains head in plane with body or ventral suspension, head lag on pull to sit	<i>Reflex:</i> stepping reflex fades	Smiles on social contact, attracts to voice	Coos
4 mo	Head up to vertical axis in prone position, bears weight on arms, extends legs, symmetric posture with hands in midline in supine position, no head lag on pull to sit, pushes with feet in standing position, holds head erect in sitting position	<i>Fine:</i> grasps and attains object, brings to mouth <i>Reflex:</i> grasps, Moro, tonic neck fade; downward parachute present	Laughs out loud, voices displeasure if contact is broken, excites at sight of food, regards a small pellet	Vowel sounds, visually searches for speaker
6 mo	Sits alone with rounded back, rolls over, pivots, creeps	<i>Fine:</i> rakes at pellet, transfers, turns body to reach <i>Reflex:</i> sideways parachute present	Prefers mother, responds to emotion, imitates banging, visually follows dropped objects	Polysyllabic babble, blows bubble ("raspberry"), laughs
9 mo	Sits with erect back, crawls, walks holding both hands, pulls to stand, can get to sitting position	<i>Fine:</i> pokes with forefinger, uses assisted pincer grasp <i>Reflex:</i> forward (7 mo) and backward parachute present, plantar grasp fades	Plays "peekaboo," "pat-a-cake"; waves bye-bye; finds an object after watching it hidden; may cry at sight of unfamiliar person	Responds to some verbal commands: "no"; imitates some sounds; uses "mama," "dada" nonspecifically
12 mo	Cruises holding on, stands alone, may take several steps, walks holding hand	<i>Fine:</i> neat pincer grasp, releases on request; puts 2 cubes in cup, pellet in bottle	Plays ball, adjusts posture when dressing, drinks from a cup, imitates activity (talks on toy phone)	1-2 true words, symbolic gestures (e.g., shakes head "no"), points to indicate wants
15 mo	Walks alone, crawls up stairs, walks backward, rises after stooping	<i>Fine:</i> dumps pellet from bottle or draws line with crayon when demonstrated, scribbles spontaneously, stacks 2 cubes	Feeds self with utensils, performs simple household tasks (pick up toys), hugs parent	Points to body parts, jargons, follows one-step command without gestures
18 mo	Runs stiffly, sits on small chair, walks up stairs with hand holding rail	<i>Fine:</i> tower of four cubes, dumps pellet on request, imitates line with crayon	Feeds self with utensils; kisses parent with pucker; explores drawers, wastebaskets; removes garments; seeks help when in trouble	10 words, says "no," names pictures, points to one body part
24 mo	Runs well; walks up and down stairs, one at a time; jumps in place, climbs on furniture; kicks ball	<i>Fine:</i> tower of seven cubes, "train" of four cubes; imitates vertical and circular crayon stroke; imitates folding paper	Listens to story with pictures, helps to undress, dresses with help, parallel play, uses spoon well	30-50 words; two- or three-word sentences; uses pronouns, sometimes incorrectly; relates recent experience; speech 50% intelligible
36 mo	Alternates feet climbing stairs, stands on one foot briefly, broad jumps with both feet, pedals tricycle, throws ball overhand	<i>Fine:</i> tower of 10 cubes, imitates "bridge" of 3 cubes, imitates cross, copies circle, attempts to draw person	Knows age and gender, counts three objects, repeats three serial numbers, understands turn-taking, washes and dries hands, helps with dressing	States full name; uses complete sentences; speech 75% intelligible to stranger; uses plurals, past tense, pronouns correctly
48 mo	Hops on one foot, throws ball overhand, balances on each foot 2-3 seconds	<i>Fine:</i> uses scissors to cut out pictures; copies cross, square; draws man with head and two to four body parts (pairs count as 1 part); tells a story	Counts four objects correctly, group play with role playing, toilets independently, dresses with little supervision	—
60 mo	Skips, balances on each foot 4-5 seconds	<i>Fine:</i> copies triangle, eight- to 10-part person	Counts 10 objects, prints first name, domestic role playing, asks meaning of words, dresses and undresses independently	Uses complete sentences, names four colors, repeats 10-syllable sentence, follows three-stage command

DEVELOPMENTAL SCREENING IN YOUNG CHILDREN

Key Points

- Always refer the child to audiology if language is delayed.
- Never ignore parents' concerns.
- Suspect delays and refer early.
- Developmental screening, using standardized parent report measures, is more accurate than clinical judgment.
- Autism usually manifests as language delay.

Every encounter between a physician and child involves developmental and behavioral issues. Attention to such matters can benefit every child. By monitoring development, the primary care physician has the opportunity to customize anticipatory guidance based on the child's current abilities and temperament (Sturner and Howard, 1997).

Additionally, the family physician has a responsibility to identify children with delayed development. Federal law (Individuals with Disabilities Education Act [IDEA]) mandates physicians to refer children with suspected delays to early intervention (birth to 3 years) or early childhood services (3 to 5 years). The specifics of these services vary from state to state but are free and individualized according to the child's and family's needs (AAP Committee on Children with Disabilities, 1999). As the professional with the most frequent—and sometimes only—contact with young children, the family physician is in the ideal position to detect possible developmental problems. Additionally, parents may feel more comfortable sharing concerns and seeking advice from a trusted physician.

Early detection of delays is important because brain development is most malleable in the early years of life (Shonkoff and Phillips, 2000). Early intervention has been shown to be cost effective, resulting in better intellectual, social, and adaptive behavior; increased high school graduation and employment rates; and decreased criminality and teen pregnancy (Gomby et al., 1995; Reynolds et al., 2001). Unfortunately, fewer than half of children with developmental difficulties are identified before kindergarten (Pelletier and Abrams, 2002).

Research shows that clinical impression alone is quite poor at detecting developmental delays (Glascoe, 2000). This has led the AAP to recommend routine monitoring (surveillance) at all preventive care visits and use of standardized developmental screening tests at 9, 18, and 24 or 30 months of age, with the addition of autism-specific

screening at 18 and 24 or 30 months (AAP Council on Children with Disabilities, 2006). Newer screening tools based on parent report can facilitate fulfilling this recommendation. Parent report has been found to be a reliable way to identify children in need of further developmental assessment, particularly if the concerns are elicited and interpreted in a standardized manner (Glascoe and Macias, 2003).

Parent report measures can be used in a variety of ways. They can be completed in the waiting room; sent out to be returned at the next appointment; or completed via an interview, either in person or by telephone with a staff member. It is helpful to have a staff member routinely inquire if the parents would like someone to go over the measure with them; this ensures that literacy or language issues are not barriers to screening. Even if staff administer the parent report, parent report measures are the most accurate, time-effective, and cost-efficient method of developmental screening currently available. Accurate screening tools with acceptable sensitivity and specificity (70%-80%) are listed in Table 22-13. Physicians can bill for screening, although reimbursement varies widely (Glascoe and Macias, 2003). More information regarding developmental screening, including coding and billing aspects, can be found at <http://www.dbpeds.org>.

EVALUATION OF DEVELOPMENTAL DELAY

Developmental disabilities are common, affecting approximately 15%, or one in six children in the United States (Boyle et al., 2011). Although this includes attention-deficit hyperactivity disorder (ADHD), which is often not manifest until school age, many children present with other developmental delays. Some children present with delays in multiple areas, or global developmental delay. *Global developmental delay* is defined as significant delay in two or more areas of development (gross or fine motor, speech and language, cognition, social and personal, and activities of daily living). The more severe the delay, the more likely a cause can be determined (Roberts et al., 2004). When a significant delay is recognized, parents are often eager to know the cause. The family physician can be instrumental in referring for appropriate intervention, as well as overseeing an initial workup.

Although many physicians refer to specialists (e.g., developmental pediatricians, neurologists) for further evaluation, these specialists may have long waiting lists. Some aspects of the workup can easily be ordered by the family physician. Guidelines from the American Academy of Neurology and Child Neurology Society for the workup of the child with global developmental delay are shown in Table 22-14 (Michelson et al., 2011; Shevell et al., 2003). The guidelines listed in the table are evidence based and

Table 22-14 Evaluation of Global Developmental Delay

Indication	Workup
Everyone	
First-line workup	Comprehensive history and physical examination Hearing and vision screening Metabolic studies and thyroxine (if newborn screen results not known) EEG if symptoms of seizures Screen for autism if language delayed
Positive Family History	
Genetic, metabolic, or CNS disorder	Test for specific condition
Nonspecific developmental delays	Microarray and fragile X
Signs or Symptoms Present	
Specific genetic disorder	Specialized genetic testing
Hypothyroidism	Thyroid studies
CNS abnormality	MRI
Other	
Possible lead exposure	Lead level
Regression of skills or parental consanguinity	MRI, microarray, fragile X, metabolic testing, EEG, genetics evaluation
No specific signs or symptoms (stepwise in order)	MRI, microarray, fragile X, metabolic testing, Rett syndrome testing
Motor delays	Low muscle tone-CK, thyroid studies High muscle tone-MRI

CK, Creatinine kinase; CNS, central nervous system; EEG, electroencephalogram; MRI, magnetic resonance imaging; T₄, thyroxine.

Data from Roberts G, Pafrey J, Bridgemohan C. A rational approach to the medical evaluation of a child with developmental delay. *Contemp Pediatr*. 2004;21:76-100; Shevell M, Asheval S, Donley D, et al. Practice parameter: evaluation of the child with global developmental delay. *Neurology*. 2003;60:367-380; Michelson D, et al. Evidence report: genetic and metabolic testing on children with global developmental delay. *Neurology*. 2011;77:1629-1635; and Noritz G, Murphy NA; Neuromotor Screening Expert Panel. Motor delays: early identification and evaluation. *Pediatrics*. 2013;131:e2016.

could be readily used by family physicians to start the workup while waiting for a specialist appointment. Results of the workup may facilitate more specific referrals. Even if not globally delayed, all children with language delays should have a formal audiology assessment to rule out hearing impairments.

AUTISM SCREENING

Autism is a developmental disability involving difficulties with communication and social interaction as well as unusual and restricted behavior. The prevalence of autism appears to be rapidly increasing, for reasons not yet clear (Fombonne, 2003; Yeargan-Allsopp et al., 2003). The latest prevalence estimates are one in 68 children (Autism and Developmental Disabilities Monitoring Network Surveillance, 2014). This makes it essential that all primary care physicians seeing children be able to recognize the signs and symptoms suggesting autism and refer for further evaluation promptly. Early diagnosis allows earlier initiation of

Table 22-15 Red Flags and Absolute Indications for Immediate Evaluation

Age	Sign
12 mo	No babbling No pointing No gestures
16 mo	No single words
24 mo	No two-word phrases
Any age	Loss of language or social skills

Modified from Filipek PA, Accardo PJ, Ashwal S, et al. Practice parameter: screening and diagnosis of autism. *Neurology*. 2000;55:468-479.

intensive behavioral intervention, which has been shown to be very helpful (Butter et al., 2003). Table 22-15 lists “red flags” that should prompt referral for further evaluation (Filipek et al., 2000). A formal audiology evaluation is also indicated, as well as lead screening if the child has pica. It is important to keep in mind that most young children with autism are presented to their physicians with the chief complaint of language delay. The physician should consider autism in the differential diagnosis for a child with language delay.

ASSESSING DEVELOPMENT IN THE SCHOOL-AGE CHILD

Developmental surveillance in a school-age child should focus on identification of unsuspected learning problems, including ADHD, mild mental retardation, and learning disabilities, as well as detection of emotional problems such as anxiety, depression, or school phobia. Emotional problems can be screened for using the Pediatric Symptom Checklist (PSC). The PSC is a one-page questionnaire that is relatively easy to administer and interpret during routine well-child care. Positive results should prompt the physician to probe further with questions regarding school, friends, family, moods, and activities. Referrals to other professionals can then be made if necessary. More information regarding the PSC is available on the Massachusetts General Hospital’s PSC website.

Asking the child and parent about school progress and reviewing report cards and standardized testing results are simple ways for the physician to monitor school progress. Checklists completed by the parent and teacher can provide further information about specific issues (e.g., attention) or behavior in general (Table 22-16).

Federal law (IDEA) mandates a free and appropriate education for all children, regardless of handicapping condition. Therefore, if a child is suspected to have a learning disability, the school is obligated to evaluate and provide necessary services free of charge. The parent should be advised to request the evaluation, called the Multi-Factored Evaluation (MFE), in writing. Federal law requires the MFE be done within 60 days. The MFE consists of standardized assessments of various aspects of learning. After the MFE is completed, school personnel meet with the parents to review testing results and determine if the child is eligible for special education services. These services may occur in the regular classroom or in a separate one, although the

ADHD, Attention-deficit hyperactivity disorder.

law requires that services be provided in the least restrictive environment. The goal is to keep children with their typical peers as much as possible.

After a child is deemed eligible for services, an Individualized Education Plan (IEP) is developed. Parent input is required as part of the process. If the parent disagrees with the suggested IEP, the parent has the right to due process. An explanation of due process must be given to all parents at the beginning of the MFE/IEP process. After it has been developed, the IEP is updated annually. Parents should receive progress reports throughout the school year. They may request interim changes to the IEP if needed. Reevaluations are conducted at least every 3 years (Henderson, 2001).

All of this is often overwhelming for families. The physician can assist by providing simple explanations of the process as well as periodically reviewing the IEP and helping parents understand it. The physician should also encourage parents to become knowledgeable advocates for their child.

Some children have conditions that can benefit from extra assistance but that do not qualify as disabilities according to the IDEA. Conditions such as ADHD are covered by Section 504 of the Rehabilitation Act of 1973 (Henderson, 2001). The qualifications are broader under this law, allowing children with less serious issues to still receive special services. This assistance, although helpful, is often less extensive than if the child qualified for an IEP.

Regardless of the issues, communication with school personnel is often helpful. Teacher rating scales (general or specific for certain concerns) may be useful, as well as direct communication, either verbally or in writing. Such dialogue also illustrates for families the advantages of cooperative teamwork with school personnel. It is always important for physicians to follow the Health Insurance Portability and Accountability Act (HIPAA) guidelines, obtain written permission from parents, and show discretion (“need to know”) when sharing information with schools.

Immunizations

Key Points

- Avoid missed opportunities to vaccinate by reviewing the child’s immunization record at every visit.
- Schedule adolescents for an immunization visit at age 11 to 12 years to catch up on missed vaccines and administer new ones.
- Provide current vaccine information statements to parents or guardians for each vaccine given during the visit.

INDICATIONS AND CONTRAINDICATIONS

Routine immunizations are essential for the control and prevention of previously common childhood infectious diseases. During 2012, approximately 90% of U.S. children age 19 to 35 months received one or more doses of measles, mumps, and rubella (MMR) vaccine, three or more doses of poliovirus vaccine, three or more doses of hepatitis B vaccine (Hep B), and one or more dose of varicella vaccine. Although below the Healthy People 2020 objectives of 90% coverage, approximately 80% of young children received four or more doses of diphtheria, tetanus toxoids, and pertussis (DTaP) vaccines; four or more doses of pneumococcal conjugate vaccine (PCV), and the full series of *Haemophilus influenzae* type b (Hib) vaccine (CDC, 2013). However, there is still considerable disparity in immunization rates among states and communities. Young children might not be immunized at the recommended age because of missed opportunities to vaccinate, deficient health care delivery in the public sector, lack of insurance, inadequate access to medical care, lack of public awareness about the necessity for immunizations, or concern about potential or alleged

adverse effects of immunizations. Both the AAFP and AAP endorse the Recommended Immunization Schedule for Persons Aged 0 Through 18 years—2014 (see <http://www.cdc.gov/vaccines/schedules> for a full set of schedules, including catch-up schedule) (SOR: A).

Parents and guardians should be questioned about possible contraindications, precautions, and any previous adverse events in response to vaccine administration (see eTable 22-3 online). They should be informed about the potential benefits and risks of the vaccine and the risks of the natural disease if the immunization is not given. Health care providers administering any vaccine covered by the National Vaccine Compensation Injury Act or purchased by federal contract must provide the most current *vaccine information statements* (VISs) detailing the potential benefits and risks of each vaccine to the parents or guardians each time that vaccine is given (AAP Red Book, 2012, 7-8). Copies of VISs may be obtained from the CDC (<http://www.cdc.gov/vaccines/pubs/VIS/default.htm>), the Immunization Action Coalition (<http://www.immunize.org>), or state health departments.

Vaccines have become “victims of their own success” (Cooper et al., 2008). Because they no longer are confronted with the presence of vaccine-preventable diseases, some individuals, parents, and groups have become more concerned about the alleged adverse effects of immunization. A Danish study is one of many that confirmed the effectiveness of vaccines such as Hib and pertussis and did not find an association of MMR or thimerosal-containing vaccines with autism spectrum disorders (Hviid, 2006). Physicians serve as the primary source of information about immunizations, and family physicians should explain the potential benefits and risks of immunizations to parents and older patients such as adolescents (Gellin et al., 2000). If parents still do not wish to have their child vaccinated, further information and documentation may be obtained at <http://www2.aap.org/immunization/pediatricians/pdf/RefusaltoVaccinate.pdf>.

Before administering vaccines, the physician should ask about the child’s current state of health, as well as that of other family members. Pregnancy or immunosuppression of a household member usually does not contraindicate the administration of most routine live-virus vaccines, such as MMR, varicella, or rotavirus vaccines. Nasal live, attenuated influenza vaccine (LAIV) should not be given to close contacts of immunosuppressed people who require a protective environment (e.g., recipients of stem cell transplants) but may be given to others. Minor febrile illnesses are not contraindications to vaccine administration. General contraindications are a previous anaphylactic reaction to the specific vaccine or a severe hypersensitivity reaction to vaccine constituents such as gelatin or antibiotics such as neomycin, streptomycin, or polymyxin B. Latex allergy may also be a contraindication if the vaccines are supplied in vials or syringes containing natural rubber (AAP Red Book, 2012, pp. 49-53).

VACCINE ADMINISTRATION

Most immunizations must be given by deep intramuscular (IM) or subcutaneous (SC) injection. IM injections should be given in the anterolateral thigh for infants or the deltoid

muscle of the arm for older children. The sciatic nerve may be injured by deep intragluteal injections. Although acetaminophen (paracetamol) administered for 24 hours has been demonstrated to decrease mild to moderate reactions, such as temperature of 38°C (100.4°F) or greater, it may reduce antibody responses to some vaccine antigens (Prymula et al., 2009). Topical local anesthetics, sweet-tasting solutions, and breastfeeding may decrease injection pain for childhood immunizations (HELPinKIDS, 2009).

Immune responses may be impaired if two live-virus vaccines are given within 28 days of each other. Live-virus vaccines must be given simultaneously or at least 4 weeks apart (AAP Red Book, 2012, 25). If immune globulin is given, live-virus vaccine administration should be delayed for up to 3 to 6 months to allow optimal antibody production (AAP Red Book, 2012, pp. 37-38). An even longer period may be required if high doses of intravenous (IV) gamma globulin have been given.

SCHEDULE OF IMMUNIZATIONS

The recommended schedule for childhood and adolescent immunizations for ages 0 to 18 years are shown at <http://www.cdc.gov/vaccines/schedules>, including a catch-up schedule. A lapse in the immunization schedule does not require starting over the entire series. Doses of any vaccine should not be divided or reduced because this can result in an inadequate response. Premature infants should receive the same vaccine dose, usually at the same chronologic age as full-term infants. Most vaccines can be administered simultaneously using separate syringes at separate sites (AAP Red Book, 2012, 33-34).

POLIOVIRUS VACCINE

The last indigenous case of wild-type poliomyelitis in the United States occurred in 1979, and the last identified imported case occurred in 1993. From 1980 to 1996, there were approximately eight cases per year of vaccine-associated paralytic poliomyelitis (VAPP) caused by oral poliovirus vaccine (OPV) in the United States. In 2000, inactivated poliovirus vaccine (IPV) was recommended for all routine childhood polio vaccinations in the United States. In 2005, one case of VAPP was identified in a symptomatic, unimmunized, immunodeficient child and subsequently in seven other unimmunized children in the same community (AAP Red Book, 2012, 588).

MEASLES, MUMPS, AND RUBELLA VACCINE

The MMR vaccine should be given to children 12 to 15 months of age. The second MMR or measles, mumps, rubella, and varicella (MMRV) vaccine is recommended before school entry at 4 to 6 years of age, but it can be given earlier in the event of an outbreak or as a requirement for travel, provided the second dose is given at least 28 days after the first. The recommended interval between varicella doses for children 12 years old or younger is 3 months, but a minimum interval of at least 4 weeks is acceptable for children 7 to 12 years for catch-up purposes. When MMRV is given to 12- to 23-month-old children, there is a slight increase in the risk of febrile seizures (about one in 2500),

eTable 22-3 Guide to Contraindications and Precautions to Commonly Used Vaccines^{1,*†}

Vaccine	Contraindications	Precautions
Hepatitis B (HepB)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Infant weighing less than 2000 grams (4 lbs, 6.4 oz)²
Rotavirus (RV5 [RotaTeq], RV1 [Rotarix])	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Severe combined immunodeficiency (SCID) History of intussusception 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Altered immunocompetence other than SCID Chronic gastrointestinal disease³ Spina bifida or bladder exstrophy³
Diphtheria, tetanus, pertussis (DTaP) Tetanus, diphtheria, pertussis (Tdap) Tetanus, diphtheria (DT, Td)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component For pertussis-containing vaccines: encephalopathy (e.g., coma, decreased level of consciousness, prolonged seizures) not attributable to another identifiable cause within 7 days of administration of a previous dose of DTP or DTaP (for DTaP); or of previous dose of DTP, DTaP, or Tdap (for Tdap) 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Guillain-Barré syndrome (GBS) within 6 weeks after a previous dose of tetanus toxoid-containing vaccine History of arthus-type hypersensitivity reactions after a previous dose of tetanus or diphtheria toxoid-containing vaccine; defer vaccination until at least 10 years have elapsed since the last tetanus-toxoid containing vaccine For pertussis-containing vaccines: progressive or unstable neurologic disorder (including infantile spasms for DTaP), uncontrolled seizures, or progressive encephalopathy until a treatment regimen has been established and the condition has stabilized <p>For DTaP only:</p> <ul style="list-style-type: none"> Temperature of 105°F or higher (40.5°C or higher) within 48 hours after vaccination with a previous dose of DTP/DTaP Collapse or shock-like state (i.e., hypotonic hyporesponsive episode) within 48 hours after receiving a previous dose of DTP/DTaP Seizure within 3 days after receiving a previous dose of DTP/DTaP Persistent, inconsolable crying lasting 3 or more hours within 48 hours after receiving a previous dose of DTP/DTaP
Haemophilus influenzae type b (Hib)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Age younger than 6 weeks 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever
Inactivated poliovirus vaccine (IPV)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Pregnancy
Pneumococcal (PCV13 or PPSV23)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component (including to any vaccine containing diphtheria toxoid for PCV13) 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever
Measles, mumps, rubella (MMR)⁴	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy⁵ or patients with human immunodeficiency virus [HIV] infection who are severely immunocompromised)⁶ Pregnancy 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Recent (within 11 months) receipt of antibody-containing blood product (specific interval depends on product)⁷ History of thrombocytopenia or thrombocytopenic purpura Need for tuberculin skin testing⁸
Varicella (Var)⁴	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, congenital immunodeficiency, or long-term immunosuppressive therapy⁵ or patients with HIV infection who are severely immunocompromised)⁶ Pregnancy 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Recent (within 11 months) receipt of antibody-containing blood product (specific interval depends on product)⁷ Receipt of specific antivirals (i.e., acyclovir, famciclovir, or valacyclovir) 24 hours before vaccination; avoid use of these antiviral drugs for 14 days after vaccination.
Hepatitis A (HepA)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever
Influenza, inactivated injectable (IIV)⁹	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose of any influenza vaccine or to a vaccine component, including egg protein 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever History of GBS within 6 weeks of previous influenza vaccination Persons who experience only hives with exposure to eggs may receive IIV (if age 18-49 years) or, with additional safety precautions, IIV.⁹
Influenza, recombinant (RIV)⁹	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose of RIV or to a vaccine component. RIV does not contain any egg protein.⁹ 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever History of GBS within 6 weeks of previous influenza vaccination

eTable 22-3 Blood Pressure Levels for Girls by Age and Height Percentiles

Vaccine	Contraindications	Precautions
Influenza, live attenuated (LAIV)^{4,9}	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose of any influenza vaccine or to a vaccine component, including egg protein Conditions for which the ACIP recommends against use, but which are not contraindications in vaccine package insert: immune suppression, certain chronic medical conditions such as asthma, diabetes, heart or kidney disease, and pregnancy^{4,9} 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever History of GBS within 6 weeks of previous influenza vaccination Receipt of specific antivirals (i.e., amantadine, rimantadine, zanamivir, or oseltamivir) 48 hours before vaccination. Avoid use of these antiviral drugs for 14 days after vaccination.
Human papillomavirus (HPV)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Pregnancy
Meningococcal: conjugate (MenACWY), polysaccharide (MPSV4)	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) after a previous dose or to a vaccine component 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever
Zoster (HZV)⁴	<ul style="list-style-type: none"> Severe allergic reaction (e.g., anaphylaxis) to a vaccine component Known severe immunodeficiency (e.g., from hematologic and solid tumors, receipt of chemotherapy, or long-term immunosuppressive therapy⁵ or patients with HIV infection who are severely immunocompromised). Pregnancy 	<ul style="list-style-type: none"> Moderate or severe acute illness with or without fever Receipt of specific antivirals (i.e., acyclovir, famciclovir, or valacyclovir) 24 hours before vaccination; avoid use of these antiviral drugs for 14 days after vaccination.

¹Vaccine package inserts and the full ACIP recommendations for these vaccines should be consulted for additional information on vaccine-related contraindications and precautions and for more information on vaccine excipients. Events or conditions listed as precautions should be reviewed carefully. Benefits of and risks for administering a specific vaccine to a person under these circumstances should be considered. If the risk from the vaccine is believed to outweigh the benefit, the vaccine should not be administered. If the benefit of vaccination is believed to outweigh the risk, the vaccine should be administered. A contraindication increases the chance of a serious adverse reaction. Therefore, a vaccine should not be administered when a contraindication is present. Whether and when to administer DTaP to children with proven or suspected underlying neurologic disorders should be decided on a case-by-case basis.

²Hepatitis B vaccination should be deferred for preterm infants and infants weighing less than 2000 g if the mother is documented to be hepatitis B surface antigen (HBsAg)-negative at the time of the infant's birth. Vaccination can commence at chronological age 1 month or at hospital discharge. For infants born to women who are HBsAg-positive, hepatitis B immunoglobulin and hepatitis B vaccine should be administered within 12 hours of birth, regardless of weight.

³For details, see CDC. "Prevention of Rotavirus Gastroenteritis among Infants and Children: Recommendations of the Advisory Committee on Immunization Practices. (ACIP)" *MMWR* 2009;58(No. RR-2), available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.

⁴LAIV, MMR, varicella, and zoster vaccines can be administered on the same day. If not administered on the same day, these live vaccines should be separated by at least 28 days.

⁵Immunosuppressive steroid dose is considered to be 2 or more weeks of daily receipt of 20 mg prednisone or equivalent. Vaccination should be deferred for at least 1 month after discontinuation of such therapy. Providers should consult ACIP recommendations for complete information on the use of specific live vaccines among persons on immune-suppressing medications or with immune suppression because of other reasons.

⁶HIV-infected children may receive varicella and measles vaccine if CD4+ T-lymphocyte count is >15%. (Source: Adapted from American Academy of Pediatrics. Immunization in Special Clinical Circumstances. In: Pickering LK, ed. *Red Book: 2012 Report of the Committee on Infectious Diseases*. 29th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2012.)

⁷Vaccine should be deferred for the appropriate interval if replacement immune globulin products are being administered (see "General Recommendations on Immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP)" *MMWR* 2011;60(No. RR-2) available at www.cdc.gov/vaccines/hcp/acip-recs/index.html.)

⁸Measles vaccination might suppress tuberculin reactivity temporarily. Measles-containing vaccine may be administered on the same day as tuberculin skin testing. If testing cannot be performed until after the day of MMR vaccination, the test should be postponed for at least 4 weeks after the vaccination. If an urgent need exists to skin test, do so with the understanding that reactivity might be reduced by the vaccine.

⁹For more information on use of influenza vaccines among persons with egg allergies and a complete list of conditions that CDC considers to be reasons to avoid getting LAIV, see CDC. Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices (ACIP)—United States, 2013–14. *MMWR* 2013;62(No. RR07):1–43, available at www.cdc.gov/vaccines/hcp/acip-recs.html.

*Adapted from "Table 6. Contraindications and Precautions to Commonly Used Vaccines" found in: CDC. "General Recommendations on Immunization: Recommendations of the Advisory Committee on Immunization Practices (ACIP)." *MMWR* 2011; 60(No. RR-2), p. 40–41, and from Atkinson W, Wolfe S, Hamborsky J, eds. Appendix A. *Epidemiology and Prevention of Vaccine-Preventable Diseases*. 12th ed.

[†]Regarding latex allergy, consult the package insert for any vaccine administered.

and parents should be apprised of this. All children should receive the second MMR or MMRV before school entry at ages 4 to 6 years (*AAP Red Book*, pp. 493-495). Many colleges require documentation of immunity to MMR, either by immunization or serologically. Children may be immunized with MMR even if there is a pregnant or immunosuppressed family member because the vaccine viruses are not transmitted (*AAP Red Book*, 2012, p. 50).

HAEMOPHILUS INFLUENZAE TYPE B CONJUGATE VACCINE

The use of Hib conjugate vaccines has lowered the U.S. incidence of invasive Hib disease in children younger than 5 years of age by 99%. Vaccines currently available in the United States, such as PRP-OMP (PedvaxHIB) and PRP-T (ActHIB), are given beginning at age 2 months. PRP-T (Hiberix) is licensed for use as a booster in children 15 months through 4 years of age (*CDC*, 2009); PRP-OMP-HepB (Comvax) is administered at 2, 4, and 12 to 15 months of age; DTaP-IPV+PRP-T (Pentacel) is given at 2, 4, 6, and 15 to 18 months of age (*AAP Red Book*, 2012, pp. 346-351). If indicated, Hib-MenCY (MenHibrix) is given at 2, 4, and 6 months of age with a booster dose at age 12 to 15 months.

The schedule of administration varies according to the type of vaccine (visit <http://www.cdc.gov/vaccines/schedules>, which also includes a catch-up schedule). Children age 12 to 15 months of age who received the primary series need one dose of any Hib conjugate vaccine given at least 2 months after the last dose. If the child is 15 months of age or older, only one dose is needed. Children who have received a primary Hib series with a booster dose at 12 months of age or older do not need further immunization if they have hyposplenism or asplenia. However, children undergoing scheduled splenectomy may be given a booster dose of Hib 7 to 10 days beforehand. It is not known whether children with human immunodeficiency virus (HIV) infection, who are receiving chemotherapy for malignancies, or who have other immunologic impairment benefit from a booster dose of Hib. At-risk children who are unimmunized or only received one dose of Hib before age 12 months should receive two doses of Hib separated by 2 months. Children 59 months of age or older who are unimmunized with Hib and potentially at risk because of diseases such as asplenia, leukemia, or HIV should receive one dose of Hib vaccine (*AAP Red Book* 2012, pp. 349-351).

ACELLULAR PERTUSSIS VACCINE

Acellular pertussis vaccines combined with DTaP are used in the United States for the primary and booster doses in children. These vaccines (DAPTACEL, Infanrix) are immunogenic and produce fewer adverse local and systemic reactions, such as fever and irritability, than do whole-cell pertussis vaccines. Whenever possible, the same DTaP vaccine should be used throughout the entire vaccination series because there are no data on safety or efficacy when different formulations of these vaccines are interchanged. However, if the previously used vaccine is not known or is unavailable, any of the DTaP vaccines licensed for use in children may be given to complete the

immunization series. Combination vaccines such as DTaP-IPV-HepB (Pediarix) and DTaP-IPV-Hib (Pentacel) are licensed for use as the first three doses and first four doses, respectively, of their components, but DTaP-IPV (Kinrix) is licensed only as the booster fifth dose of DTaP and fourth dose of IPV at ages 4 to 6 years (*AAP Red Book*, 2012, pp. 557-566).

Two vaccines containing reduced concentrations of diphtheria toxoid and pertussis antigens combined with tetanus toxoid (Tdap) are now licensed for use in adolescents and adults (Boostrix and ADACEL). The vaccines are recommended for adolescents 11 to 18 years of age in place of the Td booster to decrease the reservoir of *Bordetella pertussis* in this population. Increasing reported cases of pertussis in the United States (>42,000 in 2012) has led to the recommendation to give one dose of these vaccines to children 7 to 10 years of age who are incompletely immunized against pertussis. In addition, one dose of Tdap should be given to pregnant women, preferably after 20 weeks of gestation, during each pregnancy and to adolescents and adults likely to have close contact with infants younger than 12 months old.

ROTAVIRUS VACCINE

Rotavirus is responsible for up to 500,000 deaths from diarrhea worldwide and 20 to 60 U.S. deaths each year. Before the introduction of rotavirus vaccines (RV1 or Rotarix, RV5 or RotaTeq), rotavirus caused 3 million infections per year in the United States, resulting in more than 400,000 physician visits and 55,000 to 70,000 hospitalizations per year (*CDC Pink Book*, 2012, pp. 263-274). RV1 is given as two oral doses at 2 and 4 months of age, and RV5 is given as three oral doses at 2, 4, and 6 months of age. The minimum interval between doses of either vaccine is 4 weeks. Neither vaccine should be started for infants age 15 weeks, 0 days of age or older, and all doses must be given by 8 months, 0 days of age. The vaccine-specific package insert should be seen for full prescribing indications and contraindications.

VARICELLA VACCINE

Two SC doses of monovalent varicella zoster virus (VZV) vaccine or MMRV are indicated in children age 12 months through 12 years. The doses should be separated by at least 3 months, with the second dose routinely recommended at age 4 to 6 years before kindergarten or first grade. Parents should be counseled that MMRV carries a slightly higher risk for febrile seizures when given as the first dose to young children and should be given a choice of MMRV or separate MMR and VZV vaccine injections. MMRV may then be used for the second dose. Persons age 13 years or older who do not have evidence of immunity to varicella should receive two doses of monovalent VZV vaccine at least 28 days apart. A second dose of varicella vaccine should be given to people who previously received only one dose. In children age 7 to 12 years, a minimum interval of at least 4 weeks is acceptable for catch-up purposes. The vaccine is generally contraindicated in pregnant women, immunodeficient persons, and those receiving high doses of systemic corticosteroids (≥ 20 mg/day of prednisone or equivalent) for 14 days or more. However, VZV vaccine may be considered for

HIV-infected patients with a CD4+ T-lymphocyte count of 15% or greater. Vaccine-strain VZV has been rarely transmitted, and vaccinated patients who develop a rash should avoid contact with immunocompromised persons (*AAP Red Book, 2012*, pp. 786-788). Zoster vaccine is not interchangeable with varicella vaccine and is not used in children.

HEPATITIS A VACCINE

Hepatitis A virus (HAV) is usually transmitted person to person through the fecal–oral route and by ingestion of contaminated food or water, but it has rarely been transmitted by transfusion of blood or blood products. Two HAV inactivated vaccines, HAVRIX and VAQTA, are licensed in the United States for use in children age 1 year and older. TWINRIX is a combined hepatitis A and hepatitis B vaccine licensed for use in persons at least 18 years old. Physicians should consult the package insert for proper dosing because there are different formulations of these vaccines.

Childhood vaccination against HAV is recommended for all U.S. children 12 to 23 months of age and should be considered for unimmunized children ages 2 to 18 years old. Indications for immunization with hepatitis A vaccine include travel to or residence in countries or areas endemic for hepatitis A; close contacts of newly arriving international adoptees; persons who receive clotting-factor concentrates; persons with chronic liver disease; injection (IDU) and noninjection drug users; men who have sex with men (MSM); and people at risk of household, sexual, and occupational exposure (e.g., handlers of primates) (*AAP Red Book, 2012*, pp. 364-367).

HEPATITIS B VACCINE

Hepatitis B virus (HBV) is endemic in Southeast Asia, the Pacific Islands, China, Africa, parts of the Middle East, and the Amazon Basin. More than 350 million people worldwide have chronic HBV infection. Although transmission in U.S. children is less likely because of high coverage with Hep B vaccine, the risk of perinatal transmission of HBV from an infected mother to her infant varies from 10% to as high as 90%, depending on whether the mother is negative or positive for hepatitis B e antigen (HBeAg) (*CDC Pink Book, 2012*, pp. 115-138).

The pediatric formulations of Hep B vaccine should be given to all infants soon after birth or before hospital discharge. Hep B vaccine should be given within 12 hours to all newborns of mothers positive for hepatitis B surface antigen (HBsAg) or infants of mothers whose HBsAg status is unknown. An infant born to an HBsAg-positive mother should receive an initial dose of 5- μ g RecombivaxHB or 10- μ g Engerix-B and 0.5 mL of hepatitis B immune globulin (HBIG) IM at separate sites within 12 hours of birth. Repeat vaccine doses should be given at ages 1 month and 6 months. If the maternal HBsAg status remains unknown, HBIG may be given within 7 days of birth. For infants of HbsAg-negative mothers, the combination DTaP-HBV-IPV (Pediarix) or PRP-OMP-HBV vaccine (Comvax) may then also be used, beginning at 6 to 8 weeks of age. Practitioners should consult the package insert for the appropriate

dose according to the formulation and intended use. Any adolescent who has not yet received Hep B vaccine should also be immunized with two doses at least 4 weeks apart, with a third dose 4 to 6 months after the second dose. An alternative schedule using two 10- μ g doses of RecombivaxHB separated by at least 4 to 6 months may be used only in adolescents 11 through 15 years old (*CDC Pink Book, 2012*, pp. 115-138).

Hepatitis B vaccine should be given to all children, but especially susceptible high-risk children or adults who are institutionalized; those who have end-stage renal disease, chronic liver disease, or HIV infection; those who receive clotting-factor concentrates; household or sexual contacts of HBsAg-positive people; MSM; IDUs; and adoptees from or long-term travelers to countries endemic for hepatitis B. Unimmunized victims of sexual assault or inmates in juvenile detention centers or adult correctional facilities as well as people ages 19 through 59 years of age with diabetes mellitus should be immunized (*AAP Red Book, 2012*, pp. 377-390).

CONJUGATE PNEUMOCOCCAL VACCINE

In 2008, more than 500,000 children younger than age 5 years died worldwide from pneumococcal disease (*O'Brien, 2013*). In 2010, the FDA licensed the 13-valent conjugate pneumococcal vaccine (PCV13) for use in children 6 weeks to 71 months old. The vaccine stimulates functional antibodies to all 13 serotypes in more than 90% of recipients and is given to infants at 2, 4, 6, and 12 to 15 months of age. Children 7 to 11 months old require two doses 2 months apart followed by a third dose at 12 to 15 months of age (two or more months later). Children 12 to 23 months old require two doses 2 months apart. One dose of PCV13 is required for all healthy children 24 to 59 months of age even if they previously received the 7-valent PCV. Children age 24 to 71 months and those age 6 to 18 years with conditions placing them at high risk for invasive pneumococcal disease (e.g., immunocompromising conditions, anatomic or functional asplenia including sickle cell disease, HIV, cochlear implants) should receive one dose of PCV13 vaccine. This should be followed 8 weeks later by the 23-valent polysaccharide vaccine (PPSV23) (*AAP Red Book, 2012*, pp. 578-580; *CDC, 2013*). PCV13 and PPSV23 have more recently been recommended for use in adults 19 years of age and older with immunocompromising conditions (*CDC, 2012*).

INFLUENZA VACCINE

Routine annual immunization with influenza vaccine is recommended for all persons 6 months of age and older, including these with high-risk conditions such as HIV or chronic pulmonary (including asthma) or cardiac, renal, or metabolic diseases; those receiving immunosuppressive or long-term aspirin therapy; those who have hemoglobinopathies; and those with any condition (e.g., cognitive dysfunction, seizure disorder, neuromuscular disorder) that could compromise respiratory function. Pregnant women and persons who are household contacts of high-risk patients, including health care workers, should also be

vaccinated. Multiple inactivated influenza vaccines (IIVs) are now available, including the trivalent vaccine containing 2 influenza A viruses and 1 B virus and the newer quadrivalent vaccines containing 2 influenza A and 2 influenza B viruses. Providers should read the prescribing information regarding the appropriate age and dosing of these vaccines. In general, children 9 years of age and older need only one dose of influenza vaccine. Children 6 months to 8 years old need two doses of vaccine separated by 4 weeks unless they have received two doses of influenza vaccine since July 1, 2010. The live, attenuated influenza vaccine (LAIV4) is now a quadrivalent vaccine approved for use in healthy people ages 2 through 49 years who are not pregnant. LAIV4 should not be used in persons with asthma or those in close contact with severely immunosuppressed hospitalized patients receiving care in a protected environment. Although most IIV and LAIV4 vaccines are produced in eggs, only a history of severe egg allergy (e.g., anaphylaxis involving cardiorespiratory or gastrointestinal symptoms or those requiring the use of epinephrine) is now considered a true contraindication to immunization. However, observation of the vaccinee for 30 minutes afterward is recommended, and appropriate resuscitative equipment must be available. A trivalent inactivated cell culture–based vaccine and a recombinant vaccine are now available for persons 18 years and older ([AAP Committee on Infectious Diseases, 2013](#)). These are not produced using eggs.

CONJUGATE MENINGOCOCCAL VACCINE

Two quadrivalent meningococcal polysaccharide–protein conjugate vaccines (MCV4-D [Menactra, Sanofi Pasteur] and MCV4-CRM [Menveo, Novartis]) have been licensed in the United States for use in persons 9 months and 2 months of age, respectively, through 55 years old. Routine immunization of all children age 11 to 12 years old with either MCV4 followed by a booster dose at 16 years is recommended. Persons receiving the first dose at 13 to 15 years old should receive a one-time booster at age 16 to 18 years. The vaccines contain serogroups A, C, Y, and W-135 that cause 75% of all cases of meningococcal disease in persons older than 11 years in the United States ([Bilukha and Rosenstein, 2005](#)). Neither vaccine is protective against serogroup B, which accounts for most of the remaining cases. Children 9 to 23 months old with persistent complement deficiency or traveling to or residing in countries where meningococcal disease is hyperendemic should receive two doses of MCV4 3 months apart. Because MCV4-D may interfere with immunity to PCV13, it is recommended not to give this vaccine until 4 weeks after the PCV13 series is completed. In children younger than 19 months with anatomic or functional asplenia, MCV4-CRM or HibMenCY (MenHibrix) is given at 2, 4, 6, and 12 to 15 months of age. In unimmunized children ages 19 to 23 months, primary doses of MCV4-CRM are given at least 3 months apart. Unimmunized children 2 to 18 years old with persistent complement deficiency or anatomic or functional asplenia should receive two doses of either MCV4 vaccine 8 weeks apart. In asplenic children, MCV4-D should not be given until 4 weeks after completion of all PCV13

doses. Children with continued risk for meningococcal disease may be given a booster in either 3 years or 5 years depending on whether they received their initial immunization series at either 2 to 6 years of age or 7 years or older, respectively ([AAP Red Book, 2012](#), pp. 505-508). Persons age 2 years of age or older traveling to or residing in countries with hyperendemic or epidemic *Neisseria meningitidis* (e.g., sub-Saharan Africa, Mecca during the Hajj) should also be immunized with one dose of MCV4 ([CDC Pink Book, 2012](#), pp. 200-201). Previously unimmunized college freshman living in dormitories also have a higher risk of meningococcal infection and should be given a single dose of MCV4.

A vaccine containing meningococcal serogroups C and Y and Hib tetanus toxoid (Hib-MenCY [MenHibrix]) is licensed for use in infants 6 weeks through 18 months old who are at increased risk for meningococcal disease. It may be given in a four-dose series to infants with complement component deficiencies or functional asplenia such as sickle cell disease. It does not prevent disease against serogroup B, which causes about 60% of disease among children ages 0 to 59 months. Because it does not contain serogroup A, infants 9 to 23 months old traveling to the Hajj or the “meningitis belt” of sub-Saharan Africa should be given two doses at least 8 weeks apart of either MCV4 vaccine before travel. If MenACWY-D is used, then it should be given at least 4 weeks after completion of the PCV13 series. Children 2 to 10 years old and adolescents who travel or reside in countries where meningococcal disease is hyperendemic should receive one dose of MCV4 ([AAP Red Book, 2012](#), pp. 505-508).

HUMAN PAPILLOMAVIRUS VACCINE

Although most human papillomavirus (HPV) infections spontaneously resolve, high-risk HPV types are found in 99% of cervical cancers with types 16 and 18, accounting for about 70% of cervical cancers worldwide. HPV is also believed to account for 90% of anal cancers; 40% of vulvar, vaginal, or penile cancers; and 12% of oral and pharyngeal cancers. Types 6 and 11 HPV account for 90% of genital warts in addition to laryngeal papillomatosis. The bivalent HPV2 (types 16 and 18) vaccine (Cervarix) and the quadrivalent HPV4 (types 6, 11, 16, and 18) vaccine (Gardasil) are recommended for routine vaccination of girls at ages 11 or 12 years and are ideally given before onset of sexual intercourse. They are also recommended for unimmunized girls and women 13 through 26 years old. HPV4 is now recommended for routine immunization of boys at ages 11 to 12 years and for unimmunized boys and men ages 13 to 21 years. Men ages 22 to 26 years may also be immunized ([AAP Red Book](#), pp. 529-530). Both vaccines are given in a three-dose series and are prophylactic only for the HPV types they contain and do not treat preexisting infection with these HPV types. They may be given at the same visit at different sites with the MCV4 and Tdap vaccines.

SPECIAL CLINICAL SITUATIONS

Children who are immunocompromised or infected with HIV usually should not be given live-virus vaccines.

However, measles can cause severe disease and death in symptomatic HIV-infected patients. MMR (but not MMRV) is recommended at age 12 months for HIV-infected children with CD4+ T-lymphocyte counts of 15% or greater. The second dose can be given 28 days later to improve the immune response. Children with age-specific low CD4+ counts should not be given measles virus-containing vaccine (*AAP Red Book, 2012*, pp. 86-87). HIV-infected children are also at increased risk from complications of chickenpox and zoster, and children with CD4+ counts of at least 15% should receive two doses of varicella vaccine 3 months apart. The MMRV vaccine is not used in this situation (*AAP Red Book, 2012*, pp. 86-87).

Most new cases of measles in the United States are imported from abroad, including European countries. Therefore, infants 6 through 11 months old traveling to foreign countries should receive one dose of MMR. This dose should be repeated when they become 12 months of age. Children 12 months of age or older should have two doses of MMR separated by 28 days before traveling abroad (*AAP Red Book 2012*, pp. 103-106).

Children with anatomic or functional asplenia have a 350-fold higher rate of septicemia than children without asplenia (*AAP Red Book, 2012*, p. 88). PCV13 is recommended for all children younger than 60 months and children 24 to 71 months old who have high-risk conditions such as sickle cell disease, functional or anatomic asplenia, HIV infection, other immune deficiencies or immunosuppressive therapies, chronic cardiac or pulmonary disease, chronic renal insufficiency, diabetes mellitus, cerebrospinal fluid leaks, or cochlear implants. High-risk children who have received four doses of PCV13 should also receive one dose of the 23-valent polysaccharide pneumococcal vaccine (PPSV23, Pneumovax-23) at 24 months. Children 24 to 71 months old who have received less than three doses of PCV13 should receive two doses of PCV13 followed by one dose of PPSV23 8 weeks later. PCV13 is now recommended for unimmunized children ages 6 to 18 years who are at risk because of anatomic or functional asplenia, HIV, cochlear implant, cerebrospinal fluid leak, or other immunocompromising conditions. PPSV23 should then be given 8 weeks later. All immunosuppressed children and those with anatomic or functional asplenia should receive a second dose of PPSV23 vaccine 5 years after the first dose (*ACIP, CDC*, pp. 521-524).

NATIONAL CHILDHOOD VACCINE INJURY ACT

The National Childhood Vaccine Injury Act of 1986 was passed to provide compensation for children inadvertently injured by any of the routinely recommended childhood vaccines and to provide liability protection for manufacturers and for health care providers who administer the vaccines. The intent of the law is to ensure a stable supply of vaccine and allow routine immunizations to continue. The physician or other health care provider must maintain permanent documentation of the date, vaccine type, manufacturer, lot number, and name, address, and title of the person administering the vaccine. A list of reportable but not necessarily compensable events is available from the Health Resources and Services Administration. Significant adverse events should be reported to the Vaccine Adverse Event

Reporting System (VAERS) at 800-822-7967 or <http://www.vaers.hhs.gov>.

KEY TREATMENT

- Administer all recommended or required immunizations, except when true contraindications or precautions are present or the immunizations are refused by the parent or patient (*AAP Red Book, 2012; Hviid, 2006*) (SOR: A).

CHAPTER OUTLINE

Sleep Problems, 453
Autism, 455
Encopresis and Enuresis, 457
Attention-Deficit Hyperactivity Disorder, 457

Oppositional Defiant Disorder, 460
Conduct Disorder, 461
Eating and Feeding Disorders, 463
Mood Disorders, 465

Primary care physicians are generally the first point of contact with a family when questions arise about a child's health and development. The onus is on the physician to allay unnecessary fears when development is progressing appropriately but also to act quickly when problems arise because early intervention is a key piece of treatment for behavioral disorders or abnormalities. Childhood behavioral problems are a complex assortment of individual mental disorders, genetic and medical disorders, family interaction difficulties, social and school problems, and combinations of these. The rates of many psychosocial problems in children and adolescents, including depression, suicide, conduct disorders (CDs), and drug and alcohol abuse, have been rising in recent years throughout Western culture (Fombonne, 1998). This increase is only partly explained by changes in diagnostic criteria and reporting. The trend is particularly troubling when the economic conditions and physical health of the population have been improving. The implication for office physicians is that psychosocial problems will encompass a growing proportion of patient care both as presenting problems and as cofactors in other medical conditions.

This chapter is arranged in problem-focused fashion along a developmental continuum from infancy through adolescence based on when various problems are most frequently encountered in practice. For conditions encountered at different developmental stages, discussions include similarities and differences in recognition and treatment at different ages. Management focuses on early, brief interventions the physician can make with the patient and family as well as suggestions about referrals.

Regardless of the behavioral concern or the child's age, general principles for evaluation and management include the following:

1. Obtain specific examples of the problem behaviors rather than general conclusions. For example, "Child is out of his seat, walking around the classroom every few minutes," rather than "Disruptive in class" and "Screams inconsolably at 2 AM" rather than "Doesn't sleep well."
2. Obtain as complete information from as many observers as possible. Unusual seizure disorders and other neurologic problems are included in the differential diagnosis of many behavioral disorders. Keys to their diagnosis are found in a careful history, including neurologic and age-appropriate mental status examination.
3. Emotional stressors and abuse, whether physical, verbal, or sexual, can be important precipitants of behavioral problems or can exacerbate existing behavioral problems. Therefore, explore these, including an interview of the child apart from their parents when the child is verbal.
4. Consider multiple diagnoses simultaneously. Multifactorial etiologies are common for many behavioral complaints, and many psychiatric diagnoses carry a high risk of comorbid conditions. Therefore, avoid a linear approach of working up one potential diagnosis at a time.
5. Use a multidimensional treatment approach. Many behavioral problems respond best to combinations of psychotherapy, medication, parent and teacher education, and other therapies rather than only one of these at a time.

Many times, a referral to a behavioral or psychiatric specialist is warranted. Knowing the resources within the community, the differences among providers, and the state statutes governing what various providers are qualified to do will help providers steer patients in the appropriate direction. For cases of psychological or behavioral difficulty that warrant counseling or psychotherapy, a referral to a licensed clinical psychologist, psychological counselor, marriage and family therapist, or clinical social worker is appropriate. Each of these professionals is qualified (in most states) to provide individual or family therapy to address specific behavioral or mood-related concerns. When a potential intellectual or developmental disorder may be causing behavioral problems, the child should be referred to a licensed clinical psychologist or neuropsychologist for evaluation. Although school psychologists can often provide assistance with academic difficulties, they are not licensed

to diagnose in many states; therefore, a private clinical evaluation is likely to be most helpful. Many primary care physicians are comfortable prescribing psychoactive medications for their well-known patients. In cases of complicated psychiatric problems with multiple comorbid complaints or in cases that have been refractory to treatment, a referral to a child and adolescent psychiatrist may be indicated. Local community mental health agencies are often helpful sources of information for patients seeking assistance.

Sleep Problems

Key Points

- Many sleep problems can be prevented with good sleep hygiene.
- Sleep disorders have important interactive and bidirectional effects with many medical and mental disorders.
- For obstructive sleep apnea syndrome (OSAS), criteria to order a sleep study in the evaluation of a child are similar to criteria for adults, but interpretation of the results requires special pediatric expertise.
- The most common cause of obstructive sleep apnea in children is adenotonsillar hypertrophy, and the treatment of choice is surgery.

Normal sleep has a well-characterized pattern of rapid eye movement (REM) and non-REM sleep that changes with age. Non-REM sleep is further categorized into stages 1, 2, 3, and 4 on the basis of electroencephalographic (EEG) characteristics, with the deepest non-REM sleep occurring in stages 3 and 4. A normal nighttime sleep cycle is about every 90 minutes, with multiple brief arousals and quick returns to sleep without memory of having awakened. Deep non-REM sleep predominates in the first several hours of sleep, and REM is most prominent in the last few hours. Children have substantial periods of very deep sleep that lessen with age. There is a gradual decrease in the amount of REM sleep and a significant decrease in deep non-REM sleep, especially in adolescence.

Children and adolescents in American society sleep less than those in other societies and less than children in the past (Dahl, 1998). This has serious implications for family physicians because short sleep duration is predictive of poor cognitive performance; increased behavior problems, including hyperactivity; and development of obesity and metabolic syndrome (Kelly et al., 2013; Scharf, et al., 2013; Xi et al., 2014). Because of the wide variations in normal sleep patterns and development, physicians should avoid rigid expectations in counseling parents, but the following are some useful guidelines. A typical infant is able to sleep 6 to 8 hours through the night by age 2 months and 10 to 12 hours by age 6 months. A child usually no longer requires a morning nap by about 1 year of age and outgrows the afternoon nap around age 3. The total daily sleep requirement decreases with age, from 16½ hours at 1 week of age to 14 hours by age 1 year, 13 hours by age 2 years, 12 hours by age 3 years, 11 hours by age 5 years, and 10 hours by age 9 years (Blum and Carey, 1996).

Table 23-1 Good Sleep Hygiene

Environment	Dark Quiet Cool
Schedule	Regular morning waking time Consistent nap length Regular bedtime
Activities	Morning sunlight exposure No late day caffeine No frightening TV or stories in the evening No late evening electronic media (TV, computer, video games) Daily physical exercise but no vigorous physical activities in the hour before bedtime Consistent bedtime routine Consistent soothing methods Child put into bed awake

From Blum NJ, Carey WB. Sleep problems among infants and young children. *Pediatr Rev.* 1996;17(3):87-92.

An important aspect of preventing sleep problems is guidance regarding good sleep hygiene (Table 23-1), the conditions that are most conducive to healthy, restorative sleep. Some children are reassured by a low-wattage night-light but more light than that may disturb sleep. Parents of newborns should be counseled to put their infant to sleep supine rather than prone unless there is a specific medical indication to the contrary. This results from the association of the prone sleeping position with sudden infant death syndrome (SIDS) in young infants (Guntheroth and Spiers, 1992) (SOR: A). Many children rest better with a “transitional object,” a favorite blanket or toy. However, parents should avoid putting the child to bed with a bottle left in the mouth because it may lead to severe dental caries. Finally, the child should be put to bed awake, so that the child develops self-soothing skills to initiate sleep and resume sleep after nighttime disruptions.

About 20% to 30% of children and adolescents have sleep problems that are a serious concern to them and their families (Dahl, 1998). Problems with sleep initiation and nighttime awakenings are most common during infancy. Parasomnias and OSAS are most common in the 3- to 8-year-old group. Sleep deprivation, delayed sleep-phase syndrome, and narcolepsy are important considerations in the adolescent age group (Carskadon and Roth, 2000).

Sleep problems have a serious negative impact on many aspects of physical, mental, and social well-being. Also, many medical problems, such as conditions that cause nighttime pain or nocturia, and mental disorders, such as bipolar disorder (BD), can lead to sleep problems. Changes made in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) from the DSM-IV acknowledge these bidirectional and interactive effects. Sleep problems early in life are predictive of many later behavioral and emotional problems (Dahl, 1998). Children with frequent nighttime awakenings are at increased risk for physical abuse, perhaps because the parents of these children show increased levels of fatigue, irritability, and depression. The assessment and management of sleep problems in general should include consideration of potential sleep interrupters as primary causes or as exacerbators. One important category of interrupters is conditions that cause pain or itching (e.g., juvenile rheumatoid arthritis, migraine, atopic

dermatitis). Another category is problems that lead to respiratory symptoms, including nocturnal asthma, gastroesophageal reflux, and obstructive sleep apnea.

SLEEP REFUSAL

Toddlers often resist going to bed when their parents want them to. Parents may have difficulty recognizing whether the resistance is related to true needs and fears or whether it is attention seeking or oppositional. The resistance often takes the form of repeated requests for a snack, a drink, or a trip to the toilet and may include fears of noises, shadows, or imaginary monsters.

A sleep diary can be helpful to sort out the etiology for the sleep refusal and direct management efforts. The parents record bedtimes and waking times for 2 weeks and indicate specific problem behaviors and their responses to each situation. Parents are often able to recognize patterns and problems themselves as they review the diary.

Many common refusal patterns can be addressed by focusing on the problem aspects of good sleep hygiene (see Table 23-1). If the problem seems to be oppositional, the best approach is for parents to ignore it. If the child gets out of bed, a parent should place the child back in bed without conversation other than a firm, "It's time for bed." When the parents actively ignore their child's efforts to get attention, the behaviors often get worse before they improve. However, even persistent children eventually respond (Blum and Carey, 1996). If standard ignoring is too stressful on the family, a "gradual ignoring" technique is also effective (Reid et al., 1999) (SOR: B). This involves briefly checking on the child every few minutes until he or she is asleep and gradually lengthening the interval between checks.

For a child who is fearful, having parents ignore them may make the fears worse. A gradual withdrawal of the parent's presence after the bedtime routine works better. The parent may sit in the room while the child falls to sleep but should avoid lengthy discussion of the child's fears. After the child is able to get to sleep without fear, the parent begins to move their chair closer to the child's door and eventually outside the bedroom. Fearful children who do not respond to this technique should be considered for referral for more intensive treatment similar to that applied toward phobias.

NIGHT WAKING

Most children wake up in the night but are able to get back to sleep without arousing their parents. The exceptions can have a serious impact on the entire family, as previously noted. As with sleep refusal, a sleep diary can help, and parent education regarding good sleep hygiene is beneficial. However, two common problems deserve particular attention: night terrors and nightmares (Table 23-2).

Night terrors come about as a sudden partial arousal from the deepest non-REM sleep. Essentially, part of the brain snaps into wakefulness, but part remains soundly asleep. Because deep non-REM sleep predominates in the first 4 hours of sleep, night terrors usually happen during the early part of the night. The child bolts upright in bed, screaming, sweating, tachycardic, and tachypneic. The episodes usually last only a few minutes, ending as abruptly as they began, with the child falling back to sleep quickly

Table 23-2 Diagnostic Features of Night Terrors versus Nightmares

Feature	Night Terrors	Nightmares
Time of night	Early; usually within 4 hours of bedtime	Late
State on waking	Disoriented or confused	Upset or scared
Response to parents	Unaware of presence; not consolable	Comforted
Memory of event	None unless fully awakened	Vivid recall of dream
Return to sleep	Usually rapid unless fully awakened	Often delayed by fear
Sleep stage	Partial arousal from deep non-REM sleep	REM sleep

REM, Rapid eye movement.

From Blum NJ, Carey WB. Sleep problems among infants and young children. *Pediatr Rev.* 1996;17(3):87-92.

unless fully awakened by the parents. Not fully awake, these children do not respond to the parents' efforts to comfort them. The child appears disoriented and confused, often with a blank stare, and has no recall of the event the next morning. Night terrors usually occur in children ages 2 to 6 years and are more common during times of illness, stress, or sleep deprivation. A nocturnal seizure should be considered in the differential diagnosis if the events are more likely right at sleep onset or if there is a personal or family history of seizures (Dahl, 1998).

Nightmares, on the other hand, are frightening dreams that awaken the child from REM sleep. Therefore, they tend to occur during the second half of the night, leaving the child upset or scared with a vivid recall of the dream. The child responds to comforting efforts by the parent but may be slow to go back to sleep because of fear. As with night terrors, nightmares occur most often during the toddler to preschool years and are more common during stressful times.

Management

In general, sedative medications are not indicated for night waking. Instead, behavior management techniques similar to those outlined for sleep refusal are appropriate for most cases.

There is no specific treatment for night terrors. Parents should be reassured with the explanation that the problem is common and self-limited. They should not try to wake the child up because this may only frighten the child or slow the child's return to sleep. For children who thrash violently, the parent should take precautions to provide protection for them. If the child sleepwalks into potentially dangerous situations, the parents can hang a bell or electronic movement alarm on the child's bedroom door to warn them. Because overtiredness is a major factor in the tendency to have night terrors, increasing the total amount of sleep and keeping a consistent sleep-wake cycle should be emphasized.

Because nightmares tend to occur at times of emotional stress, the focus of treatment should be on assisting parents with effective ways to manage the underlying stress. When a nightmare has occurred, the child is awake and frightened. The parent should comfort the child *without* a detailed

review of the nightmare contents or “flashlight searches for monsters” (Blum and Carey, 1996), which can further increase the child’s fears.

OBSTRUCTIVE SLEEP APNEA SYNDROME

Habitual snoring occurs in 3% to 12% of preschool-age children. The childhood incidence of OSAS is estimated to be 2%. The American Academy of Pediatrics (AAP) has published an evidence-based guideline for the diagnosis and management of OSAS (Marcus et al., 2012).

In children, OSAS is most often associated with large adenoids or tonsils, as well as specific facial features such as micrognathia, macroglossia, and Down syndrome. Unlike adults with sleep apnea, children can be affected without large drops in blood oxygen levels because children can have frequent brief awakenings to quickly reestablish their airway. Thus, the primary clinical issue may be sleep fragmentation. In the context of a child with snoring and restless sleep, OSAS should be considered any time there are symptoms or signs suggesting sleep deprivation, such as difficulty paying attention, emotional lability, partial arousals during the night (night terrors, sleepwalking), or difficulty waking up in the morning (AAP, 2012).

Because only a portion of children with snoring and adenotonsillar hypertrophy have OSAS, a sleep study is recommended to avoid unnecessary surgery. A caution, however, is that sleep studies in children require special expertise that may not be available at an adult sleep center.

Treatment of a child with OSAS on the basis of adenotonsillar hypertrophy is surgery. Continuous positive airway pressure (CPAP) is effective in children but is reserved for when adenotonsillectomy is contraindicated or unsuccessful (AAP, 2012) (SOR: A).

SLEEP DEPRIVATION AND DELAYED SLEEP-PHASE SYNDROME

Sleep deprivation and delayed sleep-phase syndrome are common problems in adolescents for several reasons. The total sleep requirement is as much or more in adolescence as in preadolescence (Carskadon and Roth, 2000), but adolescents tend to attain less sleep for both biologic and cultural reasons. School-age children are more likely to be “larks,” preferring to wake up early even if they are up late at night. At puberty, a circadian rhythm change occurs that results in a switch from larks to “owls,” the preference for a late-night bedtime and late-morning awakening. This biologic tendency is encouraged by the availability of stimulating activities late into the night, whether social events, part-time jobs, or technologic advances (e.g., TV, Internet). Stimulants such as caffeine and tobacco also act to delay sleep. Despite these factors that act to delay sleep, school schedules often require the adolescent to awaken early. Thus, sleep deprivation develops. Also, jet lag–like shifts often develop between the weekday and weekend or holiday schedule. These schedule shifts probably play a role in the most common adolescent sleep problem: delayed sleep-phase syndrome (Dahl, 1998).

The assessment is by history. The main differential diagnosis to consider from delayed sleep-phase syndrome is a teenager who is choosing a late-night schedule for some secondary gain. This person is not distressed by the

dysfunctional sleep pattern and is unmotivated to change it. Therefore, the adolescent with secondary gain requires treatment directed at the underlying school or family issues rather than the sleep disturbance.

Treatment of the cooperative adolescent involves attempting a schedule shift and consistently maintaining it. Those with marked difficulty initiating timely sleep may respond to staying awake through an entire night and then reestablishing a regular schedule. Mindell and Owens (2009) provide a practical clinical guide for sleep in children.

NARCOLEPSY

Although rare, narcolepsy is an important cause of daytime sleepiness because it can affect personal safety and school performance, but it is readily treatable. Normally, REM sleep only occurs when a person has been asleep for 60 to 90 minutes and follows all four stages of non-REM sleep. Narcoleptic patients, on the other hand, experience sudden episodes of REM sleep in the middle of a wakeful state or immediately after falling asleep.

The key feature of narcolepsy is recurrent *sleep attacks*: sudden, unintentional, irresistible bouts of sleep that occur in inappropriate situations, such as during conversations or while driving. Other common findings include *cataplexy* (sudden bilateral loss of muscle tone without loss of consciousness), *hypnagogic hallucinations* (vivid dreamlike imagery just before falling asleep), and *sleep paralysis* (inability to move or speak just after morning awakening). Any child or adolescent with unexplained daytime sleepiness who does not respond to initial management with good sleep hygiene or who has a family history of narcolepsy should be considered for evaluation. A sleep study is required to make the diagnosis.

Narcolepsy treatment combines behavioral approaches with medications. The patient should adhere to good sleep hygiene. Therapeutic naps enhance daytime alertness and reduce the necessary dose of stimulants. Stimulant medications, such as methylphenidate, dextroamphetamine, or modafinil, are very helpful for daytime sleepiness (Vgontzas and Kale, 1999) (SOR: A). The antidepressants are REM suppressants that help prevent cataplexy or hypnagogic hallucinations. The nonsedating antidepressants, especially the selective serotonin reuptake inhibitors (SSRIs), work synergistically when combined with stimulants (Vgontzas and Kale, 1999) (SOR: B).

Autism

Key Points

- Autism spectrum disorder (ASD) has an onset before age 3 years and is characterized by impaired social interaction; impaired communication; and repetitive, stereotyped patterns of behavior.
- Autism is not caused by thimerosal-containing vaccines.
- Standard developmental screening tests have poor sensitivity for autism.
- Early intervention with a multidisciplinary approach improves autism outcomes.

Autism spectrum disorder describes a constellation of symptoms in two primary categories: (1) impaired social interaction and communication and (2) repetitive, stereotyped patterns of behavior. It is estimated that one in 88 children are diagnosed with ASD with a higher prevalence in boys (CDC, 2008). Children diagnosed with ASD under the DSM-5 criteria experience difficulty in social-emotional reciprocity, use and interpretation of nonverbal gestures, and maintaining relationships. They must also experience symptoms in at least two of the following areas: stereotyped or repetitive use of speech, movement, or objects; excessive adherence to rituals, resistance to change, or ritualized patterns of behavior; restricted interests unusual in their intensity or focus; or unusual sensory interests or reactions (American Psychiatric Association [APA], 2013). The DSM-5 also removes the requirement that symptoms are fully evident before age 3 years, instead using the criterion that symptoms may manifest when social demands exceed the capacity of the child or adolescent. Thus, children whose social deficits do not emerge until middle school or high school, when social interactions become more complex and require greater skill, may still qualify for a diagnosis of ASD if all criteria are met. Qualifying statements may be added to the ASD diagnosis in cases of accompanying intellectual impairment; language impairment; association with medical, genetic, and environmental factors; or association with another neurodevelopmental, mental, or behavioral disorder (e.g., attention-deficit hyperactivity disorder [ADHD]).

Former related disorders including Asperger disorder and pervasive developmental disorder, not otherwise specified (PDD, NOS) have been removed from the diagnostic profile of the DSM-5. A lack of scientific evidence distinguishing among the disorders drove members of the revision committee to join these disorders under one spectrum because of the clinical practice of inconsistently interchanging diagnoses of high-functioning autism and Asperger disorder. Whereas some children with prior diagnoses of Asperger disorder or PDD, NOS may no longer qualify for an ASD diagnosis, others may meet diagnostic criteria for a new category of social (pragmatic) communication disorder (without repetitive or stereotyped behaviors). The impact of this categorical change on eligibility for community-based and educational services is currently unknown.

Evidence is mounting that both genetic and environmental factors influence the etiology of autism (Kolevzon et al., 2007; Schaefer and Mendelsohn, 2008). Approximately 15% of autism cases are related to known genetic mutations; however, specific gene contributions vary among families, and it is suspected that more than 100 genetic loci may contribute independently to the ASD phenotype (APA, 2013). Assertions that autism is caused by thimerosal-containing vaccines have been discounted by a comprehensive meta-analysis (Parker et al., 2004; Thompson, 2013).

ASSESSMENT

Developmental screening should be part of each well-child examination. Physicians should take parental concerns about delayed speech and language development seriously,

especially beyond 18 months of age. In addition to delayed speech development, the other common presenting symptom is *challenging behavior*: The behaviors may include a violent reaction to minor changes in the environment or routine, stereotypic movements such as clapping or rocking, and preoccupation with narrow interests or inanimate objects. The AAP released a policy statement on developmental surveillance in primary care, offering an algorithm for determining when specialized assessment is needed (AAP, 2006). Frequently used general screening measures include the Denver II Developmental Screening Test (Frankenburg et al., 1992) and the Ages and Stages Questionnaire (ASQ; Bricker and Squires, 1999), although these measures are not specific for ASD. ASD-specific measures appropriate for primary care include the Modified Checklist for Autism in Toddlers (M-CHAT), a brief, freely available screener that quickly identifies children in need of more intensive assessment (Robins et al., 2001).

When autism is suspected, a thorough evaluation should be performed, including appropriate intellectual testing, speech-language assessment, and assessment of behaviors specific to ASD. The gold standard evaluation tools include the Autism Diagnostic Interview–Revised (ADI-R; Rutter et al., 2008) and the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Lord et al., 2012), although these are not required for an accurate diagnosis of ASD. Referral to a multidisciplinary clinic, developmental behavioral pediatrician, clinical psychologist, or clinical neuropsychologist may be appropriate. Because hearing loss can mimic autism, the evaluation should also include formal audiologic testing. Common comorbidities include anxiety, depression, and obsessional behavior (Prater and Zylstra, 2002).

MANAGEMENT

Early intervention is critical in improving outcomes in children with ASD (Rogers and Vismara, 2008). The landmark autism treatment study by Lovaas (1987) suggests intensive, individualized behavioral intervention with massed practice is key in improving outcomes. Currently, the most successful programs use a multidisciplinary approach that includes behavior modification, development of social communication, active involvement of parents and families, and use of psychotropic medications for dangerous behaviors that do not respond to behavior modification (Myers and Johnson, 2007). Referral to an established program is recommended. Early intensive behavioral interventions (EIBIs) are conducted with the goal of improving intellectual, social, behavioral, and emotional outcomes using empirically supported, consistently implemented, data-driven behavioral interventions across a range of the child's environments (LeBlanc and Gillis, 2012), and these EIBIs are the only autism interventions with consistent demonstration of efficacy. Despite anecdotal reports on the effectiveness of alternative and complementary treatments (e.g., dietary changes), none has shown consistent benefit in clinically controlled trials. Young adults with autism have persistent difficulties functioning in the community, with just more than one third achieving any level of postsecondary education and approximately half maintaining any level of paid employment (Shattuck et al., 2012). Clear

gains in language by age 5 years is the most important predictor of adult outcomes (Bryson et al., 2003).

KEY TREATMENT

- Comprehensive EIBIs that address the child and parents across settings (e.g., home, school, community) hold the most research evidence of efficacy (LeBlanc and Gillis, 2012).
- Risperidone effectively treats irritability, repetition, and social withdrawal in individuals with autism, with weight gain as the most prominent side effect (Jesner et al., 2007).

Encopresis and Enuresis

See eAppendix 23-1 online at www.expertconsult.com.

Attention-Deficit Hyperactivity Disorder

Key Points

- Consider ADHD in a child presenting with hyperactivity, impulsivity, inattentiveness, academic underachievement, or behavior problems.
- Use the DSM-5 diagnostic criteria when assessing for ADHD.
- Obtain information from the parents, child, and teacher using standardized behavior reports, if possible.
- When planning treatment, recognize that ADHD is a chronic condition for which medication only temporarily decreases symptoms and improves functioning.
- Stimulants are the first and second lines of medication treatment.

Attention-deficit hyperactivity disorder is the most frequently diagnosed behavioral disorder of childhood. The prevalence among school-age children is at least 5%, with a 2:1 ratio of boys to girls (DSM-5 2013). ADHD is a chronic disorder persisting from childhood into adolescence and adulthood in the majority of cases. Obvious hyperactivity usually subsides, but inattention and impulsivity persist, leading to potentially serious consequences. ADHD should be considered and assessed in any child age 4 to 18 years who presents with symptoms of inattention, hyperactivity, or impulsivity and academic or behavior problems related to these (AAP, 2011).

The heritability of ADHD appears to be about 77% with a polygenic mechanism of inheritance. Thus, children who are diagnosed with the disorder very often have parents who are also affected. Environmental factors with a positive evidence of association with ADHD include maternal smoking, fetal exposure to alcohol, pregnancy and delivery complications, psychosocial adversity, and exposure to environmental toxins such as PCBs or pesticides. Widely held public beliefs blaming food additives or television

viewing have not been supported when studied scientifically (Banerjee et al., 2007; Bouchard et al., 2010).

Comorbidity is common in ADHD, including oppositional defiant disorder (ODD) (54%-84%), smoking (19%), language or learning disorder (25%), anxiety (up to 33%), and depression (up to 33%) (Dobie et al., 2012).

ASSESSMENT

There is no independent valid test to determine that a child has ADHD. The diagnosis can only be obtained reliably by using a combination of established diagnostic criteria and comprehensive evaluation methods. The recently published DSM-5 made only minor revisions to the criteria set forth in the DSM-IV (Table 23-3). Instead of the prior “types” of ADHD, the DSM-5 refers to three “presentations”: (1) combined, (2) predominantly inattentive, and (3) predominantly hyperactive and impulsive. The individual criteria for each presentation are unchanged from the DSM-IV except that more behavioral examples are given for each, including examples that apply to adults. Also, a diagnosis in adults requires the presence of just five of nine criteria under each category instead of six of nine as required for children. The biggest change in the DSM-5 is that symptoms must be present before age 12 years (rather than age 7 years). The potential these changes have to increase the prevalence of ADHD will be a matter of future study.

Comprehensive diagnostic evaluation for ADHD includes obtaining information from the child, parents, teacher(s), and other caregivers. The process is greatly facilitated by the use of standardized behavior reports, such as the Conners Rating Scales (1997 revision), National Institute for Children’s Health Quality (NICHQ) Vanderbilt forms, or the Swanson, Nolan, and Pelham (SNAP) checklist. Broadband behavioral rating scales, such as the Child Behavior Check List (CBCL, Achenbach), do not effectively discriminate between ADHD and non-ADHD children but do assist in identifying comorbid disorders (Dobie, 2012). Because of the significant prevalence of comorbid psychiatric disorders, the assessment should include inquiring about these conditions. In addition to psychiatric symptoms, the ability of the child to function normally in different domains must also be assessed, including family relationships with adults and siblings, peer social relationships, community behavior, school academic performance, school behavior, interests and play activities, and subjective psychological distress.

The physician should conduct a medical screening examination, including hearing and vision tests. Other diagnostic tests, including laboratory screening tests for lead intoxication, abnormal thyroid function, neuroimaging for brain tumor, or seizure disorder, should be conducted when indicated by the history and physical examination (Dobie, 2012). Computerized continuous performance tests and a full psychological evaluation are not required for diagnosis of ADHD. In fact, most straightforward cases can be diagnosed in a primary care setting using standardized parent and teacher questionnaires and a careful clinical history.

MANAGEMENT

The clinician should establish a comprehensive management program that recognizes ADHD as a chronic

Encopresis

Key Points

- Encopresis is associated with constipation in the vast majority of children.
- The evaluation of encopresis should include consideration of possible sexual or rectal abuse.
- Treatment should include intensive medical therapy with enemas and laxatives to produce daily bowel movements as well as behavior therapy that involves both the child and the parents.

Encopresis is the repeated passage of feces into inappropriate places, such as the clothing or floor, by a child who is developmentally older than 4 years of age. The passage of stool is usually involuntary and associated with constipation in the vast majority of cases. Chronic constipation leads to an overflow incontinence of feces. Constipation can also lead to rectal pain and fissures that further worsen fecal retention and thus the encopresis.

Fecal retention can initially develop for a variety of psychological and physiologic reasons. Psychological factors include fears that develop around toilet training or loss of privacy during toileting, as in public places or daycare. Physiologic factors include diet transitions, such as from breast milk to formula or the initiation of cow's milk in the diet. An occasional case of encopresis not associated with constipation may be caused by organic disease. When incontinence is clearly deliberate, it is usually in the context of oppositional defiant disorder or conduct disorder. Encopresis occurs in about 1% of 5-year-old children and is more common in boys than girls ([American Psychiatric Association, 2013](#)). It is accompanied by enuresis in more than 40% of cases.

ASSESSMENT

The primary goals of evaluation are to assess the presence or absence of constipation in the child with encopresis and to identify any serious psychological or pathophysiologic factors that are present. This can be achieved in most cases through a conscientious history and physical examination, including a digital rectal examination. An extremely useful tool is a 5-day to 7-day symptom and diet diary. The family is asked to record the frequency and character of the stool and episodes of pain or encopresis. The diet history establishes nutritional adequacy and fiber content. Tricyclic antidepressants are a potential cause of constipation. The possibility of sexual or rectal abuse should be explored. On physical examination, growth and weight gain

are important screens for medical causes of encopresis. Measurement of umbilical girth is a useful indicator of the degree of abdominal distention, especially for following response to fecal evacuation treatment. Hirschsprung disease is often included in the differential diagnosis of constipation, but a key clinical feature of Hirschsprung disease is the absence of encopresis.

MANAGEMENT

Prevention involves effective toilet training and treatment of constipation before it becomes chronic ([Kiddoo et al., 2006](#)). The success of encopresis treatment depends heavily on the understanding and cooperation of the patient's family. The greatest success has been demonstrated when behavioral interventions are combined with aggressive laxative therapy ([Brazzelli and Griffiths, 2006](#)). Biofeedback does not appear to add additional benefit. Treatment typically includes disimpaction with a series of enemas followed by adequate laxatives and fiber supplements to produce at least one painless soft stool each day. After the child establishes a regular bowel pattern of one to three stools per day without soiling episodes, the laxative dose is gradually decreased.

KEY TREATMENT

- Behavioral intervention plus laxative therapy improves continence in children with functional fecal incontinence associated with constipation better than laxative therapy alone ([Brazzelli and Griffiths, 2006](#)) (SOR: A).

Enuresis

Key Points

- In children with primary nocturnal enuresis who are otherwise asymptomatic and have negative physical examination and urine study results, treatment can be initiated without further workup.
- Secondary enuresis and enuresis that occurs solely during the day suggest possible psychosocial pathology.
- All three of the most common treatments for nocturnal enuresis—electronic enuresis alarms, desmopressin (DDAVP), and imipramine—are effective, and each has important advantages and disadvantages.

Enuresis is repeated voiding into the bed or clothing after a person has reached an age at which continence is expected.

Enuresis is most frequently nocturnal (occurring at night) but can be diurnal (occurring during the day) or both. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5) defines the age at which continence is expected as 5 years, but as many as 15% to 20% of 5-year-old children have nocturnal enuresis. The spontaneous cure rate is 15% per year of age, leading to a prevalence of 5% to 10% in 10-year-old children and 1% to 2% in 18-year-old teens. This prevalence indicates that nocturnal enuresis is second only to allergic disorders as the most common chronic ailment in childhood. Enuresis may be *primary* (the child has never established urinary continence) or *secondary* (the child becomes incontinent after an initial period of continence).

The etiology of enuresis is multifactorial, with a definite genetic component. When neither parent has a history of bedwetting, the incidence in their children is 15%. The incidence increases to 40% when one parent has a positive history and to 75% when both parents have a bedwetting history.

The pathophysiologic factors that lead to nocturnal enuresis are (1) overproduction of urine through the night, (2) an abnormally small bladder volume, or (3) failure of arousal when the bladder is full. In regard to urine overproduction, there is evidence that children with nocturnal enuresis have lower levels of nighttime antidiuretic hormone (ADH) than nonenuretic children. This phenomenon probably plays an important role in childhood enuresis but has not been demonstrated to be present in adolescents with enuresis. Measured bladder capacity in those with nocturnal enuresis is usually normal. However, detrusor overactivity during sleep has been observed in many patients with enuresis, suggesting that functionally reduced bladder capacity during sleep may play a role in as many as one third of children with nocturnal enuresis. Also, children with enuresis are more difficult to arouse from sleep than nonenuretic children, as demonstrated by parent survey and sleep laboratory testing (Hjalmas, 1998).

ASSESSMENT

Patients can be categorized as having uncomplicated nocturnal enuresis or complicated enuresis based on the initial history, physical examination, and urinalysis and culture. Children with *uncomplicated* enuresis have primary nocturnal enuresis but are otherwise asymptomatic and have negative physical exam and urine studies. Treatment can be initiated in these children without further workup. *Complicated* enuresis is any case that does not meet these criteria. With a greater possibility of a significant psychosocial problem or medical abnormality, these children merit more extensive evaluation based on the initial assessment findings.

Primary nocturnal enuresis is not usually caused by psychological factors. However, a history of enuresis that is solely diurnal suggests the possibility of significant psychosocial pathology. This risk should also be considered in patients with secondary nocturnal enuresis. Stressors to consider in these patients include serious parent-child or teacher-child interaction problems, attention-getting behavior after a family system change (e.g., new sibling), and physical or sexual abuse.

Combined nocturnal and diurnal enuresis may be a symptom of a urinary tract infection (UTI). Mild urinary urgency and frequency of up to seven voids during the day are common in 7-year-olds (Hjalmas, 1998). However, significant daytime symptoms of urinary frequency and urgency even without incontinence, when combined with nocturnal enuresis, should lead to consideration of mechanical urinary problems such as posterior urethral valves. Also, if bowel incontinence accompanies the urinary incontinence, psychosocial pathology and neurologic abnormalities should be considered.

The physical examination should include specific attention to the abdomen, genitals, lower spine and neurologic function, and developmental and psychological appropriateness. A urinalysis and urine culture screen for metabolic diseases and urinary tract infection. Additional test results are reserved for patients with complicated enuresis, looking for specific secondary causes, and for patients with apparently uncomplicated nocturnal enuresis who fail initial treatment.

MANAGEMENT

Because of the high prevalence and high spontaneous resolution rate, treatment of enuresis is not encouraged until the child is at least 6 years old. Successful treatment can normalize the low self-esteem that is a common consequence of enuresis (Hagglof et al., 1998). Particularly in patients with diurnal enuresis, psychosocial issues may need to be addressed before attempting treatment aimed at the enuresis alone.

A critical factor in successful treatment of enuresis is patient and family motivation. General recommendations for nocturnal enuresis are to (1) limit evening fluid intake; (2) establish a consistent bedtime routine that includes relaxed voiding; (3) avoid sleep deprivation; (4) focus on rewards for dry nights; (5) avoid punishment for wet nights; (6) make the child responsible for cleaning up clothing and bedding in age-appropriate manner and in a matter-of-fact, nonpunitive way; and (7) if the child is aroused to void after already asleep, making sure the child awakens fully to urinate.

Treatments for nocturnal enuresis target the individual potential etiologies: inadequate ADH secretion, detrusor overactivity, and high arousal threshold. Unfortunately, no routine clinical tests can differentiate among these causes, so treatment choices must be made based on other criteria. That treatment lacks specificity in this way may account for a substantial proportion of treatment failures.

The three most common treatments for nocturnal enuresis are electronic enuresis alarms, DDAVP, and imipramine. All three approaches were found effective in a systematic review, with advantages and disadvantages for each (Glazener, 2009). *Enuresis alarms* work as a conditioning mechanism to facilitate arousal. A sensor is placed in the child's underpants and connected to an alarm attached to the bed clothing. The sensor can detect a very small volume of urine, such that the alarm sounds before the child completes voiding. The aroused child can finish voiding in the toilet and change any wet linens or clothes. The alarms are more efficient treatment than medications but put greater demands on the child and family. Enuresis alarms

are inexpensive (<\$100) and widely available but may not be reimbursed by insurance carriers.

Desmopressin is a synthetic analog of arginine vasopressin, a natural ADH. It works by reducing overnight urine output. It is available as an oral tablet or a nasal spray. Desmopressin is expensive but is often covered by third-party payers. It is immediately effective but has a high relapse rate after discontinuation. The relapse rate can be minimized by rapid titration until dryness in 1 to 3 days followed by maintenance therapy for at least 4 to 6 weeks and then very slow, stepwise dose reduction. Side effects are uncommon and generally mild. The risk of the rare but most serious potential side effect, seizures from hyponatremia, can be minimized by restricting evening fluid intake, as is recommended for enuresis in general.

The tricyclic antidepressants, particularly *imipramine*, have been used for many years to treat enuresis. The usual dose of imipramine is 1 to 2 mg/kg at bedtime. It is usually continued for 6 to 8 weeks before tapering, and a second course may be given for relapses. Although inexpensive and effective, imipramine has a serious side effect profile, including potential cardiac arrhythmias and high toxicity in accidental overdose. Therefore, imipramine is generally not first-line treatment for enuresis.

With any of these management options, follow-up is important to improve compliance. Other forms of

treatment, including bladder training exercises to increase functional bladder capacity and anticholinergic medications to relax the bladder's smooth muscle, have inadequate evidence of effectiveness to be recommended. Combination treatment with multiple modalities aimed at different etiologies (enuresis alarm plus desmopressin) has been suggested, particularly for refractory cases, but information on its effectiveness is limited. Children whose enuresis is accompanied by encopresis should have the encopresis addressed first. This is because the enuresis may resolve spontaneously after the pelvic mass of retained stool is evacuated, allowing the bladder to expand.

KEY TREATMENT

- “Alarm interventions appear to be more effective than desmopressin or tricyclics because around half the children remain dry after alarm treatment stops. Overlearning (giving extra fluids at bedtime after successfully becoming dry using an alarm), dry bed training, and avoiding penalties may further reduce the relapse rate” (Glazener et al., 2005) (SOR: A).
- Behavioral and educational interventions are not as effective as an alarm but may augment the effectiveness of an alarm (Glazener et al., 2004) (SOR: A).

Table 23-3 DSM-5 Diagnostic Criteria for Attention-Deficit/Hyperactivity Disorder

- A. A persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development, as characterized by (1) and/or (2):
1. Inattention: six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
 Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.
 - (a) Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or during other activities (e.g., overlooks or misses details, work is inaccurate).
 - (b) Often has difficulty sustaining attention in tasks or play activities (e.g., has difficulty remaining focused during lectures, conversations, or lengthy reading).
 - (c) Often does not seem to listen when spoken to directly (e.g., mind seems elsewhere, even in the absence of any obvious distraction).
 - (d) Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (e.g., starts tasks but quickly loses focus and is easily sidetracked).
 - (e) Often has difficulties organizing tasks and activities (e.g., difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganized work; has poor time management; fails to meet deadlines).
 - (f) Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (e.g., schoolwork or homework; for older adolescents and adults, preparing reports, completing forms, reviewing lengthy papers).
 - (g) Often loses things necessary for tasks or activities (e.g., school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones).
 - (h) Is often easily distracted by extraneous stimuli (for older adolescents and adults, may include unrelated thoughts).
 - (i) Often forgetful in daily activities (e.g., doing chores, running errands; for older adolescents and adults, returning calls, paying bills, keeping appointments).
 2. Hyperactivity and impulsivity: six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 months to a degree that is inconsistent with developmental level and that negatively impacts directly on social and academic/occupational activities:
 Note: The symptoms are not solely a manifestation of oppositional behavior, defiance, hostility, or failure to understand tasks or instructions. For older adolescents and adults (age 17 and older), at least five symptoms are required.
 - (a) Often fidgets with or taps hands or feet or squirms in seat.
 - (b) Often leaves seat in situations in which remaining seated is expected (e.g., leaves his or her place in the classroom, in the office or other workplace, or in other situations that require remaining in place).
 - (c) Often runs about or climbs in situations where it is inappropriate (Note: in adolescents or adults, may be limited to feeling restless).
 - (d) Often unable to play or engage in leisure activities quietly.
 - (e) Is often "on the go," acting as if "driven by a motor" (e.g., is unable to be or uncomfortable being still for extended time, as in restaurants, meetings; may be experienced by others as being restless or difficult to keep up with).
 - (f) Often talks excessively.
 - (g) Often blurts out an answer before a question has been completed (e.g., completes people's sentences; cannot wait for turn in conversation).
 - (h) Often has difficulty waiting his or her turn (e.g., while waiting in line).
 - (i) Often interrupts or intrudes on others (e.g., butts into conversations, games, or activities; may start using other people's things without asking or receiving permission; for adolescents and adults, may intrude into or take over what others are doing).
- B. Several inattentive or hyperactive-impulsive symptoms were present prior to age 12 years.
 C. Several inattentive or hyperactive-impulsive symptoms are present in two or more settings (e.g., at home, school, or work; with friends or relatives; in other activities).
 D. There is clear evidence that the symptoms interfere with, or reduce the quality of, social, academic, or occupational functioning.
 E. The symptoms do not occur exclusively during the course of schizophrenia or another psychotic disorder and are not better explained by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, personality disorder, substance intoxication or withdrawal).

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition.

Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Publishers; 2013.

condition and works with the parents, child, and teachers to identify the most important problems as targets of treatment. Indications for referral to a specialist include (1) children with ADHD plus a comorbid psychiatric disorder and (2) children with ADHD who do not respond to initial treatment. More specific guidance in assessment and management may be obtained by consulting practice guidelines or parameters ([American Academy of Child and Adolescent Psychiatry \[AACAP\], 2007](#); [AAP, 2011](#); [Dobie, 2012](#)). An initial effort must be made to educate the parents and child about ADHD (see [Web Resources](#)).

Psychosocial Therapy

The physician or staff should review techniques of parent behavioral management to assess how well they are understood and effectively implemented. This includes the proper use of positive reinforcers and punishment. A structured and standardized system, called the "token economy," can

be very effective but requires considerable time and effort by the parents. Common mistakes made by parents include too much punishment versus positive reinforcement, too long a delay in receiving a reward, making the system too difficult initially so the child never achieves success, inconsistent implementation, and poor supervision.

Assessing for proper educational placement is important. At a minimum, the parents should consult with the child's classroom teacher and confirm close supervision of the child, a structured classroom, good behavioral management, and good communication with parents. If this effort is not sufficient, the parents can request educational accommodations under Section 504 of the 1973 Rehabilitation Act. This federal law provides for special accommodations and services in a person with a chronic disabling condition, including psychiatric disorder. The request must be accompanied by a physician statement documenting the disabling condition and directed to the building principal or school

Table 23-4 Stimulant Medications Used in Treatment of Attention-Deficit Hyperactivity Disorder

Drug	Brand Name	Dosage Forms	Duration of Behavioral Effects	Suggested Dosage
Methylphenidate, plain	Ritalin regular Methylin	5-, 10-, 20-mg tablet Methylin is also available in chewable tablet and solution	1-4 hr	0.3-2.0 mg/kg/day in divided doses FDA approved for use in children age ≥ 6 yr Maximum dose, 60 mg/day
Methylphenidate, extended release	Ritalin SR	20-mg tablet	3-9 hr	Titrate quickly up to 0.5 mg/kg in a single dose. Observe for benefit and titrate to maximum dose if necessary (2 mg/kg/day up to 60 mg).
	Ritalin LA	10-, 20-, 30-, 40-mg tablet	10-12 hr	—
	Metadate ER	20-mg tablet	8 hr	—
	Metadate CD	10-, 20-, 30-, 40-, 50-, 60-mg capsule	8-12 hr	—
	Concerta	18-, 27-, 36-, 54-mg capsule	12 hr	Start all patients at 18 mg/day and titrate up prn. Child: up to 54 mg/day Adolescent and adult: up to 72 mg/day
	Quillivant XR	5 mg/mL extended release liquid	12 hr	0.3-2 mg/kg/day, single dose
Dexmethyl-phenidate	Daytrana skin patch	10-, 15-, 20-, 30-mg/9-hr patch	9 hr while patch applied	—
	Focalin	2.5-, 5-, 10-mg tablet	4-6 hr	0.3-1.0 mg/kg/day to a maximum of 20 mg/day
	Focalin XR	5-, 10-, 15-, 20-, 30-, 35-, 40-mg capsule	12 hr	30 mg maximum daily dose
Amphetamine salts	Adderall	5-, 7.5-, 10-, 12.5-, 15-, 20-, 30-mg scored tablet	6-8 hr	0.3-1.0 mg/kg/day to a maximum of 40 mg/day
	Adderall XR	5-, 10-, 15-, 20-, 25-, 30-mg capsule	10-12 hr	10 mg/day to a maximum of 30 mg/day for child or 40 mg/day for adolescent or adult
Dextroamphetamine, plain	Dexedrine	2.5-, 5-, 7.5-, 10-, 15-, 20-, 30-mg tablet	1-8 hr	0.3-1.0 mg/kg/day FDA approved for use in children age ≥ 3 yr
Dextroamphetamine, extended release	Dexedrine ER	5-, 10-, 15-mg spansule	8-9 hr	Maximum dose, 60 mg/day
	Procentra	5 mg/5 mL ER liquid	10-12 hr	3-5 yr old: start 2.5 mg/day single dose; maximum dose, 40 mg/day ≥ 6 yr old: start 5 mg/day single dose; maximum dose, 60 mg/day
Lisdexamfetamine	Vyvanse	20-, 30-, 40-, 50-, 60-, 70-mg capsule	10-13 hr	Maximum dose, 70 mg/day

ER, Extended release; FDA, U.S. Food and Drug Administration; PDR, Physicians' Desk Reference; prn, as needed.

district "Section 504 compliance officer." If this is not enough and the child is failing in one or more subjects, the parents can request a comprehensive evaluation by the Child Study Team for possible Special Education placement ("Other Health Impaired" eligibility condition—Federal Public Law 94-142, currently the Individuals with Disabilities Education Act [IDEA]). The request should be in writing and directed to the building principal. The evaluation may take up to 85 school days but could result in an *Individualized Education Program* (IEP), a description and contract of what special services the school will provide.

For children with ADHD alone, other psychosocial treatments have not been shown to be more effective than aggressive use of stimulant medication or even to provide an additional benefit (MTA Cooperative Group, 1999). However, psychosocial treatments are beneficial in children with ADHD and other comorbid disorders or those from families with chaotic functioning.

Pharmacotherapy

The stimulants are the medications of first choice at any age unless comorbid factors take precedence (Dobie, 2012).

Methylphenidate was also shown to be beneficial for very young children with ADHD through the National Institutes of Mental Health (NIMH) Preschoolers with ADHD Treatment Study (PATS); however, the benefit was not as robust as in older children, and adverse effects were more prominent (Abikoff et al., 2007; Gleason et al., 2007). Table 23-4 lists specific dosing recommendations. Of children with ADHD, 70% show a significant improvement on the first trial of a stimulant, and 85% to 90% improve significantly taking at least one of the listed stimulants. When the medication is in effect, motor activity decreases, certain cognitive processes improve, motivation improves, academic performance improves, and oppositional and aggressive behaviors decrease. However, the medication works only for as long as it is given, with no long-lasting or curative effect.

The physician should use a systematic approach. If the first stimulant is not effective after an adequate trial of maximum doses, a sequential trial of each available stimulant is appropriate before moving to another class of medication. At a minimum, at least one methylphenidate preparation and one amphetamine preparation should be

tried. Follow-up appointments should be regular and scheduled and should include information from the parents, teachers, and child (Dobie, 2012). Adverse effects are similar for all stimulants and can affect up to 20% of children. Important side effects include anorexia, weight loss, irritability (more likely in younger children), abdominal pain, insomnia (only if given after 5 PM), dysphoria (more likely in younger children), “behavioral rebound” after wearing off, impaired cognitive performance on laboratory tests (methylphenidate at single doses >1 mg/kg), tachycardia, and increased tic symptoms (if the patient has a tic disorder). In general, growth suppression is not a concern except in children with dramatic anorexia. There is no evidence that the legitimate prescribed use of stimulants by children and adolescents with ADHD leads to future drug abuse, and proper use may actually have a protective effect (Biederman, 1999). Sudden death in children taking stimulant medication has been raised as a potential concern to the point that the **U.S. Food and Drug Administration (FDA) issued a communication in 2009** recommending caution but not stopping the use of stimulants for ADHD. Physicians should screen patients via history and physical examination for conditions that would put them at increased risk for cardiac complications, but current evidence does not support routine electrocardiography for all patients (Dobie, 2012).

The third line of treatment (after two trials of stimulants) is atomoxetine. It is initially given at 0.5 mg/kg/day, either in the early morning or as a divided dose (morning and late afternoon). It is titrated up to a maximum dose of 1.4 mg/kg/day (or 100 mg maximum). The full benefit may not be seen for 4 weeks (Dobie, 2012). Atomoxetine is not a U.S. Drug Enforcement Administration scheduled medication, has no potential for abuse, and therefore can be written with refills. Common adverse effects include nausea, vomiting, gastrointestinal pain, anorexia, headache, fatigue, and sleepiness. Potentially serious side effects include liver injury and suicidal thinking.

Extended-release clonidine (Kapvay) and extended-release guanfacine (Intuniv) are available as adjunctive therapy to stimulants for ADHD. They can be especially useful for oppositional symptoms (Dobie, 2012).

Bupropion, the tricyclic antidepressants (TCAs, e.g., imipramine, nortriptyline), and the α -adrenergic agent clonidine do not have an official FDA indication for the treatment of ADHD. The evidence for their benefit is based on randomized controlled trials (RCTs) and nonrandomized trials with control participants (Dobie, 2012). A variety of other psychoactive medications have been studied for use in ADHD, but these generally go beyond the scope of primary physicians.

KEY TREATMENT

- The stimulants are the medications of first choice for ADHD at any age (Dobie, 2012) (SOR: A).
- Although not a first-line drug, atomoxetine is effective for treatment of ADHD (Hammerness et al., 2009) (SOR: A).
- Behavioral treatments for children with ADHD are effective adjuncts to pharmacologic therapy (Fabiano et al., 2009) (SOR: A).

Oppositional Defiant Disorder

Key Points

- The provider must establish a therapeutic alliance with both the child and the family to be successful in treating ODD.
- The diagnosis of ODD is based on reports from the parents and child; the possibility of comorbid conditions should be carefully considered.
- The best treatment of ODD usually is parent training in behavior management techniques.
- Medication may be helpful in treating the symptoms of comorbid conditions.

The prevalence of ODD in children younger than 18 years old is 1% to 11% (APA, 2013). Before puberty, rates in boys outnumber girls, but after puberty, the rates are more equal. ODD is a chronic persistent disorder marked by a pattern of angry or irritable mood, argumentative or defiant behavior, or vindictiveness with interaction patterns occurring with at least one individual other than a sibling (APA, 2013). The severity of the disorder depends on the pervasiveness of behaviors. Often, children and adolescents with ODD do not behave in an overtly defiant manner with teachers or strangers but exhibit marked behavioral difficulty in the home setting. Characteristics of headstrong and irritable behavior at age 13 years are correlated with increased callousness, depression, and delinquency in later adolescence and early adulthood (Whelan et al., 2013).

The characteristics predisposing to ODD are biologic, social, and psychological, involving the parents and child. The parents usually use poor, ineffective, inconsistent, and indiscriminate behavioral management methods, which are often combined with unusually harsh but inconsistent discipline and poor monitoring of activities. These children are usually temperamental, impulsive, active, and inattentive. The parents themselves are frequently immature, temperamental, and impulsive. The family members usually experience significant marital, financial, health, and personal distress (Barkley, 1997). Physiologic markers may include decreased skin conductance reactivity and lower resting heart rate, as well as reduced basal cortisol reactivity, although these may be more generalized to other disruptive behavior disorders (APA, 2013).

ASSESSMENT

There are two periods of developmentally normal oppositional behavior: the “terrible twos,” between 18 and 24 months of age, when toddlers behave negatively as an expression of developing autonomy, and sometimes in adolescence, when teenagers try to separate from their parents and establish autonomous identities. Unlike ODD, these stages usually last less than 6 months (Table 23-5).

A child with ODD reported by the parents may not show much oppositional behavior while being examined in the office. The symptoms of ODD that these children display are much more evident in interactions with people and situations that they know well. The child takes a self-defeating

Table 23-5 DSM-5 Diagnostic Criteria for Oppositional Defiant Disorder

- A. A pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness lasting at least 6 months with at least four of the following symptoms:
- Angry/Irritable Mood
1. Often loses temper
 2. Is often touchy or easily annoyed
 3. Is often angry and resentful
- Argumentative/Defiant Behavior
4. Often argues with authority figures or, for children and adolescents, with adults
 5. Often actively defies or refuses to comply with requests from authority figures or with rules
 6. Often deliberately annoys others
 7. Often blames others for his or her mistakes or misbehavior
- Vindictiveness
- Has been spiteful or vindictive at least twice within the past 6 months
- B. The disturbance in behavior is associated with distress for the individual or caregivers or negatively impacts social, educational, occupational, or other important areas of functioning.
- C. The behaviors do not occur exclusively during the course of a psychotic, substance use, depressive, or bipolar episode. Criteria are not met for Disruptive Mood Dysregulation Disorder.
- Severity:
- Mild: Symptoms confined to one setting
- Moderate: Some symptoms are present in at least two settings
- Severe: Some symptoms are present in three or more settings

Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Publishers; 2013.

position in arguments with adults. The struggle becomes more important than the reality of the situation, such that the child may be willing to risk losing the object or activity rather than lose the argument. Even a significant delay by the child in complying with a parental request is seen as a victory by the child. The assessment of ODD should include direct information from the child and parents regarding symptoms, age of onset, duration, and degree of functional impairment.

If oppositional behavior is confined mostly to school and not much at home (except as it relates to schoolwork), additional diagnoses must be considered in the differential, including mental retardation; borderline intellectual functioning; a specific developmental disorder (e.g., learning disability); and, most often, ADHD. No specific laboratory tests or pathologic findings can assist the clinician in making the diagnosis of ODD.

MANAGEMENT

With methodologically sound RCTs lacking and recommendations based on clinical consensus, the appropriate psychosocial interventions for ODD include parenting training in behavior management techniques, including an improved parent-child relationship, positive reinforcement, closer supervision, giving more effective commands, time-outs, and token economies. When implemented before age 6 years, there is a 50% to 67% response rate to structured behavioral interventions (Barkley, 1997). Despite the usually chaotic family situation and high emotions involved, the family physician needs to establish a therapeutic alliance with both the child and the family to have the best

chance of success (Steiner and Remsing, 2007). Interventions should be family based, targeted to specific concerns, and oriented to problem solving. Traditional individual psychotherapy, unstructured or nondirected family therapy, or short-term treatment is usually not helpful. Psychoactive medications are used to treat comorbid conditions and targeted symptoms but have not demonstrated benefit for ODD alone. Intense and prolonged treatment may be necessary for severe and persistent ODD. One-time crisis interventions (e.g., “scared straight” attempts) are not effective.

Conduct Disorder

Key Points

- A poorer prognosis for CD is associated with an earlier age at onset, lower IQ, more conduct symptoms, and greater frequency and severity of symptoms.
- Alcohol and drug use should be suspected in a teenager with CD.
- Talking to the adolescent who has CD is not sufficient; collateral sources of information (parents, teachers, courts) are essential.
- Physicians should diligently search for another, more treatable condition if it exists because CD does not have an effective treatment.
- Involvement by the juvenile court or placement outside the home may be the best option for some patients.

Conduct disorder is seen in approximately 4% of children younger than 18 years of age (APA, 2013). At all ages, rates in boys outnumber girls. Whereas boys usually exhibit more aggression, girls usually commit more covert crimes and prostitution. CD is more common in urban than rural settings and is one of the most frequent diagnoses in outpatient and inpatient psychiatric facilities for children. The mortality rate for seriously disturbed delinquents is elevated relative to non-conduct disordered youth, and misconduct in childhood may predispose individuals to poor lifestyle choices and chronic health conditions well into adulthood (von Stumm et al., 2011). Adolescents with CD are more likely to die by homicide, suicide, violent accident, or drug overdose and are more likely to engage in substance abuse behaviors and injuries inflicting persistent effects on health.

Generally, the natural history of children with severe CD is marked by the development of ADHD at a very early age followed by ODD and then finally the onset of CD. In adolescence, alcohol and substance abuse occur. The factors that determine a poorer prognosis in a patient with CD are an early age of onset of symptoms, greater number of symptoms, and greater frequency of expression of these CD symptoms. The factors that determine a better prognosis are a minimum number of CD symptoms, absence of comorbid psychiatric diagnoses, and normal intellectual functioning. Characteristics more common in childhood-onset versus adolescent-onset CD are greater frequency of neuropsychiatric disorders, lower IQ, higher levels of aggression, male gender, and greater frequency of externalizing behavior disorders in other family members. Just more

than half of individuals with childhood-onset CD, versus only 15% of those with adolescent-onset CD, go on to develop *antisocial personality disorder*, a chronic pattern of lawlessness (Burt et al., 2007).

Current views posit an interaction among genetic, biologic, and environmental factors (i.e., parental, sociocultural, psychological, prolonged abuse). No single factor accounts for more than 50% of the variance in the occurrence of CD, and no combination of factors accounts for more than 70% of the variance. Many children with risk factors do not develop CD.

ASSESSMENT

The diagnostic criteria for CD are summarized in Table 23-6. The clinician should not quickly accept the diagnosis of CD in a youth because no specific effective treatment exists and instead should diligently search for other, more treatable psychiatric conditions. Other psychiatric diagnoses that should be considered as the primary disturbance in a child presenting with CD symptoms include ADHD, ODD, intermittent explosive disorder, psychoactive substance use disorder, mood disorders (bipolar and depressive disorders), posttraumatic stress disorder (PTSD), dissociative disorder, borderline personality disorder, and adjustment disorder with disturbance of conduct. A manic episode must be seriously considered in a teenager presenting with frequent lying, physical aggression against others, impulsive sexual activity, stealing, sneaking out in the middle of the night, grandiosity, and persistent pervasive irritability.

The interview of an adolescent with CD is not sufficient, in itself, for the psychiatric evaluation. Lying is a common problem for these teenagers, as is conscious and unconscious underreporting of their problem behaviors. Other sources of information, including parents, teachers, other professionals, past records, and court personnel, are essential to obtain a valid evaluation. Complications seen in association with CD symptoms include impairment in school performance, poor social and family relationships, problems with the legal system, poor work performance, physical injuries from fighting or carelessness, sexually transmitted diseases, teenage pregnancy, drug problems, suicide, and homicide. Common examples of interpersonal impairment in these children include suspiciousness or paranoia, misperception of others' actions as hostile, difficulty relating to peers and adults, lack of guilt, and lack of empathy.

Children with CD respond differently to punishment than normal children. Whereas the frequency of negative behavior of normal children decreases when they are punished, the negative behavior of children with CD increases when they are punished.

No specific laboratory tests can assist in making the diagnosis of CD. However, the differential diagnosis for CD symptoms includes conditions for which tests may be important. These include head trauma, seizure disorder, birth injury to the brain, and encephalitis.

MANAGEMENT

One-time interventions affecting a single domain are ineffective in treating patients with CD. Interventions need to target all affected domains in a naturalistic setting for a long

Table 23-6 DSM-5 Diagnostic Criteria for Conduct Disorder

- A. A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least three of the following 15 criteria in the past 12 months, with at least one criterion present in the past 6 months.
- Aggression to People and Animals
1. Often bullies, threatens, or intimidates others
 2. Often initiates physical fights
 3. Has used a weapon that can cause serious physical harm to others (e.g., a bat, brick, broken bottle, knife, gun)
 4. Has been physically cruel to people
 5. Has been physically cruel to animals
 6. Has stolen while confronting a victim (e.g., mugging, purse snatching, extortion, armed robbery)
 7. Has forced someone into sexual activity
- Destruction of Property
1. Has deliberately engaged in fire setting with the intention of causing serious damage
 2. Has deliberately destroyed others' property (other than by fire setting)
- Deceitfulness or Theft
1. Has broken into someone else's house, building, or car
 2. Often lies to obtain goods or favors or to avoid obligations (i.e., "cons" others)
 3. Has stolen items of nontrivial value without confronting a victim (e.g., shoplifting, but without breaking and entering; forgery)
- Serious Violations of Rules
1. Often stays out at night despite parental prohibitions, beginning before age 13 years
 2. Has run away from home overnight at least twice while living in the parental or parental surrogate home, or once without returning for a lengthy period
 3. Is often truant from school, beginning before age 13 years
- B. The disturbance in behavior causes clinically significant impairment in social, academic, or occupational functioning.
- C. If the individual is age 18 years or older, criteria are not met for antisocial personality disorder.
- Specifiers:
- Childhood-onset type: Individuals show at least one symptom characteristic of conduct disorder prior to age 10 years.
- Adolescent-onset type: Individuals show no symptom characteristic of conduct disorder prior to age 10 years.
- Unspecified onset: Criteria for a diagnosis of conduct disorder are met, but there is not enough information available to determine whether the onset of the first symptom was before or after age 10 years.
- With limited prosocial emotions: The individual displays at least two of the following over at least 12 months and in multiple relationships and settings:
- Lack of remorse or guilt
 - Callous—lack of empathy
 - Unconcerned about performance
 - Shallow or deficient affect

Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Publishers; 2013.

period in a consistent manner. Multisystemic family interventions (parenting training and guidance, functional family therapy) and social skill training with a behavioral approach seem to be the most effective treatments for patients with CD (von Sydow et al., 2013). Individual therapy that focuses on problem-solving skills and empathy training can also be useful. An environment with consistent rules and consequences is helpful. Proper school placement using behavioral techniques to encourage prosocial behavior and discourage antisocial incidents is appropriate.

Factors that can cause a treatment program to fail include the following: the situation is “too hot to handle,” the youth is “too brittle,” the parents covertly support the youth’s behavior, the parents have given up on the youth, the parents are inconsistent and are unable to supervise adequately, the program is poorly designed, rewards are too costly, or the parents have little social support. Factors that can interfere with limit setting of the child or adolescent at home include parental conflict, parental absence, parental psychiatric illness, inconsistent discipline, and vague or minimal expectations regarding appropriate behavior.

Several legal options are available if parents are unable to control their children. Most state laws have a special status that can be petitioned by the county district attorney to the juvenile court judge (i.e., child or person in need of care laws) that can allow the court to supervise the child by having hearings, placing a child on probation, mandating treatment and monitoring, or eventually taking the child away from the parents and placing the child in a residential treatment facility. However, some dangers must be kept in mind when teenagers with CD are confined to a juvenile detention facility. These patients prefer to be unrestricted and active; they can become depressed and at risk for impulsively attempting suicide when placed in confinement. Inpatient psychiatric hospitalization can be used to assess and initiate treatment for comorbid psychiatric disorders. A homicidal or suicidal patient can be stabilized and then moved to a less restrictive long-term setting. However, the stay is usually too brief to effectively treat CD itself.

Medications used as the sole treatment for CD have not been demonstrated to be effective. Psychoactive medications are used for the treatment of concurrent psychiatric disorders and concurrent target symptoms (aggression, impulsiveness, mood instability). Some of these medications are lithium, antidepressants, carbamazepine, propranolol, stimulants, clonidine, and antipsychotics (usually haloperidol). The physician should be cautious when prescribing medication to a youth with CD. Medication can be “cheeked,” sold or traded, hoarded, and taken all at once in an impulsive suicide attempt.

Eating and Feeding Disorders

Key Points

- When considering a diagnosis of feeding disorder, consultation with a physician familiar with growth problems in children may be necessary because of the extensive differential diagnosis.
- The long-term mortality rate for individuals with anorexia nervosa is 6% to 20%, the highest rate for any psychiatric disorder.
- The most useful measure to assess for extreme weight loss in adolescents is age-adjusted body mass index (BMI) less than the fifth percentile.
- For anorexia nervosa, vomiting is a poor prognostic feature, as is purgative use for bulimia nervosa.
- Patients with eating disorders should be managed by a multidisciplinary team that includes a primary physician, mental health professional, and nutritionist.

Good nutrition is vital to good health, so feeding problems and eating disorders have important consequences for multiple organ systems and child development. The most serious eating disorders, anorexia nervosa and bulimia nervosa, typically have their onset in adolescence, but a variety of eating problems are common in infants and children. These include several disorders that were classified under “disorders usually diagnosed in infancy, childhood, or adolescence” in the DSM-IV and have been reclassified to “feeding and eating disorders” in the DSM-5 in recognition that they can develop at any time in life.

FEEDING AND EATING DISORDERS OF INFANCY AND EARLY CHILDHOOD

Most feeding difficulties in infants and young children are minor and self-limited and can be addressed through education and reassurance of caregivers. However, physicians must be alert for specific feeding and eating disorders that can lead to malnutrition or chronic toxicity from ingested substances. “Avoidant/restrictive food intake disorder” (ARFID) is the new term used in DSM-5 that replaces former terms of “feeding disorder of infancy or early childhood,” “psychosocial failure to thrive,” and “psychosocial dwarfism.” To warrant this diagnosis, the child must show evidence of inability to take adequate calories or nutrition through their diet beyond what can be explained by a concurrent medical condition or another mental disorder. Of children admitted to the hospital for failure to thrive, as many as half have a psychosocial etiology. Because the differential diagnosis for ARFID is complex, the nutritional consequences serious, and the social implications of potential abuse or neglect are challenging, early consultation with an experienced team is advised.

The other important consideration in young children is *pica*, the persistent eating of nonnutritive substances, such as hair, soil, paint, animal droppings, or sand. Pica can result in vitamin deficiencies, lead or other heavy metal intoxication, phytobezoars, and other complications. The prevalence of pica is not certain, but it is probably fairly common in preschool children, especially those with mental impairment. Pica can be differentiated from developmentally normal oral exploration when it occurs after approximately 24 months of age. Persistent or obsessive chewing (e.g., fingernails, clothing, straws) *without* ingestion should also be distinguished from pica. The important aspect to assessment of pica is to *ask*. Evaluation and treatment then depend on the specific substance ingested and symptoms the child exhibits, if any.

The most important aspect in assessing feeding difficulties in infants and children is tracking height and weight with each office visit. Children who are not maintaining expected gains should be observed more closely and evaluated for psychosocial causes in addition to medical conditions.

ANOREXIA NERVOSA AND BULIMIA NERVOSA

In adolescent girls, eating disorders are the third leading chronic illness, after obesity and asthma. The number of young people diagnosed with eating disorders (anorexia nervosa or bulimia nervosa) and eating disturbances (some

but not all criteria for diagnosis of a “disorder”) is increasing, the result of a combination of improved recognition and reporting as well as an apparent true increased incidence. About 95% of cases are girls or women, and the prevalence of eating disorders has been directly correlated to the rates of dieting behavior. High-risk groups include female athletes and patients with diabetes. Some patients with eating disorders find a social network online that encourages maladaptive eating behaviors. Parents and physicians should be wary of online activity related to “Ana” (anorexia) and “Mia” (bulimia) characters because these are often used to conceal discussions about dangerous eating behavior. Frequent posting of nude or nearly nude photos to these websites is also a common practice among patients who wish to compare visible evidence of weight loss.

The three essential features of anorexia nervosa are (1) persistent energy intake restriction, (2) intense fear of gaining weight or of being fat or persistent behavior that interferes with weight gain, and (3) disturbance in self-perceived weight or shape (APA, 2013). Amenorrhea, although common, is no longer required for the diagnosis in DSM-5. The long-term mortality rate for those with anorexia nervosa is 6% to 20%, the highest rate for any psychiatric disorder (Roerig et al., 2002), often as an acute suicidal act rather than slow bodily destruction alone (Pompili et al., 2006). Bulimia nervosa is characterized by binge eating and inappropriate compensation attempts to avoid weight gain, such as self-induced vomiting, misuse of laxatives or diuretics, fasting, or excessive exercise. The prevalence of bulimia nervosa is 1% to 1.5% in adolescent and young adult women, more common but less often fatal than anorexia nervosa (APA, 2013). The DSM-5 also recognizes “binge-eating disorder,” typically in obese individuals who meet the binge eating criteria for bulimia but without the subsequent purging behaviors.

Assessment

A prime objective in assessment is to distinguish “normal dieters” from individuals with eating disorders. In addition to the characteristics outlined in Table 23-7, patients with eating disorders have a pathologic reaction to weight gain. To explore this possibility, a useful question to ask is, “What would it be like to find you weighed 1 lb more next week when you get on the scale?” This may provoke an overly emotional response in a person with an eating disorder (Selzer et al., 1995).

Another important aspect to evaluation is to exclude certain medical conditions in the differential diagnosis as the primary cause of the symptoms. This includes such diverse problems as inflammatory bowel disease, hyperthyroidism, chronic infections, diabetes mellitus, and Addison’s disease. The erythrocyte sedimentation rate (ESR) and serum albumin tend to remain normal in patients with eating disorders, so an elevated ESR or a reduced albumin suggest an organic cause for weight loss (Selzer et al., 1995).

It is important to assess the acuteness and severity of malnutrition or fluid and electrolyte abnormalities. Indications for immediate referral include any patient with abnormal findings on physical examination or laboratory studies because these indicate severe and entrenched eating disorders. Laboratory studies should include a complete blood count, electrolytes, magnesium, calcium, phosphorus, urea nitrogen, creatinine, glucose, albumin, and electrocardiography (Walsh et al., 2000).

The diagnosis of anorexia nervosa no longer requires specific evidence of “extreme weight loss” but uses BMI percentile in children and adolescents to define severity from mild to extreme. For anorexia nervosa, the presence of vomiting is a poor prognostic feature, as is the use of purgatives for bulimia nervosa (Wilhelm and Clarke, 1998).

Management

Indications for inpatient management include “extremely low weight ($\leq 75\%$ of expected body weight) or rapid weight loss; severe electrolyte imbalances, cardiac disturbances, or other acute medical disorders; severe or intractable purging; psychosis or a high risk of suicide; and symptoms refractory to outpatient treatment” (Becker et al., 1999).

Patients with eating disorders should be managed by an experienced multidisciplinary team that includes a primary physician, mental health professional, and nutritionist. Family physicians should be aware of the resources available in their area and should be prepared to refer any adolescent suspected of an eating disorder or with abnormal eating behaviors who does not respond to initial efforts at diet education. A valuable resource for developing a treatment plan is a practice guideline published by the APA (Yager, 2006).

Various antidepressants are effective for treatment of bulimia nervosa but have not shown definite benefit for anorexia nervosa. Cognitive-behavioral therapy (CBT) has been shown to be the most effective psychological approach to bulimia nervosa (Berkman et al., 2006).

Table 23-7 Characteristics of Normal Dieting versus Eating Disorders

Feature	Normal Dieting	Eating Disorder
Communication with others	Dieters tell those around them that they are dieting, seeing it as “something to be proud of.”	Dieters are reluctant to discuss their diets even when it is obvious to those around them that they are restricting their intake.
Intake regulation	They use internal cues and the rules of their diet plan.	They often use external cues, such as eating less than the person at the table who eats the least, to avoid feeling selfish or gluttonous.
Behavior	When weight loss goal is achieved, they want to show off their “new body,” often in new and more revealing clothes or situations (e.g., new swimsuit, sunbathing).	They usually avoid exposing their bodies, often with baggy clothing, or regard their physical dimensions with disgust, no matter how much weight they lose.
Self-esteem	They exhibit a feeling of accomplishment and increased self-esteem when they achieve planned weight loss.	They tend to become self-critical, often depressed or irritable, and avoid social occasions.

KEY TREATMENT

- Primary prevention programs have greatly improved knowledge but with “small net effects on reducing maladaptive eating attitudes and behaviors.” Studies targeted at high-risk groups produced greater benefits. “Concerns about iatrogenic effects of including psychoeducational material on eating disorders were not supported by the data” (Fingeret et al., 2006) (SOR: A).
- Anorexia nervosa (AN): “The literature regarding medication treatments for AN is sparse and inconclusive. ... Cognitive behavioral therapy may reduce relapse risk for adults with AN after weight restoration. Family therapy focusing on parental control of renutrition is efficacious in treating AN in adolescents” (Berkman et al., 2006) (SOR: B).
- Bulimia nervosa (BN): “Fluoxetine (60 mg/day) reduced core bulimia symptoms in the short term. ... The optimal duration of treatment is unknown. Cognitive behavioral therapy is effective in both short and long term” (Berkman et al., 2006) (SOR: A).

Mood Disorders

Key Points

- Physicians should attempt to define a timeline of discrete mood “episodes” to distinguish them from stable behavior patterns (e.g., ODD, ADHD).
- Careful identification of manic symptoms distinguishes among disorders.
- Suicidal ideation and impulsive attempts are not specific to any one mood disorder.

Mood dysregulation in children and adolescents has been a controversial diagnostic issue, and one that has been addressed with changes in the DSM-5. Children can present with a range of mood symptoms, including sadness, irritability, elation, anger, and temper tantrums, which can be short-lived and developmentally appropriate or can signal more enduring and maladaptive patterns of coping. Children with other behavior disorders (e.g., ADHD, ODD) are at greater risk for mood disturbance; therefore, comorbid conditions must be carefully considered. In general, when children experience mood dysregulation of any kind, a referral to a psychotherapist and consideration of psychoactive medications may be warranted.

ASSESSMENT

Assessment of patients with mood disorders should include a careful history of symptom onset, triggering stressors or events, symptom duration, and pattern or consistency of symptoms. Determining whether the child has episodic or persistent symptoms can help differentiate among disorders by elucidating which symptoms are a change from baseline functioning (e.g., episodic psychomotor agitation concurrent with a manic episode versus hyperactivity related to ADHD). Parent, child, and teacher questionnaires

(e.g., Conners, Third Edition; *Behavior Assessment System for Children*, Second Edition; Achenbach Child Behavior Checklist) can provide standardized evaluation of a range of diagnostic dimensions correlating with DSM categories. Free tools such as the Centers for Epidemiological Studies Depression Scale for Children (CES-DC), Young Mania Rating Scale (YMRS), and Disruptive Behavior Checklist can also be useful tracking instruments; however, results should only be interpreted in the context of symptoms reported by the patient, parent, and other sources of information such as teachers.

MAJOR DEPRESSIVE DISORDER

Major depressive disorder (MDD) remains a significant risk for children and adolescents, with an 11% lifetime prevalence between 13 and 18 years of age (National Institutes of Mental Health, 2013). Diagnostic criteria have remained relatively stable in the DSM-5, including duration (at least 2 weeks) and symptom requirement (five of nine: sad or depressed mood, diminished interest or pleasure in enjoyed activities, significant weight fluctuation, sleep disturbance, psychomotor agitation or retardation, fatigue or low energy, feelings of worthlessness or guilt, inability to concentrate or make decisions, and recurrent thoughts of death). Specifiers now available include anxious distress, mixed (e.g., hypomanic) features, psychotic features, and seasonal pattern. Diagnostic criteria have also removed the bereavement exclusion, recognizing that grief is a triggering event for many major depressive episodes, even in children.

Management

Nearly all adolescents (>90%) recover fully from an initial depressive episode, although more than half experience recurrent episodes (Melvin et al., 2013). Fluoxetine became the first FDA-approved drug for treating childhood depression in 2003, and by 2005, the FDA required a black box warning on antidepressant drugs for children. A possible safety risk of increased suicidal ideation was identified, suggesting a need for increased monitoring and more careful follow-up with assessment of suicidal ideation, thoughts about death, and intent for self-harm. Despite these risks, SSRIs remain a first line of treatment for childhood and adolescent depression. Meta-analysis suggests that TCAs are not effective in treating childhood and adolescent depression (Hazell and Mirzaie, 2013). Either in combination with medication or alone, psychotherapy is also an efficacious depression treatment with evidence-based therapies, including CBT and interpersonal therapy, holding the strongest support (Curry, 2001). The combination of CBT and fluoxetine was found to be superior to either treatment alone in the Treatment for Adolescents with Depression Study (TADS; March et al., 2004).

BIPOLAR DISORDER

Pediatric BD is a controversial diagnosis with current estimates suggesting a 3% prevalence for bipolar spectrum disorders in children younger than 18 years of age ((NIMH, 2013). Diagnostic criteria for adult BD are questionable for diagnosing children with the disorder. It is generally agreed that the presence of mania or a hypomanic episode be

required for a diagnosis of pediatric BD. Proposed criteria for a “broad phenotype” (i.e., more lax diagnostic criteria) suggest that presence of four of eight DSM criteria be present, which *must* include (1) elation, (2) grandiosity, or (3) racing thoughts (Staton et al., 2008). Many clinicians do not require the episodic course criteria for diagnosis in pediatric populations because many children with a BD diagnosis are noted to “cycle” or switch moods several times within one day. The AACAP, however, recommends using the DSM criteria for purposes of clinical and research consistency, resulting in more stringent criteria for a “narrow phenotype” of the disorder. Given the frequent absence of episodic criteria (e.g., 4 days for a hypomanic episode and 7 days for a manic episode), children may meet the criteria for BD, not otherwise specified (Leibenluft and Rich, 2008).

Management

Medication with mood stabilizing agents such as lithium or anticonvulsants is often the first line of treatment of pediatric BD, although few RCTs exist to demonstrate efficacy (Leibenluft and Rich, 2008). Lithium has demonstrated effective suicide prevention in adult meta-analyses, although its effect in children and adolescents has not been well researched (Cipriani et al., 2013). Psychotherapeutic interventions should aim to (1) provide education about the disorder to children and families, (2) manage symptoms, (3) improve coping skills, (4) address social and family relationships, (5) improve academic and vocational functioning, and (6) address relapse prevention (AACAP, 2007; McClellan et al., 2007).

DISRUPTIVE MOOD DYSREGULATION DISORDER

Disruptive mood dysregulation disorder (DMDD) is a new disorder introduced in the DSM-5 consisting of a pattern of chronic, severe, persistent irritability with superimposed temper outbursts that are not developmentally appropriate. DMDD was conceptualized as an alternative explanation for behaviors that were often classified (or misclassified) as pediatric BD, with research instead suggesting that DMDD is more closely aligned with a unipolar mood disorder in adulthood (Copeland et al., 2013). These children exhibit temper tantrums three or more times per week for a period of at least 1 year. They must be at least 6 years old at the time of diagnosis and not older than 10 years at time of symptom onset. An initial community study examining the feasibility of DMDD diagnostic criteria suggested an overall prevalence between 1% and 3%; however, there was a high degree of symptom overlap with other psychiatric diagnoses, most notably ODD and depressive disorders (Copeland et al., 2013). Yet, current diagnostic criteria suggest that DMDD may not be diagnosed in the presence of ODD or BD. As a result of high rates of overlap in both community and clinical samples, the utility of the diagnosis as a separate entity has been called into question (Axelson et al., 2012).

Management

Given the status of DMDD as a new diagnosis, treatment studies are almost completely absent from the literature. Anecdotal evidence suggests symptom management as a primary target, combining treatment approaches for similar

disorders such as ODD, ADHD, depression, and BD. Parent training and behavior management can target many of the aggressive, explosive, and defiant behaviors accompanying DMDD. Patients with underlying depressive or irritable symptoms can be treated with antidepressant medications and psychotherapy. At the present time, the primary treatment approach appears to be mood stabilization with atypical antipsychotics or anticonvulsants in combination with improvement of impulsivity with stimulants or α -agonists. Controlled treatment trials will be forthcoming as clinicians and research centers begin using the diagnosis more frequently.

Child Abuse

ROBERT SHAPIRO, KAREN FARST, and CAROL L. CHERVENAK

CHAPTER OUTLINE

Implications and Long-Term Outcomes, 468
Neglect, 469

Physical Abuse, 471
Sexual Abuse, 473
Summary, 476

Our brains are sculpted by our early experiences. Maltreatment is a chisel that shapes a brain to contend with strife, but at the cost of deep, enduring wounds.

TEICHER, 2000.

A 6-month-old male infant is seen in his physician's office for decreased appetite and irritability. The physician notes that the infant's upper lip is swollen on the left and that there is a small bruise of the right temple. The physician accepts the offered explanation from the mother, that the infant had "slipped in the bathtub" the previous evening. One week later, the infant is dead from abusive head trauma (AHT). The father of the child admitted that he shook the baby and hit his face and head, resulting in his death.

"Child maltreatment is a deceptive and easily disguised entity" (Jenny et al., 1999), the diagnosis of which is very challenging. Many of these children are seen by health care providers in the weeks leading up to their deaths; often the injuries they present with are diagnosed as "accidental" (King et al., 2006). The early recognition of child abuse is critical to preventing further injury or death of a child. The risk of recurrence of abuse is approximately 50% (Alexander et al., 1990; McDonald, 2007), neglect being the type of maltreatment associated with the highest risk for future abuse (Hindley et al., 2006).

Child abuse and neglect are major causes of morbidity and mortality in the United States (U.S. Department of Health and Human Services [HHS], 2012).

- In 2011, the national estimate of child abuse and neglect victims determined by child protective services (CPS) was 681,000 (9.1 victims per 1000 children).
- A total of 79% were victims of neglect, 18% of physical abuse, and 9% of sexual abuse.
- More than 1500 children died from abuse and neglect in 2011.
- A total of 82% of all the fatalities were in children younger than 4 years old, and the majority (78%) were caused by one or more parents.
- Child abuse is the leading cause of injury-related deaths among infants and the second leading cause of injury deaths in older children (Jenny and Isaac, 2006).

- The total lifetime economic burden of child maltreatment in the United States is approximately \$124 billion (Fang et al., 2012).

As the family's health care provider, family medicine physicians are in an ideal position to detect, assess, diagnose, and intervene for children experiencing child abuse and neglect. When suspicions of child maltreatment arise, many physicians are uncomfortable confronting or blaming parents and possibly disrupting the family unit. Understanding the devastating effects of child maltreatment, becoming familiar with evidence-based indicators of abuse and neglect, and adopting strategies for assessment and management can help the physician have a positive, meaningful impact on the lives of children and families.

Physicians are required by law to report suspected or confirmed child abuse and neglect to CPS or law enforcement or both. Table 24-1 defines the different types of child abuse.

Implications and Long-Term Outcomes

The long-term impact of traumatic childhood stressors on health risk behaviors, disability, disease, and premature mortality has been extensively studied (Felitti et al., 1998). The Adverse Childhood Experiences (ACE) Study assessed more than 17,000 adult members of an HMO and collected histories of various forms of child maltreatment, exposure to domestic violence, parental substance abuse and mental illness, and parental loss. (A complete bibliography of ACE Study publications listed by topic area is available at <http://www.cdc.gov/ace>.) "Adverse childhood experiences" are common, highly interrelated, and strongly associated with multiple enduring health and social problems impacting adolescents and adults (Anda et al., 2006; Larkin et al., 2012), including ischemic heart disease, cancer, chronic lung disease, liver disease, multiple mental health diagnoses, and premature death.

Experiences during infancy and early childhood affect brain development and create the basis for the expression of intelligence, emotions, and personality (Butchart et al., 2006). Children who have suffered chronic abuse and neglect during the first few years may experience

Table 24-1 Definitions of Child Maltreatment

	Definition	Comments
Child maltreatment (Leeb et al., 2008)	Any act of commission or omission by a parent or other caregiver that results in harm, potential for harm, or threat of harm to a child; harm does not need to be intended	More than 80% of perpetrators were parents (Child Welfare Information Gateway, 2013)
Physical abuse	The intentional use of physical force against a child that results in or has the potential to result in physical injury Includes acts that do not leave a physical mark as well as those causing permanent disability, disfigurement, or death (Barnett et al., 1993)	Physical acts can include hitting, kicking, punching, beating, stabbing, biting, pushing, shoving, throwing, pulling, dragging, dropping, shaking, strangling or choking, smothering, burning, scalding, and poisoning
Sexual abuse	Any completed or attempted sexual act, sexual contact with, or exploitation (i.e., noncontact sexual interaction) of a child by a caregiver	Includes substitute caregivers (e.g. teachers, coaches, clergy, and relatives) Sexual acts: involve penetration, no matter how slight, between the mouth, penis, vulva, or anus of the child and another individual; also penetration of anal or genital opening by a hand, finger, or other object Sexual contact: includes intentional touching, either directly or through clothing, of the genitalia, anus, breast, or buttocks (excluding contact required for normal care) Noncontact sexual abuse: exposure to sexual activity, filming, or commercial sexual exploitation
Psychological (or emotional) abuse	Intentional behavior that conveys to a child that he or she is worthless, flawed, unloved, unwanted, endangered, or valued only in meeting another's needs (APSAC, 1995)	Continual or episodic (e.g., associated with caregiver substance abuse) May include blaming, belittling, degrading, intimidating, terrorizing, isolating, restraining, confining, corrupting, exploiting, spurning, or otherwise behaving in a manner that is harmful, potentially harmful, or insensitive to the child's developmental needs or that can potentially damage the child psychologically or emotionally
Neglect	Failure to meet a child's basic physical, emotional, medical or dental, or educational needs; failure to provide adequate nutrition, hygiene, or shelter; or failure to ensure a child's safety	Includes failure to provide adequate food, clothing, or accommodation; not seeking medical attention when needed; allowing a child to miss large amounts of school; and failure to protect a child from violence in the home or neighborhood or from avoidable hazards

APSAC, American Professional Society on the Abuse of Children.

Adapted from Gilbert R, Widom CS, Browne K, et al. Burden and consequences of child maltreatment in high-income countries. *Lancet*. 2009;373:68-81.

hyperarousal or dissociation, difficulty with attachment, limited capacity for empathy, and various mental health problems, including depression, posttraumatic stress disorder (PTSD), attention-deficit hyperactivity disorder, and sensory integration disorder (National Clearinghouse on Child Abuse and Neglect Information, 2001).

Neglect

Key Points

- Neglect is the most common form of child maltreatment.
- Child neglect has been associated with worse outcomes and the highest risk for future abuse compared with other forms of child maltreatment.
- There is a strong association of substance abuse with child maltreatment.
- Child maltreatment commonly occurs in homes with domestic violence.

Child neglect is common, complex, and insidious. Although difficult to clearly define and identify, neglect is the most common form of child maltreatment, accounting for 78%

of substantiated cases in 2011. Neglect has been associated with worse outcomes than other forms of child abuse over a range of cognitive, developmental, psychosocial, and physical parameters (American Professional Society on the Abuse of Children, 2008; Perez and Widom, 1994; Teicher, 2000).

Child neglect is often defined by child welfare agencies and in state law as an act of omission by a parent or caretaker, specifically the failure to provide for a child's basic physical, emotional, or educational needs or to protect a child from harm or potential harm (Table 24-2). Neglect includes isolated incidents as well as a pattern of failure over time by a parent or caretaker (Butchart et al., 2006).

A broader *child-centered* view of child neglect, however, describes neglect as occurring when a child's basic needs are not met; recognizing that multiple factors contribute, including individuals, families, communities, and society; and focusing interventions on multiple levels (DePanfilis, 2006; Dubowitz, 2009) (Table 24-3).

The approach toward neglect management is varied and depends on the identified causes of the neglect as well as an assessment of urgency. The goal of management is to assist the family in providing a safe and healthy environment for their children. A review of these management principles and steps can be found in the article by Dubowitz (2013).

Table 24-2 Types of Neglect

Types of Neglect	Definition	Comments
Failure to Provide		
Physical neglect	Caregiver fails to provide adequate nutrition, hygiene, or shelter; fails to provide clothing that is adequately clean, of appropriate size, or adequate for the weather; includes abandonment or expulsion from the home	Inadequate food may present as failure to thrive or repeated hunger Inappropriate food or poor nutrition may present as obesity Other examples: Child may be dirty or smell bad; living arrangements unstable for 2 weeks or more; home may be infested with insects or vermin; animal feces on floor and bedding; unsafe, dirty sleep environment
Emotional neglect	Caregiver ignores the child or denies emotional responsiveness or adequate access to mental health care	Includes constantly belittling the child, withholding affection; exposing the child to domestic violence; allowing the child to use drugs or alcohol
Medical or dental neglect	Failure to provide appropriate health care for a child (although financially able to do so), thus placing the child at risk of being seriously disabled or disfigured or dying	Includes nonadherence with health care recommendations; delay or failure in getting health care Religious beliefs: the AAP strongly opposes these exemptions for medical care
Educational neglect	Failure to provide access to adequate education	Includes chronic truancy; failure to enroll a child in school, to provide adequate home schooling, or to attend to special education needs
Failure to Supervise		
Inadequate supervision	Failure to ensure that the child engages in safe activities and uses appropriate safety devices; to ensure that the child is not exposed to unnecessary hazards; or to ensure appropriate supervision by an adequate substitute caregiver	Includes lack of supervision appropriate for developmental needs (e.g., infant left unattended in bathtub; toddler left home alone) Inappropriate caregiver: knowingly leaving child in the care of a sexual offender Abandonment is an extreme form
Exposure to a violent environment	Caregiver fails to take available measures to protect the child from pervasive violence within the home, neighborhood, or community	Exposure of child to criminal activities (e.g., illicit drug trade, allowing bullying of child without intervention). Exposure to domestic violence is associated with psychological harm, increased risk of abuse, and neglect.
Inadequate protection from environmental hazards	Avoidable exposure to environmental hazards in and out of the home	Examples include toxic substances in reach of children; smoking in the presence of children with asthma; and access to loaded firearms
Drug-exposed newborns and older children	In utero exposure to substance abuse; direct and indirect (e.g., ingestion, passive inhalation) exposure of older children	Includes exposure of children to illicit manufacturing of drugs, drug trafficking, parental alcohol and substance abuse, and prescription narcotic abuse or misuse

AAP, American Academy of Pediatrics.

DRUG-EXPOSED NEWBORNS AND OLDER CHILDREN

A strong association of substance abuse with child maltreatment has been well documented (Wells, 2009). Children in homes with adults who abused drugs and alcohol were found to have a nearly threefold increased risk for child abuse and fourfold risk for neglect (U.S. Department of HHS, 1998).

Prenatal substance exposure increases the vulnerability of the infant to poor caretaking, partly because of the cognitive and behavioral effects on the newborn (Zuckerman and Bresnahan, 1991). Additionally, studies have shown that children exposed prenatally to illicit substances have two to three times increased risk for abuse and neglect compared with children in the same socioeconomic class and neighborhood (Jaudes et al., 1995).

Drug-endangered children have a markedly increased exposure to interpersonal violence, traumatic events, child maltreatment, toxic chemicals in their immediate environment, and significantly higher rates of PTSD compared with other children (Sprang et al., 2008). Passive inhalation, accidental ingestion, and exposure of drugs and

alcohol through breast milk or intentional administration are all risk factors for children in homes with substance abuse.

DOMESTIC VIOLENCE AND CHILDREN

Assaultive, aggressive, coercive, or threatening behavior within the home between intimate partners victimizes not only the adult target of the violence but the child witnesses as well, whether the violence is seen or overheard. Co-occurrence rates of domestic violence and child maltreatment have been found to be between 30% and 60% (Appel and Holden, 1998; Edleson, 1999). A study of at-risk parents with firstborn children revealed that domestic violence during the first 6 months of child rearing more than tripled the likelihood of physical abuse and more than doubled the likelihood of psychological abuse and neglect occurring during the child's first 5 years of life (McGuigan and Pratt, 2001). Children exposed to domestic violence are at risk for difficulties with behavioral, emotional, and cognitive functioning, as well as dysfunctional attitudes about violence and conflict resolution (Edleson, 1999).

Table 24-3 Risk Factors for Child Maltreatment

Individual factors	Child Characteristics	Caregiver or Parent Characteristics
	Low birth weight Prematurity Chronic disability or illness Genetic abnormalities Personality or temperament perceived by parents as difficult (e.g., infant cries persistently, not easily soothed; child hyperactive, impulsive, aggressive) Child with symptoms of mental ill health	Substance abuse Mental health problems, especially depression Cognitive delay Impulsive, poor judgment Lack of nurturing or empathy toward child Involved in criminal activity Unrealistic expectations of child Poor parenting skills
Family characteristics and relationship factors	Parent-child relationship adversarial or lacks attachment Domestic violence Social isolation Criminal involvement Chaotic lifestyle (e.g., frequent moves, unstable housing) High levels of stress (e.g., poverty, unemployment)	
Community factors	Tolerance of violence Inadequate housing Poverty Few resources or support services Poor access to health care Easy availability to alcohol; illicit drug trade	
Societal factors	Poverty Limited access to health care Poor access to mental health care for adults or children Inadequate educational system Social and cultural norms that promote violence; support rigid gender roles; diminish the status of the child Conditions that enable commercial sexual exploitation of children

Predictors of neglect within low-SES families: the importance of substance abuse. *Am J Orthopsychiatry*. 2002;72(3)383-391.

Physical Abuse

Key Points

- Children from all socioeconomic groups may become victims of physical child abuse.
- Child abuse should be considered in all preambulatory children with injuries.
- Dating of bruises is often an inexact practice in the absence of history.
- A skeletal survey can provide key information regarding the likelihood of child abuse in children younger than the age of 3 years.

Recognizing physical abuse can be lifesaving and will prevent further trauma to the child. Recognizing children at risk before abuse has occurred offers an opportunity to prevent child abuse through early intervention. The family physician can support parents by helping them become more effective at parenting, advocating for their basic living needs such as food and shelter, and encouraging quality childcare.

PRESENTATIONS OF PHYSICAL ABUSE

Bruises

The most common presentation of child physical abuse is bruising. Although accidental bruising is common in ambulatory children, it is rare in the nonambulatory infant and when found should trigger an evaluation for

nonaccidental injury. Bruising in the ambulatory child is suspicious for abuse if the history does not explain the location, number, or pattern of bruising; if the history is developmentally inconsistent with the child's abilities; or if the bruising patterns or locations indicate that abusive trauma is likely. Bruising found over the trunk, abdomen, cheeks, ears, and buttocks are all concerning for abusive injury, although this list is not exclusive. Patterns of injury caused by belts, cords, hands, and paddles must be recognized. Dating of bruises is very inaccurate because of the tremendous variability in healing, from 1 day to many weeks. Bruises that are raised, tender, and abraded are likely recent, but color change within the bruise is an inaccurate method of dating. Bites are a common abusive injury in children, and recognition requires a high index of suspicion. Look for impressions of individual teeth and upper and lower arch-shaped trauma. The most common bruise mimics include coagulopathies (e.g., von Willebrand disease, vitamin K deficiency, leukemia, and hemophilia); Mongolian spots; traditional therapies such as cupping, coining, and moxibustion; Henoch-Schönlein purpura; idiopathic thrombocytopenic purpura; and accidental bruising.

Fractures

Fractures are a strong indicator of current or past child abuse. Abusive fractures are most often identified through the skeletal survey or those with fractures for which there is no satisfactory explanation. Similar to bruises, fractures in nonambulatory children are always concerning for abuse. Multiple occult fractures, fractures demonstrating different ages of healing, rib fractures, classic metaphyseal lesions (CMLs or corner fractures), and vertebral compression

fractures are most often associated with child abuse. Abusive fractures can involve any bone. The clinical signs of fracture may be absent when abuse has occurred because of a delay or absence in seeking care. In addition, the history of trauma may be withheld and a history of pain or disability not disclosed. Rarely is there bruising over the site of fracture after accidental or abusive injury. It is possible to determine if a fracture is recent or healing based on the clinical presentation and radiographic appearance, but exact dating is difficult. Signs of radiographic callous are expected to first appear at about 10 days after the fracture, although the appearance may be a few days earlier in very young infants. Lack of immobilization after fracture may result in an exaggerated callus response. Skull and vertebral fractures heal without callus formation. Remodeling may take up to 2 years to complete. The most common fracture mimics include accidental fracture, bone fragility, osteopenia, birth trauma, Menkes syndrome, neoplasms, infection, rickets, and normal radiographic variants.

Burns

Hot water burns are most often diagnosed in abusive burns, but cigarette burns, burns from irons, and lighters are also frequently seen. Hot water scalding is often associated with toileting accidents and punishment. The pattern of scald burns, coupled with a detailed history of the incident from which the burn occurred, is usually required to differentiate abusive from accidental burns. The depth of burn depends on the temperature of the water or object, the length of contact time, and the degree of skin thickness. Young children sustain deeper burns than adults; areas of thick skin such as the palms and soles may demonstrate more superficial burning. As the burn evolves over a few days, the burn pattern and depth may change, which should be considered when differentiating accidental from inflicted burns. The most common burn mimics include diaper rash, accidental burn, impetigo, and varicella.

Abusive Head Trauma

Abusive head trauma can result in serious mortality and morbidity. Terminology for AHT includes shaken baby syndrome, shaken impact syndrome, inflicted head injury, and nonaccidental head injury. Severe shaking is often involved in AHT, but even when there is no sign of contact injury to the scalp or skull, impact cannot be excluded. Victims of AHT are most often younger than 1 year old, and a history of crying is often identified as an important reason for the escalation to shaking. AHT can occur in any socioeconomic group, although it is seen more often when the social risks factors for abuse are present (see earlier discussion). The most common anatomic injury is subdural hemorrhage (SDH), although skull fractures, subarachnoid hemorrhage, and intraparenchymal injuries are also seen. The most common locations for SDH are frontoparietal and interhemispheric. Dating of SDH is difficult and should only be estimated. A mixed-density subdural density does not necessarily indicate two separate injuries because acute bleeding frequency causes this radiographic picture. Surgical intervention is not commonly required. In addition to other physical indications of child abuse, retinal hemorrhages are seen in about 85% of AHT cases. Retinal hemorrhages are also caused by birth trauma, hypertension,

vasculitis, and increased intracranial pressure. Symptoms of AHT include altered mental status, difficulty breathing or apnea, seizures, vomiting, and irritability. The clinical presentation is varied and includes mild vomiting or irritability on one end of the spectrum to cardiac arrest on the other. A history to explain the child's abusive intracranial injury is typically absent or minor, such as a fall from a couch or bed. Some reports include "rescue trauma" in which the child is shaken in response to choking or a seizure. The most common perpetrators of AHT are the child's father or the mother's boyfriend. Outcomes are typically poor and include death, significant developmental delay, seizures, or vision and hearing impairment. Some children, however, have a relatively good outcome after AHT. The most common head injury mimics include accidental injury, birth trauma, vascular malformations, and glutaric aciduria type I.

DIAGNOSIS AND EVALUATION OF SUSPECTED CHILD PHYSICAL ABUSE

A careful history and physical examination direct the assessment and often determine whether child physical abuse should be considered. When abuse is suspected, a *skeletal survey* should be obtained in all children younger than 2 years old (Duffy et al., 2011). Recent studies suggest that the age for skeletal survey should be extended to age 3 years. The skeletal survey includes 19 images of the entire skeleton (Table 24-4). A "babygram" is not sufficient for evaluation (Figure 24-1). After the evaluation is completed, if abuse is confirmed or still suspected, a follow-up skeletal survey should be obtained in 2 weeks (Harper et al., 2013). The follow-up survey often identifies fractures not recognized on the initial survey or clarifies questionable findings. Children younger than 6 months of age should have intracranial imaging even when neurologic symptoms are absent. A *head computed tomography (CT) scan* is typically most readily available, but in the asymptomatic child, brain magnetic resonance imaging is an acceptable alternative. In children for whom a diagnosis of AHT is being considered, a *dilated retinal examination* should be completed using indirect ophthalmoscopy. Retinal photography should be obtained whenever possible to document findings. The location, depth, and number of any retinal hemorrhages should be recorded. *Photographs* of any cutaneous findings should be obtained along with documentation showing the locations and measurement of injuries. When bruising or

Figure 24-1 Babygram. This should never be obtained to substitute for a full skeletal survey (see [Table 24-4](#)).

bleeding is present, serum should be obtained to *rule out a coagulopathy*. In addition, abdominal trauma is often occult in children, and an *abdominal CT* should be obtained whenever abdominal bruising is present or *liver function test* results are elevated ([Lindberg et al., 2013](#)). When bites are present, *swabs for DNA analysis* should be collected from the center of the bite mark. Siblings and household contacts of abused children should be evaluated for abuse ([Lindberg et al., 2012](#)).

Sexual Abuse

Key Points

- The majority of children and adolescents who have been sexually abused have no findings of physical trauma on examination.
- The medical evaluation for suspected child sexual abuse (CSA) should occur urgently if there was sexual contact in the past 72 to 96 hours that might have left biologic material such as semen or blood or the child is having symptoms of injury or infection.
- In most cases, the person responsible for sexually abusing a child is known to the child and family. Delays in disclosure of CSA are common because of manipulation, coercion, deception, and threats by the abuser.

The prevalence of CSA in the United States may be as high as 7.5% in boys and 25% in girls ([Pereda et al., 2009](#)). The term *child sexual abuse* is often used to describe acts in which a child is used for sexual stimulation by an adolescent or adult and includes exposure to pornography, sexual fondling, or penetration. *Sexual assault* is a term usually reserved for acute cases in which the offender is not a caretaker of the victim. *Rape* refers to either an acute or past act(s) in which there was oral, vaginal, or anal penetration (whether the victim is a child, adolescent, or adult).

There are several important differences between CSA and adolescent or adult sexual assault, but overlap does occur. Knowledge of these differences is helpful to understanding why the disclosure of CSA is often delayed and why there are typically no physical examination findings in cases of CSA. CSA typically involves a period of “grooming” when the offender builds trust with the child by spending time with the child, providing gifts, and making the child feel special. This grooming then progresses to sexual contact. Because the child trusts the perpetrator, the sexual contact may be permitted without any physical or emotional violence. However, as the sexual advances continue, coercion, manipulation, and threats of harm to the child or the child’s family may occur ([U.S. Department of HHS, 2006](#)). Disclosure of the abuse by the child victim is frequently delayed because of intimidation or guilt. Furthermore, when children do finally disclose it, their disclosure is frequently not believed. This is particularly true when a child is abused by a relative or other adult with a respected community position. Children who are abused by a relative, compared with children abused by strangers or acquaintances, are more likely to blame themselves for the abuse ([Ullman, 2007](#)) and may have more significant psychological distress. Almost one third of CSA victims reach adulthood without disclosing it, and almost half delay their disclosure for more than 5 years ([Smith et al., 2000](#)).

CLINICAL EVALUATION OF SEXUAL ABUSE

History

Best practice in the evaluation of alleged or suspected CSA involves a multidisciplinary (MDT) response that includes the local child protection agency, law enforcement, and medical team operating collaboratively. This team approach minimizes the child’s psychological trauma from the time of disclosure through prosecution and therapy. Children’s Advocacy Centers (CACs) are community-based MDT entities that work to promote a coordinated, trauma-focused approach to child abuse ([National Children’s Alliance, 2014](#)). CAC protocols minimize the number of times a child will be interviewed about his or her abuse, use forensic interview techniques to increase the validation of a child’s disclosure, and may video record the interview for future investigative uses. The CAC MDT model has been shown to result in more effective investigations, increased satisfaction by the caregiver and child, and higher referral rates for victim medical and mental health services ([Farst, 2013](#)).

The specific history regarding CSA includes the type of contact (what body parts contacted by what object or body part); under or over clothing; history of ejaculation, licking, or kissing; where the abuse occurred; the time since last contact; the identity of the alleged perpetrator(s); and the

relationship to the victim. In older children, the last menstrual period and any history of consensual intercourse should be asked. The history should include an assessment for changes such as diet, sleeping, school performance, bowel or bladder symptoms, and behavioral changes. Although physical injury is uncommon in evaluations for sexual abuse, behavioral changes are common after the trauma of CSA. The child should be asked open-ended, non-leading questions during the interview, such as: “Tell me how that felt to you” rather than “Did it hurt?” Documentation of the interview should be precise. In CACs, the interview is often audio or video recorded. If recording is not possible, the documentation should include the exact questions asked as well as the child’s responses.

Examination

The medical examination should occur emergently if there was sexual contact in the past 72 to 96 hours that might have left semen, saliva, blood, or other biologic material on the child or child’s clothing. In this situation, the examination must include collection of forensic evidence specimens while maintaining the chain of custody, and most typically is completed in the emergency department or a facility equipped for this procedure. Other factors that dictate the need for an emergent or urgent evaluation include symptomatology or assessment of child safety (Table 24-5). Most disclosures present beyond this 72- to 96-hour time frame

Table 24-5 Timing of the Medical Evaluation for Suspected Child Sexual Abuse

Emergent (without delay)	<p>The alleged assault may have occurred within the previous 72-96 hr (or other state-mandated time interval), and the transfer of trace evidence may have occurred, which will be collected for later forensic analysis (i.e., a sexual assault evidence kit should be collected because of suspected transfer of semen, blood, saliva or other DNA material).</p> <p>The need for emergency contraception (morning-after pill)</p> <p>The need for postexposure prophylaxis for STIs, including HIV (antibiotic or antiviral therapy)</p> <p>The child complains of pain in the genital or anal area.</p> <p>There is evidence or complaint of anogenital bleeding or injury.</p> <p>The child is experiencing significant behavioral or emotional problems and needs evaluation for possible suicidal ideation or plan.</p>
Urgent (scheduled within 1-2 days)	<p>None of the emergent criteria are met, but there was suspected or reported sexual contact occurring within the previous 2 weeks.</p>
Non-urgent (scheduled)	<p>None of the emergent or urgent criteria are met, but the child has disclosed abuse or sexual abuse is suspected by MDT or there is a family concern for abuse.</p>

MDT, Multidisciplinary; STI, sexually transmitted infection.

and should be scheduled with an experienced provider in a timely manner after safety issues are addressed.

The physical examination for CSA, in addition to an overall assessment of the child, includes the collection and documentation of forensically significant findings. An examiner must be knowledgeable in anogenital anatomy, examination techniques, interpretation of examination findings, and the diagnosis of sexually transmitted infections (STIs). Although primary care providers may not have the time, expertise, or equipment available to perform an in-depth assessment, they should know what local recourses are available to them for referral. The examination is well tolerated by most children when performed by an experienced clinician (Marks et al., 2009; Palusci and Cyrus, 2001). The two factors that have been shown to positively correlate with accuracy in interpreting examination findings are experience within the field of CSA and participation in expert peer review of examination findings (Adams et al., 2012). Studies have demonstrated that inexperienced clinicians are unable to identify normal female genital structures and misinterpret examination findings as indicative of abuse (Hornor and McCleery, 2000; Ladson et al., 1987; Makoroff et al., 2002).

The adolescent female anogenital examination is performed in the customary fashion using stirrups and, if indicated, a speculum. The prepubertal female genitourinary examination is always limited to an external-only examination. The most typical prepubertal examination position is supine with the soles of the feet approximated and thighs abducted. The genital area is visualized by placing gloved fingertips on the labia majora and inguinal area and gently separating the labia majora (“supine separation”). If the hymen orifice is not well visualized by this maneuver, then the labia majora are grasped by the examiner’s thumb and forefingers, and traction is applied out toward the examiner and downward toward the medial thighs (“labial traction”). If further techniques are needed to better visualize the inferior hymen, the knee–chest position can be used (Berkoff et al., 2008). A cotton-tipped swab can be used to assist with visualization of an estrogenized hymen (postpubertal), but not before puberty because touching an unestrogenized hymen is very painful. A speculum may be needed to identify a source of vaginal bleeding or to assess for a vaginal foreign body in a prepubertal girl, but only when used with sedation. The anogenital examination should be photographed with magnified digital still or video capture for the purposes of peer or forensic review (Figure 24-2).

EXAMINATION FINDINGS OF SEXUAL ABUSE

Fewer than 10% of CSA victims have physical findings present on examination that can be attributed to acute or healed trauma (Anderst et al., 2009; Berkoff et al., 2008; Heger et al., 2002; Kellogg et al., 2004). Examples of specific findings diagnostic of healed genital trauma in girls include transections and missing segments of hymen in the posterior rim (inferior to the 3 to 9 o’clock locations). Many nonspecific findings (seen in studies of both abused and nonabused children) such as variations in hymen configuration, “gaping” of the hymen orifice, and reflexive anal dilation are not indications of sexual abuse but if misinterpreted as such are misleading and potentially harmful to

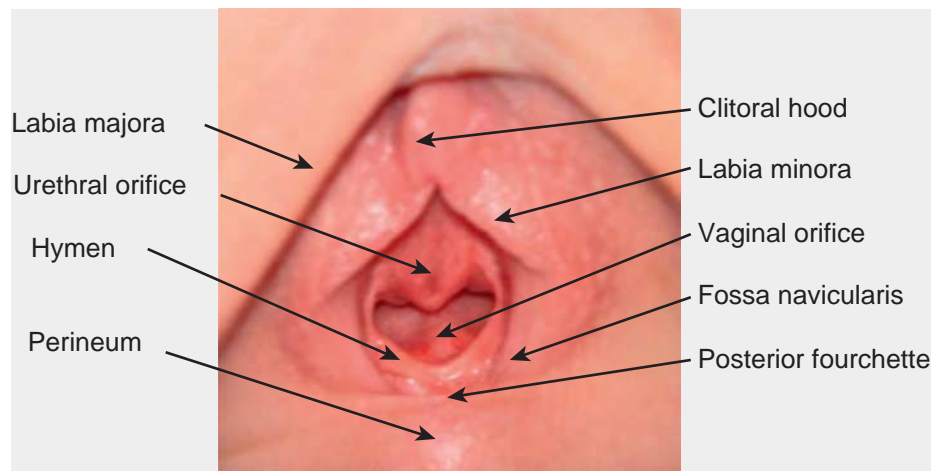

Figure 24-2 Female genitourinary anatomy.

Table 24-6 Classification of Anogenital Findings (“Adams Classification”)

Normal variants and conditions mistaken for abuse	<ul style="list-style-type: none"> Congenital variations in hymen configurations (annular, crescent, redundant) Hymen notch or cleft in superior hymen (above 3 to 9 o'clock in the supine position) Hymen bumps or mounds Erythema of anogenital tissues Labial adhesions Perianal venous pooling Diastasis ani Urethral prolapse Failure of midline fusion and perineal grooves
Indeterminate findings (no expert consensus)	<ul style="list-style-type: none"> Deep notches or clefts at the 3 and 9 o'clock position of the hymen in postpubertal girls Anogenital condyloma Anogenital herpes simplex virus

the child and family (Adams, 2011) (Table 24-6). For a more detailed description of the medical evaluation of CSA, please refer to the Guidelines by Adams et al. (2007, 2011).

SEXUALLY TRANSMITTED INFECTION TESTING FOR SEXUAL ABUSE

Testing for STIs should be considered in all cases of sexual abuse and assault of children when mucosal skin contact between the alleged perpetrator and victim has occurred

(Centers for Disease Control and Prevention [CDC], 2010). Although symptoms such as discharge or dysuria may be present in the infected child, genital *Trichomonas vaginalis* and *Chlamydia trachomatis* are well known to reside in infected individuals without causing overt symptoms, and cases of asymptomatic genital gonorrhea have been documented. Whereas testing by culture methods for trichomonas, gonorrhea, and Chlamydia provides direct identification of the involved organism, nonculture testing by nucleic acid amplification tests (NAATs) offers advantages in test sensitivity (especially for Chlamydia) and patient comfort (CDC, 2010). All positive test results should be confirmed by use of a method different than the first test, either by culture or a second NAAT that uses an alternate or different genetic target (Hammerschlag, 2011) if the infection will be significant in investigative or legal proceedings. This can be expected to occur if the test results are positive in a young child or an adolescent who has had no peer-consensual sexual activity. In prepubertal children, unless clinical indications prohibit waiting, confirmatory testing should be obtained before they are treated with antibiotics. Serologic testing for HIV, syphilis, and hepatitis should be obtained when indicated (Table 24-7).

MANAGEMENT OF SEXUAL ABUSE

Medical management for CSA and sexual assault victims is directed toward treatment or prophylaxis for conditions that could result from the sexual contact (infection and pregnancy), referral for other medical issues discovered in the course of the evaluation, mental health intervention, and reporting and collaboration with law enforcement and protective services. Postpubertal girls who have been acutely assaulted and have had genital-to-genital contact should receive antibiotic prophylaxis for gonorrhea, Chlamydia, and trichomonas after the assault because of their risk for ascending pelvic infection (CDC, 2010). Oral gonorrhea transmission as well as postexposure prophylaxis for HIV, hepatitis, and syphilis should be considered. Emergency contraception should be offered to postpubertal girls. Prepubertal girls and boys should have follow-up testing in 2 to 3 weeks after the assault without provision of postassault prophylaxis when indicated.

Table 24-7 Relationship of Sexually Transmitted Infections to Diagnosis of Child Sexual Abuse

STI Confirmed	Relationship to Sexual Abuse*	Suggested Action by Provider
Gonorrhea	Diagnostic	Report
Chlamydia	Diagnostic	Report
Trichomonas	Diagnostic	Report
HIV	Diagnostic	Report
Syphilis	Diagnostic	Report
Condyloma acuminata (anogenital warts)	Suspicious [†]	Report [‡]
Anogenital herpes simplex virus	Suspicious [†]	Report [‡]
Bacterial vaginosis	Inconclusive	Medical follow-up

*If transmission by perinatal or peer age, consensual encounters are excluded.

[†]Transmission can occur from perinatal spread, sexual contact, or nonsexual skin-to-skin contact.

[‡]Nonsexual transmission is more feasible in young children, but a thorough medical evaluation by a provider experienced in evaluation of child sexual abuse is still needed.

Adapted from Kellogg N; American Academy of Pediatrics Committee on Child Abuse and Neglect. The evaluation of sexual abuse in children. *Pediatrics*. 2005;116:506-512.

Although management focuses on the needs of the child, many cases of CSA involve trauma and stress to the entire family unit and should be addressed. Many caregivers of children who have been sexually abused have been victims of abuse themselves and never disclosed or had the opportunity to have treatment. The abuse of their child can trigger posttraumatic stress symptoms. Other sources of stress and trauma in the child's home should also be screened for and addressed at this time. Domestic violence, caregiver substance abuse, and depression should be recognized as significant adverse childhood experiences that, if left unaddressed, may have cumulative long-term negative health effects on the child's physical and emotional well-being (Felitti et al., 1998). Evidence-based or evidence-informed treatment should be offered to all victims of CSA.

Finally, CSA must be reported to the local mandated agencies. The report should be made immediately by phone and followed by a written report. Health Insurance Portability and Accountability Act (HIPAA) exclusions provide for the sharing of relevant information with children's services and law enforcement if child abuse is suspected.

SEXUAL ABUSE MYTHS

Cultural myths and societal expectations create an expectation that examination findings will prove penetration after sexual abuse and assault or that the lack of findings proves abuse did not occur. However, the majority of CSA victims have no physical evidence of the abuse. There are several reasons for this: (1) Delays in disclosure make it less likely to discover superficial injuries that heal quickly, (2) the mucosal skin of the anus and genitalia is elastic and can accommodate penetration without tearing, (3) injuries and tears to mucosal skin heal quickly and typically without scars, (4) a young girl's description of painful genital

Table 24-8 Common Myths and Misconceptions About Child Sexual Abuse

Children usually tell right away after abuse has occurred. Physical or laboratory findings should be abnormal if penetration has occurred.
The hymen is commonly injured by activities such as gymnastics and bicycle riding.
Something has to "pop," break, or bleed the first time a girl has a sexual encounter.
Sexually transmitted infections in young children are common from casual contact or fomite spread.
Family members do not sexually abuse their own children.

penetration may reflect painful contact with her unestrogenized hymen without further penetration, and (5) it is uncommon to recover trace biologic evidence from the bodies of young children but more likely to recover biologic evidence from clothing and bedding (Anderst et al., 2009; Heppenstall-Heger et al., 2003; Thackeray et al., 2011) (Table 24-8).

Summary

KEY TREATMENT

- Health care workers are mandated reporters and must report all reasonable concerns for child maltreatment to county authorities. Early recognition of child abuse can be lifesaving.
- Child neglect can result in serious developmental deficits and must be treated by placing the child in an attentive and supportive environment.
- Treatment for certain STIs should be delayed until confirmatory testing has been completed.
- Children who have been abused or neglected should be screened for the need for referral for trauma-focused cognitive-behavioral therapy.

Vaginal Discharge, 482
Vulvar Lesions, 486
Acute Pelvic Pain, 487
Menopause, 489

Patient-Centered Approach to the Well-Woman Examination

The well-woman examination is an opportunity for the family physician to promote health, prevent disease, and strengthen the physician–female patient relationship. Although women have traditionally been advised to see their doctors for an “annual examination,” which includes a Papanicolaou smear, new screening guidelines have widened the scope of the visit and deemphasized the Pap smear (which may not be needed on an annual basis). Building a trusting relationship is important because women may be more likely to volunteer sensitive problems with a physician they trust. In addition, some women may have had previous negative experiences with pelvic examinations.

EVIDENCE-BASED SCREENING GUIDELINES

Screening guidelines published by the [U.S. Preventive Services Task Force \(USPSTF\)](#) provide an evidence-based guide for family physicians to follow. Recommendations with A and B levels of evidence for adult women are included in [Table 25-1](#). Unfortunately, many established components of the well-woman examination are not supported by evidence. Testing for lipid disorders in average-risk women, type 2 diabetes screening, and physical activity counseling are examples of “uncertain” recommendations, according to the USPSTF. A physician may choose to cover these areas in a well-woman visit, but it is important to ensure that the areas with stronger evidence of benefit are thoroughly discussed. The USPSTF also lists areas of screening that have the potential to cause harm and therefore are not recommended. These include cervical cancer screening in women with previous hysterectomy for benign causes, screening for gonorrhea in low-risk women, teaching breast self-examination, and screening for ovarian cancer.

Immunizations are an important part of well-woman care. All patients benefit from disease prevention, and women are often caregivers for children or elderly persons, who are at higher risk from vaccine-preventable illnesses. Vaccines recommended by the [U.S. Centers for Disease Control and Prevention \(CDC\) Advisory Committee on Immunization Practices \(ACIP\)](#) include tetanus, diphtheria,

and pertussis (Tdap); influenza; herpes zoster for adults older than age 50 years; pneumococcal vaccine for adults older than age 65 years; and human papillomavirus (HPV) vaccine for women 26 years of age and younger.

PAP SMEAR GUIDELINES

Key Points

- Pap screening should begin at age 21 years. Women should have Pap smears every 3 years. Women age 30 years and older may have co-testing with the Pap smear and HPV testing, which can be done together every 5 years.
- Women who have had a hysterectomy for benign disease should not have Pap smear screening.
- Women are not required to have a Pap smear before starting hormonal contraception.
- Women do not need a pap smear after age 65 years if they have had normal results in the past.

Although the Pap smear is still the mainstay of cervical cancer screening, recent advances in the understanding of HPV have revolutionized this field. HPV is the most common sexually transmitted infection (STI), with its highest prevalence among the 20- to 24-year-old age group (53.8%) ([Hariri et al., 2011](#)). Although HPV is typically spread through sexual activity, 15% of women in this study who reported that they had never had sex were infected with HPV. Physicians should keep in mind that some of these women may have been uncomfortable disclosing their sexual activity, even on an anonymous survey, but others may have had sexual contact they did not consider intercourse. Risk factors for HPV infection include low socioeconomic status, number of sexual partners in the past year, lifetime number of sexual partners, age at first intercourse, and marital status.

Strength of recommendation (SOR) taxonomy level A recommendations for cervical cancer screening include starting Pap test screening at age 21 years and repeating every 3 years. A screening option for women age 30 years and older is to perform Pap smear and HPV testing together, with repeat co-testing every 5 years if results of both are

Table 25-1 USPSTF Level A and B Recommendations for Adult Women

Condition	Recommendation	SOR
Alcohol misuse	Screening and behavioral counseling	B
High blood pressure	Screening every 2 yr if blood pressure is less than 120/80 mm Hg; yearly in women with blood pressure of 120-139/80-89 mm Hg	A
Breast cancer	Mammography every 2 yr for women age 50-74 yr	B
Pap smear	Screening every 3 yr from age 21-65 yr or every 5 yr from age 30-65 yr in combination with HPV testing	A
Chlamydia	Women age 24 yr and younger who have ever been sexually active	A
Lipid disorders	Women age 45 yr and older at increased risk for heart disease Women age 20-44 yr at increased risk for heart disease	A B
Colorectal cancer	Adults age 50-75 yr, using fecal occult blood testing, sigmoidoscopy, or colonoscopy	A
Depression	Screening in adults when staff-assisted depression supports are in place	B
Type 2 diabetes	Adults with blood pressure >135/80 mm Hg	B
Obesity	Screening adults; intensive behavioral and counseling interventions	B
Osteoporosis	Screening of women age 65 yr and older and younger women at increased risk	B
Tobacco use	Screening adults; cessation interventions	A
HIV testing	Screening ages 15-65 yr; other ages if high risk	A
Hepatitis C	Screening in adults born between 1945 and 1965	B
Intimate partner violence	Screening in women of childbearing age	B

HPV, Human papillomavirus; SORT, strength of recommendation taxonomy (level of evidence).
 U.S. Preventive Services Task Force (USPSTF) recommendations available at <http://www.ahrq.gov/clinic/uspstfix.htm>.

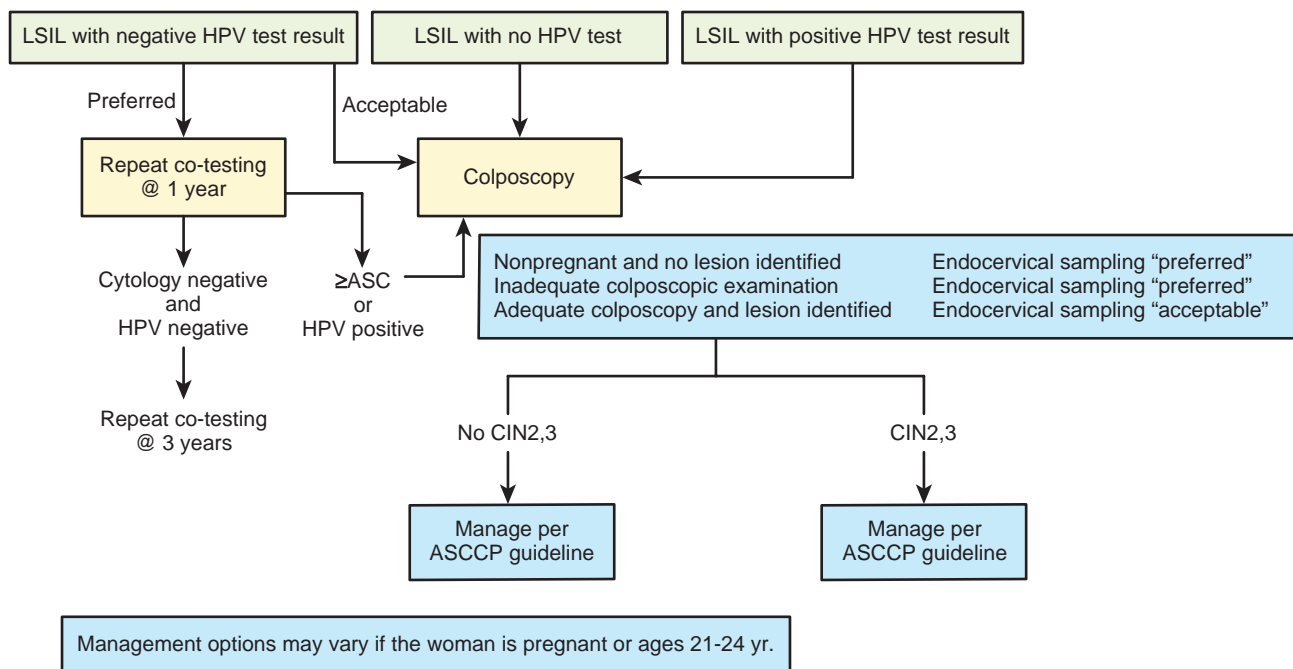

Figure 25-1 Management of women with low-grade squamous intraepithelial lesions (LSILs). (Used with permission from American Society for Colposcopy and Cervical Pathology © Copyright 2013.)

normal. The recommendations for fewer Pap tests in women younger than 21 years and older than 30 years are consistent with the epidemiology of HPV. Younger women acquire HPV infections more frequently, but most clear the infection without intervention. Older women are less likely to develop new HPV infections, and only persistent HPV is a concern for cervical cancer. Women are not required to have a Pap smear before starting hormonal contraception. Physicians can use visits when a Pap test is not needed as an opportunity to educate female patients about STIs and reproductive health, as well as perform the other, evidence-based

screening recommendations previously cited (*American College of Obstetricians and Gynecologists [ACOG], 2012a*).

Abnormal Pap Smear Management

Guidelines for management of abnormal Pap test results have also been updated to reflect understanding of the epidemiology of HPV infection (*Figure 25-1*) (*Saslow et al., 2012*). These guidelines include recommendations for the management of special populations, such as adolescents, pregnant women, and postmenopausal women, and are available online at the American Society for Colposcopy and

Cervical Pathology (ASCCP) at <http://www.asccp.org>. Most women with low-grade squamous intraepithelial lesions (LSIL), atypical squamous cells of undetermined significance (ASCUS) with positive HPV test results, and high-grade SIL (HSIL) should have colposcopy.

Abnormal Vaginal Bleeding

Key Points

- Anovulation is common in adolescents for the first 18 months after menarche.
- Bleeding disorders typically present as menorrhagia in adolescence.
- Anovulation is the most common cause of abnormal vaginal bleeding in reproductive-age women.
- The four most common causes of secondary amenorrhea are pregnancy, hyperprolactinemia, thyroid disorders, and iatrogenic.
- Evaluation of abnormal bleeding in women older than age 45 years should include an endometrial biopsy.
- Anovulatory women are at risk for endometrial hyperplasia or carcinoma from unopposed estrogen and should have regular progesterone-induced withdrawal bleeds.
- Any bleeding after menopause in a woman who is not taking hormone therapy (HT) is abnormal.
- Evaluation with an endometrial biopsy or pelvic ultrasonography can exclude endometrial cancer in postmenopausal women.

Normal menstrual bleeding is defined as regular vaginal bleeding that occurs at intervals from 21 to 35 days. A normal menstrual cycle begins with the follicular phase before ovulation and then the luteal phase after ovulation. Abnormal vaginal bleeding is a common complaint in primary care. The prevalence of some type of abnormal bleeding is 10% to 30% among women of reproductive age. The estimated annual direct and indirect costs of abnormal bleeding are \$1 billion and \$12 billion, respectively (Liu et al., 2007). Abnormal bleeding is also a common reason for women to be referred to gynecologists and is an indication for up to 25% of all gynecologic surgery (Goodman, 2000). The ACOG has recently described a classification system for abnormal vaginal bleeding in women of reproductive age—polyp, adenomyosis, leiomyoma, malignancy and hyperplasia, coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, not yet classified (PALM COEIN) (Table 25-2) (ACOG, 2012b).

A life cycle approach to abnormal vaginal bleeding is helpful in determining etiology and treatment options.

ADOLESCENTS

In adolescents, the three most common presentations of abnormal vaginal bleeding are anovulation, menorrhagia, and amenorrhea. It is normal for menstrual cycles to be anovulatory for an average of 18 months after menarche while the hypothalamic-pituitary axis matures. *Menorrhagia* (heavy bleeding) is quite common in adolescent patients and is most often caused by anovulation (Rimsza, 2002). In

Table 25-2 American College of Obstetricians and Gynecologists Classification System for Abnormal Bleeding in Reproductive-Age Women

PALM (Structural Causes)	COEIN (Nonstructural Causes)
Polyp	Coagulopathy
Adenomyosis	Ovulatory dysfunction
Leiomyoma	Endometrial
Malignancy and hyperplasia	Iatrogenic
	Not yet classified

From American College of Obstetricians and Gynecologists. Diagnosis of abnormal uterine bleeding in reproductive-aged women. Practice Bulletin No. 128. *Obstet Gynecol.* 2012;120(1):197-206.

some young women, however, menorrhagia at menarche can be a sign of a bleeding disorder. Up to 24% of adolescents with menorrhagia may have an undiagnosed bleeding disorder (Strickland, 2004). Evaluation of menorrhagia in adolescents includes a complete blood count, coagulation profile, and von Willebrand disease screening test if clinically indicated. Treatment of both anovulation and menorrhagia in adolescents is usually hormonal contraception for cycle control.

The most common causes of primary amenorrhea include pregnancy; chromosomal abnormalities (e.g., Turner or Sawyer syndrome); hypothalamic hypogonadism; congenital absence of the uterus, cervix, or vagina; and structural abnormalities (e.g., transverse vaginal septum or imperforate hymen). Evaluation of primary amenorrhea includes a careful history, pelvic examination, pelvic ultrasonography to document the presence of pelvic organs, and chromosome analysis if clinically indicated.

REPRODUCTIVE-AGE WOMEN

The most common causes of abnormal bleeding in reproductive-age women are pregnancy complications, anovulatory disorders, and benign pelvic pathology. Characteristics of ovulatory cycles include regular cycle length, presence of premenstrual syndrome symptoms, and changes in cervical mucus. In contrast, anovulatory cycles tend to be unpredictable, with varying bleeding amounts and intervals.

Abnormal bleeding in ovulatory cycles includes menorrhagia, polymenorrhea, oligomenorrhea, and intermenstrual bleeding. Menorrhagia can be associated with structural lesions (uterine leiomyomas, endometrial polyps or hyperplasia), coagulation disorder, liver failure, or chronic renal failure. *Polymenorrhea* (bleeding at short intervals) can be caused by a luteal-phase disorder (not enough progesterone is produced after ovulation to stabilize the endometrium) or a short follicular phase. *Oligomenorrhea* (infrequent bleeding) is usually caused by a prolonged follicular phase. Intermenstrual bleeding can be caused by cervical pathology (dysplasia or infection) or an intrauterine device (IUD). Evaluation of a woman with abnormal bleeding is based on the type of bleeding (Table 25-3).

Anovulation is the most common cause of abnormal vaginal bleeding in reproductive-age women. The majority of anovulation is related to hypothalamic abnormalities or polycystic ovarian syndrome (PCOS) (Table 25-4). By

Table 25-3 Clinical Evaluation of Reproductive-Age Woman with Abnormal Bleeding

Ovulatory abnormal bleeding	History, physical examination, pregnancy test <i>Menorrhagia</i> Consideration of liver function tests, BUN/Cr, CBC, coagulation profile Pelvic ultrasonography to exclude uterine fibroids Endometrial biopsy (especially if older than 35 yr) to exclude endometrial hyperplasia <i>Intermenstrual bleeding</i> Pap smear, cervical cultures Basal body temperature chart to determine length of follicular and luteal phases
Anovulatory bleeding	History, physical examination, pregnancy test <i>Laboratory studies</i> TSH level Prolactin level CBC (if acute bleeding episode or frequent heavy bleeding) Fasting glucose and insulin levels Screening for eating disorder, stress, and female-athlete triad

Idiopathic chronic anovulation
Medication induced (discontinuation of hormonal contraceptives)

definition, anovulatory cycles are unpredictable and cannot be classified by any one type of vaginal bleeding pattern. A woman may experience 14 days of heavy bleeding one month, light spotting intermittently for the next month, and then go for 3 months without a cycle. The pathologic abnormality in these cycles is a lack of ovulation, which produces an unopposed-estrogen state. The lack of progesterone production resulting from no ovulation contributes to irregular endometrial growth and nonuniform bleeding. In a normal cycle, the entire endometrium sloughs off during menstruation. In an anovulatory cycle, different sections of endometrium outgrow their blood supply at different times and bleed erratically.

Treatment of women with either ovulatory bleeding or anovulatory bleeding is not necessary unless the woman wants to become pregnant, is bothered by her bleeding pattern, or has systemic symptoms from anemia. However, anovulation is an unopposed-estrogen state, and treatment with some type of progesterone is necessary to reduce the risk of endometrial hyperplasia or carcinoma. *Unopposed estrogen* is a risk factor for endometrial cancer, along with obesity, diabetes, nulliparity, and age after 35 years. To protect against the development of endometrial hyperplasia, a precursor to endometrial cancer, all women with

Table 25-5 Treatment Options for Abnormal Vaginal Bleeding

Pregnancy desired	Ovulation induction with clomiphene citrate Referral to gynecologist
Contraception desired	Cycle control with estrogen/progestin method, depot medroxyprogesterone acetate, or levonorgestrel IUD
Acute bleeding episode	OUTPATIENT Administration of high-dose OCs, up to 4 pills daily for 5 to 7 days, with subsequent continuous OC cycling for at least 1 mo Administration of oral estrogen or oral progesterone to stop the bleeding acutely
	INPATIENT IV fluids, supportive care, IV estrogen therapy Consultation for surgical intervention
Contraception regimen used	ESTROGEN/PROGESTIN Supportive care for first 3 mo Assessment of adherence to OC regimen Add supplemental estrogen Change to method with higher dose of estrogen or different class of progestin
	PROGESTIN ONLY Add supplemental estrogen or combination OC Administer NSAID to decrease bleeding

IUD, intrauterine device; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; OC, oral contraceptive.

Modified from Ely JW, Kennedy CM, Clark EC, Bowdler NC. Abnormal uterine bleeding: a management algorithm. *J Am Board Fam Med.* 2006;19:590-602 and Schragr S. Abnormal uterine bleeding associated with hormonal contraception. *Am Fam Physician.* 2002;65:2073-2080.

chronic anovulation should have a progesterone-induced withdrawal bleed at least four times a year (Albers et al., 2004). Women may take medroxyprogesterone acetate, 10 mg/day for 10 days, and then expect a withdrawal bleed within a few days of stopping the medication.

Treatment of abnormal bleeding consists of ovulation induction if pregnancy is desired or cycle control with hormonal contraceptives if it is not. In women who are not candidates for estrogen-containing contraceptives, a monthly cycling of progesterone or continuous administration of progestin contraception (e.g., depot medroxyprogesterone acetate or levonorgestrel IUD) can also be an effective treatment. For women who do not want to take hormonal medications, nonsteroidal antiinflammatory drugs (NSAIDs) can decrease the amount of bleeding (Ely et al., 2006) (Table 25-5).

Another common presentation of abnormal bleeding is an *acute bleeding* episode. In this situation, a woman is most likely anovulatory. Evaluation in an acute bleeding episode should include hemoglobin (Hb) and hematocrit (Hct), assessment of volume status, and an endometrial biopsy in women older than age 45 years.

If a woman presents with heavy bleeding and exhibits any signs or symptoms of *hypovolemia*, she should be admitted to the hospital and either treated with intravenous (IV) estrogen to stop the bleeding or have a surgical procedure, such as dilation and curettage. If the woman is stable and her Hb and Hct are near normal, outpatient treatment with high-dose oral contraceptives (OCs), estrogen, or progesterone may be attempted (Ely et al., 2006).

A woman may also present with *amenorrhea*. The four most common causes of secondary amenorrhea (when a woman who previously had normal menses stops having menses for at least 6 months) are pregnancy, hyperprolactinemia, thyroid disorders, and iatrogenic (from medications). Other reasons for amenorrhea include outflow obstruction (e.g., Asherman syndrome, caused by scarring of uterus from instrumentation, or cervical stenosis) and primary ovarian failure. Evaluation of a woman with amenorrhea begins with a history and physical examination. Laboratory studies should include a pregnancy test and thyroid-stimulating hormone and prolactin levels. The next step is an induced withdrawal bleed after administering progesterone for 10 to 14 days. If a woman has a menstrual bleed after taking progesterone, outflow obstruction and low estrogen state (as in primary ovarian failure) are excluded as the causes of amenorrhea. If a woman does not have a withdrawal bleed after progesterone administration, a trial of estrogen supplementation for 3 weeks should be given before another course of progesterone is attempted. In this situation, if a woman has a withdrawal bleed, the diagnosis of primary ovarian failure is considered, and levels of gonadotropins (follicle-stimulating hormone [FSH], luteinizing hormone [LH]) should be obtained. If a woman does not have a withdrawal bleed after estrogen and progesterone administration, a hysterosalpingogram (radiograph of uterus and ovaries after dye injection) should be obtained to evaluate for outflow obstruction.

PERIMENOPAUSAL WOMEN

Abnormal bleeding in the 5 to 10 years before menopause is very common. The most common pathology is anovulation caused by declining numbers of ovarian follicles and decreasing inhibin B levels (Jain and Santoro, 2005). Perimenopausal women may also bleed from structural lesions (most often uterine fibroid tumors or polyps) or bleeding disorders. Evaluation of a perimenopausal woman with abnormal bleeding should include an endometrial biopsy to exclude endometrial hyperplasia or cancer. The risk of endometrial cancer increases in women who are nulliparous, diabetic, or obese (Espindola et al., 2007). Nonsmoking women in this age group can be effectively managed with hormonal contraception for cycle control. Smokers who should avoid estrogen because of a thrombotic risk can use cyclic progestin to provide a monthly withdrawal bleed.

POSTMENOPAUSAL WOMEN

Menopause is defined as 12 months without a menstrual period. After that 12-month period, any bleeding is abnormal. A large Danish study found a 10% prevalence of postmenopausal bleeding (Astrup, 2004). Bleeding episodes decreased as the time since menopause increased. The main concern in a postmenopausal woman with bleeding is endometrial carcinoma. Between 10% and 20% of all postmenopausal bleeding is caused by malignancy (Hale and Fraser, 2007). Evaluation of postmenopausal bleeding can be done effectively with either pelvic ultrasonography or an office endometrial biopsy. A pelvic ultrasound can assess the thickness of the endometrium, the *endometrial stripe*. A

stripe less than 4 mm in diameter is the cutoff to exclude endometrial cancer (ACOG, 2009). An office endometrial biopsy is an excellent diagnostic test to evaluate endometrial tissue (Dijkhuizen et al., 2000). In some postmenopausal women, however, cervical stenosis precludes a successful biopsy. In this situation, if ultrasonography is nonreassuring, a surgical procedure may be indicated.

KEY TREATMENT

- Unstable women with acute heavy vaginal bleeding should be admitted to the hospital for IV estrogen therapy or surgical intervention (ACOG, 2012b) (SOR: C).
- Treatment of abnormal bleeding includes ovulation induction if a woman desires pregnancy and hormonal cycle control if she does not (ACOG, 2012b) (SOR: C).
- To protect against the development of endometrial hyperplasia, a precursor to endometrial cancer, all women with chronic anovulation should have a progesterone-induced withdrawal bleed at least four times a year (Albers et al., 2004) (SOR: C).
- If Hb and Hct are near normal, outpatient treatment with high-dose oral contraceptives, estrogen, or progesterone may be attempted (Ely et al., 2006) (SOR: C).

Pelvic Mass

Key Points

- Pelvic examination is not sensitive or specific for the diagnosis of a pelvic mass.
- Initial evaluation of a pelvic mass should include a focused history, physical examination, pelvic ultrasonography, and CA-125 level in postmenopausal women.
- Pelvic ultrasonography with cyst morphology and Doppler flow studies can distinguish benign cysts from ovarian carcinoma, especially in postmenopausal women.
- Although combination oral contraceptives can reduce the risk of functional ovarian cysts, OCs are not useful for treatment.

DIAGNOSIS

A patient may report a symptomatic pelvic mass, or it may be discovered as part of a pelvic examination or ultrasonography done for other reasons. A pelvic mass can be associated with the uterus, ovaries, or nongynecologic organs. The first step in evaluation is to review the patient's age, history, and risk factors. For example, an ovarian cyst is more likely to be a functional cyst in a younger woman, but it has a higher potential to be ovarian cancer in postmenopausal women. Additional historical details include menopausal status, menstrual history, family history, STI risk, symptoms of hyperandrogenism, and dysmenorrhea.

Pelvic examination is not sensitive or specific for diagnosis of a pelvic mass, especially as body mass index increases (Myers et al., 2006). However, pelvic examination can

Table 25-6 Differential Diagnosis of Pelvic Mass

Diagnosis	Features
UTERUS	
Uterine fibroid	Pelvic pressure, heavy vaginal bleeding
Intrauterine pregnancy	Positive pregnancy test result, amenorrhea
FALLOPIAN TUBES	
Ectopic pregnancy	Positive pregnancy test result, adnexal pain or tenderness, hemodynamic instability
Tubo-ovarian abscess	STI risk, pelvic pain, cervical motion tenderness, vaginal discharge, fever
OVARIES	
Simple cysts	More common in premenopausal women; sharp, may have pelvic pressure
Endometriomas	Dysmenorrhea
Dermoid cysts (teratomas)	Pelvic pressure
Ovarian carcinoma	Postmenopausal women
Polycystic ovarian syndrome	Hyperandrogenism, irregular menses, multiple cysts on ultrasonography
Germ cell tumors	Pelvic pressure, chromosomal abnormalities, younger women (teens and 20s)
INTESTINES	
Appendicitis	Anorexia, right lower quadrant pain or tenderness, elevated WBC count, fever
Diverticulitis	Left lower quadrant pain or tenderness, cramping, constipation, older age, fever
URINARY TRACT	
Bladder tumor	Hematuria
Pelvic kidney	Usually asymptomatic

STI, Sexually transmitted infection; WBC, white blood cell.

provide other information helpful in the diagnosis, such as location of the mass, mobility of the mass, cervical motion tenderness, pelvic tenderness, and vaginal discharge. The initial evaluation of a pelvic mass should include pelvic ultrasonography, which can be transabdominal or transvaginal, depending on the size and location of the mass. Premenopausal women should be tested to exclude pregnancy. Doppler ultrasonography, cyst morphology, and CA-125 testing are useful in ruling out ovarian cancer in a postmenopausal woman with an adnexal mass. [Table 25-6](#) lists the differential diagnosis and common features of pelvic masses.

UTERINE FIBROIDS

Clinically significant uterine fibroids are present in approximately one third of reproductive-age women ([Viswanathan et al., 2007](#)). Although often asymptomatic, fibroids may cause pelvic pain, pressure, and heavy or irregular vaginal bleeding and are the most common reason for hysterectomy in the United States. Treatment options for fibroids include watchful waiting because most fibroids will decrease in size after menopause. Although hysterectomy is definitive treatment, it carries the risks of major surgery. Myomectomy and other uterine-sparing procedures have a high rate of symptom recurrence (up to 50% within 5 years) and may

be more effective for symptom control in perimenopausal women. Women with fibroids are more likely to be infertile, although it is not clear if the association is causative. Removal of fibroids has not been shown to improve fertility ([Metwally et al., 2012](#)). Medical treatments such as NSAIDs and OCs have not been well studied. The levonorgestrel intrauterine system (Mirena) has been shown to decrease menstrual bleeding in women with fibroids when compared with OCs ([Sayed et al., 2011](#)). Mifepristone (ru 486) has been shown to reduce heavy menstrual bleeding and improve fibroid-related quality of life ([Tristan et al., 2012](#)).

OVARIAN CYSTS AND CARCINOMA

As mentioned, the initial evaluation of an ovarian cyst includes transvaginal ultrasonography. Simple cysts are very likely to be benign, but complex cysts (with thick walls, irregularity, papillations, septa, and echogenicity) and cysts that are larger than 10 cm have a higher risk of malignancy ([Modesitt, 2003](#)). Malignant neoplasms also display increased vascularity on Doppler ultrasonography ([ACOG, 2007](#)). The Society of Gynecologic Oncologists and the American College of Obstetrics and Gynecology have developed criteria for referral to a gynecologic oncologist. Premenopausal women should be referred if they have a CA-125 level greater than 200 U/mL, ascites, evidence of metastases, or a first-degree relative with breast or ovarian cancer. Postmenopausal women should be referred if they have an elevated CA-125 level, ascites, a nodular or fixed pelvic mass, evidence of ascites, or a family history of breast or ovarian cancer in a first-degree relative ([Liu and Zanotti, 2011](#)). Although combination OCs can reduce the occurrence of functional ovarian cysts, OCs are not helpful for treatment ([Grimes et al., 2011](#)).

KEY TREATMENT

- Most simple ovarian cysts can be managed expectantly ([ACOG, 2007](#)) (SOR: B).
- The levonorgestrel intrauterine system can reduce heavy menstrual bleeding in women with uterine fibroids ([ACOG, 2007](#)) (SOR: B).
- Low-dose mifepristone decreases symptoms and improves quality of life ([ACOG, 2007](#)) (SOR: B).

Vaginal Discharge

Key Points

- Douching is not helpful for prevention or treatment of vaginitis.
- Signs and symptoms of vaginitis are not specific, but a cause can usually be diagnosed on office microscopy.
- Speculum examination is not necessary for diagnosis of vaginitis; a blind swab in the vaginal vault is equally sensitive.
- Self-diagnosis of vaginal infection by the patient is unreliable.

Table 25-7 Comparison of Findings for Vaginitis

Type	Symptoms	Signs	pH	KOH	Saline Wet Mount
Bacterial vaginosis	Malodorous discharge	Thin, gray adherent discharge	>4.5	Amine or fishy odor	Clue cells
Vulvovaginal candidiasis	Itching, burning pain	Curdlike discharge, vulvar erythema	3.8-4.5	Pseudohyphae; budding yeast	Occasional hyphae; yeast
Trichomoniasis	Fish-odor discharge	Erythema, tenderness	6-7	Negative	Trichomonads, many WBCs
Atrophic vaginitis	Dryness, pain	Pale, friable	>4.5	Negative	RBCs, WBCs; many bacteria
Aerobic vaginitis	Foul odor	Heavy purulent discharge	>4.5	Negative	Cocci or coarse rods
Irritant or allergic vaginitis	Itching, swelling	Erythema	Any	Negative	Negative

KOH, Potassium hydroxide; RBCs, red blood cells; WBCs, white blood cells.

Table 25-8 Differential Diagnosis of Vaginal Discharge: Vaginitis

Candida spp. (*Candida albicans*, *Candida glabrata*)
 Bacterial vaginosis (anaerobic bacteria: *Gardnerella vaginalis*, *Bacteroides* spp.)
 Desquamative inflammatory vaginitis: aerobic bacteria
 Trichomonas vaginalis
 Allergic vaginitis or contact dermatitis
 Chlamydial infection or gonorrhea
 Erosive lichen planus vaginitis
 Actinomyces Behçet syndrome (associated with IUC use)
 Vulvar vestibulitis
 Physiologic (leukorrhoea)
 Atrophic vaginitis

IUC, Intrauterine contraception.

Vaginitis is the most common gynecologic diagnosis made in the primary care setting. Common symptoms include increased vaginal discharge without pelvic pain or systemic symptoms, vulvar itching and burning, dysuria, and possible odor. Physiologic leukorrhoea varies and may change with a woman's menstrual cycle. If purulent cervicitis is present on examination, testing for *Chlamydia* and *Neisseria gonorrhoeae* should be performed (French et al., 2004). In postmenopausal women, vaginal irritation, dryness, and superficial bleeding are often caused by atrophic vaginitis (see the section titled "Menopause"). A medication history is important because isotretinoin and some contraceptives may also cause dryness and itching. Personal hygiene habits of excessive washing with soap and use of highly absorbent panty liners may cause irritation. If a woman has self-diagnosed and treated with an antifungal agent and symptoms persist, a clinical examination should be encouraged (ACOG, 2006). Tables 25-7 and 25-8 review the differential diagnosis and findings in vaginitis.

Office microscopy is used most often to make a diagnosis of vaginitis. A finding of many leukocytes is uncommon in candidiasis or bacterial vaginosis (BV) and suggests trichomoniasis. If trichomonads are not present, consider gonorrhea or chlamydial infection (Anderson et al., 2004). Fem V, an over-the-counter (OTC) diagnostic kit, can be used; a positive test result suggests BV or trichomoniasis; a negative test result is likely a yeast infection (Prescriber's Letter, 2006).

BACTERIAL VAGINOSIS

Bacterial vaginosis is caused by a shift from the normal lactobacilli-dominated vaginal flora to a polymicrobial flora

Figure 25-2 Bacterial vaginosis. Typical clue cells of vaginal epithelium are heavily covered by coccobacilli, with loss of distinct cell margins (magnification $\times 400$). (From Holmes KK. Lower genital tract infections in women: cystitis/urethritis, vulvovaginitis, and cervicitis. In Holmes KK, Mårdh PA, Sparling PF, et al, eds. *Sexually transmitted diseases*. New York: McGraw-Hill; 1984.)

dominated by gram-positive anaerobes. Although BV is the most common cause of vaginal discharge and foul odor, more than half of women with BV are asymptomatic (CDC, 2010). BV is associated with postoperative infection, pelvic inflammatory disease (PID), premature delivery in women with certain risk factors (French et al., 2004), and an increased risk of human immunodeficiency virus type 1 (HIV-1) transmission (Oduyebo et al., 2009). Risk factors for acquisition of BV include tobacco use; intrauterine contraception (IUC) use; new male sexual partner; sex with another woman; and use of vaginal foreign bodies, perfumed soaps, or douching (Allsworth and Peipert, 2007).

The diagnosis of BV can usually be made by history and laboratory microscopy (Figure 25-2). Self-diagnosis by the patient is unreliable (ACOG, 2006). A strong "musty cheese" odor predicts BV, but a lack of a perceived odor makes BV unlikely (Anderson et al., 2004). Use of Gram stain or the Amsel criteria on a vaginal (not cervical) sample can be used to diagnose BV in clinical practice (Table 25-9).

There are many effective options for the treatment of BV. A 2009 Cochrane review states that clindamycin and metronidazole have equivalent efficacy, regardless of regimen. The standard oral dose of metronidazole for BV is 500 mg twice daily for 7 days. Both metronidazole gel and clindamycin vaginal cream are dosed daily. Clindamycin 2% cream has lower adverse event rates. Intravaginal

Table 25-9 Amsel Criteria for Bacterial Vaginosis*

1. Vaginal pH >4.5 (most sensitive) (89% sensitivity, 74% specificity)
2. Clue cells >20% on wet-mount (74% sensitivity, 86% specificity)
3. Homogeneous discharge, gray, adherent, but wipes off easily (79% sensitivity, 54% specificity)
4. Whiff test (amine odor when KOH added; 67% sensitivity, 93% specificity)

*A score of 3 of 4 is diagnostic.

KOH, Potassium hydroxide.

Modified from Gutman RE et al. Evaluation of clinical methods for diagnosing bacterial vaginosis. *Obstet Gynecol.* 2005;105:551-556.

lactobacilli gelatin tablets are also effective (Oduyebo et al., 2009). Tinidazole is effective with no serious side effects but is more expensive (Livengood et al., 2007). The Food and Drug Administration (FDA) approved metronidazole, 750 mg/day for 7 days, and a single dose of intravaginal clindamycin for treatment of BV, but only limited data are available on efficacy (CDC, 2010). Hydrogen peroxide douching and triple-sulfonamide cream are considered ineffective (Oduyebo et al., 2009).

Recurrent BV can present a treatment challenge. If recurrence is suspected, the diagnosis should be confirmed, risk factors identified and controlled, and other causes considered while retreating BV (Alfonsi et al., 2004). Metronidazole gel used twice weekly reduces recurrences of BV but is offset by increased vaginal candidiasis and pain complaints (Sobel et al., 2006). If retreatment fails, suppressive therapy with metronidazole 0.75% gel for 10 days, then twice weekly for 4 to 6 months, should be tried. There is no evidence that treatment of sexual partners is effective to prevent recurrence (CDC, 2010). Using vaginal suppositories or consuming yogurt with *Lactobacillus* may decrease recurrences of BV (Jurden et al., 2012) (SOR: B).

KEY TREATMENT

- All symptomatic women with BV should be treated (CDC, 2010) (SOR: B).
- Asymptomatic women undergoing abortion should be treated to decrease the risk for infectious complications (British Association for Sexual Health and HIV [BASHH], 2012) (SOR: A).
- Oral or vaginal metronidazole (BASHH, 2012) and vaginal clindamycin are effective and equivalent in non-pregnant women (Kane, 2001) (SOR: A).
- Treatment of male partners does not decrease relapse rates (CDC, 2010) (SOR: A).
- Tinidazole is effective with no serious side effects but is more expensive than metronidazole (Livengood et al., 2007) (SOR: A).
- In recurrent BV, suppressive therapy with metronidazole 0.75% gel for 10 days and then twice weekly for 4 to 6 months may be successful (Alfonsi et al., 2004) (SOR: C).

CANDIDAL VAGINITIS

Vulvovaginal candidiasis (VVC) is the second most common cause of vaginitis after BV, with a lifetime prevalence in women of 70% to 75% (Spence, 2007). *Candida albicans* is the most common cause (80%-90%). Type 1 diabetes is the

Figure 25-3 Candidal vaginitis (vulvovaginal candidiasis). Candidal organisms in a saline wet-mount preparation clearly demonstrate hyphae and conidia under high-power magnification. (From Kaufman RH, Faro S: *Benign disease of the vulva and vagina*. 4th ed. St. Louis: Mosby; 1994.)

strongest risk factor for VVC; other risk factors include recent antibiotic use, condom and diaphragm use, spermicide use, receptive oral sex, OC use, pregnancy, hormone replacement therapy, and immunosuppression. Patient self-diagnosis of VVC is incorrect 50% of the time and is therefore unreliable. Asymptomatic treatment of VVC is *not* recommended even in women who have a positive swab for *Candida* (Spence, 2007). Because VVC is not sexually transmitted, routine partner treatment is also not recommended. Recurrent VVC is defined as four or more symptomatic episodes in a year. Rare complications of VVC include vulvar vestibulitis and chorioamnionitis (French et al., 2004).

The most common complaint associated with culture confirmed VVC is burning or pruritus. A thick, curdled-appearing discharge, signs of inflammation, and lack of odor all have high positive predictive value for diagnosing VVC (Anderson et al., 2004). In one study, however, a thin discharge was present in about half of women later found to have VVC (French et al., 2004).

Although office microscopy is the first line for diagnosis of VVC, culture is the “gold standard” (Figure 25-3) (ACOG, 2006). With *C. albicans*, the vaginal pH is usually 5.0 or less but may be higher with non-*albicans* species. A wet mount should be performed to exclude trichomoniasis or BV. Potassium hydroxide (KOH) examination should also be performed, but it has a wide range of sensitivity. Thus, if

candidiasis is suspected in a patient with persistent or recurrent symptoms and wet mount and KOH results are negative, a culture should be performed (French et al., 2004). The use of rapid antigen testing to detect vaginal yeast is more sensitive than a wet mount and is feasible for office practice. However, a negative result lacks sensitivity to rule out yeast, and a culture needs to be sent (Chatwani et al., 2007).

The imidazoles are the cornerstone of VVC treatment. Intravaginal OTC imidazoles (e.g., clotrimazole, miconazole, tioconazole) come in 1-, 3-, and 7-day therapy regimens and are equivalent to oral therapies for treatment, and single-dose therapy seems as efficacious as multidose therapy over days (Nurbhai et al., 2007). *Lactobacillus*, administered vaginally, orally, or both, does not prevent postantibiotic-associated vaginal candidiasis (Pirota et al., 2004).

Recurrent VVC occurs in 5% to 8% of women. The Infectious Diseases Society of America recommends treating recurrent VVC for 10 to 14 days followed by suppressive therapy using fluconazole, a single 150-mg dose weekly for 6 months (Pappas et al., 2009). It is unclear if oral regimens are better than intravaginal administration. In preventing recurrence, there is no evidence of benefit with intravaginal boric acid, tea tree oil, garlic, douching, or treating a woman's male sexual partner. *Lactobacillus*, in the form of suppositories or oral yogurt, does not appear to prevent recurrence (Jurden et al., 2012) (SOR: B). Douching is associated with increased pelvic infections (Spence, 2007). For specific treatment regimens, see <http://www.cdc.gov/std/treatment/>.

KEY TREATMENT

- Oral fluconazole and itraconazole are both effective for VVC (Spence, 2007) (SOR: A).
- Oral and intravaginal regimens are equivalent, so cost and patient preference should guide choice (Nurbhai et al., 2007) (SOR: B).
- Intravaginal imidazoles are equivalent to oral therapies for VVC treatment, and single-dose seems as efficacious as multidose therapy (Spence, 2007) (SOR: B).
- Treat recurrent VVC for 10 to 14 days followed by suppressive therapy using fluconazole, single 150-mg dose weekly for 6 months (Pappas et al., 2009) (SOR: A).

TRICHOMONIASIS

Trichomoniasis is caused by a motile protozoan and affects 120 million women worldwide every year. It is usually sexually transmitted and is associated with transmission of other STIs (Forna, 2003). Risk factors for acquisition include multiple sexual partners and possibly a decrease in the normal vaginal acidity. Men are usually asymptomatic carriers, but 10% of nongonococcal urethritis in men is caused by *Trichomonas* (French et al., 2004).

Up to 50% of women with trichomoniasis are asymptomatic. Symptomatic women may complain of a yellow-green, malodorous discharge; vaginal burning; and dysuria. On physical examination, hemorrhagic, punctate cervical lesions are pathognomonic but are only present in 2% of

Figure 25-4 Trichomoniasis. Trichomonads are seen under high-power magnification in a wet mount prepared with physiologic saline. Usually, more immature epithelial cells are seen in the secretions of active trichomoniasis. (From Kaufman RH, Faro S. *Benign disease of the vulva and vagina*. 4th ed. St Louis, Mosby, 1994.)

cases (French et al., 2004). More common signs are foul-smelling purulent discharge, vaginal tenderness, vulvar erythema, and edema. The vaginal pH is usually basic. Office microscopy is first line for diagnosis of trichomoniasis (ACOG, 2006). The sample should be taken from the posterior vault, diluted in 2 drops of saline, and assessed quickly because motility of the protozoa diminishes rapidly (Figure 25-4). Although microscopy has good specificity (99%), motile trichomonads are seen in only 50% to 80% of culture-proven cases. Both the OSOM *Trichomonas* Rapid Test and the AFFIRM VP III are FDA-approved point-of-care tests for trichomoniasis and have higher sensitivity but more false-positives results (CDC, 2010). Thus, culture is the gold standard. Trichomonads can be reported on a Pap smear, but it is not recommended as a diagnostic test because of the low sensitivity (58%) (French et al., 2004). In men, the wet prep has poor sensitivity, so culture of a urethral, urine, or semen sample or NAAT testing on urine can increase the diagnostic rate.

Metronidazole or tinidazole single-dose therapy is effective for treatment of trichomoniasis. An alternative effective regimen is metronidazole, 500 mg orally twice daily for 7 days. Metronidazole gel is less effective (<50% cure rate) compared with oral metronidazole (CDC, 2010). Desensitization is recommended for patients who are allergic to metronidazole. Avoidance of alcohol is important with all nitroimidazoles. Metronidazole is not teratogenic in the first trimester (BASHH, 2007). Because most male sexual partners have asymptomatic trichomoniasis, simultaneous treatment is recommended.

If treatment fails with a 2-g single dose of metronidazole, a trial of metronidazole, 500 mg twice daily for 7 days, or a single 2-g dose of tinidazole is recommended (CDC, 2010). If this fails, a trial of tinidazole or metronidazole, 2 g orally once daily for 5 days, is recommended. Referral is advised for persistent failure. A test of cure is unnecessary if symptoms resolve (BASHH, 2007).

KEY TREATMENT

- A women with trichomoniasis should abstain from intercourse until both she and her partner have been treated and are asymptomatic (ACOG, 2006) (SOR: A).
- A single dose of a nitroimidazole can achieve parasitologic cure; tinidazole as a single 2-g dose may be most efficacious (CDC, 2010; Fornia, 2003) (SOR: A).
- If treatment fails with a single 2-g dose of metronidazole, a trial of metronidazole, 500 mg twice daily for 7 days, or a single 2-g dose of tinidazole is recommended (CDC, 2010) (SOR: B).

OTHER FORMS OF VAGINITIS

Aerobic vaginitis is characterized by purulent vaginal discharge with a dominant abnormal aerobic flora. Patients experience a foul-smelling nonfishy discharge, and examination may reveal erythema, inflammation, and ulcers of the posterior fornix. Although culture is the gold standard, the diagnosis is usually one of exclusion, with pH greater than 6.0, white blood cells (WBCs) on microscopy, and absence of hyphae or clue cells. Treatment with topical clindamycin has a good response (French et al., 2004). The addition of a topical estrogen may increase treatment success.

Irritant and allergic vaginitis should be considered in the differential diagnosis of vaginal complaints. Common etiologies include spermicidal products, douching solutions, diaphragms, latex condoms, and topical medications. The treatment is discontinuation of intravaginal products (French et al., 2004).

Cytolytic vaginitis is caused by an overgrowth of lactobacilli and cytolysis of squamous epithelial cells. Although it may be related to intravaginal products or other medication use, its etiology remains unclear. It can mimic VVC with a white, curdled-cheese discharge, and the pH range is typically 3.5 to 5.5. Treatment is discontinuation of intravaginal medications. Baking soda douches or sitz baths have been used, but minimal data exist to support this recommendation (French et al., 2004).

Desquamative inflammatory vaginitis is characterized by copious purulent discharge with squamous epithelial cell exfoliation. The etiology is unclear but likely multifactorial. Some cases may be linked to lichen planus spectrum. Laboratory evaluation reveals a negative wet mount, KOH, and cultures. Treatment options include a trial of local or systemic corticosteroids (French et al., 2004) or clindamycin suppositories.

Vulvar Lesions**Key Points**

- Visible condyloma should be treated. (SOR: C).
- Biopsy is indicated for treatment-resistant warts; chronic symptomatic lesions; and nevus-like, pigmented lesions. (SOR: B).
- Biopsy of lichen sclerosus is recommended to rule out vulvar squamous cell carcinoma. (SOR: B).

- Topical corticosteroids are the cornerstone of management for non-neoplastic epithelial disorders of the vulva. (SOR: C).

The differential diagnosis of vulvar lesions includes external genital warts (EGWs), *Candida*, herpes simplex, lichen sclerosus et atrophicus, lichen planus, psoriasis, and eczema. EGWs are caused by HPV (90% by HPV 6 or 11), which is primarily transmitted through sexual contact. Although exophytic warts are usually diagnosable with the naked eye, application of acetic acid can make flat warts visible. Biopsy is indicated for treatment-resistant warts; chronic symptomatic lesions; and nevus-like, pigmented lesions. For EGWs, treatment is divided into patient-applied (podofilox, imiquimod, and sinecatechins) and provider-administered (cryotherapy, podophyllin resin, trichloroacetic acid, and surgical removal) modalities. Cryotherapy is as effective as trichloroacetic acid and more effective than podophyllin. Podophyllotoxin and podophyllin are equally effective for clearance of EGWs and useful for small, solitary lesions. Imiquimod cream is also effective and should be applied to intact skin. Sinecatechin ointment is effective but should be avoided in immunocompromised patients (CDC, 2010). Topical interferon is effective and preferable to systemic interferon. Electrosurgery is at least as effective as cryotherapy and more effective than podophyllin (Buck, 2006). The quadrivalent vaccine is effective protection against the types of HPV that cause 90% of genital warts (CDC, 2010).

Non-neoplastic epithelial lesions of the vulva include lichen sclerosus, lichen planus, and lichen simplex chronicus (Figure 25-5). *Lichen sclerosus* is most common in postmenopausal women and presents with intense vulvar pruritus (see Figure 25-5, A). Physical examination initially reveals thickened, white skin not involving the vagina, which progresses to a thin, wrinkled, “cigarette paper” appearance. High-potency topical steroids are effective in alleviating symptoms and preventing progressive architectural damage. *Lichen planus* is an autoimmune disorder that may involve the vagina as well as vulva. High-potency topical steroids or hydrocortisone suppositories are effective for treatment. *Lichen simplex chronicus* presents as lichenified, erythematous plaques resulting from chronic itching and scratching (see Figure 25-5, B). Breaking the itch-scratch cycle is the cornerstone of treatment (O’Connell et al., 2008).

KEY TREATMENT

- For external warts, cryotherapy is as effective as trichloroacetic acid and more effective than podophyllin; electrosurgery is at least as effective as cryotherapy and more effective than podophyllin (Buck, 2006) (SOR: B).
- For lichen sclerosus, high-potency topical steroids are effective in alleviating symptoms and preventing progressive architectural damage (O’Connell et al., 2008) (SOR: B).
- For lichen simplex chronicus, breaking the itch-scratch cycle is primary treatment (O’Connell et al., 2008) (SOR: C).

Acute Pelvic Pain

Key Points

- Acute pelvic pain can be related to multiple organ systems.
- Gynecologic pain typically includes pregnancy complications, infection, and ovarian cysts.
- Clinicians should have a low threshold for treating PID because of the potential for long-term complications.

Acute lower abdominal pain can be caused by multiple organ systems. Urinary tract infections are often associated with pain over the bladder related to dysuria, frequency, and urgency of urination. Gastrointestinal (GI) causes of lower abdominal pain include acute appendicitis, diverticulitis, irritable bowel syndrome, and ischemic bowel.

Gynecologic causes of acute pelvic pain are usually related to complications of pregnancy, infections, or ovarian pathology. *Ectopic pregnancy* is a serious cause of acute pain in the context of an early pregnancy. Ectopic pregnancy should be suspected when the quantitative human chorionic gonadotropin (hCG) level does not increase appropriately or if the hCG level is greater than 1500 mIU and transvaginal ultrasonography does not show an intrauterine gestational sac. The dilation of the fallopian tube caused by the growing embryo is the etiology of the pain. Emergent treatment with either medication or surgery is necessary to prevent rupture of the tube. Ectopic pregnancy is usually diagnosed by ultrasonography. Treatment of an ectopic pregnancy can be surgical or medical. Single-dose methotrexate is the most frequently used regimen, 50 mg/m² of body surface intramuscularly, but no studies have compared efficacy between single-dose and multidose therapies (ACOG, 2008). Degenerating fibroid tumors may also cause

pain as a result of ischemia during pregnancy, usually in the second trimester.

Pelvic infections such as acute cervicitis and PID can cause pain associated commonly with abnormal vaginal discharge and systemic symptoms of infection. On examination, most affected women will have a purulent cervicitis, a tender uterus, and cervical motion tenderness. Both outpatient and inpatient treatment options are available from the [CDC's STI treatment guidelines \(2010\)](#). Outpatient treatment of PID usually includes intramuscular (IM) ceftriaxone and doxycycline for 10 days to cover both *Neisseria gonorrhoeae* and *Chlamydia* spp. Oral cephalosporins are not indicated in treatment of PID because of the increased national resistance of gonorrhea (CDC, 2010). Untreated PID can lead to an abscess or scarring that can cause infertility. The clinical diagnosis of PID has a positive predictive value of 65% to 90% (BASHH, 2005). Therefore, clinicians should have a low threshold for treating women with suspected PID.

Ovarian cysts are common and often cause no pain. When cysts rupture, however, women experience acute pelvic pain from peritoneal irritation. Large ovarian cysts are more likely to undergo torsion and can cause pain from ischemia.

KEY TREATMENT

- Medical and surgical treatments for ectopic pregnancy are equivalent when patient selection is appropriate (ACOG, 2008) (SOR: B).
- Single-dose methotrexate is the most common regimen (50 mg/m² body surface IM) for ectopic pregnancy (ACOG, 2008) (SOR: C).
- Clinicians should have a low threshold for treating women with suspected PID because of potential long-term consequences (BASHH, 2005) (SOR: C).

CHRONIC PELVIC PAIN

Key Points

- Chronic pelvic pain is an indication for up to 40% of the laparoscopies in the United States.
- The four most common causes of chronic pelvic pain are endometriosis, pelvic adhesions, interstitial cystitis, and irritable bowel syndrome.
- Up to 70% of women with chronic pelvic pain have more than one cause for their pain.
- Up to half of all women with chronic pelvic pain have a history of abuse or trauma.

Chronic pelvic pain is defined as noncyclic pain that lasts longer than 6 months. It occurs frequently, affecting up to 15% of all women at some point in their reproductive years. Chronic pelvic pain is a diagnosis associated with up to 10% of all outpatient gynecologic consultations, 40% of all laparoscopies, and 18% of all hysterectomies performed each year in the United States (Zondervan and Barlow, 2000). In 1996, the estimated cost of services related to chronic pelvic pain was \$880 million (Yunker et al., 2012).

Almost half of all women with chronic pelvic pain have a history of past sexual abuse or depression (Latthe et al., 2006). Women with a history of trauma have more severe symptoms (Meltzer-Brody et al., 2007). A meta-analysis of women with a history of abuse found an increased prevalence of functional bowel disorders, nonspecific chronic pain, and chronic pelvic pain (Paras et al., 2009). Drug and alcohol abuse are associated with an increased likelihood of pain (Latthe et al., 2006). There is no difference in prevalence based on race, ethnicity, education, or socioeconomic status (ACOG, 2004).

The etiology of chronic pelvic pain is frequently multifactorial and comes from multiple organ systems. Up to 70% of women have more than one cause of pain (Butrick, 2007). The most common gynecologic causes of chronic pelvic pain are endometriosis and pelvic adhesions. The most common GI cause is irritable bowel syndrome, and the most common urologic cause is interstitial cystitis (Bordman and Jackson, 2006). In addition, many women who have chronic pelvic pain also have some myofascial pain from the pelvic floor muscles (Table 25-10).

The initial evaluation of a woman with chronic pelvic pain includes a careful history to determine any pattern of the pain that would lead to a possible diagnosis. For example, a history of abdominal surgery increases the risk of pelvic adhesions. A complete medical, surgical, family, sexual, and psychological history should also be completed. It is important to determine how the pain is affecting the woman's daily life. The physical examination should include a general examination in addition to a thorough pelvic assessment. Every effort should be made to replicate the pain through a bimanual or rectovaginal examination.

Laboratory evaluation is focused on the likely diagnosis. Many women have pelvic ultrasonography for further evaluation of the pelvic anatomy. Ultimately, many women undergo a diagnostic laparoscopy to evaluate the etiology of the pain. Laparoscopy is normal in 35% to 40% of these women. Endometriosis is diagnosed in about 30% of women

Table 25-10 Common Causes of Chronic Pelvic Pain

Gynecologic	Endometriosis Pelvic adhesions Pelvic congestion Pelvic inflammatory disease Adenomyosis Vulvodynia Uterine myomas
Gastrointestinal	Irritable bowel syndrome Inflammatory bowel disease Chronic constipation Colitis Diverticulitis
Urologic	Interstitial cystitis Chronic urinary tract infections Urethral syndrome Radiation cystitis Urinary calculi
Musculoskeletal	Myofascial pain (abdominal wall or pelvic floor muscles) Fibromyalgia Coccygeal or low back pain Nerve pain

Modified from Bordman R, Jackson B. Below the belt: approach to chronic pelvic pain. *Can Fam Physician*. 2006;52:1556-1562 and Reiter RC. Chronic pelvic pain. *Clin Obstet Gynecol*. 1990;33:117-118.

at laparoscopy, and adhesions are diagnosed in about 25% (Howard, 2000).

Treatment of a woman with chronic pelvic pain should be multimodal to address the multifactorial nature of her pain (ACOG, 2004; Stones et al., 2009). A strong physician-patient relationship is imperative as a basis for successful treatment. First-line treatment includes pain control with nonnarcotic medication. Hormonal manipulation with medroxyprogesterone acetate, combined hormonal contraception, or gonadotropin-releasing hormone (GnRH) analogues can be effective treatments for endometriosis-related pain. GnRH analogues can only be used for up to 6 months because of side effects (e.g., menopausal symptoms, osteoporosis).

Laparoscopic treatment of endometriosis and lysis of dense adhesions are helpful in a subset of women. Lysis of adhesions that are not severe has not consistently decreased pain (ACOG, 2004). Hysterectomy is performed in women with untreatable pain and is most effective if accompanied by bilateral oophorectomy. Hysterectomy is major surgery with many potential complications but can cure some cases of pain related to endometriosis. Uterosacral nerve ablation is not an effective method for treating idiopathic chronic pelvic pain (Daniels et al., 2009).

None of the listed treatment modalities addresses the *physiology* of chronic pain. Several newer anticonvulsants (gabapentin, topiramate, valproic acid, pregabalin) and antidepressants, such as tricyclic antidepressants and selective serotonin reuptake inhibitors, have been successful in treating neuropathic pain from other sources. However, limited data are available in women with pelvic pain. Trigger point injections and botulinum toxin (Botox) injections in pelvic floor muscles show promise for treating myofascial pain (Gomel, 2007). Multidisciplinary treatment teams should include mental health professionals and physical therapists as well as physicians.

KEY TREATMENT

- Treatment of chronic pelvic pain should be multidisciplinary and include a mental health professional (Stones et al., 2009) (SOR: A).
- Uterosacral nerve ablation is **not** an effective method for treating idiopathic chronic pelvic pain (Daniels et al., 2009) (SOR: A).
- First-line treatment includes pain control with nonnarcotic medication (ACOG, 2004) (SOR: A).
- Hormonal manipulation with medroxyprogesterone acetate, combined hormonal contraception, or GnRH analogues can be effective treatments for endometriosis-related pain (ACOG, 2004) (SOR: A).

Menopause

Key Points

- The average age of menopause is 52 years.
- Vasomotor symptoms are the most common menopausal sign.
- The Women's Health Initiative (WHI) showed that hormone replacement therapy did not prevent cardiovascular disease in postmenopausal women and in fact increased the risk of breast cancer.

Menopause is defined as the cessation of menstruation. It is a retrospective diagnosis that comes after a woman has not menstruated for 12 months. The menopausal transition occurs over several years as the number of ovarian follicles slowly decreases. This period in a woman's life can include menstrual cycles of variable lengths and durations, called the *perimenopause*. Because of the waxing number of follicles, the ovaries require higher levels of estrogen to stimulate a LH surge and subsequent ovulation. Consequently, serum levels of estrogen can vary substantially from one cycle to the next. The first physiologic change noted is a decrease in inhibin B levels (Burger et al., 1999). Subsequently, FSH level will increase in response to lower estrogen levels. An FSH level greater than 40 U/L on two separate occasions at least 1 month apart is diagnostic of menopause. The main pathologic cause of abnormal vaginal bleeding during this period is anovulation in those cycles when estrogen did not reach target levels.

The average age of menopause in the United States is 52 years old. The majority of women will go through menopause between ages 40 and 58 years. Menopause before age 40 years is defined as premature ovarian failure and may be related to other autoimmune disease. Factors associated with age at menopause include smoking and family history (Nelson, 2008).

Vasomotor symptoms, including hot flashes and night sweats, are the most common symptoms of menopause. Some women may begin to experience these symptoms years before their final menstrual period, during the months where their estrogen levels are lower. Many women experience symptoms for several years. Up to 10% of women

continue to experience vasomotor symptoms into their 70s (Politi et al., 2008). Symptoms are worse in women who experience premature ovarian failure, have a premenopausal oophorectomy, are overweight or obese, or are depressed (Hendrix, 2005). Treatment of vasomotor symptoms begins with lifestyle changes and can also include pharmacologic treatment with hormonal or nonhormonal medications. Women may be able to manage their vasomotor symptoms by wearing natural-fiber clothing in layers, avoiding spicy foods, avoiding hot environments (e.g., saunas, hot tubs), avoiding alcohol, exercising, and maintaining a healthy weight.

Pharmacologic treatment of vasomotor symptoms includes HT at the lowest effective doses orally or transdermally (Bachmann et al., 2007). HT should include both estrogen and progestin in women who have a uterus and estrogen alone in women who have had a hysterectomy. HT should be used in women at the lowest possible doses to treat symptoms for as short a time as possible (North American Menopause Society [NAMS], 2012). Transdermal HT has a lower risk of thromboembolism (ACOG, 2013). In women for whom HT is contraindicated or who are worried about the risks, several nonhormonal options have been studied. Antidepressant medications such as fluoxetine, paroxetine, and venlafaxine have been shown to be better than placebo. Gabapentin, 900 mg/day (dosed either as 300 mg three times a day or 900 mg at night), is also better than placebo in treating hot flashes (Grady, 2006).

Many women use complementary therapies to treat vasomotor symptoms. Various herbal preparations (e.g., black cohosh) have been used to treat vasomotor symptoms with varying success. Many women also obtain relief from soy products or other isoflavones. However, none of these treatments has consistently been more effective than placebo in randomized trials (Nelson et al., 2006). Stress management and meditation show promise in controlling these troublesome symptoms (Tremblay et al., 2008).

Atrophic vaginitis, or thinning of the vaginal epithelium caused by a lack of estrogen stimulation after menopause, is common, affecting 10% to 40% of all postmenopausal women. Women complain of vaginal dryness, irritation, and pain with intercourse. Unlike vasomotor symptoms, atrophic vaginitis does not develop immediately after menopause but causes symptoms months to years after the withdrawal of estrogen. Left untreated, atrophic vaginitis is progressive and is unlikely to improve spontaneously. Treatment of atrophic vaginitis begins with use of appropriate water-based lubricants to make intercourse more comfortable. The mainstay of treatment is vaginal estrogen (NAMS, 2013). Several preparations of vaginal estrogen are available in the United States. Estrogen cream, tablets, and a slow-release silicone ring are all well tolerated and are equally effective in reducing symptoms of atrophic vaginitis. Because the vaginal estrogen has limited systemic absorption, a concomitant dosing with progestin is not necessary, although safety studies are not available for more than 1 year of therapy (NAMS, 2013). The FDA recently approved a dedicated product for treating atrophic vaginitis and associated dyspareunia. Ospemifene is a selective estrogen receptor modulator and is effective at reducing symptoms related to atrophic vaginitis. Its main side effect is hot flashes (Portman et al., 2013).

Other common menopausal changes include memory difficulty (mostly with word finding), mood lability, and decreased libido (from decreased testosterone levels after menopause).

Before the WHI, HT was used for prevention of heart disease and osteoporosis. The WHI was a large (>16,000 participants) population-based study of women between 50 and 79 years studying the effectiveness of estrogen plus progesterin on congestive heart disease (CHD) prevention. The trial was stopped early because of excess cardiovascular and breast cancer events. There was an excess of seven CHD events, eight strokes, eight breast cancers, and 14 venous thromboembolic events per 10,000 women. The estrogen-only arm of the study was stopped 2 years later because of excess strokes (12 per 10,000 women). There was no statistically significant increase in breast cancer incidence in the estrogen-only group (Manson et al., 2013). The HT group in both arms of the study had fewer hip fractures.

KEY TREATMENT

- HT can be used for treatment of menopausal symptoms but should be used at the lowest possible dose for the shortest time possible with consideration of non-oral routes (NAMS, 2013) (SOR: C).
- Atrophic vaginitis is treated most effectively by vaginal estrogen cream or tablets, usually three times a week initially and titrated down based on symptoms (NAMS, 2013) (SOR: A).
- Antidepressant medications (fluoxetine, paroxetine, venlafaxine) are better than placebo in treating hot flashes (Grady, 2006) (SOR: A).
- Gabapentin (900 mg/day—dosed either 300 mg three times a day or 900 mg at bedtime) is also better than placebo in treating hot flashes (Grady, 2006) (SOR: A).
- Stress management and meditation show promise in controlling troublesome menopausal symptoms (Tremblay et al., 2008) (SOR: B).

Contraception

DIANE M. HARPER, LAUREN E. WILFLING, and CHRISTOPHER F. BLANNER

CHAPTER OUTLINE

Combined Oral Contraceptive Pills, 491
Progestin-Only Contraception, 499
Additional Contraceptive Choices, 500

Adolescent Concerns, 501
Additional Information, 501

Key Points

- Estrogen and progestin dosing often needs to be changed over time from the adolescent to perimenopausal years as a woman ages.
- There are multiple choices of estrogen and progestin contraceptives that will meet the ever-changing needs of most women.
- Progestin-only contraception creates an estrogen deficiency state, leading to early cycle bleeding or continuous bleeding throughout the cycle.
- Copper intrauterine devices (IUDs) are the most effective emergency contraception.
- Low dose progestin IUDs are recommended for early adolescence to avoid noncompliance.

Healthy People 2020 aims to reduce unintended pregnancy from 49% of pregnancies to 44% of pregnancies over the next 10 years (Guttmacher Institute, 2013). Nearly half of these pregnancies result in abortion (Figure 26-1). The youngest adolescent females have the highest rate of unintended pregnancy (Figure 26-2). This results in delayed independent social development, such as being less likely to graduate from high school or attain a GED before 30 years of age or receiving more federal aid for longer time frames than those who do not have an unintended pregnancy (Hoffman 2006; Hoffman and Maynard, 2008).

Regardless of whether the pregnancy is intentional or not or whether the mother and child are socially dependent or not, birth-related deaths are real and occur at all ages, more frequently as women age (Figure 26-3). The use of low-dose hormonal contraceptives in the form of pills, implants, IUDs, rings, and patches has significantly reduced the risk of death from hormone-related side effects in all age groups except women 40 years and older, in whom only oral contraceptive pills (OCPs), regardless of tobacco use, carry a higher death risk. The social use of contraceptives is thus twofold: to prevent premature deaths of women of childbearing age and to provide choice about conception.

The Centers for Disease Control and Prevention (CDC, 2010) has published a pictorial guide of all contraceptive methods and their failure rates (Figure 26-4). Among those 15 to 44 years old in the United States who use contraception, OCPs are the most common method used (27.5%) followed closely by female sterilization (26.6%). Male condom (16%) and male sterilization (10%) constitute the next

largest share of the contraceptive burden, with IUDs and withdrawal (coitus interruptus) each sharing about 5% of the burden (Mosher and Jones, 2010).

This chapter describes the decision-making process that has the potential to minimize side effects and maximize compliance among adolescents and women of all ages who choose to take OCPs on a daily basis. The method relies on an understanding of the side effects of estrogen and progestin and the subtle change in hormonal concentrations that may make the difference between compliance and noncompliance. The effects of the hormones on the hypothalamic–pituitary–ovarian (HPO) axis and their effects on each other cannot be separated as cleanly, as these tables represent. The metabolic activity of progestins varies widely, and the attempt to convert all compounds to a norethindrone equivalent is limited by extrapolation from animal data. But the hallmarks of this decision-making methodology, which include categorization of symptoms of each of the hormonal components, flexibility in preparations available for prescribing, and patience with trying new formulations, allow practicing physicians to find the hormonal formulations that match women’s ever-changing bodies.

Combined Oral Contraceptive Pills

Key Points

- Modern OCPs have multiple mechanisms by which they cause infertility and risks that must be weighed against the risk of pregnancy.
- Ethinyl estradiol, the estrogen component of all combined OCPs except for one, is a key driver of pill-related symptoms, and the dose should be adjusted to the particular woman’s needs.
- There are four generations of progestins currently in use in the United States, with each generation having unique symptoms and side effects leading to unique medical, social, and legal issues (Davtyan, 2012).
- OCPs can both mask and enhance androgenic symptoms in individual women, and these affects can be a key part of comprehensive contraceptive management.
- The initial selection of an OCP should be individual specific, but for those with no prior menstrual difficulties, no risk factors, and no experience with using OCPs, any preparation up to 735 µg of ethinyl estradiol per 28-day cycle is appropriate.

Exogenous hormones of sufficient concentration alter the HPO axis and inhibit ovarian cycling, thus causing temporary infertility. Low-dose combined OCPs, however, rely more on the progestational component to cross-link the cervical mucus, making it impenetrable to sperm, than on the estrogen to inhibit follicular maturation. This nuance allows personal sensitivities to hormone concentrations to direct pill-prescribing patterns.

The risk of taking estrogen-containing contraceptives must be weighed against the risk of pregnancy. Those at increased risk of side effects from combined OCPs are women who smoke more than 15 cigarettes a day; who are 35 years old or older; or who have cardiac disease, hypertension, cerebrovascular disease, renal disease, diabetes with end-organ damage or a family history of diabetes, sickle cell disease (hemoglobin SS or SC), systemic lupus erythematosus, active gallbladder disease, congenital hyperbilirubinemia (Gilbert's disease), history of death of a parent or sibling from myocardial infarction before age 50 years (especially if it was a mother or sister), family history

of hyperlipidemia, risk for deep vein thrombosis or pulmonary embolism, or migraine headaches.

No OCP should be used in women with undiagnosed abnormal genital bleeding, liver tumors, or breast cancer or other estrogen- or progestin-sensitive cancer or who are pregnant.

ESTROGEN

Prior OCP formulations used high-dose mestranol as the estrogen component of OCPs, but because of the serious side effects of mestranol, as well as other high-dose estrogens, a low-dose ethinyl estradiol is currently used in all pill formulations except for one quadriphasic pill.

The metabolism of ethinyl estradiol varies significantly from individual to individual and from one population to another population (Goldzieher, 1990) with the same single dose able to create side effects of excessive systemic estrogen in one woman and side effects of estrogen deficiency in another (Table 26-1). Individual effects of the hormones cannot be precisely defined, but the effects of estrogen are often a predominant driver of symptom expression. This decision-making guide allows changes in OCPs to trend with the woman's needs. There are six pills with ethinyl estradiol content per 28 days below 500 µg, four below 600 µg, eight below 700 µg, 10 below 800 µg, two below 900 µg, and four with ethinyl estradiol content per 28 days above 1000 µg.

PROGESTIN

There are four generations of progestins used in OCPs. The first-generation progestins (e.g., norethindrone and norethindrone acetate) were formulated for ovarian suppression. Second-generation progestins are mainly used alone in the depomedroxyprogesterone acetate (DMPA) formula or as the progestin for hormone therapy in postmenopausal women. Third- (e.g., levonorgestrel, desogestrel, gestodene) and fourth- (e.g., drospirenone) generation

Figure 26-1 Percentage of unintended pregnancies ending in abortion by age group. (Data from Finer LB, Zolna MR. Shifts in intended and unintended pregnancies in the United States, 2001-2008. *Am J Public Health.* 2014;104(suppl 1):S43-S48.)

Figure 26-2 Percentage of births that were intended at conception, by mother's age and marital status at birth: United States, 2006 to 2010. (Data from Mosher WD, Jones J, Abma JC. Intended and unintended births in the United States: 1982-2010. *Natl Health Stat Report.* 2012;(55):1-28.)

Figure 26-3 Birth-related and method-related deaths per 100,000 nonsterile women per year by age group and contraceptive choice. (Data from Ory HW. Mortality associated with fertility and fertility control: 1983. *Fam Plann Perspect*. 1983;15:50-56.)

progestins were developed for the antiestrogenic properties in the endometrium, making it inhospitable for implantation, in addition to addressing the systemic effects of estrogen excess (bloating and cyclic weight gain) and androgenic excess (acne, hirsutism, and oily skin). These progestins have minimal androgenic and increased mineralocorticoid effects (Table 26-2). Although increasing doses of estrogen in OCPs are associated with increased risk of arterial thrombotic events, an increased threefold risk of venous thrombotic events occurs equally with the first three generations of progestins (Stegeman et al., 2013).

The only fourth-generation progestin used in OCPs in the United States is drospirenone. This progestin is derived from 17 α -spironolactone rather than from the 19-nortestosterone associated with prior generations of progestins. Over time, studies have shown a doubling of the risk of venous thromboembolism in OCPs containing drospirenone than in those containing levonorgestrel, and a sixfold increase over those not using any OCP (Wu, 2013). More than \$1.6 billion has been paid in lawsuits to Yaz and

Yasmin users. Use of contraceptives containing drospirenone has plummeted for this reason.

The progestin content converted to norethindrone equivalents per 28 days ranges from less than 5 mg to more than 35 mg of norethindrone with a single formulation below 5 mg for those exquisitely sensitive to progestin excess, three formulations below 10 mg, eight at or below 15 mg, four below 20 mg, seven below 25 mg, and four above 30 mg norethindrone equivalents per 28 days.

ANDROGEN

Androgenic symptoms (Table 26-3) are only expressed when androgen is overabundant. To decrease androgen production, combined OCPs can act to suppress the ovarian testosterone production as well as increase the quantity of sex hormone-binding globulin, which binds whatever free testosterone there is available. With the lower dose contraceptive combinations, ovarian suppression is less likely to occur, allowing the exogenous progestin formulations in

Effectiveness of Family Planning Methods

CS 242797

CONDOMS SHOULD ALWAYS BE USED TO REDUCE THE RISK OF SEXUALLY TRANSMITTED INFECTIONS.

Other Methods of Contraception

Lactational Amenorrhea Method: LAM is a highly effective, temporary method of contraception.

Emergency Contraception: Emergency contraceptive pills or a copper IUD after unprotected intercourse substantially reduces risk of pregnancy.

the contraceptives to contribute to androgenic side effects. The side effects are again individual in expression and can be managed by changing pills.

CHOOSING A COMBINED ORAL CONTRACEPTIVE PILL

Table 26-4 lists the contraindications to OCPs. Table 26-5 lists the OCPs currently approved in the United States by the Food and Drug Administration (FDA), with their estrogen, progestin, and androgen content per 28-day cycle (Dickey and Dickey, 2010; Harper, 2001). Many competing products have the same composition. Of note, generics may not always be cheaper than brand-name drugs and by law need to be only 80% as effective (bioequivalent; CDC, 2014; Hupila and Smith, 2008) as the brand-name product.

Selection of the initial pill formulation should take into account the patient's body mass index because obese

women require, in general, higher doses of estrogen and progestin to induce infertility without bleeding side effects (Reifsnider et al., 2013). Other patient characteristics to consider are acne, depression, and propensity to gain weight, all of which can be modified by a change in hormonal dose. A physical examination, including blood pressure, lipid levels, liver and renal function, query about pregnancy status, and documentation of current bleeding patterns, is recommended before a woman starts OCPs.

For women with no prior menstrual difficulties, no risk factors, and no experience with using OCPs, any preparation up to 735 µg of ethinyl estradiol per 28-day cycle is appropriate. Pills with lower androgen levels may be less likely to cause acne and other adverse cosmetic effects.

A 3-month trial is necessary to understand how the body will respond to any new hormonal regimen. If this will be the patient's first experience with OCPs, warnings about breast tenderness and nausea increasing over the first

month of hormone use are necessary to prevent premature cessation (“I can’t take pills; they don’t agree with me.”). If the patient has adverse effects after 3 months, they are valid and should be addressed. She should be assured that continuing problems can likely be corrected by switching to a different pill. Only about 16% of women are unable to take OCPs for medical reasons (Shortridge and Miller, 2007). Most women quit using OCPs because of side effects that remain unaddressed by providers who lack knowledge of the 34 different hormonal combinations possible.

New pill regimens should be started at the end of a 28-day cycle of prior hormones and can be done based on patient symptomatology rather than requiring an office visit (Guttmacher Institute, 2008). Dispensing three packages at a time allows uninterrupted dosing. Symptom-based adjustments can be managed in a stepwise fashion: (1) identify the most significant adverse effects and the hormone most likely to be the cause, (2) determine the content of the current pill formulation, (3) keep the level of the components that are not causing problems stable, and (4) find a pill with a greater or lesser amount of the component responsible for the side effect (see Table 26-5).

EXAMPLES OF MANAGING COMBINED ORAL CONTRACEPTIVE PILL SIDE EFFECTS

Key Points

- Changing the estrogen-to-progestin ratios to prevent breakthrough bleeding early in the cycle before ovulation requires changing to a pill with more estrogen while keeping the progestin dose similar. Breakthrough bleeding late in the cycle after ovulation (when more progestin is needed) requires changing to a pill with more progestin while keeping the estrogen dose similar.
- Heavy bleeding with periods and bloating requires changing to a pill with a lower estrogen-to-progestin ratio, accomplished by decreasing the estrogen dose. Estrogen builds up the endometrium, leading to hypermenorrhea.
- Breakthrough bleeding throughout the cycle requires changing to a pill with more estrogen without changing the progestin dose.
- Elevated blood pressure and depressed mood require changing to a pill with less progestin.

Menstrual Irregularities

A college-age female on the cross-country team has taken Apri for the past 2 years. She reports over the past 6 months, she has 3 days of a light period followed by 4 days without bleeding and then 3 days of spotting. This breakthrough bleeding, which is distressing to her, is caused by estrogen deficiency. A pill with more estrogen and a similar amount of progestin would be ideal. Tri-Norinyl or Ortho Novum 7/7/7 is a good choice, with a sufficient increase in estrogen and almost the same amount of progestin.

A 16-year-old young woman taking Tri-Sprintec complains of brown blood spotting her underwear beginning 3 to 5 days before her period and numerous soaked pads during her period. Because she is a competitive swimmer, the heavy bleeding is particularly troublesome, leaking around tampons. Her late cycle (days 10-21) breakthrough bleeding and hypermenorrhea are probably attributable to a progestin deficiency. Tri-Sprintec has very low progestin but a common estrogen content, so there is an abundant choice for an alternative. She is switched to Necon 0.5/35. Three months later, the spotting has resolved, but her heavy periods have continued. She also reports bloating the week before her period, which she says interferes with her swimming performance. Hypermenorrhea and bloating are symptoms of estrogen excess, so she should be given a pill with less estrogen. Cyclessa, a good alternative, might work well for her.

A 42-year-old woman not yet experiencing perimenopausal symptoms has been using Mircette. Recently, she has experienced 2 days of bleeding with brown spotting every other day of her cycle. Because breakthrough bleeding is occurring continuously throughout the cycle, her endometrium needs more estrogen than Mircette provides. Desogen would increase the estrogen level while keeping her progestin and androgen levels constant. The Necon 0.5/35 group, with more estrogen, slightly less progestin, and half the androgen, is also a good candidate.

Weight Gain and Depression

An 18-year-old woman with polycystic ovarian syndrome (PCOS) was not well controlled on a low-estrogen pill and was switched to Demulen 1/35. At the 3-month follow-up, her blood pressure was mildly elevated (140/92 mm Hg), she had gained 30 lb, and she complained of a "blue mood."

She would like to stay with the pill because it has helped her PCOS symptoms, but she needs a different one. The problem appears to be a progestin excess. Many OCPs, such as Genora 1/35, have 735- μg ethinyl estradiol and less progestin. She is given a 3-month supply and scheduled for monthly blood pressure monitoring.

COMBINED PHASIC FORMULATIONS AND EXTENDED CYCLE PILLS

Initial formulations were monophasic, with no variation of estrogen and progestin doses throughout the first 21 days of the 28-day cycle, with inert placebo or iron supplementation added to the last 7 days of the cycle. Subsequent biphasic formulations attempted to reduce breakthrough bleeding and other side effects by more closely mimicking the initial estrogen peak followed by the progestin peak of the menstrual cycle.

Triphasic formulations initially varied only the progestin component to increase the dose in three steps over the course of 21 days within the cycle. Later triphasic formulations kept the progestin component constant and increased the estrogen content over the 21 days of the cycle. One set of formulations maximizes the estrogen content midcycle (low, high, low), and the progestin content progressively increases over the 21 day cycle.

Extended-cycle pills were created to minimize the risk of anemia and reduce withdrawal bleeding blood loss to four times a year. Three cycles of 28 days were combined followed by a 7-day withdrawal period. The initial extended cycle was monophasic 30 μg of ethinyl estradiol with 0.15 mg of levonorgestrel for 84 days (e.g., Seasonale, Introvale, Quasense, Jolessa). Estrogen deficiency symptoms of early cycle bleeding or continuous spotting throughout the 84-day cycle were experienced, leading to the next extended-phase formulation that remained the same for the initial 84 days but added 10 μg of ethinyl estradiol to the original 7 placebo days (e.g., Seasonique, Amethia, Camresse, Daysee). Finally, a lower estrogen and lower progestin formulation for reduced thromboembolism risk has been approved using 20 μg of ethinyl estradiol with 0.10 mg of levonorgestrel for 84 days followed by 10 μg of ethinyl estradiol for the remaining 7 days of the extended cycle (e.g., LoSeasonique, AmethiaLo, CamresseLo).

Quadriphasic pills are the most recent formulation meant to more closely mimic the menstrual cycle and reduce metrorrhagia or irregular cyclic bleeding. The 28-day cycle formulation (Figure 26-5, A) contains four different combinations of estrogen and progestin. The new estrogen formulation (estradiol valerate) initiates at the highest dose and decreases to zero over the cycle. The fourth-generation progestin (dienogest) is separated into two different doses, with the higher dose for 17 days over the midcycle.

The extended quadriphasic formulation (Figure 26-5, B) contains four doses of estrogen and a single dose of progestin. The first 42 days contain 20 μg of ethinyl estradiol and 0.15 mg of levonorgestrel in a monophasic attempt to stabilize the endometrium. There is no monophasic pill combination that contains this low dose of estrogen balanced with the highest approved dose of levonorgestrel. The next two 21-day segments increase the estrogen dose to 25 μg of ethinyl estradiol and then to 30 μg all with the

same high dose of 0.15 mg levonorgestrel. The final 7 days of the extended period reduce the estrogen dose to 10 μg of ethinyl estradiol without any progestin.

Altering the phasic component of the pill formulation should be considered after finding the best range of 28-day cycle hormone doses.

Progestin-Only Contraception

Key Points

- Unlike combined estrogen–progestin options, progestin-only options are useful for breastfeeding women in the initial postpartum period.
- Progestin-only options include pills, an injection, and a subdermal implant, all of which work by thickening cervical mucus and thinning the endometrium.
- Progestin-only pills must be taken at the same time every day to be effective.
- The loss of bone mineral density with the use of DMPA must be considered when prescribing, especially in adolescent and perimenopausal women.

Progestin-only contraceptives are useful for women who wish to immediately start breastfeeding postpartum. CDC recommendations support immediate use of progestin-only pills, DMPA injections, or progestin implants (CDC, 2011) despite some who recommend a 3-week hormone-free period because of increased risks of venous thrombosis (Marik and Plante, 2008; Rodriguez and Kaunitz, 2009). The progestin-only pills available in the United States have one dose, which is 0.35 mg norethindrone for a total of 9.8 mg per 28-day cycle. This dose of progestin causes cervical mucus thickening to be impenetrable to sperm and thinning of the endometrium to reject implantation. The short half-life of this progestin and its mechanism of action requires the woman to take the pill at the same time every day without more than 3 hours' variance (Wright et al., 1970). A European progestin-only pill contains 75 μg of desogestrel and allows up to 12 hours variance in the daily dose (Korver et al., 2005).

The most common side effects associated with the progestin-only pills are irregular bleeding, depression, and acne outbreaks (McCann and Potter, 1994; St-André et al., 2012). These symptoms are worse with the DMPA (150-mg) intramuscular shot given every 90 days and with the subdermal implants proven effective through 3 years (68 mg of etonogestrel, Nexplanon) (Hoggart et al., 2013). Of note is the bone mineral density loss that occurs within 2 years of continuous DMPA use (Isley and Kaunitz, 2011). This is especially troublesome among adolescents who have not completed their bone mass accumulation and among perimenopausal women who have started to actively lose bone mass. In 2004, the FDA added a black box warning to DMPA, but the World Health Organization (WHO) and American College of Obstetricians and Gynecologists (ACOG) have not included this risk in their recommendations (ACOG Committee on Gynecologic Practice, 2008; FDA, 2014; WHO, 2007).

Figure 26-5 Quadriphasic design. **A**, Twenty-eight-day cycle (Natazia). **B**, Ninety-one-day cycle (Quartette).

Additional Contraceptive Choices

Key Points

- A flexible, vaginally inserted plastic ring and a transdermal patch are additional contraceptive options; both have an estrogen component and the third-generation progestin, levonorgestrel, which has been associated with venous thrombosis.
- Options for emergency contraception, when used within 5 days of intercourse, are the copper IUD and hormonal options, including estrogen and progestin pills and progestin-only pills.
- Hormonal emergency contraceptives are currently sold over the counter in the United States for women 17 years of age and older.
- IUDs prevent fertilization by creating a sterile inflammatory reaction in the uterus.
- The copper-containing and levonorgestrel-containing IUD options are among the most effective reversible contraceptive options, with irregular bleeding and cramping being the most common reasons for removal.

CYCLIC HORMONAL CHOICES

Nuvaring, the only flexible plastic ring that is inserted intravaginally, has the lowest ethinyl estradiol content at 315 μg per 28-day cycle. Ortho-Evra, the only transdermal contraceptive patch, contains 420 μg per 28-day cycle. The progestin is third generation for etonogestrel and norelgestromin, respectively. These progestins have resulted in significant numbers of venous thrombotic events for which the manufacturers of Nuvaring (Merck) and Ortho-Evra (Ortho McNeil) have reached multimillion dollar settlements (Feeley and Voreacos, 2014; Voreacos, 2008). As with any contraceptive choice, a discussion with individual patients about the risks and benefits of Nuvaring or Ortho-Evra should be undertaken before its initiation, and any symptoms should be reported immediately.

EMERGENCY CONTRACEPTION

Hormonal emergency contraception has received over-the-counter approval in the United States for women age 17 years and older within 5 days of intercourse for purposes of preventing unintended pregnancies. A total of 11%

of sexually experienced women 15 to 44 years old in the United States have used hormonal emergency contraception, with the largest proportion of users 20 to 24 years of age (Daniels et al., 2013). Nine times as many women choose to use oral hormonal emergency contraception as the copper IUD (Belden et al., 2012) despite evidence of superior efficacy of the copper IUD (risk reduction of 99.2% vs. 89% and 74% with progestin-only and estrogen-progestin pills, respectively [Cheng et al., 2008; Trussell et al., 2003; Zhou and Xiao, 2001]). This is assumed to be attributable to the need for a health care professional to insert the copper IUD within 5 days of intercourse; the false impression that one cannot remove the IUD for 10 years; and, depending on the clinic, a need for upfront payment.

INTRAUTERINE CONTRACEPTIVE DEVICES

Intrauterine devices prevent fertilization, not implantation. A foreign body within the uterus causes a sterile inflammatory reaction that is toxic to sperm, causing inhibition of sperm motility, reduced sperm capacitation and survival, and sperm phagocytosis (Ammälä et al., 1995; Patai et al., 2003).

There are two types of IUDs. One contains copper as described in the emergency contraception section, with 380 mm² copper surface that remains effective for up to 20 years (ParaGard). The mechanism of action of the IUD is augmented by copper salts. The other contains levonorgestrel in two dosage forms. The 52 mg of levonorgestrel (LNg20) releases 20 µg of levonorgestrel daily, declining to 10 to 14 µg at 5 years (Mirena), and is the same size as the copper IUD. The 13.5-mg levonorgestrel dose (LNg14) releases 14 µg daily, decreasing to 5 µg at 3 years (Skyla), and is smaller for adolescents and those with a stenotic os. Both the copper and LN IUDs cause irregular bleeding and cramping, which are the most common reasons for early removal (Teal and Sheeder, 2012). The LN IUD can result in amenorrhea in some women.

Adolescent Concerns

Key Points

- Adolescents have the highest rate of unintended pregnancy at 77% for 15- to 19-year old young women in the United States.
- Discontinuation rates of all forms of contraception except IUDs and subdermal implants is highest in adolescents among all age groups; rates are greater than 50% at 24 months.
- The ACOG recommends that IUDs be considered as a first-line contraceptive option in sexually active adolescents.

Adolescents have the highest rate of unintended pregnancy and the highest discontinuation rate with any form of contraception (ACOG, 2012; Finer & Zolna, 2014; Mosher

et al., 2012). Although many adolescents chose a contraceptive method initially, they discontinue them by 24 months at the following rates: 23% for IUD (no difference between copper or LN), 31% for subdermal implants, 57% for OCPs, 60% for the patch, 59% for the ring, and 62% for DMPA (O'Neil-Callahan et al., 2013). The ACOG has recently asserted the most cost-effective method for adolescents is the long-acting reversible contraceptive choice of an IUD either with or without hormone (ACOG, 2012). The risk of infertility caused by multiple sexual partners seen in a prior generation of IUDs is vastly diminished because of the monofilament tail on this generation of IUDs.

Additional Information

Key Points

- Considering all contraceptive options except abstinence, male and female condoms offer the most protection against sexually transmitted infections.
- Sterilization methods are some of the most effective family planning methods, but failures do occur.
- Estrogen- and progestin-containing pills are one of the most commonly used contraceptive methods, with management of formulations being a key part of individualization.

The new 10th revision of the *International Statistical Classification of Diseases and Related Health Problems* (ICD-10) billing codes for reimbursement around contraceptive issues are included in Table 26-6.

No method of contraception protects completely against STIs. Barrier methods, such as the male and female condom, offer the highest protection after abstinence. Spermicides such as nonoxynol-9 are no longer recommended because of their facilitative effect for human papillomavirus and HIV infections (Gupta and Nutan, 2013). If a lubricant is desired, saline-based lubricants are safest. Diaphragms, cervical caps, and sponges offer other barrier methods that may appeal to some women.

Fertility awareness methods have the greatest failure rate but are often methods of choice because there are no exogenous hormones or devices to which side effects may occur (Gribble et al., 2008).

Sterilization is meant to be permanent, but failures do occur. Female sterilization by tubal disruption is associated with a 2 to 10 in 1000 failure rate; male sterilization by vasectomy has an 11 in 1000 failure rate (ACOG, 2013; Jamieson et al., 2004). Essure, a hysteroscopically placed nickel-containing coil, fails to scar the fallopian tubes, resulting in pregnancy in 2 or 3 of 1000 procedures (Bradley et al., 2008), and is associated with nickel allergies.

The most commonly used contraceptive methods are those using the combination of estrogen and progestin in varying proportions with monthly withdrawal bleeding. Designing the doses in the combination to result in the least amount of monthly bleeding and the fewest side effects is possible with dedication and patience.

Table 26-6 ICD-10 Codes Used for Contraception Reimbursement

Z30.0	Encounter for general counseling and advice on contraception
Z30.0.1	Encounter for initial prescription of contraceptives
Z30.011	Encounter for initial prescription of contraceptive pills
Z30.012	Encounter for initial prescription of emergency contraception
Z30.013	Encounter for initial prescription of injectable contraceptive
Z30.014	Encounter for initial prescription of intrauterine contraceptive device
Z30.018	Encounter for initial prescription of other contraceptives
Z30.019	Encounter for initial prescription of contraceptives, unspecified*
Z30.02	Counseling and instruction in natural family planning to avoid pregnancy
Z30.09	Encounter for other general counseling and advice on contraception*
Z30.2	Encounter for sterilization
Z30.4	Encounter for surveillance of contraceptives
Z30.40	Encounter for surveillance of contraceptives, unspecified*
Z30.41	Encounter for surveillance of contraceptive pills
Z30.42	Encounter for surveillance of injectable contraceptive
Z30.43	Encounter for surveillance of intrauterine contraceptive device
Z30.430	Encounter for insertion of intrauterine contraceptive device
Z30.431	Encounter for routine checking for intrauterine contraceptive device
Z30.432	Encounter for removal of intrauterine contraceptive device
Z30.433	Encounter for removal and reinsertion of intrauterine contraceptive device
Z30.49	Encounter for surveillance of other contraceptives*
Z30.8	Encounter for other contraceptive management including post-vasectomy sperm count
Z31.4	Encounter for procreative investigation and testing
Z31.41	Sperm count for fertility testing
Z31.42	Sperm count following sterilization
Z30.9	Encounter for contraceptive management, unspecified*
Z31	Encounter for procreative management
Z31.61	Procreative counseling and advice using natural family planning
Z32.0	Encounter for pregnancy test
Z32.01	Encounter for pregnancy test, result positive
Z32.02	Encounter for pregnancy test, result negative

*Code is unlikely to be reimbursed.

ICD-10, International Statistical Classification of Diseases and Related Health Problems, 10th ed.

KEY TREATMENT

- OCPs are the most commonly used method of contraception and the most commonly abandoned method because of side effects (SOR: A).
- Long-acting reversible contraceptives, such as copper IUDs and levonorgestrel IUDs, are recommended for adolescents seeking contraception (SOR: C).
- Progestin-only OCPs are useful in women who wish to breastfeed in the postpartum period (SOR: C) or are otherwise unable to tolerate an estrogen component of contraception. The short half-life of this medication requires women to take it at the same time every day, within 3 hours.
- Hormonal emergency contraception is available in both oral and intrauterine forms. Although more women are choosing to use the oral formulations, copper IUDs are the most effective in preventing unwanted pregnancies (SOR: A).

Arrhythmias, 575**

Cardiovascular disease (CVD) is the leading cause of morbidity and mortality for both men and women in the United States and most other parts of the developed world. In recent decades CVD has become a leading cause of death and disability in most regions of Asia. Enormous efforts continue to be expended to stem the physical, emotional, and socioeconomic costs attributable to CVDs throughout the world. Significant progress is being made. Between 2000 and 2010, death rates associated with CVD and stroke decreased by 31% and 35.6%, respectively (Go et al., 2014). The total costs associated with CVD and stroke is approximately \$315 billion annually in the United States alone. In the United States, one person sustains a coronary event every 34 seconds.

Considerable progress in detecting and managing CVD is being made. With the introduction of new pharmacologic interventions, development of numerous percutaneous approaches to managing cardiac valvular disease, aneurysms, and peripheral vascular disease, and innovative approaches for correcting arrhythmias, cardiovascular medicine changes rapidly. The molecular defects characterizing many forms of CVD are being brought into sharper focus, which increases the potential to develop novel therapies for preventing or managing a broad variety of cardiovascular abnormalities.

Detailed guidelines by professional societies and national commissions are being issued and continuously reevaluated and updated so as to optimize the management of risk factors and established forms of disease. Despite these efforts, compliance with guidelines remains relatively low throughout the world. In addition, although randomized clinical trials have firmly established the efficacy of numerous drug classes to reduce cardiovascular morbidity and mortality, many of these drugs are underused or are not used at appropriate doses. As populations age worldwide; as more patients survive acute cardiovascular and cerebrovascular events; and as the incidence of hypertension (HTN), dyslipidemia, metabolic syndrome, diabetes mellitus (DM), obesity, and other risk factors continues to increase, the

burden on family physicians to identify and effectively manage CVD will continue to escalate dramatically.

Atherosclerosis

Atherosclerosis is a complex, multifactorial disease that is highly prevalent throughout the world. Atherosclerotic disease is etiologic for acute coronary syndromes (ACS) such as myocardial infarction (MI) and unstable angina (UA), carotid artery disease and ischemic stroke, renal arterial stenosis, and peripheral vascular disease (Libby, 2001). The development and progression of atherosclerosis is driven by a variety of risk factors, including dyslipidemia, HTN, impairments in glycemic control, age, family history, cigarette smoking, obesity, and systemic inflammation. Novel risk factors are being recognized, and their utility for identifying patients at risk for disease are being tested in epidemiologic and clinical trial settings. Evaluating patients for global cardiovascular risk burden and aggressively treating modifiable risk factors is a significant focus of any primary care setting.

Atherogenesis is no longer viewed as an inevitable consequence of passive, progressive lipid accumulation within the arterial wall gradually resulting in symptomatic reductions in blood flow and oxygen delivery. Instead, atherosclerosis is a dynamic process encompassing a diverse array of biochemical and histologic changes that continuously modulate the establishment and evolution of atheromatous plaque (Hansson, 2005; Libby et al., 2002). Atheromatous plaque is modifiable, and therapeutic interventions can stabilize and even regress plaque, resulting in reductions in risk for cardiovascular morbidity and mortality.

Endothelial cell dysfunction is an early hallmark of atherogenesis (Toth, 2009). The endothelium is as an organ system. Endothelial cells line the luminal surface of blood vessels and mediate vascular tone and molecular trafficking into the vessel wall. When endothelium is stressed by

rheological disturbances, increased inflammatory or oxidative insult, glycemic injury, hyperlipidemia, and HTN, its functional characteristics change. Dysfunctional endothelium has less vasodilatory capacity, is more thrombogenic, and upregulates the expression of a variety of cell adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1) (Lusis, 2000). These adhesion molecules promote the binding of monocytes, T cells, and mast cells to the endothelial surface. Bound inflammatory white blood cells (WBCs) then follow a gradient of monocyte chemoattractant protein-1 and other cytokines by intercalating between endothelial cells and ultimately transmigrate into the subendothelial space. In the subendothelial space, these WBCs take up residence, where they create an inflammatory nidus. Monocytes can convert to macrophages in response to macrophage colony-stimulating factor. Inflammatory WBCs are potent sources of oxygen free radicals such as superoxide anion, peroxide, and hydroxyl. These reactive oxygen species can oxidize phospholipids and fatty acids within lipoproteins, rendering them more proinflammatory and atherogenic. When exposed to oxidatively modified atherogenic lipoproteins, macrophages upregulate the expression of cell surface scavenger receptors (e.g., CD36 and scavenger receptor A), which promote the internalization of cholesterol and cholesterol esters resulting in the formation of foam cells. Foam cells coalesce to form fatty streaks, the histologic precursor to atheromatous plaques. Resident macrophages, T cells, and mast cells facilitate additional WBC recruitment and progression of atherosclerotic disease by producing a variety of cytokines, interleukins (ILs), and oxidative enzymes that adversely impact endothelial, smooth muscle cell, and fibroblast function and proliferation.

With disease progression, the molecular and histologic dynamics of atheromatous plaque remain in continuous flux. As foam cells die, cellular debris accumulates and further potentiates the inflammatory response (Tabas, 2005). Matrix metalloproteinases (MMPs) are expressed, which degrade the collagen, elastin, and proteoglycan extracellular matrix of plaque. When this occurs in the shoulder region of a plaque, acute rupture or plaque fissuring can result. Sudden plaque rupture exposes collagen, tissue factor, and the thrombogenic lipid core to platelets and coagulation factors, ultimately resulting in overlying thrombus formation, luminal obstruction, acute ischemia, and possible infarction if tissue blood flow is not rapidly reestablished. Atheromatous plaques that are highly inflamed and contain concentrated macrophage infiltrates or large lipid cores are particularly vulnerable to architectural destabilization and acute plaque rupture. Plaque can also suddenly distend and reduce coronary luminal diameter from intraplaque hemorrhaging if the delicate vasa vasorum feeding the surrounding vascular tissue is injured from vasospasm.

In the majority of cases, culprit lesions giving rise to acute MI are not flow limiting before rupture or fissuring. Any atheromatous plaque identified on coronary angiography should be viewed as a potential cause of an ACS. Patients with evidence of atherosclerotic disease in any portion of the vascular tree require rigorous evaluation of all risk factors and the appropriate institution of lifestyle

and pharmacologic intervention to reduce the risk for both disease progression and cardiovascular morbidity and mortality.

Dyslipidemia

Key Points

- Patients undergoing screening for dyslipidemia should have a complete fasting lipid profile.
- The new American College of Cardiology/American Heart Association (ACC/AHA) guideline on the treatment of blood cholesterol has shifted to a risk-centric model.
- Statin therapy is indicated for all patients in secondary prevention and patients with a 10-yr risk for atherosclerotic cardiovascular disease (ASCVD) of 7.5% or greater.
- The intensity of statin therapy is based on risk level. Secondary causes of dyslipidemia should also be ruled out.
- Therapeutic lifestyle changes are an important component of any regimen designed to treat dyslipidemia.

Although it is pathogenic, cholesterol is also an important modulator of cell membrane fluidity and is a substrate for hormone biosynthesis by steroidogenic organs. There is an unequivocal relationship between dyslipidemia and risk for atherogenesis within the coronary, peripheral, renal, and cerebral vasculature. Dyslipoproteinemias develop in response to genetic and environmental factors and are modifiable through lifestyle modification and pharmacologic intervention. As demonstrated in the Framingham Study, Multiple Risk Factor Intervention Trial, and the Seven Countries Study, as serum levels of cholesterol increase, the risk for developing coronary artery disease (CAD) increases. The identification and treatment of dyslipidemia lower the risk for developing atherosclerotic disease and its various clinical manifestations.

Serum very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) particles deliver cholesterol and triglycerides to peripheral tissues and blood vessel walls. These lipoproteins can cross the endothelial barrier and induce atherogenesis. Atherogenic lipoproteins not taken up by peripheral tissues are cleared from the circulation by hepatic LDL receptors. Lipid-lowering therapies that upregulate hepatic LDL receptors are antiatherogenic by virtue of their ability to reduce circulating levels of atherogenic lipoproteins.

Dyslipidemia can be the result of abnormalities in gastrointestinal (GI) nutrient absorption, serum and intracellular enzyme activities, and/or cell surface receptor expression. A complete fasting (12-14 hours) lipoprotein profile (including LDL cholesterol [LDL-C], triglyceride, and high-density lipoprotein cholesterol [HDL-C]) should be obtained on anyone screened for dyslipidemia. Because of the relationship between specific lipoprotein fractions and risk for CAD, measuring total cholesterol levels has little clinical relevance.

The National Cholesterol Education Program Adult Treatment Panel III (NCEP ATPIII) recommendations are now replaced by the ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults (Stone et al., 2013). The new guideline has prompted considerable debate, and not all specialty societies have endorsed it. The new recommendations are summarized in Figure 27-1 and Table 27-1. The new guideline has shifted emphasis away from LDL-C and non-HDL-C thresholds and targets and is now basing the decision on whether or not to treat with statin therapy on overall risk for acute cardiovascular events. The Framingham risk equation is not a part of the new guideline. For patients in primary prevention, use of the new Pooled Cohort Equation is recommended for estimating 10-year risk for ASCVD, which can be downloaded at http://my.americanheart.org/professional/StatementsGuidelines/PreventionGuidelines/Prevention-Guidelines_UCM_457698_SubHomePage.jsp. ASCVD includes ACS,

history of MI, stable or unstable angina, coronary or other arterial revascularization, stroke, transient ischemic attack (TIA), or peripheral arterial disease (PAD) presumed to be of atherosclerotic origin.

The 10-year risk threshold for initiating statin therapy for patients in the primary prevention setting is 7.5% or greater irrespective of gender or race or ethnicity. The definitions for high-, moderate-, and low-intensity statin therapies are summarized in Table 27-2. There are no recommendations for treating non-HDL-C or low HDL-C. When estimating risk, consideration can also be given to LDL-C level of 160 mg/dL or greater or other evidence of genetic hyperlipidemias; family history of premature ASCVD with onset before 55 years of age in a first-degree male relative or before 65 years of age in a first-degree female relative; high-sensitivity C-reactive protein (CRP) greater than 2 mg/L; coronary artery calcium score 300 Agatston units or greater or 75 percentile or greater for age, sex, and ethnicity; ankle-brachial index (ABI) less than 0.9; or elevated

Table 27-1 ACC/AHA Guideline Recommendations for the Treatment of Blood Cholesterol

Recommendations	NHLBI Grade	NHLBI Evidence Statements	ACC/AHA COR	ACC/AHA LOE
TREATMENT TARGETS				
1. The panel makes no recommendations for or against specific LDL-C or non-HDL-C targets for the primary or secondary prevention of ASCVD.	N (no recommendation)	1-4	—	—
SECONDARY PREVENTION				
1. High-intensity statin therapy should be initiated or continued as first-line therapy in women and men ≤ 75 years of age who have <i>clinical ASCVD</i> * unless contraindicated.	A (strong)	1, 6-8, 10-23, 26-28	I	A
2. In individuals with <i>clinical ASCVD</i> * in whom high-intensity statin therapy would otherwise be used, when high-intensity statin therapy is contraindicated, [†] or when characteristics predisposing to statin-associated adverse effects are present, moderate-intensity statin should be used as the second option if tolerated.	A (strong)	13-22, 24, 27, 28	I	A
3. In individuals with <i>clinical ASCVD</i> >75 years of age, it is reasonable to evaluate the potential for ASCVD risk-reduction benefits, adverse effects, and drug-drug interactions, and to consider patient preferences when initiating a moderate- or high-intensity statin. It is reasonable to continue statin therapy in those who are tolerating it.	E (expert opinion)	—	IIa	B (16,20-43)
PRIMARY PREVENTION IN INDIVIDUALS ≥ 21 YEARS OF AGE WITH LDL-C ≥ 190 MG/DL				
1. Individuals with LDL-C ≥ 190 mg/dL or triglycerides ≥ 500 mg/dL should be evaluated for secondary causes of hyperlipidemia	B (Moderate)	75	I [‡]	B (44,45)
2. Adults ≥ 21 years of age with primary LDL-C ≥ 190 mg/dL should be treated with statin therapy (10-year ASCVD risk estimation is not required):	B (Moderate)	6, 19, 28, 33-35, 37, 38	I [§]	B
• Use high-intensity statin therapy unless contraindicated.				
• For individuals unable to tolerate high-intensity statin therapy, use the maximum tolerated statin intensity.				
3. For individuals ≥ 21 years of age with an untreated primary LDL-C ≥ 190 mg/dL, it is reasonable to intensify statin therapy to achieve at least a 50% LDL-C reduction.	E (expert opinion)	—	IIa	B (20,46-50)
4. For individuals ≥ 21 years of age with an untreated primary LDL-C ≥ 190 mg/dL, after the maximum intensity of statin therapy has been achieved, addition of a nonstatin drug may be considered to further lower LDL-C. Evaluate the potential for ASCVD risk reduction benefits, adverse effects, and drug-drug interactions and consider patient preferences.	E (expert opinion)	—	IIb	C (51)

Continued on following page

Table 27-1 ACC/AHA Guideline Recommendations for the Treatment of Blood Cholesterol (Continued)

Recommendations	NHLBI Grade	NHLBI Evidence Statements	ACC/AHA COR	ACC/AHA LOE
PRIMARY PREVENTION IN INDIVIDUALS WITH DIABETES MELLITUS AND LDL-C 70-189 MG/DL				
1. Moderate-intensity statin therapy should be initiated or continued for adults 40-75 years of age with diabetes mellitus.	A (strong)	19, 29-34, 40	I	A
2. High-intensity statin therapy is reasonable for adults 40-75 years of age with diabetes mellitus with a $\geq 7.5\%$ estimated 10-year ASCVD risk [†] unless contraindicated.	E (expert opinion)	—	Ila	B (49,52)
3. In adults with diabetes mellitus who are <40 or >75 years of age, it is reasonable to evaluate the potential for ASCVD benefits, for adverse effects, and for drug–drug interactions and to consider patient preferences when deciding to initiate, continue, or intensify statin therapy.	E (expert opinion)	—	Ila	C (53-62)
PRIMARY PREVENTION IN INDIVIDUALS WITHOUT DIABETES MELLITUS AND WITH LDL-C 70-189 MG/DL				
1. The pooled cohort equations should be used to estimate 10-year ASCVD [‡] risk for individuals with LDL-C 70-189 mg/dL without <i>clinical</i> ASCVD* to guide initiation of statin therapy for the primary prevention of ASCVD.	E (expert opinion)	—	I	B (11)
2. Adults 40-75 years of age with LDL-C 70-189 mg/dL, without <i>clinical</i> ASCVD* or diabetes and an estimated 10-year ASCVD [‡] risk $\geq 7.5\%$ should be treated with moderate- to high-intensity statin therapy.	A (strong)	28, 34-36, 38, 42-44, 47, 49-56, 76	I	A
3. It is reasonable to offer treatment with a moderate-intensity statin to adults 40-75 years of age, with LDL-C 70-189 mg/dL without <i>clinical</i> ASCVD* or diabetes and an estimated 10-year ASCVD [‡] risk of 5% to <7.5%.	C (weak)	28, 34-36, 38, 42-44, 47, 49-56, 76	Ila	B
4. Before initiating statin therapy for the primary prevention of ASCVD in adults with LDL-C 70-189 mg/dL without <i>clinical</i> ASCVD* or diabetes, it is reasonable for clinicians and patients to engage in a discussion that considers the potential for ASCVD risk reduction benefits and for adverse effects and for drug–drug interactions and patient preferences for treatment.	E (expert opinion)	—	Ila	C (63)
5. In adults with LDL-C <190 mg/dL who are not otherwise identified in a statin benefit group or for whom after quantitative risk assessment a risk-based treatment decision is uncertain, additional factors [¶] may be considered to inform treatment decision making. In these individuals, statin therapy for primary prevention may be considered after evaluating the potential for ASCVD risk reduction benefits, adverse effects, drug–drug interactions, and discussion of patient preferences.	E (expert opinion)	—	IIb	C (11,13)
HEART FAILURE AND HEMODIALYSIS				
1. The Expert Panel makes no recommendations regarding the initiation or discontinuation of statins in patients with NYHA class II-IV ischemic systolic heart failure or in patients on maintenance hemodialysis.	N (no recommendation)	71, 72	—	—

**Clinical* ASCVD includes acute coronary syndromes, history of MI, stable or unstable angina, coronary or other arterial revascularization, stroke, TIA, or peripheral arterial disease presumed to be of atherosclerotic origin.

[†]Contraindications, warnings, and precautions are defined for each statin according to the manufacturer's prescribing information (64-70).

[‡]Individuals with secondary causes of hyperlipidemia were excluded from the RCTs reviewed. Triglycerides >500 mg/dL were an exclusion criteria for almost all RCTs. Therefore, ruling out secondary causes is necessary to avoid inappropriate statin therapy.

[§]No RCTs included only individuals with LDL-C ≥ 190 mg/dL. However, many trials did include individuals with LDL-C ≥ 190 mg/dL, and all of these trials consistently demonstrated a reduction in ASCVD events. In addition, the cholesterol treatment trialists meta-analyses have shown that each 39-mg/dL reduction in LDL-C with statin therapy reduced ASCVD events by 22%, and the relative reductions in ASCVD events were consistent across the range of LDL-C levels. Therefore, individuals with primary LDL-C >190 mg/dL should be treated with statin therapy.

^{||}Estimated 10-year or "hard" ASCVD risk includes first occurrence of nonfatal MI, congestive heart disease death, and nonfatal and fatal stroke as used by the Risk Assessment Work Group in developing the Pooled Cohort Equations.

[¶]These factors may include primary LDL-C >160 mg/dL or other evidence of genetic hyperlipidemias, family history of premature ASCVD with onset <55 years in a first-degree male relative or <65 years in a first-degree female relative, high sensitivity-C-reactive protein >2 mg/L, CAC score ≥ 300 Agatston units or ≥ 75 percentile for age, sex, and ethnicity (for additional information, see <http://www.mesa-nhlbi.org/CACReference.aspx>), ABI <0.9, or lifetime risk of ASCVD. Additional factors that may aid in individual risk assessment may be identified in the future.

lifetime risk of ASCVD. Secondary causes of dyslipidemia to be evaluated and treated are summarized in [Table 27-3](#).

Therapeutic lifestyle change is first-line therapy for patients at risk for cardiovascular events ([NCEP ATP III, 2001](#)). Patients who smoke should stop. The amount of daily-consumed cholesterol should be less than 200 mg. The distribution of calories from nutrients is summarized in [Table 27-4](#). Reduced saturated fat and increased consumption of mono- and polyunsaturated fats promote serum LDL-C reduction. The ingestion of viscous fiber and plant stanols decrease cholesterol absorption. Ideally, patients should exercise for 20 to 30 minutes five times per week. Regular exercise promotes weight loss and relieves visceral adiposity and insulin resistance.

Table 27-4 Dietary Recommendations for Therapeutic Lifestyle Change

Dietary Component	Recommendation Allowance
Polyunsaturated fat	$\leq 10\%$ of total calories
Monounsaturated fat	$\leq 20\%$ of total calories
Total fat	25%-35% of total calories
Carbohydrate	50%-60% of total calories
Dietary fiber	20-30 g/day
Protein	$\approx 15\%$ of total calories
Dietary cholesterol	< 200 mg/day

PHARMACOLOGIC INTERVENTIONS

Statins

The statins are reversible, competitive 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors. HMG-CoA reductase is the rate-limiting step for cholesterol biosynthesis in the liver and systemic tissues. Statins are the most potent agents for reducing serum levels of LDL-C. The statins augment the elimination of atherogenic apoB100-containing lipoproteins (VLDL, VLDL remnants, and LDL) from plasma by upregulating the LDL receptor on the surface of hepatocytes. The statins also reduce VLDL secretion and stimulate apoprotein A-I expression and hepatic HDL secretion.

In a large number of prospective, placebo-controlled clinical trials, the statins have been shown to significantly reduce rates of MI, stroke, and coronary and all-cause mortality in the primary ([Downs et al., 1998](#); [Heart Protection Study Group, 2002](#)) and secondary prevention settings ([Cannon et al., 2004](#); [LaRosa et al., 2005](#); [Scandinavian Simvastatin Survival Study Group, 1994](#)) ([Table 27-5](#)). Statins reduce the frequency of stable and unstable angina and decrease atheromatous plaque progression, and based on intravascular ultrasonographic measurements ([Nissen et al., 2004](#)), quantitative coronary angiography, and high-resolution magnetic resonance imaging (MRI) ([Corti et al., 2002](#)), even stimulate some degree of plaque resorption. The statins reduce cardiovascular events in men and women, blacks and Hispanics,

Table 27-5 Prospective Randomized Statin Trials in Both Primary and Secondary Prevention

PRIMARY PREVENTION STUDIES			
Study	Drug	Design	Outcomes
AFCAPS/ TexCAPS	Lovastatin, 20 mg/d to 40 mg/d vs placebo	6605 men and women	40% reduction in fatal and nonfatal MI; 37% reduction in first ACS; 33% reduction in coronary revascularizations; and 32% reduction in unstable angina
ASCOT	Atorvastatin 10 mg/d vs placebo	10,305 hypertensive men (<i>n</i> = 8463) and women (<i>n</i> = 1942) with treated high BP and no previous CAD	36% reduction in total CHD/nonfatal MI; 27% reduction in fatal and nonfatal stroke; and total coronary event reduced by 29%
CARDS	Atorvastatin 10 mg/d vs placebo	2838 patients with type 2 diabetes mellitus and ≥1 CHD risk factor(s)	37% reduction in major cardiovascular events; 27% reduced total mortality; 13.4% reduction in acute CVD events; 36% reduction in acute coronary events; 48% reduction in stroke
Heart Protection Study	Simvastatin 40 mg/d vs placebo	20,536 high-risk (previous CHD, other vascular disease, hypertension among men aged > 65 yr, or diabetes)	25% reduction in all-cause and coronary death rates and in strokes; 24% reduction in need for revascularization; 25% reduction in fatal and nonfatal stroke; 38% reduction in nonfatal MI; 18% reduction in coronary mortality; 13% reduction in all-cause mortality; 24% reduction in cardiovascular event rate
PROSPER	Pravastatin 40 mg/d vs placebo	5804 men (<i>n</i> = 2804) and women (<i>n</i> = 3000) aged 70 to 82 yr	15% reduction in combined endpoint (fatal/nonfatal MI or stroke); 19% reduction in total/nonfatal CHD; no effect on stroke (but 25% reduction in TIA)
WOSCOPS	Pravachol therapy 40 mg/d vs placebo	6595 men	31% reduction in CHD death from nonfatal MI; 32% reduction in CVD death; 22% reduction in total mortality
SECONDARY PREVENTION STUDIES			
Study	Drug	Design	Outcomes
4S	Simvastatin 20 mg/d vs placebo	4444 patients with angina pectoris or history of MI	42% reduction in coronary mortality; 37% reduction in myocardial revascularization; 30% reduction in all-cause mortality; 34% reduction in nonfatal major coronary event; 30% reduction in fatal and nonfatal stroke
AVERT	Atorvastatin 80 mg/d vs angioplasty + usual care	341 patients with stable CAD	36% reduction in ischemic event; 36% reduction in delayed time to first ischemic event
CARE	Pravastatin 40 mg/d vs placebo	3583 men and 576 women with history of MI	24% reduction in death from CHD or non-fatal MI; 37% reduction in fatal MI; 27% reduction in CABG or PTCA
IDEAL	Atorvastatin 80 mg/d vs simvastatin 20-40 mg/d	8888 men and women with CHD	13% reduction in major cardiac events; 17% reduction in nonfatal MI; 23% reduction in revascularization; 24% reduction in peripheral arterial disease
JUPITER	Rosuvastatin 20 mg/d vs placebo	17,802 men (>50 yr) and women (>60 yr) with no history of CAD or DM, entry LDL <130 mg/dl and CRP >2.0 mg/L	44% reduction in primary endpoint of major coronary events; 65% reduction in nonfatal MI; 48% reduction in nonfatal stroke; 46% reduction in need for revascularization; 20% reduction in all-cause mortality
LIPID	Pravachol 40 mg/d vs placebo	9014 patients	24% reduction in coronary mortality; 19% reduction in stroke; 24% reduction in fatal CHD or nonfatal MI; 29% reduction in fatal or nonfatal MI
LIPS	Fluvastatin 40 mg/d vs placebo	1667 men and women aged 18-80 yr post-angioplasty for CAD	22% lower rate of major coronary events (i.e., cardiac deaths, nonfatal MI, or reintervention procedure)
MIRACL	Atorvastatin 80 mg/d vs placebo	3086 patients with ACS	16% reduction in composite endpoint; 26% reduction in ischemia; 50% reduction in stroke
PROVE IT	Atorvastatin 80 mg/d vs pravastatin 40 mg/d	4162 patient with ACS	16% reduction of composite endpoint; 14% reduction in CHD death, MI, or revascularization; 14% reduction in revascularizations; 29% reduction in unstable angina
REVERSAL	Atorvastatin 80 mg/d vs pravastatin 40 mg/d	654 patients with CAD	Atheroma: atorvastatin -0.4%, pravastatin 2.7%, difference of -3.1%, <i>P</i> = 0.02
TNT	Atorvastatin 10 mg/d vs 80 mg/d	10,003 patients with CHD and LDL cholesterol 130-250 mg/dL	22% reduction in composite endpoint; 22% reduction in MI; 25% reduction in stroke

ACS, Acute coronary syndrome; AFCAPS/TexCAPS, the Air Force/Texas Coronary Atherosclerosis Prevention Study: Implications for Preventive Cardiology in the General Adult US Population; ASCOT, Anglo-Scandinavian Cardiac Outcomes Trial-Lipid Lowering Arm; AVERT, Atorvastatin versus Revascularization Treatment Investigators; CABG, coronary artery bypass grafting; CAD, coronary artery disease; CARDS, Collaborative Atorvastatin Diabetes Study; CARE, Cholesterol and Recurrent Events Trial; CHD, coronary heart disease; 4S, the Scandinavian Simvastatin Survival Study; IDEAL, Incremental Decrease in End Points Through Aggressive Lipid Lowering Study; JUPITER, the Justification for the Use of Statins in Prevention: an Intervention Trial Evaluating Rosuvastatin; LDL, low-density lipoprotein; LIPID, Long-Term Intervention with Pravastatin in Ischemic Disease; LIPS, Lescol Intervention Prevention Study; MI, myocardial infarction; MIRACL, Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering Study; PROSPER, pravastatin in elderly individuals at risk of vascular disease; PROVE IT, Pravastatin or Atorvastatin Evaluation and Infection Therapy study; PTCA, percutaneous transluminal coronary angioplasty; REVERSAL, The REVERSing Atherosclerosis with Aggressive Lipid Lowering study; TNT, Treating to New Targets Trial; WOSCOPS, West of Scotland Coronary Prevention Study. In Comprehensive Cardiovascular Medicine in the Primary Care Setting (Toth, PP and Cannon CP, editors) Humana-Springer, Philadelphia. 2010.

individuals with HTN or diabetes, smokers, and patients older than 70 years of age. In addition, based on meta-analyses performed by the Cholesterol Treatment Trialists Collaboration, statins provide benefit largely independent of baseline LDL-C levels and Framingham risk score and are not associated with increased risk for any type of malignancy (Cholesterol Treatment Trialists, 2012a, 2012b).

Seven statins are currently available. These drugs differ by potency and a number of pharmacokinetic properties. The choice of statin and its dosing depend on the magnitude of LDL-C and non-HDL-C reduction required (baseline vs. risk-stratified NCEP target). The LDL-C lowering efficacy of the statins is as follows: rosuvastatin (Crestor), 45% to 63% (5-40 mg/day); atorvastatin (Lipitor), 26% to 60% (10-80 mg/day); simvastatin (Zocor), 26% to 47% (10-80 mg/day); lovastatin (Mevacor), 21% to 42% (10-80 mg/day); fluvastatin (Lescol), 22% to 36% (10-20 mg/day); pitavastatin (Livalo), 32% to 43% (1-4 mg/day); and pravastatin (Pravachol), 22% to 34% (10-80 mg/day) (e.g., Jones et al., 2003). Each doubling of a statin's dose yields an additional 6% reduction, on average, in serum LDL-C (the so-called "rule of 6s"). Patients who are heterozygous or homozygous for familial hypercholesterolemia frequently require high-potency statins at their highest doses coupled with stringent restriction in dietary lipid ingestion and the addition of one or more other lipid-lowering agents. The statins induce significant reductions in serum triglyceride levels (typically 10%-25%) and modest elevations in serum HDL-C (2%-14%). Unlike the other statins, atorvastatin therapy is associated with decreasing capacity for raising HDL-C as a function of increasing dose. In patients with high baseline serum triglyceride levels (>300 mg/dL), simvastatin and rosuvastatin raise HDL-C up to 18 and 22%, respectively.

The statins display significant differences in their pharmacokinetic profiles. Due to their relatively short half-lives (1-4 hours), lovastatin, fluvastatin, pravastatin, and simvastatin should be taken after the evening meal to intercept the peak activity of HMG-CoA-reductase, which occurs around midnight. Rosuvastatin and atorvastatin can be taken at any time during the day or night because of their long half-lives (≈19 hours and 14 hours, respectively). The coadministration of drugs or compounds that inhibit cytochrome P450 3A4 (macrolide antibiotics [erythromycin, clarithromycin], azole-type antifungals [ketoconazole, itraconazole], cyclosporine, HIV protease inhibitors, nefazodone, >1 qt of grapefruit juice daily) with atorvastatin, simvastatin, and lovastatin is contraindicated because these statins are dependent on this P450 isozyme for oxidative modification and elimination (Neuvonen et al., 1998). P450 3A4 inhibition is associated with increased risk for myopathy and hepatotoxicity. The dose of simvastatin should be 20 mg/day or less in patients being treated with amiodarone, amlodipine, or verapamil.

Although there is some concern about the potential toxicity of statins, their benefits significantly outweigh their risks. Moreover, because the risk of true hepatotoxicity from a statin is quite low, the Food and Drug Administration (FDA) issued an advisory stating that in general, the monitoring of liver enzymes in patients treated with statins is no longer necessary given the low yield of findings. The

majority of cases of elevated transaminases in these patients are caused by hepatic steatosis.

Liver toxicity is defined as an alanine aminotransferase (ALT) elevation ≥ 3 the upper limit of normal (ULN) on two occasions at least 1 month apart. Mild elevations in serum transaminase levels early during the course of therapy are observed and usually resolve spontaneously. If hepatotoxicity develops, statin therapy should be discontinued until transaminase levels normalize and therapy with a different statin can be initiated. There is no documented evidence that the statins increase risk for liver failure.

The most important adverse events associated with statin therapy are rhabdomyolysis, myoglobinuria, and renal failure. The risk for rhabdomyolysis is less than 0.1%. Symptoms of rhabdomyolysis include worsening muscle pain, proximal weakness, nausea and vomiting, and brownish-red discoloration of urine. The statins can cause myalgia. If a patient develops myalgia or muscle weakness, a serum creatine kinase level can be obtained. The diagnosis of myopathy is made when creatine kinase levels exceed 10 times ULN. When assessing myalgia, it is important to evaluate patients for pain that is caused by arthritis, tendinopathy, thyroid dysfunction, electrolyte disturbances, fibromyalgia, polymyalgia rheumatica, blunt muscle trauma, and muscle strain induced by exertion. There are no large, convincing randomized studies demonstrating that coenzyme Q or vitamin D supplementation reduces statin-associated muscle pain or weakness.

A newly elucidated potential adverse event associated with statin therapy is new-onset DM. It is not yet established how statins cause DM. Meta-analyses suggest that the risk of new-onset DM with statin therapy is approximately 1 per 1000 patients treated per year (Sattar et al., 2010). Patients treated with maximum doses of statin therapy have a risk of approximately one per 500 patients treated per year (Preiss et al., 2011). It appears that the patients at increased risk for new-onset DM are the ones who have established impaired glucose tolerance or one or more other components of the metabolic syndrome. All major guideline-writing bodies throughout the world recommend that statin therapy not be withheld out of concern that it may cause DM. The benefits of statin therapy still outweigh its risks, and statin therapy is highly efficacious for reducing risk of cardiovascular events in patients with DM.

Ezetimibe (Zetia)

Dietary and biliary sources contribute significantly to serum levels of cholesterol (Figure 27-2). Although plant sterols and stanols block GI cholesterol absorption, ezetimibe is the first member of a class of lipid-lowering drugs known as cholesterol absorption inhibitors. Mechanistically, ezetimibe inhibits the Niemann-Pick C1-like-1 protein, which mediates cholesterol and phytosterol transport along the brush border of the jejunal enterocyte (Altmann et al., 2004; Davis et al., 2004). After undergoing glucuronidation, ezetimibe undergoes enterohepatic recirculation with negligible systemic exposure. The half-life of ezetimibe is approximately 22 hours. When dosed at 10 mg once daily, ezetimibe reduces serum LDL-C on average by 20%, but up to 24% of patients experience a reduction of 25% or greater (Ballantyne et al., 2004; Davidson et al., 2002). Ezetimibe also decreases triglycerides by up to 8% and raises

Figure 27-2 Gastrointestinal (GI) absorption of dietary and biliary lipid and cholesterol. In the GI tract, cholesterol and triglycerides arising from biliary and dietary sources are assimilated with bile salts and phospholipids to form micelles. Micelles transport cholesterol and lipid to the jejunal brush border. Along the enterocyte surface, the sterol transporter known as Niemann Pick C1-like 1 (NPC1L1) protein is responsible for importing cholesterol and phytosterols into the neurocyte. After being internalized, the cholesterol is esterified to cholesterol esters via the activity of acyl-CoA acyltransferase (ACAT). The esterified cholesterol is packaged with triglycerides, phospholipids, and apoprotein B48 (ApoB48) to form chylomicrons in an assimilation reaction catalyzed by microsomal transfer protein (MTP). The chylomicrons are released into GI lacteals, which conduct these lipoproteins into the central circulation. Excess intracellular sterols can be excreted back into the GI tract via the activity of the sterol exporter complex ABCG5/G8 (ATP-binding membrane cassette transporter G5/G8). (Reproduced with permission from Toth PP, Davidson MH. Cholesterol absorption blockade with ezetimibe. *Curr Drug Targets Cardiovasc Haematol Disord*. 2005;5:455-462.)

HDL-C by up to 4%. Ezetimibe does not decrease the absorption of bile acids; steroid hormones (ethinyl estradiol, progesterone); or such fat-soluble vitamins as vitamins A, D, E, or α - and β -carotenes. In addition to its indication for reducing LDL-C, ezetimibe is approved for use in patients with β -sitosterolemia, a rare genetic disorder that gives rise to severe elevations in serum levels of plant sterols (campesterol, β -sitosterol, and others) and premature onset CAD.

The risk of hepatotoxicity with ezetimibe is nearly identical to placebo (0.5% vs. 0.3%), and there is no documented evidence of increased risk for myopathy. Fixed-dose ezetimibe is also available in combination with increasing doses of simvastatin (Vytorin; 10/10; 10/20; 10/40; 10/80 mg/day) and atorvastatin (Liptruzet). Ezetimibe can also be safely used in combination with other statins (Toth, 2005). Ezetimibe provides additive changes in lipoprotein levels to that observed with statin therapy. The addition of ezetimibe to a statin provides incremental LDL-C reduction equivalent to three titration steps of a statin.

Bile Acid Binding Resins

The bile acid sequestration agents (BASAs) are orally administered anion exchange resins that bind bile acids in the GI tract and prevent them from being reabsorbed into the enterohepatic circulation. These drugs reduce serum LDL-C by two mechanisms: (1) increased catabolism of cholesterol secondary to the upregulation of 7- α -hydroxylase, the rate-limiting enzyme for the conversion of cholesterol into bile acids, and (2) increased expression of LDL receptors on the hepatocyte surface, which augments the clearance of apoB100-containing lipoproteins from plasma. At

maximum doses, the BASA can reduce serum LDL-C by 15% to 30% and increase HDL-C by 3% to 5%. It is recommended that these drugs be used in conjunction with a statin whenever possible because BASA therapy increases HMG-CoA reductase activity in the liver, which leads to increased hepatic biosynthesis of cholesterol, thereby offsetting the effects of the BASA over time. The BASA are contraindicated in patients with serum triglycerides greater than 400 mg/dL because they can exacerbate hypertriglyceridemia.

There are currently three different BASAs available. These include cholestyramine (Questran; 4-24 g/day in 2-3 divided doses daily), colestipol (Colestid; 5-30 g in two or three divided doses daily), and colesevelam (Welchol; 1250 mg two to three times daily). The development of constipation, flatulence, and bloating are relatively frequent, but colesevelam has the most favorable side effect profile of the three available BASAs. Increasing water and soluble fiber ingestion ameliorates some of the difficulty with constipation. The BASAs bind negatively charged molecules in a nonspecific manner. Consequently, they can decrease the absorption of warfarin, phenobarbital, thiazide diuretics, digitalis, β -blockers, thyroxine, statins, fibrates, and ezetimibe. These medications should be taken 1 hour before or 4 hours after the ingestion of BASA. The BASA can reduce the absorption of fat-soluble vitamins. Colesevelam also has an indication to reduce serum glycated hemoglobin levels in patients with DM.

Fibrates

The fibrates are fibric acid derivatives that exert a number of effects on lipoprotein metabolism. These agents reduce

serum triglycerides by 25% to 50% and raise HDL-C by 10% to 20%. Fibrates activate lipoprotein lipase by reducing levels of apoprotein CIII (an inhibitor of this enzyme) and increasing levels of apoprotein CII (an activator of lipoprotein lipase) (Andersson et al., 2011). This stimulates the hydrolysis of triglycerides in chylomicrons and VLDL. Fibrates increase HDL-C by two mechanisms. First, the fibrates are peroxisome proliferator-activated receptor α (PPAR- α) agonists and stimulate increased hepatic expression of apoproteins AI and AII. Second, by activating lipoprotein lipase, surface coat mass derived from VLDL is ultimately used to assimilate HDL in serum. In some patients, fibrate therapy may be associated with an increase in serum LDL-C (the so-called “ β ” effect) secondary to increased enzymatic conversion of VLDL to LDL. This effect may diminish over time as the patient increases the expression of hepatic LDL receptors.

The fibrates are particularly valuable for treating dyslipidemia in patients with a combination of hypertriglyceridemia and low HDL-C levels. In this patient type, post hoc evaluations of data from three studies (Helsinki Heart Study, Fenofibrate Intervention and Event Lowering in Diabetes, and the Bezafibrate Infarction Prevention Study) have demonstrated substantial cardiovascular event rate reductions using fibrate therapy (Bezafibrate Infarction Prevention Study Group, 2000; Manninen et al., 1988). In the Veterans Affairs High-Density Lipoprotein Intervention Trial (VA-HIT), men with CAD and low HDL levels (mean, 31 mg/dL) were treated with either gemfibrozil (600 mg orally twice a day) or placebo over a 5-year follow-up period (Robins et al., 2001). With a 6% elevation in HDL, no change in LDL, and a 31% decrease in triglycerides, gemfibrozil therapy resulted in a 22% reduction in the composite end point of all-cause mortality and nonfatal MI compared with placebo (Rubins et al., 1999). Gemfibrozil therapy also reduced the risk of stroke and TIAs by 31% and 59%, respectively (Rubins et al., 2001). Among the patients with diabetes in VA-HIT treated with gemfibrozil, there was a 32% reduction in the combined end point (41% in coronary heart disease [CHD] death and 40% in stroke) (Rubins et al., 2002). Fibrates have been shown to exert many of the same pleiotropic effects as statins and reduce atheromatous plaque progression in native coronary vessels and in coronary venous bypass grafts (Diabetes Atherosclerosis Intervention Study Investigators, 2001; Ericsson et al., 1996).

Similar to the statins, fibrates are associated with a low incidence of myopathy and mild elevations in serum transaminases. Fibrate therapy can increase the risk for cholelithiasis and can increase the prothrombin times by displacing warfarin from albumin binding sites. The periodic monitoring of serum transaminases (6-12 weeks after initiating therapy and twice annually thereafter) is recommended. The two most commonly used fibrates are gemfibrozil (Lopid; 600 mg twice daily) and fenofibrate (Tricor; 54 or 160 mg/day). Bezafibrate is available in Europe and is dosed at 400 mg/day. The use of therapies combining a statin and fibrate is becoming more common in clinical practice, especially as the incidence of complex dyslipidemias increases (Davidson and Toth, 2004). Gemfibrozil significantly reduces the glucuronidation of statins, which decreases their elimination (Backman et al., 2002; Prueksaritanont et al., 2002a, 2002b). This

increases the risk for myopathy or rhabdomyolysis and hepatotoxicity. When used in combination with gemfibrozil, the doses for simvastatin and rosuvastatin should not exceed 10 mg/day. In general, when embarking on combination therapy, fenofibrate is a safer choice because it does not adversely impact the glucuronidation of the statins (Bergman et al., 2004).

In both Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) and Action to Control Cardiovascular Risk in Diabetes (ACCORD) trials (Ginsberg et al., 2010), fenofibrate reduced the risk of progression of retinopathy in patients with diabetes by approximately one third. Fenofibrate has also been shown to reduce microalbuminuria. Reducing the risk of blindness and progression of albuminuria are important therapeutic considerations in patients with DM. Among patients with low HDL-C and high triglycerides, post hoc subgroup analyses demonstrate that fenofibrate reduces risks for the primary composite end point of cardiovascular events by 27% and 31% in the FIELD and ACCORD trials, respectively. Although post hoc findings must be considered hypothesis-generating only, there is remarkable consistency of benefit in patients given fibrate therapy when triglycerides are high and HDL-C is low.

Among patients in whom serum triglycerides do not normalize in response to a low-fat diet and fibrate therapy, consideration should be given to the addition of other agents. Patients with severe hypertriglyceridemia frequently possess mutations in lipoprotein lipase, which reduce the lipolytic activity of this enzyme. In this scenario, the addition of orlistat (Xenical; 120 mg with meals) can reduce the absorption of dietary fat and hence the circulating levels of chylomicrons and triglycerides. The addition of fish oil (see next section) should also be considered.

Fish Oils

Fish oil capsules enriched with ω -3 (eicosapentaenoic acid) and ω -6 (docosahexaenoic acid) fatty acids can reduce serum triglyceride and VLDL levels and raise HDL-C in a dose-dependent manner. The ω -3 fatty acids inhibit the enzyme diacylglycerol acyltransferase-2, thereby reducing intrahepatic triglyceride biosynthesis. They also stimulate mitochondrial β -oxidation of fatty acids, decrease VLDL production and biosynthesis, and stimulate triglyceride hydrolysis by lipoprotein lipase. Dietary supplementation with the n-3 polyunsaturated fatty acids (PUFAs) eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) has also been shown to lower the risk of death, nonfatal coronary events, and stroke after MI (GISSI-Prevenzione Investigators, 1999). In several clinical trials, PUFAs have been shown to reduce triglyceride levels by 20% to 30% and up to 50% in patients with severe hypertriglyceridemia (triglyceride level > 500 mg/dL) (O’Keefe and Harris, 2000).

The Japan EPA Lipid Intervention Study (JELIS) evaluated whether the addition of fish oils to patients already taking a statin would provide incremental risk reduction. Approximately 19,000 Japanese men and women with hypercholesterolemia were prospectively randomized to statin therapy with or without 1800 mg/day of EPA (Yokoyama et al., 2007). Combination therapy resulted in an additional 19% reduction in major coronary events at 4.6 years of follow-up compared with statin monotherapy.

Niacin

Niacin or nicotinic acid is a B vitamin that exerts multiple beneficial effects on lipoprotein metabolism. In contrast to statins and fibrates, niacin does not stimulate hepatic biosynthesis of HDL. Niacin appears to block HDL particle uptake and catabolism by hepatocytes without adversely impacting reverse cholesterol transport. This helps to increase circulating levels of HDL. Niacin reduces hepatic VLDL and triglyceride secretion according to two mechanisms: (1) it decreases the flux of fatty acids from adipose tissue to the liver by inhibiting lipase activity, and (2) it inhibits triglyceride formation within hepatocytes by inhibiting diacylglycerol acyltransferase. Niacin also reduces serum LDL-C concentrations by increasing the catabolism of apoB100. Consequently, niacin beneficially impacts all components of the lipoprotein profile.

When used as monotherapy at 3.0 g/day, crystalline niacin significantly reduced the incidence of MI and stroke in patients with established CAD in the Coronary Drug Project ([Coronary Drug Project Research Group, 1975](#)). In the HDL-Atherosclerosis Treatment Study (HATS), patients (baseline LDL-C, 124 mg/dL; HDL-C, 34 mg/dL) treated with combinations of high-dose niacin (2-4 g) with simvastatin reduced cardiovascular morbidity and mortality by up to 90% compared with those given placebo ([Brown et al., 2001](#)). This combination therapy also induced atheromatous plaque stabilization over a 3-year follow-up period. Two more recent clinical trials demonstrate that when atherogenic lipoprotein burden in serum is low, niacin therapy provides no incremental benefit over and above background therapy with a statin or statin–ezetimibe. In the Atherothrombosis Intervention in Metabolic syndrome with low HDL/high triglycerides: Impact on Global Health outcomes (AIM-HIGH) trial, patients with CAD and exquisitely well-controlled lipids (baseline LDL-C, 70 mg/dL; non-HDL-C, 106 mg/dL; and apoprotein B, 80 mg/dL) derived no benefit from the addition of 1.5 to 2.0 g of niacin ([Boden et al., 2011](#)). However, in the subgroup with HDL-C less than 32 mg/dL and triglycerides greater than 200 mg/dL, niacin therapy was associated with a significant 37% incremental reduction in the primary composite end point ([Guyton et al., 2013](#)). In the HPS2-THRIVE trial, the addition of niacin and laropiprant (an agent that reduces the flushing associated with niacin therapy) provided no incremental benefit in patients with CAD and remarkably well-controlled baseline levels of lipoproteins (LDL-C, 63 mg/dL; HDL-C, 44 mg/dL; and triglycerides, 125 mg/dL) (<http://www.thrivestudy.org>).

In patients with mixed dyslipidemia whose lipids are not adequately controlled on statin therapy, the addition of niacin can be considered as adjuvant therapy. Niacin should be started at a low dose and gradually titrated upward based on the results of follow-up lipid panels. When evaluated as a function of dose (500-2000 mg/day), Niaspan induces the following changes in serum lipid levels: LDL-C, 3% to 16% reduction; triglycerides, 5% to 32% reduction; and HDL-C, 10% to 24% elevation ([Capuzzi et al., 1998](#)).

Niacin therapy is associated with a number of side effects. The most common side effect with niacin is cutaneous flushing. Taking a 325-mg tablet of aspirin 1 hour before taking niacin can reduce the incidence of this. The flushing is prostaglandin mediated. Limiting fat intake for 2 to 3

hours before taking niacin also helps as fat is a source of arachidonic acid, the substrate for cyclooxygenase. Niaspan is a sustained-release preparation of niacin associated with less flushing. Other side effects include bloating, pruritus, acanthosis nigricans, transient disturbances in glycemic control, and increased serum concentrations of uric acid. Niacin appears to increase rates of proximal tubular reuptake of urate from the glomerular ultrafiltrate. Niacin is available as a combination pill with lovastatin (Advicor; 500/20 mg, 1000/20 mg, and 2000/40 mg) or simvastatin (Simcor; 500/20 mg, 750/20 mg, and 1000/20 mg), with the two drugs in each combination pill providing additive changes in the levels of serum lipoproteins.

KEY TREATMENT

- Statins, fibrates, niacin, ω -3 fish oils, and bile acid sequestration are highly efficacious agents for treating dyslipidemia (SOR: A).
- Statins are the most efficacious drugs currently available for reducing serum levels of LDL-C and significantly impact the risk for both cardiovascular morbidity and mortality (SOR: A). The ω -3 fish oils also appear to impact cardiovascular mortality, although the evidence is not as strong as with statins.
- Fibrates have the greatest capacity to reduce serum triglycerides (SOR: A). The fibrates have not yet been shown to beneficially impact mortality as an independent end point in clinical trials. The fibrates have been shown to reduce rates of atherosclerotic disease progression in both individuals with diabetes and without diabetes who have CAD. Fenofibrate reduces the risk of progression of retinopathy and albuminuria. Gemfibrozil as monotherapy reduces the risk for cardiovascular events in men in both the primary and secondary prevention settings as demonstrated in the Helsinki Heart Study and VA-HIT trial, respectively (SOR: A).
- Niacin raises serum levels of HDL-C significantly better than other currently available antilipidemic medications, and it also reduces LDL-C, triglycerides, and lipoprotein (a) (SOR: A). As demonstrated in both AIM-HIGH and HPS2-THRIVE, niacin does not provide incremental benefit if the atherogenic lipoprotein burden is already well controlled with other lipid lowering agents.
- Therapy with combinations of drugs (statin–fibrate, statin–niacin, fibrate–niacin, statin–ezetimibe) is frequently required in patients with mixed forms of dyslipidemia and increases the likelihood of improving multiple abnormal components of the lipid profile. However, incremental reductions in primary cardiovascular outcomes have not yet been demonstrated in trials testing combination therapy (SOR: C). In the ACCORD trial, the addition of fenofibrate to ongoing statin therapy in patients with diabetes with LDL-C of 100 mg/dL, HDL-C of 39 mg/dL, and normal triglyceride levels did not provide incremental benefit. The impact of ezetimibe adjuvant therapy with a statin is currently being evaluated in the IMPROVE-IT trial in patients who are status post an ACS.
- Antilipidemic agents can induce myalgia and myopathy and, rarely, hepatotoxicity (SOR: A).
- It is common for statins and fibrates to induce transient elevations in serum transaminases. If this occurs, these

Continued

KEY TREATMENT—continued

- drugs should be discontinued if levels exceed three times the ULN (SOR: A). However, if levels are below this threshold, it is acceptable to monitor liver function tests (LFTs) because transaminase levels usually decrease and trend toward normal spontaneously. Often, these drugs are discontinued prematurely, to the detriment of patient care. If LFTs do elevate, it is important to rule out drug interactions and evaluate the patient for baseline hepatic dysfunction (e.g., viral hepatic infection, structural injury, steatosis).
- When combining a statin with a fibrate, the use of gemfibrozil should be discouraged because it impairs the glucuronidation and elimination of the statins to varying degrees (SOR: A). This can result in increased risk for hepatotoxicity and rhabdomyolysis. Fenofibrate and fenofibric acid are safer choices in this context.
 - Patients complaining of myalgias or weakness, especially if escalating, should be monitored for myopathy. The statins and fibrates should be discontinued if serum creatinine kinase levels exceed 10 times the ULN (SOR: A). However, myalgias are common and not necessarily attributable to statin and fibrate usage. Other etiologies for myalgia and myopathy (fibromyalgia, polymyalgia rheumatica, muscle injury, electrolyte disturbances) should be investigated as appropriate.
 - In patients presenting with rhabdomyolysis, antilipidemic medications should be discontinued immediately. Patients should be hospitalized and hydrated with intravenous (IV) fluids and provided with all manner of supportive care (SOR: A).

Hypertension

Key Points

- Hypertension is highly prevalent, affecting one third of the adult population.
- Undertreatment is common, with only 50% of people achieving goals in the United States.
- Attention to proper technique for office blood pressure (BP) measurement is mandatory to accurately characterize BP levels and HTN control.
- Most patients should use proper home BP monitoring to aid in the proper diagnosis and management of HTN.
- The goal BP is a matter of considerable controversy. The panel members appointed to the Eighth Joint National Committee (JNC 8) suggest a goal of less than 140/90 mm Hg in patients under 60 years of age and 150/90 mm Hg in patients older than 60 years. Other influential guidelines suggest a more general application of 140/90 mm Hg as BP goal.
- Goal home BP averages are less than 135/85 mm Hg. Goal 24-hour ambulatory BP levels are less than 130/80 mm Hg.
- In uncomplicated HTN without compelling indications because of comorbidities, the specific choice of drug is less important than the attainment of goal BP. However, most patients should avoid monotherapy with a β -blocker or an α -blocker, given clinical trial evidence demonstrating their inferiority.

- If BP is more than 20/10 mm Hg above target level, then starting two antihypertensive medications (e.g., a combination pill) should be strongly considered.
- The use of combination therapy to treat HTN allows for the interruption of multiple mechanisms etiologic for this disorder and increases the likelihood of therapeutic success. Most recent evidence suggests that the majority of patients (perhaps 75%) will require two or more medications to obtain goals.
- The most compelling evidence suggests that if two agents are required, a combination of an angiotensin-converting enzyme (ACE) inhibitor plus a calcium channel blocker (CCB) (amlodipine) should be used first line based on the Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) study. Other combination agents, such as an ACE inhibitor plus a thiazide diuretic, are acceptable alternative regimens.
- The combination of two or more agents that block the renin-angiotensin system (e.g., ACE inhibitor angiotensin receptor blocker [ARB]; ARB + renin inhibitor) is almost always contraindicated.
- The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) encouraged the use of specific antihypertensive agents in the setting of HTN complicated by congestive heart failure (CHF), CAD, MI, and nephropathy, among other forms of CVD. Although more recent guidelines focus less on selecting specific agents, the importance of the “compelling indications” for an ACE inhibitor (or ARB) as the first-line treatment should still be considered, particularly among patients with CHF or proteinuria. The report of the panel members appointed to JNC 8 presents several additional considerations regarding compelling indications.
- Assuring adherence and persistence with medications and the institution of proven lifestyle modifications are important components of successful HTN management.
- Resistant HTN is common, affecting approximately 10% of the hypertensive population. Numerous approaches to obtain BP control have been shown to be helpful, including the empirical usage of aldosterone blockade (spironolactone 25-50 mg/day).
- In difficult cases, referral to an HTN expert may be warranted.
- Health care providers may believe that diastolic blood pressure (DBP) impacts CVD risk more than systolic blood pressure (SBP). The opposite is true among people older than 50 years of age.
- Therapeutic inertia (e.g., underaggressive dosing, underuse of combination medications, infrequent follow-up) is common and a prevalent cause of uncontrolled HTN.
- Suboptimal patient education about high BP and incomplete adherence to medical therapy are common causes of poorly controlled HTN.
- Underuse of diuretics, in particular chlorthalidone (a longer acting and more potent thiazide), is a frequent cause of uncontrolled HTN.
- The CCBs (both dihydropyridines and nondihydropyridines) tend to be underused because of peripheral edema. Combining these drugs with a low dose of an ACE inhibitor reduces the incidence of edema.
- ACE inhibitors and ARBs tend to be withheld in patients with mild to moderate renal insufficiency. However, such patients benefit significantly from these drugs. An increase in serum creatinine of up to 30% to 40% is

not unexpected and is acceptable (if it stabilizes), and patients should be monitored for hyperkalemia.

- β -Blockers are often overprescribed given the belief that they prevent MIs more than other agents in primary prevention. This is untrue, and given their inferior prevention of strokes, they should not be given as first-line agents in most patients for the treatment of HTN.
- Thiazide diuretics and β -blockers can antagonize glycemic control in patients with insulin resistance and impaired glucose tolerance and are associated with an increased risk for diabetes. ACE inhibitors and ARBs are metabolically beneficial and should be prescribed in most situations among such patients.

Hypertension is defined as persistently elevated BP 140 mm Hg or greater SBP or 90 mm Hg or greater DBP (Chobanian et al., 2003; James et al., 2014). It is a common and increasingly prevalent disorder affecting roughly one third of adults in the United States (Go et al., 2013) and at least one fourth of adults around the globe (Kearney et al., 2005). A higher than ideal BP (i.e., >115/75 mm Hg) is a well-established risk factor for CAD, MIs, left ventricular hypertrophy (LVH), CHF, PAD, aneurysmal diseases, strokes, chronic kidney disease (CKD), and sudden death. Approximately half of all strokes and ischemic heart disease (IHD) worldwide are attributable to HTN (Lawes et al., 2008). The Global Burden of Disease study has demonstrated that HTN is the single leading cause of morbidity worldwide (Lim et al., 2012). Moreover, there is a well-established log-linear relationship between the severity of HTN and cardiovascular risk. Data from 1 million adults demonstrate that every 20/10 mm Hg elevation in BP leads to an approximate doubling of risk of death from IHD and other vascular causes (Lewington et al., 2002). Even “pre-HTN” (120-139/80-89 mm Hg) is associated with an approximate doubling of cardiovascular risk (Mancia et al., 2013). In this context, the standard definition of HTN is arbitrary from a cardiovascular health standpoint. Nevertheless, a definition of HTN based on 140/90 mm Hg has been widely accepted because of a lack of large-scale randomized trials proving that treatment of BP initially below this threshold reduces morbidity and mortality (Law et al., 2009; Mancia et al., 2013).

RISK FACTORS FOR HYPERTENSION

The incidence of HTN increases as a function of age (Egan et al., 2010). Patients who are normotensive at age 55 years have a 90% risk of developing HTN at some point in their lives (Vasan et al., 2002). Some of the most important environmental risk factors predicting its incidence are obesity (\approx 1 mm Hg increase per kilogram of weight gain) (Staessen et al., 1988), excess sodium (>1.5-2.3 g/day) and alcohol intake (>10-20 g/day), lack of physical activity, and use of several over-the-counter (OTC) and prescription medications (e.g., stimulants, decongestants, estrogen-containing birth control pills, nonsteroidal antiinflammatory drugs [NSAIDs]) (Chobanian et al., 2003; Mancia et al., 2013). These risks are compounded in the setting of an underlying genetic predisposition. Although monogenic abnormalities exist (most typically affecting the kidney and

renal sodium handling; Simonetti et al., 2012), the genetic underpinning of the vast majority of “primary” HTN is attributable to the inheritance of multiple genes (Munroe et al., 2013). As such, a history of HTN doubles the risk for developing abnormal BP levels in other first-degree family members. Several common genetic variants (\approx 29 independent alleles have been identified) associate with HTN in genome-wide association studies (Munroe et al., 2013). The effect of each of these common variants on the risk of developing HTN appears to be small, although the cumulative effect of many risk-causing variants might be clinically important (i.e., altering BP by 4-6 mm Hg) (Mancia et al., 2013).

Hypertension is rarely caused by mutations in a single gene. However, in these uncommon scenarios, the onset of HTN is often observed during childhood and typically with other pertinent signs (e.g., low potassium) or characteristic phenotypes (e.g., Turner syndrome) (Simonetti et al., 2012). It is important for primary care physicians to be aware that some uncommon genetic disorders can lead to early-onset (and often severe) HTN that strongly clusters in families. Well-defined conditions include Liddle syndrome, the syndrome of apparent mineralocorticoid excess, congenital adrenal hyperplasia, and several familial syndromes of early-onset hyperaldosteronism or pheochromocytomas. However, by far the majority of HTN cases in children and adolescents are attributable to “primary” polygenic-environmental HTN, largely caused by increasing rates of obesity in the population (Koebnick et al., 2013). Guidelines for the management of HTN in special situations such as in children and adolescents have been published (Mancia et al., 2013).

THE ASSESSMENT OF HYPERTENSION IN ADULTS

The JNC 7 provides a comprehensive framework for defining and managing HTN among adults older than 18 years of age in the United States (Chobanian et al., 2003). However, these guidelines are now more than 10 years old and do not account for the findings of several important clinical trials published in the interim. The recently published report by the JNC 8 panel members highlights the lack of placebo-controlled trials targeting a BP less than 150/90 mm Hg in patients older than the age of 60 years (James et al., 2014). The panel members recommend that in the general population age 60 years of age and older, a BP of 150/90 mm Hg should be threshold for treatment and the treatment goal. In addition, the JNC 8 panel members placed less emphasis on thiazide-like diuretics as initial therapy for HTN compared with the JNC 7 recommendations. A comprehensive current set of guidelines has been published by the European Society of HTN (Mancia et al., 2013). The JNC 7 classifications of BP were not addressed by the JNC 8 panel members, and they remain valid (Table 27-6) (Chobanian et al., 2003). The importance of following careful methods and scrupulous attention to proper technique for the clinic measurement of BP cannot be overstated. Numerous patient and health care provider factors are involved as outlined by the AHA in detail (Pickering et al., 2005). A few of the most critical issues are to assure adequate patient rest time (5 minutes) in a seated position with the feet and back fully

Table 27-6 JNC 7 Blood Pressure Classification*

BP Classification	SBP (mm Hg)	DBP (mm Hg)	Lifestyle Modification	Drug Therapy
Normal	<120	and <80	Yes	Usually no treatment
Prehypertension	120-139	and 80-89	Yes	Yes, for compelling JNC 7 indications
Stage 1 hypertension	140-159	or 90-99	Yes	Yes
Stage 2 hypertension	≥160	or ≥100	Yes	Yes

*This classification is based on blood pressure (BP) levels being measured in at least duplicate readings on two or more separate occasions in a stable situation. This represents the “average” prevailing BP. Single elevations, sporadic, or transient increases in BP, such that might occur during pain, stress, illness, or anxiety, do not represent hypertension and should not be used to classify BP. The ESH 2013 classifies patients with systolic blood pressure (SBP) ≥180 or diastolic blood pressure (DBP) ≥110 mm Hg as having “stage 3” hypertension.

JNC, Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure.

From *The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure*. Washington, DC: U.S. Department of Health and Human Services. National Institute of Health Publication No. 04-5230. August 2004.

supported before measurement, a properly supported arm with the brachial artery at heart-level (defined as the fourth intercostal space), use of an appropriate size cuff for the arm circumference (the length and width of the bladder should be 80% and 40% arm circumference, respectively), the averaging of duplicate-to-triplicate BP recordings obtained 30 to 60 seconds apart, and assuring that the sphygmomanometer is routinely validated as being accurate (Mancia et al., 2013). Under most circumstances, a well-trained medical assistant or nurse should measure BP in a clinical setting given that most epidemiologic studies and clinical trials have been based on BP measurements obtained by nonphysicians. BPs are higher when measured by a physician because of an exaggerated “white coat” effect (Mancia et al., 1987). Several validated oscillometric office-based automated BP devices are currently available. These monitors can be programmed to measure multiple BP recordings while health care providers are absent from the clinic room, thus substantially reducing the “white coat” effect; studies have shown them to provide readings closer to BP levels obtained by home and ambulatory BP monitoring (Pickering et al., 2005) and to be superior predictors of cardiovascular morbidity (Pickering et al., 2008).

Both the JNC 7 and ESH 2013 guidelines outline standard recommendations for the assessment of patients with elevated BP levels (Chobanian et al., 2003; Mancia et al., 2013). These include an evaluation of HTN-related target organ status (TOS) and other concomitant cardiovascular risk factors (i.e., absolute global CVD risk estimation) and obtaining basic laboratory tests. A standard evaluation of TOS involves a funduscopic, neurologic, cardiac, and vascular physical examination and history looking for evidence of prior HTN-related disease(s) (e.g., MI, CHF, PAD, carotid stenosis, stroke, abdominal aneurysm) that might affect subsequent management decisions, including the use of specific medications or treatment targets. At a minimum, a resting electrocardiogram (ECG) and urinalysis for protein should also be obtained. Basic laboratory tests include a metabolic panel (creatinine, potassium, glucose, and estimated glomerular filtration rate [GFR]), thyroid-stimulating hormone, complete blood count, and a lipoprotein profile. An evaluation for other cardiovascular risk factors (e.g., diabetes, hyperlipidemia, low HDL-C, tobacco smoking, family history of HTN and CVDs) should be performed. Further testing (e.g., novel risk factors) and the evaluation of TOS in greater detail (e.g., echocardiography, stress testing, carotid or renal ultrasonography, coronary artery

calcium) should be performed on a case-by-case basis (Chobanian et al., 2003).

“SECONDARY” HYPERTENSION

It has been suggested that up to about 10% of HTN cases are attributable to “secondary” causes (Omura et al., 2004); however, the true prevalence is unknown and varies depending on the population assessed (Mancia et al., 2013). There are no well-adjudicated factors guiding clinicians when and how to evaluate for secondary or correctable causes of high BP. Although numerous rare causes exist, both JNC 7 and ESH 2013 provide outline recommendations regarding some of the most common scenarios (Chobanian et al., 2003; Mancia et al., 2013). It is suggested that patients with “resistant” HTN (BP uncontrolled on three or more medications, including a diuretic), those with sudden or severe alterations in BP levels, people with a paucity of risk factors for “primary” HTN, individuals without prior pre-HTN, patients admitted for hypertensive emergencies, and those with new HTN at extremes of age (<35-40 years or >70 years) should be considered for secondary HTN evaluation.

Pathological signs that suggest a certain etiology might also warrant specifically directed investigation. Common conditions to consider and their symptoms and signs include CKD (anemia, low GFR, small kidney), hypothyroidism (high TSH), renovascular HTN (abdominal bruit, elevated plasma renin activity, asymmetric kidney sizes, >30% elevation of creatinine after starting BP-lowering agents), hyperparathyroidism (high calcium), and obstructive sleep apnea (OSA) (excessive daytime somnolence, snoring, witnessed apnea) (Mancia et al., 2013). Although OSA is extremely common among patients with HTN, treatment with continuous positive airway pressure (CPAP) provides only a modest reduction in BP (≈2-4 mm Hg SBP) on average among patients with HTN and OSA (Martinez-Garcia et al., 2013). Nonetheless, there are some individuals with severe OSA and refractory HTN in whom CPAP can be extremely helpful in achieving BP control. Similarly, several recent studies (e.g., Cardiovascular Outcomes in Atherosclerotic Renal Disease [CORAL]) demonstrate that under most circumstances, renal artery stenting, even with significant stenosis, provides on-average minimal benefit in regards to protection of kidney function and BP lowering (Cooper et al., 2014). As a general rule, the limited number of patients that might benefit from renal revascularization

should be considered carefully when evaluating patients for renovascular HTN. Several reviews of the evaluation and management of renal artery stenosis have been published (Meier, 2011).

Although frequently suspected, pheochromocytoma is extraordinarily uncommon (<0.1-0.5% of cases of HTN; Omura et al., 2004). The classic symptoms include the “5 Ps,” which are palpitations, pain (headache), pressure (high BP), perspiration, and pallor (skin blanching) (Callender et al., 2011). The optimal screening test is the plasma free metanephrines, which have a negative predictive value greater than 98% (Vaclavik et al., 2007). This test is minimally altered by medications, and results are constantly elevated in affected individuals given its continuous non-cyclic release from tumors. However, given the rarity of this disorder, most patients with this symptom constellation or borderline abnormal blood test results (two to three times elevated plasma free metanephrines) will have other etiologies (e.g., pseudopheochromocytoma, panic disorder, migraines, arrhythmias, autonomic failure, baroreceptor failure). Confirmatory tests (e.g., clonidine suppression testing) and imaging (e.g., computed tomography [CT], MRI, nuclear medicine functional tests [metaiodobenzylguanidine or MIBG]) for tumor localization may be required if repeat testing is abnormal, symptoms persist, paroxysmal HTN episodes continue, or BP remains elevated. Guidelines for the evaluation and management of pheochromocytomas are available (Pacak et al., 2007).

Finally, the past decade has witnessed a resurgence of evidence suggesting the importance of primary aldosteronism in the etiology of HTN in up to about 5% to 10% of patients (Fardella et al., 2000; Schwartz and Turner 2005). An inappropriate elevation of aldosterone from adrenal hyperplasia or an adenoma (“Conn disease”) may be the single most common secondary etiology of HTN, and primary care physicians should have a low threshold for its consideration among difficult-to-control patients. Contrary to common thought, classic signs such as hypokalemia actually occur in fewer than 50% of patients (Funder et al., 2008). A screening seated ratio of serum aldosterone (ng/dL)/plasma renin activity (ng/mL/hr) obtained in an ambulatory setting is a reasonable first test. A ratio greater than 25 to 30 warrants further evaluation, and if hyperaldosteronism is confirmed, then localization with imaging studies is warranted. Whether or not to manage medically with aldosterone-blocking agents or with surgical removal (if an adenoma is found) should be considered on a case-by-case basis. Endocrine Society recommendations for the management of primary aldosteronism have been published (Funder et al., 2008).

GENERAL MANAGEMENT OF HIGH BLOOD PRESSURE IN ADULTS

The management of high BP in adults has been outlined in the ESH 2013 guidelines (Mancia et al., 2013). Recently, the AHA along with the ACC and the Centers for Disease Control and Prevention (CDC) released a science advisory outlining an “effective approach to high blood pressure control” (Go et al., 2014). This document provides recommendations for achieving BP targets, including a practical algorithm for pharmacological therapy (Figure 27-3).

In rare circumstances when BP is found to be severely and persistently elevated (e.g., >180/110-120 mm Hg) by accurate clinic readings or symptoms or signs of acute HTN-related target organ damage are reported (e.g., acute stroke or TIA, encephalopathy, CHF, aortic dissection, acute MI, rapid deterioration in renal function), patients may require urgent (within 1 week) or emergent (immediate hospital admission) evaluation and treatment. Management of HTN “emergencies,” defined as a severe elevation in BP with the presence of new or ongoing target organ damage, are outlined in the JNC 7 and ESH 2013 guidelines (Mancia et al., 2013).

DIETARY AND LIFESTYLE TREATMENT

All guidelines agree that most patients with BP values above ideal should be educated about the lifestyle modalities proven effective to lower BP. Given that drug treatment of pre-HTN is not recommended at this point in time unless patients have compelling indications because of other comorbidities (e.g., CHF), people with BP levels between 120 to 139/80 to 89 mm Hg are ideal candidates for aggressive dietary and lifestyle changes to lower BP and prevent the onset of overt HTN. The AHA, American Society of HTN, and ESH 2013 have promulgated several dietary-lifestyle changes, including a low sodium diet (<1.5 to 2.3 g/day), a diet consistent with the Dietary Approaches to Stop Hypertension (DASH) eating pattern, weight reduction if the body mass index (BMI) is greater than 25 kg/m², alcohol restriction to less than 10-20 g/day, and aerobic exercise (target of 150 min/wk) (Mancia et al., 2013). Although not proven to reduce hard CVD events, each of these lifestyle treatments is well established to lower BP on average by 4 to 6 mm Hg SBP in a dose-response and additive manner. As such, most patients with pre-HTN and many with stage I HTN (without compelling indications for a specific BP-lowering medication) can be successfully managed and reach BP targets using one or more of these nonpharmacologic interventions. More recently, the AHA also published recommendations regarding the use of other nonpharmacologic alternative approaches to help manage HTN (Brook et al., 2013). For select individuals, it was concluded that some alternative treatments, notably resistance and isometric exercise, device-guided slow breathing, and certain meditation techniques, can serve as effective and helpful adjuvants to lower BP. Whether or not patients are able to adhere to these nonpharmacologic lifestyle treatments to control BP over several years remains uncertain. Primary care physicians should carefully monitor BP and healthy lifestyle patterns among such individuals.

CLINICAL TRIAL EVIDENCE GUIDING PHARMACOLOGIC THERAPY

The pharmacologic reduction of BP using most classes of antihypertensive drugs reduces the risk for cardiovascular events (strokes, CHF, CKD, MIs) and end-organ injury (LVH, microalbuminuria) and prevents the onset of more severe forms of HTN (Mancia et al., 2013). The latest comprehensive meta-analysis demonstrates a consistent reduction in CVD events by antihypertensive treatment whereby a 10/5-mm Hg reduction produces an approximate 40% and

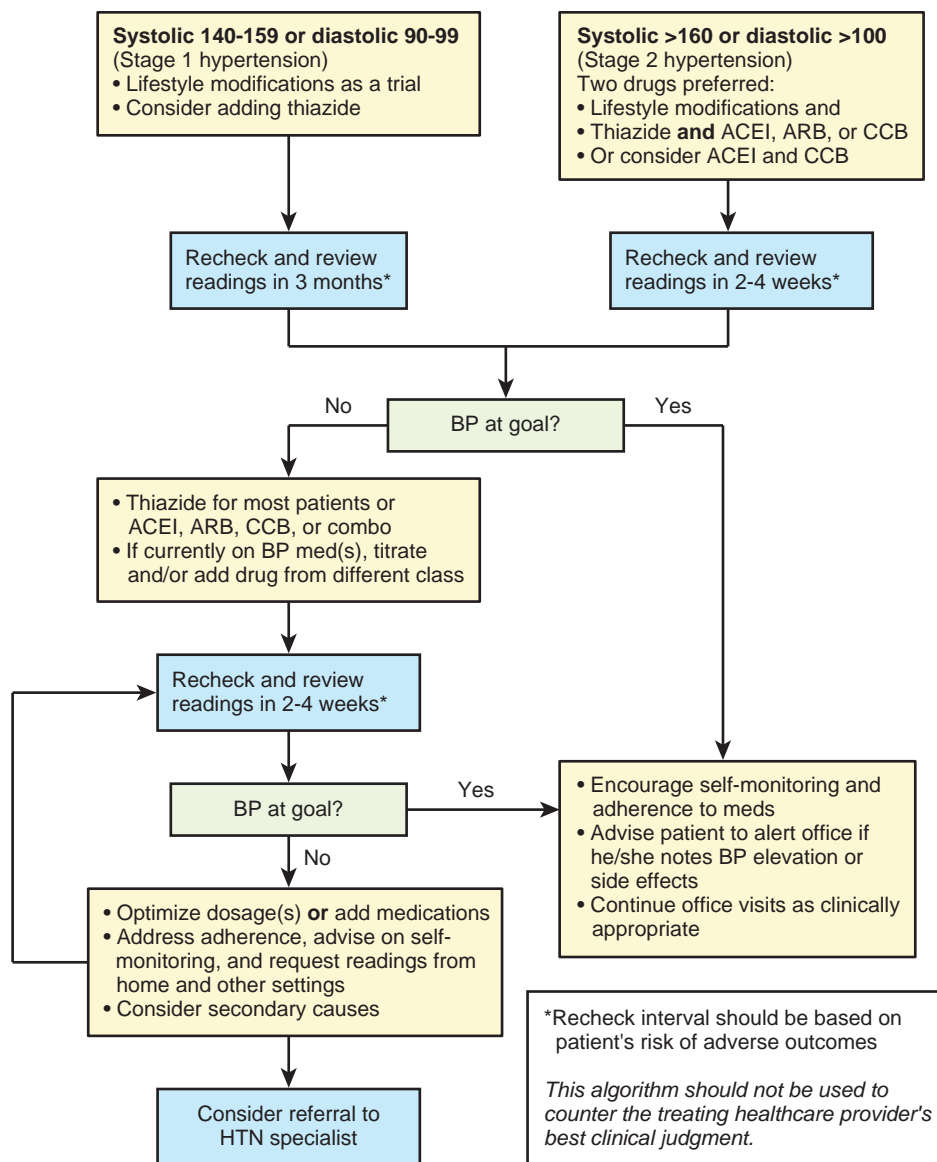

Figure 27-3 Practical approach for blood pressure control. (Used with permission from Go AS, Bauman M, King SM, et al. An effective approach to high blood pressure control: a science advisory from the American Heart Association, the American College of Cardiology, and the Centers for Disease Control and Prevention. *Hypertension*. 2014;63(4):878-885.)

20% reduction in strokes and IHD events, respectively (Law et al., 2009). Importantly, this improvement in outcomes occurs rapidly within 1 year of treatment and, based on modern medical therapy, is a health benefit consistent with what would be expected by prospective cohort studies.

Numerous clinic trials have been performed over the past several decades. Several key points from these trials as summarized in the most recent meta-analyses are as follows. Achieving BP goal target is of preeminent importance. The antihypertensive agents used are of secondary importance (Mancia et al., 2013). Prevailing expert opinion contends that unless there are compelling indications for the use of a specific drug class because of background cardiovascular or renal disease, it makes little difference which agent is first prescribed in the setting of uncomplicated HTN (SOR: A) (Julius et al., 2004; Law et al., 2009; National Institute for Clinical Excellence 2004; Pepine et al., 2003; Turnbull 2003; Williams 2005). As supported by the most recent

comprehensive meta-analysis, risk reduction is predominantly driven by the magnitude of BP reduction rather than the specific mechanism by which it is achieved (SOR: A) (Law et al., 2009). If a single agent can be used to obtain goals, recent data support that monotherapy with a β -blocker (in particular atenolol because of excess risks of strokes) or an α -blocker (caused by excess risks of CHF events by doxazosin in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack [ALLHAT] study) should be discouraged because they are less effective than most other agents (Law et al., 2009). Although β -blockers might be effective in the secondary prevention of IHD, they are no more effective than other agents (in particular thiazides) in the primary prevention of MIs. Meta-analyses suggest that β -blockers are inferior in the prevention of strokes (Bangalore et al., 2007). In the past, thiazides were recommended as first-line drugs for most patients based on their low costs and abundant clinical trial

evidence (Chobanian et al., 2003). However, given the reduction in costs and generic formulation availability for all classes of antihypertensive agents, there is no compelling evidence against starting as a first-line agent any of the following: thiazides, CCBs, ACE inhibitors, and ARBs. There are marginal differences in outcomes among these agents observed in trials and meta-analyses (Law et al., 2009). Nevertheless, if a diuretic is chosen, the longer acting and more potent agent chlorthalidone should be considered as first-line treatment given that it has the highest level of clinical trial evidence supporting its use. Many experts recommend it over other thiazides (e.g., hydrochlorothiazide); however, head-to-head outcome trials have not been performed (Beckett et al., 2008; Mancina et al., 2013).

It is also important to highlight that “isolated systolic HTN” (i.e., SBP >160 mm Hg with DBP <90 mm Hg) is a potent risk factor for strokes and CVDs (Mancina et al., 2013). Among patients older than 50 years, SBP levels are more strongly related to CVD and renal disease than DBP (Leonetti et al., 2000; Nielsen et al., 1997). Treatment of isolated systolic HTN leads to improved CVD outcomes regardless of achieved DBP levels on treatment (Berl et al., 2005). Although there have been long-standing concern and debate about the risks of the “J-curve,” whereby excessive reductions in DBP may lead to increased risk for CHD events, the overall evidence supports that this effect is limited largely to high-risk patients with established CAD. Treatment-induced reduction in SBP to less than 140 mm Hg typically provides a greater overall event reduction than is offset by any adverse effect of excessive lowering of DBP (Mancina et al., 2013). Nevertheless, careful monitoring of certain individuals in this scenario is warranted, including those older than 80 years, patients with active angina worsened by BP lowering, and people with excessively low DBP (<65 mm Hg) or orthostatic hypotension.

ALGORITHM FOR ANTIHYPERTENSIVE MEDICATION PRESCRIPTION

A large number of antihypertensive medications are available. These medications, along with their dosing regimens, are summarized in Table 27-7. Despite the recognized dangers of HTN and the large number of available medications, only about 50% of patients with this disorder are treated to target BP levels in the United States (Go et al.,

2013). Given this public health shortcoming and the lack of clear evidence that any single BP-lowering medication is the most effective in reducing cardiovascular events in any subgroup of individuals, more practical approaches for controlling HTN have been advocated recently compared with past guidelines. The ESH 2013, AHA 2013, and JNC 8 documents outline straightforward algorithms for prescribing antihypertensive regimens based on the most recent level of evidence from clinical trials (Go et al., 2013; James et al., 2014; Mancina et al., 2013). We agree with the approach offered by the AHA 2013 statement; it is a reasonable recommendation applicable to most patients (see Figure 27-3).

Although recommendations regarding the selection of the first drug class have figured less prominently in recent guidelines (ESH 2013, AHA 2013), most experts agree that starting or rapidly intensifying treatment to combination antihypertensive therapy among most patients who have BP levels greater than 20/10 mm Hg above goals is important. Given that a majority of patients will ultimately require two or more BP-lowering medications to achieve goals (Hansson et al., 1998), elucidating the optimal combination of agents is becoming more important to determine. There has only been one clinical trial in HTN with hard cardiovascular outcomes that based treatment limbs on differing initial combination regimens. The Avoiding Cardiovascular events through COMbination therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial (Jamerson et al., 2008) demonstrated a significant 20% reduction in combined cardiovascular events in patients treated with a combination of an ACE inhibitor plus CCB (benazepril + amlodipine) compared with patients treated with an ACE inhibitor plus a thiazide diuretic (benazepril + hydrochlorothiazide) (Jamerson et al., 2008). This occurred in the overall population and in the subsets of patients with diabetes, CAD, and CKD. All subsets of outcomes evaluated were reduced by a greater extent by the ACE inhibitor-CCB combination except CHF, which was neutral. This includes the prespecified outcome of hard CKD end points. Thus, we have previously suggested that most patients who require dual antihypertensive therapy should strongly consider starting with an ACE inhibitor plus a CCB (Brook and Weder, 2011). In this manner, our recommendations slightly differ from the official AHA 2013 and ESH 2013 guidelines that suggest an ACE inhibitor plus either a CCB or thiazide is reasonable.

Table 27-7 Oral Antihypertensive Drugs

Drug	Trade Name	Usual Dose Range, Usual Milligrams Per Dose (Usual Frequency of Doses Per Day)	Selected Side Effects and Comments
DIURETICS (PARTIAL LIST)			Short term: increase cholesterol and glucose levels; biochemical abnormalities; decrease potassium, sodium, and magnesium levels Increase uric acid and calcium levels; rare: blood dyscrasias, photosensitivity, pancreatitis, hyponatremia
THIAZIDE AND THIAZIDE-LIKE DIURETICS			
Chlorthalidone (G)	Thalitone	12.5-50 (1)	
Hydrochlorothiazide (G)	Microzide	12.5-50 (1)	
Indapamide (G)		1.25-2.5 (1)	Less or no hypercholesterolemia

Continued on following page

Table 27-7 Oral Antihypertensive Drugs (Continued)

Drug	Trade Name	Usual Dose Range, Usual Milligrams Per Dose (Usual Frequency of Doses Per Day)	Selected Side Effects and Comments
Loop Diuretics			
Bumetanide (G)		0.5-2 (1-2)	Short duration of action; no hypercalcemia
Ethacrynic acid	Edecrin	25-100 (1-2)	Only nonsulfonamide diuretic, ototoxicity
Furosemide (G)	Lasix	20-80 (2)	Short duration of action, no hypercalcemia
Torsemide (G)	Demadex	5-10 (1-2)	
Potassium-Sparing Agents			Potentially fatal hyperkalemia
Amiloride hydrochloride (G)	Midamor	5-10 (1)	
Spironolactone (G)	Aldactone	12.5-100 (1)	More gynecomastia
Eplerenone (G)	Inspra	25-50 (1-2)	Less gynecomastia
Triamterene (G)	Dyrenium	50-100 (1)	Hypertension is an unlabeled use
ADRENERGIC INHIBITORS			
Peripheral Agents			
Reserpine (G)		0.05-0.25 (1)	Nasal congestion, sedation, depression, activation of peptic ulcer
Central α -agonist			Sedation, dry mouth, bradycardia, withdrawal hypertension
Clonidine hydrochloride, oral (G)	Catapres	0.1-0.8 (2-3)	More withdrawal
Clonidine, transdermal patch (G)	Catapres-TTS	0.1-0.3 mg/24 hour patch replaced every 7 days	
Guanfacine hydrochloride, immediate release (G)	Tenex	1-2 (1)	Less withdrawal
Methyldopa (G)		250-500 (2)	Hepatic and "autoimmune" disorders Can elevate HDL
α-Blockers			
Doxazosin mesylate, immediate release (G)	Cardura	2-16 (1)	
Prazosin hydrochloride (G)	Minipress	1-10 (2)	
Terazosin hydrochloride (G)	Hytrin	1-20 (1)	
β-Blockers			
			Increased risk of diabetes mellitus, bronchospasm, bradycardia, heart failure; may mask insulin-induced hypoglycemia, hypoglycemia unawareness; impaired peripheral circulation, insomnia, fatigue, decreased exercise tolerance, hypertriglyceridemia (except agents with intrinsic sympathomimetic activity), reduced HDL
Acebutolol (G)	Sectral	200-400 (1-2)	
Atenolol (G)	Tenormin	25-100 (1-2)	
Betaxolol hydrochloride (G)		10-20 (1)	
Bisoprolol fumarate (G)	Zebeta	2.5-10 (1)	
Metoprolol tartrate (G)	Lopressor	25-200 (2)	
Metoprolol succinate (G)	Toprol XL	25-300 (1)	
Nadolol (G)	Corgard	40-80 (1)	
Nebivolol	Bystolic	5-20 (1)	Vasodilating agent with less metabolic abnormalities
Penbutolol sulfate	Levadol	10-20 (1)	
Pindolol (G)		5-15 (2)	
Propranolol immediate release (G)	Inderal	40-120 (2)	
Propranolol extended release (G)	Inderal LA	80-160 (1)	
Timolol maleate (G)		10-20 (2)	
Combined α- and β-Blockers			Postural hypotension, bronchospasm
Carvedilol, immediate release (G)	Coreg	6.25-25 (2)	
Carvedilol, extended release	Coreg CR	20-40 (1)	
Labetalol (G)		100-400 (2-3)	
Direct vasodilators			Headaches, fluid retention, tachycardia

Table 27-7 Oral Antihypertensive Drugs (Continued)

Drug	Trade Name	Usual Dose Range, Usual Milligrams Per Dose (Usual Frequency of Doses Per Day)	Selected Side Effects and Comments
Hydralazine hydrochloride (G)		10-100 (4)	Lupus-like syndrome, myocardial ischemia
Minoxidil (G)		2.5-40 (1)	Hirsutism, edema, pericardial effusion
CALCIUM ANTAGONISTS			
Nondihydropyridine			
Diltiazem hydrochloride (G)	Cardizem CD, Cardizem LA, Dilacor XR, Tiazac	120-360 (1)	Conduction defects, worsening of systolic dysfunction, gingival hyperplasia
Verapamil hydrochloride (G)	Calan SR, Verelan, Covera-HS	90-240 (2) 120-480 (1)	Nausea, headache
Dihydropyridines			
Amlodipine besylate (G)	Norvasc	2.5-10 (1)	Edema of the ankle, flushing, headache, gingival hypertrophy
Felodipine (G)	Plendil	2.5-10 (1)	
Isradipine (G)	Dynacirc	2.5-10 (2)	
Nicardipine hydrochloride, sustained release (G)	Cardene SR	30-60 (2)	
Nifedipine (G)	Procardia XL, Adalat CC	30-60 (1)	
Nisoldipine (G)	Sular	20-40 (1)	
ANGIOTENSIN-CONVERTING ENZYME INHIBITORS			
Common: cough, hyperkalemia; rare: angioedema, rash, loss of taste, leukopenia			
Benazepril hydrochloride (G)	Lotensin	5-40 (1)	Hyperkalemia, angioedema (very rare [association with ARBs is controversial])
Captopril (G)	Capoten	25-50 (2-3)	
Enalapril maleate (G)	Vasotec	5-40 (1)	
Fosinopril sodium (G)	Monopril	10-40 (1)	
Lisinopril (G)	Prinivil, Zestril	5-40 (1)	
Moexipril hydrochloride (G)	Univasc	7.5-30 (1)	
Quinapril hydrochloride (G)	Accupril	5-80 (1)	
Ramipril (G)	Altace	1.25-20 (1)	
Trandolapril (G)	Mavik	1-4 (1)	
Angiotensin II Receptor Blockers			
Losartan potassium (G)	Cozaar	25-100 (1-2)	Hyperkalemia, hypotension, angioedema, diarrhea, cough, seizures, rash, gout, and renal stones. Contraindicated in patients with diabetes who are treated with an ARB or ACE inhibitor; avoid use with ARB or ACE inhibitor in patients with moderate to severe renal impairment
Valsartan (G)	Diovan	80-320 (1)	
Irbesartan (G)	Avapro	150-300 (1)	
Telmisartan	Micardis	40-80 (1)	
Olmesartan	Benicar	40-40 (1)	
Azilsartan	Edarbi	40-80 (1)	
Candesartan (G)	Atacand	4-32 (1)	
Direct Renin Inhibitor			
Aliskiren	Tekturna	150-300 (1)	

G indicates that a generic formulation is currently available.

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; HDL, high-density lipoprotein.

Combinations of drugs that are efficacious and those associated with undesirable side effect profiles are summarized in [Table 27-8](#). The most important recent observation from clinical trials is that under most circumstances, combination blockade of the renin-angiotensin system is not warranted and may be dangerous. The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint

Trial (ONTARGET) study demonstrated that combined ACE inhibitor-ARB therapy does not prevent cardiovascular events more than monotherapy ([Yusuf et al., 2008](#)). However, renal outcomes were worsened by this combination. The Aliskiren Trial in Type 2 Diabetes Using Cardiorenal Endpoints (ALTITUDE) study also showed that combined ARB plus direct renin inhibition is not protective to renal

Table 27-8 Antihypertensive Drug Combinations

Desirable or Acceptable	Not Desirable
THIAZIDE OR THIAZIDE-LIKE DIURETIC PLUS:	β-BLOCKER PLUS:
ACE inhibitor*	Central adrenergic inhibitor
Aldosterone antagonist	Rate-lowering CCB (NDHPCCB)
Angiotensin receptor blocker*	ACE inhibitor/ARB: less effective
β-Blocker	CCB plus:
CCB	Diuretic: less effective
Direct renin inhibitor	ACE inhibitor plus:
CCB plus:	ARB [†]
ACE inhibitor [†]	ARB plus:
ARB*	Direct renin inhibitor [†]
β-Blocker (if DHPCCB)	

*Acceptable alternative (second-line) combination regimens.

[†]Considered most effective combination based on blood pressure-lowering efficacy and should be strongly considered first-line treatment or most patients based on evidence from outcome trials (Avoiding Cardiovascular Events through Combination Therapy in Patients Living with Systolic Hypertension [ACCOMPLISH] trial).

[‡]These combinations should be avoided under most circumstances.

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCB, calcium channel blocker; DHPCCB, dihydropyridine calcium channel blocker; NDHPCCB, nondihydropyridine calcium channel blocker.

function among patients with diabetes and poses excess side effect risk (Parving et al., 2012). Recommendations for attaining BP targets in the more challenging patients who often require multiple BP-lowering agents are summarized in Table 27-9. There are numerous benefits to prescribing combination agents to achieve control of HTN. Comprehensive recommendations regarding combination antihypertensive regimens have been published (Gradman et al., 2011).

COMPELLING INDICATIONS FOR MEDICATIONS

JNC 7 guidelines recommended tailoring first-line antihypertensive therapy choices in the context of other comorbidities (Chobanian et al., 2003). Certain medication choices may be appropriate initial selections and more strongly considered for subsets of individuals based on ancillary benefits (e.g., reduction in proteinuria by ACE inhibitor and ARBs). On the other hand, other agents may be avoided because of potential side effects (e.g., worsening glycemic control by thiazides and β-blockers). Prior recommendations for “compelling indications” based on JNC 7 guidelines are summarized in Table 27-10. Nevertheless, the most important considerations that remain valid are in relation to the following disease states. Individuals with heart failure (HF) with reduced ejection fraction (EF) should receive either an ACE inhibitor or ARB, with the careful addition of a β-blocker (e.g., metoprolol or carvedilol). Many patients with CHF should thereafter have an aldosterone blocker added if tolerated (Pitt et al., 2003). Diabetic and nondiabetic patients with overt proteinuria and CKD should receive either an ACE inhibitor or ARB as part of their BP-lowering regimen (Brenner et al., 2001; Lewis et al., 1993; Lewis et al., 2001). Whether or not patients with CKD or diabetes must receive these agents in the absence of frank proteinuria remains a matter of debate; however, given their ability to reduce microalbuminuria and their beneficial metabolic profile, these drugs remain excellent selections for BP control (Mancia et al., 2013).

Table 27-9 Ten Tips for Attaining Goal Blood Pressure

1. If BP $\geq 20/10$ mm Hg above goal, monotherapy is unlikely to be effective, so consider a combination antihypertensive agent. The strongest evidence is for an ACE inhibitor or ARB + CCB based on outcome studies (ACCOMPLISH). A combination with ACE inhibitor or ARB + thiazide is an acceptable alternative.
2. In most situations, allow for 2-4 weeks of treatment before titrating BP medications upward (or adding additional drugs) to establish the full efficacy of the medication(s). However, a longer delay can lead to “therapeutic inertia” and should be avoided in most scenarios if BP remains above target.
3. Realize that most hypertensive patients ($\approx 75\%$) will ultimately require two or more drugs to attain goal BP, especially persons with diabetes, obesity, decreased kidney function, or proteinuria. Use of one or more combination antihypertensive agents is effective for achieving BP targets.
4. Initiate lifestyle modifications for most patients: DASH diet, low sodium (<1.5 - 2.3 g/day) and alcohol intake (<2 drinks/day); aerobic exercise; and weight loss (if indicated). Ask about adherence and assure persistence with diet, lifestyle, and prescribed medications if BP remains elevated.
5. To avoid falsely high BP measurements (pseudo-HTN, pseudo-resistance, white coat HTN), careful attention to BP measurement technique is critical to obtain accurate readings in the clinical setting.
6. Minimize exposure to medications known to raise BP such as NSAIDs. Ask about all recreational and OTC medications and prescription medications that can elevate BP.
7. A diuretic appropriate to the level of kidney function is essential to the multidrug regimen when three or more antihypertensives are prescribed. Thiazide diuretics are typically more effective BP-lowering agents than loop diuretics unless stage IV or V CKD is present. Chlorthalidone is more potent and longer acting than hydrochlorothiazide and has more clinical trial outcome evidence, so it should be considered as the first diuretic choice in most patients.
8. Self-measured blood pressure and 24-hour ABPM can be useful adjuncts, especially when white coat hypertension or white coat worse hypertension are suspected or when BP appears to be refractory to treatment. If discordant from clinic BP values, the ABPM readings are typically more accurate estimates of true BP levels and future CVD risk.
9. Diuretic doses may need to be relatively high (e.g., furosemide 160 mg/day in divided doses or metolazone 10-20 mg/day) when kidney function is <30 mL/min/1.73 m². Combination loop + thiazide diuretics can be effective in this scenario to achieve BP targets with severe CKD.
10. In “resistant hypertension,” if BP remains above goal on three or more antihypertensives (one of which is a diuretic) at near-maximal doses, consider referral to a hypertension specialist. Empirical treatment with an aldosterone antagonist (spironolactone 25-50 mg/d) may be highly effective in difficult-to-control HTN and should be strongly considered. Novel treatments (e.g., renal sympathetic nerve ablation) and evaluation for secondary HTN (e.g., primary aldosteronism) are warranted.

BLOOD PRESSURE TARGETS

Prior guidelines, including JNC 7, emphasized lower BP goals ($<130/80$ mm Hg) for certain individuals, including those with CKD and diabetes. Recent outcome trials have tested the benefits of more aggressive treatment among

patients with diabetes. The ACCORD trial demonstrated that aggressive reduction of BP (target <120/80 mm Hg) did not reduce combined cardiovascular and renal outcomes compared with usual care (target BP <140/90 mm Hg) (Cushman et al., 2010). Among secondary outcomes, strokes were reduced by the lower BP goals but at the expense of twice as many serious side effects. Several meta-analyses have demonstrated that lowering BP to below 130 mm Hg systolic does not reduce mortality rates or most cardiovascular outcomes (Mancia et al., 2013). The exception to this rule is that a lower BP level below 130/80 mm Hg may be protective against strokes in both primary and secondary prevention (Benavente et al., 2013; Weber et al., 2013). There is little evidence to support more aggressive BP targets even among individuals with CKD in the absence of overt proteinuria (>500 mg/day) (Mancia et al., 2013). In the latter case with significant levels of proteinuria, tighter BP control to below 130/80 mm Hg or lower might be helpful; however, compelling evidence from clinical trials is still lacking.

The ideal BP level remains questionable; however, few studies support lowering BP below a value of 140/90 mm Hg in most patients. Hence, the old JNC 7 targets among patients with diabetes and those with CKD have not been promulgated by more recent ESH 2013 and JNC 8 guidelines (James et al., 2014; Mancia et al., 2013). In rare circumstances (prevention of strokes) and among complicated patients (e.g., aortic aneurysms, recurrent cardiovascular events), lower BP targets can be selected on an individual basis.

EMERGING MANAGEMENT STRATEGIES, RESISTANT HYPERTENSION, AND CONTROVERSIES

Emerging strategies for assessment of BP include use of self-measured home BP and 24-hour ambulatory blood pressure monitoring (ABPM) (O'Brien et al., 2013; Pickering et al., 2008). Home BP is a useful adjunct to clinic BP measurements, which are often affected by the “white coat effect.” ABPM can rule out “white coat” HTN and “white coat worse” HTN and has the added benefit of assessing nocturnal BP, which may be a more important predictor of cardiovascular events than daytime BP (Clement et al., 2003). Both techniques may also uncover “masked HTN,”

a scenario when clinic BP is controlled in the setting of high out-of-office BP readings (Yano and Bakris, 2013). Although white coat HTN is not associated with excess cardiovascular risk (Fagard et al., 2000), masked HTN conveys an equal risk as sustained elevations in BP observed in the clinic. The availability of ABPM is more limited than the availability of home BP, which depends primarily on the patient’s ability to obtain an automated oscillometric BP cuff and to follow detailed instructions. A normal home BP is lower than a normal clinic BP, with 135/85 mm Hg suggested by some authorities as differentiating normal from HTN (Hodgkinson et al., 2011). ABPM values for a 24-hour average greater than 130/80 mm Hg are considered elevated. Although there is compelling evidence that both home and ABPM levels are more strongly related to cardiovascular morbidity and mortality than traditional clinic readings, few data support tailoring treatment goals based on these values. Guidelines for both home and ABPM have been published (O'Brien et al., 2013; Pickering et al., 2008). Several expert societies now support that home BP monitoring should be performed in most (if not all) patients with HTN (Pickering et al., 2008).

To tailor drug therapy and reduce the number of people requiring more than one or two medications, several strategies have been proposed. The most well-known algorithm suggests selecting drug therapy based on ambulatory measurement of plasma renin activity (Mulatero et al., 2007). Those defined as “low-renin” (<0.65 ng/mL/hr) patients are treated with diuretics or CCBs; others are treated with ACE inhibitors, ARBs, or β -blockers. Although this approach can improve the rates of BP control in selected patients and clinical trials, the usefulness of this strategy in real-world clinical setting remains unclear. Other strategies based on hemodynamic monitoring (e.g., cardiac bioelectrical impedance), demographic profiling, and pharmacogenetics have been proposed. It has also been proposed to start most patients with combination medications (even in stage I) given that more than 50% to 75% of people will inevitably require two or more drugs. Whether or not these approaches will be effective in a broad clinical setting remains to be proven. For the time being, following the clinical strategies outlined in guideline documents is recommended (Go et al., 2013) (see Figure 27-3).

The optimal treatment of HTN “emergencies” remains unproven (Mancia et al., 2013). The standard guidelines

Table 27-11 Parenteral Drugs for Treatment of Hypertensive Emergencies

Drug	Dose	Onset of Action	Duration of Action	Adverse Effects	Special Instructions
Sodium nitroprusside	0.25-10 $\mu\text{m}/\text{kg}/\text{min}$ as IV infusion (maximal dose for 10 min only)	Immediate	1-2 min	Nausea, vomiting, muscle twitching, sweating, thiocyanate and cyanide intoxication	Most hypertensive emergencies; caution with high ICP or azotemia
Nicardipine hydrochloride	5-15 mg/hr IV	5-10 min	1-4 hr	Tachycardia, headache, flushing, local phlebitis	Most hypertensive emergencies except acute heart failure; caution with coronary ischemia
Fenoldopam mesylate	0.1-0.3 $\mu\text{m}/\text{kg}/\text{min}$ as IV infusion	<5 min	30 min	Tachycardia, headache, nausea, flushing	Most hypertensive emergencies; caution with glaucoma
Nitroglycerin	5-100 $\mu\text{m}/\text{min}$ as IV infusion	2-5 min	3-5 min	Headache, vomiting, methemoglobinemia, tolerance with prolonged use	
Enalaprilat	1.25-5 mg every 6 hr IV	15-30 min	6 hr	Precipitous fall in pressure in high-renin states; response variable	Acute LV failure; avoid in acute MI
Hydralazine hydrochloride	10-20 mg IV 10-50 mg IM	10-20 min 20-30 min	3-8 hr	Tachycardia, flushing, headache, vomiting, aggravation of angina	Eclampsia; caution with coronary ischemia
Labetalol hydrochloride	20-80 mg as IV bolus every 10 min 0.5-2.0 mg/min as IV infusion	5-10 min	3-6 hr	Vomiting, scalp tingling, burning in throat, dizziness, nausea, heart block, orthostatic hypotension	Most hypertensive emergencies except acute heart failure
Esmolol hydrochloride	250-500 $\mu\text{m}/\text{kg}/\text{min}$ for 1 min, then 50-100 $\mu\text{m}/\text{kg}/\text{min}$ for 4 min; may repeat sequence	1-2 min	10-20 min	Hypotension, nausea	Aortic dissection; perioperative
Phentolamine	5-15 mg IV	1-2 min	3-10 min	Tachycardia, flushing, headache	Catecholamine excess
Clevidipine	1-2 to 16 mg/hr	2-4 min	5-15 min	Hypotension, tachycardia	Avoid with hyperlipidemia No use with egg or soy allergy

IM, Intramuscular; IV, intravenous; ICP, intracranial pressure; LV, left ventricular; MI, myocardial infarction.

are to lower mean arterial pressure by 20% to 25% within hours and to avoid overaggressive treatment, which may worsen outcomes, particularly cerebrovascular function when cerebral perfusion pressures may be altered. Few trials have compared the effectiveness of various medications and treatment approaches. Nonetheless, numerous agents are available (Table 27-11). The optimal management of HTN in the setting of an acute ischemic or hemorrhagic stroke in particular has undergone many recent clinical trials; however, the optimal treatment goals and timing of medications remain unclear (Mancia et al., 2013). At present, the most recent clinical trials do not support early or aggressive BP lowering in most patients with ischemic strokes or TIAs (He et al., 2013).

Patients with resistant HTN are defined as having a BP above target (usual >140/90 mm Hg) despite taking three or more BP-lowering agents (one of which is a diuretic appropriate for renal function). Its prevalence is estimated at approximately 10% of the HTN population. The AHA has published guidelines outlining management approaches in these difficult-to-control patients (Calhoun et al., 2008). The evidence outlined suggests that close to 85% to 95% of all patients with HTN can achieve BP goals despite the U.S. national control rate of only 50%. One important strategy with some clinical evidence is the empirical usage of add-on aldosterone blockade (e.g., spironolactone 25-50 mg/day; eplerenone 25-50 mg twice a day) while watching potassium and creatinine closely. Even in the absence of overt hyperaldosteronism, this approach has proven effective in

helping to control BP among those with resistant HTN (Calhoun et al., 2008). A common error in the effective treatment of resistant HTN is underuse of diuretic therapy. Changing less potent diuretics (e.g., hydrochlorothiazide) to a more potent, longer acting thiazide-like diuretic such as chlorthalidone has also proven effective in further lowering BP (Matthews et al., 2013). Furthermore, several triple-drug combination pills are available that combine a thiazide, an ARB, and amlodipine. Finally, the addition of a fourth and fifth agent may be necessary in rare individuals; however, there are few data to support an evidence-based approach. Empiric addition with dose titration of an α -blocker (e.g., doxazosin), a direct vasodilator such as minoxidil (typically in conjunction with a loop diuretic to control volume status and a heart rate–slowing agent), or a central sympatholytic (e.g., guanfacine, clonidine) may be effective approaches.

The prevalence of patients uncontrolled on more than four or five medications who are truly adherent to the regimen is unknown. What does the future hold for managing the most difficult cases? Several novel treatment strategies are undergoing clinical trials for patients with truly “refractory HTN,” which includes BP levels greater than 160 mm Hg systolic despite taking three or more appropriately dosed antihypertensive agents, including a diuretic. Primary care physicians should be aware that endovascular radiofrequency ablation of the renal artery sympathetic nerves and baroreceptor activation therapy (via electrical stimulation from an implanted pacemaker) are emerging

interventions that may be therapeutic options for select patients in the near future. The completion of ongoing trials will determine the usefulness of these interventional approaches.

SUMMARY

Hypertension is the leading risk factor for premature morbidity and mortality in the world. Successful treatment of an elevated BP to target goals requires a concerted effort on the part of the health care provider and patient alike. Comprehensive approaches involving home BP monitoring that involve patients in their own care in conjunction with diet and lifestyle changes, alternative approaches (in select individuals), medications, and combination regimens are generally successful. However, among the truly refractory HTN cases, several novel approaches may soon be available.

Metabolic Syndrome

Key Points

- Metabolic syndrome is an insulin-resistant state associated with visceral adiposity, HTN, hyperglycemia, dyslipidemia, and a proinflammatory and pro-oxidative state.
- Metabolic syndrome is not a CAD risk equivalent but is associated with a heightened risk for CVD and DM. Comprehensive risk factor evaluation should be undertaken in all of these patients.
- Patients with metabolic syndrome should be treated with aggressive lifestyle modification, including weight loss, exercise, smoking cessation, and dietary modification. As shown in the Diabetes Prevention Project, lifestyle modification can reduce risk of developing DM by 58%.
- Weight loss can be achieved through caloric restriction; exercise; and, when indicated, pharmacologic intervention or bariatric surgery.
- The dyslipidemia and HTN of metabolic syndrome should be treated pharmacologically if lifestyle modification does not help to normalize these risk factors.

The incidence of obesity is rising worldwide. With increased mechanization and changes associated with increased food availability and lower average daily caloric expenditure, people are experiencing continuous weight gain with aging. Being overweight and the development of obesity now constitute the second most important preventable cause of mortality. Among Americans 20 years and older, 154.7 million are overweight or obese, including 79.9 million men and 74.8 million women (AHA, 2013). The incidence of obesity is rising among both genders as well as all racial and ethnic groups. One very important consequence of obesity is the development of insulin resistance and the metabolic syndrome (Haffner et al., 2003; Haffner and Taegtmeier, 2003). The metabolic syndrome is defined by a constellation of cardiovascular risk factors and is associated with heightened risk for new onset DM as well as cardiovascular

Table 27-12 NCEP ATP III Criteria for Diagnosing the Metabolic Syndrome*

Risk Factor	Defining Level
Abdominal obesity	Men, waist >40 in Women, waist >35 in
Triglycerides	≥150 mg/dL
HDL-C	Men <40 mg/dL Women <50 mg/dL
Blood pressure	≥130/≥ 85 mm Hg
Fasting glucose	≥100 mg/dL

*Patients having any three of the above five risk factors meet criteria for the diagnosis of the metabolic syndrome.

HDL-C, High-density lipoprotein cholesterol; NCEP ATP III, National Cholesterol Education Program Adult Treatment Panel III.

morbidity and mortality. A variety of definitions of the metabolic syndrome have been developed, but the one with the greatest clinical utility is that defined by the NCEP ATP III (Eckel et al., 2005; Grundy et al., 2004a, 2004b). Waist circumference, BP, fasting blood sugar, and serum triglyceride and HDL-C levels are used to make the diagnosis (Table 27-12). When three of the five criteria are met, the diagnosis of metabolic syndrome can be made. Based on data from the third National Health and Nutrition Examination Survey, the incidence of metabolic syndrome increases in a linear fashion in both men and women as a function of age (Ford et al., 2002; see also Alexander et al., 2003). Hispanic and Native Americans are disproportionately affected. Current estimates suggest that 32% of the population in the United States has metabolic syndrome. In the Kuopio Ischaemic Heart Disease Risk Factor Study, patients with metabolic syndrome experienced a 3.77- and 2.43-fold increase in risk for CHD mortality and all-cause mortality, respectively, over a 12-year period of follow-up compared with patients without the metabolic syndrome (Lakka et al., 2002).

As waist circumference increases, visceral adiposity increases. Visceral adipose tissue is metabolically highly active. An important conceptual shift has occurred in recent years with respect to how adipose tissue is viewed. It is no longer seen as a passive storage site for excess caloric ingestion. Instead, it is clear that visceral adipose tissue displays many features of an endocrine organ (Bradley et al., 2001; Toth, 2005a) (Figure 27-4). Visceral adipose tissue produces a variety of inflammatory cytokines (tumor necrosis factor [TNF], transforming growth factor- β), ILs (IL-1, IL-6), and effector molecules that regulate appetite (leptin) as well as insulin sensitivity and resistance (adiponectin and resistin, among others). As the mass of visceral adipose tissue increases, adiponectin production decreases, which is associated with increased insulin resistance in adipose tissue, skeletal muscle, and the hepatic parenchyma (see Figure 27-4). As adipose tissue becomes more insulin resistant, its capacity to regulate the catabolism of stored triglycerides becomes progressively more dysregulated and unresponsive to systemic tissue needs. Serum levels of free fatty acids (FFA) rise. The portal circulation becomes flooded with FFAs. This results in both increased triglyceride

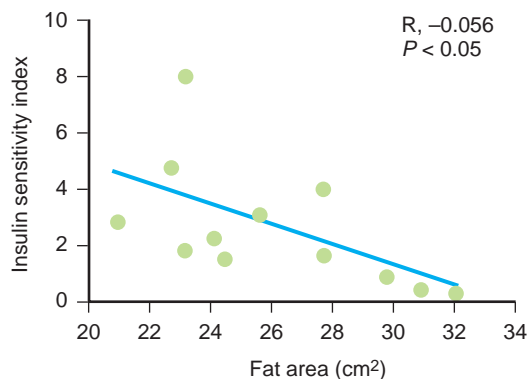

Figure 27-4 Insulin sensitivity and degree of adiposity. (From Fujimoto WY, Abbate SL, Kahn SE, et al. The visceral adiposity syndrome in Japanese-American men. *Obes Res.* 1994;2:364-371.)

Figure 27-6 Severity of hepatic fat deposition as visceral adiposity worsens. (From Banerji MA, Buckley MC, Chaiken RL, et al. Liver fat, serum triglycerides and visceral adipose tissue in insulin-sensitive and insulin-resistant black men with NIDDM. *Int J Obes.* 1995;19:846-850.)

Figure 27-5 Risk of major coronary heart disease (CHD)-related event associated with quintile of insulin levels in nondiabetic men enrolled in the Helsinki Policemen Study. (From Pyorala M, Miettinen H, Laakso M, Pyorala K. Hyperinsulinemia predicts coronary heart disease risk in healthy middle-aged men: the 22-year follow-up results of the Helsinki Policemen Study. *Circulation.* 1998;98:398-404.)

deposition within the liver (nonalcoholic steatohepatitis [NASH] or fatty liver) (Banerji et al., 1995) and increased VLDL secretion, resulting in hypertriglyceridemia. A fatty liver in the absence of excessive alcohol intake is an important marker for insulin resistance and is highly correlated with the magnitude and severity of adiposity; it is also associated with ectopic fat deposition in skeletal muscle, myocardium, and the pancreas (Figure 27-5). Elevations in FEA induce progressive deterioration in glycemic control by (1) interfering with normal phosphorylation of the insulin receptor, resulting in less expression of a glucose transporter (GLUT 4) necessary for the internalization and oxidation of serum glucose (Dresner et al., 1999), and (2) the induction of “lipotoxicity,” the process by which FEAs induce premature apoptosis and dropout of pancreatic β -islet cells. Patients experiencing concomitant worsening insulin resistance and progressive loss of insulin-producing capacity experience a continuum of glycemic disturbances, beginning with impaired fasting glucose, then impaired glucose tolerance, and ultimately DM. As serum levels of insulin rise, the risk for CAD-related events increases

precipitously (Pyorala et al., 1996) (Figure 27-6). Patients with metabolic syndrome have a three- to fivefold increased risk for developing diabetes compared with patients without metabolic syndrome.

Insulin resistance and increased visceral adiposity in the setting of metabolic syndrome are associated with changes in multiple risk factors (Lamon-Fava et al., 1996; Figure 27-7). Insulin-resistant adipose tissue is a potent source of angiotensinogen, the precursor to vasoconstrictor angiotensin II. The BP in these patients also increases because (1) insulin stimulates increased sodium reabsorption at the level of the proximal tubular epithelium, increasing intravascular volume; (2) there is reduced endothelial nitric oxide production (Caballero, 2003); and (3) there is increased vascular sympathetic tone. In the face of insulin resistance, obesity can steadily worsen because of dysregulation of central centers transducing the signals for appetite and satiety in the hypothalamus. Serum levels of HDL decrease for three principal reasons (Figure 27-8). First, as the liver becomes insulin resistant, the capacity for insulin to stimulate the hepatic production of apo AI and AII is compromised. This results in less HDL secretion. Second, in patients with insulin resistance, lipoprotein lipase is relatively inhibited. This reduces the hydrolysis of triglycerides in VLDL and chylomicrons. These large lipoproteins remain incompletely catabolized and form atherogenic remnant particles. Unless they are broken down further, they cannot release many of the surface coat constituents that can be used to assimilate HDL in serum. Third, as HDL particles become more enriched with triglycerides, they become a better substrate for hepatic lipase, an enzyme that catabolizes HDL and promotes its clearance from serum (Toth, 2005b). Patients with metabolic syndrome also tend to have smaller, denser LDL particles. These small LDL particles are believed to be more atherogenic than the larger, more buoyant variety because they are more easily oxidized and have reduced affinity for the hepatic LDL receptor, resulting in less systemic clearance, and they appear to more easily access the subendothelial space because of their smaller volume (St. Pierre et al., 2001). Visceral adipose tissue promotes increased systemic inflammation by secreting inflammatory mediators and by stimulating hepatic production of CRP via IL-6. As serum levels of such acute

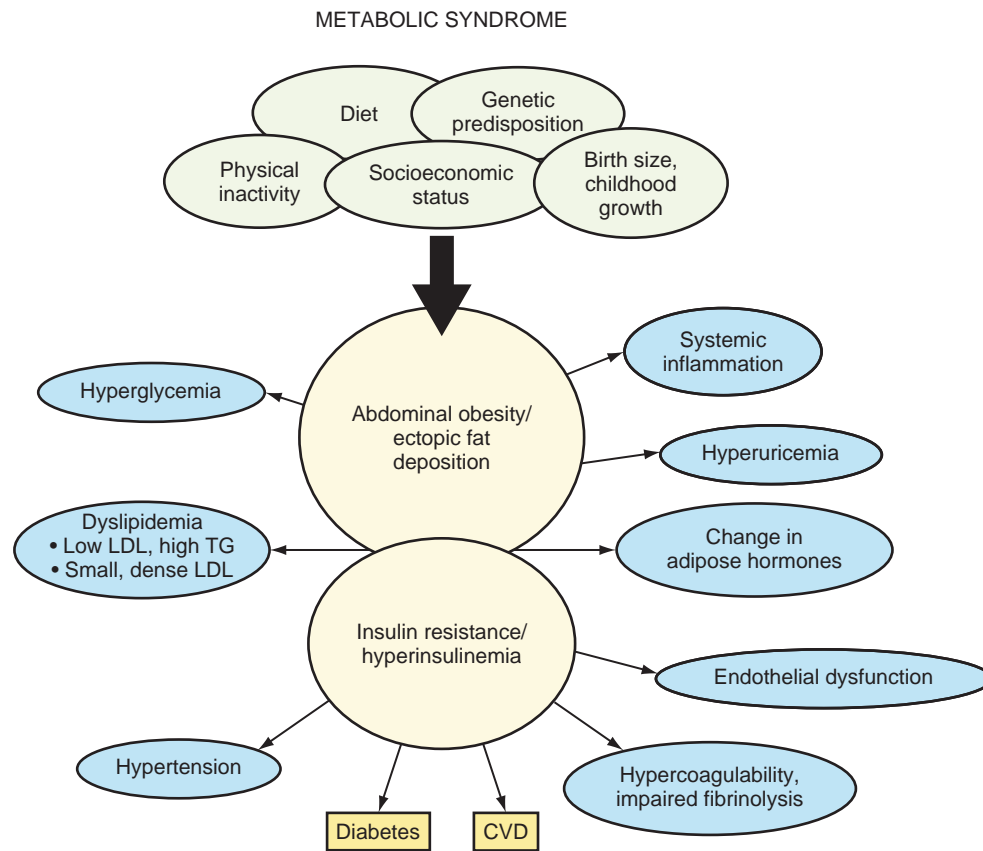

Figure 27-7 Complex interactions among genetic, environmental, and socioeconomic factors increase the risk for developing visceral adiposity; insulin resistance with risk factor generation and clustering; and, ultimately, diabetes mellitus with atherosclerotic disease. CVD, Cardiovascular disease; LDL, low-density lipoprotein; TG, triglyceride.

phase reactants as fibrinogen, CRP, and plasminogen activator inhibitor-1 (PAI-1) rise, the risk for metabolic syndrome and diabetes increases (Dandona et al., 2005; Festa et al., 2002). As shown in the Women's Health Study, as serum CRP levels increase in women with metabolic syndrome but no prior history of CAD, the risk for an acute cardiovascular event increases significantly (Ridker et al., 2003). As insulin resistance worsens, risk for NASH increases steadily (see Figure 27-7).

Metabolic syndrome is not defined by NCEP as a CAD risk equivalent. It is crucial that these patients undergo comprehensive evaluation of their global cardiovascular risk factor burden. Aggressive lifestyle modification with weight loss, increased exercise and physical activity, smoking cessation, and reductions in carbohydrate and saturated fat intake constitute front-line therapy for patients with the metabolic syndrome (Grundy et al., 2004b; Liu and Manson, 2001; Salmeron et al., 2001). Referral to a dietitian is frequently helpful. Weight loss and aerobic exercise are associated with improved insulin sensitivity and significant improvements in BP and lipid levels (DeFronzo et al., 1987; Franssila-Kallunki et al., 1992). As shown in the Diabetes Prevention Project, aggressive lifestyle modification reduces the risk for new-onset DM in obese middle-aged patients by 58% (Tuomilehto et al., 2001). In motivated patients unable to achieve adequate weight loss, pharmacologic intervention is an option. Orlistat (Xenical) is a GI lipase inhibitor that reduces the absorption of dietary fat from the

gut. It facilitates weight reduction and should be taken with meals. The major side effect of the medication is fatty, oily stools that can precipitate diarrhea. Newer drugs such as lorcaserin and extended-release phentermine-topiramate can also be considered. Bariatric surgery for morbidly obese patients has been shown to relieve insulin resistance, promote substantial weight loss, reduce BP, and improve dyslipidemia. The Mediterranean diet (increased consumption of fish, legumes, whole grains, and olive oil) is associated with weight loss and improvements in lipid, insulin sensitivity, and inflammatory indices.

Diabetes Mellitus

Key Points

- DM is a CAD risk equivalent.
- More than three quarters of people with diabetes will die of complications of macrovascular disease.
- Tight control of glycemia, dyslipidemia, and HTN to nationally defined standards is tantamount for aggressive risk reduction.
- Nephropathy increases risk for CVD and should be screened for and treated when discovered with ACE inhibitors, ARBs, or both (SOR: A).

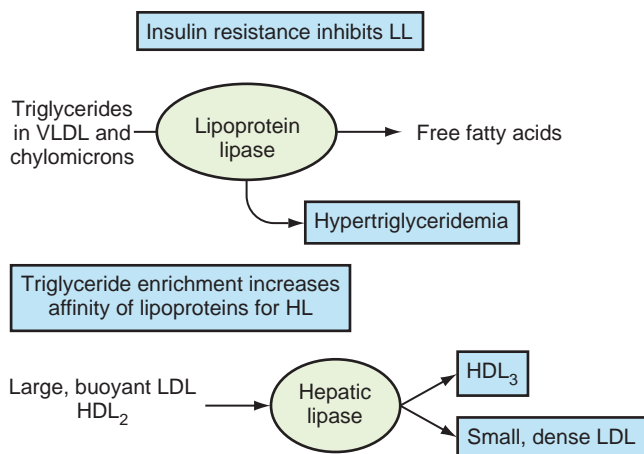

Figure 27-8 Molecular mechanisms etiologic for the atherogenic lipid triad in patients with insulin resistance. As a patient becomes insulin resistant, the activity of lipoprotein lipase (LL) decreases. This can occur secondary to reduced apolipoprotein CII or increased apolipoprotein CIII production. With reduced capacity to hydrolyze the triglycerides in such large lipoproteins as very-low-density lipoprotein (VLDL) (derived from the liver) and chylomicrons (derived from the gut), triglycerides, and large remnant particles accumulate in serum. In this scenario, low-density lipoprotein (LDL) levels in serum tend to be relatively low because less VLDL is being converted to LDL. As high-density lipoprotein (HDL) and LDL particles become progressively more enriched with triglycerides, these lipoproteins become better substrates for the enzyme hepatic lipase. Hepatic lipase catabolizes these lipoproteins to form small, dense LDL and HDL. The small HDL particles can be further degraded to their phospholipid and apoprotein constituents, thereby reducing circulating levels of this beneficial lipoprotein. (Based on Toth PP, Davidson MH. Comparative effects of lipid-lowering therapies. *Prog Cardiovasc Dis.* 2004;47:73-104.)

According to statistics compiled by the American Diabetes Association, approximately 1.9 million new cases of DM were diagnosed in people age 20 years and older in 2010. A total of 25.8 million people have DM in the United States, and 79 million have prediabetes. One third of people with the disease are undiagnosed and usually have multiple other risk factors for CVD (<http://www.diabetes.org/diabetes-basics/diabetes-statistics/>). Nearly all adult patients with DM (90%-95%) have the type II or non-insulin dependent form. However, as the disease progresses and pancreatic islet cell mass is progressively lost, many will become insulin dependent over time. The World Health Organization (WHO) estimates that by the year 2025, there will be more than 350 million people with diabetes throughout the world (King et al., 1998; see also Amos et al., 1997). Diabetes significantly magnifies the risk for MI, sudden death, stroke, CHF, adult-onset blindness, loss of lower extremities, and end-stage renal disease. Given the burgeoning incidence of this disease, the complications stemming from DM will likely incur a level of human suffering that is unprecedented outside of wartime. This is an issue that must be addressed head on by family physicians throughout the world.

Diabetes induces diffuse atherosclerotic disease throughout the vascular tree. Nearly 80% of people with diabetes will die of CVD. The hyperglycemic, insulin-resistant milieu of type 2 DM initiates a broad-ranging cascade of pathophysiology that accelerates atherogenesis. Unfortunately, because of increasing obesity and metabolic syndrome in adolescents and young adults, type 2 DM is becoming

relatively common in those younger than 21 years of age. Diffuse endothelial dysfunction, the accumulation of damaging advanced glycation end products within the vasculature, and a heavy risk factor burden typify the patient with DM. Diabetes induces a pro-oxidative and proinflammatory state. People with diabetes also tend to have hypercoagulability (Meigs et al., 2000). This likely results from (1) increased hepatic production of coagulation factors; (2) increased platelet reactivity and aggregability; and (3) as endothelial dysfunction progresses, the endothelium produces less tissue plasminogen activator (tPA), and more PAI-1, rendering the surface of the vascular lumen more prothrombotic. This hypercoagulability and disordered fibrinolysis increase the likelihood that if a person with diabetes experiences acute plaque rupture, it will result in greater and perhaps complete vascular luminal obstruction with acute ischemia and infarction.

It is critical for people with diabetes to be diagnosed early and that their risk factors are evaluated and treated comprehensively. In addition to monitoring indices of glycemia, BP, serum lipids, smoking and obesity status, and baseline renal function should be evaluated. HTN, dyslipidemia, and albuminuria or proteinuria require aggressive management. Based on the East-West (Haffner et al., 1998) and Organization to Assess Strategies for Ischemic Syndromes (OASIS) (Malmberg et al., 2000) studies, the NCEP has defined DM as a CAD risk equivalent. As shown in the European Prospective Investigation of Cancer (EPIC)-Norfolk Study, as hemoglobin A1c (HbA1c) levels steadily rise above 5.0, the risk for coronary events rises continuously (Khaw et al., 2004). The American Diabetes Association recommends that HbA1c be below 7.0% (American Diabetes Association, 2013), but the American College of Endocrinology endorses a level below 6.5%. With more aggressive diabetes management, the risk for vascular disease development decreases, but the risk for episodic hypoglycemia increases (Diabetes Control and Complications Trial Research Group, 1995). If a patient tolerates an HbA1c level that is below 6.5% without undue risk for hypoglycemia, then more aggressive control should be encouraged. In contrast, if an insulin-dependent diabetic patient has CAD and is prone to hypoglycemia, then an HbA1c level of 7.5 or 8.0% may be more appropriate. The intensity of glycemic control should be balanced against the risks of hypoglycemia. The United Kingdom Prospective Diabetes Study (UKPDS) 35 demonstrated that for every 1% drop in HbA1c, people with diabetes experience a 21% reduction in any diabetes-related end point, a 14% drop in MI, a 12% reduction in stroke, and a 37% reduction in risk of microvascular disease (Stratton et al., 2000). In the STENO-2 Study, intensive therapy of blood sugars, BP, and serum lipids resulted in a 50% lower incidence of the primary composite cardiovascular end point compared with “conventional” therapy, which was substantially less aggressive (Gaede et al., 2003). In the UKPDS, it was shown that metformin therapy reduces the risk for acute cardiovascular events by 38%. Unless there is a contraindication, individuals with diabetes should take prophylactic aspirin therapy.

Patients with diabetes should be treated with a statin. In such studies as the Collaborative Atorvastatin Diabetes Study (Colhoun et al., 2004) and Scandinavian Simvastatin Survival Study (Dunstan et al., 2002; Pyorala et al.,

1998), statin therapy was associated with a 37% and 42% reduction in the risk of cardiovascular events among people with diabetes in the primary and secondary prevention settings, respectively. Fibrate therapy has also been shown to reduce risk for cardiovascular events and rates of atherosclerotic plaque progression in patients with DM.

Cigarette Smoking

Key Points

- Cigarette smoking is the single most preventable cause of mortality in the United States.
- Cigarette smoking cessation reduces the risk for MI and death by 36%.
- Smoking cessation is facilitated by patient education about the dangers of smoking and pharmacologic intervention with nicotine replacement products, bupropion, and varenicline.
- Relapse rates are high in the absence of education, encouragement, and individualized courses of therapy and follow-up.

According to the CDC, 19% of U.S. adults were cigarette smokers in 2011 (<http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6144a2.htm>). Unfortunately, the incidence of smoking among adolescents and teenagers continues to rise despite legislation limiting some forms of advertising and the sale of cigarettes to minors. Smoking is the single most *preventable* cause of death in the United States. In addition to increasing the risk for developing pulmonary, oral, laryngeal, and bladder neoplasms, cigarette smoking significantly raises the risk for developing all forms of atherosclerotic disease and potentiates myocardial ischemia, adverse structural damage to the lung parenchyma, and arterial aneurysm formation. More than 440,000 Americans succumb annually from tobacco-related disease.

Cigarette smoke contains more than 4000 exogenous chemicals. Cigarette smoking is associated with increased intravascular oxygen free radical production and induces diffuse endothelial dysfunction, resulting in marked reductions in nitric oxide and tPA production (Chia and Newby, 2002). These changes result in increased oxidative injury to cells and lipoproteins, vasoconstriction, and reduced capacity for fibrinolysis in the setting of plaque rupture and overlying thrombus formation. In addition to accelerating rates of atherogenesis in native arteries, continued smoking reduces rates of arterial and venous graft patency in the heart and peripheral vasculature. Cigarette smoking is associated with increased serum levels of multiple emerging risk factors, including CRP, fibrinogen, and homocysteine compared with nonsmokers (Bazzano et al., 2003).

Achieving lifelong smoking cessation in patients who have or are at risk for CVD is a critical therapeutic goal. Smoking cessation results in a 36% reduction in risk for MI and mortality (van Berkel et al., 1999). Bupropion (Zyban 150-300 mg/day orally) reduces the intensity of withdrawal symptoms in patients trying to quit smoking by inhibiting the neuronal reuptake of norepinephrine, serotonin, and dopamine. These neurotransmitters are

associated with central centers modulating addiction and craving or appetitive behaviors. After taking Zyban for approximately 2 weeks, patients can begin to wean themselves from cigarette smoke according to a plan established with their providers. Sustained smoking cessation is facilitated by continuing Zyban for 3 to 6 months after the patient smokes his or her last cigarette. Continued counseling and encouragement are important. Smoking cessation classes are also usually available as part of community health awareness programs. Another approach involves the use of nicotine replacement therapies, such as NicoDerm CQ or Habitrol (transdermal delivery systems) and Nicorette gum. These therapies also control withdrawal and craving by providing an alternative source of nicotine that can be progressively weaned over the course of weeks to months. One recommended regimen for the nicotine patch is to wear each dose (21, 14, and 7 mg) for 1 month in a stepped-down fashion. Patients wearing the patch should be counseled not to smoke because this can induce headache, nausea, flushing, and even angina. If a patient cannot achieve smoking cessation on single-agent therapy, the combination of Zyban and a transdermal nicotine patch has been shown to increase success rates compared with the use of either agent alone. Varenicline therapy is another pharmacologic option for controlling withdrawal and promoting smoking cessation (Rollema et al., 2006). Patients can smoke while taking varenicline and can wean themselves from cigarettes gradually. Smoking cessation success rates are approximately doubled by this drug compared with placebo. Patients should be cautioned about the possibility of new-onset depression, anxiety, and suicidal ideation, although in general it is well tolerated. Varenicline therapy can also increase the vividness and intensity of dreams, which some patients find unpleasant.

Coronary Artery Disease

STABLE ISCHEMIC HEART DISEASE

Chronic stable ischemic heart disease (SIHD) affects 17 million Americans, 10 million of whom have chronic angina. This disease is more prevalent with age, affecting approximately one third of men and one fourth of women older than 80 years of age (Fihn et al., 2012). SIHD can be asymptomatic or present with typical angina (definite), atypical angina (probable), and noncardiac chest pain. Definite angina meets the following criteria: (1) chest pain with characteristic quality and duration that is (2) provoked by stress and (3) resolved with rest or nitroglycerin. Probable angina meets two of these criteria, and noncardiac pain meets none or one of these criteria (Fihn et al., 2012). Angina is classified by the Canadian Cardiovascular Society Classification into four classes: class I, no chest pain with ordinary activity or exertion; class II, chest pain with moderate exertion (e.g., walking more than 2 blocks or flight of stairs); class III, angina with mild exertion (e.g., walking 1-2 blocks or 1 flight of stairs); and class IV, angina with no or minimal activity.

Angina is a symptom of myocardial ischemia. Stable angina is caused by a mismatch between coronary blood supply and myocardial oxygen demand. The latter is determined by several factors, including heart rate and left

ventricular (LV) wall stress and contractility (Braunwald, 2000). Coronary supply is determined by oxygen transport capacity and delivery and conditions that regulate the coronary circulatory system, such as endothelial secretory products (e.g., nitric oxide, endothelin), the autonomic nervous system, metabolic activity, neural control, and perfusion pressure. Several pharmacologic interventions, such as adrenergic receptor activation or blockade, adenosine, and acetylcholine, also affect the coronary circulation. Most coronary flow occurs during diastole; only 25% of flow occurs in systole (Feigl, 1998; Yada et al., 1999).

In stable angina, blood flow cannot meet myocardial oxygen demands because of an obstructive atherosclerotic plaque in one or more coronary arteries. Atherosclerosis develops early in life, with progression depending on age and the severity of one or more risk factors as established by such longitudinal cohorts as the Framingham Heart Study. As the volume of atherosclerotic plaque increases, there is a compensatory outward bulging of the vessel that maintains the diameter and patency of the arterial lumen. This generally is not appreciated on an angiogram and can be seen best using intravascular ultrasonography (Figure 27-9). This is referred to as the Glagov phenomenon. It is not until atherosclerotic plaque reaches almost 40% of the plaque surface area before compensatory mechanisms start to fail and the plaque starts to impinge on the lumen. Coronary blood flow starts to decline when the lumen becomes narrowed at about 70% or more. An early clinical manifestation of this pathophysiologic change is the occurrence of chest pain or dyspnea with exertion that resolves within minutes of rest. This “stable angina” pattern does not usually occur at rest. Nonatherosclerotic obstructive CAD may also cause angina. Although infrequent, it could be mediated by myocardial bridging, vasculitis, or congenital malformation of the coronary arteries. In addition,

conditions without obstructive coronary disease such as cardiomyopathies or valve disease can also trigger angina (Lee, 2002).

Symptoms of stable angina differ among patients. Angina can be perceived as a pressure, tightness, squeezing, or heaviness in the chest. This can radiate to the arm, jaw, shoulders, back, or abdomen. The pain can be associated with an increase in shortness of breath, a feeling of nausea, diaphoresis, or occasional vomiting. Lightheadedness and anxiety may accompany these symptoms. Chest pain or angina may not be present in patients with IHD. Myocardial ischemia with no chest pain is commonly present in people with diabetes secondary to glycemic injury to pain-sensing fibers in the myocardium. Also, dyspnea without chest pain can be an anginal equivalent. Ischemia can induce stiffness in the myocardium and reduces ventricular relaxility, which in return raises LV end-diastolic pressure and leads to dyspnea. Angina or anginal-equivalent symptoms typically resolve with rest or the administration of nitroglycerin.

Noncardiac chest pain typically occurs with certain maneuvers, such as taking a deep breath (e.g., pleuritic sharp pain, pneumothorax, pneumonitis), palpation of the chest wall (as in musculoskeletal pain, costochondritis, rib fracture, fibrositis), after ingestion of certain types of food (esophagitis, gastroesophageal reflux, pancreatitis, gallbladder disease), or as a clinical manifestation of the reactivation of a latent varicella-zoster virus (shingles) (Ma et al., 2007) generally occurring before the appearance of the rash. Other causes of noncardiac pain may also need to be considered, such as pulmonary embolism (Lee, 2002; Lee and Goldman, 2000), aortic dissection (Collins et al., 2004), pericarditis, or psychiatric (anxiety, panic) disorder. When a clear diagnosis explains noncardiac chest pain, additional cardiac evaluation may not be necessary and likely depends on whether the presenting symptom continues after addressing the primary etiology.

Several signs can be noted on examination in a patient with angina. Paradoxical splitting of the second heart sound, systolic murmurs, or S3 or S4 sounds can be appreciated during an anginal episode. Findings of cardiomyopathy or valvular disorders can also be present and might help in establishing the diagnosis of a noncoronary cause of chest pain. Patients can also have hypertension, signs of hyperlipidemia (corneal arcus, periorbital xanthelasma, tendinous xanthomas), or findings of DM (peripheral neuropathy or diabetic retinopathy).

Noninvasive Testing

Electrocardiography. The ECG quite often does not show ischemic changes in patients with stable angina who are at rest and have no symptoms. The resting ECG might show, however, nonspecific ST segment and T-wave abnormalities in a patient with known severe CAD. False-positive results are common in patients with LVH, digoxin intake, electrolyte imbalances, or electrical conduction anomalies such as bundle branch blocks or preexcitation syndromes.

Electrocardiograms need to be compared with old ones. Quite often, new Q-wave abnormalities or the emergence of conduction disturbances might indicate an interval change in the patient’s cardiac status. The ECG can be helpful during an episode of chest pain in which more than 50% of patients with normal resting ECGs show new changes.

Figure 27-9 Glagov remodeling of the coronary lumen in response to early plaque formation.

Typically, these changes include the presence of ST segment depression or elevation in two contiguous leads, new T-wave inversions, or pseudonormalization of already inverted T waves.

At present, it is considered reasonable to obtain a 12-lead ECG on patients with SIHD at 1-year or longer intervals. Performing an ECG, however, should be performed in patients with new or worsening symptoms.

Echocardiography. Echocardiography is currently not indicated in SIHD patients with stable symptoms or no symptoms. However, echocardiography should be done in patients with new or worsening HF or new MI to assess LV function and regional wall motion.

Noninvasive Stress Testing in Patients with Stable Ischemic Heart Disease

Exercise Treadmill Testing. Exercise stress testing uses different protocols (Bruce, modified Bruce, and Naughton) based on a patient's ability to exercise. The patient exercises at different inclines and speeds until achieving 85% of peak predicted heart rate for age ($[(220 - \text{Age}) \times 85\%]$). The test provides information about the presence of ischemic ST segment changes, reproducibility of chest pain, arrhythmias, changes in BP and heart rate, and functional capacity. The mean sensitivity of this test is 68% and specificity is 77% (Gibbons et al., 2002). Some studies indicate that, when selection bias is removed, the sensitivity can be as low as 40% to 50% but specificity as high as 85% to 90% (Detrano et al., 1989; Gianrossi et al., 1989; Gibbons et al., 2002). Despite this reduced accuracy, patients with good functional capacity generally have a good prognosis. An

early positive stress test result (in the first two stages of exercise) can indicate a worse prognosis and denotes a high risk finding. Furthermore, if a patient experiences chest pain and 1-mm ST segment depression during exercise, the test can be 90% predictive of the presence of CAD. A 2-mm ST segment depression accompanied by chest pain is almost pathognomonic of the presence of obstructive CAD.

The test specificity is reduced when baseline ECGs are abnormal with LVH, preexcitation syndrome, or a bundle branch block or if the patient is taking digoxin (Sketch et al., 1981; Sundqvist et al., 1986) or has electrolyte abnormalities (Froelicher et al., 1999; Gibbons et al., 2002). Also, if a patient cannot reach target heart rate, the diagnostic accuracy of the test is diminished. It should be noted that the presence of antiischemic agents (nitrates, β -blockers, and CCBs) can reduce the sensitivity of the test and should be withheld for 2 to 3 days before the procedure for long-acting drugs and 24 hours for short-acting drugs if the intent is for the test to diagnose the presence of obstructive disease (Gibbons et al., 2002).

The absolute contraindications to stress testing are decompensated CHF, symptomatic severe aortic valve stenosis, ongoing rest chest pain, a recent MI (within the past week), severe HTN, and intractable arrhythmias. When patients have conditions that reduce the specificity of a stress test, an imaging stress test (nuclear or echocardiographic) can be an alternative, more accurate means by which to evaluate for CAD.

Stress Myocardial Perfusion Imaging. Myocardial perfusion imaging (99mTc-sestamibi, 99mTc-tetrofosmin, or thallium-201) (Figure 27-10) provides a more accurate

Figure 27-10 Myocardial perfusion scan shows reversible ischemia in the anterior wall, apex, and inferior wall.

modality to diagnose the presence of obstructive CAD than a treadmill ECG alone. The sensitivity and specificity of this test have been reported to be 88% and 72%, respectively. When referral bias is accounted for, the specificity of this test is as high as 90%. In addition to myocardial perfusion, the test provides information about EF and wall motion abnormalities and is very valuable to predict a patient's prognosis (Klocke et al., 2003).

Nuclear stress testing is useful in patients with a low-specificity treadmill ECG. Nuclear imaging can provide information about prognosis and myocardial viability in regions of wall motion abnormalities and can help localize the area of myocardium in jeopardy. Similar to most stress tests, they are best ordered in patients with an intermediate likelihood of obstructive CAD.

Myocardial perfusion imaging also can be performed with the induction of pharmacologic stress. Adenosine and dobutamine are the most commonly used pharmacologic agents. Adenosine is a vasodilator and stresses the heart by a "steal phenomenon." Adenosine and dipyridamole dilate normal coronaries, shunting blood away from abnormal regions of the myocardium and creating a discrepancy in perfusion between normal and abnormal regions. Dobutamine increases heart rate and contractility and therefore increases myocardial oxygen demand.

Adenosine is typically infused over 4 or 6 minutes, depending on the protocol used. The infusion rate of 140 $\mu\text{g}/\text{kg}/\text{min}$ starts with ECG monitoring. Usually halfway through the infusion, sestamibi ("Myoview") or thallium is injected. Adenosine causes flushing, shortness of breath, nausea, chest pain, and a "strange" feeling in most patients, and this does not reflect the presence of CAD. Adenosine can also cause bradycardia and a high-degree atrioventricular (AV) block. Patients should not take any caffeinated beverages for at least 12 to 24 hours before the test. Also, adenosine can precipitate asthma and should not be used in patients with hyperreactive airway disease. Adenosine is an excellent choice for a test in patients who cannot exercise on a treadmill. The sensitivity and specificity of adenosine stress imaging are 90% and 82%, respectively (Klocke et al., 2003).

Dobutamine is infrequently used and is reserved for patients who cannot exercise on a treadmill and have a contraindication to taking adenosine. Dobutamine is infused at 10 $\mu\text{g}/\text{kg}/\text{min}$ for 3 minutes and then increased by increments of 10 $\mu\text{g}/\text{kg}/\text{min}$ every 3 minutes to a maximum of 50 $\mu\text{g}/\text{kg}/\text{min}$ or if target heart rate has been achieved. If despite this high dose of dobutamine, target heart rate is not achieved, atropine is administered to a maximum of 1 to 2 mg. Cardiolite is injected typically at target heart rate, and the infusion is then terminated. Patients are generally observed for at least 10 minutes after the test or until the heart rate is below 100 beats/min. Dobutamine can cause a shaky feeling, nausea, and arrhythmias. In general, it is well tolerated.

Although pharmacologic nuclear stress imaging provides similar diagnostic accuracy to treadmill nuclear stress testing for the presence of obstructive CAD, patients are best exercised on a treadmill because more information can be obtained from this test, including functional capacity, which is a strong predictor of prognosis, the presence of

arrhythmias with exercise, and the hemodynamic response to physical exertion.

Stress Echocardiography. Stress echocardiography (Cheitlin et al., 2003) is an alternative imaging stress test to a nuclear stress test. However, the sensitivity is slightly lower with an increase in specificity, making the overall accuracy of this test similar to that of stress nuclear imaging. Stress echocardiography is performed by obtaining an initial resting echocardiogram to assess a patient's left ventricular ejection fraction (LVEF), wall motion characteristics, and cavity size. In about 25% of patients, it may be difficult to obtain optimal echocardiographic images for adequate interpretation of the test, and therefore an alternative form of stress testing is needed. This is particularly true in patients with severe chronic obstructive pulmonary disease (COPD) and patients with severe obesity. Patients are exercised on a treadmill using a symptom-limited protocol. Patients need to achieve the minimum target heart rate for age (85% of maximum predicted) but preferably a higher rate to allow ample time for the sonographer to obtain immediate post-stress echocardiographic images while the heart rate is still over target for age. Typically, the sonographer needs about 20 to 30 seconds to obtain these images. In patients who cannot exercise, dobutamine can be used as described earlier to achieve target heart rate, and the infusion is discontinued when all echocardiographic images are acquired.

Choice of the Stress Test or Imaging Modality. The choice of the stress test depends on several factors, including the patient population being tested (whether SIHD is suspected or known); the ability of the patient to exercise; the presence of an interpretable 12-lead ECG; whether the test is being performed for initial or follow-up risk stratification; and whether the patient has SIHD with stable symptoms, is asymptomatic, or has new, recurrent, or worsening symptoms (that do not meet the definition of moderate- or high-risk UA). Table 27-13 summarizes level A choices as recommended by the ACC/AHA recent guidelines (Fihn et al., 2012).

The main goal of noninvasive stress testing in patients with stable symptoms or asymptomatic SIHD is risk stratification to guide revascularization and to improve hard outcomes. Symptomatic patients with SIHD who continue to be limited in their daily activity despite guideline-directed medical therapy need to undergo coronary angiography and revascularization for symptom control and to restore normal activities irrespective of risk stratification.

As a general rule, if a patient is able to exercise and has an interpretable baseline ECG, a regular treadmill stress test is recommended for initial evaluation of suspected SIHD. If the ECG is noninterpretable, myocardial perfusion imaging (MPI) can be added to the exercise stress test. Pharmacologic MPI is preferred in patients who are unable to exercise. If patients with known SIHD have a change in symptoms, the same recommendations hold for repeat testing. It is highly discouraged in these patients to perform pharmacologic MPI if they are able to exercise and have a baseline interpretable ECG. An interpretable baseline ECG should have no evidence of LVH or conduction abnormalities, there should be no electrolyte disturbances, and the patient should not

Table 27-13 Choice of Stress Testing in Patients with Stable Ischemic Heart Disease*

Patients with suspected (not yet documented) SIHD: initial evaluation	<p>Exercise ECG if patient is able to exercise and ECG is interpretable</p> <p>Exercise with nuclear MPI or echocardiography if patient is able to exercise and ECG is uninterpretable</p> <p>Avoid exercise with nuclear MPI or echocardiography in patients who are able to exercise and who have an interpretable ECG but have a low pretest probability for disease; could consider regular ECG testing</p> <p>Pharmacologic stress test with MPI, echocardiography, or CMR should be avoided in patients who are able to exercise and with an interpretable ECG</p> <p>Pharmacological stress with nuclear MPI or echocardiography should be performed as the first choice in patients who are unable to exercise</p> <p>If a patient is unable to undergo stress testing, has an inconclusive stress test, or has symptoms despite normal stress test, consider coronary CTA</p>
Patients with SIHD and stable symptoms or asymptomatic for risk stratification	<p>Exercise ECG if patient is able to exercise and ECG is interpretable. Can consider exercise with nuclear MPI or echocardiography (less evidence)</p> <p>Exercise with nuclear MPI or echocardiography if patient is able to exercise and ECG is uninterpretable</p> <p>Pharmacologic stress test with MPI, echocardiography or CMR, or CCTA should be avoided in patients who are able to exercise and with an interpretable ECG</p> <p>Pharmacologic stress with nuclear MPI or echocardiography should be performed as the first choice in patients who are unable to exercise; pharmacologic stress CMA or CCTA can be considered (less evidence)</p> <p>Nuclear MPI, echocardiography or CMR with exercise, or pharmacologic stress test or CCTA is not recommended for follow-up assessment in patients with SIHD if performed more frequently than at 5-year intervals after CABG or 2-year intervals after coronary angioplasty</p>
Patients with SIHD and new, recurrent, or worsening symptoms (not unstable angina)	<p>Exercise ECG if patient is able to exercise (at least moderate physical functioning with no disabling comorbidity) and ECG is interpretable</p> <p>Exercise with nuclear MPI or echocardiography if patient is able to exercise and ECG is uninterpretable</p> <p>Consider exercise with nuclear MPI or echocardiography in patients at high risk for multivessel disease or who have had prior requirement for imaging with exercise</p> <p>Pharmacologic stress test with MPI, echocardiography or CMR, or CCTA should be avoided in patients who are able to exercise and with an interpretable ECG</p> <p>Pharmacological stress with nuclear MPI or echocardiography should be performed as first choice in patients who are unable to exercise; pharmacologic stress CMA can be considered (less evidence)</p> <p>CCTA should not be performed if a patient has severe calcification or a prior stent</p>

*Level A, American College of Cardiology/American Heart Association guidelines (Fihn et al., 2012).

CABG, Coronary artery bypass graft; CCTA, cardiac computed tomography angiography; CMA, cardiac magnetic angiography; CMR, cardiac magnetic resonance; CTA, computed tomography angiography; ECG, electrocardiography; MPI, myocardial perfusion imaging; SIHD, stable ischemic heart disease.

be taking digoxin (Melin et al., 1985). When adjusting for the pretest probability of disease, women have only a slightly reduced specificity on a regular stress test compared with men. In addition, a baseline borderline ST segment depression of less than 1 mm is not an exclusionary criterion to perform a treadmill stress test.

For stable or asymptomatic patients with SIHD, there is currently no SOR: A evidence defining the frequency of risk stratification on follow-up. Current guidelines by the ACC/AHA recommend nuclear perfusion imaging, echocardiography, or cardiac mitral regurgitation (MR) with exercise or pharmacologic stress testing at longer than 2-year intervals in patients with SIHD and with prior evidence of silent ischemia or at high risk for recurrent event and who meet one of the following criteria: (1) unable to exercise to an adequate workload, (2) have an uninterpretable ECG, or (3) have a history of incomplete revascularization (Fihn et al., 2012). These tests, however, should not be performed at more than 5-year or longer intervals after bypass surgery or 2-year or longer intervals after coronary angioplasty. In this patient population, the use of routine periodic follow-up imaging stress testing is preferred over regular stress testing.

Irrespective of the modality of stress testing, a test should be terminated when a patient displays significant arrhythmias, lightheadedness, a symptomatic drop in BP, or significant ischemic changes on the ECG, particularly if associated with anginal symptoms. Also a stress test should not be performed in patients with unstable rest symptoms, frequent arrhythmia, known severe left main (LM) disease,

severe symptomatic valvular disease, or decompensated CHF. The test needs to be closely monitored at all times by the technician, and a provider needs always to be in the immediate vicinity while the test is being conducted. Providers or supervising staff need to be trained in advanced cardiac life support.

PHARMACOLOGIC MANAGEMENT OF THE PATIENT WITH STABLE ANGINA

Patients with stable angina have an imbalance between coronary blood supply and demand. They are at increased risk of MI and arrhythmias. The management of these patients is predominantly medical with intensive guideline-based therapy focusing on alleviating angina, reducing plaque progression and risk of rupture, and restoring a patient's functional capacity. Some reversible causes of angina need to be evaluated, such as conditions that increase myocardial oxygen demand. These include fever, thyrotoxicosis, anemia, and cardiac stimulants such as cocaine or amphetamines. Severe valvular dysfunction and CHF might be also precipitating factors. Interventional therapies in stable angina are reserved for patients with continued limiting symptoms despite optimal medical therapy and those patients with high-risk findings on their noninvasive evaluation.

Nitrate Therapy

Nitrate therapy reduces myocardial oxygen demand by increasing venous capacitance and, therefore, reducing

venous return and ventricular wall stress. Also, nitrates increase coronary blood supply by dilating the coronary arteries (Parker, 1993; Parker et al., 1995; Parker and Parker, 1998). Administering nitrates to patients with stable angina increases their symptom-free walking distance and reduces the frequency and severity of their anginal episodes. Nitrates are not known to significantly reduce risk for MI or prolong survival. On a chronic basis, nitrates can be administered orally or transdermally. Irrespective of the mode of administration, it is important to have 8 to 10 hours of a nitrate-free period to avoid tolerance to this drug (Parker et al., 1995). IV nitroglycerin is reserved for the UA patient to reduce anginal pain and intracardiac filling pressures and to improve symptoms of HF.

β-Blockade

β-Blockers reduce myocardial oxygen demand primarily by reducing heart rate and contractility. β-Blockers are essential in patients with stable angina and a history of prior MI or reduced LV function. In these conditions, β-blockers can prolong survival and should be administered to these patients unless absolutely contraindicated (Gottlieb et al., 1998). In patients with normal LV systolic function after MI or other ACS, β-blockers should be continued for 3 years. If, however, LV function remains reduced at 40% or less in patients with a history of MI or who have CHF, β-blockers need to be continued indefinitely. β-Blockers are best limited to those with data that have shown reduction in mortality. These include metoprolol XL, carvedilol, and bisoprolol.

It is unclear whether β-blockers improve survival or serious arrhythmias in patients with stable angina and no prior infarction or LV dysfunction. Relative or absolute contraindications to β-blocker therapy include patients with severe hyperreactive airway disease, heart block, severe bradycardia, or severe symptomatic peripheral vascular disease.

Calcium Channel Blockers

Long-acting CCBs are potent antiischemic drugs and can also be used to treat patients with stable angina (Braunwald, 1982). Generally, short-acting calcium blockers need to be avoided because they could potentially increase adverse events. Dihydropyridines (e.g., amlodipine or nifedipine XL) do not alter heart rate significantly and are primarily vasodilators. Whereas diltiazem reduces heart rate but also increases coronary blood supply, verapamil reduces oxygen demand primarily by reducing heart rate with less vasodilatory effects. The CCBs are generally used as a second-line treatment if there is inadequate response to β-blockers. Also, nondihydropyridine CCBs may be used as first-line treatment in patients intolerant of β-blockers.

Ranolazine (Ranexa)

Ranolazine is indicated to treat chronic stable angina. It can be used in conjunction with other antiischemic drugs, including β-blockers, nitrates, and CCBs. Also, in patients intolerant to β-blockers, ranolazine can be an effective substitute.

Ranolazine is metabolized through the CYP3A cytochrome system. Therefore, it should not be administered to patients taking strong CYP3A inhibitors (e.g., ketoconazole, clarithromycin, and some antiretroviral drugs) or

CYP3A inducers (e.g., rifampin, phenobarbital, phenytoin, St. John's wort) or with a history of hepatic cirrhosis. Ranolazine has been shown to increase the QTc interval in a dose-dependent manner, but no increase in arrhythmia or sudden death has been demonstrated. Ranolazine has been shown to increase exercise duration and delay anginal onset and ST depression on treadmill testing in severe chronic angina patients. The number of anginal attacks and the need for sublingual nitroglycerin are reduced with ranolazine (Chaitman et al., 2004; Stone et al., 2006). The most common side effects of ranolazine are dizziness, headache, constipation, and nausea. The starting dose is 500 mg orally twice a day, which is increased to 1000 mg twice a day as needed. In patients on moderate CYP3A inhibitors (e.g., diltiazem, verapamil, erythromycin, fluconazole, and grapefruit juice) the dose is limited to 500 mg twice a day. The advantage of ranolazine is its lack of effect on BP and heart rate; therefore, it can be used in patients with a low rate-pressure product as an add-on antiischemic drug.

Antiplatelet Agents

In high-risk patients, aspirin (81 mg) reduces vascular events by approximately 35% and is a primary therapy in patients with stable angina (Antiplatelet Trialists Collaboration, 1994). Aspirin is very effective in reducing MI in healthy subjects with elevated serum CRP levels (Ridker et al., 1997).

Aspirin resistance has been reported recently and can be present in approximately 25% of patients. Also, aspirin hypersensitivity is common and primarily related to GI side effects. The side effects (including bleeding and dyspepsia) of aspirin can be reduced without compromising the effectiveness of this drug with the use of enteric-coated aspirin. The dose of aspirin is best limited to 81 mg with no compromise to its effectiveness and with a reduced bleeding risk compared with a full aspirin dose (325 mg).

Clopidogrel (Plavix) is an adenosine diphosphate (ADP) receptor antagonist and a potent, irreversible antiplatelet drug. In the Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events [CAPRIE] study (CAPRIE Steering Committee, 1996), clopidogrel was slightly but statistically more effective than aspirin in reducing cardiovascular events in high-risk patients with a history of stroke, MI, or peripheral vascular disease (8.7% relative risk reduction; $P=0.043$). Clopidogrel is an effective alternative to patients who are unable to tolerate aspirin.

Dipyridamole is not recommended as an antiplatelet therapy in patients with stable IHD because it has not been shown to be beneficial. Also, there are no data to substitute aspirin with NSAIDs, which should be avoided in general in patients with SIDH.

The combination of clopidogrel (75 mg/day) and aspirin (81 mg/day) (i.e., dual antiplatelet therapy) is required in patients with recent percutaneous intervention. For patients receiving a bare-metal stent or balloon angioplasty alone without stenting, clopidogrel may be administered for 3 to 4 weeks. For patients receiving a drug-eluting stent, dual antiplatelet therapy needs to be continued for a minimum of 1 year. The optimal duration of this dual antiplatelet therapy after a drug-eluting stent is currently unknown and is being evaluated in large-scale studies. There is no evidence that continuing clopidogrel and aspirin

combination beyond 1 year after the deployment of a drug-eluting stent carries an added advantage. Aspirin alone, on the other hand, should be continued indefinitely (Bhatt and Topol, 2004).

Angiotensin-Converting Enzyme Inhibitors

In patients with SIHD, ACE inhibitors are recommended in patients with concomitant LV systolic dysfunction, HTN, DM, and CKD unless contraindicated. In patients with severe renal insufficiency (creatinine clearance <30 mL/min), ACE inhibitors are generally avoided. Providers should expect a slight rise in creatinine with the initiation of an ACE inhibitor. A rise of creatinine of 0.5 is not unusual and should not be a reason to stop this medication. If a patient develops a cough from ACE inhibitor therapy, consideration can be given to the use of ARBs as a substitute (Fihn et al., 2012).

Influenza Vaccination

All patients with SIHD, unless they have a clear contraindication, should receive an annual influenza vaccination. The purpose of this treatment is to reduce cardiovascular events. Data suggest that the influenza virus may precipitate plaque rupture, and vaccination against this virus can prevent the onset of ACS and death.

In addition to these measures, aggressive management of dyslipidemia, weight, HTN, impaired glucose control, and smoking cessation are essential interventions to reduce future cardiovascular events in the stable angina patient. Cardiac rehabilitation is a critical therapeutic modality in patients with CAD, particularly after revascularization. It is advisable that patients have 30 to 60 minutes of moderate-intensity aerobic activity at least 5 and preferably 7 days per week. Identifying and managing depression are also important steps in the management of patients with SIHD. The initiation of hormone replacement therapy in postmenopausal women is not indicated for cardiovascular risk reduction.

MECHANICAL AND REVASCULARIZATION STRATEGIES FOR TREATING STABLE ANGINA PATIENTS

Coronary Angioplasty and Bypass Surgery

Revascularization in SIHD can be performed for improving survival or for improving symptoms when unacceptable angina remains despite optimal medical therapy.

Revascularization for Improving Survival

Patients with unprotected left main disease are best treated with bypass surgery. Current guidelines (Fihn et al., 2012), however, support the treatment of LM disease with angioplasty and stenting for improvement of survival if the LM anatomy is favorable and surgery is high risk, a decision that will be made by the cardiac care team. Also, patients with three-vessel CAD or two-vessel disease that include the proximal left anterior descending (LAD) artery are best treated with bypass surgery to improve survival. Also, there is evidence that one-vessel proximal LAD treated with the left internal mammary artery (LIMA) provides a long-term survival benefit. Bypass surgery is also preferred for patients with three-vessel disease and reduced LV function

(35%-50%) or patients with three-vessel disease and those with diabetes even in the absence of disease in the LM or proximal LAD. Bypass surgery or angioplasty is indicated in survivors of sudden cardiac death with presumed ischemia-mediated ventricular tachycardia (VT).

Revascularization for Improving Symptoms

Both bypass surgery and angioplasty can be considered as first-line treatment in symptomatic patients with one or more significant stenoses (LM $\geq 50\%$, non LM $\geq 70\%$, or physiologic fractional flow reserve ≤ 0.8) and optimized on medical treatment or who cannot tolerate additional medications or if the patient's preference is to not take medications. Angioplasty is preferred for symptom control in patients with prior bypass surgery and unacceptable angina despite good medical treatment (Fihn et al., 2012).

Angioplasty should be avoided in patients with low-risk findings on noninvasive testing who have only one- or two-vessel, nonproximal LAD disease or one chronically occluded vessel who are asymptomatic or minimally symptomatic without medications. Angioplasty is not indicated in patients who are asymptomatic on no treatment and have only one- or two-vessel nonproximal LAD disease or one chronically occluded vessel and intermediate findings on noninvasive testing. The value of revascularization in this same patient population is unclear even if high-risk findings are seen on noninvasive imaging. In general, however, it is acceptable to revascularize the majority of patients with high-risk findings on noninvasive testing, particularly those who are symptomatic on medical treatment and have proximal LAD involvement or three-vessel disease (Patel et al., 2012).

NONPHARMACOLOGIC OR REVASCULARIZATION STRATEGIES TO TREAT CHRONIC STABLE ANGINA

Mechanical interventions such as enhanced external counterpulsation (EECP) can be effective in the treatment of patients with stable angina who are not candidates for revascularization and have continued chest pain despite medical therapy (Michaels et al., 2005). This therapy requires approximately 32 sessions each of about 1 hour duration for 5 days weekly. The functional mechanism of EECP is largely unknown. EECP, however, improves exercise tolerance, reduces exercise-induced myocardial ischemia, and improves LV diastolic filling (Urano et al., 2001) in patients with CAD. *Spinal cord stimulation* and *laser transmyocardial revascularization (laser-TMR)* can also be considered with possible benefits. *Acupuncture* has no role in the treatment of patients who are refractory to conventional pharmacologic and revascularization means.

KEY TREATMENT

- In symptomatic SIHD, regular treadmill stress testing is the preferred modality in patients who are able to exercise and have an interpretable baseline ECG. If the baseline ECG cannot be interpreted, then treadmill exercise imaging tests are preferred. Pharmacologic testing is best reserved for patients who cannot exercise (SOR: A, ACC/AHA guidelines).

- β -Blockers are recommended as initial therapy in the absence of contraindications in patients with prior MI or ACS and should be continued for at least 3 years in patients with normal LV systolic function or indefinitely in patients with EF less than 40% (SOR: A, ACC/AHA guidelines).
- Aspirin (75-162 mg/day) is strongly recommended in patients with stable angina and should be continued indefinitely in the absence of contraindications (SOR: A, ACC/AHA guidelines).
- All patients with SIHD, unless they have a clear contraindication, should receive the annual influenza vaccination (SOR: A, ACC/AHA guidelines, 2012).
- Comprehensive risk factor management and cardiac rehabilitation are essential in the management of patients with stable angina (SOR: A, ACC/AHA guidelines).
- Several OTC medications or vitamins should not be used to treat SIHD. These include vitamins C, E, B₆, B₁₂, β -carotene, folate, CoQ10, chromium, selenium, garlic, chelation, and estrogen therapy in postmenopausal women (SOR: A, ACC/AHA guidelines, 2012).

ACUTE CORONARY SYNDROMES

The ACS occur as a result of sudden atheromatous plaque rupture. Plaques with heightened inflammation, irrespective of severity, can rupture, leading to overlying platelet and fibrin mesh formation, resulting in abrupt reduction or cessation of coronary blood flow secondary to luminal obstruction (Ikeda, 2002; Zhou, 1999). Patients might experience UA or MI depending on whether myocardial necrosis occurs. In the United States, 2.3 million people have ACS annually.

Several crucial facts need to be considered by the practicing family physician. First, a large percentage of angiographically “normal” coronaries have significant plaque burden by intravascular ultrasonography or MRI, particularly in patients older than the age of 40 years (St Goar, 1992). Second, more than 60% of MIs are induced by culprit lesions that initially obstruct less than 50% of the arterial lumen. These lesions are generally not detected by stress testing. Third, when an ACS occurs, multiple vulnerable plaques generally coexist at the same time throughout the vascular tree. In an inadequately managed patient, any one of these lesions could suddenly rupture and precipitate an ACS. Therefore, a normal stress test result does not necessarily exclude the possibility of underlying CAD and risk for ACS. The prevention of MI should focus on reducing the chance of plaque rupture by controlling and normalizing as much as possible multiple cardiac risk factors, including HTN, uncontrolled diabetes, insulin resistance or metabolic syndrome, dyslipidemia, obesity, lack of routine exercise, a heightened inflammatory state, and smoking.

Unstable Angina and Non-ST Segment Myocardial Infarction

Patients with UA or a non-ST segment elevating myocardial infarction (NSTEMI) experience a partial occlusion of coronary flow as a result of plaque rupture and thrombus formation, microembolization, or the release of vasoactive substances, leading to localized spasm. UA is defined as class IV rest angina of at least 20 minutes in duration occurring

at rest (within 1 week of presentation), new-onset class III angina occurring within 2 months of presentation, or previously diagnosed chronic angina increased by more or equal 1 class in severity in the 2 months before presentation (Fihn et al., 2012). Prolonged rest angina (generally >30 minutes to 1 hour) typically leads to myocardial necrosis and NSTEMI. Patients are generally at high risk of developing ST segment elevation MI (STEMI) and sudden death. Data from the Thrombolysis in Myocardial Infarction III (TIMI III) registry indicate that death and MI could occur in these patients at a rate of 7.3% to 18.5%, depending on the severity of their symptoms, with postinfarction angina carrying the highest risk (Sharis et al., 2002). Patients may have ECG changes to indicate ischemia, mostly ST segment depression in contiguous leads, T-wave inversion, or pseudo-normalization of T waves. However, the ECG could also be silent in UA/NSTEMI. Comparing the ECG with a previous one can be very helpful for detecting subtle but significant new changes.

Patients with suspected UA should be referred to the emergency department (ED) or a specialized chest pain unit as soon as possible. They should be encouraged to call 911 and not drive themselves to the ED. A complete evaluation of their chest pain, including a comprehensive physical examination and history; obtaining an ECG within 10 minutes of arrival; chest radiography; and cardiac enzymes, including troponin I and creatinine kinase with MB fraction (CKMB), needs to be performed. Patients should be admitted to the hospital if they have a suspicion of UA and one or more of these high-risk features: elderly (>70 years of age), have had history of SIHD or revascularization, have ischemia on the ECG (ST segment deviation or new T-wave abnormalities or left bundle branch block), ongoing chest pain (>20 minutes or accelerating), abnormal cardiac biomarkers, or developing CHF or hemodynamic instability. Patients who do not have these high-risk UA features may be treated medically and then risk stratified on an elective basis either in the chest pain unit or shortly after discharge from the ED. If they do not have high-risk features on noninvasive imaging, they can continue to be treated medically. If high-risk noninvasive features are detected, then angiography and revascularization are indicated.

Abnormal cardiac enzymes allow a definite diagnosis of MI. The most frequently used cardiac markers are myoglobin, CK and CKMB fractions, and troponins T (TT) and I (TI). Myoglobin becomes abnormal in the first 1 to 2 hours after myocardial necrosis and remains abnormal for at least 7 to 12 hours. Its sensitivity is high for myocardial injury (sensitivity of 83% within 6 hours of onset of symptoms), but it has a lower specificity. A positive myoglobin can be due to muscle trauma, muscle disorders, rigorous exercise, and certain drugs such as statins. A more sensitive and specific marker than myoglobin is CK and its cardiac isoform, CKMB. This marker is 90% accurate for the diagnosis of MI at 6 hours from symptom onset. CK reaches its peak at about 24 hours of symptom onset and returns to normal or near normal by 72 hours. Troponin I is a very sensitive test for the diagnosis of MI at about 10 to 14 hours after the onset of chest pain. Its sensitivity and specificity at 6 hours are approximately 58% and 94%, respectively, and 92% and 95%, respectively, at 10 hours. Troponin I levels remain abnormal for several days after myocardial injury.

Table 27-14* High-Risk Indicators in Patients with Unstable Angina*

New or presumably new ST segment depression
Elevated troponin T or I
Recurrent angina at rest
Reduced LV function (EF <40%)
Heart failure or new or worsening MR
Sustained ventricular arrhythmias
Hemodynamic instability
History of bypass surgery
History of recent angioplasty within the past 6 months
High risk based on noninvasive stress testing
High-risk score (e.g., TIMI or Grace)

*Level A, American College of Cardiology/American Heart Association guidelines (Braunwald et al., 2002).

EF, Ejection fraction; LV, left ventricular; MR, mitral regurgitation; TIMI, Thrombolysis in Myocardial Infarction.

Depending on the time of onset of chest pain, these markers have different levels of utility in the diagnosis of MI. For instance, the diagnosis of MI in a patient who had chest pain more than 72 hours after presentation is best made with TI because the CK enzymes could have normalized on presentation. CK enzymes should not be used as the sole markers to assess the presence of an acute coronary event in the ED. A negative TI result after 8 to 12 hours of chest pain indicates a low chance for a cardiac event in the immediate near future. Therefore, patients who present with chest pain and have a negative TI result at 8 to 12 hours after the onset of chest pain and no ECG changes to indicate ischemia can undergo a stress test either in the ED or within 72 hours of discharge (Anderson et al., 2013).

Patients with definite UA/NSTEMI benefit significantly from early aggressive intervention with angiography and revascularization, particularly when early high-risk indicators exist (Table 27-14). The early invasive strategy can be immediate or at 12 to 48 hours after hospital admission, depending on the patient's hemodynamic stability and continued symptoms. An early conservative treatment can be adopted in patients with no high-risk features. Angiography can then be performed if high-risk features reappear or based on the presence of moderate to high risk findings on noninvasive imaging.

The Treat Angina with Aggrastat and Determine Cost of Therapy with an Invasive or Conservative Strategy (TACTICS TIMI-18) study (Cannon et al., 2001) randomized UA/NSTEMI patients to an early aggressive therapy with revascularization (within 48 hours of presentation) versus an early conservative therapy in which patients were treated medically and then risk stratified with exercise stress testing. In this study, a significant reduction in the primary combined end point of death, MI, and rehospitalization for ACS was noted at 6 months (odds ratio, 0.78; 95% CI [0.62, 0.97]; $P=0.025$). Other high-risk features include advanced age (>70 years); history of vascular disease; diabetes; and elevated high-sensitivity C-reactive protein (hsCRP), WBC count, and B-type natriuretic peptide (BNP). Furthermore, based on data for the TIMI 11B trial (Antman et al., 1999), Antman and coworkers (2000) predicted that the risk of death, reinfarction, or recurrent severe ischemia requiring revascularization increased from 5% to 41% depending on the sum of the following individual prognostic variables: age older than 65 years, more than three coronary risk

Table 27-15 Acute Pharmacologic Therapy of Patients with Unstable Angina/Non-ST Elevation Myocardial Infarction*

Aspirin (or clopidogrel in patients who cannot take aspirin) should be administered as soon as possible after onset of symptoms and continued indefinitely.
Antithrombin therapy with UFH, fondaparinux, or enoxaparin (preferred over UFH unless bypass surgery is planned within 24 hours) should be started in conjunction with aspirin.
Clopidogrel should then be added to antithrombin and aspirin in hospitalized patients and continued for 1 year whether the patient is treated medically, with bare-metal stent, or with drug-eluting stent.
Fondaparinux should not be used when patient is undergoing PCI procedures (catheter and wire thrombosis have been described).
The use of upstream intravenous GP 2b/3a inhibitors such as tirofiban (Aggrastat) or eptifibatide (Integrilin) may be considered in patients with early recurrent ischemic discomfort, delay to revascularization, or high-risk features.
If bivalirudin is planned as the antithrombin of choice during the procedure, GP 2b/3a inhibitors are not used except as a bail-out treatment.
Fibrinolytics are contraindicated in patients with unstable angina NSTEMI.

*Level of evidence: A, American College of Cardiology/American Heart Association guidelines (Braunwald et al., 2002).

GP, Glycoprotein; NSTEMI, or non-ST segment elevation myocardial infarction; PCI, percutaneous coronary intervention; UFH, unfractionated heparin.

factors, prior angiographic coronary obstruction, ST segment deviation, more than two angina events within 24 hours, use of aspirin within 7 days, and elevated cardiac markers. These variables have been incorporated into the TIMI score to assess the risk of death and MI and need for urgent revascularization in patients with UA.

Although most ACS are caused by plaque rupture, thrombosis, and superimposed spasm, rapidly progressive plaques can infrequently lead to an unstable syndrome. In addition, UA can be precipitated by secondary causes such as thyrotoxicosis, severe HTN or valvular stenosis, tachycardia, anemia, hypotension, and hypoxia.

Pharmacologic Therapy of Unstable Angina or Non-ST Segment Myocardial Infarction

Pharmacologic management of patients with UA or NSTEMI can be divided into *acute* and *chronic* therapy. In the *acute* phase (Table 27-15; SOR: A, ACC/AHA guidelines), patients are typically treated with an antithrombin drug (unfractionated heparin [UFH] or low-molecular-weight heparin), aspirin, clopidogrel, β -blockers, statins, IV nitrate therapy, ACE inhibitors (in patients with LV dysfunction and continued HTN or in those with diabetes), and supplemental oxygen therapy (in patients with respiratory distress and hypoxemia). The use of upstream IV glycoprotein (GP) IIb/IIIa inhibitors such as tirofiban (Aggrastat) or eptifibatide (Integrilin) may be considered in patients with early recurrent ischemic discomfort, delay to revascularization, or high-risk features. If bivalirudin (Angiomax) is planned as the antithrombin of choice during the procedure, GP IIb/IIIa inhibitors are not used except as a "bail-out" intervention.

Low-molecular-weight heparin (e.g., Lovenox) has been shown to have some advantages over UFH. These include more reliable anticoagulation with predictable pharmacokinetics, resistance to inhibition by platelet factor 4, a lower

risk of causing heparin-induced thrombocytopenia, greater anti-Xa activity, and possibly greater efficacy in reducing risk for ACS. In the Efficacy and Safety of Subcutaneous Enoxaparin in Non-Q-Wave Coronary Events (ESSENCE) trial (Cohen et al., 1997), enoxaparin (Lovenox) plus aspirin was more effective than UFH plus aspirin in reducing the incidence of the combined end points of death, MI, and recurrent angina (19.8% vs. 23.3%, respectively; $P = 0.016$) in patients with UA or NSTEMI at 1 month of follow-up. A recent meta-analysis of 22,000 patients also demonstrated that enoxaparin is more effective than UFH in preventing the combined end point of death or MI (Petersen et al., 2004). Currently, enoxaparin 1 mg/kg given subcutaneously twice a day is preferred over UFH (70 units/kg bolus IV, then 1000 units/hour adjusted every 6 hours with partial thromboplastin time checks) in patients who present with UA/NSTEMI and in whom a conservative approach has been the initial management therapy. Both enoxaparin and UFH, however, have level A evidence to support their use in these patients.

Continued chest pain despite optimal medical therapy indicates that the patient should be brought to the cardiac catheterization laboratory for emergent angiography and revascularization to minimize the chance of irreversible myocardial injury and loss of function. As noted earlier, even in a pain-free UA patient with high-risk features, an aggressive approach to therapy is indicated and needs to be implemented within 48 hours of symptom onset. Morphine sulfate can be used to treat acute pain unresponsive to antiischemic therapy.

Adenosine Diphosphate Receptor Antagonists. Optimal antiplatelet treatment is needed with antithrombin drugs in the management of the patients with ACS. Vascular injury leads to platelet activation and aggregation with subsequent fibrin deposition and thrombosis. Antithrombin therapy alone without optimal platelet inhibition leads to an inferior outcome during percutaneous coronary intervention (PCI). Early experience with PCI was performed with UFH in patients pretreated with aspirin. Aspirin is only partially effective as an antiplatelet drug by inhibiting cyclooxygenase and therefore partially blocking thromboxane A₂ and collagen-mediated platelet activation and aggregation (Shammas, 2005).

Platelet inhibition with clopidogrel (Plavix) is dose and time dependent. After a single loading dose of 600 mg of clopidogrel, inhibition of platelet aggregation reaches steady state in 2 to 3 hours. In contrast, 75 mg/day of clopidogrel requires 5 to 7 days to reach the same level of inhibition of platelet aggregation. In patients with ACS, blocking the ADP receptor on platelets with clopidogrel is an important step to reduce the combined end point of cardiovascular death, nonfatal MI, or stroke, whether they have been treated aggressively with bare-metal stents or drug-eluting stents or managed conservatively. In the Clopidogrel for the Reduction of Events During Observation (CREDO) study (Steinhubl et al., 2002), pretreatment of patients with 300 mg of clopidogrel at least 15 hours before intervention reduced long-term adverse events. In the Intracoronary Stenting and Antithrombotic Regimen Rapid Early Action for Coronary Treatment (ISAR-REACT) trial (Kandzari, 2004), pretreatment with 600 mg of clopidogrel

provided similar outcomes in low- to intermediate-risk patients irrespective of whether they were assigned to abciximab or placebo, with maximum antiplatelet effect seen within 2 to 3 hours of treatment before intervention. In the Antiplatelet therapy for Reduction of MYocardial Damage during Angioplasty (ARMYDA-2) study (Patti et al., 2005), 600 mg of clopidogrel was more effective in reducing cardiac events than 300 mg of clopidogrel when given at a mean time of 6 hours before PCI in both arms. ARMYDA-2 also did not exclude patients from receiving GP IIb/IIIa inhibitors, thereby supporting the hypothesis that optimal ADP receptor antagonism before PCI might be essential even when intraprocedural inhibition of platelet aggregation is achieved with GP IIb/IIIa inhibitors.

Currently, clopidogrel is given to all patients with an ACS with an oral loading dose of 600 mg followed by 75 mg/day. Clopidogrel is generally administered after initiating treatment with aspirin and antithrombin and as part of a conservative management strategy or preceding PCI.

Prasugrel (Effient) is also a thienopyridene and oral ADP receptor antagonist. It is indicated in ACS patients undergoing PCI. It is not indicated in patients with stable angina or those not undergoing PCI. Prasugrel is also absolutely contraindicated in patients with any prior history of stroke or TIA. It is relatively contraindicated in older patients older than the age of 75 years and in patients who weigh less than 60 kg. In the TRITON TIMI-38 study, Prasugrel was shown to be superior to clopidogrel in reducing the primary end point of cardiovascular death, nonfatal MI, or stroke and reducing acute stent thrombosis. However, it did have a higher incidence of major and minor bleeding than clopidogrel, including fatal bleeding. Prasugrel is reserved for patients when their coronary anatomy becomes known in the cardiac catheterization laboratory and it has become clear that they will be undergoing PCI. It can, however, be administered to patients with STEMI in the ED because these patients are predominantly managed by PCI. The loading dose of prasugrel is 60 mg with a maintenance dose of 10 mg/day orally or 5 mg/day orally (for patients weighing less than 60 kg) (Wiviott et al., 2007).

Ticagrelor (Brilinta) is the most recently introduced ADP receptor antagonist. It is indicated in patients with ACS who are treated either medically or who undergo PCI. The loading dose is 180 mg orally followed by a maintenance dose of 90 mg twice daily. Ticagrelor was compared with clopidogrel in the Ticagrelor versus Clopidogrel in Patients with Acute Coronary Syndrome (PLATO) trial (Wallentin et al., 2009). It was shown to be superior to clopidogrel in reducing the composite end point of cardiac death, nonfatal MI, and stroke and in reducing acute stent thrombosis. It increases the risk of non-coronary artery bypass graft major bleeding compared with clopidogrel. The PLATO trial excluded patients with sick sinus syndrome (SSS) or heart block. Ticagrelor inhibits adenosine reuptake and can worsen bradycardia and heart block. Also, it can cause dyspnea that leads to cessation of the drug in 0.9% of patients. Patients receiving ticagrelor should not receive more than 100 mg/day of aspirin because doses that exceed this appear to attenuate the efficacy of ticagrelor. In addition, they should not receive drugs that are potent inhibitors (e.g., ketoconazole, clarithromycin, and some antiviral

drugs) or inducers (e.g., rifampin, antiepileptic drugs) of the CYP3A system.

In the *chronic* phase, typically after a revascularization procedure, the mainstay of therapy is aspirin indefinitely, clopidogrel (or prasugrel–ticagrelor) for 12 months, statins, ACE inhibitors, and β -blockade. In the Heart Outcomes Prevention Evaluation (HOPE) (Yusuf et al., 2000) trial, ramipril (10 mg/day) was shown to reduce cardiovascular events significantly, including cardiovascular and total mortality and strokes. In HOPE, patients were 55 years or older, and the majority had a history of vascular disease (80% history of CAD and 42% with PAD). Similar results were obtained in the European Trial on Reduction of Cardiac Events with Perindopril in stable CAD (EUROPA) (Fox, 2003). In the EUROPA trial, 13,655 patients were included with previous MI (64%), angiographic evidence of CAD (61%), coronary revascularization (55%), or a positive stress test result only (5%). The mean age was 60 years, and patients had no CHF or stable CAD. In this study, 10% of placebo and 8% of perindopril (8 mg once daily) patients experienced the combined primary end point of cardiovascular death, MI, or cardiac arrest (20% relative risk reduction; $P = 0.0003$ favoring perindopril therapy) at a mean follow-up period of 4.2 years.

Patients also need to quit smoking; exercise; adhere to a low-fat and low-carbohydrate diet; lose weight if obese; enroll in cardiac rehabilitation; and, if they have diabetes, achieve aggressive control of their blood sugar to keep their HbA_{1c} below 7%.

KEY TREATMENT

- Patients with definite ACS should be evaluated for immediate reperfusion therapy based on the presence of high-risk features (SOR: A, ACC/AHA guidelines).

- Whether an invasive or conservative strategy is chosen, aspirin (or clopidogrel if aspirin intolerant) needs to be initiated. In conservatively managed patients, enoxaparin or fondaparinux (first choice) or UFH (second choice) needs to be initiated. In aggressively managed patients, UFH, enoxaparin, or bivalirudin needs to be initiated. Fondaparinux should be avoided in the setting of angioplasty. Clopidogrel is then initiated before angiography in the aggressively managed group and in all patients managed conservatively (SOR: A; ACC/AHA, 2007).
- In patients with UA/NSTEMI, aspirin (81 to 162 mg/day) and clopidogrel 75 mg/day for preferably 1 year should be administered in patients treated conservatively (SOR: A, ACC/AHA guidelines, 2012).
- In patients with UA/NSTEMI receiving bare-metal stents, aspirin 162 to 325 mg/day should be administered for 1 month followed by 81 to 162 mg/day indefinitely and clopidogrel 75 mg/day orally for at least 1 year (SOR: A, ACC/AHA guidelines, 2012).
- In patients with UA/NSTEMI receiving drug-eluting stents, aspirin 162 to mg/day should be administered for 3 to 6 months followed by 81 to 162 mg/day indefinitely and clopidogrel 75 mg/day orally for at least 1 year (SOR: A, ACC/AHA guidelines).

ST ELEVATION MYOCARDIAL INFARCTION

STEMI occurs secondary to a sudden interruption of coronary blood supply (Figure 27-11) to a part of the myocardium as a result of a complete thrombotic occlusion of a coronary artery (DeWood et al., 1980). Plaque rupture is the predominant mechanism of STEMI, with subsequent platelet and fibrin deposition. It is estimated that there are 0.5 million STEMI events in the United States annually.

Figure 27-11 Acute inferior myocardial infarction. **A**, Sudden occlusion of the right coronary artery with a filling thrombus at the occlusion site. **B**, The same vessel after initial angioplasty showing multiple filling defects, indicating thrombus.

Emergent and complete revascularization is the most important goal in the acute therapy of STEMI. Current guidelines indicate that a patient with symptoms and signs of STEMI should undergo emergent revascularization with primary angioplasty if possible within 90 minutes of arrival to the ED (door to balloon) (Antman et al., 2004). Currently, angioplasty is considered the first choice of therapy because it leads to overall superior results (Magid et al., 2000), primarily reducing the rate of nonfatal MI, and leading to fewer intracranial bleeds compared with thrombolysis. Stronger evidence exists for primary angioplasty in STEMI because the risk of fibrinolysis increases (Hochman et al., 2001; Kent et al., 2002; Wu et al., 2002). If angioplasty is not available or if transfer to a nearby facility with primary angioplasty is not possible to achieve with first medical contact to revascularization occurring at less than 120 minutes, then fibrinolysis needs to be administered in the absence of contraindications. Even after lytic therapy is administered, it is recommended that patients be transferred to a facility with primary angioplasty capability. This ensures that patients who fail lysis can be treated with rescue angioplasty in a timely manner. The door-in, door-out, or the time from arrival to transfer to a primary PCI facility, should be less than 30 minutes. It is currently acceptable to pursue an early elective angioplasty between 3 and 24 hours of successful lysis (O'Gara et al., 2013).

Patients with cardiogenic shock (Hochman et al., 2001) or severe CHF (Wu et al., 2002) benefit more from primary angioplasty. Irrespective of the delay time for door to balloon, it is recommended that patients with cardiogenic shock be treated immediately or transferred for primary angioplasty. Fibrinolysis is not recommended in cases of cardiogenic shock except in patients unsuitable for angioplasty or bypass surgery.

Primary angioplasty is best done in intermediate- and high-volume centers (Canto et al., 2000) with an experienced catheterization team and interventional cardiologists on call and an approved hospital process that has been agreed upon by various disciplines involved in the care of the patient. This MI "alert system" should be capable of effectively mobilizing all resources available to stay within the 90-minute timeframe to first balloon inflation from arrival to the ED.

Thrombolytic therapy has been shown to reduce mortality rates in patients with STEMI. Thrombolytics are contraindicated in patients with NSTEMI because they have been shown to have no clinical benefit and carry unwarranted risks. Thrombolysis enhances the body's own fibrinolytic system by accelerating the formation of plasmin from plasminogen (Shammas et al., 1993). Plasmin degrades fibrin and several plasma proteins, including fibrinogen, prothrombin, and factors V and VIII, leading to a defective hemostasis. Thrombolytic agents are classified as clot-specific (alteplase [tPA], reteplase [recombinant-PA], and tenecteplase [TNK-tPA]) or non-clot specific (streptokinase [SK], urokinase [UK], and anisoylated plasminogen activator complex [APSAC]). Whereas clot-specific thrombolytics activate plasminogen at the site of the clot, non-clot-specific ones act by generalized systemic lysis. In the United States, clot-specific thrombolytics are most commonly used. The different dosages and mode of administration

Table 27-16 Thrombolytics Commonly Used in the Treatment of Acute Myocardial Infarction

Drug	Dose	Cautions
Streptokinase	1.5 million IU IV Give infusion over 60 min	Watch for hypotension, anaphylaxis, severe bleeding, and stroke.
Retavase	10 U IV over 2 min Give second dose of 10 U IV 30 min after first dose if no complications	Watch for intracranial hemorrhage, arrhythmia, and hemorrhage.
Activase	15 mg bolus IV; then 0.75 mg/kg (maximum, 50 mg) over 30 min; then 0.5 mg/kg (maximum, 35 mg) over 60 min; give with heparin	Watch for intracranial hemorrhage, arrhythmia, severe bleeding, and anaphylaxis.
Tenecteplase	Wt <60 kg: 30 mg IV; maximum, 50 mg Wt 60-69 kg: 35 mg IV; maximum, 50 mg Wt 70-79 kg: 40 mg IV; maximum, 50 mg Wt 80-89 kg: 45 mg IV; maximum, 50 mg Wt >90 kg: 50 mg IV; maximum, 50 mg	Watch for intracranial bleeding, anaphylaxis, and reperfusion arrhythmias.

IV, Intravenous.

Table 27-17 Contraindications to Fibrinolytic Therapy*

Absolute	History of intracranial hemorrhage Known intracranial neoplasm or vascular lesions Active bleeding or known bleeding disorder (exclude menses) Embolic stroke within 3 mo (exception: embolic stroke within 3 hr) Suspected aortic dissection Significant facial or head trauma within 3 mo
Relative	Uncontrolled severe hypertension (>180 mm Hg systolic; >110 mm Hg diastolic) Prolonged CPR (>10 min), recent surgery (<3 wk), or noncompressible vascular puncture Recent internal bleeding or active peptic ulcer disease Pregnancy Currently anticoagulated with high INR For streptokinase: prior exposure to the drug or history of allergic reaction

*American College of Cardiology/American Heart Association guidelines (Antman et al., 2004).

CPR, Cardiopulmonary resuscitation; INR, international normalized ratio.

of these thrombolytics are provided in Table 27-16. Contraindications for fibrinolysis are listed in Table 27-17.

Upon arrival to the ED, patients with chest pain should get ECG done within 10 minutes of arrival. If the ECG does not show ST segment elevation, it is advised that the ECG be repeated within 5 to 10 minutes in patients with continued chest pain to rule out the possibility of late appearance STEMI. It should be noted that ST segment depression in the anterior leads with early precordial transition could indicate ST elevation posterior wall MI, particularly if associated with ST elevation in the inferior leads (inferoposterior MI). Right-sided precordial leads can be helpful in patients with acute inferior wall MI to determine right

*Strength of recommendation: A (American College of Cardiology/American Heart Association guidelines, [Antman et al., 2004](#)).

ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker; DM, diabetes mellitus; EF, ejection fraction; GP, glycoprotein; IV, intravenous; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSAID, nonsteroidal antiinflammatory drug; PCI, percutaneous coronary intervention; PO, oral; STEMI, ST segment elevation myocardial infarction; UFH, unfractionated heparin.

ventricular (RV) involvement (ST elevation will be seen in the right precordial leads) (Figure 27-12).

Patients with STEMI should receive supplemental oxygen, morphine sulfate for pain control, IV nitrate therapy if they do not have hypertension and have not ingested a phosphodiesterase inhibitor for erectile dysfunction, 162 mg of chewable aspirin, β -blockade, a statin, an ACE inhibitor (particularly in patients with CHF, reduced LV function, hypertension, or diabetes), and an ADP receptor antagonist (Table 27-18). At present, β -blockers are recommended in the first 24 hours of a STEMI when there are no contraindications to their use. IV β -blockers are reasonable to administer at the time of presentation if the patient is

hypertensive or has ongoing ischemia. The general use of IV β -blockers at the time of presentation has not been shown to alter the combined end point of death, MI, and stroke in STEMI patients ([Chen et al., 2005](#)).

Hemodynamic instability should be aggressively treated with pressor agents (typically dopamine started at 5 μ g/kg/min and titrated every 5 minutes to keep the systolic pressure >90 mm Hg). Normal saline fluid boluses can be helpful, particularly in patients with inferoposterior MI with right-sided involvement. In these patients, bradycardia also needs to be aggressively treated if associated with hypotension with either atropine (1 mg IV, which can be repeated twice), or with a temporary pacemaker if there is inadequate response to atropine. Patients with RV involvement usually respond well to a fluid challenge, correcting the bradycardia, administering dopamine, and maintaining sinus rhythm because they rely on a normal atrial kick for increasing their end-diastolic volume and cardiac output. If hypotension does not respond well to these conservative measures, patients need to have an intraaortic balloon pump inserted. Typically, these patients should be brought emergently to the cardiac catheterization laboratory for more definitive management because their mortality rate is excessively high without immediate revascularization ([Hochman et al., 2001](#)).

Induced hypothermia is highly recommended in comatose patients and out-of-hospital cardiac arrest caused by ventricular fibrillation (VF) or pulseless VT, including patients who undergo angioplasty ([O'Gara et al., 2013](#)).

The long-term management of these patients is similar to that for those with UA/NSTEMI with aggressive preventive measures and continued long-term aspirin, β -blockers, ACE inhibitor, statins, exercise, and a low-fat diet. Smoking cessation, control of HTN and diabetes, and achieving ideal body weight are of paramount importance to prevent further progression of disease and recurrent MI. Preferably, ADP receptor antagonists need to be continued for 12 months irrespective of whether the patient received a revascularization procedure with drug-eluting stents or bare-metal stents or was conservatively managed.

Valvular Heart Disease

AORTIC STENOSIS

Key Points

- Echocardiography is recommended for the diagnosis and assessment of aortic stenosis (AS) severity, LV wall thickness, size, and function (SOR: A; ACC/AHA 2008 guidelines).
- Echocardiography is recommended for monitoring asymptomatic patients with aortic valve stenosis (every 3-5 years for mild AS, every 1-2 years for moderate AS, and every year for severe AS) (SOR: A; ACC/AHA 2008 guidelines).
- Exercise testing should not be performed on symptomatic patients with severe AS (SOR: A; ACC/AHA 2008 guidelines).
- Cardiac angiography is recommended before aortic valve replacement if CAD is suspected (SOR: A; ACC/AHA 2008 guidelines).

Aortic stenosis is defined as an obstruction that impedes blood flow from the LV to the aorta and is mostly secondary to aortic valvular disease. Other less common causes of AS include supra- and subvalvular stenosis, which are generally congenital.

Aortic valvular stenosis is the most common valvular abnormality in the United States. It can be congenital, rheumatic, or calcific or degenerative. Whereas calcific aortic valve stenosis (Figure 27-13) is most prevalent in patients older than 70 years of age, congenital, mostly bicuspid valve disease (Figure 27-14) is more common in younger patients. A bicuspid aortic valve leads to flow turbulence and valve trauma, which in return precipitates fibrosis, stiffness, and calcification. One third of bicuspid valves will become stenotic between the fourth and sixth decades of life and account for half of all surgical cases. In age-related calcific valves, the valve is affected by the same risk factors as atherosclerosis, in which inflammatory cells (macrophages and T lymphocytes), lipid and calcium

deposits, and the development of fibrosis are seen. To date, statin therapy has not been shown to reduce rates of progression of aortic valve stenosis or reduce the need for aortic valve replacement. Rheumatic aortic valve stenosis is now uncommon in developed countries and is mediated by adhesion and the fusion of cusps after streptococcal infection.

The aortic valve surface area is normally 3.0 to 4.0 cm². Symptoms typically do not appear unless the valve is narrowed to at least one fourth of its normal surface area. Stenosis is graded as mild (valve area >1.5 cm²), moderate (>1.0-1.5 cm²), or severe (≤1 cm²) (Rahimtoola, 1989). The valve area narrows at an average rate of 0.12 cm² per year (Otto et al., 1997). As the valve narrows, cardiac output remains stable at rest but diminishes with exercise. As disease progresses, LV mass increases, and diastolic dysfunction becomes evident with an increase in LV filling pressure. Myocardial oxygen demand typically increases, and even in the absence of CAD, patients may experience angina. Patients with AS have a good prognosis if they do not have symptoms of angina, CHF, or syncope or near syncope, particularly with activity. Surgical management of the valve becomes necessary in symptomatic patients because the incidence of sudden cardiac death increases in these patients.

Patients with severe aortic valve stenosis describe progressive dyspnea; chest pain and syncope with exertion; and symptoms of HF, including orthopnea, paroxysmal nocturnal dyspnea, and edema. Syncope at rest is typically arrhythmia induced. Patients with severe aortic valve stenosis have an approximate 5% history of sudden cardiac death. In addition, these patients may give a history of rheumatic fever or rheumatic heart disease, TIAs from calcium deposit systemic embolization, and intermittent GI bleeding from an increased incidence of arteriovenous malformations.

The typical physical signs of severe aortic valve stenosis are diminished carotid pulses (delayed and weak); a sustained apical impulse; a single second heart sound; an S4 gallop; and a midsystolic crescendo-decrescendo murmur with late peaking best heard at the base of the heart, although in elderly patients, it might be heard only at the

Figure 27-13 Aortic valve stenosis with calcification as seen with two-dimensional Doppler echocardiography.

Figure 27-14 Bicuspid aortic valve.

Figure 27-15 Velocity gradient across a calcified stenotic aortic valve, as seen with Doppler echocardiography.

apex. Aortic valve stenosis can be distinguished clinically from dynamic left ventricular outflow tract (LVOT) obstruction such as in hypertrophic obstructive cardiomyopathy (HOCM) by certain clinical maneuvers at the bedside. An HOCM murmur tends to increase during the strain phase of the Valsalva maneuver and during standing up from a squatting position. In both maneuvers, the preload of the LV is reduced, leading to a smaller cavity size and an increase in the LVOT obstruction.

Diagnostic tests include chest radiography, which could show a calcified valve, pulmonary venous congestion, or an increase in ascending aortic root size secondary to poststenotic dilation. Also, a 12-lead ECG may show LVH and conduction abnormalities. An echocardiogram typically confirms the diagnosis. Valve structure can be assessed, including the presence of calcification, reduction in cusp motion, and congenital abnormalities such as a bicuspid or abnormal tricuspid valve. A gradient can be measured across the valve (Figure 27-15), and the valve area can be determined using Doppler flow with reasonable accuracy (Currie et al., 1986). The presence of concomitant aortic valve insufficiency can also be visualized using color Doppler flow characteristics. Other important findings on echocardiography include the presence or absence of LVH and assessment of LV compliance, atrial size, and associated other valvular abnormalities. If noninvasive findings support the diagnosis of severe AS and the patient is symptomatic, then diagnostic angiography is indicated to confirm the presence of severe aortic valve stenosis and assess the coronary arteries. Also, it is important to recognize low-gradient severe aortic valve stenosis ($<1 \text{ cm}^2$) in patients with EFs less than 40%. In these patients, it is unclear whether the severity of the aortic valve stenosis is overestimated because of a low cardiac output state or if it is true severe AS. Obtaining baseline hemodynamics with echocardiography and then repeating them with dobutamine stress will help in distinguishing true severe AS from pseudo AS. If the gradient across the aortic valve increases and the valve area worsens, this indicates that the stenosis of the aortic valve is truly severe. Stress testing is contraindicated in the setting of symptomatic, severe aortic valve stenosis.

The treatment of aortic valve stenosis depends on the presence or absence of symptoms. Symptomatic severe aortic valve stenosis carries a poor prognosis, with an average life expectancy of 2 to 3 years (Ross and Braunwald, 1968). The 5- and 10-year mortality rates are approximately 52% to 80% and 80% to 90%, respectively (Horstkotte and Loogen, 1988; Turina et al., 1987). Aortic valve surgery with or without coronary artery bypass grafting is the treatment of choice (Lund, 1990; Schwarz et al., 1982). Aortic valvuloplasty carries a poor outcome and is reserved as a palliative therapy for inoperable patients. Typically, the improvement in the aortic valve gradient is mild with valvuloplasty, and a recurrence of severe stenosis can be expected within 6 months (Block and Palacios, 1988; Davidson et al., 1990). Surgery is typically not advised for patients with asymptomatic severe valvular stenosis. Patients with dyspnea and progressive LV dysfunction need to be considered for valve replacement. Most patients with asymptomatic, severe aortic valve stenosis will, however, develop symptoms within 5 years of follow-up. The 1-, 2-, and 5-year event-free probabilities were 80%, 63%, and 25%, respectively. Independent predictors of all-cause mortality include age, chronic renal failure, inactivity, and aortic valve velocity (Pellikka et al., 2005). A low threshold to intervene in patients with asymptomatic severe AS may be considered, particularly when peak systolic velocity (PSV) is 4.5 m/sec or greater on Doppler echocardiography (Pellikka et al., 2005; Rosenheck, 2000) if associated with moderate or severe valvular calcification (Rosenheck, 2000). Predictors of survival in asymptomatic AS include a PSV across the valve of more than 4 m/sec, the rate of change of the PSV over time, and functional class (Otto et al., 1997). It is currently recommended that patients with severe AS undergo aortic valve replacement if they have symptoms (chest pain, syncope, or HF), if EF is less than 50%, or in conjunction with another valve surgery or bypass surgery (even if the aortic valve is moderate in severity). Furthermore, European guidelines currently favor aortic valve replacement in patients with severe AS with a valve area less than 0.6 cm^2 (irrespective of symptoms), rapidly progressing valve area severity, or an abnormal response to exercise testing (Vahanian et al., 2012).

Patients need to be advised about antibiotic prophylaxis to prevent endocarditis, especially with rheumatic valve disease (Dajani et al., 1997) (Table 27-19). Patients with moderate to severe aortic valve stenosis need to avoid moderate to severe physical exertion (Cheitlin et al., 1994). Arrhythmias need to be corrected promptly in patients with severe AS. Follow-up echocardiography is indicated every year in patients with asymptomatic severe AS and every other year in those with moderate stenosis (Bonow et al., 1998).

Aortic valve replacement can be performed with a mechanical valve or a tissue valve. Mechanical valves are more durable than bioprosthetic valves but require lifetime anticoagulation. The choice of the valve depends on the patient's clinical situation but takes into consideration the patient's age, need for future pregnancies, ability to take anticoagulants, compliance, and preference. For instance, patients who have a contraindication to anticoagulation with warfarin should receive a bioprosthetic valve. These valves typically do not require anticoagulation with

Table 27-19 Prophylaxis for Bacterial Endocarditis*

Drug	Adult Dose	Pediatric Dose*	Time before Procedure
GENERAL PROPHYLAXIS			
Amoxicillin	2 g	50 mg/kg PO	1 hr
	2 g IV or IM	50 mg/kg IM or IV	30 min
PENICILLIN-ALLERGIC PATIENTS			
Clindamycin	600 mg	20 mg/kg PO	1 hr
Clarithromycin	500 mg	15 mg/kg PO	1 hr
Azithromycin	500 mg	15 mg/kg PO	1 hr
Clindamycin	600 mg	20 mg/kg IV	30 min
Cefazolin	1 g	25 mg/kg IM or IV	30 min

*Pediatric dose should not exceed adult dose.

IM, intramuscular; IV, intravenous; PO, oral.

From Dajani AS, Taubert KA, Wilson W, et al. Prevention of bacterial endocarditis: recommendations by the American Heart Association. *Circulation*. 1997;96:358-366.

warfarin, and patients are generally put only on an aspirin subsequent to the procedure. Younger patients and those with no contraindication to Coumadin are best served with mechanical valves because they are more durable and hopefully will obviate the need for another valve surgery in the future. Very elderly patients (in their 80s) are typically given a tissue valve to obviate the need for anticoagulation. Antibiotic prophylaxis to prevent endocarditis is strongly recommended in patients with prosthetic valves.

Transcatheter aortic valve replacement (TAVR) using a stent valve has recently emerged as a less invasive procedure to replace severe aortic valve stenosis in patients who are deemed inoperable or are at high risk for conventional aortic valve surgery. In the Placement of Transcatheter Aortic Valve (PARTNER) trial (cohort B), patients with severe symptomatic aortic valve stenosis and an estimated high likelihood of death with conventional aortic valve surgery (>50%) were randomized to receive the Edwards SAPIEN valve versus standard therapy (Leon et al., 2010). At 1 year, the rate of death from any cause was 30.7% with the SAPIEN valve versus 50.7% with conservative treatment ($P < 0.001$). Also, the rate of the composite end point of death from any cause or repeat hospitalization was 42.5% with TAVR versus 71.6% with conservative treatment ($P < 0.001$). In cohort A of the PARTNER trial, patients with high operative surgical risk (>15% mortality rate) were randomized to open aortic valve surgery versus TAVR (Smith et al., 2011). No difference in mortality was seen with both modalities, but there was more bleeding and atrial fibrillation (AF) with surgery and more vascular complications with TAVR. TAVR is approved at this time for both inoperable and high-risk patients for open aortic valve replacement.

KEY TREATMENT

- Aortic valve replacement is indicated in symptomatic patients with severe AS (SOR: A, ACC/AHA 2008 guidelines).
- Aortic valve replacement is indicated in patients with severe AS and LV dysfunction (SOR: A, ACC/AHA 2008 guidelines).

Figure 27-16 Aortic valve regurgitation, as seen with color Doppler echocardiography. Note the blue turbulent jet into the left ventricle in diastole.

AORTIC VALVE REGURGITATION

Key Points

- Echocardiography is indicated to confirm the presence and severity of aortic insufficiency (SOR: A, ACC/AHA 2008 guidelines).
- Periodic echocardiography is recommended to evaluate LV function and cavity size in patients with asymptomatic severe aortic insufficiency (SOR: A, ACC/AHA 2008 guidelines).
- Coronary angiography is indicated before valve surgery in patients with severe aortic insufficiency if there is suspicion of CAD (SOR: A, ACC/AHA 2008 guidelines).

Aortic valve regurgitation (AR) is defined as blood flow from the aorta to the LV in diastole because of an incompetent aortic valve (Figure 27-16). Aortic valve insufficiency is generally acquired because of valve infection, dilation and dissection of the aortic root, trauma, or long-term degenerative change of the valve, particularly in the setting of HTN. Patients with a history of prosthetic valves (Figure 27-17) can also have aortic valve insufficiency. Aortic insufficiency can also be caused by a congenital bicuspid aortic valve.

Aortic valve regurgitation leads to volume overload of the LV and an increase in LV end-diastolic pressure. In chronic AR, symptoms might not appear before LV cavity dilation, and a reduction in LV function develops. Patients will have a long diastolic murmur, a wide pulse pressure, and bounding pulses. In acute AR, a sudden rise of LV end-diastolic pressure occurs because of the inability of the LV to acutely dilate in response to a sudden volume overload. Patients are generally acutely symptomatic with HF. Patients have a short diastolic murmur and a soft S1 with tachycardia.

Patients with severe AR will eventually become symptomatic, displaying symptoms of dyspnea and CHF. Angina is less common, but it can occur as a result of reduction in

Figure 27-17 Mechanical prosthetic valve. Note the acoustic shadowing generated by the mechanical prosthesis.

Figure 27-18 Rheumatic mitral valve stenosis. Note the doming of the stenotic mitral valve with thickening of the anterior leaflet.

coronary perfusion pressure. Physical signs of severe AR include a rapid and quick arterial pulse (Corrigan pulse); a wide pulse pressure; an early high-pitched, blowing diastolic murmur heard best over the left sternal border; an S3 gallop; and a low-pitched diastolic murmur at the apex (Austin-Flint murmur).

The ECG shows LVH and possibly conduction abnormalities. Echocardiography can help make the diagnosis accurately and provides information about LV function and cavity size. Other associated valvular abnormalities can also be assessed by the echocardiogram. Aortic root size and left atrial size can also be measured (Zoghbi et al., 2003). Echocardiographic findings of severe AR include a color jet width of more than 60%, vena contracta of more than 6 mm, half-time AI of less than 200 msec, regurgitant volume of more than 60 mL, and an effective regurgitant orifice of greater than 30 mm². Stress testing can provide information about functional capacity and hemodynamic response to exercise. Diagnostic angiography allows the verification of the severity of the AR and helps in the assessment of the aortic root size, cavity size, and the presence or absence of CAD.

The surgical treatment of AR is indicated in symptomatic patients with dyspnea, angina, or CHF (Bonow, 2000). Asymptomatic patients should undergo surgery if the LVEF is 50% or less, LV end-systolic dimension approaches 5.5 cm, or there is an LV end-diastolic dimension of more than 75 mm. Patients also should be advised on prophylaxis against infective endocarditis (Dajani et al., 1997) (see Table 27-19). Patients with moderate to severe AR should avoid competitive sports, heavy workloads, and weight lifting. Patients with severe AR do not benefit from chronic long-acting vasodilators such as nifedipine XL or enalapril (Evangelista et al., 2005). After valve replacement for AR, the use of β -blockers may improve cardiac performance (Matsuyama et al., 2000).

Patients with AR may have a dilated ascending aortic root. Patients with bicuspid aortic valve and (1) ascending aortic root size of larger than 5 cm or (2) increasing aortic root size of more than 0.5 cm per year need to be considered for ascending aortic root repair. Also, if patients with

bicuspid aortic valve need to undergo aortic valve repair for severe AS or AR, an ascending root of larger than 4.5 cm should be corrected at the same time (Bonow et al., 2008).

KEY TREATMENT

- Vasodilator therapy is indicated in patients with symptomatic severe aortic insufficiency when surgery is not an option (SOR: A, ACC/AHA 2008 guidelines).
- Aortic valve replacement is recommended for severe symptomatic aortic valve insufficiency irrespective of LV function (SOR: A, ACC/AHA 2008 guidelines).
- Aortic valve replacement is recommended in asymptomatic patients with chronic severe aortic insufficiency and LV systolic dysfunction and in patients undergoing bypass surgery or aortic surgery (SOR: A, ACC/AHA 2008 guidelines).

MITRAL STENOSIS

Key Points

- Echocardiography should be performed in patients with mitral stenosis (MS) to assess hemodynamic severity, concomitant valvular lesion, and assessment of valvular morphology (SOR: A, ACC/AHA 2008 guidelines).
- Echocardiography should be performed in patients with MS and prior embolic event (SOR: A, ACC/AHA 2008 guidelines).

Mitral stenosis is defined as the reduced ability of blood to move from the left atrium to the LV in diastole. It is mostly caused by dysfunction in the mitral valve, which lacks the ability to open its leaflets in diastole. MS (Figure 27-18) is predominantly caused by rheumatic carditis and is more prevalent in females (Bonow et al., 1998). Acute rheumatic carditis leads to valvular disease in approximately 50% of affected patients. The mitral valve is the most commonly affected by rheumatic heart disease, followed by the aortic

valve, and then combined aortic and mitral valves. MS is considered severe if the valve area is less than 1 cm² (normal mitral valve area is 4 to 6 cm²). A valve area of 1.5 cm² or smaller associated with severe dyspnea (class III or IV New York Heart Association [NYHA] class C) or severe pulmonary HTN (pulmonary pressure of >50 mm Hg at rest and ≥60 mm Hg with exercise) is also considered clinically significant and warrants therapy.

The main symptom of MS is slowly progressive dyspnea and fatigue. In advanced MS, left atrial pressure and a redistribution of blood to the chest occurs. Patients might complain of orthopnea and paroxysmal nocturnal dyspnea. Pulmonary HTN can become severe, and right-sided ventricular failure can then lead to dependent edema, hepatomegaly, and right upper quadrant pain. An increase in left atrial size can lead to palpitations secondary to AF as well as subsequent cardioembolic strokes if not recognized in a timely fashion.

Most auscultatory signs of MS are missed if not performed in the left lateral decubitus position. Typically, the first heart sound, S₁, is accentuated. A low-pitched diastolic rumble, heard with the bell of the stethoscope over the apex, is also present. The high-pitched *opening snap* (OS), caused by the abrupt stopping of the domed mitral valve into the LV, is also appreciated in most patients midway between the left sternal border and apex. A shorter A₂–OS distance indicates a more severe MS. Signs of pulmonary HTN such as a loud P₂ and right ventricular hypertrophy (RVH) can also be present as MS becomes more severe.

The ECG findings in MS might show a biphasic P wave in V₁, a large P wave in lead II, and possibly AF. Chest radiography could show evidence of an enlarged left atrium and an increase in pulmonary congestion with interstitial edema. An echocardiogram can accurately diagnose MS and assess valvular and subvalvular structure and valve area (Rahimtoola et al., 2002). In addition, an echocardiogram can help distinguish the cause of MS, whether it is valvular or from different causes such as tumors, vegetations, extreme calcification of the annulus, left atrial myxoma, cor triatriatum, or presence of a large thrombus. An echocardiogram can also help estimate pulmonary pressures and assess for right-sided enlargement. Typically, LV function is preserved in MS. In addition, echocardiography can help in calculating a mitral valve score that takes into account leaflet mobility, thickening, valve calcification, and distortion of the subvalvular apparatus. The interventional cardiologist typically uses the valve score to determine the feasibility of balloon valvuloplasty. A score of less than 8 generally indicates a good prognosis from mitral valvuloplasty. Furthermore, because a transthoracic echocardiogram is not well suited to see the left atrial appendage, a transesophageal echocardiogram becomes necessary to rule out the presence of an atrial thrombus before valvuloplasty because this can be a significant risk factor for an embolic stroke. Finally, a left and right heart catheterization remains the best modality to assess mitral valve severity and full hemodynamics and determine coronary anatomy before contemplated corrective surgery.

Treatment of Mitral Stenosis

All patients with rheumatic mitral valve disease require bacterial endocarditis prophylaxis before dental, genitourinary,

Figure 27-19 Left atrial appendage thrombus seen on transesophageal echocardiography.

or GI procedures. Increasing diastolic filling time is important in the treatment of moderate to severe MS. Therefore, drugs such as β -blockers or verapamil might be used. Maintaining sinus rhythm can also reduce symptoms as loss of atrial contraction reduces ventricular emptying. Patients with AF need to be aggressively treated with rate control and anticoagulation with warfarin to reduce embolic strokes. Chemoverversion (with amiodarone or other antiarrhythmics) or cardioversion can be performed after the patient has been anticoagulated for at least 3 or 4 weeks before the procedure. Anticoagulation should be maintained after the procedure for a minimum of 1 month. Generally, anticoagulation is maintained long term because the recurrence of AF can be unpredictable. Transesophageal echocardiography can be performed before cardioversion to rule out the presence of a left atrial thrombus (Figure 27-19). Even when a thrombus is excluded, patients need to be heparinized for at least 48 to 72 hours before cardioversion then maintained on warfarin afterwards. The target international normalized ratio (INR) in patients with AF needs to be 2.0 to 3.0.

Patients with moderate to severe symptoms (NYHA class II to IV) or asymptomatic patients with severe MS (valve area <1.5 cm²) and pulmonary HTN (pulmonary pressure >50 mm Hg at rest and ≥60 mm Hg with exercise) require percutaneous valvuloplasty, mitral valve repair, or mitral valve replacement.

Balloon valvuloplasty leads to commissural separation as the main mechanism that leads to an improvement in valvular function. Mitral valvuloplasty is currently the preferred method of treating severe MS when no contraindications exist (Table 27-20). The procedure carries an exceedingly low risk of death, with an acute success rate greater than 95% and very good long-term results similar to results for surgical commissurotomy (Rahimtoola et al., 2002). Patients who are qualified for valvuloplasty (favorable valve score) can undergo valve repair if balloon valvuloplasty is not available or left atrial thrombus persists despite anticoagulation. Mitral valve surgery is reserved for those patients with a calcified valve and a high valve score

Table 27-20 Common Contraindications for Mitral Balloon Valvuloplasty

Presence of left atrial thrombus seen on transesophageal echocardiography
Associated severe mitral regurgitation
Associated coronary artery disease that requires bypass surgery
A high valve score as determined by echocardiography (unfavorable valve morphology)
Associated other valvular pathology or aortic pathology that will require surgical interventions
Difficulty in obtaining access

on echocardiography who are essentially excluded from balloon valvuloplasty.

KEY TREATMENT

- Percutaneous mitral balloon valvotomy is effective for symptomatic patients with moderate to severe MS and favorable valve morphology when no left atrial thrombus or moderate to severe MR is present (SOR: A, ACC/AHA 2008 guidelines).
- Mitral valve surgery is indicated in patients with moderate to severe MS when mitral balloon valvotomy is not available or not feasible or in patients with concomitant moderate to severe mitral insufficiency (SOR: A, ACC/AHA 2008 guidelines).

MITRAL REGURGITATION**Key Points**

- Echocardiography is indicated in symptomatic patients with suspected MR (SOR: A, ACC/AHA 2008 guidelines).
- Echocardiography is indicated annually or semiannually in asymptomatic patients with severe mitral insufficiency to assess LV cavity size and EF (SOR: A, ACC/AHA 2008 guidelines).
- Transesophageal echocardiography is indicated to evaluate the mitral valve apparatus before surgery to determine the feasibility of repair or replacement (SOR: A, ACC/AHA 2008 guidelines).
- In patients with suspected CAD and severe MR, coronary angiography is indicated before surgery (SOR: A, ACC/AHA 2008 guidelines).

Mitral regurgitation is defined as an abnormal blood flow into the left atrium in systole as a result of an abnormal closing of the mitral valve. In chronic mitral insufficiency, the LVEF and cavity size may remain preserved for several years. However, LV remodeling eventually occurs, cavity size begins to dilate, EF becomes reduced, and patients enter a decompensated state. In acute MR, the left atrium and LV have no chance for gradual dilation and, therefore, a sudden rise in LV and pulmonary venous pressure occurs, leading to pulmonary edema.

Chronic MR is generally asymptomatic or associated with minimal symptoms of dyspnea or generalized fatigue. When

Figure 27-20 Left ventriculogram in the right anterior oblique projection showing severe mitral insufficiency.

LV function declines severely, patients can become symptomatic, with symptoms and signs of HF. Patients might provide a history of rheumatic fever, endocarditis, CAD, or CHF. Acute MR needs to be in the differential diagnosis of a patient with a sudden onset of pulmonary edema.

On examination, patients display a systolic murmur, most often holosystolic, high pitched, and present at the apex with radiation to the axilla, left scapula, midback, or left sternal border, depending on the direction of the regurgitant jet. A midsystolic click is often heard if associated mitral valve prolapse (MVP) is seen. Occasionally, a low-pitched diastolic rumble and an S3 sound can be heard.

The ECG often displays an enlarged left atrium (biphasic P wave in V1), large QRS complex secondary to LV enlargement, and possible AF, and, in ischemic MR, evidence of old or acute inferior infarcts can be seen. The chest radiograph may show an enlarged cardiac silhouette, a calcified mitral valve, or increased pulmonary vascular congestion. Echocardiography provides the diagnosis by assessing the presence of the MR; its severity; and its cause, such as severe prolapse, endocarditis, calcification, papillary muscle or chordae rupture, or a degenerative valve. Regurgitant volume (30-59 mL is moderate; ≥ 60 mL is severe) and effective regurgitant orifice (20-39 mm² is moderate; ≥ 40 mm² is severe) can be calculated. Left and right heart catheterization is indicated before corrective surgery to determine the presence of CAD and confirm the diagnosis of MR with the use of left ventriculography. MR is graded based on the amount of contrast seen in the left atrium in systole: grade I, contrast does not opacify entire left atrium; grade II, contrast opacifies all left atrium but less dense than the contrast in the LV; grade III, contrast equally opacifies left atrium and LV; grade IV, contrast in the left atrium is darker than the LV with opacification of pulmonary veins (Figure 27-20). Also, the angiogram can quantitatively determine

the regurgitant fraction (RF). RF greater than 50% generally indicates severe MR that requires corrective surgery.

Treatment of Mitral Regurgitation

Patients with a history of mitral insufficiency need to have bacterial endocarditis prophylaxis. Those with chronic MR benefit from long-term afterload reduction, although this remains controversial. Aggressive treatment of AF with rate control and warfarin anticoagulation is needed. Patients with moderate to severe MR need to be closely monitored for EF and LV cavity size. A lower threshold for surgical intervention is generally agreed upon when compared with AR. Symptomatic patients (NYHA class II-IV) or asymptomatic patients with a LV end-systolic dimension approaching 4.0 cm or LVEF of 60% or less should undergo intervention. Patients with lower EF and a bigger cavity size carry a poorer outcome after surgery. However, those with an EF of 30% to 50% and a LV cavity size in systole between 50 mm and 55 mm may also benefit from surgery. Asymptomatic patients with preserved LV function and cavity size but with AF might benefit from surgery.

Patients with acute MR should be treated aggressively with afterload reduction such as sodium nitroprusside. These patients generally require immediate surgery but do best if they can be initially treated medically and enter a compensated state before surgery. Most regurgitant mitral valves can now be repaired instead of replaced. Techniques for percutaneous repair of the mitral valve are now being tested and hold significant promise.

MITRAL VALVE PROLAPSE

Mitral valve prolapse is described as bulging of one or more of the mitral leaflets into the left atrium in systole (see [Figure 27-20](#)). Although it is a common cause of significant MR ([Cheng and Barlow, 1989](#)), it can be isolated without valvular insufficiency. MVP carries a benign course ([Freed et al., 2002](#)). In rare occasions, it can be associated with significant arrhythmias and sudden cardiac death. When associated with MR, patients need to be carefully monitored for progressive left atrial and LV cavity dilation and AF.

Primary MVP might be familial and is inherited as an autosomal dominant trait with different rate of penetrance and commonly found in patients with connective tissue disease, cardiomyopathies, and Marfan syndrome ([Pyeritz and Wappel, 1983](#)). Secondary MVP is generally seen in patients with CAD and rheumatic heart disease.

Patients with MVP are often asymptomatic. However, some patients describe palpitations, chest pain, dyspnea, and fatigue with or without MR. Although previously thought that strokes occur more frequently in patients with MVP, recent data do not support this conclusion ([Gilon et al., 1999](#)). Panic attacks have been frequently described. A high-pitched midsystolic click is often heard that occurs shortly after the first heart sound and can be associated with a systolic murmur. Baseline ECG is quite often unrevealing, and routine stress testing carries a high false-positive rate. Stress imaging is more accurate in evaluating these patients for myocardial ischemia. An echocardiogram is the most helpful methodology for making the diagnosis of MVP. A displacement of the leaflets beyond the mitral

annulus on a parasternal short-axis view is strongly suggestive of MVP. Cardiac catheterization is generally not needed for diagnostic purposes.

Asymptomatic patients with MVP generally do not require treatment unless they have severe associated MR ([Devereux et al., 1989](#)). Symptomatic patients with MVP can be treated with β -blockers. Flail mitral leaflets caused by chordae rupture or severe MR associated with MVP needs to be followed, and mitral valve repair becomes indicated if patients develop symptoms of dyspnea (NYHA class III or IV), the EF and cavity size become adversely affected, or AF appears.

TRICUSPID VALVE DISEASE

Tricuspid regurgitation (TR) is commonly present on echocardiography in the majority of patients and therefore, when mild, is considered a normal variant. Severe TR can occur, however, and can create significant symptoms of right-sided CHF (cor pulmonale) and dyspnea. Isolated TR is commonly seen in drug addicts secondary to tricuspid valve endocarditis but can also be caused by carcinoid syndrome, trauma, RV infarction, and certain congenital anomalies. The most common etiology of TR is, however, annular dilation caused by RV cavity dilation.

Patients with TR present with various symptoms depending on the etiology of the valvular abnormalities. Typically, dyspnea, right- and left-sided failure, and in the case of endocarditis, fever and night sweats can be present. The RV is generally dilated, and a precordial lift is present. The jugular veins are pulsatile and increased. A systolic murmur is generally heard along the left sternal border that increases with respiration.

Patients with severe TR are treated with diuretics and digitalis to treat the associated right-sided failure. ACE inhibitors are indicated if LV dysfunction is present. It is recommended that tricuspid valve replacement or repair be performed if severe TR is present and the patient is undergoing simultaneous mitral valve surgery or if severe TR is present as a primary disorder in a symptomatic patient.

Tricuspid valve stenosis (TS) is mostly caused by rheumatic heart disease and is typically associated with other valvular involvement. TS can also be caused by the carcinoid syndrome (most commonly causes TR) and certain connective tissue diseases. Secondary causes of TS such as tumors or thrombi can also precipitate secondary TS.

In TS, patients can be dyspneic with activity. Typically, there is an increase in the jugular vein, with a large a wave indicating atrial contraction against a stiff tricuspid valve. TS is typically treated with percutaneous valvular commissurotomy unless it is unfeasible. Open commissurotomy is then performed, or valve replacement is then performed if the leaflets and subvalvular structures are not repairable. Bioprosthetic valves are typically used, and patients are generally prescribed warfarin after tricuspid valve replacement.

PULMONIC VALVE DISEASE

Pulmonary valve regurgitation (PR) is typically acquired because of increased pulmonic pressures (pulmonary HTN). Primary valve abnormalities caused by endocarditis can

also cause PR. PR due to pulmonary HTN causes a diastolic murmur along the left sternal border (Graham Steel murmur). Surgery on acquired PR is rarely performed.

Pulmonic valve stenosis (PS) is mostly congenital, but secondary causes such as tumors, endocarditis, or carcinoma can also cause PS. PS is best treated with percutaneous valvuloplasty with good long-term results.

ENDOCARDITIS

Endocarditis is defined as an oscillating intracardiac mass without alternate anatomic classification, the presence of an abscess, or dehiscence of a new prosthetic valve (Durack et al., 1994). Endocarditis is treated with a prolonged course of IV antibiotics. Surgical management can be considered in patients who develop HF or LV dysfunction, damage to the valve annulus with an abscess or perforation of the leaflet, or isolating a resistant organism to antibiotics after 1 week of treatment. Large vegetations, particularly those that are increasing in size and recurrent emboli, are to be considered as indications for valve surgery. Prophylaxis for endocarditis is now limited to patients with prosthetic valves or rings, a history of prior endocarditis, congenital heart disease, or transplant with valvular heart disease.

PROSTHETIC VALVES

Echocardiography (transthoracic, transesophageal, or both) is indicated to evaluate stenotic or regurgitant prosthetic valves. Prosthetic valves are associated with several complications, including infective endocarditis, a paravalvular leak, thrombosis and embolization, pannus formation, and hemolytic anemia.

Prosthetic valve thrombosis requires surgery if it is a left-sided valve and is associated with advanced HF (class III and IV NYHA) and there is large clot burden. Lytic treatment for these valves is not recommended because of the associated high stroke risk. On the other hand, lysis can be considered for right-sided valve thrombosis when a large thrombus burden or advanced HF is present (Bonow et al., 2008).

Heart Failure

Heart failure is a clinical syndrome resulting from the inability of the heart to meet the metabolic requirements of the body at normal filling pressures. Although HF can be precipitated by LV systolic dysfunction, it can also be secondary to diastolic dysfunction. HF with preserved EF (HFpEF) is nearly equally common to HF with reduced EF (HFrEF). HFpEF is characterized with EF more than 45% to 50% and impaired LV filling or relaxation. HFrEF is characterized with EF less than 45% to 50% with reduced LV contraction. Fluid retention and pulmonary congestion are hallmarks of HF but are not universally present. In fact, patients may describe dyspnea and a reduction in exercise capacity with no fluid overload. Because pulmonary congestion may be absent in HF patients, the term *heart failure* is preferred over *congestive heart failure*.

Heart failure is highly prevalent in the United States. More than 650,000 new cases are diagnosed annually. Also, the mortality rate remains very high, with more than

300,000 people dying every year from this syndrome (Hunt et al., 2001). The mortality rate from HF remains at about 50% within 5 years of diagnosis. Hospitalization for HF in the United States is rising in both men and women at a prohibitively high cost to the health care system (O'Connell and Bristow, 1993). One-month rehospitalization after discharge has remained at about 25%. HF costs have reached \$39.2 billion in 2010 (Roger et al., 2012). It is important for family physicians to understand the pathophysiology of HF and apply known effective therapies.

PATHOPHYSIOLOGY OF HEART FAILURE

The hemodynamic model of HF has been largely abandoned and replaced by the concept of LV remodeling (Francis, 1998; Francis, 2001). Remodeling of the LV indicates stretching and dilation with subsequent reduction in LV function. The remodeling process can be triggered by a multitude of potential injuries (Kannel et al., 1994; Levy et al., 1996), including CAD, MI, HTN, valvular heart disease, diabetes, congenital heart defects, anemia, and alcoholism. Remodeling is a reversible process with appropriate therapy.

Irrespective of the precipitating injury, neurohormonal mechanisms are activated and promote the remodeling process. These include the renin-angiotensin-aldosterone (RAAS) system and the sympathetic nervous system (SNS). A rise in endothelin-1 production, a product of dysfunctional endothelium, also occurs and contributes to vasoconstriction. In addition, inflammatory markers and cytokines are increased, thereby further exacerbating endothelial dysfunction (Blum and Miller, 2001; Francis, 1998). At the cellular level, MMPs and tissue inhibitors of MMP are increased, leading to cardiac fibrosis and collagen deposition. Also, alterations in calcium fluxes, β -adrenergic receptors, and cardiac metabolism with dependence on glycolysis instead of oxidation of FFAs occur (Braunwald et al., 1976).

Pharmacologic interventions that block neurohormonal activation can reduce mortality and morbidity in patients with HF (Figure 27-21). A rise in angiotensin II (AII) promotes cardiac myocyte programmed cell death (apoptosis), hypertrophy, and ventricular fibrosis. AII also causes an increase in aldosterone secretion (Figure 27-22), which in return augments the harmful effects of AII on the myocardium and promotes adverse remodeling. Aldosterone, however, "escapes" angiotensin suppression (McKelvie et al., 1999); therefore, selective aldosterone blockade is needed in addition to therapy with ACE inhibitors or ARBs (Pitt et al., 1999, 2001). A rise in circulating levels of catecholamines in response to SNS activation can lead to the suppression of adrenergic receptors (Bristow, 1993) and has direct toxic effects (Mann et al., 1992) on the myocardium. Catecholamines mediate toxicity as a result of β -adrenoceptor-mediated cyclic adenosine monophosphate-dependent calcium overload of cardiac myocytes (Mann, 1998). Also, catecholamines increase myocardial oxygen consumption and coronary blood flow requirements and decrease myocardial mechanical efficiency (Nikolaidis et al., 2004). Catecholamines also induce LVH and can precipitate potentially debilitating and fatal arrhythmias.

Inappropriate high cardiac output (>4 L/min/m²) can precipitate HF. Causes include hyperthyroidism, Paget

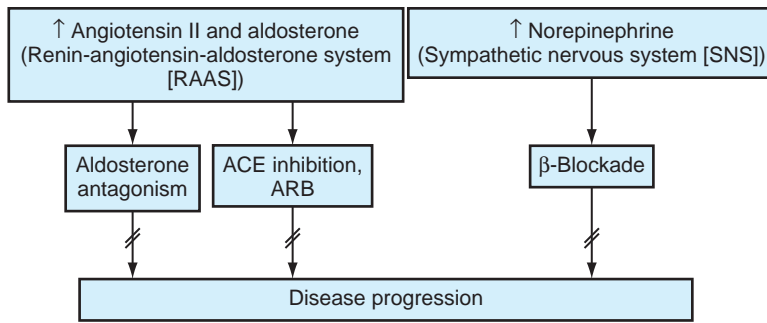

Figure 27-21 The renin–angiotensin–aldosterone system and the sympathetic nervous system are currently the target for treating patients with congestive heart failure. ACE, Angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

disease, thiamine deficiency (beriberi), anemia, multiple myeloma, and arteriovenous malformations.

ACC/AHA CLASSIFICATION OF CONGESTIVE HEART FAILURE

A relatively new classification for HF was proposed by the ACC/AHA (Hunt et al., 2001), which takes into account the risk factors for developing HF in addition to the presence of LV dysfunction and symptoms. This classification complements the NYHA classification and takes into account recent advances in pharmacologic and nonpharmacologic approaches to evaluate and treat the HF patient (Ahmed, 2003). Four stages have been proposed:

Stage A describes patients who are at risk of HF but are asymptomatic and have no LV dysfunction. More than 60 million people fall into this category and include those with IHD, HTN, DM, and a family history of cardiomyopathy. Stage A is an additional classification that was not present in the prior NYHA class.

Stage B describes patients with LV dysfunction but who are asymptomatic. This is equivalent to class I of the NYHA classification. This includes about 10 million people in the United States.

Stage C describes patients with LV dysfunction who are symptomatic with exertion. This is equivalent to the NYHA class II and III. This includes about 5 million people in the United States.

Stage D describes patients with symptoms at rest. This is equivalent to class IV of the NYHA classification. This includes about 200,000 people in the United States.

This classification reliably allows the physician to follow patients as their HF progresses from one stage to the next and offers a unique set of treatments appropriate to each stage. Patients with advanced class III and IV HF are now further classified into seven different profiles using the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database (Stevenson et al., 2009). INTERMACS was developed in a joint effort by the National Heart Lung and Blood Institute, Centers for Medicare and Medicaid Services, FDA, clinicians, scientists, and industry representatives for the purposes of following patients receiving mechanical circulatory support device therapy. Patients presenting with very advanced HF symptoms INTERMACS 1 to 3 (on IV inotropes whether stable or not) have a poorer survival outcome compared with those with INTERMACS 4 and 5 (on oral therapy at home or with symptoms with minimal activity) after mechanical assist device implantation or transplantation, likely reflecting a more advanced degree of end-organ damage in these patients.

EVALUATION OF PATIENTS WITH CONGESTIVE HEART FAILURE

Patients with symptoms and signs of HF need to have ECG, chest radiography, and, when available, natriuretic peptides. Abnormalities seen on these tests should trigger a structural heart evaluation with echocardiography. If LV dysfunction is documented, testing for the etiology and initiating treatment are indicated (Swedberg et al., 2005). Patients with HF (Hunt et al., 2001) need to have a complete history and physical examination with a focus on cardiovascular risk factors that lead to progression of failure. A careful documentation of their NYHA stage, history of hospitalizations, medications, and a full review of systems is indicated. A comprehensive physical examination should also include volume status and weight. Diagnostic tests should include a complete blood count; serum electrolytes; kidney and liver functions; urinalysis; blood glucose; thyroid function test; iron saturation test and ferritin; sedimentation rate; antinuclear antibodies to rule out connective tissue disease; sleep apnea testing (if suspected); 12-lead ECG; an echocardiogram; and coronary angiography,

particularly in those with significant reduction in LV function and a suspicion of obstructive CAD.

Routine myocardial biopsy and Holter monitoring are not recommended. Biopsy is recommended, however, in patients with new-onset HF (<2 weeks) with (1) a normal-sized or dilated LV and hemodynamic compromise, (2) new-onset HF (2 weeks to 3 months) with dilated LV and new ventricular arrhythmias, or (3) heart block or failure to respond to therapy (Cooper et al., 2007). Levels of catecholamines might be obtained if clinically indicated in patients with severe episodic HTN and tachycardia. MRI can be considered if available to evaluate for infiltrative disease or scar. The rapid development of HF with reduced LV function in the absence of a clear etiology should raise suspicion of a viral cardiomyopathy, especially in younger patients. This can be suspected if the patient had a recent viral syndrome over the past several weeks followed by a progression of dyspnea and HF. Therapy for viral cardiomyopathy and HF consists of supportive therapy and the use of β -blockers, diuretics, ACE inhibitors, and, if failure is advanced (class III and IV), administration of spironolactone. Patients with fulminant myocarditis with hemodynamic instability may require support with a mechanical assist device.

RISK FACTOR MODIFICATION

Patients with HF should have their cardiovascular risk factors modified aggressively. HTN is strongly linked to the development of HF and should be aggressively treated (Vasan and Levy, 1996). The target BP should be 130/85 mm Hg or less except in patients with diabetes in whom the target is lowered to 125/85 mm Hg or less.

Control of dyslipidemia and diabetes is also very important in the management of patients with HF. Screening for sleep apnea and thyroid disease and aggressively treating these conditions if present needs to be done. The avoidance of alcohol, illicit drugs, and smoking is strongly advised. Losing weight and establishing a routine exercise program are also important preventive measures. Patients with a history of heart palpitations need to be evaluated for tachycardia because this is a well-established risk factor for cardiomyopathy and HF. If patients have daily palpitations, then a 24-hour Holter monitor is sufficient to help establish the type of arrhythmia. On the other hand, if palpitations occur infrequently (a few times per month), then an event care monitor is more useful because patients can keep this type of monitor with them at home for a longer time and record the arrhythmia as it occurs. Newer monitors have the ability to be autotriggered when arrhythmias are detected and can be useful in some asymptomatic patients. If palpitations are very infrequent, it is unlikely that they contribute to tachycardia-induced cardiomyopathy, but their diagnosis can be made with an implantable loop recorder, typically done by an electrophysiologist.

PHARMACOLOGIC THERAPY OF CONGESTIVE HEART FAILURE

Diastolic Dysfunction

Diastolic dysfunction is typically diagnosed by echocardiography. It is characterized by normal LV systolic function but

impaired relaxation. Conditions that increase LV stiffness include CAD, HTN, diabetes, valvular heart disease, and age (Ewy, 2004).

Currently, the term *HF with preserved LVEF (HFpEF)* is used for patients with symptoms of HF in the setting of normal LV systolic function. These patients are typically treated with aggressive BP control and with the use of diuretics, β -blockade, or nondihydropyridine CCBs (diltiazem or verapamil). ACE inhibitors or ARBs can have long-term value in reducing LVH and, theoretically, may improve LV compliance (Mandinov et al., 2000).

Left Ventricular Systolic Dysfunction. Patients with *asymptomatic* LV dysfunction (stage B, ACC/AHA classification) benefit significantly from ACE inhibitors and β -blockade. The correction of anatomic abnormalities that are linked to LV systolic dysfunction, including severe mitral or aortic insufficiency and AS, is also important. Periodic follow-up of these patients is indicated with serial assessment of LV function using echocardiography or isotope ventriculography. Patients with familial LV systolic dysfunction need to have their immediate family members screened for asymptomatic cardiomyopathy.

Symptomatic LV systolic dysfunction (stage C, ACC/AHA classification) requires intensive pharmacologic treatment and close follow-up. Echocardiography or isotope ventriculography (IVG) are typically done to monitor LVEF over time when new symptoms or changes in therapy have been introduced. An IVG provides a more accurate assessment of EF (within $\pm 3\%$ variability in reading) than an echocardiogram but is more expensive and subjects the patient to radiation exposure. Whether an echocardiogram or an IVG is ordered depends on the patient's clinical presentation and history and the management approach of the treating physician. Diuretics are important in patients with hypervolemia, and digoxin improves symptoms in patients with clinical evidence of systolic HF in the setting of severely reduced LV function. There are no data, however, to support that diuretics or digoxin alter a patient's long-term survival. Current therapies known to impact a person's mortality are summarized below (Cohn, 1996; Hunt et al., 2001; Packer et al., 1999). Drugs and their dosages in treating patients with HF are summarized in Table 27-21.

Although there is no one way to start pharmacologic therapy for HF patients, it is advisable that patients be started on a small dose of β -blockers, ACE inhibitor, or both. Diuretics are generally reserved for patients with fluid overload. Caution needs to be exerted when a diuretic and an ACE inhibitor are started simultaneously because hypotension could occur, and serum creatinine levels can rise markedly. β -blockers (Hori et al., 2004) and ACE inhibitors (Majumdar et al., 2004) need to be titrated to the maximum tolerated dose to achieve maximal therapeutic efficacy.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors reduce the mortality rate by an absolute 4% and relative 15% to 20% in patients with LV systolic dysfunction (EF <40%). In addition, ACE inhibitors reduce the combined end point of morbidity (HF hospitalizations) and mortality by 30% to 35%. Despite the benefits of ACE inhibitors (Wong et al., 2004), the mortality rate from HF remains at 50% within 5 years

Table 27-21 Selected Drugs and Their Dosages Currently Used in the Treatment of Congestive Heart Failure

Drug	Dosage
ANGIOTENSIN-CONVERTING ENZYME INHIBITORS	
Enalapril	2.5-20 mg PO BID; maximum, 40 mg/day; start at 2.5 mg QD
Captopril	12.5-50 mg PO TID; maximum, 150 mg/day; start at 6.25-12.5 mg PO TID
Ramipril	5 mg PO BID; maximum, 10 mg/day; start at 2.5 mg PO BID
Lisinopril	5-20 mg PO QD; maximum, 40 mg/day; start at 2.5 to 5 mg PO QD
Perindopril	4-16 mg PO QD; maximum, 16 mg/day; start at 2 mg PO QD
Monopril	10-40 mg PO QD/BID; maximum, 80 mg/day; start at 10 mg PO QD
ANGIOTENSIN RECEPTOR BLOCKERS (FOR ACE INHIBITOR-INTOLERANT PATIENTS)	
Losartan	25-100 mg PO QD; maximum, 100 mg/day; start at 25-50 mg PO QD*
Candesartan	8-32 mg PO QD; maximum, 32 mg/day; start at 16 mg PO QD*
Valsartan	40-160 mg PO BID; maximum, 320 mg/day; start at 40 mg PO BID
Irbesartan	75-300 mg PO QD; maximum, 300 mg/day; start at 75 mg PO QD*
β-BLOCKERS	
Carvedilol	3.125-25 mg PO BID; maximum, 50 mg PO QD; start at 3.125 mg PO BID
Metoprolol succinate	12.5-200 mg PO QD; maximum, 200 mg/day; start at 12.5 mg PO QD
Metoprolol	12.5-100 mg PO BID; maximum, 100 mg PO BID; start at 12.5 mg PO BID*
ALDOSTERONE ANTAGONISTS	
Spironolactone	12.5-25 mg PO BID; maximum, 50 mg/day; start at 12.5 mg PO BID
Eplerenone	50 mg PO QD; maximum, 50 mg/day; start at 25 mg PO QD†

*Off-label use.

†For heart failure patients after myocardial infarction.

ACE, Angiotensin-converting enzyme; BID, twice a day; PO, oral; QD, once a day; TID, three times a day.

of the diagnosis, and 30% of patients are rehospitalized within 3 months.

Several trials have noted a mortality reduction with ACE inhibitors in patients with clinical evidence of HF after sustaining an MI (*Acute Infarction Ramipril Efficacy Study [AIRE] Study Investigators, 1999; Kober et al., 1995*). The AIRE showed a 27% ($P = 0.002$) reduction in the 30-month cumulative mortality rate with ramipril over placebo in post-MI HF patients. Furthermore,trandolapril reduced the mortality rate by 22% ($P = 0.01$) in patients with reduced LV function after an MI (*Kober et al., 1995*). Guidelines also emphasize the use of ACE inhibitors in patients with asymptomatic LV dysfunction and a history of MI. These patients are at high risk of developing LV remodeling and CHF several months after the initial insult (*Jessup and Brozena, 2003*).

Angiotensin Receptor Blockers

Early studies comparing ARBs and ACE inhibitors in the management of HF patients suggested that an ARB was as safe, effective, and tolerable as an ACE inhibitor. In the Randomized Evaluation of Strategies for Left Ventricular Dysfunction (RESOLVD) pilot study (*McKelvie et al., 1999*), 768 patients in NYHA classes II to IV and EF less than 40% received candesartan, candesartan plus enalapril, or enalapril alone for 43 weeks. LV cavity size increased less and BNP levels decreased more with combination therapy compared with an ARB or ACE inhibitor alone. In the Losartan Heart Failure Survival Study ELITE II (*Pitt et al., 2000*), 3152 patients age 60 years or older with NYHA class II to IV and EF of less than 40% were randomly assigned to losartan ($n = 1578$) titrated to 50 mg once daily or captopril ($n = 1574$) titrated to 50 mg three times daily. There were no differences in all-cause mortality or sudden death between the two groups. In a subset of the Val-HeFT (Valsartan in Heart Failure Trial) trial of patients intolerant to ACE inhibitors, valsartan (titrated to 160 mg twice daily) reduced both all-cause mortality and combined mortality and morbidity compared with placebo (17.3% vs. 27.1%, $P = 0.017$ and 24.9% vs. 42.5%, $P < 0.001$, respectively) (*Maggioni et al., 2002*). In this trial, adding an ARB (Valsartan) to an ACE inhibitor in HF patients with EF below 40% did not reduce mortality further, but the combined end point of mortality and morbidity was reduced by about 27.5%, mostly because of a reduction in HF hospitalizations (*Cohn et al., 2001*).

In the Candesartan in Heart Failure Assessment of Reduction in Mortality and morbidity (CHARM) study, candesartan (titrated to 32 mg once daily) significantly reduced cardiovascular deaths and hospital admissions for HF (*Pfeffer et al., 2003*). In the “overall programme” of this study, which included both preserved and reduced LV function, total mortality was not reduced compared with placebo. However, in a subset analysis, in patients with symptomatic HF and reduced LV function (<40%), candesartan significantly reduced all-cause mortality, cardiovascular death, and HF hospitalizations when added to standard therapies, including ACE inhibitor, β-blockers, and aldosterone antagonists (*Young et al., 2004*). These patients should have their BP, creatinine, and serum potassium carefully monitored. The Valsartan in Acute Myocardial Infarction Trial (VALIANT) randomized patients 0.5 to 10 days after an acute MI with reduced LV function to valsartan (4909 patients) titrated to 160 mg twice a day, valsartan (80 mg twice a day) plus captopril (50 mg three times a day) (4885 patients), or captopril (4909 patients) titrated to 50 mg three times a day in addition to standard therapy (*Pfeffer et al., 2003*). Valsartan was equally effective to captopril in reducing all-cause mortality. For reasons that remain unclear, combining valsartan with captopril did not improve survival compared with either captopril or valsartan alone but did increase adverse events.

Currently, the recommendation is to use an ACE inhibitor as first-line therapy to treat HF patients. However, a growing body of evidence suggests that an ARB could be as effective as an ACE inhibitor in the treatment of HF patients with reduced LV function.

Aldosterone Blockers

Aldosterone is secreted by the zona glomerulosa of the adrenal gland and is induced by AII, adrenocorticotropic hormone, and potassium. Aldosterone leads to sodium and water absorption and the excretion of potassium. Although AII is a dominant stimulus of aldosterone secretion (Weber, 2001), ACE inhibitors used as monotherapy are not sufficient to therapeutically block aldosterone secretion (McKelvie et al., 1999; Schjoedt et al., 2004). Until recently, the role of aldosterone blockade in the management of patients with HF has been unclear.

Two large trials investigated the role of aldosterone antagonists in HF management. The Randomized Aldactone Evaluation Study (RALES) (Pitt et al., 1999) randomized patients with advanced HF and EF less than 35% to spironolactone 25 mg/day or placebo in addition to standard therapy. After a mean follow-up period of 24 months, spironolactone reduced the mortality rate by 30% caused by a reduction of progression of HF and sudden cardiac death. In addition, patients who received spironolactone had a significant improvement in the symptoms of HF as assessed by the NYHA functional class ($P < 0.001$). Recurrent hospitalization caused by worsening HF was also reduced by 35% ($P < 0.001$). The Eplerenone Post-AMI Heart Failure Efficacy and Survival Study (EPHESUS) (Pitt et al., 2001) randomized patients with HF and an EF less than 40%, 3 to 14 days after MI, to eplerenone (25 mg-50 mg/day) or placebo. At a mean follow-up period of 27 months, eplerenone, a competitive, relatively selective mineralocorticoid receptor antagonist, reduced the total mortality rate by 15% ($P = 0.008$), cardiovascular mortality or cardiovascular hospitalizations by 13% ($P = 0.002$), and sudden cardiac death by 21% ($P = 0.03$). Based on these trials, aldosterone antagonists are now considered to be a primary therapy in patients with LV dysfunction and HF.

β -Blockade in Heart Failure

The activation of the SNS in patients with HF leads to excess catecholamine secretion, which adversely affects the myocardium and contributes to LV remodeling and HF. Multiple β -blockers have been tested in patients with HF. β -Blockers have been shown to reduce the mortality rate by approximately 35% when added to an ACE inhibitor in mild to moderate (MERIT-HF with metoprolol succinate, US Carvedilol trials with carvedilol and CIBIS-II trial with bisoprolol) (CIBIS-II, 1999; MERIT-HF study group, 1999; Packer et al., 1996) or in very advanced HF (Copernicus trial with carvedilol) (Packer et al., 2001). β -Blockers also reduce hospitalizations by 33% to 38% (Fowler et al., 2001; MERIT-HF study group, 1999; Packer et al., 1996) and work synergistically with ACE inhibitor to reduce cardiac remodeling, reduce cavity size, and improve EF (Remme et al., 2004).

There are differences in the antiadrenergic actions of β -adrenergic blocking drugs. The ratio of β_2 - and α_1 -adrenergic receptors in the damaged heart changes compared with normal myocardium (Bristow, 1993). β_1 receptors are reduced, and α_1 receptors are increased with little change in the β_2 receptors. Almost 50% of the adrenergic receptors on the failing myocardium are β_2 and α_1 ,

which are typically not affected by selective β_1 blockade. Norepinephrine is known to exert negative effects through β_1 -, β_2 -, and α_1 -receptors. The theory whether a non-selective β_1 , β_2 , and α_1 blocker yields better mortality reduction than a β_1 blocker alone was recently tested in the Carvedilol Or Metoprolol European Trial (COMET trial) (Poole-Wilson et al., 2003; Torp-Pedersen et al., 2005). In this study, 3029 patients with class II to IV HF were recruited at 317 centers in 15 European countries. At 58 months, there was a 17% reduction in mortality rate with carvedilol compared with metoprolol tartrate ($P = 0.0017$). Despite the controversy about the adequacy of β -blockade and the use of the shorter-acting metoprolol tartrate instead of the long-acting metoprolol succinate in this study, the data seem to favor the theory that the non-selective adrenergic blockade is superior to the selective short-acting β_1 receptor blockade in reducing mortality in HF patients.

Carvedilol (6.25-25 mg twice daily) was shown in The Glycemic Effects in Diabetes Mellitus: Carvedilol-Metoprolol Comparison in Hypertensives (GEMINI) study not to alter glycemic control in patients with diabetes compared with metoprolol tartrate (50-200 mg twice a day). Also, it did improve some components of the metabolic syndrome such as insulin sensitivity (Bakris et al., 2004). Carvedilol appears to be a favorable drug in patients with diabetes, in contrast to other selective β -blockers.

Aggressive titration of β -blockers is needed in patients with HF. Higher levels of β -blockade are associated with better improvement of EF and greater reductions in cardiovascular hospitalizations (Bristow et al., 1996; Hori et al., 2004). A stepwise approach in titration of β -blockade is generally followed with an increase in the dose every 2 weeks as tolerated until achieving the maximum tolerable dose. Current β -blockers approved for treatment of systolic HF in the United States are carvedilol, metoprolol XL, and bisoprolol. β -Blockade should be used in asymptomatic patients with a recent MI regardless of EF. Also, β -blockade should be used in all stable stage C patients unless contraindicated (SOR: A, ACC/AHA guidelines).

Miscellaneous Therapy

In addition to pharmacologic therapy, HF patients should be instructed on dietary salt restriction (2 g/day of sodium), daily weight monitoring (with reporting of 3 lb per week weight increase to their doctors), free water restriction to 1 L daily, smoking cessation, regular exercise, avoidance of alcohol intake, and aggressive treatment of HTN and lipid disorders. Supplemental oxygen is needed in patients with oxygen saturation of less than 92% on room air after ambulation. Finally, sleep apnea has been associated with HF, and these patients need to be screened and aggressively treated for moderate to severe apnea. Patients with symptomatic HF are best treated within an HF clinic that ensures that appropriate therapy is administered by a specialized provider, might increase patients' compliance, and reduces the chance of recurrent hospitalizations. An HF clinic will also ensure that national benchmarks in the management of HF patients are met. These include the optimal use of ACE inhibitor and β -blockers, documentation of LV function, and smoking cessation.

KEY TREATMENT

- Two-dimensional echocardiography with Doppler should be performed during initial evaluation of patients presenting with CHF to assess LVEF, LV size, wall thickness, and valve function (SOR: A) (Hunt et al., 2009).
- Control of systolic and diastolic HTN in accordance with established guidelines is strongly indicated in HF patients (SOR: A, ACC/AHA guidelines).
- ACE inhibitors are recommended in all patients with HF and LV dysfunction unless a contraindication exists (SOR: A, ACC/AHA guidelines).
- ACE inhibitors should be used in all patients with history of MI and reduced LV function (SOR: A, ACC/AHA guidelines).
- Angiotensin receptor blockade can be used in patients who are being treated with digitalis, diuretics, and a β -blocker and who cannot be given an ACE inhibitor because of cough or angioedema (SOR: A, ACC/AHA guidelines).

Myocardial and Pericardial Diseases

CARDIOMYOPATHIES

Key Points

- The following elements of a good history need to be obtained in patients with cardiac dysfunction: family history, duration of illness, weight loss or gain, anorexia, severity and triggers of dyspnea and fatigue, presence of edema, palpitations or difficulty breathing at night, prior hospitalizations, current and past medications, and diet (ACCF/AHA 2013 Heart Failure Guidelines).
- The physical examination needs to focus on BP and heart rate, BMI, recent change in weight, presence of jugular vein distention, orthostatics, extra heart sounds, presence of RV heave, apical displacement, presence of organomegaly or edema, lung auscultation, and peripheral extremity temperature (ACCF/AHA 2013 Heart Failure Guidelines).

Cardiomyopathy is defined as a disorder of the heart muscle and has been classified by the WHO/International Society and Federation of Cardiology into dilated, restrictive, hypertrophic, arrhythmogenic right ventricular (ARVC), and unclassified (Richardson et al., 1996). Cardiomyopathy is a common cause of HF but is not HF. HF is a clinical diagnosis characterized by fatigue and dyspnea in the setting of normal or compromised LV systolic function and may occur with or without pulmonary congestion. A thorough history and examination are important in the initial evaluation of patients with suspected cardiomyopathy.

DILATED CARDIOMYOPATHY

Strictly speaking, cardiomyopathy is a primary disorder of the heart muscle that is not secondary to ischemia, HTN, or

valvular, congenital, or pericardial disease. In this section, both primary and secondary dilated cardiomyopathy (DC) are addressed. DC is characterized by enlargement (increase in both end-systolic and end-diastolic volumes) and weakness of the LV (i.e., remodeling). Multiple risk factors can lead to DC, including the presence of CAD, HTN, connective tissue disease (lupus, scleroderma, juvenile rheumatoid arthritis, dermatomyositis), infiltrative diseases (amyloidosis, sarcoidosis), glycogen storage disease, hemochromatosis, vasculitis, sleep apnea, viral infections, valvular disease, metabolic abnormalities (endocrine, nutritional, electrolytes, obesity), hypersensitivity myocarditis (sulfa, penicillin, methyldopa, tetanus toxoid, hydrochlorothiazide, dobutamine, phenytoin, amphotericin B), tachycardia, anemia, various toxins (including alcohol, doxorubicin, and anthracycline), muscular dystrophies, and peripartum or unknown causes (idiopathic or primary DC). Irrespective of the etiology, the reduction in systolic heart function leads to neurohormonal activation, including activation of the sympathetic and RAAS systems, endothelial dysfunction, inflammation (Pankuweit et al., 2004), endothelin production, vasoconstriction, and sodium and fluid retention. Common cardiomyopathies encountered in a primary care practice are ischemic, valvular, hypertensive, and idiopathic.

Patients with DC have progressive dyspnea, fatigue, and occasional chest pain even in the absence of CAD. They could display signs of both left- and right-sided HF. Arrhythmias are encountered and could be supraventricular, such as AF or atrial flutter (AFL), or ventricular. Patients with AF or AFL need to be anticoagulated with warfarin to reduce risk for thromboembolic events. Electrocardiographic findings are nonspecific. Nondiagnostic ST/T changes, conduction abnormalities, and supraventricular or ventricular arrhythmias can be seen. Echocardiography generally confirms the diagnosis, revealing enlarged and dilated cardiac chambers with a reduced LVEF. Echocardiography can also help define the presence of valvular pathology and rule out the presence of a thrombus in the left-sided chambers of the heart. Isotope ventriculography is used to determine LVEF and therapeutic efficacy. Cardiac catheterization is important in patients in whom there is a suspicion of CAD, intracardiac shunts, or severe valvular abnormalities. Determining the presence of IHD with angiography is important because noninvasive imaging has a lower sensitivity in patients with severe three-vessel CAD or LM disease, conditions known to reduce LV function. Cardiac catheterization is also important in patients in whom cardiac transplantation is contemplated to assess pulmonary pressures and pulmonary vascular resistance and to test whether vasodilators can reduce elevated pulmonary resistance.

Secondary Cardiomyopathies

Ischemic Cardiomyopathy. Ischemic DC is caused by obstructive CAD and a history of MI. A small injury to the myocardium can precipitate remodeling with subsequent weakness in cardiac function. In fact, up to 40% of patients with anterior MI display remodeling within 12 months. Therapy of ischemic CM is the same as described in the CHF section of this chapter and consists mostly of β -blockers, ACE inhibitors or ARBs, and aldosterone antagonists. Digoxin is for symptomatic patients and appears to improve

symptoms but has no effect on mortality. Diuretics are reserved for patients who are fluid overloaded. Revascularization is necessary in patients with ischemic, hibernating myocardium in whom viability can be demonstrated. Viability tests might include rest–redistribution thallium-201 scanning, low-dose dobutamine echocardiography, positron emission tomography, or cardiac MRI.

Hypertensive Cardiomyopathy. Hypertension initially leads to LVH of the myocardium. Eventually, untreated HTN leads to dilation and weakness of the LV and subsequent DC. The initial stage of hypertensive cardiomyopathy is diastolic dysfunction with no LVH followed by diastolic dysfunction and LVH, then CHF with normal LV systolic function, and finally DC with reduced LV systolic function (Iriarte et al., 1995). HTN is a significant risk factor for developing cardiomyopathy and should be aggressively managed (Vasan and Levy, 1996). The presence of LVH on ECG doubles the chance of developing HF. Several mechanisms have been implicated in the development of HF in patients with hypertension, including collagen deposition in the interstitial space impairing the diffusion of oxygen and nutrients to myocytes (Verdecchia, 2000). ACE inhibitors, diuretics, and β -blockers are important therapies for the treatment of hypertensive DC.

Valvular Cardiomyopathy. Mitral insufficiency and aortic insufficiency are the most common valvular abnormalities that precipitate DC. A severe reduction in LV function can occur in mitral insufficiency that remains silent until significant remodeling of the LV occurs. Early diagnosis and mitral valve repair or replacement is particularly important when LV function is still preserved ($\geq 60\%$). The lower the EF, the worse the immediate and long-term surgical results. The mortality rate is excessively high in patients with severely reduced LVEF ($< 25\%$).

Aortic insufficiency is poorly tolerated over time. Surgical repair, however, leads to significant improvement in LV function and symptoms, even with a reduced EF. Surgery needs to be considered, however, if the EF is 55% or less. Aortic valve stenosis leads to LVH and subsequent DC if not treated. MS generally does not affect ventricular function and size. Tricuspid insufficiency and pulmonic insufficiency, if severe, can lead to RV fluid overload and dilation and failure of the right-sided chambers of the heart. A pattern of right HF becomes apparent, including jugular venous distention, pulsatile and enlarged liver, ascites, and lower extremity edema.

Primary Cardiomyopathies

Viral Cardiomyopathy. Viral DNA was found in 67.4% of patients with DC within the genome of myocardial cells (Kuhl et al., 2005). Evidence of prior viral infection in these patients suggests a causal relationship. Viral cardiomyopathy is postulated to be the most common cause of DC.

Familial Dilated Cardiomyopathy. It is estimated that 30% of patients with idiopathic DC have a genetic cause, although familial DC remains clinically underappreciated. Familial DC is an inherited autosomal dominant condition; the symptom onset varies with different families. Obtaining a family history of DC is important in all patients who

present with cardiomyopathy, including a history of unexplained sudden death (Schmidt et al., 1988). The diagnosis is suspected if two or more affected individuals are in the same family or if sudden death has occurred in a first-degree relative before the age of 35 years (Mestroni et al., 1999). The family of patients with suspected familial cardiomyopathy should undergo periodic serial echocardiography at least every 3 to 5 years in conjunction with genetic counseling as needed (Yancy et al., 2013).

Alcoholic Cardiomyopathy. Alcohol cardiomyopathy (Piano, 2002) is likely due to a direct toxic effect of alcohol on muscle cells with variable genetic vulnerability. Other mechanisms include a potential increase in norepinephrine and acetaldehyde. Alcohol consumption of several drinks per day for approximately 10 years or more increases the risk of alcoholic cardiomyopathy (10 oz of whiskey, 32 oz of wine, 64 oz of beer). Abstinence from alcohol is essential in all patients with DC, including alcoholic cardiomyopathy.

Tachycardia-Induced Cardiomyopathy. Prolonged rapid heart rate can induce DC and is generally reversible upon controlling the arrhythmia (Cruz et al., 1990). The main treatment of this cardiomyopathy is in the control of the rapid heartbeat. This condition is frequently seen in patients with unrecognized AF with rapid ventricular response but also can be caused by sinus tachycardia and ventricular arrhythmias.

Takotsubo Cardiomyopathy. Apical ballooning syndrome, or Takotsubo cardiomyopathy, typically occurs in women older than 50 years of age, precipitated by emotional or physiologic stress with subsequent LV dysfunction (involving the apex and typically sparing the base of the ventricle). Patients present with acute ischemia and have normal coronaries. Wall motion abnormality extends beyond a single coronary territory. In the majority of patients, the cardiomyopathy resolves within weeks of presentation. The long-term prognosis of patients is good with no further deterioration of heart muscle on follow-up (Sharkey et al., 2011).

Drug-Induced Cardiomyopathy. Dilated cardiomyopathy has been well described with several antineoplastic agents such as anthracyclines (doxorubicin), high-dose cyclophosphamide, trastuzumab (Herceptin), and tyrosine kinase inhibitors (sunitinib). Doxorubicin-induced myopathy is dose dependent and is generally irreversible (Lipshultz et al., 1995; Steinherz et al., 1991). Other drugs that can induce cardiomyopathy include cocaine (Felker et al., 1999), ecstasy (3,4-methylenedioxymethamphetamine) (Mizia-Stec et al., 2008), ma huang (Ephedra) (Samenuk et al., 2002), and amphetamine (Crean and Pohl, 2004).

Peripartum Cardiomyopathy. Peripartum cardiomyopathy occurs in one in 1300 to one in 1400 births. Etiologic factors remain unknown but likely include autoimmune factors, myocarditis, toxemia, nutritional deficiencies, and tocolytics. Risk factors include age older than 30 years, African American race, multiparity, HTN and preeclampsia, cocaine use, and pregnancy with multiple fetuses.

Patients with history of peripartum cardiomyopathy should be advised against future pregnancies.

Idiopathic Dilated Cardiomyopathy. The presence of DC without an identifiable cause is called idiopathic dilated cardiomyopathy (IDC). The cardiac chambers are enlarged, and LV function is reduced. Myocytes can be hypertrophied or atrophied with interstitial fibrosis present. It is unclear what precipitates IDC, but an autoimmune mechanism has been hypothesized.

The treatment of DC consists of diuretics, digoxin, ACE inhibitors, and β -blockade. Aldosterone antagonists are reserved for patients with advanced symptoms (class III or IV) or those with ischemic cardiomyopathy and a history of prior MI. Mechanical therapies with biventricular pacing and cardiac resynchronization therapy can be very helpful to improve symptoms in patients with a wide QRS on ECG and an abnormal, asynchronous septal wall motion.

Patients with DC and a prior history of sustained ventricular arrhythmias have a high risk of sudden cardiac death. The implantation of an internal defibrillator is associated with improved mortality outcomes in these patients (Moss et al., 2002, 2004; Moss 2003). Defibrillator therapy is also indicated for patients with asymptomatic depressed LV systolic function regardless of the etiology (Bardy et al., 2005). Empiric antiarrhythmic therapy to prevent sudden death in patients with DC did not show a mortality benefit. Internal defibrillators are now advised for patients with an LVEF 35% or less at least 40 days from an MI and revascularization or 3 months from initiation of optimal medical treatment in noninfarct patients.

Hypertrophic Cardiomyopathy. Hypertrophic cardiomyopathy (HCM) is characterized by inappropriate LV wall thickness larger than 15 mm in the setting of normal cavity size, impaired diastolic filling, and, in some patients, LV outflow obstruction. Patterns of hypertrophy are variable in HCM (Klues et al., 1995) and depend on the phenotypic expression of the autosomal dominant mutations in genes encoding protein components of the sarcomere (chromosomes 1, 11, 14, and 15) and its myofilaments (Alcalai et al., 2008; Ly et al., 2005). LVH can be concentric, apical (Yamaguchi disease), or involving the free wall of the LV in 75% of HCM patients. In the remaining 25%, it is septal (idiopathic hypertrophic subaortic stenosis or asymmetric septal hypertrophy). HCM affects 0.2% of the population (Zou et al., 2004) and is the leading cause of nonviolent death among young people in the United States.

Hypertrophic cardiomyopathy is sometimes characterized by normal systolic function with asymmetric LVH and variable degrees of LV outflow obstruction. The LV outflow in HCM is caused by the asymmetric hypertrophy of the LV septum and the systolic anterior motion (SAM) of the anterior leaflet of the mitral valve. Patients with HCM can have abnormal intramural coronary arteries that contribute to fibrosis and myocardial ischemia even in the absence of obstructive atherosclerotic lesions.

Patients can be asymptomatic (10%-15%) or more typically present with dyspnea or pulmonary congestion (90%), chest pain (75%), occasional dizziness, and syncope events, and in young athletes with a significant LV outflow obstruction, sudden death can be the first manifestation of the

disease (1%-3% annual incidence and can be as high as 6% in childhood). HCM is quite often first uncovered on physical examination when a systolic ejection murmur is first appreciated along the lower left sternal border that is made worse with Valsalva maneuver or standing up from a squatting position. Patients might also have a bisferiens carotid pulse and an S4 gallop. These signs are mostly present in patients with a significant LV outflow obstruction and can be absent in nonobstructive HCM.

The ECG in patients with HCM might show LVH, deep inferior and lateral Q waves, poor R wave progression across the precordium, left anterior fascicular block, and an enlarged left atrium. The echocardiogram is generally diagnostic. Asymmetric LVH can be seen along with SAM of the anterior leaflets and secondary mitral insufficiency. LV outflow obstruction can be measured with Doppler flow and its severity to provocative maneuvers can be assessed, including inhalation of amyl nitrite and Valsalva maneuver. A gradient of 30 mm Hg or more at rest or with provocative measures indicates the presence of obstructive HCM (Panza et al., 1992; Sasson et al., 1988). The resting gradient is associated with progression to severe CHF and death from HF but does not correlate with sudden cardiac death or correlate with overall prognosis. Cardiac catheterization might be necessary in some patients to confirm the diagnosis and to assess gradients accurately. Cardiac MRI is helpful in establishing the diagnosis of HCM in patients in whom echocardiography is inconclusive and can provide information about the pattern of hypertrophy. The accuracy of myocardial perfusion nuclear imaging is reduced in HCM and may lead to high false-positive findings.

The natural history of HCM is variable, with an annual mortality rate of 1% to 2% (Hess and Sigwart, 2004). Patients at high risk of premature sudden cardiac death include young patients (30 years of age or younger) irrespective of the degree of obstruction of the LVOT, history of syncope or prior cardiac arrest, massive LVH (wall thickness >29 mm), nonsustained VT on Holter monitoring, sustained ventricular arrhythmias, abnormal BP response to exercise, or family history of sudden cardiac death. Certain gene defects are also associated with sudden cardiac death (α -tropomyosin) in younger patients. A 12-lead ECG is recommended for all athletes involved in organized competitive sports in addition to a detailed history and physical examination to screen for HCM and other potential lethal cardiac diseases (Corrado et al., 2005).

In patients with stable mild to moderate symptoms, pharmacologic therapy is indicated, including β -blockers to a heart rate of 60 beats/min and the CCB verapamil if the patient remains symptomatic. Patients with progressive symptoms might benefit from the addition of disopyramide to a β -blocker (with or without verapamil). In general, physicians need to avoid the use of dihydropyridine CCBs, digoxin, inotropes, or disopyramide with no β -blockers.

Patients with severe symptoms and a LV gradient of 50 mm Hg or greater at rest need to be considered for dual-chamber pacing, alcohol septal ablation (Hess and Sigwart, 2004), or septal myotomy or myectomy and consideration for an implantable cardioverter-defibrillator (ICD), particularly in those at high risk of sudden cardiac death (Maron

et al., 2000). Mitral valve replacement is generally not indicated in those with HCM with an obstructive gradient over 50 mm Hg.

Patients with symptomatic HCM should avoid participation in competitive sports. Low-intensity exercise is reasonable in patients with asymptomatic HCM (bowling, golfing, brisk walking, modest biking). Patients should not be involved in competitive sports or sports that require systematic training.

In the setting of acute hypotension in patients with LVOT obstruction, increasing afterload with the use of IV phenylephrine or another selective vasoconstrictor is an important step to reduce the LV outflow obstruction.

Restrictive Cardiomyopathy. Restrictive cardiomyopathy (RC) is a disease of the heart muscle characterized by reduced relaxation (diastolic impairment) and restrictive filling in the presence of normal or nearly normal ventricular function and cavity size. It can be idiopathic or familial or caused by infiltrative or storage diseases. Secondary causes of RC are many and include amyloidosis, sarcoidosis, hemochromatosis, glycogen storage disease, and Fabry disease. Certain connective tissue diseases, including scleroderma and pseudoxanthoma elasticum, can also lead to RC. Endomyocardial diseases such as hypereosinophilic (Loeffler) syndrome, endomyocardial fibrosis, carcinoid, and malignant infiltration can also lead to RC.

Idiopathic RCM is equally present in males and females. A familial pattern is present in some cases. One third of patients may have thromboembolic complications. LVH and interstitial fibrosis are present to varying degrees. Amyloidosis-induced RCM is secondary to extracellular amyloid protein deposition throughout the heart and can be diagnosed with biopsy. There are four types of amyloidosis that depend on the amyloid protein composition: (1) primary amyloidosis caused by myeloma protein fibrils diffusely deposited throughout the myocardium, (2) secondary amyloidosis, (3) senile amyloidosis, and (4) familial amyloidosis. Amyloidosis should be suspected if patients complain of peripheral neuropathy, carpal tunnel syndrome, difficulty swallowing, hoarseness, macroglossia, hepatomegaly, autonomic neuropathy, and nephrotic syndrome. Patients frequently have elevated jugular venous pressure. Kussmaul sign is generally not present. Pleural effusions, hepatomegaly, and peripheral edema are present. Echocardiography may show a granular, sparkling appearance with biventricular thickening and biatrial enlargement. EF is typically normal. Serum and urine immunofixation electrophoresis looking for free light chains and tissue amyloid deposits on biopsy (apple-green birefringence when stained with Congo red and viewed under polarizing microscopy) are tests that can be performed to establish the diagnosis.

Sarcoidosis-induced RCM is characterized by the formation of granulomas in multiple organs with cardiac involvement in about 25% of patients (2% clinically). It is frequently seen in African Americans, women, and patients between the age of 25 and 50 years. Patients can present with heart block and ventricular arrhythmias. Sarcoid is diagnosed by biopsy. Clinically cardiac sarcoidosis is suspected if there is an extracardiac manifestation of the disease and there are two major or one major and one minor cardiac criteria met.

Major cardiac criteria include heart block, EF less than 50%, positive gallium scan, and basal thinning of the ventricular septum. Minor criteria include abnormal ECG, abnormal echocardiogram, perfusion defects on myocardial perfusion imaging tests, and abnormal MRI with delayed enhancement and presence of fibrosis (Soejima and Yada, 2009).

Patients with RC typically present with dyspnea and signs of left and right-sided failure. The jugular venous pulse is elevated with a prominent X and Y descent. The ECG is nonspecific and might show low voltage, conduction abnormalities, and increase in atrial sizes. Echocardiography will show diastolic dysfunction and might help in the diagnosis of infiltrative diseases such as amyloidosis. It can also help exclude the diagnosis of other causes of HF and assess valvular function. In addition, tissue Doppler and color M-mode Doppler can facilitate the diagnosis of RC.

Restrictive cardiomyopathy might be difficult to distinguish from constrictive pericarditis. The distinction between these two entities is important because RC has no cure, but constrictive pericarditis can be cured surgically by pericardial stripping. Several parameters can be used in the angiography suite to help distinguish between these entities. Typically, RC patients have a higher end-diastolic pressure in the LV compared with the RV (>5 mm Hg), a RV pressure that exceeds 50 mm Hg, and a RV end-diastolic pressure to RV systolic pressure ratio less than 1 : 3. The overall predictive accuracy of these parameters independently is 85%, 70%, and 76%, respectively, but if all were concordant in one patient, the diagnostic accuracy can reach 90% (Vaitkus and Kussmaul, 1991). Imaging modalities such as MR and CT scanning can help in determining whether pericardial thickening is present as in the case of constrictive pericarditis. Endomyocardial biopsies can be helpful in determining the presence of infiltrative disease.

Treatment of RC is mostly palliative and symptom directed. Small doses of diuretics can be helpful, but caution should be taken not to dehydrate the patient because cardiac output heavily relies on adequate preload volumes in these patients.

Arrhythmogenic Right Ventricular Dysplasia. Arrhythmogenic right ventricular dysplasia (ARVD) is a form of cardiomyopathy caused by either a replacement of the RV myocardium with fat or a genetically susceptible RV to environmental agents leading to myocarditis (Fontaine et al., 1999). ARVD is autosomal dominant in 50% of patients; therefore, first-degree relatives should be screened. Clinically, ARVD can present with VTs with a left bundle branch block pattern or VF (Corrado et al., 2001). ARVD can cause sudden cardiac death in young, otherwise healthy persons and athletes. Multiple modalities can be used to assist in the diagnosis, including ECG (inverted T waves in V1-V3 with epsilon waves in V1-V3), echocardiography, MRI, and contrast ventriculography. MRI is emerging as an important technique for assisting in the diagnosis and follow-up of these patients (Kayser et al., 2002). On MRI, the RV appears thin (<2 mm) with focal regions of hypertrophy, dilated with regional dysfunction, enlarged right ventricular outflow tract (RVOT), and with abnormal morphology (trabecular disarray). Therapy of ARVD consists of antiarrhythmic drugs, catheter ablation, and implantable

defibrillators (McRae 3rd, 2001). In cases of refractory HF, cardiac transplantation should be considered.

KEY TREATMENT

- Endomyocardial biopsy is indicated in: (1) patients with recent onset HF (<2 weeks) in the presence of normal or dilated LV and hemodynamic compromise and in (2) patients with HF onset between 2 weeks and 3 months and with dilated LV and new ventricular arrhythmias, heart block, or not responding to medical treatment in 1 to 2 weeks (SOR: A) (Cooper, 2007).
- Patients with HCM should undergo yearly ECG, Holter at baseline, echocardiography at baseline, repeat echocardiography for children 12 years of age or younger every 12 to 18 months if history of sudden cardiac death or playing sports, MRI if echocardiography is inconclusive, and cardiac angiography if chest pain and intermediate to high risk of CAD. There is no indication to perform an echocardiogram more than once per year (SOR: A) (Gersh et al., 2011).
- ICD therapy is indicated in patients with prior cardiac arrest or VT or fibrillation and should be strongly considered in patients with a family history of sudden cardiac death, severe wall thickness (≥ 30 mm), syncope, non-sustained VT on Holter monitoring, or a drop in BP with exercise and in high-risk children (SOR: A) (Gersh et al., 2011).

MYOCARDITIS

Myocarditis is an acute injury to the myocardium with subsequent autoimmune and inflammatory response leading to further damage to the myocardium (Blauwet and Cooper, 2010). Myocarditis can be triggered by several agents, most commonly the coxsackie B virus. Other viruses can precipitate myocarditis, including echovirus, human immunodeficiency virus (HIV), influenza, cytomegalovirus, adenovirus, respiratory syncytial virus, varicella zoster, and arbovirus. Various nonviral agents, including bacterial, fungal, and parasitic (toxoplasmosis and schistosomiasis) agents, can also trigger myocarditis. Noninfectious etiologies are also numerous and include systemic diseases (sarcoidosis, celiac disease), drugs and toxins (anthracyclines, cocaine), autoimmune disease (giant cell myocarditis, lupus), radiation, genetic, environmental (carbon monoxide, lead), endocrine, and metabolic.

A variety of clinical presentations can be encountered, from minimal symptoms and a very benign course to severe symptoms and cardiogenic shock. Damage to the myocardium can be a direct result of the injurious insult to the myocardium or secondary to an autoimmune reaction against the invading agent. Patients can give a history of a viral infection several weeks before the onset of cardiac symptoms, which include dyspnea, chest pain, and CHF. Palpitations, dizzy spells, syncope, and even sudden cardiac death can occur as a result of arrhythmias. Patients display signs of CHF with S3 gallops and rales in their lungs. A pericardial rub can be heard in some when the pericardium is also involved. An elevated erythrocyte sedimentation rate (ESR), WBC count, and cardiac enzymes can be seen. ECG

changes are nonspecific but can show ST/T changes diffusely, sinus tachycardia, a prolonged QT interval, conduction delays, and low voltage. Echocardiography shows a reduced LV function and possibly segmental wall motion abnormalities and ventricular thrombus. RV dysfunction is a poor prognostic indicator in acute myocarditis (Mendes, 1994). The value of endomyocardial biopsy is questionable except in recent unexplained HF in the setting of fulminant myocarditis with normal or dilated LV and in suspected giant cell myocarditis (Blauwet and Cooper, 2010).

Treatment of myocarditis is the same as treatment of CHF. Steroids and other immunomodulatory agents are not known to be helpful. Recovery is generally the rule with a good long-term prognosis. NSAIDs should be avoided in those with acute myocarditis (Khatib et al., 1990). Mechanical hemodynamic support in the acute phase may be needed when hemodynamic compromise is present. Patients should avoid aerobic exercise for 6 months. Patients with giant cell myocarditis may require transplantation as a definitive therapy.

PERICARDIAL DISEASE

The pericardium consists of two layers: the outer fibrous pericardium and the inner double-layer serous pericardium that consists of the visceral epicardium (covers the heart and great vessels) and the parietal pericardium (covers the fibrous pericardium). The pericardium contains from 15 to 50 mL of plasma ultrafiltrate. Pericardial disease can present itself as pericarditis (acute or chronic recurrent), pericardial effusion (with or without hemodynamic consequences), or constrictive disease (Khandaker et al., 2010).

Pericarditis

Acute pericarditis is an inflammatory process involving the pericardium. It occurs in 0.1% of hospitalized patients and up to 5% of noncoronary chest pain patients presenting to the ED (Spodick, 2003). Acute pericarditis is mostly idiopathic with no identifiable cause. Several factors, however, can cause acute pericarditis, including infectious (bacterial, viral, fungal, parasites, HIV), neoplastic (primary or metastatic), inflammatory, metabolic (uremia, hypothyroidism), traumatic, pharmacologic, and iatrogenic caused by instrumentation and radiation.

Acute pericarditis is diagnosed if at least two of four criteria are met: (1) chest pain characteristic of pericarditis, (2) pericardial rub, (3) characteristic ECG changes, and (4) a new or worsening pericardial effusion. Patients with pericarditis for the first time should be admitted to the hospital for inpatient observation. In multivariable analysis, being female, having large effusion or tamponade, and failure of aspirin or of NSAIDs are predictors of poor outcome in acute pericarditis (Imazio et al., 2007).

The symptoms of pericarditis include sharp retrosternal pain, localized or radiating to the neck, shoulder, or arms, that is made worse with lying down and improves with sitting up. The pain is sharp in nature and is worse with a deep breath. Patients can have associated dyspnea, cough, hiccups, and dysphagia (Hoit, 1991). A pericardial friction rub may be heard in both systole and diastole and is best heard at the left lower sternal border with the diaphragm of the stethoscope.

The ECG typically shows diffuse ST segment elevation that lasts for days followed by T-wave inversions with normal ST segments that then normalizes within 2 weeks. The chest radiograph can show an enlarged heart if a pericardial effusion is present. The echocardiogram confirms typically the presence of the effusion and helps in assessing whether hemodynamic compromise is present. Blood tests generally show an elevation of ESR and possibly cardiac enzymes if myopericarditis is present. Finally, serology is of low yield in the diagnosis of acute pericarditis. Antiviral titers in general will not alter the management of the patient (Permanyer-Miralda, 2004; Zayas, 1995).

The mainstay of treatment of acute pericarditis is NSAIDs for approximately 3 weeks (Maisch et al., 2004). Aspirin is preferred as first-line therapy. If symptoms persist, colchicine (Adler et al., 1998; Imazio et al., 2005) is then recommended for 4 to 6 weeks if the patient has no severe hepatic or renal impairment. Treatment with steroids needs to be avoided unless all other treatments have failed because it is associated with relapse of pericarditis. Steroids may be used as first-line treatment, however, in cases of autoimmune disease or uremic pericarditis (Imazio et al., 2004). Pericardiectomy is reserved for patients with recurrent pericarditis who are unresponsive to aggressive medical treatment. Pericardiectomy, however, may not always eliminate the symptoms of recurrent pericarditis.

Pericardial Effusion

Pericarditis can lead to pericardial effusion and subsequent cardiac tamponade. In this condition, there is an equalization of pressures in the right atrium, left atrium, wedge pressure, and the pulmonary end-diastolic pressure with a blunted or absent y descent on the right atrial tracing. Typically, pulsus paradoxus is present in which there is a more than 10-mm Hg drop in systolic BP with inspiration. Tachycardia is the first compensatory mechanism to increase cardiac output, and when it fails, hypotension occurs. The most common cause of pericardial effusion is malignancies, particularly of the breast and lung, lymphomas, and melanomas. An aortic dissection can cause a hemorrhagic pericardial effusion, and avoiding pericardiocentesis in this case is important to minimize rapid blood loss. Treatment should be disease-specific. For instance, bacterial pericarditis and effusion should be treated with appropriate antibiotics and surgical drainage; myxedematous pericardial effusions respond to thyroid hormone replacement; and uremic pericardial effusion responds to steroids (Hoit, 2002).

When pericardial fluid develops acutely, tamponade physiology can result with less than 150 cc of fluid because the pericardium has not had a chance to expand to accommodate the fluid in the pericardial space, and the intrapericardial pressure rises sharply. Chronic pericardial effusion that has developed slowly, however, can accumulate without hemodynamic compromise with up to 2 to 3 L of fluid. Eventually, the pressure in the pericardial space rises over the intracardiac pressures with subsequent diminished venous return and reduced cardiac output and hypotension. Cardiac tamponade can occur in the setting of a localized effusion, generally postoperatively, or because of gas-producing bacteria (pneumopericardium) after penetrating chest trauma.

The ECG findings in tamponade are low voltage or electrical alternans. Echocardiography can make the diagnosis of tamponade when clinically suspected. Typically, the right-sided chambers of the heart show collapse with an increase in the size of the inferior vena cava. The presence of both right atrial and RV collapse has a positive predictive value of 74% for tamponade physiology (Mercé, 1999). Mitral inflow variability by the Doppler flow is also seen and exceeds 25% with respiration. Fluid in the pericardial space can be identified and its quantity estimated. These echocardiographic findings are reversible after the fluid is removed from the pericardial space.

The preferred treatment of hemodynamically significant tamponade is pericardiocentesis. A needle is directed under local anesthetic into the pericardial space, typically guided by echocardiography, and the fluid is aspirated. In the case of a malignant effusion, a drainage catheter is left in the pericardium for 24 to 48 hours to drain most of the accumulating fluid. Surgical drainage offers an advantage over pericardiocentesis in recurrent pericardial fluid when a complete drainage can be achieved and the creation of a pericardial window prevents reaccumulation of fluid. Fluid removed from the pericardium needs to be sent for detailed analysis, including cell count, chemistries, cultures (bacterial and fungal), and cytology. Pericardial tissue also needs to be sent for pathologic and microbiologic analyses to assist in identifying the etiology of the pericardial fluid.

Chronic Constrictive Pericarditis

Pericarditis can result in a thickened and scarred pericardium that impairs cardiac filling. Patients have a normal systolic function and a small cavity size. The most common etiologies of constrictive pericardial disease are idiopathic, iatrogenic secondary to surgeries and radiation therapies, inflammatory, infectious, and secondary to neoplasms and renal failure.

Patients have high intracardiac filling pressures and pulmonary HTN and complain of dyspnea and fatigue. They display signs of right-sided HF, including hepatosplenomegaly, central venous congestion and ascites, lower extremity edema, and an elevated jugular venous pressure with a deep Y descent. Patients may have a pericardial knock in diastole. Kussmaul sign, a paradoxical rise in venous pressure with inspiration, is also present. When constrictive pericarditis presents acutely, patients will have agitation; tachycardia; or the Beck triad of elevated jugular veins, hypotension, and a small quiet heart. The ECG may display a low QRS voltage and the presence of supraventricular arrhythmias. Pericardial thickening can be seen on CT or MRI and assists in the diagnosis. Pericardial thickening may not be present in almost 18% of patients. As noted earlier, distinguishing between restrictive and constrictive pericardial disease is challenging but very important because constrictive pericardial disease can be effectively treated with pericardiectomy. Cardiac catheterization is an important procedure to help in distinguishing between these two diagnoses.

Patients with mild to moderate symptoms can be treated initially with diuretics and digoxin. A trial of antiinflammatory drugs and possibly steroids has been suggested in patients with acute symptoms before considering surgery, as 15% of these patients could have a reversible course. Pericardiectomy is associated with more than 6% mortality

Management of peripheral arterial disease (PAD). TransAtlantic Inter-Society Consensus (TASC). *J Vasc Surg.* 2000;31(suppl):S1-S296.)

rate, particularly in elderly patients or those with advanced HF, prior radiation treatment, pulmonary HTN, and renal insufficiency (Bertog et al., 2004; DeValeria et al., 1991).

Peripheral Arterial Disease

EPIDEMIOLOGY

Atherosclerotic PAD is an underdiagnosed, undertreated, age-dependent disease that profoundly impacts patient quality of life and is an independent predictor of mortality (Criqui et al., 1992; Nikolsky et al., 2004; Vogt et al., 1993a). On average, the mortality rate of claudicant patients is 2.5 times higher than nonclaudicant patients (Figure 27-23). Atherosclerosis is a ubiquitous process that affects the entire arterial tree in the coronary, cerebral, visceral, and upper and lower extremity. Patients with PAD are at increased risk of cardiovascular and cerebrovascular events, including death, MI, and ischemic stroke. The clinical continuum of PAD ranges from asymptomatic stenosis to limb-threatening ischemia. Intermittent claudication (IC) is defined as ischemic limb pain in one or both legs that occurs with exertion and is alleviated with rest. IC is associated with marked limitations in walking ability, which translates into a considerable negative impact on occupational, social, and leisure activities (Olsen et al., 1988; Regensteiner et al., 1990; Vogt et al., 1994).

Atherosclerosis begins in childhood and evolves over decades (Freedman et al., 1988), affecting more than 85% of adults older than the age of 50 years old (Tuzcu et al., 2001). However, many patients remain entirely asymptomatic; thus, estimating the true prevalence of PAD is difficult and highly dependent on the definition of disease. Most epidemiologic studies only report symptomatic disease; therefore, the true incidence of PAD is not accurately known and is underestimated. In addition, published reports on the incidence and prevalence of PAD vary greatly because the true occurrence of disease is directly related to the risk group of the population studied and the sensitivity and specificity of the diagnostic testing methodology (Criqui et al., 1985).

INTERMITTENT CLAUDICATION

Intermittent claudication is only a symptom of PAD and can be misleading in measuring the prevalence of PAD. For example, a patient with advanced PAD may not have significant IC because of functional decline and inactivity, but someone who is very active may have significant IC even if he or she only has mild disease. Several questionnaires, such as the WHO/Rose Questionnaire, the Edinburgh Claudication Questionnaire, and the Walking Impairment Questionnaire, have been developed to identify patients with IC. The prevalence of IC based on the Rose criteria ranged from 0.4% to 14% of the adult population (Dormandy and Rutherford, 2000). Although these questionnaires are typically highly specific in excluding healthy patients, as assessed by a physician, they are only moderately sensitive in detecting disease. Only approximately one third of patients with PAD have typical symptoms of IC (Schroll and Munck, 1981; Zheng et al., 1997). Furthermore, asymptomatic patients are not at all detected by questionnaire screening. These individuals can only be diagnosed via noninvasive or invasive imaging. Therefore, epidemiologic studies based solely on the use of questionnaires significantly underestimate the true prevalence of disease.

ASYMPTOMATIC DISEASE

More than 50% of patients with PAD are asymptomatic and only identified by noninvasive testing, such as the ABI. Most epidemiologic studies have used a resting ABI less than 0.9 as the criteria for the diagnosis of PAD. However, this definition has several limitations and leads to an underestimation of the true prevalence of disease. For example, this definition will miss mild to moderate disease in patients who have normal resting ABIs but may have a considerable ischemic drop in the ABI with exercise. Furthermore, heavily calcified vessels, particularly in people with diabetes, will have falsely elevated ABIs because of an inability to compress the vessel. Nonetheless, the Systolic Hypertension in the Elderly Program (SHEP) found a prevalence of asymptomatic PAD in 25.5% of 1537 patients (Newman et al., 1993) using a resting ABI less than 0.9 as the diagnostic criterion. The Peripheral Arterial Disease Detection, Awareness and Treatment in Primary Care (PARTNERS) program was a nationwide cross-sectional study that screened patients for PAD in a primary care setting. A total of 6979 patients age 70 years of age or older or age 50 to 69 years old with a history of either diabetes or cigarette smoking were evaluated by history and ABI. The diagnosis of PAD was made based on a resting ABI less than 0.9, a documented medical history of PAD, or a prior lower extremity revascularization. The PARTNERS program found a prevalence of PAD in 29% of patients. However, more concerning is that 83% of patients with a known prior history of PAD were aware of their diagnosis, but only 49% of their physicians were aware of this diagnosis (Hirsch et al., 2001).

CRITICAL LIMB ISCHEMIA

Critical limb ischemia (CLI) is defined by the presence of ischemic resting pain in the distal foot, ischemic nonhealing

ulcerations, or gangrene and represents fewer than 10% of patients with PAD (Hiatt, 2001). Although this subset represents the smallest percentage of patients with PAD, these patients have tremendous disease burden and are clearly the highest risk subset for morbidity and mortality, with up to 73% to 95% progressing to limb loss or death at 1 year if left untreated (Wolfe and Wyatt, 1997). Each year, there are approximately 150,000 to 200,000 nontraumatic lower extremity amputations in the United States, and it has been estimated that 85% to 90% of these could be avoided through early revascularization and aggressive risk factor management. Amputation carries a high rate of long-term morbidity and mortality. The fate of those with amputations is poor, particularly in elderly individuals. The level of amputation also dictates the overall prognosis, but two to three times as many below-the-knee (BK) amputees achieve full mobility compared with above-the-knee (AK) amputees, the initial rehabilitation may take up to 9 months. In addition, 5 years after a BK amputation, 30% of patients will have had a major contralateral amputation, 50% will be dead, and only 20% will be alive with one leg intact (Dormandy and Rutherford, 2000).

PATHOPHYSIOLOGY

Peripheral arterial insufficiency is caused by hemodynamically significant narrowing of the arterial lumen usually caused by atherosclerosis, which clinically reduces blood flow to the affected limb. Longitudinal, epidemiologic studies such as the Framingham Heart Study (Murabito et al., 1997) and the INTERHEART (Yusuf et al., 2004) study have defined the risk factors for PAD.

TRADITIONAL RISK FACTORS

Age

The prevalence of PAD increases with age. The incidence of IC in five large population-based studies is four times higher, and the prevalence is eight times higher comparing the 35- to 39-year-old age group with the 70- to 74-year-old age group (Dormandy and Rutherford, 2000).

Smoking

Smoking is a very strong independent risk factor of atherosclerotic PAD. The severity of PAD increases with the number of cigarettes smoked (Cronenwett et al., 1984; Powell et al., 1997) and the amount of exposure to second-hand smoke (Barnoya and Glantz, 2005). In a series of epidemiologic studies, the incidence of developing IC among smokers is approximately two- to threefold higher than nonsmokers (Dormandy and Rutherford, 2000). Smokers develop IC approximately a decade before nonsmokers (Kannel and Shurtleff, 1973), and the association between smoking and PAD may be stronger than the association between smoking and CAD (Fowkes et al., 1992; Kannel et al., 1994). Moreover, smokers are much more likely to progress to CLI than nonsmokers. Smokers with IC have an 11-fold greater amputation rate than nonsmokers (Dormandy et al., 1999).

Smoking cessation slows the progression of disease, improves the symptoms of IC, decreases the likelihood of amputation, improves the patency of revascularization

procedures (Krupski, 1991), and improves overall longevity (Taylor et al., 2002). Finally, all-cause mortality is significantly reduced by smoking cessation but not by smoking reduction (Godtfredsen et al., 2002). It is imperative that patients entirely cease smoking and not just reduce their consumption of tobacco products.

Diabetes

Diabetes or glucose intolerance is one of the most powerful independent modifiable risk factors that contribute to the development of PAD, IC, and CLI (Fowkes et al., 1992; Kannel and McGee, 1979; Murabito et al., 1997). The incidence of IC in patients with diabetes is approximately two times higher than those without diabetes (Dormandy and Rutherford, 2000). Diabetes not only has a significant effect on the larger vessel arterial circulation but also causes microangiopathy as well. Therefore, in conjunction with diabetic peripheral neuropathy, these patients are particularly vulnerable to amputation.

Approximately 60% of all nontraumatic amputations performed in the United States each year are in patients with diabetes (American Diabetes Association Fact Sheet, 2005). A patient with diabetes with PAD has approximately a 10-fold higher amputation rate than a patient without diabetes (Da Silva et al., 1979). There does not appear to be any significant difference in microvascular or macrovascular comorbidity between type 1 and type 2 diabetes (Zander et al., 2002). However, there is a dose-response relationship between the HgbA_{1c} level and the risk of amputation (Lehto et al., 1996). Therefore, patients with diabetes should be aggressively treated to normalize glycemic control. In addition, patients with diabetes should be instructed on good foot care, such as properly fitting shoes and foot hygiene, to avoid skin breakdown and ulcer formation.

Hyperlipidemia

As in CAD, LDL-C and triglyceride levels are directly related, but HDL-C levels are indirectly related to the progression of PAD, and the observed risk seems to demonstrate a linear relationship (Fowkes et al., 1992; Murabito et al., 2002). The majority of the data on lipid-lowering therapy is in patients with CAD. However, several studies have specifically demonstrated an improvement in the relative risk of an abnormal ABI, walking distance on a treadmill, frequency and severity of claudication, and limb loss (Blankenhorn et al., 1991; Buchwald et al., 1996; Mohler et al., 2003; Pedersen et al., 1998), suggesting that all patients with PAD should be treated with statin therapy irrespective of baseline LDL-C.

Hypertension

Hypertension is a major risk factor for PAD and carries a 2.5-fold age-adjusted risk for men and a 3.9-fold age-adjusted risk for women (Kannel and McGee, 1985; Murabito et al., 1997). There have been concerns, based on early case reports, that β -blockade therapy may worsen the symptoms of IC. A meta-analysis on this subject and critical review of these studies concluded that β -blockers are safe and do not worsen IC (Radack and Deck, 1991). ACE inhibitors may offer significant benefits for the prevention of atherosclerotic vascular disease beyond that expected from a

reduction in BP alone (Fox, 2003; The Heart Outcomes Prevention Evaluation Study Investigators, 2000). However, there remains considerable debate as to whether or not the data from the HOPE study and the EUROPA study can be generalized to all ACE inhibitors.

Gender

The initial data from Framingham suggested that men develop IC approximately 10 years before women (Kannel et al., 1970). More recent data do not support this observation (Hirsch et al., 2001; Murabito et al., 2003; Reunanen et al., 1982). In light of these data, patients should be screened for PAD regardless of gender.

Obesity

Obesity, as measured by an increased BMI greater than 30, has long been recognized as a risk factor for atherosclerotic disease. It is now recognized that adipocytes, particularly visceral adipocytes, contribute to a pro-inflammatory state by generating a variety of cytokines such as IL-6, TNF- α , and CRP, which play a direct role in the development of atherosclerosis (Hansson, 2005). This theory is further supported by the fact that liposuction does not seem to lower risk for CAD because liposuction reduces subcutaneous fat mass but has no effect on reducing visceral fat mass (Klein et al., 2004).

NONTRADITIONAL RISK FACTORS

High-Sensitivity C-Reactive Protein

Atherosclerosis is a disease of chronic low-grade inflammation. hsCRP is a nonspecific marker of inflammation that is emerging as a simple yet powerful marker of atherosclerotic risk. Prospective data from the Physicians' Health Study demonstrate that baseline levels of hsCRP independently predict a future risk of developing symptomatic PAD (Ridker et al., 1998).

Lipoprotein(a)

Lipoprotein(a) [Lp(a)] is an atherogenic subspecies of LDL that is covalently linked to apoprotein(a). Apo(a) is homologous to plasminogen. Lp(a) may exacerbate risk for ACS by inhibiting endogenous fibrinolysis (Hajjar et al., 1989). Furthermore, Lp(a) may augment the release of endothelial PAI-1, which further impairs fibrinolysis (Etingin et al., 1991). The net result is that Lp(a) contributes to atherogenesis and a prothrombotic or hypercoagulable state.

Lipoprotein(a) has been implicated as an independent predictor of PAD (Cheng et al., 1997; Prior et al., 1995); however, many of these studies are cross-sectional or retrospective and cannot establish causal relationships between risk factors and disease. Prospective data from the Physicians' Health Study did not show a significant relationship in baseline Lp(a) levels and the future development of PAD (Ridker et al., 2001). Widespread screening of Lp(a) levels in the general population is not recommended. However, this should be considered in patients who present with premature vascular disease and few or no traditional risk factors. Niacin can modestly reduce Lp(a) levels. There is no clinical trial evidence to prove that reducing serum levels of Lp(a) reduces risk for the development or progression of PAD.

Fibrinogen

Fibrinogen has been implicated in atherogenesis by early epidemiologic studies (Kannel et al., 1987). However, fibrinogen is an acute phase reactant, and there is considerable inpatient variability in its expression over time. Other markers of inflammation, such as hsCRP, have a more powerful association in predicting PAD. Furthermore, fibrinogen levels are directly related to age, obesity, cigarette smoking, diabetes, and LDL-C and inversely related to HDL-C, physical activity, alcohol use, and estrogen levels. There is controversy regarding the independent predictive value of hyperfibrinogenemia. Therefore, routine fibrinogen level screening is not recommended unless there is suspicion of a hypercoagulable state.

NATURAL HISTORY OF DISEASE

Atherosclerosis is an age-dependent disease that begins in childhood and progresses throughout adulthood, particularly if the risk factors are left unchecked. Yet early studies suggested that PAD led a contrary, benign course that was not progressive (Imparato et al., 1975; McAllister, 1976). However, in most of these studies, IC was used as an end point rather than ABI or even a patient functional assessment. IC is a relatively insensitive marker of PAD. Those studies typically reported a stabilization or improvement in IC over time, which does not necessarily indicate stabilization or improvement in the disease process, ability to ambulate, or functional status. Early authors suggested that relief of IC over time was a sign of improved collateral flow, yet to experience IC, a patient must be physically active. McDermott et al. (2004) demonstrated that the stabilization or improvement of IC was strongly related to functional decline (i.e., patients walked at a slower pace and for shorter distances to avoid experiencing IC). Thus, PAD is a progressive disorder that leads to a significant decline in quality of life.

COEXISTING VASCULAR DISEASE

The most important fact regarding the diagnosis and management of PAD is that PAD is a powerful, independent predictor of mortality (Criqui et al., 1992). IC and CLI can have a significant impact on quality of life. Many patients may accept their physical limitations as a consequence of aging and tolerate this morbidity. Fewer than 5% of patients with IC will ever progress to amputation. Much more significant, however, is that PAD is a systemic disorder, and it has considerable overlap with CAD and cerebrovascular disease, ultimately leading to an increase in mortality. Approximately 40% of patients with atherosclerotic vascular disease manifest symptoms in more than one vascular bed (Figure 27-24) (Ness and Aronow, 1999). Compared with people without PAD, patients with PAD have an approximately fourfold higher likelihood of having an MI (Criqui et al., 1992), and a two- to threefold higher likelihood of having a stroke (Wilterdink and Easton, 1992). The all-cause mortality rate in patients with PAD is approximately equal between men and women and is elevated even in asymptomatic patients (Hiatt, 2001). The lower the ABI is, the greater the risk for cardiovascular events. Patients with CLI, who typically have the lowest ABIs, have an annual

Figure 27-24 Overlap of atherosclerotic disease. Patients often manifest symptoms in more than one vascular bed. (Modified from Ness J, Aronow WS. Prevalence of coexistence of coronary artery disease, ischemic stroke, and peripheral arterial disease in older persons, mean age 80 years, in an academic hospital-based geriatrics practice. *J Am Geriatr Soc.* 1999;47:1255-1258.)

mortality rate of 25% (Dormandy et al., 1999; McKenna et al., 1991; Vogt et al., 1993b).

DIAGNOSIS

A thorough history and physical examination can accurately suggest a diagnosis of PAD 80% to 90% of the time.

History

The vast majority of disorders related to the peripheral vascular system are (1) atherosclerosis involving the arterial tree or (2) thrombophlebitis involving the venous circulation, both predominantly affecting the lower extremities more so than the upper extremities or viscera. Patients with suspected vascular disease typically present for evaluation with (1) varying types of limb pain or discomfort, (2) ulcerations or gangrene of the extremities, or (3) swelling of the affected limb.

The majority of limb pain or discomfort typically falls into three etiologies: (1) vascular, (2) musculoskeletal, or (3) neuropathic. The majority of limb swelling is caused by (1) venous obstruction or insufficiency; (2) increased venous pressure, such as HF; (3) decreased oncotic pressure, such as hypoproteinemia or hypoalbuminemia; (4) lymphedema; or (5) lipoedema. Many patients, particularly elderly patients, have multifactorial etiologies of pain or swelling, which can usually be distinguished by a thorough history and physical examination. Using a systematic approach with key pointed questions, a presumptive diagnosis can often be deduced on clinical grounds and subsequently confirmed with noninvasive testing. The history should focus on identifying risk factors for atherosclerosis. The past medical history should concentrate on prior vascular events such as MI; stroke; amputation; deep vein thrombosis; and revascularizations in any vascular bed, either percutaneously or surgically, as well as, but not limited to, a history of HF; back problems; osteoarthritis; inflammatory conditions such as rheumatoid arthritis, plantar fasciitis, or polymyalgia rheumatica; gout; varicose veins; and lymphatic obstruction, such as that after surgery or radiation therapy.

The cause of leg pain can be determined by the characteristics, severity, location, duration, frequency, and precipitating or alleviating factors of the discomfort. Claudication is typically described as a cramping or aching discomfort in the muscle associated with exertion and alleviated with rest. Most often this occurs in the calf, but it can also occur in the hip and buttocks if there is occlusive disease in the aortoiliac segment. Nocturnal cramping of the calf and foot is not typically vascular in etiology and is most likely caused by an exaggerated neuromuscular response to stretch that occurs while sleeping.

Critical limb ischemia can cause resting pain that is constant throughout the day and night. Nocturnal pain from CLI is a moderate to severe aching paresthesia or dysesthesia while lying horizontal that is alleviated by dangling the leg over the side of the bed. Pain from CLI can be so severe that it may not be relieved by narcotic analgesia. On the other hand, patients with diabetes with severe peripheral neuropathy may be completely insensate despite significant tissue loss. Distinguishing the etiology of constant resting limb pain between a vascular and nonvascular etiology can be done by physical examination and noninvasive testing. Pain that occurs at rest may be caused by CLI if there are other findings in the history and physical examination that support the diagnosis of advanced atherosclerosis. Otherwise, pain that occurs at rest, with change in position, or simply standing without exertion is more typically musculoskeletal or neuropathic in nature. Tables 27-22 and 27-23 list the distinguishing features and differential diagnosis of the most common types of leg pain and swelling, respectively.

For example, acute loss of motor or sensory function in the distal extremities, particularly with associated acute severe pain, pallor, and coolness of the limb, is a sign of acute arterial occlusion. However, chronic motor or sensory loss may be vascular in etiology but more likely is neuropathic. Several standardized classification schemes exist for categorizing the severity of both acute and chronic limb ischemia. Table 27-24 is the revised Rutherford-Becker classification for acute limb ischemia and Table 27-25 is the combined Fontaine classification, which is more popular in Europe, and the Rutherford-Becker scheme for chronic limb ischemia (Dormandy and Rutherford, 2000; Rutherford et al., 1997).

Physical Examination

The physical examination in patients with PAD should consist of inspection, palpation, auscultation, and even percussion. Observations should note any asymmetry between the limbs, joint deformities, varicose veins, skin discoloration, absence of hair, swelling, ulcerations, tissue loss, and gangrene. Acute CLI from embolism or thrombosis typically causes pallor with decreased capillary refill that eventually leads to mottling unless adequate collateral flow can be recruited. Patients with chronic ischemia may have a normal skin color with relatively normal or slightly delayed capillary refill, particularly if collateral flow has developed. Chronic advanced CLI can lead to dependent rubor caused by chronic dilation of the postcapillary venules. The toes of the dependent limbs can become red with brisk capillary refill. This is often mistaken for hyperemia rather than a sign of severe ischemia. A cadaveric pallor on elevating the

Table 27-22 Differential Diagnosis of Claudication

Diagnosis	Location of Discomfort	Characteristic of Discomfort	Onset Relative to Exertion	Onset Relative to Standing	Effect of Rest	Effect of Body Position	Miscellaneous Characteristics
Arterial claudication	Depends on level of stenosis or occlusion: aortoiliac disease affects hip, thigh, or buttock or can affect the entire limb; infrainguinal disease affects the calf and foot	Aching, cramping, weakness	Consistently reproduced with same degree of activity	Unrelated to standing	Relieved promptly	None	Gradual onset of discomfort with exercise Very reproducible
Venous claudication	Entire limb; usually worse in thigh and groin	Tight, tense sensation	After exercise	Unrelated to standing	Relieved slowly	Relieved more quickly with elevation	History of DVT, edema, or venous congestion
Chronic critical limb ischemia	Always involves foot; symptoms may be more proximal with more proximal disease	Severe burning, aching but may be asymptomatic in patients with profound neuropathy	Worse with minimal activity	Unrelated to standing	Improved but incompletely	Symptoms may be improved with dangling foot over side of bed while sleeping	Gradual or subacute onset Dependent on rubor Elevation pallor Gangrene
Acute critical limb ischemia	Always involves foot; symptoms may be more proximal with more proximal disease	Severe aching, cramping, painful	Worse with minimal activity	Unrelated to standing	Improved but incompletely	Symptoms may be improved with dangling foot over side of bed while sleeping	Acute onset Pale, cold Loss of motor or sensory function is an emergency
Arthritis	Joints	Aching; may be sharp with position change	Variable	Weight bearing reproduces pain	Variable; may be present at rest	Less pain in non-weight-bearing position	Variable; may be related to weather May have effusion
Lumbar back pain (e.g., herniated disc, nerve root compression)	Lumbar region; may radiate down dermatomes if there is nerve root compression	Sharp, stabbing, shooting	Immediate	Weight bearing reproduces pain	Variable; may be present at rest	Certain positions exacerbate or alleviate pain	History of back problems Worse with lifting May have motor or sensory deficits
Sacroiliitis	Sacroiliac region	Sharp, stabbing, shooting	Immediate	Weight bearing reproduces pain	Variable; may be present at rest	Certain positions exacerbate or alleviate pain	Reproducible with percussion Inflammatory disorder Reproducible with palpation
Plantar fasciitis	Plantar region	Sharp, stabbing, searing	Immediate	Weight bearing reproduces pain	Immediate relief with non-weight bearing	Less pain in non-weight-bearing position	Reproducible with palpation
Peripheral neuropathy	Stocking glove distribution	Paresthesia, dysesthesia; may be quite severe	Unrelated to activity	Unrelated to standing	Usually a constant sensation, unrelated to rest	Unrelated to change in position	Common in people with diabetes Present 24 hr a day; may interrupt sleep
Myopathy	In the muscle groups, may be systemic	Dull, aching, weakness	Immediate	Variable	Improved with less physical activity	May exacerbate discomfort	Reproducible with palpation Statin myopathy common Inflammatory disorders are rare

DVT, Deep vein thrombosis.

Table 27-23 Differential Diagnosis of Chronic Leg Swelling

Clinical Feature	Venous	Lymphatic	Cardiac Orthostatic	"Lipedema"
Consistency of swelling	Brawny	Spongy	Pitting	Noncompressible (fat)
Relief by elevation	Complete	Mild	Complete	Minimal
Distribution of swelling	Maximal in ankles and legs; feet spared	Diffuse; greatest distally	Diffuse; greatest distally	Maximal in ankles and legs; feet spared
Associated skin changes	Atrophic and pigmented, subcutaneous fibrosis	Hypertrophic, lichenified skin	Shiny, mild pigmentation, no trophic changes	None
Pain	Heavy, ache, tight or bursting	None or heavy ache	Little or none	Dull ache, cutaneous sensitivity
Bilaterality	Occasionally but usually unequal	Occasionally but usually unequal	Always but may be unequal	Always

limb to greater than 45 degrees above the horizontal for 1 to 2 minutes followed by slow venous filling with rubor after returning to a dependent position (Buerger sign) is also a sign of advanced CLI.

Ulcerations may be caused by chronic venous insufficiency or edema or arterial insufficiency. Chronic venous disease typically causes pigmentation of the lower legs due to extravasation of red blood cells with superficial ulcers in the calves, more often medially than laterally. Arterial ulcerations are characteristically distal, involving the toes and even forefoot in advanced disease.

Palpation of the pedal pulses should be a mandatory part of the routine physical examination. It should be noted that even in healthy individuals, the dorsalis pedis (DP) pulse, the posterior tibial (PT) pulse, or both are unable to be palpated 8.1%, 2.9%, and 0.7% of the time, respectively (McGee and Boyko, 1998). This is because of normal anatomic variations. Wide and prominent femoral or popliteal

pulses may be a sign of an aneurysm. A significant temperature gradient from proximal to distal and between ipsilateral and contralateral limbs often is a sign of advanced disease. The abdomen should be palpated to assess for the presence of an abdominal aortic aneurysm (AAA). Reproduction of pain with palpation over joints is not due to vascular disease and is thought to be a sign of such orthopedic conditions as degenerative joint disease, sacroiliitis, gout, trauma, or plantar fasciitis. Reproduction of pain with palpation of muscle groups may be vascular in etiology if there is severe ischemia, but one should also consider other causes of myopathy such as fibromyalgia, polymyalgia rheumatica, drug-induced myalgia, and trauma.

The carotid arteries, abdomen, and femoral arteries should be auscultated for bruits. Only gentle pressure should be applied with the stethoscope over the carotid and femoral arteries because pseudobruits can be created

by compression of the underlying vessel. Finally, percussion over the lumbar spine may be useful in eliciting pain caused by sacroiliitis, lumbar disk disease, or nerve root compression.

Noninvasive Testing

Noninvasive vascular testing is useful to confirm clinical suspicion of PAD in patients with leg discomfort or screen asymptomatic patients who are at risk for vascular disease, particularly individuals with diabetes. Noninvasive testing is also very helpful for the surveillance of vessel patency after percutaneous or surgical intervention.

Noninvasive Vascular Study. A complete noninvasive vascular study (NIVS) consists of the ABI, segmental BPs, and pulse-volume recordings (PVRs) obtained at rest. When physically possible, the ABIs should also be ordered with exercise to assess for an ischemic response. A normal NIVS is shown in [Figure 27-25](#).

The ABI is defined as the highest SBP of either the DP artery or PT artery divided by the higher of the SBP from either the right or left brachial artery. Segmental BPs provide more specific information as to the location of the stenosis or obstruction. BP readings are obtained at the high thigh, low thigh, calf, ankle, metatarsal, and toe level, specifically looking for pressure gradients proximally to distally. PVRs are plethysmographic measurements that detect changes in the blood volume flowing through the limb. A normal PVR tracing resembles a normal arterial pulse wave tracing with a rapid upstroke, prominent dicrotic notch, and rapid down stroke. As the severity of the disease increases, the waveforms become more blunted, the dicrotic notch disappears, and ultimately the waveforms become flat.

The standard exercise protocol of Rutherford (walking on a treadmill for 5 minutes at 2 mph at a 12% grade) ([Rutherford et al., 1997](#)) is quite modest compared with the workload involved in a routine Bruce protocol that is typically used for cardiac stress testing. The purpose of the Rutherford protocol is not to induce coronary ischemia and thus is typically well tolerated from a cardiopulmonary standpoint. Relative contraindications to walking on a treadmill include severe symptomatic CAD (i.e., Canadian Cardiovascular Society class 3 or 4), severe decompensated CHF (i.e., New York Heart Association class 3 or 4), severe symptomatic COPD, orthopedic or balance disorders that preclude safe ambulation on a treadmill, or severely depressed resting ABIs (i.e., ABI < 0.5). If patients are unable to walk on a treadmill, then other means of exercise may suffice, such as stationary bicycling, walking in the hallway, or toe lifts. However, these alternative forms of exercise are not standardized and may impact the diagnostic sensitivity and specificity of the study.

Commonly, patients with mild PAD may have an ABI that is actually normal at rest yet may be significantly decreased with exercise, as shown in [Figure 27-26](#). In fact, comparing angiography, which is the gold standard for diagnosing PAD, with ABIs, there actually needs to be a rather severe single stenosis or moderate diffuse multilevel disease to have a depression in the resting ABI. Even a mildly depressed resting ABI implies that there is a considerable burden of disease. Therefore, ABIs that are done at rest only and not

with exercise will have a relatively high false-negative rate, and many patients with a normal resting ABI will be misdiagnosed as having nonvascular limb pain when indeed the true etiology of their discomfort is PAD. A corollary to this is that many epidemiologic studies use only resting ABIs as a diagnostic criteria for PAD, which leads to underestimation of the true incidence of PAD. It should be noted, however, that a recent update of the 2005 U.S. Preventive Services Task Force (USPSTF) recommendation on screening for PAD concluded that the current evidence does not support the use of resting ABI as a sole screening method in asymptomatic, unselected patients with no known PAD, CAD, severe CKD, or diabetes ([Moyer, 2013](#)).

Another potential pitfall of ABIs is vascular calcification. Severe calcification of the arterial wall eventually leads to an inability to compress the blood vessels despite cuffs inflated to suprasystolic pressures. Consequently, ABIs can be falsely elevated, and caution should be used in interpreting an ABI greater than 1.4. This is particularly common in patients with diabetes and patients on chronic hemodialysis. In this instance, the toe-brachial index has been established as an adequate surrogate to the ABI ([Sahli et al., 2004](#)).

A NIVS can provide a general region (e.g., the femoropopliteal segment) that is diseased. Yet a NIVS is not precise enough to determine the exact location of the stenosis or occlusion. In other words, a NIVS provides physiologic information with limited anatomic localization of disease. Arterial duplex Doppler ultrasonography, computed tomography angiography (CTA), and magnetic resonance angiography (MRA) are studies that are more suited to provide detailed anatomic information and complement the data obtained with a NIVS.

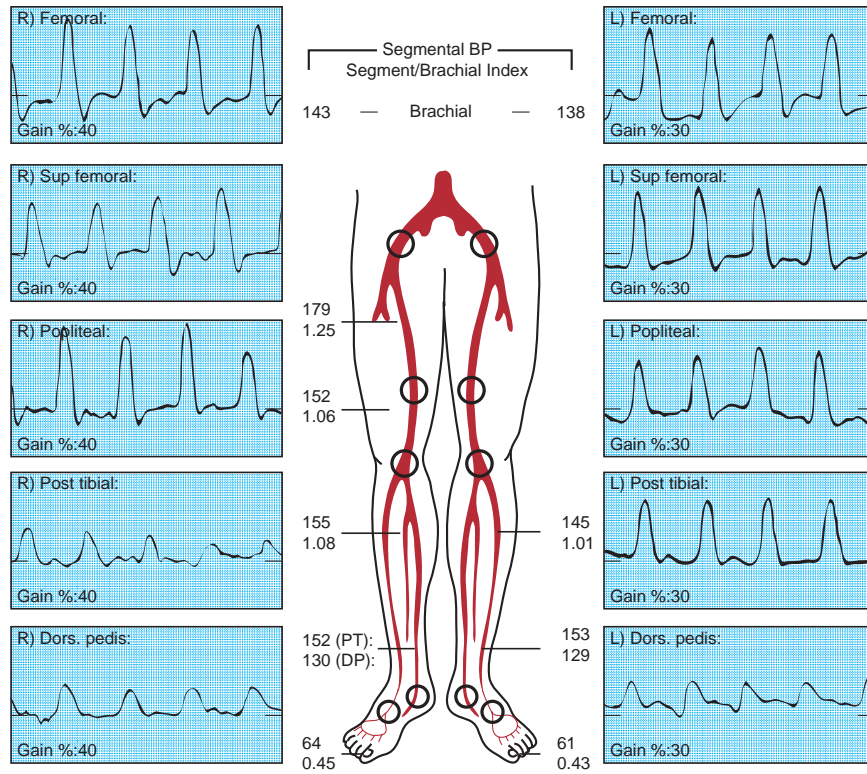

Doppler Ultrasonography. Arterial duplex Doppler ultrasonography uses high-frequency sound waves, typically in the 5.0- to 7.5-MHz range, to provide real-time vascular images that can accurately localize atherosclerotic disease. Color-flow encoding is useful to quickly localize vessels and determine the presence or absence of blood flow. Doppler technology uses the physical principles of the reflected sound wave frequency in relation to the transmitted frequency to determine the velocity of blood flow. As the severity of stenosis increases, the PSV of flow increases. By using established criteria of the absolute PSV and the ratio of PSV in the proximal normal reference segment compared with the PSV in the diseased segment, the overall range of stenosis can be determined. A peak systolic velocity ratio (PSVR) of 2.4 or higher is considered indicative of obstructive disease. A PSVR of 3.0 or higher is likely to indicate functionally significant obstruction.

Ultrasonography is particularly useful for assessing stent or graft patency after a revascularization procedure. Potential pitfalls of ultrasonography include visualizing the tibial vessels, which are relatively small and deep in the calf, as well as visualizing highly calcified vessels, which are acoustically shadowed by the calcium.

Computed Tomography and Magnetic Resonance Angiography. Computed tomographic angiography (CTA) and MRA are noninvasive imaging modalities that have essentially replaced traditional invasive diagnostic

Figure 27-26 Normal noninvasive vascular study at rest. The right ankle-brachial index (ABI) is 0.93, and the left ABI is 1.09. However, there is a marked ischemic response to exercise. Note the pronounced drop of the red and blue lines with exercise and the severe drop of the right ABI to 0.14 and the left ABI to 0.49. This patient had bilateral, focal, 95% to 99% stenoses in the superficial femoral arteries, which were successfully stented. This example clearly demonstrates the importance of obtaining ABIs at rest and with exercise. Failure to obtain ABIs with exercise, particularly when the resting values are normal, often fails to diagnose the disease. BP, Blood pressure.

angiography. Both CTA and MRA produce similarly accurate anatomic information and provide highly detailed images that can be used to plan revascularization procedures, assess the size and location of aneurysms, and occasionally find incidental pathology such as occult malignancy. These two technologies are fundamentally very different.

Traditional CT has evolved by the addition of multiple detectors, now up to 320 slices per machine. Multidetector CT allows much shorter acquisition times and submillimeter resolution; thus, an entire body scan can be performed in seconds to minutes with excellent spatial resolution. By adding three-dimensional reconstruction software, the bone, soft tissue, and organs can be virtually removed and the vasculature reconstructed and viewed from multiple projections. An example of a normal and abnormal CTA is shown in Figure 27-27.

CTA uses ionizing radiation and iodinated contrast. Therefore, multiple scans (because of accumulative radiation dose) and renal insufficiency are relative contraindications to CTA. Other limitations in CTA imaging include severe vascular calcifications and prosthetic joints, which cause scatter artifact. The lumen of a stented vessel can be visualized with CTA, although there will be a mild to moderate degree of scatter artifact that makes accurate assessment of in-stent restenosis difficult.

Traditional MRI has also evolved through the development of more powerful magnets and improved scanning algorithms. Similar to CTA, MRA can produce

submillimeter spatial resolution. In contrast to CTA, the scanning time for MRA can be up to 1 hour per patient. In a busy practice or hospital, this can lead to problems with patient throughput. Software can also reconstruct MRA images into three dimensions.

MRA uses magnetic fields and variable frequency radio-waves to detect changes in alignment and distribution of protons in a given tissue. The obvious advantage over CTA is that MRA does not use ionizing radiation or iodinated contrast. Thus, there is practically no risk of stochastic injury or iodine contrast nephropathy. However, MRA often uses gadolinium-based contrast, a paramagnetic metal ion, to provide an improved image of body organs, tissues, and blood vessels. Nephrogenic systemic fibrosis has been reported with gadolinium-based contrast, which is listed as a boxed warning to the label of these agents. Although gadolinium is not FDA approved for MRA (only approved for MRI), it is often used by radiologists for better visualization of the blood vessels. MRA can be performed without gadolinium, and the ordering provider may want to specify avoiding this contrast, particularly in patients with renal insufficiency. Patients with pacemakers or defibrillators cannot undergo MRA because the magnet can interfere with device function. Recently, MRA-compatible pacemakers have become available. Finally, severely calcified vessels can be adequately imaged with MRA, but stents appear as voids and thus falsely give the impression of a totally occluded artery even if the stent is widely patent.

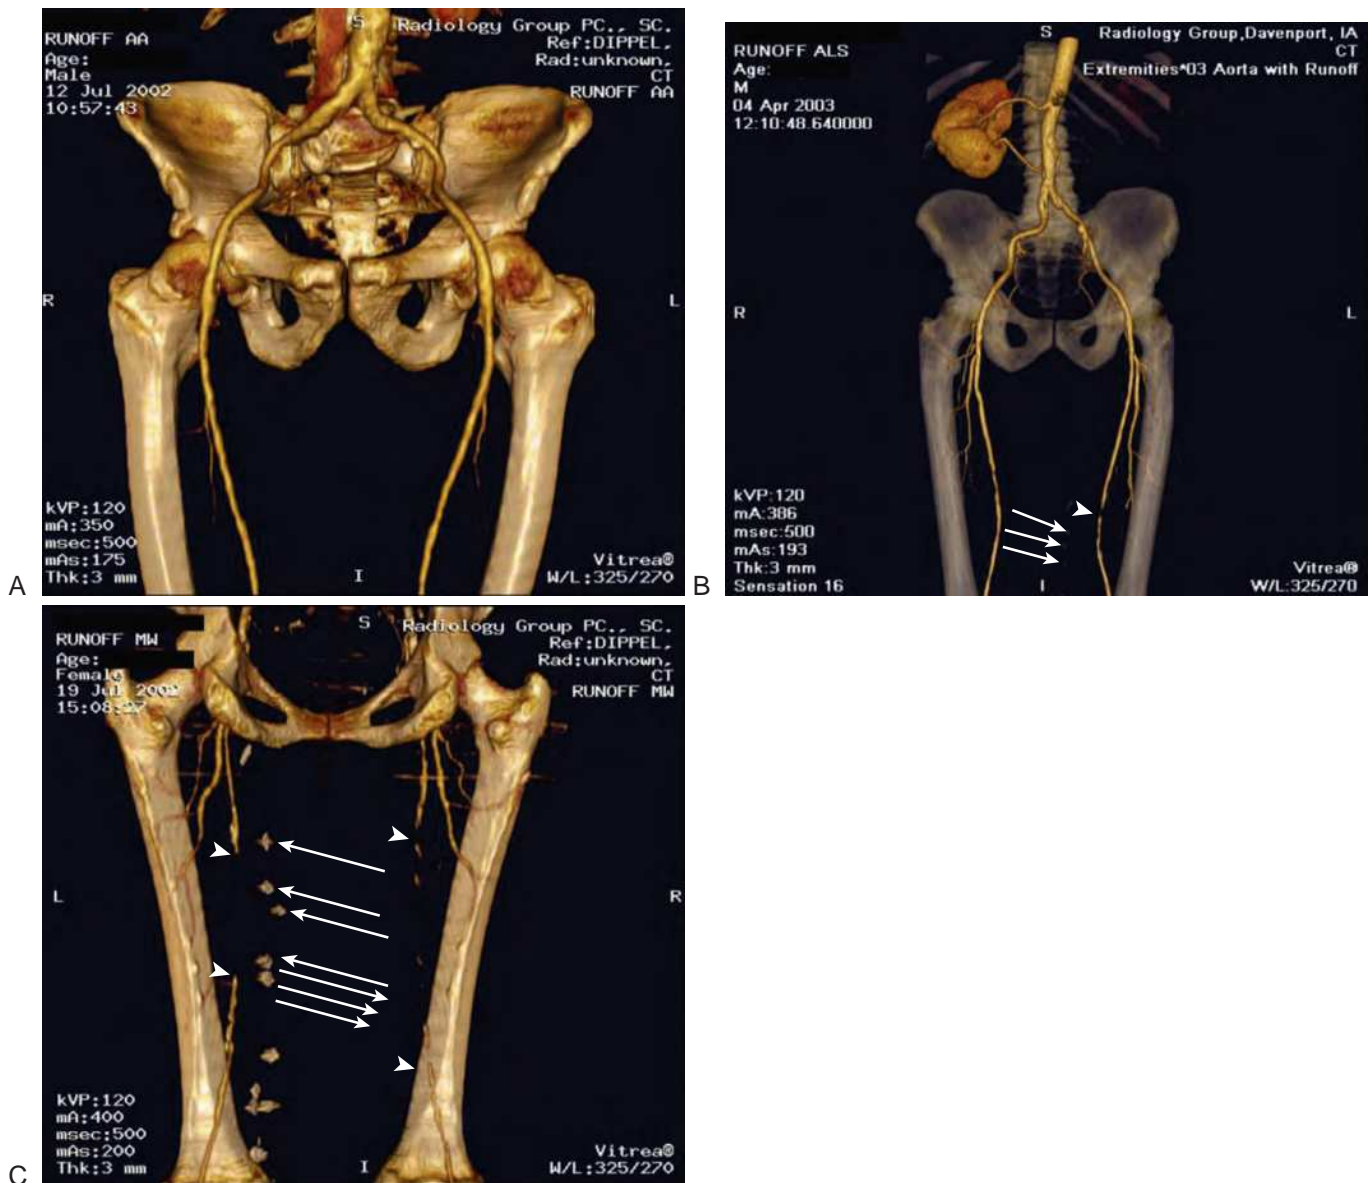

Figure 27-27 **A**, Anteroposterior (AP) view of a multidetector computed tomography angiogram (CTA) reconstructed with three-dimensional imaging software. This image shows the distal aorta, iliac arteries, common femoral arteries, and proximal superficial femoral arteries. There are minimal plaques in the distal aorta, common iliac arteries, and superficial femoral arteries. **B**, AP view of a multidetector CTA demonstrating a short total occlusion of the distal left superficial femoral artery (*arrowhead*). Note surgical clips from prior saphenous vein harvest (*arrows*). Note absence of the left kidney. **C**, Posterior view of a multidetector CTA demonstrating a long total occlusion of superficial femoral arteries (between *arrowheads*). These were successfully stented. Again, note vascular clips from prior saphenous vein harvest (*arrows*).

The false-positive rate for detecting a hemodynamically significant stenosis is considerably higher with MRA than CTA. With CTA, the lumen of the vessel that is visualized is essentially a column of contrast; thus, a precise assessment of the degree of stenosis is usually possible. However, MRA technology requires flow through the vessel to determine where the lumen exists. The pitfall occurs when the vessel runs through the same plane as the frequency of the radio-wave. This leads to flow voids, which appear as gaps in the vessel and are frequently overdiagnosed as stenoses. This phenomenon is particularly common at the origin of the renal arteries and throughout the tortuosity of the carotid arteries.

Invasive Imaging

Traditional invasive diagnostic angiography has been the gold standard for diagnosing PAD since the 1950s. This technique involves the percutaneous placement of catheters within the vessel, injecting iodinated contrast through the catheters, and recording fluoroscopic and cineographic images. Similar to CTA, conventional angiography uses ionizing radiation, and the same relative risks apply. The potential complications include vascular access site injury, pseudoaneurysm or arteriovenous fistula formation, bleeding, dissection, and atheroembolization. For these reasons, angiography is mostly reserved for patients in whom a revascularization procedure is anticipated.

THERAPY

Therapy for PAD should involve a patient care plan consisting of (1) patient education as to the pathophysiology of atherosclerosis, the risk factors that contribute to the disease, and the prognosis of the condition; (2) encouragement of lifestyle changes that emphasize risk factor modification and routine exercise; (3) pharmacologic therapy both for the relief of symptoms and treatment of risk factors; and (4) revascularization procedures to relieve IC and limb salvage in the case of CLI. The goals of therapy are to (1) improve the patient's functional status by relieving symptoms, improving the quality of life, and improving exercise capacity; (2) preserve the limb via revascularization and decrease or limit the extent of amputation; (3) prevent the progression of atherosclerosis by aggressive risk factor modification; and (4) reduce cardiovascular and cerebrovascular mortality and nonfatal events such as MI and stroke.

Risk Factor Management

The most important therapy for prevention of PAD is aggressive management of the risk factors for atherosclerosis. Both the AHA and the NCEP recommend the same level of risk factor modification in patients with PAD as in patients with known CAD (Grundy et al., 2004c; Smith et al., 2001). Despite the growing recognition that PAD is associated with a higher mortality rate, the risk factors in patients with PAD have historically been grossly undertreated. This is exemplified by data from Rehring et al. (2005), who reported on a cohort of 1733 patients with known PAD and no overt CAD. Of these patients, only 33.1% were receiving β -blockade therapy, 28.9% were receiving ACE inhibitors, and 31.3% were treated with a statin. Furthermore, 92% had a recent BP measurement, but 56% had a SBP greater than 130 mm Hg, 45.5% had a DBP greater than 80 mm Hg, and 13.6% had a DBP greater than 90 mm Hg. In addition, only 62.6% had a screening lipid profile, yet 56% had an LDL-C greater than 100 mg/dL and 21% had an LDL-C greater than 130 mg/dL. Finally, in patients with diabetes, HbA_{1c} was greater than 7.0% in 54.2% of patients (Rehring et al., 2005). Current practice patterns should markedly improve on these statistics. The risk factors of atherosclerosis must be aggressively identified and treated to reduce the risk for disease progression.

Exercise

Routine aerobic exercise is recommended for all patients with PAD. The benefit of walking programs has been clearly established to increase time to claudication and maximal walking distance (Hiatt and Regensteiner, 1990; Hiatt et al., 1994). Regular exercise has a strong impact on improving functional capacity and quality of life. A minimum of 30 to 45 minutes of exercise is recommended preferably daily but at least three times per week. This should be supplemented by an increase in daily lifestyle activities, such as walking breaks at lunch, gardening, or household chores (Smith et al., 2001).

Weight Management

Obesity is at epidemic levels, which ultimately contributes to the progression of atherosclerosis. Patients should be

counseled on weight loss strategies with a target BMI of 18.5 to 24.9 kg/m² (Smith et al., 2001).

Pharmacologic Therapy

Pharmacologic treatment can be divided into two separate but important components: (1) therapy for the control of risk factors and (2) therapy for the relief of symptoms of ischemia or claudication.

Pharmacologic therapy for risk factor modification is the same as for any other forms of atherosclerotic vascular disease, such as coronary or cerebrovascular disease. The most important thing to keep in mind is that the mortality rate of patients with PAD is high; thus, these patients should be treated aggressively. Current national guidelines exist and should be adhered to for the primary and secondary prevention of atherosclerotic vascular disease (American Diabetes Association, 2005; Grundy et al., 2004c; The Seventh Report, 2004; Smith et al., 2001). The four primary categories of pharmacologic therapy are (1) antiplatelet therapy, (2) lipid-lowering therapy, (3) antihypertensive therapy, and (4) glycemic control. Specific therapies and therapeutic targets are listed elsewhere in this chapter. It should be kept in mind that these therapies are complementary and confer additive benefit. From a practical standpoint, patients with several comorbidities can end up taking multiple medications a day, and thus to ensure compliance, the patients should be repeatedly educated as to the importance of risk factor control.

The only FDA-approved pharmacologic therapy that has a consensus of benefit for the relief of claudication is cilostazol. Cilostazol is a phosphodiesterase III inhibitor, which increases the intracellular concentration of cAMP (cyclic adenosine monophosphate), leading to significant antiplatelet and vasodilatory properties and possibly antiproliferative properties (Tsuchikane et al., 1999). Cilostazol undergoes extensive metabolism by the hepatic cytochrome P450_{3A4} (CYP3A4) isoform enzyme and to a lesser extent the 2C19 and 1A2 isoforms. Although cilostazol does not inhibit the CYP450 system, drugs that inhibit CYP3A4, CYP2C19, and CYP1A2 can lead to increased levels of cilostazol in serum.

Pentoxifylline is another drug that was approved by the FDA for claudication in 1984. However, no randomized data demonstrate it to be any better than placebo. Therefore, there is no recommendation to use this agent for the treatment of claudication.

There have been eight randomized trials comparing cilostazol with placebo and pentoxifylline (Smith, 2002). In all eight studies, cilostazol demonstrated a statistically significant improvement in objective and subjective end points compared with placebo. In one study comparing cilostazol 100 mg twice a day with pentoxifylline 400 mg three times a day or placebo, the maximal walking distance on a treadmill increased by 54% from baseline in the cilostazol group compared with a 30% increase in the pentoxifylline group ($P < 0.001$) and a 34% increase in the placebo group (Figure 27-28) (Dawson et al., 2000).

Revascularization

Peripheral arterial revascularization is indicated for relief of ischemic symptoms, including IC and resting ischemic pain, and limb preservation in the setting of CLI. Historically,

Figure 27-28 Mean percentage change from baseline maximum walking distance on a treadmill for patients with intermittent claudication randomly assigned to cilostazol, pentoxifylline, or placebo. Asterisk indicates $P < 0.05$ at each 4-week point for cilostazol versus placebo and pentoxifylline. (Reprinted with permission from Excerpta Medica. Dawson DL, Cutler BS, Hiatt WR, et al. A Comparison of cilostazol and pentoxifylline for treating intermittent claudication. *Am J Med.* 2000;109:523-530.)

Figure 27-29 Volume trends for percutaneous revascularization and surgical revascularization for the lower extremities from 1980 through 2000. Data were obtained by reviewing *International Classification of Diseases*, edition 9, codes for all vascular procedures using the National Hospital Discharge Survey of nonfederal U.S. hospitals. (Modified from Anderson PL, Gelijns A, Moskowitz A, et al. Understanding trends in inpatient surgical volume: vascular interventions, 1980-2000. *J Vasc Surg.* 2004;39:1200-1208.)

revascularization has been performed surgically; however, with advances in endovascular technology, a percutaneous approach is now being performed as a first-line therapy. From 1995 to 2000, there was a nearly 1000% increase in the number of percutaneous revascularizations performed in the United States compared with approximately a 30% to 35% decrease in the number of surgical revascularizations (Figure 27-29) (Anderson et al., 2004).

An endovascular approach confers a similar acute procedural success rate with considerably less periprocedural morbidity, shorter recovery time, shorter hospitalization time, and less pain than a surgical procedure. On the other hand, restenosis by neointimal hyperplasia of an

endovascular procedure is a well-documented, slow process that occurs over weeks to months, and thus a higher rate of repeat revascularization is needed, particularly over an intermediate follow-up range. Surgery, on the other hand, carries a higher initial risk of morbidity and mortality, but a less frequent need for repeat revascularization is anticipated. Surgery, however, can only be repeated a limited number of times because dissection planes, surgical targets, and anastomosis sites become obliterated by repetitive surgery and conduit becomes exhausted. An endovascular procedure can be repeated as often as necessary to maintain vessel patency.

The attractiveness of a minimally invasive approach for revascularization is that it significantly lowers the threshold of when patients are treated. Because of the higher initial risk with surgery, the traditional surgical dogma has reserved revascularization until there is a limb-threatening situation. However, this leaves many patients left to face debilitating IC inadequately treated. Endovascular therapy offers a paradigm shift in this philosophy. Because it is safer, effective, and reproducible, patients can be treated earlier in the disease process when they are in the claudication stage, with significant improvement in their quality of life (Dippel et al., 2004). An example of an artery before and after an endovascular revascularization is shown in Figure 27-30.

There are approximately 150,000 to 200,000 nontraumatic amputations done annually (American Diabetes Association Fact Sheet, 2005). The alarming statistic is that 40% to 50% of limbs are amputated without doing an angiogram beforehand. It is estimated that more than 90% of these limbs could be salvaged or converted to a lesser amputation with revascularization. Another advantage of an endovascular approach over a surgical approach is that totally occluded arteries can be revascularized endovascularly with a high acute procedural success rate even when there are no distal targets available to bypass and surgery is not technically feasible. Therefore, it is recommended that patients with CLI or symptom-limiting claudication that is not adequately alleviated with medical therapy be referred for endovascular revascularization. If an endovascular approach is not viable, then surgical therapy should be considered as a second-line alternative.

CONCLUSIONS

Peripheral vascular disease is an underdiagnosed, under-treated, highly prevalent, age-dependent condition that is associated with a high mortality rate caused by cardiac and cerebrovascular events. PAD has a very strong negative impact on quality of life, and patients have a functional status similar to NYHA class 3 symptoms of CHF. Clinicians must be more diligent in diagnosing and treating PAD. The diagnosis consists of a goal-directed history and physical examination, noninvasive vascular studies, and CTA or MRA imaging. Therapy consists of routine exercise, smoking cessation, treating the appropriate risk factors to their target goals, and relief of ischemic symptoms either pharmacologically or via a revascularization procedure. Patients with CLI, with or without tissue loss, should be referred urgently for revascularization. An algorithm for management is shown in Figure 27-31.

Figure 27-30 **A**, Baseline angiogram of the right superficial femoral artery demonstrates a short, chronic total occlusion. **B**, Angiogram of the same artery 2 weeks after stent placement.

KEY DIAGNOSTIC TESTS

- “The resting ABI should be used to establish the lower extremity PAD diagnosis in patients with suspected lower extremity PAD, defined as individuals with 1 or more of the following: exertional leg symptoms, nonhealing wounds, age ≥ 65 years, or ≥ 50 years with a history of smoking or diabetes.” Also, “The toe-brachial index should be used to establish the lower extremity PAD diagnosis in patients in whom lower extremity PAD is clinically suspected but in whom the ABI test is not reliable due to noncompressible vessels” (Anderson et al., 2013) (SOR: A, ACC/AHA guidelines).
- “Duplex ultrasound of the extremities is useful to diagnose anatomic location and degree of stenosis of PAD. Duplex ultrasound is recommended for routine surveillance after femoral-popliteal or femoral-tibial-pedal bypass with a venous conduit. Minimum surveillance intervals are approximately 3, 6, and 12 months, and then yearly after graft placement” (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- “MRA of the extremities is useful to diagnose anatomic location and degree of stenosis of PAD. MRA of the extremities is useful in selecting patients with lower extremity PAD as candidates for endovascular intervention” (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).

KEY TREATMENT

- “Patients who are smokers or former smokers should be asked about status of tobacco use at every visit. Patients should be assisted with counseling and developing a plan for quitting that may include pharmacotherapy and/or referral to a smoking cessation program. In the absence of contraindication or other compelling clinical indication, 1 or more of the following pharmacological therapies should be offered: varenicline, bupropion, and nicotine replacement therapy” (Anderson et al., 2013) (SOR: A, ACC/AHA guidelines).
- “Antihypertensive therapy should be administered to hypertensive patients with lower extremity PAD to achieve a goal of less than 140 mm Hg systolic over 90 mm Hg diastolic (individuals without diabetes) or less than 130 mm Hg systolic over 80 mm Hg diastolic (individuals with diabetes and individuals with chronic renal disease) to reduce the risk of MI, stroke, CHF, and cardiovascular death. β -Adrenergic blocking drugs are effective antihypertensive agents and are not contraindicated in patients with PAD” (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- “A program of supervised exercise training is recommended as an initial treatment modality for patients with intermittent claudication. Supervised exercise training should be performed for a minimum of 30 to 45 minutes, in sessions performed at least 3 times per week for a minimum of 12 weeks” (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- “Antiplatelet therapy is indicated to reduce the risk of MI, stroke, and vascular death in individuals with symptomatic atherosclerotic lower extremity PAD, including those with intermittent claudication or CLI, prior lower

- extremity revascularization (endovascular or surgical), or prior amputation for lower extremity ischemia” (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- Patients should take aspirin 81 to 325 mg/day unless there is a contraindication to aspirin therapy such as active GI bleeding or a history of allergy to aspirin (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- Clopidogrel 75 mg/day can be used as an alternative to aspirin (SOR: A, ACC/AHA guidelines).
- Cilostazol (100 mg orally twice per day) is indicated as an effective therapy to improve symptoms and increase walking distance in patients with lower extremity PAD and IC (SOR: A, ACC/AHA guidelines) (Anderson et al., 2013).
- LDL-C should be lowered to less than 100 mg/dL, preferably to less than 70 mg/dL. A statin should be considered first-line pharmacologic therapy in addition to diet and exercise (SOR: A, ACC/AHA guidelines).
- In patients with CLI and an estimated life expectancy of more than 2 years, bypass surgery, when feasible, may be considered when an autogenous vein conduit is available (SOR: A, AHA/ACC guidelines) (Anderson et al., 2013).
- Patients should be referred for a revascularization procedure when an exercise program and cilostazol therapy fail to adequately alleviate ischemic symptoms (SOR: A, ACC/AHA guidelines).
- All patients with critical limb-threatening ischemia with or without tissue loss should be urgently referred for a revascularization procedure (SOR: A, ACC/AHA guidelines).

Aortic Disease

The aorta is subject to several histopathologies, including atherosclerotic, degenerative, genetic, and vasculitis or inflammatory (Hiratzka et al., 2010). Aneurysms of the aorta can be thoracic, abdominal, or both. Thoracic aortic aneurysms (TAAs) are caused by several factors, including (1) cystic medial degeneration, commonly seen in Marfan syndrome and affecting the root and ascending aorta; (2) genetic, mostly associated with bicuspid aortic valve, Turner syndrome, Ehlers-Danlos syndrome, or familial TAA; (3) atherosclerotic, more frequently seen in the abdominal aorta than the thoracic aorta; (4) inflammatory, as in giant cell aortitis and Takayasu arteritis; and (5) infectious, as in syphilitic aortitis and mycotic aneurysms.

Patients with TAA are generally asymptomatic, with the diagnosis made on a routine chest radiography or CT scan. They may also have aortic valve insufficiency, and the diagnosis becomes evident on an echocardiogram. Large TAAs can have a mass effect and cause dysphagia, cough, and hoarseness. However, they can also present acutely with dissection, intramural hematoma, and rupture. In general, the growth rate of the aneurysm becomes accelerated (0.79 cm/yr) when the size reaches more than 5.0 cm. With the exception of certain inherited disorders, repair of the TAA should be done when the size reaches 5.5 cm or larger or 6.5 cm or larger in high surgical risk patients. A rapid expansion of the TAA size, however (>0.5 cm/yr), severe valvular insufficiency, and the presence of symptoms

should warrant earlier repair. Repair of TAA is, however, advised at 4.5 to 5.0 cm in patients with Marfan syndrome (women with Marfan syndrome contemplating pregnancy should have their ascending aortas repaired when they exceed 4 cm), 5.0 to 5.5 cm in patients with bicuspid aortic valve or familial TAA, and 4.4 to 4.6 cm in patients with Loeys-Dietz syndrome. Patients with TAA should be treated with β -blockers as the mainstay of therapy to keep their BP at 110 to 125 mm Hg systolic and heart rate at 50 to 60 beats/min. ARBs are also important in patients with Marfan syndrome (Hiratzka et al., 2010).

Patients with TAA should be followed with an MRA or CTA at the time of diagnosis and then repeated in 6 months. If the size remains stable, then yearly CT or MRA is indicated. In certain genetic disorders such as Loeys-Dietz syndrome, complete imaging of the aorta (ascending, descending, and abdominal) is indicated. Echocardiography should also be performed at least once yearly in patients with TAA. More frequent testing is indicated if the size of the TAA has progressed rapidly (Hiratzka et al., 2010).

Abdominal aortic aneurysm is more prevalent in men. Risk factors include older age, family history of AAA, atherosclerosis, and smoking (Lederle et al., 2000). Predictors of AAA rupture at 3 years of follow-up were female sex, larger initial aneurysm diameter, lower forced expiratory volume in 1 second (FEV₁), current smoking, and higher mean BP (Brown et al., 1999). The USPSTF recommends one-time ultrasound screening of men who have ever smoked and are older than the age of 65 or men older than the age of 60 years with siblings or parents with AAA. Currently, it is recommended that in an average-sized man, a diameter of 5.5 cm or larger is a reasonable target for repair unless preceded by a rapid change in size on follow-up. For women, a threshold of 4.5 to 5.0 cm is appropriate. Monitoring of the aneurysm should be done on a 6-month to yearly basis. Repair can be surgical or endovascular based on several factors, including location and size of the aneurysm, aortic size and tortuosity, surgical risk, and patient's preference.

Acute aortic syndromes are caused by several factors, including a rapidly expanding aortic aneurysm, aortic dissection, intramural hematoma, penetrating atherosclerosis ulcer, or trauma. Aortic dissection is the classic presentation. Predictors of aortic dissection include advanced age, HTN, male gender, history of aortic aneurysm, iatrogenic during angiography or cardiac surgery, pregnancy, or in association with bicuspid valve or Marfan syndrome. This condition is life threatening and is an emergency. Death generally occurs at 1% to 2% per hour. An abrupt onset of severe chest or interscapular tearing or stabbing pain should raise suspicion for aortic dissection, particularly in patients with the described risk factors. CTA can provide an accurate diagnosis of this condition. Aortic dissections involving the ascending aorta or the arch (Stanford type A) are surgical emergencies, but those extending distal to the left subclavian artery (Stanford type B) may be handled medically if no organ compromise, rupture or impending rupture, or intractable pain is present. The mainstay of treatment is β -blockers and IV vasodilators with avoidance of cardiac catheterization and pericardiocentesis for cardiac tamponade. Survivors of acute aortic dissection should be followed closely as outpatients with serial imaging of the

aorta (1, 3, and 6 months after discharge and then one or two times per year). BP control and aggressive preventive risk factor modification are strongly indicated.

Peripheral Venous Disease

Venous disease is highly prevalent, with more than 25 million people in the United States being affected (Brand et al., 1988). It is estimated that it costs more than 2 million work days and a cost of \$1.4 billion dollars annually to treat. It is estimated that 5% or fewer of patients seek medical attention, the majority of whom have significant venous reflux disease. The incidence of venous reflux disease is higher in women than men irrespective of age. Also, with increasing age, both men and women have a higher incidence of chronic venous insufficiency. Besides age and gender, there are several other risk factors for venous insufficiency, including heredity, obesity, standing occupation, sedentary lifestyle, and prior injury or surgery. The great saphenous vein and its tributaries, the small saphenous vein or perforator veins, are likely to be the culprit in chronic venous insufficiency. These are initially treated with compression stockings, exercise, and weight loss or with non-surgical ablative methods (radiofrequency or laser). The deep venous system may also have significant reflux, but its treatment is limited to conservative management.

Venous insufficiency may result from overdistention of the veins or actual damage to the venous valve. This leads to an inability of the valves to close properly, leading to blood pooling in the lower legs, venous HTN, edema, pain, itching, heaviness, restless legs, skin hyperpigmentation, and eventually ulcerations. These classic findings are worse as the day progresses and improve in the early hours of the morning when the feet are elevated in bed. Two-thirds of patients also have improvement in symptoms with graded compression stockings, exercise, and weight loss, which are important initial conservative therapies.

A primary care physician needs to obtain a thorough history, including the location and frequency of symptoms; history of deep vein thrombosis or trauma; gynecologic and obstetric history; family history of venous insufficiency or clotting disorder; prior treatment with medications, sclerotherapy, ablation, or surgical stripping; symptoms of itching; involuntary movement of the legs; ulcerations or hyperpigmentation, particularly over the shins or medial aspect of the ankles; change of symptoms with leg elevation or compression stockings; claudication with ambulation; and presence of varicosities. In addition, the legs need to be physically inspected for venous stasis, hyperpigmentation, lower extremity pulses, auscultation over the veins to rule out arteriovenous fistula, varicosities, dermatitis, ulcerations, pitting edema, presence of cords or lipodermatosclerosis, unilateral or bilateral swelling, and CEAP (clinical signs, etiologic classification, anatomic distribution, and pathophysiologic distribution) classification.

The CEAP classification is commonly used to describe the severity of venous disease. The etiologic classification is the most commonly used in an office practice and includes CEAP class 0, no visible or palpable signs of venous disease; CEAP class 1, telangiectasias or reticular veins; CEAP class 2, varicose veins; CEAP class 3, edema; CEAP class 4a and

4b, skin changes, including pigmentation and venous eczema or with lipodermatosclerosis; CEAP class 5, healed venous ulcer; and CEAP class 6, active venous ulcer. Also, photographic documentation of the legs before and after any treatment is advised.

Cardiac Electrophysiology and Arrhythmias

The accurate understanding and interpretation of ECGs, rhythm strips, and unusual cardiac beats is a rewarding practice. Understanding is based not only on recognition of patterns but also on the knowledge of electrical activation and repolarization of individual cells alone and in the aggregate. Anticipation of what should be happening will aid in determining what is happening during any particular beat. Appreciation of the history of electrophysiology and arrhythmology further aids in rhythm management. Through this understanding, accurate interpretation and treatment of arrhythmias in individuals can be made.

Normal cardiac cellular actions may include automaticity, rhythmicity, conductivity, and contractility. Specialized cardiac cells may perform one of these functions better than a prototypical myocyte, thus facilitating organ function. Clinical arrhythmias result from disorders of impulse formation, abnormal impulse conduction, or a combination of these events (Akhtar et al., 1988; Zipes and Jalife, 1990).

The correct action of all cardiac cells is dependent on a normally functioning cell membrane or sarcolemma. Similar to central and peripheral neurons, cardiac cells have bilayer cell membranes composed of phospholipid molecules with specialized channels or pores that function as a semipermeable membrane to a variety of molecules. Sodium (Na^+), potassium (K^+), calcium (Ca^{++}), chloride (Cl^-), and other ions move across the cell membrane in an organized fashion, resulting in depolarization of the cell from a resting electronegative state. Specialized structures along both the long axis and short axis of cardiac cells facilitate the coupling of mechanical and electrical action (Hoyt et al., 1989).

Two specialized electrical cell types with different permeability characteristics for Na^+ and Ca^{++} give rise to specialized action. Slow depolarizing and conducting calcium-dependent cells are more abundantly found in the sinus node and the AV junctional area. Rapidly depolarizing, fast-conducting sodium-dependent cells are more widespread and include atrial and ventricular myocytes and specialized His-Purkinje fibers as well as abnormal cardiac structures such as bypass tracts discussed later in this section. Medications, ischemia, injury, fibrosis, and external stimulation affect these cells differently, allowing for treatment and diagnosis of a variety of arrhythmias.

CARDIAC ANATOMY

The normal heart beat results from a series of electrical and mechanical actions that result in forward output of blood. Alterations in cardiac performance occur from changes in heart rate and contractility in response to variation in autonomic tone and metabolic stress. To carry this out, the heart has developed a specialized conduction system.

Sinus Node Complex

Arising in the right atrium in the superior septal aspect at the junction of the lateral margin of the superior vena cava with the right atrium and the atrial appendage, the sinoatrial (SA) node extends laterally into the crista terminalis (Schlant et al., 1994). The sinus node includes three types of cells: nodal cells, transitional cells, and atrial muscle cells. Impulse formation and rhythmicity in primates are influenced by rich innervation with postganglionic adrenergic and cholinergic nerve terminals (Billman et al., 1989). Impulses leaving the sinus node complex travel through the right and left atrium and converge on the AV node. Controversy still exists as to whether conduction spreads preferentially through specialized internodal and interatrial conduction pathways of the anterior, middle, and posterior internodal pathways or simply through atrial myocytes (Racker, 1989). Regardless, right and left atrial depolarization occurs over 55 to 100 msec, resulting in the surface P wave. Cells residing in the SA node complex are predominantly Ca^{++} dependent and slow conducting and have a higher resting membrane potential than atrial or ventricular myocytes and Purkinje tissue (Sperelakis, 1979).

Atrioventricular Nodal Complex

The AV node lies at the apex of the triangle of Koch. This is formed by the septal leaflet of the tricuspid valve and the tendon of Todaro (Anderson et al., 1988). The AV node is subendocardial and is not visible on gross inspection. The node extends through the A-V groove into the ventricle as the His bundle before branching into the right and left bundle branches of the His-Purkinje system. The AV node contains cells similar to the sinus node P cells. These cells and the associated transitional cells comprise a slowly conducting structure richly innervated with cholinergic and adrenergic fibers. Automaticity and conduction speed is influenced by this innervation. Slow, calcium-dependent cells predominate in the AV node. Conduction time through the AV node is roughly determined from the end of the P wave to the onset of the QRS complex.

Bundle Branch Network and His-Purkinje Tissue

The distal portion of the AV node becomes the His bundle. These cells have fast-conducting sodium channel-dependent cells with more negative resting potentials. Branching off into the right and left bundle branches and finally the endocardial Purkinje network, these fibers transmit impulses 10 times faster than atrial or ventricular myocytes and 50 to 60 times faster than sinus or AV nodal cells (Sperelakis, 1979). Rapid activation of the His-Purkinje network results in global, nearly simultaneous activation of the RV and LV myocytes. Purkinje activation results in a narrow QRS complex (<120 msec) noted on the surface ECG. Abnormalities of the right or left bundle branches result in slower activation of myocardium through cell-cell activation and thus the typical wide bundle branch block QRS on the surface ECG (>120 msec).

Atrial and Ventricular Myocytes

Myocardial cells are specialized cells designed to shorten when activated by a threshold electrical stimulus, thus providing mechanical force to produce contraction. The cell

Figure 27-32 Currents and channels involved in generating the resting and action potential: *left*, time course of a stylized action potential of atrial and ventricular cells; *right*, time course of sinoatrial node cells. Above are the various channels and pumps that contribute the currents underlying the electrical events.

membrane is characterized by fast sodium channel activation. Depolarization of the cell results in release of sarcoplasmic calcium and cardiac cell contraction. Conduction velocities are intermediate between SA and AV nodal cells and the Purkinje cells. Cell death, injury resulting in scarring or functional conduction slowing, or changes in cellular automaticity may result in clinical arrhythmias (Zipes, 1992).

THE ACTION POTENTIAL

Considerable consternation on the part of student and physician arises from diagrams of action potentials of cardiac tissue. However, by understanding a few simple concepts on the microscopic or cellular level, arrhythmia evaluation and treatment become easier.

In **Figure 27-32**, the schematic representation of the transmembrane action potentials of the fast, Na^+ inward current cell and the slow, Ca^{++} inward current cell are shown. In the left panel, *Phase 4* represents the resting transmembrane potential and is -90mV , with the intracellular area being negative. This membrane potential difference is maintained by a sodium/potassium pump using energy to maintain the difference. The membrane is permeable to potassium (K^+) and impermeable to Na^+ at rest. By expending energy, 3 Na^+ ions are pumped out of the cell in exchange for two K^+ ions into the cell. Positive K^+ ions flow across their chemical gradients out of the cell, thus leaving the intracellular space electronegative.

Phase 0 is characterized by the rapid influx of Na^+ ions into the cell, thus depolarizing the cell. Sodium influx is gated. When a sufficiently large depolarization occurs, ion channels are recruited and open, allowing for more influx of ions. Conductance declines as the channel is open and the equilibrium potential for the ion is reached. The channel closes, and Na^+ is again impermeable to influx. *Phase 1* represents a rapid repolarization of the cell through transient K^+ outward currents and β -adrenergic, AMP, and histamine-activated chloride (Cl^-) inward current, restoring the membrane potential toward 0 mV.

Phase 2 or the plateau phase is a long phase that may last several hundred milliseconds. Conductance to all ions falls dramatically. Continued Na^+/K^+ pump activity reduces the membrane potential slightly. An inward-rectifying K^+ current further depolarizes the cell, along with continued Ca^{++} influx through the slow inward calcium channels.

Phase 3 represents the final rapid repolarization of the cell membrane. This occurs from inactivation of the slow inward calcium current and from activation of an outward K^+ current. The intracellular space becomes more negative, and potassium conductance increases in a regenerative manner.

Phase 4 resumes at the end of phase 3. However, in portions of the heart, a small depolarization current occurs and may result in threshold being reached and depolarization of the cell. This inward-depolarizing current is noted in the SA node, distal AV node, and His-Purkinje fibers. This results in automaticity. The rate of depolarization is greater in the SA node than in other structures and thus results in the SA node as the dominant pacemaker. Adrenergic and cholinergic modulation further results in the SA node as the faster pacemaker, subordinating the automaticity of other pacemaker-like tissues. More frequent stimulation results in shortening of the phase 2 and phase 3 of the action potential, resulting in unchanged or slightly increased conduction velocity.

In the *right panel*, the action potential of the slow inward current type cells is shown. In these cells, calcium and potassium play a greater role in setting the resting membrane potential slightly less negative than in Purkinje or myocytes (phase 4). Phase 0 occurs through activation of slow Ca^{++} current. No phase 1 is noted, and the plateau phase is not as prolonged, owing to the relative importance of the Ca^{++} and K^+ currents dominated by the slow activating and inactivating Ca^{++} current. More frequent stimulation leads to a decrease in the resting membrane potential, lower peak phase 0 velocity, slower phase 3 repolarization, and ultimately slower overall conduction velocity (Rosen and Schwartz, 1991).

Antiarrhythmic drugs have differential effects on the Na^+ , K^+ , and Ca^{++} channels or on receptors that mediated the channels. By slowing or enhancing cellular membrane pore activity, one observes changes in either conduction or repolarization characteristics. This may be reflected in changes in the surface ECG as well.

SURFACE ACTION POTENTIAL (ELECTROCARDIOGRAM)

The surface action potential can be thought of as a series of discrete electrical events occurring over time. **Figure 27-33** schematically demonstrates cardiac events with the

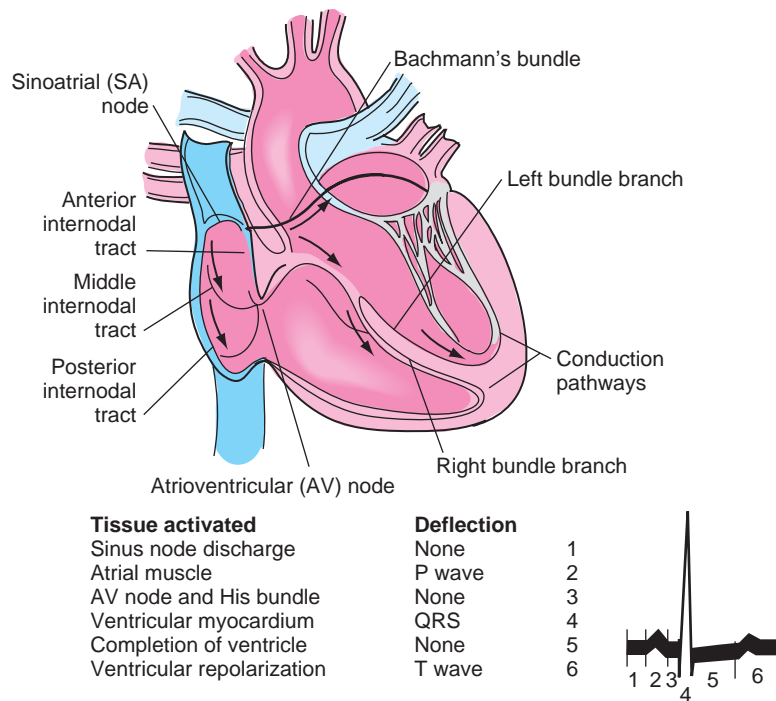

Figure 27-33 Schematic diagram of the cardiac chambers and the associated surface electrocardiogram findings.

surface ECG. The P wave begins with spontaneous depolarization of the SA node with propagation throughout the right and left atrium. This is upright in the inferior leads as depolarization occurs from the topmost portion of the atrium and converges on the atrial septum at the AV node. The depolarization of and conduction through the AV node result in no surface activity, resulting in an isoelectric portion beginning at the end of the P wave and continuing to the onset of the QRS. The P-R interval is the total time from SA node activation through the AV node until the beginning of ventricular depolarization. The His-Purkinje network is activated, rapidly depolarizing the large mass of ventricular myocardium. This results in the large QRS complex. The Q-T interval represents myocardial repolarization and may be prolonged in the setting of bundle branch block, drug effect, and genetic disorders causing abnormal ion channel function.

MECHANISMS OF ARRHYTHMIAS

Two main mechanisms for the initiation and perpetuation of arrhythmias have been proposed. Putative mechanisms include disorders of *impulse formation* and disorders of *impulse conduction*. These may occur alone or in combination and result in isolated electrical events and sustained arrhythmias. Alterations in automaticity or triggered activity are two main areas of disordered impulse formation. Clinical examples of abnormal automaticity include inappropriate sinus tachycardia, multifocal atrial tachycardia, sinus pauses, idioventricular rhythm after MI, and ectopy in the setting of HF. Triggered activity, or spontaneous depolarization dependent on prior stimulation, is characterized as early or late after depolarizations. This mechanism may be responsible for arrhythmic events during hypoxia, use of sotalol or the metabolite of procainamide, or in patients

with idiopathic and acquired long Q-T syndrome and digitalis toxicity.

Changes in impulse conduction can be clinically divided into *block* with or without *reentry*. Simple block occurs when the propagation of the impulse results in an inadequate depolarization stimulus to the adjacent tissue and the impulse terminates. Clinical examples include SA or AV block or simple bundle branch block. In SA block, normal depolarization of the SA node is inadequate to excite adjacent tissue, resulting in absence of a P wave. In AV block, block may occur within the AV node or as it attempts to depolarize His tissue. This results in a P wave followed by a delayed or absent QRS complex. On the surface ECG, differentiation between block in the AV node or His bundle is only a guess. Bundle branch block or hemiblock is a result of block in a specific branch of the specialized conduction tissue. Activation of tissue beyond the bundle branches must then occur through slower myocyte-to-myocyte activation.

In *block with reentry* (Figure 27-34), unidirectional block within a tissue results in activation of adjacent tissue. Tissue not initially activated then becomes excited by the conducting tissue. Tissue that has had time to recover excitability may then be activated again in a single or perpetual event. Clinical examples may occur within the SA node or AV node, within the atrium such as AFL, and in Purkinje and myocardial tissue as VT. Additional macroreentrant rhythms include atrial reentry and preexcitation with orthodromic and antidromic reciprocating tachycardias.

DIAGNOSIS OF CARDIAC ARRHYTHMIAS

Electrocardiographic Evaluation of Arrhythmias

The basic *single lead* rhythm strip is still used in many offices as a quick verification of ongoing abnormal rhythms. New

Figure 27-34 Mechanism of typical atrioventricular (AV) nodal reentry. The AV node (AVN) is drawn schematically with fast and slow pathways. Differential conduction and refractoriness is noted between the two pathways. The β pathway (fast pathway) has fast conduction and long refractoriness; the α pathway has slower conduction and shorter refractoriness. *Left*, The depolarization wave front from the atrium penetrates both pathways. The β pathway conducts the wave front faster than the slow pathway, and the P-R interval is normal. *Center*, Block occurs in the fast pathway. The slow pathway conducts the wave and depolarizes the ventricle. The β pathway (fast pathway) has time to recover, and conduction proceeds retrograde up the fast pathway and depolarizes the atrial tissue again, resulting in an AV node echo beat. *Right*, Continuation of the reentry can occur. As the fast pathway is activated in the retrograde fashion during an echo beat, the slow pathway, with a shorter refractory period, is able to recover. The excitable tissue can then be activated, and conduction again proceeds back down the slow pathway (α pathway), and the cycle continues.

or used inexpensive equipment can be found through many equipment vendors. This allows for rapid evaluation of symptoms reported during an office visit. Slightly more expensive 12-lead ECG machines provide not only useful information on the ongoing rhythm but may also demonstrate ischemic changes or prior or ongoing injury pattern. Multiple lead analyses helps discern difficult to see P waves during arrhythmia evaluation as well.

Both the single lead and 12-lead ECG are helpful only for ongoing arrhythmia analysis. Obviously, short-lived events or events that occur unpredictably are rarely identified by these simple techniques. Twenty-four-hour ambulatory recording of a single or multiple leads is performed through Holter monitoring. Small patches or electrodes are placed on the skin and are attached to a digital or analog recording device usually worn on the belt. Offline data analysis is performed and relayed to the interpreting provider. Monitoring over 24 to 48 hours allows for increased sensitivity in ambulatory screening. Longer periods of monitoring can be performed using small 30-day recorders. By recording and repeatedly overwriting the last several minutes of a rhythm, individuals with very infrequent events can lock in a symptomatic event and then transmit the information over the phone. This method may also be helpful in monitoring response to pharmacologic therapy such as rate control in AF. However, prolonged electrode contact can result in skin irritation and poor patient acceptance.

Newer, implantable loop monitors became available in the early 1990s. Devices smaller than a disposable lighter are implanted under the skin overlying the chest wall. Lasting 18 to 30 months, these loop recorders have

automatic and activated memory. Evaluation of the recorded events is performed in the clinician's office, remote from the clinical event. Implantation is usually performed by a cardiologist or electrophysiologist when other recording efforts have failed.

Exercise testing may also be useful for clinical events that occur during activity or stress. Elevations in adrenergic state facilitate conduction and repolarization. Unmasking of sinus node, AV node, or His-Purkinje disease resulting in block may occur. Initiation of various supraventricular or even VTs may also occur. Ischemia as a trigger for arrhythmias may also be detected. Exercise testing should be considered in patients with reproducible activity-associated arrhythmias and in patients in whom evaluation suspects long-QT syndrome or manifest preexcitation.

Inpatient evaluation of arrhythmias is seldom needed. However, patients with clinical syncope or the transient loss of postural control thought to be arrhythmic in nature, patients in whom ischemia-induced arrhythmias is a concern, or patients with a clinical history concerning a life-threatening ventricular arrhythmia should be considered for inpatient evaluation. In this setting, an organized testing regimen may be used during continuous ECG monitoring.

A comprehensive discussion of rhythm and 12-lead ECG findings is beyond the scope of this chapter. However, using a standard, stepwise approach to all rhythm strips can be easily learned. Keeping in mind changes in impulse formation and impulse propagation, the correct ECG diagnosis can usually be made. Clinical information such as drug therapy or prior myocardial injury can be equally useful. Similar questions that should be addressed with each rhythm analysis are as follows:

1. What is the origin of the impulse? In essence, determine the P-QRS relationship. Determine if the P wave is the initial event or the secondary event and if it is associated with neighboring depolarizations. If P waves exist, examine the morphology and determine if it is appropriate for the lead reviewed. If the rhythm is irregular, do the irregular beats look the same? These steps will help determine if the rhythm comes from the atrium, AV junction, or ventricle. Further differentiation into irregular atrial events such as AF or multifocal atrial tachycardia can be made. Wide QRS beats may arise from premature ventricular contractions (PVCs), bundle branch block, or preexcitation.
2. What is the basic heart rate? Is the rate appropriate for the origin of the impulse? This will discern tachycardias from bradycardias or normal rates for the rhythm (e.g., sinus arrhythmia).
3. Is the rhythm regular? Is this appropriate? A fixed regular ventricular response in the setting of AF suggests third-degree AV block and may be due to digitalis toxicity if the rate is greater than expected for a junctional escape.
4. Are intervals appropriate and constant? Changes occur in setting of altered origin of impulse, basic heart rate, and with varying degrees of block (e.g., type I second-degree SA or AV block).
5. Are QT segments, ST segments, or T waves helpful? Are Q waves present? This may give clues to ongoing metabolic, ischemic, or drug effects that cause common

arrhythmias. With these few questions in mind, most rhythm strips can be interpreted correctly.

Basic interpretation begins with a rhythm strip of good quality, typically representing lead I, II, or V1. Multiple leads aid in the diagnosis but are not always necessary. Evaluation of heart rate, intervals, and axis is necessary. Regularity of the rhythm; consistency of the P waves, QRS complexes, and T waves; and abnormalities of the ST segment should be characterized. Examples of various rhythms, possible causes, and treatments are presented in the following sections.

PATTERN RECOGNITION OF ARRHYTHMIAS

Atrial Rhythms

Key Point

- Treatment of asymptomatic or minimally symptomatic, non-life-threatening atrial rhythms should be less risky than no treatment at all. The proarrhythmic side effects of drug therapy including VF should be carefully weighed before initiation of drug therapy.

Disorders of sinus rhythm: *Sinus rhythm* is a regular, organized atrial rhythm between 60 and 100 beats/min at rest in healthy individuals. Slower rates as low as 40 to 50 beats/min may be normal in some individuals. Originating in the high right atrium, sinus P waves should be positive in limb leads I and II. *Sinus bradycardia* originates in the sinus node with a P wave indistinguishable from the normal sinus beat but at a rate slower than the established lower limit of 60 beats/min. This is physiologically normal in patients during sleep, in athletic individuals, and as a consequence of many adrenergic-blocking drugs such as β -blockers. Excessive bradycardia may come as a consequence of changes in vagal tone in sleep apnea, during painful stimuli, or with mesenteric stretch. There are

typically no significant changes in the P-QRS-T intervals with resting sinus bradycardias. During vagal-mediated sinus slowing, associated prolongation in the P-R interval may give a clue as to the etiology. Typically, no treatment is necessary in this benign condition. If the heart rate slowing is excessive or symptomatic, acute atropine administration, epinephrine, and dopamine may be used acutely. For the long term, pacemaker implantation may be necessary. *Sinus arrhythmia* is the normal variation of heart rate likely caused by changes in volume and vagal tone as a consequence of respiration. Occasional slowing below 60 beats/min at rest is considered acceptable. Patients with high adrenergic tone such as HF often lose normal variations in heart rate and a reduction in the degree of sinus arrhythmia. A *wandering atrial pacemaker* is said to occur if at normal heart rates, there is significant variation in the P-wave morphology and regularity. Associated PR interval and RR intervals are variable because of the different atrial origin and variations in the prematurity of the atrial beat. It is more frequent in young individuals and as a result of changes in vagal tone. The origin of the impulse may arise from within the sinus node complex but at distant sites within the right atrium, giving rise to the changes in P-wave morphology.

A *sinus pause* and the more extreme case of *sinus arrest* are demonstrated as a sudden change in the heart rate, often preceded by mild slowing in the general sinus rate. A sinus pause is typically due to changes in vagal tone such as gagging, carotid sinus stimulation, or pain and as a consequence of neurocardiogenic activation (Figure 27-35). Very long episodes of no surface atrial activity are considered to have *sinus arrest*. This may occur as a consequence of atrial tissue disease, drug therapy, metabolic derangements, and significant vagal activation. Figure 27-36 demonstrates a long pause noted during neurocardiogenic reflex activation during a tilt-table test in the evaluation of syncope. The pause was approximately 50 seconds and resulted in loss of consciousness. Typically, withdrawal of the offending agent, improvement in cardiac function, and elimination of stimuli causing reflex vagal activation result in improvement in symptoms. In difficult symptomatic

Figure 27-35 Sinus rhythm is followed by sinus arrest and motion artifact during a seizure. Sinus rhythm then resumes.

Figure 27-36 Sinus rhythm slows slightly before sinus arrest occurs for 50 seconds. Return of sinus rhythm is not shown.

Figure 27-37 Sinus rhythm with type I Wenckebach sinoatrial block. Note shortening of the P-P interval before the dropped P wave and the pause of less than twice the shortest P-P interval. The return cycle length is longer than the cycle length before the pause.

Figure 27-38 Sinus rhythm with type II second-degree sinoatrial block. Note the almost constant P-P interval before loss of P-wave activity. The pause is twice the cycle length of sinus rhythm. The return cycle length is the same as before the pause.

cases and in patients without a reversible cause, pacemakers may be necessary. Demonstration of sinus pauses and sinus arrest as a cause of symptoms of dizziness or syncope may be difficult and require prolonged ambulatory monitoring.

A pause may also occur as a consequence of sinus node disease. In patients with atrial disease, myofibrosis and atrial pressure overload, changes in the automaticity, and rhythmic depolarization of the SA node may be affected. Regular impulses may fail to exit the sinus node complex and depolarize the atrium, resulting in no P wave on the surface ECG and no atrial mechanical contraction. This may occur in regular patterns such as in *type I SA block*, characterized by sequential shortening of the P-P interval and then absence of a P wave. The return cycle length is less than two times the shortest cycle length, and the next cycle is longer than the cycle length just before the dropped P wave (Figure 27-37). *Type II SA block* is characterized by constant P-P intervals followed by a missing P wave. The pause is twice the cycle length of the P-P interval, and the return cycle length is the same as the sinus rate (Figure 27-38).

Premature atrial contractions (PACs) or depolarizations may occur frequently in normal patients. The ECG finding is that of an abrupt early P wave that may or may not be followed by a QRS complex. PACs may occur as isolated events, as couplets, or as sequential events. Most individuals are minimally symptomatic if at all. Benign causes include exogenous stimulants such as tobacco, caffeine, alcohol excess, and sympathomimetic drugs. Digitalis

toxicity should be considered in patients on digitalis treatment. Patients with underlying heart or lung disease or ectopy as a consequence of extrinsic compression on the atrium and adjacent abnormal structures may become symptomatic. Reducing automaticity or triggered activity through antiarrhythmic therapy and treating hypoxia and IHD may reduce the patient's symptoms. In asymptomatic patients, no specific therapy is necessary. β -Blockers and CCBs may reduce ectopy rates and slow or block the ventricular response to the PACs, thus reducing symptoms. Potent antiarrhythmic medications (class Ia, Ic, or III) may occasionally be necessary.

An *ectopic atrial rhythm* is said to occur when the P wave does not have the normal upright morphology in limb leads I, II, and III. Heart rate during the rhythm can be slower than, equal to, or greater than normal sinus rhythm. Ectopic rates greater than 100 beats/min are termed *ectopic atrial tachycardia* (Figures 27-39 and 27-40). The morphology of the ectopic P wave should be consistent, and the P-P intervals should be approximately equal. This helps to distinguish this from sequential PACs. Asymptomatic ectopic atrial rhythms are usually benign and do not require therapy. Patients with incessant, rapid tachycardias may eventually develop rate-related cardiomyopathy. Treatment for or prophylaxis against this type of cardiomyopathy is warranted.

Several additional atrial tachyarrhythmias deserve attention. *Sinus tachycardia* or sinus rhythm at a rate greater than expected for the physiologic state may be seen. Atrial wave morphology is normal. However, sustained increased rates

Figure 27-39 An ectopic atrial rhythm at 85 beats/min with negative P waves in lead II is replaced by slower sinus rhythm with upright P waves and then returns at the end of the rhythm strip. A dual-chamber pacemaker senses and tracks both types of P waves and paces the ventricle accordingly.

Figure 27-40 Ectopic atrial tachycardia is initiated by a premature atrial complex. Note the P-wave morphology change of the faster ectopic atrial rhythm.

Figure 27-41 The rapid, irregular nature of atrial fibrillation and its chaotic activation of atrial tissue results in no discrete P waves. Conduction through the atrioventricular node is variable, resulting in the irregular ventricular response.

Figure 27-42 Atrial flutter is more organized, resulting in a sawtooth appearance in the limb leads and precordial leads. Atrial rates of almost 300 beats/min are noted, with variations in the ventricular response.

may be related to failure of autonomic regulation, metabolic stress, drug use (prescribed or illicit), or from idiopathic causes. Inappropriate sinus tachycardia syndrome is usually a self-limited problem of the young and may be caused by a variety of factors. Positional orthostatic tachycardia syndrome is a condition of marked increases in heart rate with upright posture, not always associated with a decrease in BP. Volume status is usually normal and differentiates this from simple orthostatic hypotension with reflexive tachycardia. Treatment of these disorders using β -blockers and serotonin antagonists has been helpful in some individuals. Expansion of plasma volume may also be helpful (<http://home.att.net/~potsweb/POTS.html>).

Multifocal atrial tachycardia is characterized as irregular atrial activity at rates greater than 100 beats/min. There are three or more P waves present as the driving force of the tachycardia. Patients in metabolic stress and with hypoxia are prone to this arrhythmia. Treatment is usually supportive, but verapamil has been shown to help in some. Treatment with digoxin is rarely helpful, and upward titra-

tion may result in toxicity indistinguishable from the original rhythm disorder (Hazard and Burnett, 1987).

The ECG findings of AF are the absence of organized atrial activity with an irregular, usually rapid ventricular response (Figure 27-41). Atria are depolarized from widespread regions of both the left and right atrium and result in chaotic activation at rates exceeding several hundred beats per minute. AF may be asymptomatic or highly symptomatic, ranging from simple palpitations to MI and HF. Recognition of the arrhythmia is the first step in good care. Treatment using an appropriate anticoagulation strategy, ventricular rate control, and consideration of restoration of sinus rhythm is necessary even in asymptomatic patients. Further discussion of AF is provided later in the chapter.

Atrial flutter is also a rapid rhythm of the atrium, usually at a rate near 300 beats/min. The ventricular response may be fixed or variable. Sawtooth flutter waves are usually noted in the inferior limb leads (Figure 27-42). Misidentification of AFL with 2:1 conduction as sinus tachycardia is common and should be considered in all regular

Figure 27-43 Atrial flutter waves noted in leads II, III, and aVF terminate abruptly, and sinus rhythm is restored. An intracardiac ventricular recording and output from a radiofrequency (RF) generator are shown in the lower portion of the diagram. RF application was made at the tricuspid–inferior vena cava isthmus. (From Feld GK, Fleck P, Chen PS, et al. Radiofrequency catheter ablation for the treatment of human type I atrial flutter: identification of a critical zone in the reentrant circuit by endocardial mapping techniques. *Circulation*. 1992;86:1233-1240.)

Figure 27-44 Junctional rhythm at a rate greater than the sinus node dominates the rhythm. Conduction through the atrioventricular node occurs with the fifth QRS complex and resets the junctional rhythm. Excessive bradycardia and the associated junctional rhythm may be associated with digoxin toxicity.

tachycardic rhythms. Similar to AF, treatment strategies including anticoagulation with Coumadin should be considered. In contrast to AF, atrial activation is organized and frequently is caused by macroreentry. The wave front ascends the right atrial septum, crosses the roof of the right atrium, and down the lateral wall along the cristae. The wave front then extends between the inferior vena cava and the tricuspid annulus along the isthmus and proceeds to the atrial septum. Targeting the isthmus with linear radiofrequency lesions to effect cure is common (Figure 27-43).

Junctional Rhythms

Similar to PACs, earlier than expected depolarization arising from the AV node complex results in a QRS without a preceding P wave termed a *premature junctional complex* (PJC). Retrograde, inverted P waves may be seen within the early portion of the QRS or following the QRS complex. These are usually benign but may be an early sign of occult cardiac disease. Drugs, adrenergic stimulants, and metabolic stress may be associated with PJCs. In the absence of heart disease or underlying medical condition, these usually asymptomatic beats do not require treatment.

When the AV junction has rhythmic spontaneous depolarization, a *junctional* or *nodal rhythm* occurs (Figure 27-44). The normal pacemaker function of the AV node cells occur at a rate of 35 to 50 beats/min. In sinus node failure, the junctional pacemaker rate may be higher than the sinus rate, resulting in junctional bradycardia. Abnormal reentry within the AV node results in *junctional tachycardia* usually at a rate between 120 and 190 beats/min and is considered a form of supraventricular tachycardia. Differentiation of accelerated junctional tachycardia from more typical supraventricular tachycardias is not possible by surface ECG. Because of simultaneous activation of the

ventricle and retrograde activation of the atrium, junctional rhythms may be more symptomatic than their rate would predict.

DISORDERS OF ATRIOVENTRICULAR NODE CONDUCTION

Key Points

- Atropine may worsen AV block if block occurs at the level of the Purkinje system. Increased sinus rates conducting through the AV node will be blocked because of the refractory His-Purkinje tissue. In contrast, epinephrine may enhance both AV conduction and shorten Purkinje refractoriness, thus resulting in decreased block. Atropine delivery may thus be helpful in distinguishing the level of AV block and determining the urgency of permanent pacing.
- The atrial rate must be faster than the escape rate to confirm complete heart block. A-V dissociation can occur when the escape rate is faster than the atrial rate. This will initially appear to be complete heart block. However, appropriately timed atrial beats may conduct to the ventricle and advance the ventricular cycle, confirming some degree of interaction. Digoxin toxicity and ischemia as well as other drug toxicities may cause accelerated junctional rhythm and should be considered when this rhythm is seen.

First-degree AV block is demonstrated as a P-R interval of greater than 200 msec (Figure 27-45). Persistent AV delay is usually noted, but variations may be seen depending on heart rate. Whereas adrenergic tone shortens the AV delay,

drugs such as β -blockers and CCBs may worsen AV conduction, leading to more progressive types of AV block. First-degree AV block is almost always at the level of the AV node. Except for very long AV intervals resulting in atrial contraction while the prior ventricular beat is maintaining AV valve closure, first-degree AV block typically does not require treatment. Advanced age is often associated with this conduction disorder.

Second-degree AV block is separated into type I (Wenkebach); type II, 2 : 1; and high-grade AV block. *Type I second-degree AV block* is characterized by a progressive prolongation of the PR interval followed by failure to conduct and depolarize the ventricle. The PR interval on the return beat will be shorter than the PR just before the block (Figure 27-46). Similar to first-degree AV block, this typically does not require treatment with a pacemaker and does not predict life-threatening complete heart block. In patients with concomitant bundle branch block, one should question if block is actually occurring at the level of the His-Purkinje system. Withdrawal of drugs indicated in AV block is indicated. Dual-chamber pacing in symptomatic patients may be necessary.

Type II second-degree AV block is the abrupt failure of conduction through the AV node and absence of a QRS complex. The PR intervals should be similar before and after block. AV block may occur both at the level of the AV node and His bundle and is indistinguishable without invasive electrophysiology study. Pacing is usually indicated to avoid unpredictable progression to complete heart block. Withdrawal of AV conduction-blocking drugs is indicated. *Two-to-one AV block* can result in very low heart rates and considerable symptoms, including syncope and low-output HF. Loss of ventricular activation every other beat typifies this rhythm. Block at the level of the AV node is suggested

Figure 27-45 Sinus rhythm with first-degree atrioventricular block and bundle branch block.

Figure 27-46 Sinus rhythm with type I (Wenkebach) second-degree atrioventricular block. There is prolongation of the P-R interval and then a dropped QRS.

Figure 27-47 Sinus rhythm with third-degree (complete) atrioventricular block. There is complete dissociation of atrial and ventricular activity. The escape rate is less than 30 beats/min, and QRS complex is wide, suggesting a ventricular escape.

by preexistent PR prolongation, but block at the level of the His-Purkinje system cannot be excluded by surface ECG.

High-grade AV block or intermittent complete AV block is similar to type II second-degree AV block. However, greater than one consecutive QRS complex is absent with the block. This degree of AV block is strongly suggestive of significant AV node disease or distal Purkinje disease, and one should strongly consider permanent pacemaker implantation. The one exception may be that of high-grade AV block occurring at night in the setting of sleep apnea.

Third-degree AV block results from failure of atrial impulses from the sinus node to conduct down to the ventricle (Figure 27-47). The finding on a rhythm strip or ECG indicates serious cardiac disease and may be related to significant valvular or coronary disease. An escape rhythm that is narrow suggests that the level of block is above the His-bundle complex and may be more stable. Adrenergic stimulation or atropine may result in an accelerated junctional escape. A slow, wide QRS escape suggests the level is below the His bundle and atropine is unlikely to help. Adrenergic stimulation may help increase the escape rate. Urgent temporary or permanent pacing is indicated. Transcutaneous pacing may be used temporarily but is unreliable and poorly tolerated by the patient.

Ventricular Rhythms

The presence of a wide QRS is usually caused by one of three things: (1) normal AV conduction with bundle branch block aberrancy, (2) presence of preexcitation, or (3) origin of the beat within the ventricle as a PVC or consecutive ventricular activation as seen in VT. A PVC is noted as an early beat, arising before normal atrial activation through the AV node can activate the His-bundle system and depolarize the ventricle. PVCs occur as single beats and couplets but may consecutively appear much like VT. Unifocal PVCs typically are thought of being more benign than multifocal PVCs. The origin of the abnormal beats is usually caused by enhanced automaticity or triggered activity. Cardiac literature has demonstrated higher mortality rates in patients with IHD with decreased EF and increased rates of ventricular ectopy. Suppression of these ectopic beats with class I or III antiarrhythmic medicines, however, has not significantly improved mortality rates (Cardiac Arrhythmia Suppression Trial II Investigators, 1992; Echt et al., 1991).

Ventricular ectopy in patients with normal hearts is not correlated with significant increases in mortality rate.

Figure 27-48 Nonsustained monomorphic tachycardia is seen in the setting of underlying atrial fibrillation with increased ventricular response. This terminates spontaneously.

Figure 27-49 Torsades de pointes polymorphic ventricular tachycardia is initiated by sequential premature ventricular contractions (PVCs) that prolong the Q-T interval in a rate-dependent manner. An early PVC landing in the long Q-T interval results in the characteristic twisting about the axis. Spontaneous termination is seen.

Figure 27-50 Sinus rhythm is noted to degrade initially to a polymorphic ventricular tachycardia and then organizes (not shown in entirety). A premature ventricular contraction during ventricular tachycardia results in ventricular fibrillation, to which the patient ultimately succumbed.

Patients are usually asymptomatic, but in some individuals, even low-frequency ectopy may be quite bothersome. Treatment of these patients with β -blockers often results in symptomatic improvement. In highly symptomatic patients, membrane-active drugs (type I or III) may occasionally be required. Referral to an electrophysiologist should be made if antiarrhythmic medications are used. Some symptomatic patients may also be treated with radiofrequency ablation of the arrhythmic focus.

Ventricular tachycardia is clinically divided into two main categories. In *monomorphic VT*, QRS complexes are nearly identical, and the R-R interval is typically regular. Slight variations at the beginning and end of a run of VT tend to show greater fluctuations in rate. This tends to occur more frequently in scar-related reentry in patients with prior MI and in patients with “normal heart” VT such as RVOT tachycardia and idiopathic LV tachycardia (Figure 27-48). In *polymorphic VT (PMVT)*, the QRS morphology is constantly changing, and the R-R intervals are often inconsistent. Torsades de pointes is a specific clinical PMVT and is characterized by a long QT interval present in the first

beat of the tachycardia and a twisting about the axis on a rhythm strip (Figure 27-49). In almost all cases, referral to a cardiologist or electrophysiologist is indicated. Frequently, inpatient evaluation is necessary.

Ventricular fibrillation is a disorganized electrical rhythm of the ventricle and leads to no meaningful ventricular contraction. Without cardiac resuscitation and electrical cardioversion, the individual will die. Figure 27-50 demonstrates a patient hospitalized with an MI. Immediate hospitalization is recommended in patients who have had prior episodes of near syncope or syncope in which VT is suspected because of known underlying ischemic or nonischemic heart disease. Patients suspected of long QT syndrome or VT associated with clinically significant HOCM should be considered for inpatient or invasive evaluation. Patients who are resuscitated from an out-of-hospital VF arrest must be referred to a cardiac specialist for further evaluation and treatment because of the high rate of recurrence (Huikuri et al., 2001). Inpatient evaluation may include invasive coronary angiography or electrophysiology testing.

Paced Rhythms

Key Point

- Determination of the site of pacing is important. A bundle branch block pattern on surface ECG contralateral to the site of pacing should occur. Inappropriate LV endocardial lead placement delivered across a patent foramen ovale can be detected before serious consequences of embolic stroke. In addition, appropriate LV epicardial pacing accomplished through lead placement via the coronary sinus can be confirmed through paced right bundle branch block morphology. RV endocardial pacing results in a left bundle branch block pattern on surface ECG.

Temporary or permanent pacemaker implantation is now performed at almost all hospitals in which a cardiologist practices. Activation of myocardium results in a nearly normal P wave but with a notable bundle branch block pattern of ventricular capture on the surface ECG. The ECG recorder may amplify the energy from the pacemaker pulse, resulting in a pacing artifact on the surface 12-lead ECG or rhythm strip to aid in interpretation. Knowledge of the type of pacemaker and the current programming may be necessary for complete analysis. The pacing morphology can be reviewed to confirm consistent and appropriate lead placement. Sensed cardiac events may result in pacemaker inhibition and masking of its presence. Evaluation of unexpected events on the ECG may identify abnormal pacemaker operation, as noted in [Figure 27-51](#). Detailed pacemaker ECG interpretation is beyond the scope of this chapter.

Figure 27-51 Dual-chamber pacing with loss of ventricular output.

Figure 27-52 Sick sinus syndrome is characterized by rapidly conducted atrial fibrillation, pauses during restoration of sinus rhythm, and excessive bradycardia in normal rhythm.

SPECIAL CLINICAL ELECTROCARDIOGRAPHIC SYNDROMES

Sick sinus syndrome is a group of electrocardiographic and clinical findings. Patients often have symptoms of fatigue, palpitations, and heart racing and may have dizzy spells or even syncope. The findings of paroxysmal atrial tachycardia, AF, or AFL results in tachypalpitations and heart racing. Excessive SA node suppression often occurs with drugs used to slow AV conduction or reduce atrial arrhythmias. [Figure 27-52](#) demonstrates typical ECG findings seen in SSS. Pharmacologic treatment to reduce symptoms is often problematic, and permanent pacing is often required. Anticoagulation with Coumadin in patients with documented AF should be considered. Patients without documented AF should be considered for aspirin anticoagulation because of the high frequency of asymptomatic AF in this patient population ([Myerburg et al., 1994](#)).

There are at least two types of supraventricular tachycardias that should be routinely considered for referral. Patients with *preexcitation syndrome* (Wolfe-Parkinson-White [WPW] syndrome) or AV reciprocating tachycardia (AVRT) and paroxysmal, symptomatic *AV node reentrant tachycardia* (AVNRT) may benefit from drug therapy or radiofrequency ablation therapy. The ECG signature of WPW is the delta wave. Atrial activation of the ventricle is through the AV node–Purkinje system and is activated through a bundle or bypass tract of muscle inserting along one of the AV valves. The combined activation pattern results in the delta wave. [Figures 27-53](#) and [27-54](#) demonstrate presence and absence of the delta wave before and after ablation therapy for supraventricular tachycardia associated with the bypass tract. Supraventricular tachycardia results from a macroreentrant circuit in which

Figure 27-53 Sinus rhythm with obvious delta waves consistent with a right-sided septal or posteroseptal origin. Twelve-lead electrocardiography is performed before radiofrequency ablation.

Figure 27-54 Normal electrocardiogram after radiofrequency ablation of the manifest right posteroseptal bypass tract.

conduction proceeds down the AV node into the ventricular myocardium and retrograde up the bypass tract to activate the atrium. The circuit is completed as the AV node is again activated. Tachycardias moving in the opposite direction are identified as wide QRS tachycardias and may be indistinguishable from VT by surface ECG. Adenosine administration during tachycardia may terminate WPW tachycardia but is unlikely to terminate VT. Caution to avoid hypotension or VF during diagnostic atropine administration in nonhypotensive wide complex tachycardia is recommended. Advanced cardiac life support equipment should be available during administration.

In AVNRT, sudden rapid onset and offset of narrow complex tachycardia occurs. There is either an inverted P wave immediately after the QRS complex or it may not be visible at all. Termination of the arrhythmia using vagal

maneuvers such as carotid sinus massage, Valsalva maneuver, or stimulation with ice cold water may be used clinically. Treatment with AV node-blocking agents can be successful in most patients. Safe, highly effective treatment with invasive electrophysiology study and ablation therapy is common at most larger centers. Figures 27-54 and 27-55 illustrate the mechanism and ECG findings.

Long QT syndrome, a disorder of myocardial repolarization, occurs because of abnormalities in membrane ion channels. Syncope and life-threatening polymorphous VT and VF may result. Autosomal dominant inheritance patterns and variable phenotypic penetrance may be seen. Diagnosis in affected individuals is difficult because the QT interval may be occasionally normal. Provocative maneuvers by a trained specialist may be necessary. Genetic testing for some but not all of the genetic abnormalities are

Figure 27-55 Sinus rhythm is noted in the *upper panel*. In the *lower panel*, supraventricular tachycardia consistent with atrioventricular nodal reentrant tachycardia is seen. Retrograde (inverted) P waves immediately after the QRS complex during tachycardia are evident. During the tachycardia at almost 150 beats/min, the normal P-R interval is no longer seen.

available for confirmation. Families with a history of sudden cardiac death or syncope should be evaluated carefully to determine the need for treatment, including β -blockers and implantable defibrillators (Priori et al., 2003).

Atrial fibrillation is the most frequent arrhythmia requiring treatment. In the United States, 2.2 million people have persistent or permanent AF (Feinberg et al., 1997). A basic understanding to the approach of AF can render most patients asymptomatic and dramatically reduce their risk of stroke. The AFFIRM trial represents a landmark study treating all patients with AF with Coumadin. Patients were then randomized to either (1) *control of heart rate* using AV nodal-blocking agents or, if necessary, AV junction ablation and pacemaker therapy or (2) *maintenance of sinus rhythm* using antiarrhythmic drug therapy and repeated direct current cardioversion. Patients were followed for up to 5 years. Patients had similar mortality rates. Patients randomized to rhythm control had more hospitalizations and adverse drug effects mostly related to antiarrhythmic drug therapy. Stroke events were similar but were higher in patients who discontinued Coumadin, regardless of treatment arm (AFFIRM Investigators, 2002).

Based on this study, patients who are candidates for either heart rate control or rhythm control can pursue either treatment strategy with similar efficacy. In patients undergoing restoration of sinus rhythm, the use of direct current cardioversion is safe and effective. Anticoagulation with an INR goal of 2 to 3 in nonvalvular AF is recommended for a minimum of 3 weeks before a cardioversion.

Conscious sedation with short-acting narcotics and IV benzodiazepines allows for synchronized shock delivery in the American Society of Anesthesiologists (ASA) class I and II patients by experienced physicians. In patients adequately anticoagulated with Coumadin, direct current cardioversion can restore sinus rhythm at least transiently in 70% to 90% of patients (Lundstrom and Ryden, 1988; Sodermark et al., 1975; Van Gelder et al., 1991). Maintenance of sinus rhythm at 12 months on antiarrhythmic medications may be as low as 40%, depending on drug selection and the patient population (Van Gelder et al., 1996). Despite this, the practicing physician may elect to gain expertise in conscious sedation and cardioversion when referral electrophysiologists are not readily available and in patients not

requiring or intolerant to drug therapy. Prior recommendations for discontinuation of Coumadin after 6 weeks in sinus rhythm are being scrutinized because of the high stroke rate in patients in the AFFIRM trial who discontinued Coumadin despite being in SR. Caregivers may treat patients long term, even after sinus rhythm is restored or in patients with asymptomatic AF. Because of the high 6-month recurrence rate after cardioversion, many physicians leave patients on anticoagulation for 6 or more months before considering stopping anticoagulation.

Stroke prevention continues to be a primary objective in arrhythmia management. A working knowledge of current anticoagulation guidelines is key to proper management of patients seen in the office and hospital during routine clinical care. For patients with prosthetic mechanical heart valves or with valvular AF (presence of clinically significant MS), the recommendation and use of oral vitamin K antagonists is unchanged. However, changes are ongoing in risk assessment for stroke in patients with paroxysmal, persistent, and permanent nonvalvular AF.

Over the past decade, the CHADS₂ score has been used to help objectively quantify a patient's stroke risk in nonvalvular AF. Using the readily available clinical variables of (1) clinical HF, (2) HTN, (3) age 75 years or older, (4) diabetes, and (5) prior stroke or TIA, reasonable prediction of annual stroke risk in the nonanticoagulated patient can be made (Gage et al., 2001). One point is allocated for each of the first four clinical indicators and 2 points for stroke or TIA. Guidelines have recommended no anticoagulation or aspirin only in patients with a CHADS₂ score of 0. Warfarin or aspirin is indicated for a CHADS₂ score of 1 and warfarin for a score of 2 or greater (Task Force for the Management of Atrial Fibrillation, 2010).

Additional evaluation of stroke rates in individuals with AF has suggested that the CHADS₂ scoring system has undervalued age and female gender in the assessment of stroke risk (Karthikeyan and Eikelboom, 2010; Keogh et al., 2011). The CHA₂DS₂-VASc score currently used in Europe and Canada looks at similar risk factors as the CHADS₂ scoring system but increases the weight of age and includes female gender if the patient is older than 65 years of age. In addition, CHF is defined as LV systolic dysfunction. Age equal to or greater than 65 years receives 1 point and equal to or greater than 75 years receives an additional point. Female gender (older than 65 years of age) is allocated 1 point and evidence of vascular disease a final point.

The purpose of the CHA₂DS₂-VASc scoring system is to identify very-low-risk patients in whom anticoagulation bleeding risk outweighs stroke reduction benefit, including the use of aspirin. Individuals with CHA₂DS₂-VASc scores of 0 have very low stroke rates, and bleeding risk from either aspirin or full-dose anticoagulation would be excessive. As a consequence, patients with a CHA₂DS₂-VASc score of 0 are currently indicated to be on no anticoagulation for a history of AF (Camm et al., 2012; Oelsen et al., 2011).

In individuals with a CHA₂DS₂-VASc score of 1, oral anticoagulation with adjusted-dose vitamin K antagonist, a direct thrombin inhibitor, or oral factor Xa inhibitor should be considered based on an assessment of the risk of bleeding complications and patient preferences. Individuals with a CHA₂DS₂-VASc score of 2 or greater should be on oral anticoagulation (Camm et al., 2012).

Newer oral anticoagulants have become mainstream in stroke prevention across the globe. As of the publication of this text, three agents have been approved for stroke prevention in patients with nonvalvular AF. Agents fall into one of two classes: the oral direct thrombin inhibitors (dabigatran) and the oral direct factor Xa inhibitors (rivaroxaban, apixaban). These agents, commonly referred to as the novel oral anticoagulants (NOACs), block a specific step in the coagulation cascade in contrast to vitamin K antagonists, which block multiple steps. In addition, these agents have an abrupt onset (within hours) and shorter half-lives (less than 24 hours) compared with warfarin (Camm et al., 2012).

Clinical data from the RE-LY trial, the ROCKET-AF trial, and the ARISTOTLE trial have demonstrated noninferiority or superiority over vitamin K antagonists in stroke prevention and systemic embolism. At currently approved doses, the NOAC are at least noninferior to vitamin K antagonists, and in the case of some of these agents may be superior and associated with decreased bleeding incidence. Importantly, the NOACs are associated with a significant reduction in intracranial hemorrhage (Connolly et al., 2009, 2010; Granger et al., 2011; Patel et al., 2011).

Weighing the risk of anticoagulation against bleeding is a vexing clinical problem in daily practice. Many calculators of bleeding risk have been developed over the past several years. However, the HAS-BLED calculator has grown in popularity (Pisters et al., 2010). Cumulative points are assigned for uncontrolled HTN, abnormal renal or liver function, bleeding tendencies, older age, compounding drug use or abuse, and prior stroke. Individuals with a score greater than or equal to 3 are at high risk of bleeding. A high score does not preclude anticoagulation use, but closer evaluation and follow-up or early discontinuation of anticoagulation may be indicated.

Despite the emergence of risk tools for anticoagulation indication and bleeding probability, predicting the effect of a given anticoagulant on an individual continues to be difficult. Each patient must be clinically evaluated for subtleties in his or her clinical status that improve the safety and efficacy of these potent agents. It is clear, however, that clinicians tend to underanticoagulate patients in current practice. Continued vigilance in evaluating patients for appropriate anticoagulation and the initiation and maintenance of safe dosing in the setting of AF must be maintained to reduce preventable debilitating stroke or systemic embolism.

Syncope is the sudden loss of postural tone and may be due to both cardiac and noncardiac causes. Up to 30% of patients may ultimately have no explanation. A detailed history, including dietary and fluid intake, personal and family history, medication use and timing, and precipitating factors, will aid in the diagnosis. The best single determinant of an etiology is likely the history. Additional testing depends on the presence or absence of structural heart disease. Invasive electrophysiology study in the setting of structural heart disease may identify up to half of patients' causes (Linzer et al., 1997). In the absence of structural heart disease, tilt table testing may identify between 11% and 87% of patients by two reports (Kapoor, 1990, 1992). Referral to an electrophysiologist should be considered in the setting of structural heart disease.

Table 27-26 Classification of Rhythms

Atrial	Sinus rhythm Sinus bradycardia Sinus pause Sinus node exit block (types I and II) Sinus arrest Sinus tachycardia Premature atrial contraction Wandering atrial pacemaker Ectopic atrial rhythm Ectopic atrial tachycardia Multifocal atrial tachycardia Atrial fibrillation Atrial flutter
Junctional rhythms	Premature junctional beat Junctional rhythm Accelerated junctional tachycardia AV nodal reentrant tachycardia AV conduction block First-degree AV block Second-degree AV block Type I Type II 2:1 High grade Third-degree AV block (complete AV block)
Ventricular rhythms	Premature ventricular contractions Accelerated idioventricular rhythm Ventricular tachycardia (monomorphic and polymorphic) Ventricular fibrillation
Special rhythms	Preexcitation AV reciprocating tachycardia Long QT Paced rhythms

AV, Atrioventricular.

TREATMENT OF CARDIAC ARRHYTHMIAS

An organized approach to the treatment of cardiac arrhythmias is paramount. Initial steps include identification and verification of the arrhythmia type and an assessment of potential harm to the patient. Table 27-26 outlines various rhythms categorized by their cardiac chamber of origin. As described earlier, inpatient evaluation is recommended in some patients. In patients in whom pharmacologic therapy is recommended, knowledge of the side effects and proarrhythmia potential must be known. Table 27-27 outlines antiarrhythmic agents according to the Vaughan Williams classification system. A newer classification, the Sicilian Gambit, is a system based on channel effects and mechanisms of arrhythmogenesis that, although helpful, is too complex for most individuals to use and has not gained favor in today's era of invasive arrhythmia therapy (Rosen and Schwartz, 1991).

ROLE OF THE CONSULTATIVE CARDIOLOGIST OR ELECTROPHYSIOLOGIST

Evaluation and treatment of patients with arrhythmias is a rewarding practice. Many arrhythmias can be symptomatically improved through use of medications, lifestyle changes, and reassurance. However, meta-analysis of antiarrhythmic drug trials and the CAST studies demonstrate the potential dangers of drug therapy in the treatment of

Table 27-27 Indication, Route of Administration, and Considerations for Use of Common Antiarrhythmic Drugs*

Type of Drug	Typical Indications	Route	Considerations, Contraindications, and Complications	Frequency of General Use
CLASS I				
Class Ia				
Disopyramide (Norpace)	PACs, AF, SVT, PVCs	PO	Useful in normal hearts without ischemia; prolongs QT; atropine effect	Atrial arrhythmias only
Procainamide (Procan, Procanbid)	AF, PAC, PVC, VT	PO, IV	Wider range of use in mild LV dysfunction; lupus side effect; prolongs QT and QRS; best used in normal hearts only; renally excreted with active metabolite (class III)	Atrial arrhythmias; acute suppression of VT after CABG
Quinidine (Quinidex, Quinaglute)	AF, AFL, PACs, PVC, VT	PO, IV	Marked QT prolongation, myasthenia; idiosyncratic blood defects; may enhance AV conduction	Limited use; mostly AF, AFL
Class Ib				
Lidocaine	VT, torsades de pointes	IV	Rapid onset; may cause CNS changes and seizures	Acute VT termination and suppression; being replaced by IV amiodarone
Mexiletine (Mexitil)	PVCs, VT	PO	Significant GI upset; mild proarrhythmia; mild effect; can be used carefully in setting of LV dysfunction	PVC suppression when other agents fail
Phenytoin (Dilantin)	VPB, VT	PO, IV	CNS effects; rash; blood dyscrasias	Rarely used; minimal effect
Tocainide (Tonocard)	VT	PO	CNS effects; blood dyscrasias; GI upset; pneumonitis	Rare use
Class Ic				
Flecainide (Tambocor)	AF, AFL, PACs, EAT, WPW	PO	Well tolerated; may increase conduction of slowed atrial flutter; contraindicated in CHF	Frequently used for AF, AFL
Propafenone (Rythmol)	PACs, EAT, AF, AFL, PVC	PO	Contraindicated in CHF	Frequently used for AF, AFL
CLASS II				
β-Nonselective				
Propranolol	ST, AT, IST, PVCs, VT, AF*	PO, IV	Excess bradycardia; hypotension; CNS effects; negative inotrope; pulmonary bronchospasm	Short acting, rapid onset; increased replacement by longer-acting cardiac selective agents
β-Selective				
Atenolol	ST, AT, IST, PVCs, VT, AF*	PO, IV	Excess bradycardia; hypotension; CNS effects; negative inotrope	Inexpensive, resulting in frequent use
Metoprolol (Lopressor, Toprol)	ST, AT, IST, PVCs, VT, AF*	PO, IV	Excess bradycardia; hypotension; CNS effects; negative inotrope	Frequently used, long-acting preparation with infrequent side effects
Pindolol	ST, AT, IST, PVCs, AF*	PO	Excess bradycardia; hypotension; CNS effects; negative inotrope	Intermediated use
Timolol	ST, AT, IST, PVCs, AF*	PO	Excess bradycardia; hypotension; CNS effects; negative inotrope	Low-frequency use
Esmolol (Brevibloc)	ST, AT, IST, PVCs, AF*	IV	Short acting; excess bradycardia; nonselective at high doses	Low-frequency use because of IV form only
Mixed α and β				
Carvedilol (Coreg)	CHF, PVCs, AF*	PO	Excess bradycardia; hypotension; exacerbation of CHF; fatigue	Infrequent as first choice for arrhythmias but primarily indicated for systolic heart failure
CLASS III				
Ibutilide (Corvert)	AF, AFL	IV	Proarrhythmia frequent, including PVCs, VT, and torsades de pointes; prolongs QT and slows heart rate; requires acute monitoring	Intermediate use has high efficacy in acute AF and AFL but with potential serious acute side effects
Dofetilide (Tikosyn)	PACs, AF, AFL	PO	High efficacy; prolongs QT and QRS; proarrhythmic, including torsades de pointes	Low-frequency use because of inpatient initiation and potential dangerous proarrhythmia; requires training to prescribe; is mortality neutral in CHF and MI patients
Sotalol (Betapace)	ST, AT, IST, PVCs, VT, AF*	PO	Excess bradycardia; prolongs QT with potential torsades de pointes	Moderate-frequency use; reasonably safe in setting of mild LV dysfunction in absence of ischemia

Continued on following page

Table 27-27 Indication, Route of Administration, and Considerations for Use of Common Antiarrhythmic Drugs (Continued)

Type of Drug	Typical Indications	Route	Considerations, Contraindications, and Complications	Frequency of General Use
Amiodarone (Pacerone, Cordarone)	ST, AT, AF, AFL, PVCs, VT, AF*	PO, IV	Class I, II, III, and IV effects; very well tolerated but may produce serious thyroid dysfunction and lethal pulmonary and liver dysfunction; close monitoring for side effects mandatory	High-frequency use owing to very low acute side effect profile and very high efficacy in a variety of arrhythmias; indiscriminate use is discouraged
CLASS IV				
Diltiazem (Cardizem, Cartia)	AF*, PVCs, calcium-dependent VT	PO, IV	Bradycardia; hypotension; exacerbation of systolic heart failure; continuous infusion available	Used frequently for AV node slowing in setting of AF with or without LV dysfunction
Verapamil (Calan, Isoptin)	AF*, PVCs, calcium-dependent VT	PO, IV	Bradycardia; hypotension; exacerbation of systolic heart failure	Used frequently for AV node slowing in setting of AF
CLASS V (OTHER)				
Adenosine (Adenocard)	SVT	IV	Acute onset with very powerful AV node block and to less extent SA block, producing marked bradycardia and transient asystole; temporary pulmonary symptoms	Agent of choice for abrupt termination of most AV node-dependent arrhythmias
Digoxin	AF*	PO, IV	Proarrhythmic, including heart block and enhancing bypass tract conduction; GI side effects	Frequent adjuvant drug for slowing ventricular response in AF
Atropine	SB	IV	Avoid in patients with acute-angle glaucoma	Acute treatment for sinus bradycardia and heart block not caused by Purkinje failure
Magnesium sulphate	Torsades de pointes, PVCs, VT suppression	PO, IV	Caution in renal failure	Frequent adjuvant drug for VT suppression

*Drugs are organized according to the Vaughan Williams classification scheme. Indications represent both approved and nonapproved indications as of the date of publication.

AF, Atrial fibrillation; AF*, atrioventricular node blockade in atrial fibrillation; AFL, atrial flutter; AT, atrial tachycardia; AV, atrioventricular; CABG, coronary artery bypass graft; CHF, systolic congestive heart failure; CNS, central nervous system; GI, gastrointestinal; IST, inappropriate sinus tachycardia; IV, intravenous; LV, left ventricular; MI, myocardial infarction; PAC, premature atrial contraction; PO, oral; PVC, premature ventricular contraction; SA, sinoatrial; SB, sinus bradycardia; ST, sinus tachycardia; VPB, ventricular premature beats; VT, ventricular tachycardia; W/PW, Wolfe-Parkinson-White.

cardiac arrhythmias (Echt et al., 1991; Sodermark et al., 1975). In addition, invasive evaluation and treatment of common bothersome or malignant arrhythmias is carried out by cardiac specialists trained in electrophysiology. In addition to drug therapy, an electrophysiologist may offer invasive techniques to treat arrhythmias. Arrhythmia ablation, implantation of pacemakers and defibrillators, and cardiac resynchronization therapy are all techniques to help reduce morbidity and mortality rates.

ELECTROPHYSIOLOGY STUDY AND ABLATION

Patients in whom invasive arrhythmia therapy is recommended are evaluated in special catheterization suites. During an electrophysiology study, several electrodes or wires are inserted through the femoral or jugular vein and advanced to the right atrium, RV, coronary sinus, and the region of the AV node–His-bundle complex. Special pacing sequences and premature beat delivery are used to initiate arrhythmias. The wires may then be moved to different sites within the heart. Application of radiofrequency current through the tip of the catheter electrode results in elimination of the arrhythmia focus. Variations in duration and power of the current are used to alter lesion size. Studies may last less than 1 hour to several hours depending on the

nature of the arrhythmias treated. This essentially painless method replaced the older technique of direct current lesion application, which was poorly controlled, was quite painful, and required general anesthesia to carry out. Radiofrequency ablation is now used as the standard technique in treatment of AV node–dependent arrhythmias, including AVNRT, AV reciprocating tachycardia, and junctional tachycardia. AFL is successfully cured in most cases, and even paroxysmal AF may be suppressed or cured by this technique. Termination of AFL is demonstrated in Figure 27-43. Future refinements of this technique may one day be used to cure countless numbers of patients with bothersome AF.

Alternate energy sources, including microwave, ultrasound, and cryotherapy, are being investigated and used. Radiofrequency, however, remains the energy source in almost all cases for the routine treatment of supraventricular arrhythmias treated with ablation. Treatment of arrhythmias through open-chest procedures was once the only method to cure arrhythmias. Considered high risk in most patients and too invasive for nonlethal arrhythmias in the era of radiofrequency ablation, surgical ablation for AF has enjoyed a resurgence as adjunct therapy during valvular heart surgery with cryotherapy and radiofrequency therapy of pulmonary veins (Todd et al., 2007).

PACEMAKERS AND DEFIBRILLATORS

Significant development in the area of pacing has occurred since transvenous pacemakers were first produced and implanted. Once able to pace only in a single chamber at a preset rate and without the ability to detect underlying rhythms, the pacemakers of today are more sophisticated. A pacemaker is in its simplest form a battery, a pulse generator, and a lead to deliver an impulse. The use of sensing and timing circuits coupled with motion detectors within the pacemaker allow inhibition of pacing when sensed events occur and an increase in paced rate with motion or activity. As technology has advanced, pacemakers are able to pace effectively in the atrium and ventricle, and AV or PR intervals can be adjusted. Telemetry through the skin using proprietary programmers allows adjustment in the physician's office. Miniaturization has now resulted in sophisticated pacemakers in a package not much larger than a half-dollar coin that can pace the heart when necessary, detect rapid rhythms, and attempt to pace terminate the arrhythmia (Figure 27-56; Furman et al., 1993).

Figure 27-56 Dual-chamber pacemaker with endocardial passive and active fixation leads. (Courtesy Medtronic, Minneapolis, MN.)

Implantable defibrillators with endocardial leads were developed in the early 1990s, allowing for a safer and less invasive procedure. These devices are now able to identify and attempt to terminate ventricular arrhythmias through painless overdrive pacing or using an endocardial shock that can be uncomfortable if the patient is not syncopal (Figures 27-57 and 27-58).

CARDIAC RESYNCHRONIZATION AND DEFIBRILLATOR THERAPY

Patients with refractory clinical CHF have a six- to ninefold increase in sudden cardiac death compared with the general population (AHA, 2002). Despite medical therapy with β -blockers, ACE inhibitors, angiotensin II receptor blockers, diuretics, spironolactone, digoxin, and invasive revascularization strategies, patients continue to have significant morbidity and mortality from systolic CHF. Electrophysiologists for more than a decade have been impacting mortality and morbidity through cardiac pacing resynchronization therapy and defibrillator placement.

The slowing of conduction through the LV in the setting of bundle branch block or significant scarring leads to dyssynchronous lateral and septal contraction. This dyssynchrony results in excess energy expenditure and decreases cardiac performance. Placement of a pacing device capable of pacing in the RV and additionally at the lateral LV has resulted in significant reductions in morbidity and mortality. The addition of a defibrillator further results in reduction of mortality (Abraham et al., 2002; Bristow et al., 2004; Cleland et al., 2005; Young et al., 2003).

Figure 27-59 shows the radiographic appearance of a biventricular system. Pacing in both ventricles demonstrates a shortening of the QRS complex and is associated with improvements in cardiac contractility and over time reduction in LV chamber size, reduction in mitral valve regurgitation, improvements in 6-minute walk test results, quality of life, and NYHA HF classification (Abraham et al., 2002). In Figure 27-60, changes in the QRS morphology are demonstrated depending on the site of electrical

Figure 27-57 Ventricular tachycardia is pace terminated by three rapid ventricular pulses from the implanted pacemaker-defibrillator. Atrioventricular sequential pacing resumes after termination of the ventricular tachycardia.

Figure 27-58 Attempt at pace termination of ventricular tachycardia with acceleration of the ventricular tachycardia into ventricular fibrillation. The transient of the endocardial shock is noted, and pacing resumes with organized cardiac activity.

Figure 27-59 Radiographs from a dual-chamber biventricular defibrillator. Right and left anterior oblique views are shown in a patient treated for left ventricular systolic dysfunction and New York Heart Association class III heart failure. Standard leads terminate in the right atrium and the right ventricular septum. A third lead enters the coronary sinus from the right atrium and extends into a branching vein to provide synchronous left and right ventricular activation.

Figure 27-60 Left bundle branch block (BBB) and right BBB are produced from contralateral ventricular pacing. Right ventricular pacing with left BBB morphology is noted on the *left*. Pacing activates one side of the ventricle earlier and therefore results in a BBB pattern of the opposite side of the chamber paced. On the *right*, inappropriate left ventricular endocardial lead placement delivered across a patent foramen ovale was detected before serious consequences of embolic stroke. Epicardial pacing of the left ventricle is also accomplished through lead placement through the coronary sinus.

stimulation. During right and LV activation, the QRS morphology in lead V1 is shown.

Patients with lethal tachycardia events such as VT and VF have been extensively studied. For much of modern electrophysiologic history, the electrophysiologic study was used to induce VT in patients with syncope and structural heart disease, in patients with symptomatic stable VT, and in patients resuscitated from arrhythmic sudden cardiac death. Drugs were then initiated, and repeat testing was performed to test the success of the antiarrhythmic drug. More recent studies have challenged this approach. Drug versus implantable defibrillator therapy trials have demonstrated mortality benefit as secondary prevention of syncope VT or resuscitated sudden cardiac death with structural heart disease (*Antiarrhythmics versus Implantable Defibrillators Investigators, 1997; Connolly et al., 2000; Kuck et al., 2000*). Further studies have demonstrated mortality benefit from implantable defibrillators compared with drug therapy in primary prevention trials. Specific groups of patients have demonstrated superiority of device therapy compared with drugs: (1) patients with asymptomatic ventricular ectopy with inducible VT, (2) patients with prior MI and EFs less than 30%, and (3) patients with EFs less than 35% with class II or III NYHA

HF for longer than 3 months (*Bardy et al., 2005; Buxton et al., 2000; Moss et al., 1996, 2002*). Patients fulfilling these criteria should be referred to an electrophysiologist.

SUMMARY

Treatment of patients with symptoms referable to an arrhythmia is possible for many physicians. Accurate diagnosis of the arrhythmic event may prove difficult, and additional diagnostic tests not readily available to the family physician may need to be used. More conscientious use of antiarrhythmic drugs is necessary as we learn more about the proarrhythmic effects. Implantable device therapy continues to evolve and promises to alter the natural history of many malignant cardiac disease states.

Primary care providers can perform many common surgical procedures in an outpatient setting without significant sedation. This chapter provides the foundational competency skills in common procedures, including adequate preparation, appropriate setup, informed consent, good technical skills, and awareness of potential complications. A discussion of the basic surgical skills and setup required, patient consent, and local anesthesia is followed by a review of common office procedures in family medicine, with tips to perform these successfully with minimal complications.

As the U.S. health care system grapples with medical home concepts, family medicine providers must develop proficient skills to carry out common procedures in primary care clinics. The health care system has provided high remuneration for procedural medicine in the past but is evolving to a system driven by outcomes, competency, and the ability to provide cost-effective, competent procedural services in a primary care medical home.

For a brief history of surgery, see [eAppendix 28-1](#) online.

Basic Skills

THE PATIENT HISTORY

The physician must begin with a pertinent comprehensive health history and thorough understanding of the patient and his or her current health condition before undertaking any surgical procedure. Preexisting diagnoses such as diabetes or hemophilia may affect wound healing or bleeding.

Allergies to medication, tape, or preparation agents should be elicited along with any personal or family history of bleeding or thrombosis. Anticoagulant use, including aspirin, clopidogrel, warfarin, nonsteroidal antiinflammatory drugs (NSAIDs), ticlopidine, and dipyridamole, may affect bleeding and hemostasis during any procedure.

Guidelines on perioperative anticoagulation divide these medicines into three categories. There are vitamin K–dependent anticoagulants (VKAs) such as Coumadin, aspirin and NSAIDs, and clopidogrel. Patients taking VKAs who are undergoing minor dental procedures may continue the VKAs and take a dose of vitamin K or stop the VKAs for

2 to 3 days before the minor dental procedure. Patients taking VKAs who are undergoing minor dermatologic procedures are advised to continue vitamin K–dependent anticoagulation, continue aspirin and NSAIDs, and consider stopping clopidogrel if not at high risk for cardiac disease ([Douketis et al., 2012](#)).

Aspirin and other antiplatelet medications may be resumed 24 hours after surgery. If a superficial procedure is performed on a high-risk patient, the physician should continue the blood-thinning agent and consider using local anesthesia with epinephrine for vasoconstriction. Local cautery, direct ligation of bleeding vessels, and direct pressure are used as needed for hemostasis.

A change in approach is warranted when a history of delayed healing or keloid (thick scar) formation is elicited. Preventive measures should be undertaken in a patient with a history of a prior vasovagal event or fainting episode during or after a procedure.

KEY TREATMENT

- Patients taking aspirin for secondary prevention of cardiac disease who are having minor dental, dermatologic, or cataract surgery should continue the aspirin *and NOT stop it 7 to 10 days before surgery as previously advised* (SOR: C) ([Douketis et al., 2012](#)).
- Warfarin should be stopped 2 to 3 days before the procedure in low-risk patients. High-risk patients may need heparin bridging (SOR: A) ([Singer et al., 2008](#)).
- Fish oil and omega-3 fatty acids have not been shown to increase bleeding (SOR: A) ([Villani et al., 2013](#)).

SKIN PREPARATION

The skin should be prepared with an appropriate antiseptic solution, starting in the middle of the surgical site and going outward in concentric circles in aseptic fashion. Alcohol, chlorhexidine, povidone-iodine (Betadine), or a combination may be used as an antiseptic cleansing agent ([Mangram et al., 1999](#)).

The U.S. Centers for Disease Control and Prevention (CDC) and Healthcare Infection Control Practices Advisory Committee updated guidelines in 2002 on skin preparation

History of Surgery

The earliest surgeries documented were *trepanations*, or drill burr holes in the skull, found in skeletal remains dating back to 12,000 BC. Sumerian civilization in ancient Mesopotamia (modern Iraq) had cuneiform text depicting surgical tools. The Sumerian Codex Hammurabi (1790 BC) contains information on specific types of surgeries along with malpractice and compensation rates. The *Sushruta Samhita* (600 BC) is the first surgical textbook. Ancient Indian plastic surgery techniques, similar to modern procedures, are depicted, including rhinoplasty and flap advancement for nose amputations. Trainees are advised in this text to practice on inanimate objects before operating on humans.

Abul al-Qasim al-Zahrawi (936-1013 AD), also known as Abulcasis, was born in al-Zahra near Cordoba, Spain. He developed hundreds of surgical tools, including the surgical needle; pioneered the internal use of catgut; and advocated use of silk thread for better cosmesis. He is also credited with

developing stick antiperspirant and plaster bandages. Abulcasis wrote the *Kitab al-Tasrif*, a 30-volume encyclopedia of medical and surgical practices distilled from his prolific 50-year practice of medicine, research, and teaching. The *Kitab al-Tasrif* was translated into Latin in the 12th century and was known as *Concessio ei Data qui Componere Haud Valet*. This ancient textbook has pictures of surgical instruments along with detailed descriptions on surgical procedures (eFigure 28-1). The physician-patient relationship is emphasized; patient observation is encouraged, and physicians are advised not to perform procedures to enrich themselves. Abulcasis is known as the “father of modern surgery,” and his surgical training text was the standard in Europe for more than 500 years.

Anesthesia, sterile technique, and research have improved modern surgery significantly. Infection rates and complications continue to challenge family physicians, although these have improved as well.

eFigure 28-1 Pictures of instruments designed and used by Abulcasis (~1000 AD). (From al-Zahrawi AQ, Leclerc L. La chirurgie d'Abulcasis: precedee d'une introduction. Bailliere. 1861.)

related to reducing central line infections. The CDC had issued additional guidelines for the prevention of surgical site infection in 1999. The U.K. National Institute for Health and Clinical Excellence–Surgical Site Infection guidelines from 2008 concurred with the CDC’s recommendations. Skin aseptic preparation with chlorhexidine 2% plus 70% isopropyl alcohol was the best at preventing surgical site infections because it achieves greater reductions in skin microflora and has greater residual activity after a single application (Mangram et al., 1999).

Chlorhexidine gluconate is effective even in the presence of blood or serum proteins, but blood and serum proteins may inactivate povidone-iodine. Based on chlorhexidine dilution and duration studies, the best reduction of bacterial load occurred with 4% solution applied at least two minutes before incision. The bacteriocidal effects lasted an hour (Stinner et al., 2011). Isopropyl alcohol 70% is effective immediately, but the antiseptic effect is not sustained. Combinations are superior to isopropyl alcohol or chlorhexidine alone (Adams et al., 2005; Hibbard, 2005).

Many surgical site infections are from endogenous staphylococcal skin flora. An increasing number are also resistant to antibiotics, such as methicillin-resistant *Staphylococcus aureus* (MRSA). Good handwashing and aseptic technique are primary for the prevention of MRSA-related surgical site infections (Siegel et al., 2006). Patients who wash preoperatively with soap and water or chlorhexidine may reduce bacterial skin flora, but this did not reduce the incidence of surgical site infections (Webster and Osborne, 2012). Various guidelines on the prevention of soft tissue surgical site infections found that broad routine MRSA screening is not indicated before surgery (Glick et al., 2013).

KEY TREATMENT

- Chlorhexidine plus alcohol-containing skin preparations were better than povidone-iodine for surgical site antiseptics (Darouiche et al., 2010) (SOR: A).
- Hair should not be removed before surgery unless the hair is at or around the incision site and would interfere with the procedure. If hair removal is required, it should be clipped immediately before surgery, and it should not be shaved (Mangram et al., 1999) (SOR: A).

BITES

Bites represent special risks for laceration repair. Animal bites often involve deep puncture wounds and should be cleaned and irrigated thoroughly. They are generally not closed but are allowed to heal by secondary intention. Facial bites may be primarily closed after wounds are cleansed.

Untreated cat bite infection rates are 18% to 33% (Dire, 1991). Treating cat bites with prophylactic antibiotics significantly reduces infection rates. Dog bites may be more lacerated, and after high-pressure flushing at greater than 7 psi (obtained flushing with a 50-cc syringe and saline), they may be closed primarily in the first 6 hours after the injury. Infection rates for dog bites are less than 20% (Dire, 1992).

Primary suture closure is not generally recommended for nonfacial bite wounds, especially deep punctures, bites to the hand, and clinically infected wounds. Anecdotal data suggest an increased risk of infection after closure of these wounds. Sterile skin closure strips or delayed closure may be appropriate (Singer et al., 2008).

Human bites on the hands and specifically overlying the metacarpophalangeal joints are problematic because of potential damage to underlying tissue, tendons, and joint spaces. Hand injuries may therefore lead to aggressive deep secondary infections. Documentation of sensation, range of motion, and exploration to determine joint or deep space involvement may still miss serious intraarticular bites. Profuse flushing of human hand bites or lacerations, prophylactic antibiotics, and consultation are advised. These wounds may need to be surgically opened under anesthesia to adequately flush them. Seeking care may be delayed, and rates of infection rapidly increase if seen after 24 hours. Late assessment after 24 hours usually involves operative debridement and flushing along with intravenous antibiotics. Bite wounds evaluated, deemed to not involve deep tissues, and flushed within the first 24 hours may be treated conservatively with oral antibiotics; physicians should be aware that there may still be deep penetration, which leads to urgent operative care.

Wounds to both the hands and face need immediate care because infection rates almost double to 29% if not treated within 12 hours. Prophylactic antibiotics should be used with hand and facial bite wounds. Facial wounds may be flushed and closed primarily because of the good blood supply and a risk for poor cosmesis if they are left open (Henry et al., 2007).

KEY TREATMENT

- Antibiotics should be used prophylactically in human bites to the hand (number needed to treat [NNT] = 4) (Medeiros and Saconato, 2001) (SOR: A).
- Prophylaxis with amoxicillin/clavulanate should be considered for all bite wounds that are primarily closed, all puncture wounds, cat bites to the hand and wrist, clenched fist injuries, and crush wounds (Morgan, 2005) (SOR: C).
- Clenched fist human “fight bites” should be radiographed for broken teeth and foreign bodies (Sternberg and Jacob, 2010) (SOR: C).

IMMUNIZATIONS

Tetanus immunization should be updated if indicated with any laceration or open skin injury. If a patient has received three or more primary tetanus immunizations, he or she should receive a booster if the last immunization was more than 10 years ago for a clean wound and if more than 5 years ago with a dirty wound. Patients should receive tetanus immune globulin and begin their tetanus immunization series if they have had fewer than three primary tetanus immunizations in the past. Diphtheria toxoid and pertussis antigens with tetanus toxoid (Tdap) should replace a single dose of Td for adults aged 19 through 64 years who have not received a dose of Tdap previously and require a booster. Tdap may be given as close as 2 years after a Td;

data suggest it is safe even if given within 21 days of Td. Td can be given every 10 years when needed after one Tdap dose is received (CDC, 2010; see [Web Resources](#)).

Patients should be offered the hepatitis B immunization series for any human bite or for mucous membrane blood exposure. Patients should be offered and consent to baseline testing for hepatitis B virus (HBV) and C virus (HCV) and human immunodeficiency virus (HIV). Appropriate follow-up based on test results must be arranged (Panlilio et al., 2013). HBIG is indicated if the patient has injuries from a person known to be positive for hepatitis B surface antigen; however, needle stick guidelines suggest that the injured patient receive only a hepatitis B immunization series and not HBIG if the contact person has an unknown or negative carrier status. In the case of a needle stick, HIV prophylaxis with three drugs is recommended if the contact person is known to be HIV positive. If the source patient has an unknown HIV status, postexposure prophylaxis (PEP) generally is not indicated unless there is concern that the source is higher risk, in which case a three-drug PEP is recommended (Clinician Consultation Center, 2014; Panlilio et al., 2005; Schillie et al., 2013; see [Web Resources](#)).

PROCEDURE ROOM

A clean procedure room with a table that elevates and an overhead surgical light that can be adjusted and focused gives the provider the best environment to carry out procedures. An adjustable and mobile mayo stand allows the most comfortable access to sterile trays and instruments. Surgical instruments should be stored in sterile packs, ideally set up for specific procedures. Extra equipment may be in individual sterile packs and should be readily available. Sterility expiration dates for all packaged equipment should be checked.

Patients should be made comfortable for the procedure with use of an adjustable bed and pillows as needed. Open, supportive conversation with an empathetic approach encourages relaxation and reassurance before, during, and after the procedure. An assistant is helpful in setup and during the procedure and provides support for the patient during care. In children undergoing a procedure, a family-focused dialog and ongoing conversation are similar to using midazolam in reducing anxiety and speeding recovery (Kain et al., 2007). Prior to starting any procedure, do a “time out” to review a patient procedure check list to make sure everyone agrees on the patient, procedure, and code word to stop the procedure if any team member notes something of concern. This is similar to a pilot’s preflight inspection and reduces error (Haynes et al., 2009).

Equipment

The most basic sterile pack for skin procedures contains a needle driver, Adson tissue forceps with teeth, iris or suture scissors, and scalpel handle with blade. The instruments should comfortably fit the provider’s hands.

Three primary scalpel blade styles are used in the outpatient setting. A #10 blade has a large, rounded cutting surface and may be used for longer, straight incisions on larger body areas with thicker skin, such as the trunk or limbs. A #15 blade has a smaller, rounded cutting surface to allow more mobility for nonlinear incisions and may be

Figure 28-1 The use of forceps or a skin hook to evert the wound edge. This technique allows the operator to see the needle path, thereby ensuring that the proper depth has been reached, and promotes eversion of the skin edges. (From Roberts JR. *Methods of wound closure*. In Roberts JR, ed. *Roberts & Hedges’ clinical procedures in emergency medicine*. 6th ed. Philadelphia: Saunders; 2014.)

used on most skin procedures. A #11 blade has a pointed surface without a curve and is better used for paring superficial lesions, such as warts or calluses, or puncturing skin abscesses. The Adson forceps with teeth has one side with one tooth and the other side with two teeth. Less tissue trauma occurs using the single tooth on the external tissue while everting the skin edges or using a skin hook (Fig. 28-1).

Needle drivers should fit the provider’s hand; the ring finger fits in the lower handle hole, and the thumb may fit in the top circle of the handle with the index finger extended along the shaft to stabilize the needle driver. The needle is loaded by locking the needle driver about three quarters of the way up the needle shank, with the needle held perpendicular to the needle driver. Sharps are kept in the same area of the sterile field to reduce needle stick injuries.

Suture

Three basic types of suture exist: natural absorbable, synthetic absorbable, and nonabsorbable. Sutures are sized according to the 1937 U.S. Pharmacopeia classification system. A smaller suture has a higher number of zeroes (e.g., 4-0 is finer than 2-0). The physician should use the smallest suture size that provides adequate initial tensile strength to close the wound and not fail during the healing process. The clinician should use deep subcutaneous sutures to reduce surface tension if the wound is deep and there is high skin surface tension. Ideally, superficial skin sutures gently approximate the skin edges with minimal tension.

Absorbable types of suture include plain gut; chromic gut; and synthetic sutures made of polyglycolic acid, polylactic acid, polydioxanone, and caprolactone. Whereas plain gut suture used externally has a tensile strength lasting 5 to 7 days, chromic gut used internally has a tensile strength lasting 10 to 14 days. The synthetic absorbable

Table 28-1 EMLA Dosing

Age and Weight Requirements	EMLA Cream (maximum total dose, g)	Maximum Application Area (cm ²)	Maximum Application Time (hr)
0-3 mo or <5 kg	1	10	1
3-12 mo and >5 kg	2	20	4
1-6 yr and >10 kg	1	100	4
7-12 yr and >20 kg	20	200	4

EMLA, Eutectic mixture of lidocaine and prilocaine.

Developed from EMLA drug information. In *Facts and comparisons*, 2010. <http://online.factsandcomparisons.com/MonoDisp.aspx?monoID=fandc-hcp14927&quick=341644%7c5&search=341644%7c5&isstemmed=true>.

types of suture vary in length of tensile strength and rate of absorption. Nonabsorbable suture is made of nylon, special silk, polypropylene, or polyester. These sutures are made in different colors and are inert. Most have long-lasting tensile strength. Nonabsorbable sutures are used externally but can also be used internally for prolonged tissue reinforcement. Nonabsorbable sutures cause less immune response and therefore less scarring. Frequently, they are used superficially when cosmetic outcome is critical.

Traditionally, absorbable suture was only placed below the skin's surface because of its porous structure and concern it would wick bacteria from the skin surface. However, this recommendation is not evidence based. A meta-analysis of two randomized, controlled trials (Jadad scores 3) comparing absorbable versus nonabsorbable sutures in the management of traumatic lacerations and surgical wounds showed no changes in infection rates, scar appearance, patient satisfaction, or dehiscence. In children, the benefit is not requiring suture removal (Al-Abdullah et al., 2007).

Needles

Suture needles are classified by the geometry of their points. Taper needles have a round body that tapers smoothly to a point. Cutting needles are triangular with a sharp cutting edge on the inside curve of the needle; reverse cutting needles have the cutting edge on the outside of the curve. A taper-cut needle is round but ends in a short, triangular cutting point. Some needles are attached permanently to suture and others, called "pop-offs," separate from the suture with a sharp pull. With the wide range of needle types, physicians should be familiar with their own supplies and examine the outsides of packages closely before use. Reverse cutting needles are stronger than conventional cutting needles; both minimize trauma to the skin and so are appropriate for most skin closure.

ANESTHESIA

Topical Anesthesia

An equal mixture of prilocaine 2.5% and lidocaine 2.5%, EMLA (eutectic mixture of lidocaine and prilocaine) cream, may be used as a topical anesthetic. EMLA works best if it is applied to the dermal site at least 1 hour before the procedure and covered with an occlusive dressing. Its use is limited because of the time needed for onset of anesthesia; the increased expense; and the risk of methemoglobinemia in susceptible individuals, such as those with congenital disease; pyruvate kinase-deficient and glucose-6-phosphate dehydrogenase (G6PD)-deficient patients; and those with

rare, acquired forms resulting from medications (e.g., prilocaine, antimalarials, sulfonamides). Patients younger than 3 months of age are vulnerable to developing methemoglobin because the breakdown product, orthotoluidine, can produce methemoglobinemia after systemic doses of prilocaine approximating 8 mg/kg. A rectangle measuring 1.5 × 0.2 inches is about 1 g of EMLA or 25 mg of prilocaine. The maximal area of application is age and weight dependent (Table 28-1).

Other topical anesthetics are used in some circumstances. Ethyl chloride cools the skin superficially and works well for needle punctures. Unfortunately, it is flammable and has a brief action, limiting its usefulness. A 30% lidocaine cream must be applied with an occlusive patch at least 45 minutes before any procedure. Liposomal encapsulation forms of topical tetracaine and lidocaine are as efficacious as EMLA (Eidelman et al., 2005). Lidoderm patches are only at 5% concentration and are not potent enough for topical surgical skin anesthesia (Video 28-1).

Local Anesthesia

For most office procedures, a local injection is a quick and easy way to provide anesthesia by blocking the fast sodium channels and stopping pain fiber neurotransmission. However, an injection of local anesthetic may distort skin edges and adversely affect skin anatomy and alignment. Consider marking incisions and vital points of alignment before infiltrating with a local anesthetic. Anesthetize before flushing the wound in repair of contaminated lacerations. Infiltration of 1% lidocaine does not damage local defenses, promote infection, or exhibit antimicrobial activity that would obscure a culture from a wound (Edlich et al., 2010).

The two groups of local anesthetics are amides and esters. Allergies are more common to the esters. Allergy to an amide is usually caused by the preservative methylparaben. If a patient has an ester allergy, use an amide. No cross-reactivity occurs between classes (Archar and Kunder, 2002) (Table 28-2).

The most common locally injected anesthetic is lidocaine, with or without epinephrine. One percent lidocaine contains 10 mg/mL of lidocaine. Lidocaine dosing should not exceed 4.5 mg/kg without epinephrine (maximum, 300 mg in adults or 30 mL of 1% lidocaine) or 7 mg/kg of lidocaine with epinephrine (maximum, 500 mg in adults or 50 mL of 1% lidocaine with epinephrine) (Tetzlaff, 2000). Others list the recommended safe dose of infiltrated lidocaine as 200 mg or less in an adult, which is 20 mL of 1% lidocaine (Rosenberg et al., 2004). If doing a paracervical or pudendal block, the maximum total dose over 90 minutes is 200 mg of lidocaine or 20 mL of 1% lidocaine total (10 mL

Table 28-2 Local Anesthetic Classifications

Amides	Lidocaine (Xylocaine)
	Bupivacaine (Marcaine)
	Prilocaine (Citanest)
	Etidocaine (Duranest)
	Mepivacaine (Carbocaine)
	Articaine (Septocaine, Zorcaine)
	Ropivacaine (Naropin)
	Dibucaine (Nupercainal)
Esters	Procaine (Novocain)
	Tetracaine (Pontocaine)
	Chlorprocaine (Nesacaine)
	Cocaine
	Benzocaine (Lanacaine, Americaine)
	Proparacaine (Alcaine, Ophthetic, Paracaine)

Expanded from Archar S, Kundar S. Principles of office anesthesia. Part I, infiltrative anesthesia. *Am Fam Physician*. 2002;6:91-94.

per side). Lidocaine has an elimination half-life of 1.5 to 2.5 hours in most patients, and average infiltrative anesthesia lasts 2 to 6 hours. Bupivacaine has a longer onset and duration of action with an elimination half-life of 2.7 hours in adults and 8 hours in neonates. Data on mixing lidocaine and bupivacaine are limited.

To make the injection more comfortable, the following have been shown to be helpful in some studies: distraction and reassurance, prior application of a topical anesthetic (EMLA or ethyl chloride spray), warming the solution, buffering the solution (1 : 10 dilution with sodium bicarbonate), using a fine-gauge long needle, injecting slowly, using the least amount of solution necessary, infiltrating through the wound edges, injecting from looser subdermal to tighter intradermal skin, and blocking nerves where possible (Quaba et al., 2005).

Some local anesthetics have epinephrine as an additive to help with hemostasis in very vascular locations. The past recommendation was to avoid the use of epinephrine on end-artery areas, including the fingers, ears, nose, lips, penis, and toes. However, a recent review on the use of local anesthesia with epinephrine in a digital block challenges this dogma (Mohan and Cherian, 2007). To be safe, epinephrine should not be used in distal-end vascular beds until the data are more conclusive (Video 28-2).

Local Ring Anesthesia Block

For anesthesia around a superficial skin lesion, a ring block can be placed with good results and reduced tissue distortion. Use a larger needle to draw up the anesthetic and a 25- to 30-gauge needle to infiltrate the tissues. Insert the needle into the subcutaneous skin a few millimeters outside the planned incision line and advance along that circular line around the lesion. Aspirate intermittently for blood to avoid direct instillation of anesthetic into a vein or artery. Infiltrate the local anesthetic as the needle is advanced. Use anesthetized areas to puncture the skin and inject more distal areas as needed around the planned surgical field until the lesion is fully circumscribed.

Digital Block

A digital block can be an effective method for providing anesthesia for fingers and toes. A dorsal or interdigital approach is used to provide anesthesia to the digit. The digital nerves are 3 to 5 mm under the skin at the 2, 4, 8,

Figure 28-2 Digital nerve block. (From Frank BL. Principles of pain management. In Auerbach PS, ed. *Wilderness medicine*. 6th ed. Philadelphia: Mosby; 2012:420.)

and 10 o'clock positions around the digit. Each location can be infiltrated with 1 to 2 cc (mL) of 1% lidocaine without epinephrine. It may take 5 to 30 minutes for distal anesthesia to develop after injection. Occasionally, local anesthesia is needed at the base of the digit circumferentially if achieving complete anesthesia becomes difficult (Fig. 28-2). Patients may continue to feel pressure and motion but should not feel sharp pain when the anesthesia is effective (Video 28-3).

Complications with Local Anesthesia

Recognizing the various side effects and reactions to local anesthesia is critical to prevent serious complications. The most common complication with the use of local infiltrative anesthesia is a vasovagal episode. Lying the patient down in reverse Trendelenburg positioning with both legs elevated can increase blood return to the heart and vagally depressed cardiac output. Atropine can reverse vagal bradycardia but is rarely needed. Recovery occurs spontaneously within minutes, but the queasiness may persist for 30 to 60 minutes.

Inadvertent instillation of an anesthetic into a blood vessel may cause seizures, jitteriness, or palpitations and may be avoided by always aspirating before infiltrating the local anesthetic. If a flash of blood is obtained on aspiration, pull the needle back partially, aspirate again, and instill only if no blood return occurs. Other reactions to local anesthesia are discomfort, bruising, and edema of the injection site. True anaphylaxis to lidocaine is estimated to occur in fewer than 1% of injections (Haugen and Brown, 2007). If anaphylaxis occurs, administer epinephrine 1 : 1000 subcutaneously every 5 minutes as needed and give diphenhydramine (Benadryl), 25 to 50 mg (adult dose) orally, intravenously, or intramuscularly. The adult dose of epinephrine 1 : 1000 is 0.3 to 0.5 mL/kg, and the pediatric dose is 0.01 mL/kg at the same intervals. Emergency response personnel should be immediately notified, and prolonged observation in the emergency department is advised.

Sedation

Some patients may require minimal to mild conscious sedation during a procedure in the outpatient clinic setting. Use of a low-dose benzodiazepine, such as 1 to 2 mg of lorazepam or 0.5 to 1 mg of alprazolam, may be appropriate for light conscious sedation. Sedation may also be accomplished with a dose of an oral opioid such as hydrocodone or oxycodone. These patients should not operate a car or heavy machinery, and another person should provide their transportation. Use of an opioid in combination with a benzodiazepine may cause significant respiratory depression and requires additional constant monitoring of cardiac and oxygenation status, which may not be available in some ambulatory clinical practices.

WOUND IRRIGATION

Wound healing is affected by infection, tension, perfusion, and alignment. Cleaning a wound with tap water or isotonic saline removes debris and bacteria mechanically from the wound and reduces infection rates. One study found no clinically important differences in infection rates between wounds irrigated with tap water or a normal saline solution (Valente et al., 2003).

Many studies recommend 7 psi (lb/in²) or greater for adequate irrigation of dirty wounds and 0.5 psi for clean wounds. Whereas irrigation of the wound with a 35- to 50-mL syringe and a 19-gauge needle produces 7 psi, using a bulb syringe only produces 0.5 psi, which is inadequate to flush and decontaminate a dirty wound. The potential for lateral subcutaneous dissemination with use of high-pressure irrigation can make a clean wound more susceptible to infection, so it should be reserved for contaminated wounds when the benefits are greater than the risk of dissemination. The low-pressure bulb syringe is used for clean lacerations. The pressure is more important in dislodging adherent bacterial and small particles than the amount of solution used. All health care professionals should use a splash protector during irrigation (Edlich et al., 2010).

There is debate on using povidone-iodine (Betadine) to cleanse dirty wounds. In general, avoid Betadine surgical scrubs within the laceration because it can be toxic to tissue. If used, dilute Betadine 1 : 10 with water. Chlorhexidine and hydrogen peroxide may also be toxic to tissue inside a laceration and should be used with care. Poloxamer-188 solutions are safe to use within wounds and are even used on ophthalmologic skin surgeries to cleanse the conjunctiva and by dentists to cleanse oral mucosa.

KEY TREATMENT

- Studies recommend 7 psi or greater for adequate irrigation of dirty wounds (Edlich et al., 2010) (SOR: A).

DEBRIDEMENT

A dirty, uneven wound may benefit from direct, sharp debridement back to clean, viable tissue. Obtaining clean, even skin edges may improve healing, facilitate repair, and reduce scarring. If road grit is present, it must be removed with scrubbing as needed to avoid infection and tattooing.

Generally, unless high-pressure irrigation is unable to remove grit, scrubbing is avoided because it may disrupt clotting along the skin edges. Wounds from high-velocity trauma, deep bites, and soil and fecal contamination are best cleaned in the operating room and allowed to heal open by secondary intention because primary closure is contraindicated (Edlich et al., 2010).

Good anesthesia is critical to appropriate irrigation and debridement. If significant debridement is planned, the physician should document neurologic function in the injured area and distally before infiltration of the anesthetic.

Principles of Healing

Wound healing begins immediately after the initial trauma or cut. Traditional descriptions of wound healing use three distinct but overlapping phases (inflammatory, proliferative, remodeling), but others use four phases to better describe the healing process. Surgical technique and smoking are modifiable risk factors for poor wound healing. Other factors affecting wound healing include anemia, vascularity, diabetes, malnutrition, HIV infection, and cancer.

Trauma to surrounding tissue by the injury and surgical techniques (e.g., too much tension on sutures) may affect healing. Adequate oxygenation and blood flow are critical to good healing. Medications that affect healing include steroids, NSAIDs, and immunosuppressive medications.

STAGES OF HEALING

Exudative or Inflammatory Phase

Immediately after a laceration, fibrin deposits with an influx of platelets, forming a visible clot. The platelets secrete various wound-healing growth factors that activate macrophages and fibroblasts. These growth factors and more than 30 cytokines cause an influx of cellular structures. This phase occurs from 0 to 72 hours (Figure 28-3).

Resorptive Phase

After 24 to 72 hours, the degradation products of fibrin lead to activation of chemotaxis in the resorptive phase. Leukocytes and macrophages migrate into the wound, causing inflammation. The cellular components then begin autolysis and remove injured tissue by a fermentative process. This process creates an effective phagocytosis, a sterilizing defense, and an activation of the immune system.

Proliferative Phase

Between 72 hours and 7 days, fibroblasts migrate into the wound, and vascular proliferation occurs. Granulation tissue formation marks the proliferative phase. Epidermal cells begin to grow at the edges of the wound. A delicate balance of cytokine systems leads to new capillary formation to feed and oxygenate the budding granulation tissue. Extracellular matrices form and act as struts to support the new tissue. The primary clots are broken down by naturally developing fibrinolytic compounds (Figure 28-4).

Regenerative or Remodeling Phase

The remodeling stage is a continuation of the proliferative phase, with ongoing maturation of collagen. The

thickening collagen leads to an increased resistance to shearing and tearing forces. The regenerative phase is characterized by epithelialization and scar formation. This last phase may take up to 1 year. Collagen type III is converted into the mature type I collagen (Figure 28-5). The extracellular matrix and cells within the wound are regulated by cytokines and integrins (transmembrane cell receptors) (Figure 28-6).

KELOIDS

Keloids are fibrous elevated scars that extend outside wound margins. Keloids are unlikely to regress, are likely to recur if excised, and are most likely to occur in patients with darker skin (relative risk, 15-20). Keloids are frequently located over the midline chest, cheeks, and earlobes, and the peak incidence is age 10 to 20 years. Wounds that heal by secondary intention and burn wounds are at high risk for developing keloids. Keloids may be painful as well as

cosmetically unacceptable (Juckett and Hartman-Adams, 2009) (Figure 28-7).

HYPERTROPHIC SCARS

Hypertrophic scars are limited to the wound edges and tend to regress over the first year. The treatment of both keloid and hypertrophic scars is similar, except hypertrophic scars have better outcomes. Genetic expression of various cytokines and inflammatory pathways may affect the myofibrocytes in granulation tissue to continue producing scar tissue, but the exact causes are being investigated. Pressure dressings and colloidal silicone placed on scars after suture removal or on burn scars may reduce the incidence of both keloids and hypertrophic scars, but onion-skin extract (Mederma) alone is not effective (Karagoz et al., 2009). For a review of the prevention and treatment of excessive dermal scarring, review Roseborough et al. (2004).

Figure 28-7 Skin keloid. (From Habib TP. *Clinical dermatology.* 5th ed. Philadelphia: Elsevier; 2010:16.)

KEY TREATMENT

- Cryotherapy is useful for smaller lesions such as acne scars and keloids (SOR: B).
- Pressure dressings in burns help prevent hypertrophic scars (SOR: B).
- Intralesional corticosteroid injections are first-line primary care therapies for keloids; surgery is a second-line option (SOR: B).

WOUND DRESSINGS

Covering the wound with an occlusive dressing prevents drying and allows the wound to be moist, promoting healing with collagen synthesis and angiogenesis (Field and Kerstein, 1994). Using a topical antibiotic reduces infection only in wound laceration repairs (Dire et al., 1995), not in elective hospital or office surgical procedures (Smack et al., 1996). Studies show no dressing preference for burn wound care (American Burn Association, 2001), but it should be based on wound origin, depth, size, location, exudate, and degree of contamination (Singer et al., 2008). Wounds closed with tissue adhesives provide their own protection and require no additional dressing. Review warning signs of infection with the patient and advise on standard post-operative wound care and timing of suture removal.

NONHEALING WOUNDS

Patients' underlying healing status may be affected by their nutritional status and underlying medical conditions. Healing may be slowed by smoking as well as age. Surgical repairs with too much tension on skin closure increase the chance of tissue necrosis, dehiscence, and reduced healing. In the United States, chronic wounds affect 6.5 million patients. More than \$25 billion is spent annually on treatment of chronic wounds (Sen et al., 2009).

Principles of Skin Closure

Closure techniques should minimize skin trauma, result in good skin-edge approximation without undue tension, and result in a cosmetically pleasing appearance (Figure 28-8). The best cosmetic results can be achieved by using the finest suture appropriate for skin thickness and tension. Generally, a 3-0 or 4-0 suture is appropriate on the trunk and scalp, 4-0 or 5-0 on the extremities with finer suture more distal, and 5-0 or 6-0 on the face. Forceps with teeth and skin hooks should be used to reduce crush injury to wound edges. Use the least number of sutures to close the skin with good approximation and without open space deep to the wound. Sutures on the face should be removed on days 3 to 5; wounds not under tension on days 7 to 10; and wounds under tension, on the hands, or over joints on days 10 to 14. If you remove a suture and the wound begins to open, cease removing the other sutures and place a sterile adhesive strip over the area, then ask the patient to return in 2 days.

Sutures are an option along with staples, tissue adhesives, and hair to tie edges together on some scalp wounds.

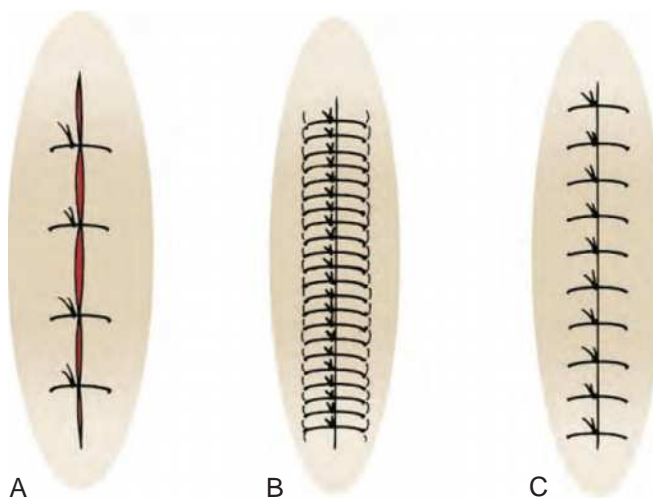

Figure 28-8 Wound repair: skin closure. **A**, Too few sutures used. Note the gapping between sutures. **B**, Too many sutures used. **C**, Correct number of sutures used for a wound under an average amount of tension. (From Lammers RL. Methods of wound closure. In Roberts JR, Hedges JR, eds. *Clinical procedures in emergency medicine*. 5th ed. Philadelphia: Elsevier; 2010.)

Avoid staples in the scalp if computed tomography (CT) or magnetic resonance imaging (MRI) is planned. Expedient cleaning, debridement, and closure with the least trauma to the wound should be the goal.

SKIN TENSION ORIENTATION

Surgeons searching for an ideal guide for elective incisions have developed 36 named guidelines. Karl Langer (1819-1887) studied and drew skin lines of cleavage after noting that round punctures in cadaveric skin produced ellipses. The topographic orientation of these lines coincides with the dominant axis of mechanical tension in the skin. Langer lines were developed by studying skin tension in cadavers with rigor mortis and therefore may not be representative of a living human's skin tension lines. Kraissl noted tension lines in living tissue and developed lines oriented perpendicular to the contraction of the underlying muscles. Later, Borges described *relaxed skin tension lines* (RSTLs), which follow furrows formed when the skin is relaxed and are produced by pinching the skin. These are only guidelines, however, and many factors contribute to the camouflaging of scars, including wrinkles and contour lines. RSTLs are formed by the natural tension on the skin from underlying soft tissue and rigid bony or cartilaginous substructure.

Superior scar revision results occur when making incisions parallel or nearly parallel to RSTLs. The Borges RSTLs and Kraissl lines may be the best guides for elective incisions of the face and body and are often mislabeled "Langer lines." The face can be divided into parallel variations of the four main facial lines: the facial median, nasolabial, facial marginal, and palpebral lines. When performing cosmetically sensitive punch biopsies, stretch the skin 90 degrees perpendicular to the RSTLs so that the resulting ellipse-shaped wound and closure are parallel to the RSTL (Figure 28-9).

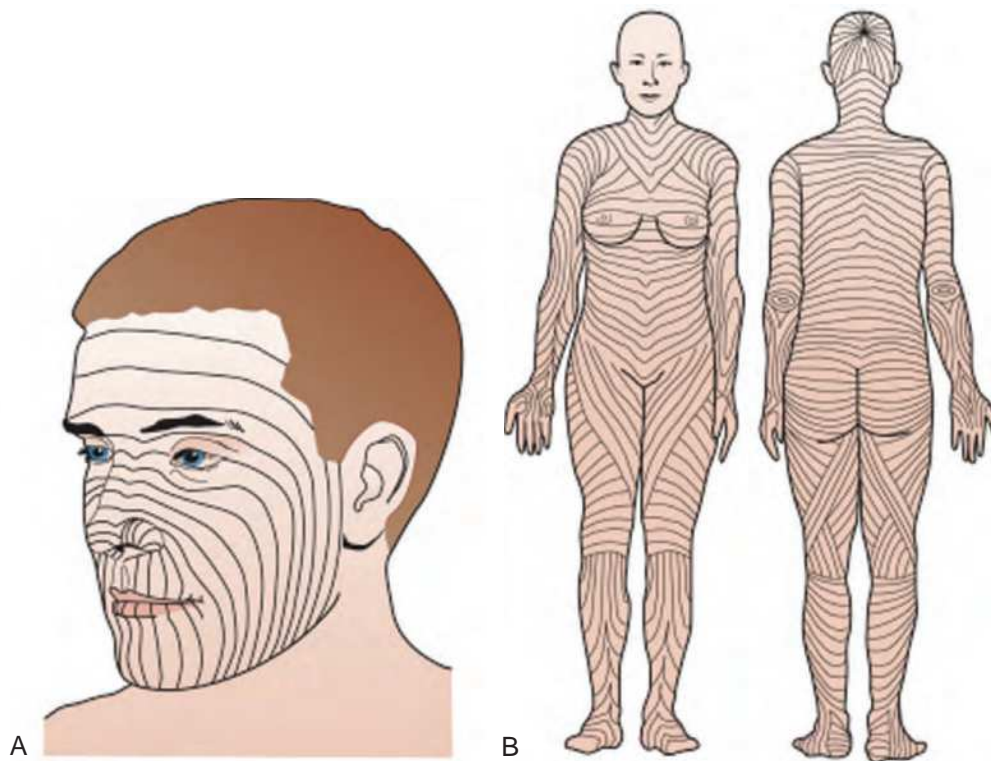

Figure 28-9 **A**, Facial relaxed skin tension lines (RSTLs). **B**, RSTLs of the entire body. (From Trott A. *Wounds and lacerations: emergency care and closure*. 2nd ed. St. Louis: Mosby; 1997 and Burns JL, Blackwell SJ. *Plastic surgery*. In Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston textbook of surgery: the biological basis of modern surgical practice*. 19th ed. Philadelphia: Saunders; 2012.)

SKIN TENSION ON CLOSURE

Ideally, any wound, excision, or repair should be designed so that the superficial skin edges approximate under minimal tension. The surgeon may undermine surrounding tissue and trim wound edges to improve approximation if it is a clean laceration or elective excision. Debridement or excision of dirty wound edges may remove devitalized tissue, improve alignment, and allow improved closure. Placement of tension-relieving sutures or deep sutures should always be considered to facilitate direct closure of uninfected wounds under tension. If a suture is less than ideal, it is best to remove and replace it.

Wound tips and beveled lacerations are challenging because too much tension may be placed on the narrowest edges and contribute to wound necrosis or breakdown. Ideally, the skin sutures are used to approximate slightly everted superficial edges and not to close deep tissue under high tension. If the wound or excision has a clean approximation under minimal tension, a single-layer repair is preferred. If not, deep interrupted sutures are used to close the underlying space to avoid deep pockets where a hematoma, infection, or abscess could develop (Figure 28-10 and Video 28-4).

TISSUE ADHESIVE

On clean, dry lacerations under low tension, skin adhesives are an appropriate substitute for standard sutures. Adhesives may also work on shallow, irregular, beveled lacerations and are useful on pediatric scalp lacerations.

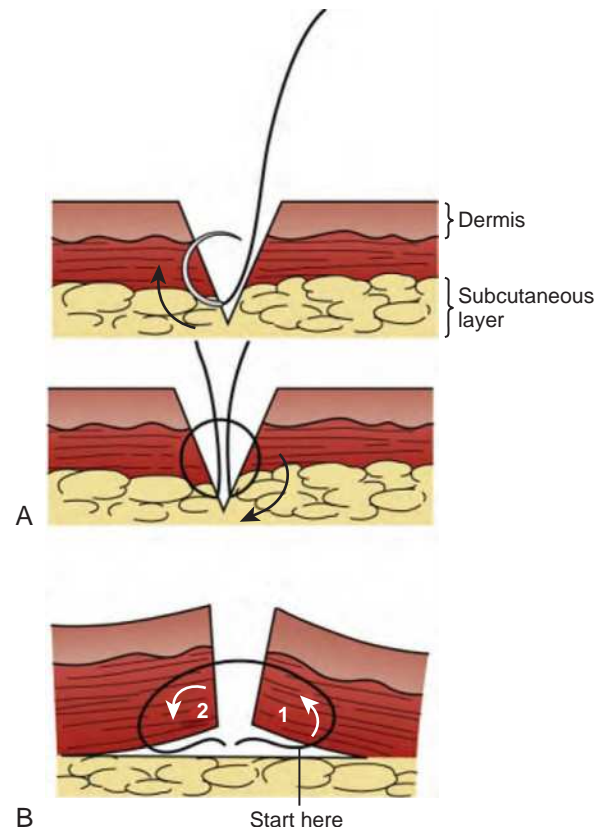

Figure 28-10 Inverted subcutaneous stitches, starting in opposite directions. (From Lammers RL. *Methods of wound closure*. In Roberts JR, Hedges JR, eds. *Clinical procedures in emergency medicine*. 5th ed. Philadelphia: Elsevier; 2010.)

Since 1998, the medical tissue adhesive 8-carbon 2-octylcyanoacrylate (OCA) has been available in the United States for tissue adhesive closure of wounds. OCA is more durable and flexible than the short-chain butylcyanoacrylates. The longer chain cyanoacrylates create less dehiscence in wounds longer than 8 cm. Avoid adhesive use on moist or hair-bearing areas, mucous membranes, nonhemostatic wounds, over joints or highly mobile tissue, and on bite wounds or dirty lacerations. Consider the adhesives to have about the same strength as 5-0 sutures. If OCAs are used, the patient may shower immediately, but if the butylcyanoacrylates are used, the repaired wound should be kept dry for at least 48 hours. Moisture exposure increases the dehiscence risk (Singer and Dagum, 2008). If the area to repair is under higher tension, deep sutures approximating the skin edges are used before closing with a superficial adhesive (Singer and Thode, 2004).

Tissue adhesive agents form their own bandage, and no additional care is needed. Full tensile strength is achieved after 2.5 minutes. Antibiotic and white petrolatum ointments can dissolve tissue adhesives, so patients should avoid their use (Forsch, 2008).

Dehiscence occurred on 2.5% of wounds closed with tissue adhesives in an animal study compared with 2- and 10-cm laceration repairs with various suture types and stitches. In the 2-cm wounds, results were identical. The 10-cm wounds favored deep suturing even if tissue adhesive was used. The final decision on the method and materials used for wound closure depends on the length and location of the wound as well as the efficiency needed and time of closure (Zeplin et al., 2007 and Video 28-5).

KEY TREATMENT

- Wound closure of superficial lacerations by tissue adhesives is quicker and less painful than conventional suturing, with a similar outcome on appropriate wounds (Aukerman et al., 2005) (SOR: A).

SUTURE PLACEMENT

Interrupted Sutures

Individually placed single sutures are the most common form of wound closure. Although slower to place than a running suture, single sutures have a better cosmetic result and a reduced risk for dehiscence. Slightly everting the skin edges will result in the best wound appearance. Enter the skin 2 to 3 mm from the skin edge with the needle perpendicular to the skin plane and rotate the wrist smoothly. Go an equal distance in depth as the horizontal distance from the wound edge. If unable to obtain an equidistant point on the opposite side of the wound in one step, use an additional pass. Bring the needle out through the laceration, enter at the same level within the laceration, and come out through the skin at a symmetric distance from the wound edge (Figure 28-11 and Video 28-6).

One may reduce the risk for “dog ears” by placing a suture in the middle of a laceration and then another in the middle of the remaining sides until equal tension and alignment approximates the skin edges in a cosmetic and hemostatic fashion. If bleeding persists, ligate or cauterize the

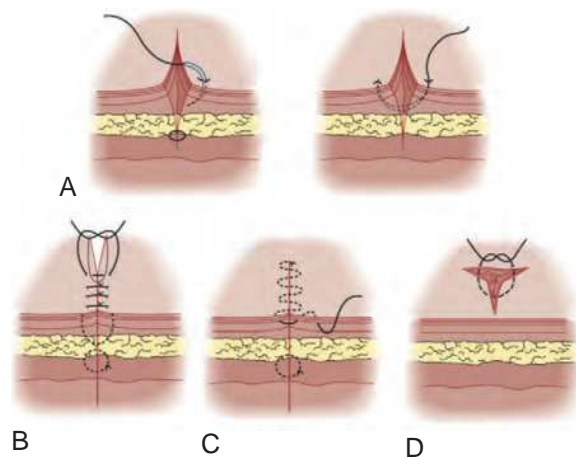

Figure 28-11 Suture technique and methods. **A**, Sutures are placed through the entire thickness of the dermis at right angles to the skin and suture line while everting the wound edge. **B**, Sutures are placed 2 to 3 mm apart and 2 to 3 mm from the wound edge. **C**, The subcuticular stitch prevents crosshatch scarring. **D**, Intradermal sutures help preserve peninsular flaps in this stellate wound. (Modified from Wright CV, Ronaghan JE: Office surgery. In Rakel R, ed. *Textbook of family practice*. 5th ed. Philadelphia: Saunders; 1995.)

vessel before further closure. If suturing a landmark such as vermilion borders on lip edges, consider marking opposing points of the wound before instilling anesthesia and then place an aligning suture at this location first.

Running Sutures

If rapid suture placement is needed and an area is not over a highly mobile joint, the physician can use a running suture. If the suture breaks, however, the entire wound may dehisce. If the running sutures are left too long, “baseball lacing” tracks may remain visible on the skin. In one study (not funded by manufacturers), deeply buried absorbable suture used along with running subcuticular polyglactin 910 (Vicryl) suture left in place resulted in the best results on trunk and extremity scar healing from elective excision of atypical moles (Alam et al., 2006; Halstead, 1889).

Subcuticular Sutures

Halstead first described the subcuticular suturing technique in 1889 as a way to approximate wound edges with the least scarring. A running intradermal, buried subcuticular suture is useful in places where the dermis is shallow and when skin edges are well approximated under minimal tension, such as on the face. Placing subcuticular sutures on the back, chest, and other areas under tension without other supporting deep interrupted sutures may give poor results.

For subcuticular suture placement, use either absorbable or nonabsorbable 4-0 suture and anchor it in the skin on one end external to the wound. Enter the skin and come out in the apex of one end of the wound. Place horizontal zig-zagging subcuticular sutures with level symmetric entry and reentry sites on each side of the wound. If using absorbable suture, tie and bury a knot near the end of the wound by tying the knot and then place one more stitch to come out through the skin near the wound; then cut the suture

Figure 28-12 View from above stellate laceration, showing closure with half-buried mattress sutures. For some stellate lacerations, it is best to cover them with Steri-Strips and revise the scar later or, if small, excise the laceration and convert it to a linear repair. (From Lammers RL. Methods of wound closure. In Roberts JR, Hedges JR, eds. *Clinical procedures in emergency medicine*. 5th ed. Philadelphia: Elsevier; 2010.)

flush with the skin while pulling upward on the suture. The knot will be retracted below the skin for later absorption. Alternatively, with either absorbable or nonabsorbable suture, place the last stitch and exit the skin away from the wound and tie off the suture externally. A nonabsorbable suture may be removed after 1 to 3 weeks by cutting one end of suture and gently pulling with countertraction from the other end of the wound (Video 28-7).

Half-Buried Mattress or Tip Sutures

Half-buried mattress sutures can be used on stellate edges and on triangular defects to approximate the skin edges with reduced tension on the tips (Figure 28-12). Tip sutures are similar and used to secure a laceration tip with minimal tension. Tension sutures can reduce blood and oxygen flow to the distal tip and cause ischemia (Video 28-8).

Pulley Sutures

The far-near, near-far pulley sutures are a modification of the vertical mattress suture and may be used as a temporary measure to reduce tension and approximate skin edges to allow placement of interrupted sutures. These sutures are used for longer repairs but should not be left in too long or placed too tightly because cross-hatching scars may occur. For placement, enter with the needle 4 to 6 mm back from the wound edge; come out on the opposite side 2 mm from the wound; and loop back across the wound opening, entering the skin 2 mm from the edge and coming out on the opposite side 4 to 6 mm back from the edge (Wu, 2006).

Modified pulley sutures offer some mechanical advantage in vitro by requiring less force to achieve closure compared with horizontal mattress or single interrupted sutures. These pulley sutures are generally used when a wound is under moderate tension (Austin and Henderson, 2006).

Z-PLASTY

The Z-plasty technique is used to improve the appearance of long scars, correct contractures over joints, and change the orientation of the scar line to align better with RSTLs.

Figure 28-13 Classic equilateral triangle 60-degree Z-plasty. (Modified from Thomas JR, Holt GR. *Facial scars, incisions, revision, and camouflage*. St. Louis: Mosby; 1989 and Thomas JR, Mobley SR. Scar revision and camouflage. In Cummings CW, Flint PW, Haughey BH, et al, eds. *Otolaryngology: head and neck surgery*. 4th ed. Philadelphia: Mosby; 2005.)

The key is to measure the laceration and then draw a line of the same length as the laceration on each side of the laceration at 60-degree angles for proper alignment on the repair (Figure 28-13).

COMPLICATIONS

Dog-ear formations occur when the two sides of a wound are of unequal length. Tissue may be trimmed before suturing. An ellipse can be cut around the dog ear or an extension laterally at an angle and then repaired (Fig. 28-14). Another technique is called “leashing the dog ear.” Tie off the repair near the start of the dog ear. Place a single, interrupted suture by diving through the wound along the axis of the wound and out behind the dog ear. When tied down, this suture may flatten a small dog ear (Khachemounie et al., 2005).

Excisions

Incisions should be made perpendicular to the skin with symmetric edges and no angulation. Poor technique may jeopardize healing. In general, the physician should make an elliptical incision with the length three to four times the width. Some limited data suggest less tissue removal and better healing if a round excision is used with adequate margins and subsequent repair of any dog ears. With this technique, though, 59% of the repairs required dog-ear correction (Seo et al., 2008).

If a portion of a pigmented lesion has a worrisome appearance, complete excision is recommended. The American Cancer Society uses the ABCDE mnemonic to recognize lesions of high malignant concern: A, asymmetry; B, border irregularity; C, more than one color; D, diameter greater than 6 mm; and E, increased elevation or enlargement. If a lesion has one or more of these concerns, an excisional biopsy should be considered. In other lesions, the clinician may consider a shave biopsy or punch biopsy (Videos 28-9 to 28-11).

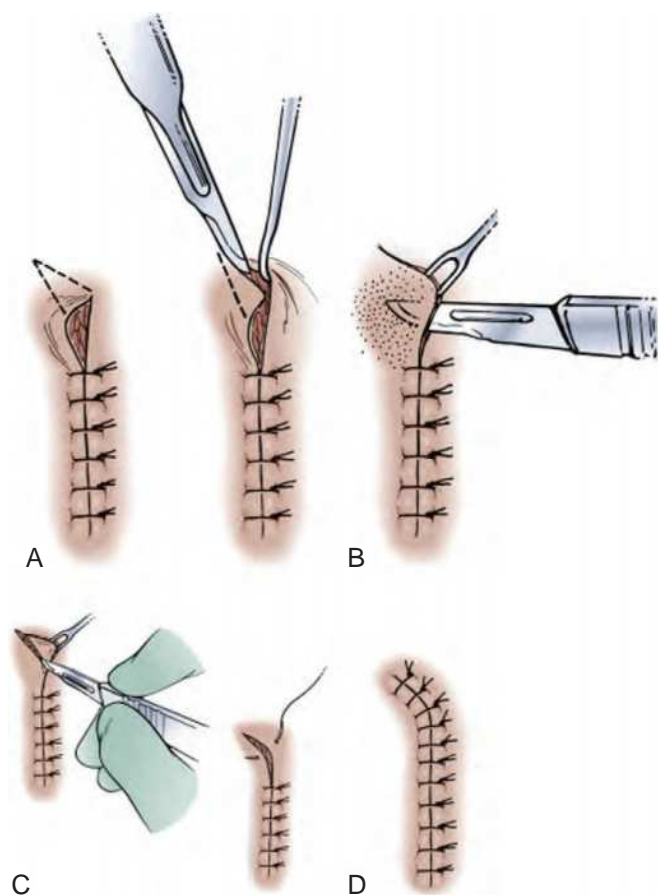

Figure 28-14 Dog-ear repair. A dog ear may develop if tension and length vary along both sides of the laceration. **A**, Drawing the wedge to remove to create a “hockey stick” to fix the dog ear. **B**, Undermining the skin. **C**, Removing the wedge of skin. **D**, Repairing the “hockey stick” with both sides having even tension. (Modified from Simon BC. Skin and subcutaneous tissue. In Rosen P, Chan T, Vilke G, et al, eds. *Atlas of emergency procedures*. St. Louis: Mosby; 2001; and Simon B, Hern HG. Soft tissue injuries. In Marx JA, ed. *Rosen’s emergency medicine*. 7th ed. Philadelphia: Mosby; 2009.)

ATYPICAL MOLES AND PIGMENTED LESIONS

Elliptic full-thickness excisional biopsies are preferred for any suspicious pigmented mole. Punch biopsies can easily miss positive findings because of fusiform invasion in other portions of the lesion (Chang et al., 2009).

Management of dysplastic nevi with positive margins remains controversial. A National Institutes of Health (NIH) Consensus Conference established margin guidelines for excision of dysplastic nevi (0.2-0.5 cm), but no clear guidelines exist regarding whether an incompletely removed nevus with mild or moderate dysplasia should be reexcised. Dermatopathologists are discordant in identifying dysplasia and differing degrees of atypia, further complicating decision making. Most dermatologists recommend that nevi with severe atypia should be reexcised because they may represent early melanoma or a lesion evolving into melanoma (Goodson et al., 2010).

In 2008, the National Cancer Comprehensive Network published guidelines indicating that a 5-mm excisional margin may be inadequate for lentigo maligna and lentigo maligna melanoma (Bosbous et al., 2009). Despite recurrence rates of 8% to 20% and a growing body of literature suggesting the inadequacy of a 5-mm marginal excision

in these cases, a definitive guideline change has not been made.

Melanomas account for 90% of the deaths associated with cutaneous tumors. An assessment of tumor depth is critical in the diagnosis and prognosis of melanomas. Confirmed melanomas are initially excised with 10- to 20-mm safety margins both in depth and laterally if possible. Unsuspected melanomas found on excisional biopsies should have their bases reexcised for appropriate 1- to 2-cm margins as a second procedure. Sentinel lymph node dissection is routinely offered as a staging procedure in patients with tumors more than 1 mm in thickness, although there is no resultant survival benefit. Interferon- α can be offered as adjuvant therapy to patients with melanoma more than 1.5 mm thick and stage II to III because it increases relapse-free survival.

KEY TREATMENT

- Elliptic full-thickness excisional biopsies are preferred for suspicious pigmented moles (Chang et al., 2009) (SOR: A).
- A 5-mm excisional margin may be inadequate for lentigo maligna and lentigo maligna melanoma (Bosbous et al., 2009) (SOR: A).
- Confirmed melanomas are initially excised with 10- to 20-mm safety margins (SOR: A).

BASAL CELL CANCER

The excision of small basal cell cancers (BCCAs) of less than 20 mm with well-defined borders and a 3-mm peripheral surgical margin will remove the tumor in 85% of cases. A 4- to 5-mm peripheral margin will increase the clearance rate to approximately 95%. Approximately 5% of small, well-defined BCCAs extend more than 4 mm beyond their apparent clinical margins. Morpheic (morpheaform) and large BCCAs require wider surgical margins to maximize the chance of complete histologic removal. On initial removal of morpheic lesions, the rate of complete excision with a 3-mm margin is 66%; 5-mm margin, 82%; and 13- to 15-mm margin, more than 95% (Telfer et al., 2008).

Standard vertical-section processing of excision specimens allows the pathologist to examine only representative areas of the peripheral and deep surgical margins, and at best an estimated 44% of the entire margin can be examined in this manner. Therefore, tumors that appear fully excised occasionally recur (Telfer et al., 2008). If the BCCA is on an area with little extra excisable tissue, consider Mohs microscopic surgery to obtain adequate margins and minimize tissue removal.

If the BCCA lesion is completely excised, the recurrence rate is about 1%. If not completely excised, BCCAs have recurrence rates of 17% to 35% for lateral-margin positivity and 33% for deep-margin positivity. Only one third of positive-margin BCCA lesions recur, so the provider should reexcise the margins but could consider reexcision only if a recurrence develops, with the following exceptions: lesions of long duration, size greater than 2 cm, previous recurrence, and aggressive histologic features (including perineural and perivascular invasion and infiltrative, morpheiform, or micronodular appearance). If marginal

positivity is detected in such cases after excision, reexcision and removal of the residual tumor is advised over watchful observance (Ünlü et al., 2009) (Video 28-12).

KEY TREATMENT

- A 4- to 5-mm peripheral margin will increase the cure rate of BCCAs to approximately 95% (Telfer et al., 2008) (SOR: A).
- Morpheaform and large BCCAs require wider surgical margins (Telfer et al., 2008) (SOR: A).

Cryotherapy

Cryotherapy can be easily mastered for treatment of many skin lesions. Cryotherapy is well tolerated and results in minimal to no scar. It is best used in those with lighter skin and in non-hair-bearing areas because of occasional pigment changes or hair loss with deeper treatments. Liquid nitrogen, the most widely available, cost-effective medical cryogen, boils at -196°C , and temperatures of -25° to -50°C can be achieved in 30 seconds of appropriate skin application. Destruction of benign lesions occurs at -20° to -30°C , and malignant lesions often require temperatures of -40° to -50°C for destruction (Andrews, 2004). Correct use of cryotherapy results in selective cell destruction while sparing the tissue matrix of collagen and fibroelastic tissue and reducing the risk of scar formation. Repeated freeze-thaw applications can increase tissue damage.

INDICATIONS AND CONTRAINDICATIONS

Cryotherapy can be an important treatment option for many lesions commonly encountered in a primary care clinical practice. It can be used in all age groups to treat a number of dermatologic lesions. Even though well tolerated, cryosurgery also has contraindications (Table 28-3). Some body areas or conditions should be approached with prudence because of increased complication risks. BCCAs, particularly in the nasolabial fold or periauricular area, tend to be more extensive than expected and more likely to recur. The vermilion border, periorbital area, and areas overlying cutaneous nerves present confounding variables to safe cryotherapy.

EQUIPMENT AND TECHNIQUE

Liquid nitrogen can be applied with a regular or modified cotton-tipped applicator, cryogen spray device, or cryoprobe, all readily available to providers. The cotton-tipped applicator is the least expensive and can be modified to hold more cryogen or to match the size or shape of the lesion with a cotton ball. Liquid nitrogen can be stored in an insulated device in the office and taken out in small aliquots in a polystyrene cup for individual use with patients.

Handheld cryogen spray devices have significantly improved. Traditional cryotherapy systems provide a reservoir for the liquid nitrogen and an applicator tip to dispense the cryogen. The applicator tip can have a varying aperture for altering cryogen dispersion. Some providers use an otoscopy cone to protect surrounding skin and direct the spray

Table 28-3 Cryotherapy: Indications and Contraindications

Indications	Verruca (warts) Condylomata acuminata Papular nevi Selected basal cell cancer Seborrheic keratosis Molluscum contagiosum Granulation tissue Selected squamous cell cancer Actinic keratosis Acrochordons (skin tags) Cervical intraepithelial neoplasia
Contraindications	ABSOLUTE Prior cryotherapy sensitivity Vascular compromise Complication nonacceptance Steroid therapy Melanoma Invasive skin cancer Need for tissue diagnosis Expected poor wound healing RELATIVE* Hepatitis B and C Mononucleosis Leukemia Lymphoma Myeloma Systemic lupus Nephritic syndrome Nephrotic syndrome Macroglobulinemia Rheumatoid arthritis

*Underlying medical conditions in which medications or the condition itself may slow healing.

onto a small central lesion. The unit is generally held 1 to 2 cm above the lesion and the spray directed at a 90-degree angle and aimed at the lesion center. Newer spray devices use a continuous infrared sensing device to determine the treatment site skin temperature and ensure consistent freeze times. These modifications can improve accuracy and assist in achieving optimum cryotherapy results (Cry-Ac Tracker, <http://www.brymill.com>).

Before freezing, the depth and diameter of the cryotherapy must be anticipated to minimize injury to surrounding tissues. Mark the skin to ensure adequate treatment in critical cryotherapy sessions. Keratin layers are very resistant to cryotherapy and can be treated for 1 to 2 weeks with topical 40% salicylic acid plaster or mechanically pared away before cryotherapy. Application of salicylic acid alone is equally efficacious to cryotherapy of warts for many patients (Gibbs and Harvey, 2006). A well-hydrated skin lesion can increase cryotherapy success rates.

For superficial benign skin lesions, the cryotherapy applicator should almost cover the lesion and should be applied for 20 to 40 seconds to create an ice ball edge 2 to 3 mm beyond the edge of the lesion. In contrast, deeper or premalignant lesions should be treated with an applicator smaller than the lesion to ensure a depth more equal to the radius of treatment. It should be applied for 40 to 90 seconds to form an ice ball 3 to 4 mm outside the lesion. Superficial malignant lesions also require a smaller applicator but applied for 1 to 3 minutes for an ice ball 5 to 8 mm beyond the lesion. Malignant cells are more resistant to cryotherapy, and destruction requires temperatures at -40° to -50°C . In most cases, the depth of a freeze is similar to the

radius of the superficial ice ball formed. The lethal zone for tissue destruction is 2 to 3.5 mm inward from the outer margin of the ice ball (McNabb and Pfenninger, 2010).

COMPLICATIONS

Cryotherapy results in minimal scarring. Vascular or hypertrophic lesions are resistant and sometimes require multiple treatments 2 to 3 weeks apart. Most patients experience pain and burning for 1 to 2 days. During these first days, the skin may be red and sensitive and may form a hemorrhagic bulla followed by sloughing. Infection and pyogenic granuloma formation are rare complications. In deeper cryotherapy, the potential damage to underlying neural structures must be considered (Video 28-13).

KEY TREATMENT

- A significant keratin layer is resistant to cryotherapy (SOR: B).
- The lethal zone for cryogen tissue destruction is 2 to 3.5 mm inward from the outer margin of the ice ball (McNabb and Pfenninger, 2010) (SOR: A).
- Salicylic acid application alone to warts is equally efficacious to cryotherapy (Gibbs and Harvey, 2006) (SOR: A).

Incision and Drainage of Cutaneous Abscesses

A cutaneous abscess is identified by a fluctuance, or compressible softness, in skin surrounded by induration, inflammation, warmth, and tenderness. *Furuncles* are superficial and result from abscess formation in a sweat gland or hair follicle. *Carbuncles* are deeper and extend into the subcutaneous tissue. Offending bacteria include *S. aureus*, streptococci, and occasionally gram-negative rods. These infections can be severe in patients with diabetes or vascular disease. Primary treatment of an abscess is surgical drainage. An area of induration alone with no fluctuance indicates isolated cellulitis and is treated with antibiotics and warm compresses.

When performing an incision and drainage of an abscess, the skin is prepared with a sterilizing and cleansing agent. Local anesthetics do not work well in the acidic environment of an abscess, so a ring or field block can be infiltrated around the periphery of the lesion. Superficial cooling of the surface of the skin with ethyl chloride or liquid nitrogen can also provide brief anesthesia for a stab incision.

A linear incision is made over the area of maximal fluctuance and has been shown to heal in a shorter time than derroofing procedures used in the past (Sørensen et al., 1987). A #11 scalpel blade is inserted with the cutting edge away from the provider in a stabbing motion deep enough to access the abscess but not passing completely through it. The tip is lifted up to create an adequate incision for drainage. The abscess cavity is then probed with a curved hemostat to disrupt any internal loculations. The abscess cavity is packed with ¼- to 1-inch gauze to prevent early superficial wound closure and allow secondary healing. Primary

closure is not recommended (Korownyk and Allan, 2007). A bulky sterile dressing can be applied to absorb any drainage and the packing and dressing changed every 1 to 2 days or when soiled. Evidence does not support using oral antibiotics after surgical drainage. Routine swabbing for culture in immunocompetent individuals is not recommended (Korownyk and Allan, 2007). Patients are educated on wound care and return in 2 to 7 days for follow-up (see Video 28-13).

Recurrent skin abscesses should be investigated based on location. Crohn disease, subcutaneous fistulas, and pilonidal cysts can present as recurrent cutaneous abscesses. MRSA should be suspected in recurrence skin infections as well.

KEY TREATMENT

- The primary treatment of an abscess is surgical drainage (SOR: A).
- Incision and drainage of an uncomplicated abscess does not require oral antibiotic treatment (SOR: A).
- Routine culture of abscess drainage in immunocompetent individuals is not recommended (SOR: A).

Lipomas

Lipomas are mature adipose tissue arranged in a nodular formation surrounded by a capsule and commonly located in the subcutaneous tissues. Lipomas can be diagnosed by clinical examination and identification of their unique, well-circumscribed, round, mobile character with a doughy consistency. Although most do not require it, excision may be considered for large tumors, rapidly growing lipomas, and those causing pain. Lipomas can occur in isolation or with other systemic diseases, as a component of genetically inherited disorders or in other connective tissue layers.

A steroid injection or liposuction can be used to treat select lipomas. Steroid injections can be used to treat painful lipomas smaller than 2.5 cm in size and in which pathologic examination is likely unnecessary. An injection of 1 to 3 mL of triamcinolone diluted with 1% lidocaine to a 10 mg/mL concentration can be performed into the center of the lipoma monthly to shrink the tumor to the desired size. Formal liposuction can be done with cannula or 16-gauge syringe under local anesthesia (Salam, 2002). Neither of these procedures is likely to eliminate the lipoma in its entirety, and recurrences are frequent.

Surgical excision of a lipoma removes the neoplasm from the tissue and allows for pathologic examination. Marking the boundaries of the lipoma is helpful for identification of the tumor edges before a local anesthetic field block is placed. The skin is prepared with a povidone-iodine or chlorhexidine solution. Small lipomas can be enucleated with their capsule using blunt dissection through a small incision. Larger lipomas require excision through a linear or elliptic incision. Blunt and, rarely, sharp dissection can be used to free the mass from the surrounding tissues using hemostats or clamps for traction. Hemostasis should be confirmed and cautery or ligature placement used to ensure a dry wound base. The remaining dead space is closed with

buried, interrupted, absorbable subcutaneous sutures, and the skin is closed with interrupted sutures or staples depending on location and cosmetic need. A compression dressing should be used for 1 to 2 days to prevent formation of a hematoma, and sutures are removed in 5 to 10 days depending on location. Submit any specimen for pathologic examination. Caution should be used when deciding on removing large lipomas of the low back because they can be larger than the surface appearance suggests. Cases have been reported of an abdominal hernia presenting posteriorly and being mistaken for a lipoma (Video 28-14).

Surgery of the Nail and Digits

INGROWN NAIL (ONYCHOCRYPTOSIS)

The great toe's lateral and distal nail beds are the most common locations for ingrown nails. Poorly fitting shoes, poor nail-trimming techniques, and trauma can result in their formation. Most ingrown nails respond to conservative local treatment of warm soaks and elevation of the distal nail with cotton to allow unobstructed nail growth. If poor toenail trimming is the cause, a shard of nail is usually remaining in the distal lateral nail groove and impaling the skin. It can be simply trimmed and removed for resolution of pain with standard curved or straight iris scissors.

When conservative measures fail, a partial or complete nail excision is performed to remove the portion of offending nail. The toe is cleansed and a digit block placed using 1% lidocaine. A snug tourniquet at the base of the toe can help with hemostasis. A nail elevator is used to separate the section of nail to be removed from the underlying nail bed down to the base of the nail and germinal matrix. The elevator can also remove the cuticle from the nail. Then an iris or bandage scissors can be used to cut the nail longitudinally to the matrix. A straight hemostat is used to grasp the portion of nail to be taken off and the nail is rolled laterally for removal. Hemostasis can be obtained with compression, aluminum chloride solution, or silver nitrate. A bulky tube-gauze dressing can be placed for protection. Recurrent ingrown nails unresponsive to conservative measures can be ablated after nail removal. A phenol solution is applied to a hemostatic germinal nail matrix under the proximal nail fold for 30 to 60 seconds before neutralizing the phenol with rubbing alcohol. (Video 28-15).

NAIL PLATE AVULSION FOR ONYCHOMYCOSIS

Conservative treatment of onychomycosis is the first-line choice for management. A fungal culture of nail clippings can be done to confirm the diagnosis but may take up to 1 month for growth and identification. Oral terbinafine (250 mg/day for 12-16 weeks) produces higher clinical cures than pulse-dosed terbinafine, pulse-dosed itraconazole, or weekly fluconazole (Volk et al., 2013). Even with terbinafine, failure rates can reach 50%. When onychomycosis causes dystrophic nails resulting in pain or toe dysfunction, a complete nail plate avulsion can be performed, with high patient satisfaction (see [Ingrown Nail \[Onychocryptosis\]](#)).

KEY TREATMENT

- Oral terbinafine (250 mg/day for 3 months) is the most effective oral treatment for fungally infected toenails (Volk et al., 2013 (SOR: A)).

PARONYCHIA

Whereas an *acute* paronychia is caused by a bacterial infection of the lateral or proximal nail folds after minimal to significant trauma, a *chronic* paronychia results from an inflammatory condition caused by repetitive irritant contact exposure. Acute paronychia without abscess can be treated conservatively with warm soaks, gentle compression, topical steroid creams, and topical or oral antibiotics (Rigopoulos et al., 2008). Chronic paronychias usually respond to removal of the offending agent or treatment of the underlying condition or inflammatory cause, but they sometimes require drainage, oral antibiotics, and antifungals (Franko and Abrams, 2013).

When the local cellulitis of an acute paronychia develops into an abscess, incision and drainage is indicated followed by oral antibiotics to cover both methicillin-sensitive and resistant *S. aureus* and streptococci (Franko and Abrams, 2013). If the fluctuant pocket of the abscess is superficial and underlying the cuticle or nail fold, a 23-gauge needle or #11 blade tip can be used to lift the edge of the fold and allow drainage without local anesthesia. A digital nerve block can be performed if the infection is deeper and requires more extensive drainage or for patient comfort. After anesthetization, an incision into the abscess can be placed parallel to the nail fold with a stab incision using a #11 bladed with subsequent drainage and exploration to break up loculations if warranted. Warm soaks should follow with oral antibiotics for the cellulitis (Figure 28-15).

EVACUATION OF SUBUNGUAL HEMATOMA

Trauma to the nail causing bleeding between the nail plate and nail bed can be excruciatingly painful. Subungual

Figure 28-15 Incision and drainage of paronychia. The tip of a #11 scalpel is advanced just under the cuticle and parallel to the nail. The size of the incision should be large enough to include all fluctuant areas and no more. (From Chavez MC, Maker VK. Office surgery. In Rakel RE, ed. *Textbook of family medicine*. 7th ed. Philadelphia: Saunders; 2007.)

hematomas can be drained easily in an office setting by creating a 2-mm hole through the nail and draining the blood using a handheld cautery unit or heated end of a metal paper clip. If trauma was significant or a hematoma involves more than 50% of the nail, the provider should consider an underlying nail bed laceration that may require primary closure after evaluating the digit radiographically. Phalanx tuft fractures can underlie the hematoma after significant trauma (Wang and Johnson, 2001).

Anorectal Disease

Bleeding, pain, discharge, or change in bowel habits can indicate active anorectal disease, and all warrant medical evaluation. The directed complete patient history and anorectal examination lead to a clear diagnosis in most complaints. Inflamed internal hemorrhoids or rectal polyps typically cause painless rectal bleeding because they occur above the dentate line. Painful anal bleeding can result from anal fissures, proctitis, thrombosed external hemorrhoids, or a draining perianal abscess. Palpable chronic masses can indicate an anal skin tag, polyp, or prolapsed rectal mass, and acute masses are usually caused by abscesses or thrombosed hemorrhoids. More than 90% of anorectal complaints can be managed in the primary care physician's office using simple techniques (Pfenninger and Zainea, 2001).

ANOSCOPY

Anoscopy is performed easily in the office to evaluate and treat many anorectal conditions. Scopes can be 7 to 10 cm long and 2 to 3 cm wide and range from a slotted or beveled metal version to a disposable plastic tubular version. The tubular version can be used for diagnosis, and the slotted style allows for ease in treating most anorectal conditions. For a thorough examination, the patient can be placed in a comfortable lateral decubitus position with the hips flexed. The examiner should don nonpermeable protective clothing and eyewear. A digital rectal examination should precede anoscopy to assess for internal pain or mass. The anal tissues should be examined for tags, hemorrhoids, fissures, dermatitis, condylomata, and masses.

During examination, the thumb can be pressed against the internal index finger to determine tenderness, induration, or abscess formation in the perianal tissues in all quadrants. The lubricated anoscope with obturator is introduced fully into the anal canal with gentle, constant pressure. When fully inserted, the obturator is removed and the anorectal mucosa visualized through 360 degrees during gradual withdrawal. Adequate lighting is essential. The Valsalva maneuver may distend vascular lesions for ease in identification. Anal Pap smears can be obtained if warranted for anorectal cancer concerns and biopsies performed using a Kevorkian or Tischler biopsy forceps. Hemostasis is obtained using silver nitrate sticks (Video 28-16).

HEMORRHOIDS

Hemorrhoids are submucosal vascular beds located in the anal and rectal canal that assist with defecation and the

sensation of anorectal fullness. These vascular beds can occur in insensate areas above the dentate line as internal hemorrhoids or below the dentate line as external hemorrhoids in exquisitely sensitive areas. Hemorrhoid development may result from genetic factors, aging, or serial local trauma. One study found that 4.4% of the United States population, or 10 million people, complain of hemorrhoid disease (Reese et al., 2009).

Internal Hemorrhoids

Internal hemorrhoids are classified according to the severity of prolapse. First-degree hemorrhoids do not prolapse, and second-degree disease is characterized by spontaneously reducible prolapse. These can generally be treated with conservative methods. Third-degree hemorrhoids prolapse and require manual reduction, and fourth-degree hemorrhoids have irreducible prolapse. As the prolapse progresses, surgical treatment becomes a more common treatment.

Painless, bright-red rectal bleeding is the primary symptom of internal hemorrhoids. Anoscopy can be used for identification of the site of bleeding acutely. Internal hemorrhoids typically occur in three locations in the anal canal: right anterior, right posterior, and left lateral. A flexible sigmoidoscopy or colonoscopy is performed if the patient's symptoms or history warrants more extensive colonic evaluation or if the site of colorectal bleeding is not easily identified or persists after treatment. Patients older than age 40 years who have hemorrhoidal bleeding may have other colorectal pathology and should have further colorectal evaluation (Chong and Bartolo, 2008).

Dietary management consisting of adequate fluid and fiber intake is the primary noninvasive treatment of symptomatic hemorrhoids (Cataldo et al., 2005). Persistent hemorrhoid symptoms decreased by 53% in those receiving dietary fiber for hemorrhoid care (Alonso-Coello et al., 2005). Conservative therapy can be offered for mild first- and second-degree hemorrhoids, but more advanced disease may require surgical management. Rubber band ligation or hemorrhoid banding is known to be highly effective in outpatient treatment of first-, second-, and some third-degree internal hemorrhoids (Reese et al., 2009). Other options include sclerotherapy, infrared coagulation, radiofrequency coagulation, and cryotherapy (Cataldo et al., 2005).

Prolapsing internal hemorrhoids can be easily treated in the office with rubber band ligation using a McGilvney ligator or similar device. After appropriate consent is obtained, a slotted or beveled anoscope is inserted into the anus. The hemorrhoid is then identified, and with the circular McGilvney ligator in place within the anoscope, the hemorrhoid is grasped with a forceps and drawn into the ligating cylinder. Sensation of the hemorrhoid is assessed to prevent ligation of a high external hemorrhoid. Care is taken not to draw too much tissue into the ligator to avoid denuding the anal canal. When the base of the hemorrhoid is in the ligator, two rubber bands are released from the ligator by one cylinder sliding over the other. The bands cause ischemic necrosis of the hemorrhoid, and the tissue sloughs over days. Bleeding can occur for up to 1 to 2 weeks and is occasionally significant. Patients may feel some rectal fullness, a spasm, or dull ache for a few days after banding.

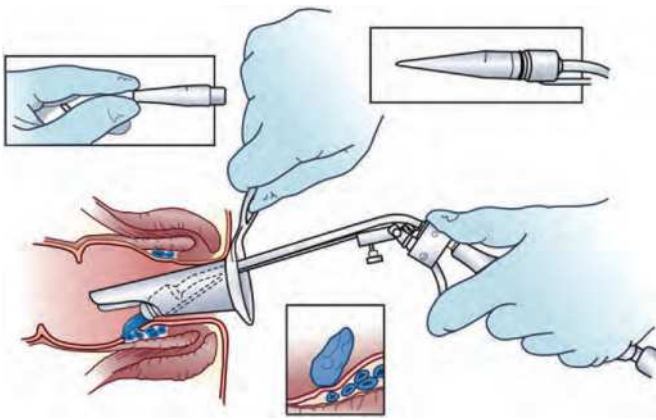

Figure 28-16 Rubber band ligation for an internal hemorrhoid. The band is advanced onto the end of the ligator instrument using a conical attachment (*insets*). The hemorrhoid is identified at a level proximal to the dentate; this area is tested for sensation before banding. Occluding the suction port of the ligator instrument draws the hemorrhoid into the open end of the ligator, and the instrument is fired. The banded hemorrhoid typically sloughs in 1 week. (Courtesy Mayo Foundation and Nelson H, Cima RR. Anus. In Townsend CM, Beauchamp RD, Evers BM, Mattox KL, eds. *Sabiston textbook of surgery: the biological basis of modern surgical practice*. 19th ed. Philadelphia: Saunders; 2012.)

Rare episodes of pelvic cellulitis have been reported. Only one site should be treated per patient visit ([Figure 28-16](#)) ([Video 28-17](#)).

Sclerotherapy can be performed on first- and second-degree hemorrhoids using a sclerosant of 5% phenol or saline. The base of the hemorrhoid is injected with 1 to 2 mL of the sclerosant through a syringe while viewed through an anoscope. More late complications can be seen with sclerotherapy than with banding. In a systematic review, sclerotherapy had unknown effectiveness in treating hemorrhoids. Infrared photocoagulation was found to be likely beneficial and as effective as rubber band ligation in the same review. The infrared coagulator light is fired three to five times at the base of the hemorrhoid through an anoscope for 1.5 seconds during one treatment session. Multiple sessions may be required for infrared treatment of first-degree through small third-degree hemorrhoids. Radiofrequency coagulation is performed with a Bicap probe placed at the base of the hemorrhoid above the dentate line and activated four to six times for 2 seconds, forming a white coagulum. Because of prolonged healing after cryotherapy, it is no longer recommended ([Reese et al., 2009](#)).

KEY TREATMENT

- Patients older than the age of 40 years who have hemorrhoidal bleeding should have further colorectal evaluation for other pathologic causes. ([Chong and Bartolo, 2008](#)) (SOR: B).
- Dietary management of symptomatic hemorrhoids consists of adequate fluid and fiber intake ([Alonso-Coello et al., 2005](#)) (SOR: B).
- Rubber band ligation is known to be highly effective outpatient treatment for first-, second-, and some third-degree hemorrhoids ([Reese et al., 2009](#)) (SOR: B).

External Hemorrhoids

A nonpainful or painful anal swelling can represent an external hemorrhoid. Hemorrhoids can be differentiated from anal skin tags, condylomata, fissures, and abscesses on anal examination. Symptomatic external hemorrhoids can be excised if conservative treatment fails. The patient is placed in the lateral decubitus position with the hips flexed. The external hemorrhoid or tag is identified and anesthetized at its base with buffered 1% lidocaine with epinephrine. The area is cleansed with povidone-iodine or chlorhexidine. A radially oriented elliptic incision is made around the hemorrhoid or tag and the center removed with the hemorrhoid vein. The resulting defect may need to be cauterized and is frequently left open and allowed to heal. Stool softeners and topical anesthetics may be very beneficial. Because of the vascularity, healing usually occurs in 5 to 10 days ([Video 28-18](#)).

Thrombosed External Hemorrhoids. An external hemorrhoid can become thrombosed and be identified by an acute onset of perianal pain and development of a purplish nodule with or without bleeding. Thrombosed hemorrhoids can be managed conservatively with avoidance of constipation, patient analgesia, and ice or sitz baths ([Cataldo et al., 2005](#)). Office surgical excision, not incision, of a thrombosed external hemorrhoid results in a lower recurrence rate and earlier resolution of symptoms ([Greenspon et al., 2004](#)). Simple incision of the thrombosed hemorrhoid may not remove multiple clots and can result in higher recurrence rate and even extension.

To excise a thrombosed hemorrhoid, the patient is placed in the lateral decubitus position with the buttocks separated for visualization. The surface can be cleansed and anesthesia provided with a local injection of buffered lidocaine or bupivacaine with epinephrine at the base of the hemorrhoid. After anesthetization, an elliptic incision is made in a radial orientation around the hemorrhoid, and all thrombus is removed with excision of the hemorrhoidal vein at its base. Bleeding can be controlled with pressure, Monsel solution, or careful electrocautery. More complex hemorrhoids and those associated with partial rectal prolapse should be referred to a colorectal specialist.

KEY TREATMENT

- Office surgical excision, not incision, of a thrombosed external hemorrhoid results in a lower recurrence rate and earlier resolution of symptoms ([Greenspon et al., 2004](#)) (SOR: B).

ANORECTAL ABSCESS

An anorectal abscess can lead to severe pain and disability in patients. Abscesses occur most often in the third or fourth decade of life and in a 3:1 to 2:1 male-to-female ratio ([Hebra, 2009](#)). An anorectal abscess develops from an infection originating in the anal glands and crypts at the level of the dentate line and tracking along the lines of least resistance. This tracking results in up to 50% of abscesses being associated with simultaneous fistula development.

Figure 28-17 Classification of perirectal abscesses: 1, perianal; 2, ischioanal; 3, intersphincteric; 4, high intramuscular; and 5, peltivrectal. (From Hill GJ II, ed. *Outpatient surgery*. 3rd ed. Philadelphia: Saunders; 1988 and Coates WC. *Anorectal procedures*. In Roberts JR, Hedges JR, eds. *Clinical procedures in emergency medicine*. 5th ed. Philadelphia: Elsevier; 2010.)

Locations of the abscess can vary and may be located in the perianal area (60%), ischioanal area (20%), intersphincter region (5%), supraleator region (4%), and submucosal location (1%) (Figure 28-17). Abscesses can result from other anorectal infections or pathology such as Crohn disease fistulas, adenocarcinoma, trauma, immunosuppression, and sexually transmitted diseases. A thorough anorectal examination, frequently under anesthesia, is required for complete evaluation. Most abscesses can be localized by physical examination. Deep or large abscesses require a pelvic CT scan to determine the extent of tracking and to plan surgical intervention.

An anorectal abscess should be treated by incision and drainage. The lack of fluctuance should not delay a timely drainage procedure. Antibiotics are an unnecessary addition to routine incision and drainage of uncomplicated perianal abscesses (Whiteford et al., 2005). There is no conclusive evidence that simple drainage is less effective than a sphincter-cutting procedure in the treatment of anorectal abscess (Quah et al., 2006). Antibiotics should be considered only as an adjunct to drainage in patients with immunosuppression, diabetes, prosthetic devices, or significant systemic illness.

Before surgical decompression, an anoscopy should be performed to identify a potential internal draining fistula source at the dentate line. Injecting an agent over or under the mass can provide local anesthesia, although rarely patients may need spinal or general anesthesia. Incision and drainage of superficial abscesses can be accomplished with use of a #11 blade over the area of maximal fluctuance or swelling in a radial orientation. Loculations can be broken by probing with a forceps or gloved finger. A Penrose drain or gauze packing can be placed for continued drainage with appropriate follow-up in 1 to 2 days. Recurrent abscesses can occur when there is an unrecognized and untreated underlying fistula. A fistulotomy must be performed in these cases.

KEY TREATMENT

- About 50% of perirectal abscesses are associated with simultaneous fistula development.
- The lack of fluctuance should not delay a timely drainage procedure for perianal abscesses (Whiteford et al., 2005) (SOR: B).
- Antibiotics are an unnecessary addition to routine incision and drainage of uncomplicated perianal abscesses (Whiteford et al., 2005) (SOR: A).

ANAL FISSURE

An anal fissure is a tear in the anal mucosa that can cause severe anal pain and rectal bleeding and results from local stool trauma. Most occur posteriorly in the midline. Other causes or locations should prompt a more complete anorectal evaluation. On examination, the anus is exquisitely tender and may demonstrate internal anal sphincter spasm. Evaluation can occur with gentle spreading of the anus, but some require anoscopy to assess their extent. A radial tear is seen that can be bleeding and very tender.

Most acute anal fissures can be managed conservatively with dietary fiber, prevention of constipation, adequate hydration, and stool softeners. Sitz baths may provide symptomatic improvement. Topical anesthetics such as 5% lidocaine ointment or gel can be used for comfort or before defecation until healing. No surgical treatment is warranted in uncomplicated occurrences. Chronic anal fissures do not resolve after the 3-month acute phase and are generally less tender. Chronic fissures are still associated with significant internal sphincter spasm and may present with a large, protuberant sentinel tag, sometimes confused with a hemorrhoidal tag.

Conservative therapy includes continued constipation prevention. Other therapeutically equal treatment options include topical nitroglycerin ointment, botulinum toxin injections, or calcium channel blockers such as diltiazem or nifedipine for 30 days. However, no conservative medical therapy approximates the efficacy of surgical sphincterotomy for chronic fissures (Nelson, 2006). An open or closed partial lateral internal sphincterotomy appears to be equally efficacious as surgical treatment (Nelson, 2008). An experienced specialist in the technique and anorectal anatomy should perform this procedure.

KEY TREATMENT

- No conservative medical therapy approximates the efficacy of surgical sphincterotomy for chronic fissures (Nelson, 2006) (SOR: A).

PILONIDAL CYST AND ABSCESS

Pilonidal disease may manifest itself as a chronically draining sinus or fistula at the base of the spine in the intergluteal crease 5 to 10 cm from the anus. Pilonidal cysts can also become infected and may lead to extensive presacral abscess formation. Multiple hair shafts may be seen within the cyst. Incision and drainage or an elliptic incision under local

anesthesia over the sinus track is performed. Drainage is the preferred office management technique and is similar to standard abscess treatment. Packing of the wound should be done, and referral is recommended for excision of the extensive presacral complex. Recurrence is common without excision.

Gynecologic Office Procedures

See also [Chapter 25](#).

PARACERVICAL BLOCK

A paracervical block can be placed before any uterine procedure requiring instrumentation of the cervix or cervical dilation. Contraindications include current desired pregnancy, infection, and bleeding disorders. The local anesthetic used, often 0.5% lidocaine or bupivacaine, is determined by the length of anesthesia required.

The patient is placed in a dorsal lithotomy position, and a vaginal speculum is placed to allow adequate visualization of the cervix. Two 10-mL syringes are drawn up of a 1 : 1 ratio of 1% lidocaine or bupivacaine and sterile saline. The cervix and vaginal canal are cleansed with chlorhexidine or povidone-iodine. An injection of 1 to 2 mL of this mixture is placed in the anterior cervical lip, where a single-toothed cervical tenaculum is placed. The cervix is lifted upward and deviated laterally to obtain access to the lateral posterior fornix. Eight to 10 mL of this mixture is injected starting in the cervicovaginal reflection at the apex of the posterior fornix at the 4 and 8 o'clock positions and is advanced 2 to 3 cm in depth along the external serosa of the uterus to provide anesthesia to the uterine plexus of nerves near the uterine arteries. Intravascular injection is avoided by aspiration on the syringe plunger before infiltration. Women have less pain during uterine intervention with paracervical block than with placebo injections (SOR: B).

CONTRACEPTIVE DEVICES

Diaphragms

Latex diaphragms have an arcing, coil, or flat spring, and silicone devices have a wide-seal rim and an arcing or coil spring. The arcing spring diaphragm is used most often because it is easier to place in the posterior fornix without an introducer. When fitting a diaphragm, the size can be determined with a simple pelvic examination.

With the patient in a dorsal lithotomy position, the provider inserts the lubricated, gloved index and middle finger straight into the vagina to the posterior fornix. The spot where the inferior pubic arch impacts the index finger is noted. The fingers are withdrawn, and the distance from that point on the index finger to the end of the middle finger is noted; this is about the diameter of diaphragm needed. Diaphragms come in 5-mm increments from 60 to 90 mm, with 75 and 80 mm most common. The diaphragm is then inserted and size confirmed with placement, posteriorly, in the posterior fornix behind the cervix and, anteriorly, behind the pubic arch. Removal of the diaphragm can be accomplished by hooking the anterior rim with a finger and

gently extracting. Women should be given an opportunity to remove and replace the diaphragm to confirm placement in the office before use.

The diaphragm can be placed in the posterior vagina covering the cervix up to 6 hours before intercourse. Generally, women have used 5 mL of spermicide within the diaphragm at insertion, although a Cochrane review failed to prove its contribution to contraceptive effectiveness (Cook et al., 2003). Additional spermicide can be inserted in front of the diaphragm before each act of intercourse without dislodging the diaphragm. The diaphragm is removed at least 6 hours and not more than 24 hours after the last intercourse. An increased risk of urinary tract infections (UTIs) exists with diaphragm use and risk of toxic shock syndrome exists if the diaphragm is left in place for more than 24 hours. The diaphragm size needs to be reestablished after a weight change of 10 to 15 lb, pregnancy, or pelvic surgery. The failure rate for diaphragms is 18% but may be better with perfect use.

Cervical and Vaginal Barrier Methods

Two brands of cervical and vaginal barriers are currently approved and marketed in the United States. Although neither requires specific fitting by a practitioner, both require a prescription for pharmacy or manufacturer dispensation. Whereas FemCap comes in three sizes and is ordered based on pregnancy history, Lea's Shield comes in one size for all women with normal anatomy.

The FemCap is a silicone rubber nonhormonal intravaginal contraceptive (IVC) cervical cap. The smaller rim size (22 mm) is for women who have never been pregnant. The medium size (26 mm) is intended for women who have been pregnant, even for up to as little as 2 weeks with no vaginal delivery. The larger diameter cap (30 mm) is for women who have had a full-term vaginal delivery. When in doubt of prior pregnancy, the 26-mm cap should be used. The patient places the cap over the cervix with up to $\frac{3}{4}$ tsp of 2% nonoxynol-9 spermicide used around the outside groove at least 15 minutes before sexual arousal. Placement over the cervix is critical and accomplished best while squatting. After it is in place, the cap should be pushed over the cervix for at least 10 seconds to ensure firm placement against the vaginal wall, because it does not fit snug against the cervix. Additional spermicide should be placed with each act of intercourse without removing the cap. Hooking a finger under the removal strap in a squatting position, and withdrawing gently removes the cap. The cap must be removed at least 6 hours but not longer than 48 hours after the last act of intercourse. During a 6-month clinical trial for approval, the FemCap was 86.5% successful in preventing pregnancy (FemCap, 2013). The device is washed and dried thoroughly between uses.

Lea's Shield is a silicone rubber IVC vaginal barrier placed at any time before intercourse. It is inserted with spermicide vaginally to the depth of the cervix, and any trapped air is vented through a one-way valve, creating a tight fit between the vaginal wall and the device. The Shield is removed using the incorporated removal loop with a finger more than 8 hours after the last intercourse. Women had an 8.7% chance of becoming pregnant within 6 months when using the Lea's Shield. The shield is cleaned with warm soapy water and dried for reuse.

KEY TREATMENT

- Failure rates for the diaphragm are 18% but may be better with perfect use (Cook et al., 2003) (SOR: A).
- FemCap was 86.5% successful in preventing pregnancy over 6 months of use (FemCap, 2013) (SOR: B).

Intrauterine Devices

Insertion. Long-acting reversible contraception has become increasingly popular in the form of intrauterine devices (IUDs). IUDs are T-shaped devices that are very easy to place in an office setting and have a failure rate less than 1% to 2% per year. They can be used in nulliparous and parous women and have a high continuance rate after 1 year of use (78%-81%). The devices have attached strings at the proximal end for removal in the office, and pregnancy rates return to normal soon afterward. IUDs are contraindicated in women with a current or suspected pregnancy, abnormal uterine cavity, pelvic inflammatory disease or endometritis, known endometrial or cervical malignancy, genital bleeding of unknown etiology, artificial heart valve placement, or allergy to IUD components.

A pregnancy during use of an IUD is more likely to be ectopic, but the overall rate of ectopic pregnancy is less than in sexually active women who use no contraception. Complications of IUD placement include pelvic infection, embedment in the uterine wall, IUD migration or expulsion, and perforation of the uterus. Unlike oral contraceptives, IUDs can be used during lactation and are not contraindicated in women with a history of venous thromboembolic events, those at increased risk of myocardial infarction or stroke, or those who smoke. Perforation rates are 0.6 to 1.6 per 1000 insertions but are higher during the 6 to 8 weeks after delivery, so postpartum placement is delayed until a later visit (McCarthy, 2006).

Before placement of an IUD, the federally mandated patient information included with the IUD should be fully reviewed with the patient and formal written consent obtained after a discussion of risks and benefits. The physician should confirm a pregnancy test result is negative and consider placement during the first 5 to 7 days of her menstrual cycle. A pelvic examination must be performed before insertion to assess the uterine size and location and evaluate for current cervical infection. A prescription dose of an NSAID (e.g., ibuprofen 600-800 mg) should be provided 30 to 60 minutes before placement to help with analgesia. After placement, the patient may continue to use an NSAID for cramping and can expect to have some spotting for a few days. She should be willing to check for the IUD strings monthly to confirm proper retention.

KEY TREATMENT

- IUDs have a failure rate less than 1% to 2% per year (SOR: A).
- IUDs can be used during lactation and are not contraindicated in women with a history of venous thromboembolic events, those at increased risk of myocardial infarction or stroke, or those who smoke (SOR: A) (McCarthy, 2006).

Mirena. The Mirena IUD is a levonorgestrel-releasing intrauterine contraceptive system measuring 32 × 32 mm placed for up to 5 years. The 52-mg levonorgestrel-containing IUD releases 20 mcg/day of hormone per day after insertion and decreases to 10 mcg/day after 5 years. Systemic levonorgestrel is minimal at 150 to 200 pg/mL. Variable to no menstrual bleeding is the norm for patients after 3 to 6 months.

The Mirena device is supplied in its own delivery system, aiding with placement. The patient is placed in a dorsal lithotomy position, and a sterile speculum is introduced into the vagina. The cervix and vaginal mucosa is cleansed with a chlorhexidine or povidone-iodine solution. A paracervical block can be placed as described earlier for analgesia. The anterior or posterior cervix is grasped with a single toothed cervical tenaculum for stabilization of the cervix during the procedure. If normal, the uterus should be sounded to depths of 6.5 to 8.5 cm. If the uterus is sounded to a different depth, consider misplacement, cervical stenosis, or uterine perforation. The cervix can be dilated for placement if significant stenosis is present.

Open the Mirena package, release the IUD threads, position the IUD arms, and position the flange at the proper sounded depth. When in the same plane as the inserter system, retract the arms into the inserter by pulling on the strings at the end of the system and pushing forward on the green thumb slider. Lock the strings into the cleft at the end of the inserter. Insert the IUD system gently through the cervix into the uterus but stop 1.5 to 2 cm before the fundus. Pull back on the thumb slider to the designated mark and release the arms outward. Wait for 10 to 15 seconds to allow the arms to fully extend. Hold the slider with the thumb and advance the system fully forward to place the IUD arms against the uterine fundus. Now pull only the slider all the way outward to release the threads at the proximal end of the inserter and then remove the entire inserter system from the cervix, leaving behind the IUD with threads. Cut the two threads to a length of 3 to 5 cm. Remove the tenaculum and observe for any significant bleeding. Monsel solution or pressure can be used for hemostasis. Remove the speculum and give the patient instructions for follow-up visits and postinsertion care (Video 28-19).

Skyla. Skyla is the newest commercially available IUD system in the United States after being approved in 2000 by the U.S. Food and Drug Administration. Skyla is approved for 3 years of use and contains 13.5 mg of levonorgestrel that is released 14 mcg/day at 24 days after insertion and drops to 5 mcg/day in 3 years with an average in vivo release of 6 mcg/day. The dimensions are smaller than the Mirena device at 28 × 30 mm and require a slightly smaller inserter diameter (3.8 mm vs. 4.75 mm). As opposed to other IUD systems, Skyla has been specifically approved for use in nulliparous as well as parous women.

Insertion of Skyla is very similar to the Mirena insertion process above. The primary difference is the internal containment of the strings until insertion is complete. This reduces the variability of string movement during loading and insertion but also prevents reloading of the IUD into the inserter if there is insertion failure. In addition, Skyla has a 99.95% pure silver ring at the top of the vertical stem,

making it more visible by ultrasonography. Skyla should be noted on any MRI order because it does require special specific conditions for MRI scanning because of the silver.

Paragard T380A. The Paragard can be placed for up to 10 years in a similar manner as the Mirena IUD. Patients should receive counseling and informed consent for the Paragard IUD, with specific warnings about contraindications in patients with Wilson disease because of the copper content of the Paragard.

Positioning of the patient, placement of the speculum, cleansing of the vagina and cervix, placement of the tenaculum, and uterine sounding are the same as described for Mirena. However, the IUD arms are loaded differently into the Paragard inserter and are folded backward with the distal arm ends inserted into the distal end of the inserter tube to lie next to the IUD shaft. The IUD system is then inserted through the cervix to the uterine fundus. The white inserter plunger is held steady and the outside clear tube retracted 1 to 2 cm to release the arms. The clear tube is then advanced back to the fundus to assist in extending the arms and placing them in the apex of the fundus. The central plunger is then removed before the outside tube to prevent inadvertent removal of the IUD (Figure 28-18). After the inserter is removed, the two threads can be cut to 3 to 5 cm in length and the tenaculum and speculum removed, with hemostasis as needed. The patient is instructed in postplacement care and subsequent monthly cervical thread checks. Warning signs for infection, perforation, and bleeding are given (see Video 28-19).

Removal. Removal of an IUD is quite simple for all devices. An oral NSAID is beneficial to assist with analgesia. The

patient is placed in a dorsal lithotomy position, and a speculum is placed in the vagina. The two IUD strings are identified and grasped with a ring forceps. The strings are gently pulled on, and the IUD should easily follow for removal. If the strings are not present, the IUD strings are generally just inside the cervical os. One can use a Cytobrush to retrieve the strings, grasp the strings in the os with a straight hemostat, or consider cervical dilation and use of an IUD hook or extractor for removal. In some women, the IUD may be malpositioned, and ultrasonography or plain abdominal radiography can locate the system for removal. If the IUD is not easily removed or is disconnected from the strings, hysteroscopy-assisted IUD removal may be necessary in rare cases.

Intradermal Contraceptive Device

Implanon is a device 4 cm long and 2 mm wide containing 68 mg of etonogestrel. Nexplanon is the radiopaque version of Implanon. Both are inserted on the inner side of the nondominant upper arm 8 to 10 cm above the medial epicondyle in a subdermal location for up to 3 years of contraception. Insertion should occur during the first 1 to 5 days of a patient's menstrual cycle. The site for insertion is selected, marked, and locally anesthetized. The device is placed using a subdermal insertion trochar. Complications from Implanon insertion are 1% and from removal 1.7%. Irregular bleeding is the most common side effect (11% of patients). The manufacturer requires providers to complete a 3-hour comprehensive training program, which should be completed before device placement (<http://www.Implanon-usa.com> or www.nexplanon-usa.com).

BARTHOLIN GLAND ABSCESS OR CYST

The Bartholin glands are located between the hymen and labia minora bilaterally at the 4 and 8 o'clock positions. Cysts occur when the duct is blocked from trauma or edema, and abscesses occur when retained secretions become infected. Treatment relies on drainage of the cyst or abscess; treatment of any associated cellulitis with oral antibiotics if indicated; and creation of a track that eventually epithelializes, allowing normal gland drainage and reduced recurrence.

For drainage, the patient is placed in the dorsal lithotomy position, and the cyst or abscess is identified by the area of maximal swelling and fluctuance. Topical anesthesia is used on the surface or a local anesthetic injected under the mass for patient comfort. The cyst wall is grasped through the mucosal surface with two clamps 3 to 5 mm apart and a #11 blade used to puncture between the clamps. After drainage, the fluid is cultured and the cyst packed with gauze until healed. To prevent frequent recurrences, a Word catheter can be placed. The latex stemmed catheter with an inflatable balloon is inserted into the incision between the clamps, with care taken to place the balloon in the cyst center. The balloon is then filled with 2 to 3 mL of normal saline and left in place for 4 to 6 weeks to allow epithelialization of the track. The catheter can then be removed. If the incision was done inside the hymen ring, the catheter end can be tucked into the vagina for comfort during the healing process (Video 28-20).

Figure 28-18 **A**, Paragard T380A is displayed above Mirena. Note that both intrauterine devices (IUDs) have their IUD arms extended. **B**, End of Paragard T380A is displayed above end of Mirena with both IUDs having arms fully retracted in opposite directions and ready for placement.

COLPOSCOPY

Colposcopically directed cervical biopsy and cervical curettage is primarily used to investigate abnormal findings on routine pelvic examination or an abnormal Pap smear. Consensus guidelines for the management of cervical intraepithelial neoplasia have been developed (Massad et al., 2013). Colposcopy requires diligent record keeping and patient communication, with close follow-up pending pathologic results. Colposcopy contraindications are current infection and delivery within the preceding 6 weeks. Pregnancy does not preclude colposcopy, but cervical biopsy or endocervical curettage may cause increased bleeding or miscarriage. A pregnancy test is best performed before a biopsy is contemplated. Patients should receive informed consent and accept their responsibility to follow up based on examination findings.

Colposcopy is performed with a stereoscopic operating microscope with correct focal length. The patient is placed in the dorsal lithotomy position, and the vulva and introitus are inspected for lesions. A speculum is placed in the vagina, with the size selected to maximize visualization of the cervix and minimize patient discomfort. The vaginal canal and cervix are visualized and any lesions of concern noted.

Acetic acid (3%-5%) is applied to the vaginal canal and cervix liberally with a cotton swab. Abnormal areas will display as acetowhite. Higher grade lesions may show punctation, mosaicism, or frank abnormal changes of superficial vessels best seen with a green light filter. Lugol solution, taken up by glycogen in normal mature squamous cells and not by dysplastic, metaplastic, or columnar epithelial tissues, can be applied to improve identification of abnormal tissue. Findings are recorded in a drawing to correlate with biopsy sites and abnormal pathology. Satisfactory examination includes full visualization of the entire transformation zone between squamous and columnar epithelium at the cervical os where most pathology is located. An endocervical speculum can be used to assist in visualization. Planning for lesion treatment options should be done at the time of the colposcopy.

ENDOCERVICAL CURETTAGE

Endocervical sampling is performed frequently with colposcopy and particularly if an ectocervical lesion extends into the cervical canal. Abnormal endocervical lesions can require more extensive evaluation and treatment. Endocervical curettage should precede external cervical biopsies. An endocervical curette is placed into the cervix with the sharp edge against the wall of the canal. The curette is then drawn back and forth against the cervical canal in a 360-degree sampling twice around. The sample removed can be retrieved with an endocervical brush and sent for pathologic assessment separate from any other specimens. Endocervical curettage is contraindicated in pregnant patients (Video 28-21).

CERVICAL BIOPSY

If abnormal areas are identified on the ectocervix, they should be correlated for consistency with the Pap smear results. A biopsy of the abnormal areas identified by the

colposcope can be undertaken using a Kevorkian or Tischler colposcopy forceps. To aid in visualization and to prevent cross-contamination, biopsies are done on the posterior cervix first followed by the anterior aspect. The fixed end of the biopsy forceps is usually placed into the cervical os, and biopsies are done in a radial orientation to obtain a sampling of the squamocolumnar transition zone where a lesion is identified. Samples should be deep enough to include the epithelial surface and a small amount of underlying stroma.

After biopsies are completed, hemostasis is best achieved with use of a Monsel paste applied with a cotton applicator or silver nitrate stick. The vagina is wiped of remaining debris and the speculum withdrawn. The patient is instructed to use analgesics as needed, to abstain from intercourse and tampon use for 10 to 14 days, and to expect some intermittent spotting. Any excessive bleeding, fever, discharge, or significant pelvic pain should lead to an investigation for the cause. Confirm the preferred method to relay the results and treatment recommendations when the pathologic results return with the patient.

ENDOMETRIAL BIOPSY

An endometrial biopsy can be performed to evaluate abnormal uterine bleeding in women who are premenopausal or postmenopausal in conjunction with ultrasonography. It can also be used to assess for a short luteal phase in infertility and abnormal or atypical glandular cells seen on Pap smear in women older than 40 years of age. Only patients with an endometrial stripe 5 mm or larger need sampling because an endometrial thickness of less than or equal to 4 to 5 mm in patients with postmenopausal bleeding reliably excludes endometrial cancer (American College of Obstetricians and Gynecologists, 2009).

A number of endometrial biopsy devices are available; the disposable flexible plastic aspirator is the easiest to use. This aspirator can be used with most women and even those with mild cervical stenosis. Before biopsy, a pregnancy test should be completed if the patient is of child-bearing age and an oral NSAID given. The patient is placed in the dorsal lithotomy position, and uterine size and location are assessed. A speculum is placed to allow full visualization of the cervical os. The vaginal canal and cervix are cleansed with a chlorhexidine or povidone-iodine solution, and a single-toothed tenaculum is placed on the anterior cervix to aid in stabilization. A paracervical block can be placed for patient comfort.

When the preparation is complete, the aspirator is inserted into the cervical os using the tenaculum for countertraction. It is advanced to the fundus, and then the central plunger is retracted to create intrauterine negative pressure for suction of endometrial contents. The aspirator catheter is then withdrawn to the lower uterine segment and advanced again repetitively to the fundus and rotated to sample all aspects of the uterine cavity. Endometrial cells and blood will have entered the aspirator catheter and can be sent for pathologic examination. The tenaculum and speculum are then removed and withdrawn. The patient may experience uterine cramping and bleeding for a few days and should refrain from intercourse until this resolves. Excessive bleeding, fever, or pelvic pain warrants immediate

evaluation in the postoperative period. Pathology results are discussed with the patient when available and any treatment arranged. If the sample is insufficient, the patient should be triaged to transvaginal ultrasonography in a low-risk group or full dilation and curettage for any high-risk patients (Brand et al., 2000) (Video 28-22).

KEY TREATMENT

- An endometrial biopsy can be performed with ultrasonography to evaluate abnormal uterine bleeding in premenopausal or postmenopausal women.
- Women with spontaneous postmenopausal bleeding and an endometrial thickness greater than 5 mm should be further evaluated with an endometrial biopsy (American College of Obstetricians and Gynecologists, 2009) (SOR: B).
- If the endometrial sample is insufficient, the patient should be triaged to a transvaginal ultrasonography in a low-risk group or dilation and curettage for high-risk patients (Brand et al., 2000) (SOR: B).

CERVICAL POLYP REMOVAL

Cervical polyps are generally benign and asymptomatic and are noted most often during routine gynecologic examinations. Most polyps arise from the endocervical mucosa and occur in perimenopausal women age 30 to 50 years. For polyp removal, the patient is placed in the dorsal lithotomy position, and a speculum is inserted vaginally. A Pap smear should be obtained and the base of the polyp identified to prevent inadvertent removal of a prolapsed endometrial polyp. The polyp is then grasped as close to its base as possible with a ring forceps and twisted. This twisting motion will dislodge the polyp, which should be sent for pathologic assessment. Hemostasis is obtained with Monsel solution or silver nitrate sticks if direct pressure is not sufficient (Video 28-23).

UTERINE ASPIRATION FOR BIOPSY OR MISCARRIAGE MANAGEMENT

Manual vacuum aspiration (MVA) can be used in the office setting for easy sampling of the uterine endometrium using a 4- or 5-mm cannula when a small endometrial biopsy catheter is insufficient (Figure 28-19). The MVA can also be used in the office for removal of retained products of conception after an incomplete or missed miscarriage up to 12 weeks without the added cost of an emergency department visit, surgical suite, and general anesthesia. The MVA device is a handheld plastic aspirator syringe attached to a plastic cannula of varying sizes. The cannula can be flexible or rigid to allow for provider preference. Vacuum aspiration is safe, quick to perform, and less painful than sharp curettage and should be recommended for use in the management of incomplete abortion (Forna and Gulmezoglu, 2001).

Confirmation of a nonviable pregnancy or incomplete abortion is verified with a falling serum β -hCG level, appropriately timed ultrasonography, or clinical findings of uterine bleeding in pregnancy with significant cervical dilation in the first trimester. A blood type and hematocrit are

Figure 28-19 The Ipas manual vacuum aspirator (MVA) is displayed with 4-mm and 5-mm cannulas used for miscarriage management in an outpatient setting. Note the thumb buttons that close the barrel entrance to hold negative pressure in the canister when the plunger is retracted. The buttons are then released to transfer the suction pressure to the cannula once in place.

obtained to determine if RhoGAM is necessary or if bleeding has been significant. After informed consent outlining the risks of bleeding, pelvic infection, uterine perforation, Asherman adhesions, and possible need for reaspiration is obtained, the patient may receive a sedative, analgesia, or anesthesia. Most women do well with an oral NSAID for analgesia and a paracervical block for local anesthesia. For comfort, the patient should void before the procedure.

The patient is placed in the dorsal lithotomy position, and uterine size, location, and shape are assessed. Transvaginal or transabdominal ultrasonography can be performed at this time to confirm findings but is not required. A speculum is placed intravaginally, the vagina and cervix are cleansed, and a paracervical block is placed before the procedure. A single-toothed tenaculum is placed on the anterior cervix.

The uterus is sounded to the fundus to determine intracavitary size and position. If not already dilated, the cervical os is successively dilated to a size in millimeters corresponding to the gestational age using Denniston, Pratt, or Hegar dilators. The MVA curette size is generally chosen in millimeters to correspond to the gestational age in weeks as well. Thumb buttons are used to occlude the opening to the MVA barrel, and the plunger is retracted and allowed to snap into place to develop the negative pressure for suction. The cannula is attached to the MVA and placed through the cervix to the uterine fundus. The thumb buttons on each side are released, and the negative suction from the syringe is transferred to the endometrial cavity. The MVA barrel can be rotated and then brought in and out in a piston motion to dislodge the remaining products of conception. These can be observed passing through the cannula and can be evaluated fully by visual or pathologic examination after the procedure. The syringe may need to be emptied and the negative pressure reapplied based on the volume of the uterine contents. A sensation of grittiness is present in the fundus and all four uterine quadrants when the products of conception are completely removed and the cannula makes contact with the myometrium.

On completion, the MVA cannula is removed from the uterus, tenaculum from the cervix, and speculum from the vagina. The patient is observed for 15 to 30 minutes to

assess for excessive bleeding, hemodynamic stability, and unusual pain. Intrarectal or intravaginal misoprostol, intracervical or intramuscular methylergonovine, and intramuscular carboprost may be used for excessive bleeding. The patient may be discharged and instructed to refrain from intercourse for 2 weeks or until the bleeding resolves. She should return for excessive bleeding, significant pelvic or abdominal pain, and fever. A form of contraception is provided if the patient desires.

BREAST MASS

In a patient who presents with a breast mass, a careful clinical and family history with focused physical examination, mammography or ultrasonography, and fine-needle aspiration (FNA) of the mass is termed a triple test. Most primary care physicians can perform the triple test that includes (1) careful clinical examination, (2) mammography or ultrasonography, and (3) FNA. A positive triple test (considered positive if any of the three items result in indeterminate, suspicious, or malignant findings) has been found in 99.6% of breast cancers. On the other hand, if the results of all three test components are negative and the patient is deemed low risk by personal or family history, the patient requires no further workup and has a less than 1% risk of cancer ([National Breast Cancer Centre, 2006](#)).

BREAST CYST ASPIRATION

When a discrete breast mass is first discovered, a rapid determination can be made with one of two methods. Ultrasonography can be used to identify a cystic or solid mass rapidly with minimal discomfort to the patient. If ultrasonography is not available, an aspiration can be performed to determine if it is a breast cyst.

The patient can be placed in a recumbent position and the skin over the breast cleansed. The mass is stabilized between the thumb and index and middle fingers on the nondominant hand. Anesthesia can be used locally, but most women feel minimal discomfort. A 1.5-inch, 20- to 23-gauge needle is attached to a 10- to 30-mL syringe. The skin is punctured and the end of the needle directed into the mass with continuous suction on the syringe. The fluid of a cyst is aspirated completely before the needle is removed. Fluid should be sent for pathologic evaluation. Straw- to green-colored fluid is usually benign, and bloody brown to red fluid is more suspicious for malignancy. If bloody fluid is obtained in an atraumatic aspirate or if a lump remains, the patient should be referred for a core needle or open biopsy (Video 28-24).

KEY TREATMENT

- Vacuum aspiration is safe, quick to perform, and less painful than sharp curettage and recommended in the management of incomplete abortion ([Forna and Gulmezoglu, 2001](#)) (SOR: B).
- The triple test of (1) careful clinical examination, (2) mammography or ultrasonography, and (3) FNA of a breast mass approaches the false-negative rate of surgical breast biopsy and the false-positive rate of frozen section ([National Breast Cancer Centre, 2006](#)) (SOR: B).

- If bloody fluid is obtained on an atraumatic breast mass aspirate or if a lump remains after drainage, the patient is referred for surgical consult for core or open biopsy ([National Breast Cancer Centre, 2006](#)) (SOR: B).

FINE-NEEDLE ASPIRATION CYTOLOGY OR BIOPSY

Fine-needle aspiration can be performed in the office with minimal equipment for diagnosis of a discrete, solid breast mass. FNA testing results in a sensitivity of 90% and a false-negative rate of 3% to 10% in experienced hands ([Valea and Katz, 2007](#)). Contraindications include an overlying skin infection, underlying pulsatile mass, and a history of bleeding disorders.

The patient is properly given informed consent. She is recumbent in position, and the area of puncture is identified, marked, and cleansed. A local injection of 1 to 2 mL of anesthetic is infiltrated into the skin over the mass. The mass is stabilized with the three-finger technique previously mentioned. A 10- to 20-mL syringe with 18- to 22-gauge needle attached is advanced into the mass. Full aspiration suction is performed, and the needle is passed through the mass in different planes three to five times for an adequate sample. The suction is released and the needle removed. The cell sample, frequently only in the needle itself, is placed on a cytology slide and fixed for proper pathologic assessment. FNA provides histologic diagnosis but cannot determine architectural features. FNA should not be used to investigate microcalcifications because FNA cannot distinguish ductal carcinoma in situ from invasive cancer. A core or open biopsy should be performed in these patients for more definitive diagnosis before excision or definitive treatment (see Video 28-24).

Neonatal Circumcision

Circumcision has been used in religious rites for centuries and was used in ancient Egypt as a method for hygiene. Modern data in the United States are conflicting as to the benefits versus risks. By age 5 years, 90% of boys have a spontaneously retractable foreskin. The incidence of phimosis decreases with age and may be treated with a steroid cream. The medical approach to phimosis is initially successful in about 80% of cases, and 1 year later, 60% had no phimosis ([Ku and Huen, 2007](#)). Many parents still elect to have their male infants circumcised.

The American Urological Association revised its policy to say that circumcision should be presented for health benefits ([Tobian et al., 2010](#)). The American Academy of Pediatrics, American Medical Association, and American College of Obstetrics and Gynecology all consider the procedure elective with minimal benefits ([Lannon et al., 1999](#)). The World Health Organization–United Nations program on HIV/AIDS concluded that male circumcision is efficacious in reducing sexual transmission of HIV from women to men. In Africa, circumcision decreased HIV acquisition by 53% to 60%. Herpesvirus type 2 is decreased by 28% to 34% and human papillomavirus prevalence by 32% to 35% in circumcised men. Among female partners of circumcised

men in these African studies, the incidence of bacterial vaginosis was reduced by 40% and *Trichomonas vaginalis* by 48%; genital ulcers decreased as well (Tobian et al., 2010).

The incidence of UTI is reduced with circumcision in some populations. If a population has a baseline UTI incidence of 3% or higher and circumcision complication rate less than 2%, circumcision is helpful in reducing UTIs. In normal infants, the risk of UTI is 1% or less; in those with prior UTI, it is 10%; and in those with vesicoureteral reflux, it is 30% (Singh-Grewal, 2005). The main risk is bleeding followed by infection. Actual rates of hemorrhage in medically indicated or ritual hospital-based circumcision range from 0.2% to 3% (Bocquet et al., 2010).

Although numbers may be declining in some U.S. areas, circumcision remains one of the most common procedures performed. A neonatal circumcision is normally performed at 12 to 48 hours old when the infant has stabilized after birth but may be performed up to 4 to 6 weeks of age. Before the procedure, each patient should be examined thoroughly for signs of congenital anomalies of the penis, urethra, or urinary tract. If hypospadias is present, circumcision is stopped or not performed to allow the tissue to be used in a corrective surgical procedure to repair the urethra and glans.

Many locations recommend no oral intake for 1 hour before the procedure to prevent aspiration. Oral sucrose can be used to reduce pain during the procedure (Gatti, 2003). A dorsal penile block or penile ring block is more effective than EMLA cream or sucrose. EMLA cream provides anesthesia but has a risk of methemoglobinemia (Brady-Fryer et al., 2004).

Inspect first to make sure there is no hypospadias or hidden penis. If the penis is normal and parental consent has been obtained, the infant is placed on a circumcision restraint board and the skin prepared. A dorsal block is achieved by injecting 0.4 to 0.5 mL of 1% lidocaine without epinephrine at the base of the penile shaft at both the 10 and 2 o'clock positions and 5 mm distal to the skin reflection onto the pubic area. Inject 1 to 3 mm deep under the Buck fascia after aspirating to ensure you are not in a blood vessel. A ring block can also be done, slightly higher on the penile shaft circumferentially in the subcutaneous tissues, taking care to avoid injury to the urethra or vasculature (Figure 28-20).

When anesthesia is complete, grasp the foreskin distally at 3 and 9 o'clock with two hemostats. All techniques require freeing of adhesions with blunt dissection, usually done with a straight Kelly clamp inserted between the foreskin and glans in a superior direction to avoid the urethra. Open the clamp and sweep laterally. Avoid the highly vascular frenulum. Free the adhesions to the coronal sulcus of the glans. Use a straight hemostat to clamp the free dorsal foreskin, again making sure the tip is held up and away from entering the urethra. Clamp three fourths the length of the foreskin dorsally. Insert iris scissors and carefully cut the foreskin along the crushed line. Peel back the foreskin to reveal the glans. Avoid degloving the shaft and damage to the frenulum.

GOMCO CLAMP

The Gomco is the most common circumcision clamp. Test the clamp's fit with the base before use. Estimate the correct

Figure 28-20 Dorsal penile block. The dorsal penile nerve is anesthetized using no more than 1.0 mL total of 1% lidocaine without epinephrine. The anesthetic is administered at the dorsum of the penis approximately 0.5 cm distal to the penile root at the 10 and 2 o'clock positions. (From Pfenninger JL, Fowler G, eds. *Procedures for primary care physicians*. 2nd ed. St. Louis: Mosby; 2003 and Chavez MC, Maker VK. Office surgery. In Rakeil RE, ed. *Textbook of family medicine*. 7th ed. Philadelphia: Saunders; 2007.)

size so that the bell covers at least seven-eighths of the glans (1.1, 1.3, and 1.5 sizes available). The glans is then covered with the Gomco bell and the foreskin pulled over it, sometimes with the aid of a clamp or safety pin. The bell and foreskin are then pulled through the hole in the base plate and the foreskin is arranged to ensure even tissue removal. The clamp is then placed on the base plate and the bell stem hooked over the clamp bar. After positioning is confirmed, the clamp is tightened for 5 to 10 minutes and the remaining foreskin removed with a #10 scalpel. If hemostasis is confirmed, the clamp is removed, and the glans is covered regularly with petroleum jelly at each diaper change. Healing should take 4 to 10 days. Complications include bleeding, infection, and trauma to the penis. Bleeding can be controlled with silver nitrate or a simple suture if not resolved with pressure (Video 28-25).

PLASTIBELL

The Plastibell device is a plastic ring on the end of a central removable post. The ring is placed between the glans and foreskin. A tight ligature of moistened suture is placed around the foreskin and tightened into a sulcus on the ring. Foreskin distal to the ring is excised and the handle of the device broken off. The plastic ring stays in place, with the ligature tied tightly around the protective ring, for 5 to 10 days and falls off spontaneously. The appearance of the small amount of necrotic skin may worry parents, and it may be complicated with incomplete or irregular skin edges if the ligature is not tied tightly enough.

MOGAN CLAMP

The Mogan clamp is used in traditional Jewish circumcisions and may cause less pain by being faster. The foreskin is grasped with the nondominant hand and the glans pushed downward. The foreskin is slid into the clamp from anterior to posterior, taking care not to trap the glans. The clamp opens only 3 mm to prevent major glans entrapment. When in place and the glans is confirmed below the plate, the clamp is closed and the distal foreskin removed. The clamp is left in place for a few minutes and then removed, and the foreskin is retracted over the glans.

KEY TREATMENT

- Oral sucrose reduces painful procedures in infants (Gatti, 2003) (SOR: A).
- Dorsal penile block or penile ring blocks are more effective than EMLA cream or sucrose (Brady-Fryer et al., 2004) (SOR: A).
- EMLA cream provides anesthesia but has a risk of methemoglobinemia (Brady-Fryer et al., 2004) (SOR: A)

Musculoskeletal Office Procedures

ASPIRATION OF KNEE JOINT (ARTHROCENTESIS)

The knee is one of the largest and most accessible joints for arthrocentesis or joint injection. Aspiration of joint fluid from the knee is performed to assess for infection, inflammation, crystal deposition, or traumatic complications. Infections may show a significantly high white blood cell infiltrate with visible organisms on Gram stain. Inflammation may show the same without organisms seen. Crystal disease may show urate or calcium pyrophosphate crystals. Trauma may produce a bloody aspirate with tears of a ligament or cartilage and fat lobules with an intraarticular fracture.

Before the aspiration, the patient is consented and placed in a recumbent position with the knee flexed slightly with a rolled towel. The knee is assessed for effusion and the aspiration site marked and cleansed with a sterilizing wash. The knee joint space can be entered with a 22-gauge needle on a syringe on either side but usually from the lateral aspect 1 cm lateral and superior to the patella and directed 45 degrees downward, angling under the patella, with aspiration done during insertion. When the joint space is entered, fluid should enter the syringe rapidly. Milking the lateral and medial recesses of the knee toward the needle tip will remove more fluid. The needle is removed after aspiration, or it is left in place and the syringe changed under sterile conditions for a steroid injection to follow if necessary. Large joints can be injected with 20 to 40 mg of triamcinolone or 6 to 12 mg of betamethasone with 3 to 6 mL of 1% lidocaine for inflammatory conditions unrelated to infections. Procedural risks include septic arthritis, mild injury to the articular cartilage, and hemarthrosis. (Videos 28-26 and 28-28).

SHOULDER INJECTION

The subacromial bursa is another location frequently treated with steroid injection for bursitis or tendonitis.

Injections of 10 to 20 mg of triamcinolone with 2 to 4 mL of lidocaine can be performed into the subacromial bursa. The easiest approach to the subacromial space is with the patient seated comfortably and arms resting at the sides. The lateral shoulder is prepared with a sterile solution after palpating landmarks. The acromial process is identified on the lateral shoulder above the humeral head. In the sulcus between the humeral head and the acromial process lies the subacromial bursa. Marking the lateral border of the acromial process can provide some assistance. A 22- to 25-gauge needle on a syringe with the injection is then aimed directly into the sulcus between the bones 1 cm below the acromial process perpendicularly through the deltoid muscle. Ligamentous and muscular structures resist injection, but the bursa should allow free infusion. Relief of pain may be noted in a few minutes if lidocaine is used and confirms the injection was placed appropriately (Video 28-27)

	Special Concerns for Female Athletes, 646

Sports medicine involves the care of patients with illnesses and injuries related to sports and exercise. Both orthopedic and medical conditions affect a wide spectrum of patients during sports and recreational activities. The field of primary care sports medicine has emerged over the past 30 years as a leader in the comprehensive care of athletes, teams, and exercising individuals. Although sports medicine is often viewed in the context of professional and elite athletes, the principles and practice of sports medicine apply to athletes of all levels and ages.

The role of a sports medicine physician is to promote the health and safety of exercising individuals, prevent injury and illness, optimize function, and minimize disabilities that would preclude sports participation. Sports medicine physicians work closely with a multidisciplinary team of health care providers (specialty physicians and surgeons, athletic trainers, physical therapists, nutritionists, psychologists, and conditioning coaches) to satisfy the complete medical needs of athletes.

Sports medicine includes a rapidly expanding core of knowledge related to medical issues in sports and exercise for which the primary care sports medicine physician is uniquely trained. *Primary care sports medicine* is a subspecialty designation obtained through completion of an accredited sports medicine fellowship and passing the Certificate of Added Qualification examination. Many practicing primary care providers also gain vast experience in sports medicine through office treatment of orthopedic injuries, event coverage, and preparticipation screening evaluations. Musculoskeletal problems account for up to 20% of all primary care office visits (Urwin et al., 1998; Woodwell and Cherry, 2004), and approximately 90% of all sports injuries are treated nonsurgically. Thus, a sound clinical foundation in the evaluation and treatment of musculoskeletal disorders is critical to primary care providers and helps guide appropriate referral to orthopedic and rehabilitative specialists.

This chapter focuses on both the medical aspects of sports medicine and common orthopedic injuries in

athletes. Detailed reviews cover the preparticipation physical evaluation (PPE); cardiac disorders in athletes; concussion assessment and management; cervical spine injuries; on-the-field assessment of injured athletes; facial trauma; environmental influences such as exertional heat illness; common infections in athletes; and a systems-based review of dermatologic, pulmonary, hematologic, gastrointestinal (GI), and genitourinary disorders in athletes. Orthopedic areas common in primary care sports medicine are also included, such as athletic low back pain (LBP), muscle strains, tendinopathy, shin pain, stress fractures, and issues unique to pediatric and female athletes. See [Chapters 30 and 31](#) for a comprehensive review of additional musculoskeletal problems relevant to sports medicine and the care of exercising individuals.

Preparticipation Physical Evaluation

Key Points

- The primary objective of the PPE is to detect preexisting medical or musculoskeletal conditions that predispose an athlete to injury, disability, or catastrophic injury.
- Syncope that occurs during exercise is a serious warning sign and warrants a comprehensive cardiology evaluation to rule out an underlying cardiac disorder that predisposes to sudden death.
- Any athlete with a systolic murmur of grade 3/6 in severity, a murmur that gets louder with a Valsalva maneuver or on standing (suspicious for hypertrophic cardiomyopathy), a diastolic murmur, a family history of premature sudden cardiac death, or concerning exertional symptoms should be further evaluated by a cardiovascular specialist.

A PPE, or “sports physical,” is frequently required for medical clearance before participation in organized sports.

The *Preparticipation Physical Evaluation* monograph, first introduced in 1992, provides recommendations for the content and format of the evaluation ([American Academy of Family Physicians \[AAFP\] et al., 2010](#)). The fourth edition of the monograph, updated in 2010, is supported by six national medical societies: the AAFP, American Academy of Pediatrics, American College of Sports Medicine, American Medical Society for Sports Medicine, American Orthopaedic Society for Sports Medicine, and American Osteopathic Academy of Sports Medicine. The fourth edition also includes collaboration with the American Heart Association (AHA) regarding the preparticipation cardiovascular evaluation.

The primary objectives of the PPE include the following:

1. Detection of potentially life-threatening or disabling medical or musculoskeletal conditions before athletic clearance
2. Identification of preexisting conditions that may predispose athletes to injury
3. Satisfying legal or administrative requirements

Secondary objectives of the PPE include the following:

1. Promoting the health and safety of athletes in training and competition
2. Serving as an entry point into the health care system for athletes
3. Providing an opportunity for a general health assessment

The recommended frequency of the PPE varies widely according to the requirements of the specific school, organization, or state. AHA first published consensus recommendations for cardiovascular screening in athletes in 1996 and reaffirmed these recommendations in 2007, which have influenced the format and timing of the PPE ([Maron et al., 1996b, 2007](#)). A comprehensive PPE is recommended on entry into middle school, high school, and college before participation in competitive sports. For youth and high school athletes, a comprehensive PPE should be repeated every 2 years. For years not requiring a comprehensive PPE, annual updates consisting of a comprehensive history and determination of height, weight, and blood pressure, along with a problem-focused evaluation of new concerns, illnesses, or injuries, should occur on interval years for youth and high school athletes and on all subsequent years for college athletes.

The PPE history focuses on symptoms related to exercise, such as exertional syncope, lightheadedness, chest pain, palpitations, dyspnea, wheezing, and fatigue with less than expected activity ([Table 29-1](#)). A past medical history of preexisting cardiac or pulmonary conditions, murmurs, hypertension, coronary artery disease risk factors, asthma, concussions, illicit drug use, prior orthopedic injuries, or other medical conditions that place an athlete at risk of injury should be noted. Specific questions to identify a family history of premature death, cardiovascular disease, and hereditary cardiac disorders (e.g., hypertrophic cardiomyopathy, Marfan syndrome, long QT syndrome) are also recommended.

The PPE examination consists of both medical and musculoskeletal components. The cardiovascular examination

Table 29-1 Preparticipation Physical Evaluation: Cardiovascular History Questions

1. Have you ever passed out or nearly passed out during or after exercise?
2. Have you ever had discomfort, pain, pressure, or tightness in your chest during exercise?
3. Do you get lightheaded or feel more short of breath than expected during exercise?
4. Does your heart ever race or skip beats (irregular beats) during exercise?
5. Has a doctor ever told you that you have a heart problem, high blood pressure, high cholesterol, a heart murmur, a heart infection, Kawasaki disease, or an unexplained seizure disorder?
6. Has a doctor ever ordered a test for your heart (e.g., electrocardiography or echocardiography)?
7. Has any family member or relative died of heart problems or had an unexpected or unexplained sudden death before age 50 years (including drowning, motor vehicle crash, or sudden infant death syndrome)?
8. Has anyone in your family had unexplained fainting, seizures, or near drowning?
9. Does anyone in your family have a heart problem, pacemaker, or implanted defibrillator?
10. Does anyone in your family have hypertrophic cardiomyopathy, Marfan syndrome, arrhythmogenic right ventricular cardiomyopathy, long QT syndrome, short QT syndrome, Brugada syndrome, or catecholaminergic polymorphic ventricular tachycardia?

is a major focus of the medical evaluation and consists of a blood pressure measurement, palpation of the radial and femoral artery pulses, cardiac auscultation with the patient both supine and standing, and recognition of the physical manifestations of Marfan syndrome ([Maron et al., 1996b, 2007](#)). Any heart murmur detected should be further assessed during the Valsalva maneuver or while moving the patient from a squatting to a standing position. These maneuvers decrease venous return and may accentuate the murmur of hypertrophic cardiomyopathy, the leading cause of sudden cardiac death in young athletes. However, hypertrophic cardiomyopathy is difficult to detect on examination alone because outflow tract obstruction, which causes the harsh systolic murmur, is present in only about 25% of patients with the disorder ([Maron, 1997](#)) ([Figure 29-1](#)).

The musculoskeletal assessment serves as a screening evaluation of the spine and upper and lower extremities. Joint range of motion (ROM), strength, and stability should be tested. Several functional tests, such as hopping, squatting, and “duck walking,” assess many anatomic areas at once and make the evaluation more efficient. Previous orthopedic injuries can also be evaluated in more detail to detect problems that require further rehabilitation or protective bracing before sports participation.

WARNING SYMPTOMS IN ATHLETES

Warning or “red flag” symptoms that may indicate the presence of an underlying cardiovascular disorder should be recognized and further assessed before medical clearance. Syncope that occurs during but not after exercise is of great concern and warrants a comprehensive cardiology evaluation to rule out the presence of an occult cardiac disorder that may lead to sudden death. Other worrying symptoms include palpitations, chest pain, lightheadedness, and fatigue or dyspnea greater than expected for the level of

Figure 29-1 Hypertrophic cardiomyopathy. **A**, Gross appearance. **B**, Histologic appearance. Note the myocardial fiber disarray. (From Braunwald E. *Essential atlas of heart diseases*. 3rd ed. Philadelphia: Saunders; 2000.)

activity. Athletes with warning symptoms should be evaluated by an electrocardiogram (ECG), echocardiogram, and exercise stress test and referred to a cardiologist. In addition, systolic murmurs of grade 3/6 in severity, all diastolic murmurs, any murmur that becomes louder with a Valsalva maneuver or on standing (suspicious for hypertrophic cardiomyopathy), and a concerning family history of premature sudden cardiac death or hereditary cardiac disorder should be further evaluated by a cardiovascular specialist.

If a cardiac abnormality is identified, the decision to withhold medical clearance for participation in competitive sports is difficult and should be carefully considered on an individual basis. The American College of Cardiology 36th Bethesda Conference defined eligibility recommendations for athletes with cardiovascular abnormalities (Maron and Zipes, 2005).

LIMITATIONS OF CARDIOVASCULAR SCREENING

Despite efforts to standardize the format and approach to the PPE, several limitations of the screening process still exist. In 2007, only 19% of U.S. states used forms that were considered adequate by AHA, and 35% of states allowed practitioners with limited cardiovascular training to perform the evaluation (Glover et al., 2007). Unfortunately, recommendations to use a comprehensive personal and family questionnaire to guide the PPE are not widely adopted, and recommended screening protocols are often incompletely or inadequately implemented. In addition, the PPE is screening for medical conditions that place an athlete at increased risk of sudden death, and no outcomes-based research has demonstrated that the PPE is effective in preventing sudden death or potentially catastrophic events or for identifying athletes at risk. A complicating feature of the screening process is that athletes who harbor underlying structural heart disease may be asymptomatic until the sudden cardiac arrest. In a review of 134 cases of sudden cardiac death, only 18% of athletes had symptoms of cardiovascular disease in the 3 years before their death, and only 3% were suspected of having a cardiovascular condition after PPE (Maron et al., 1996a).

Limitations in the traditional screening process have led to widespread debate regarding the addition of noninvasive

cardiovascular screening techniques, such as ECG, to the PPE. In 2007, the AHA reaffirmed recommendations against universal ECG screening in athletes, citing a low prevalence of disease, poor sensitivity, high false-positive rate, poor cost-effectiveness, and a lack of clinicians to interpret the results (Maron et al., 2007). In contrast, the European Society of Cardiology, the International Olympic Committee, and the governing associations of several U.S. and international professional sports leagues endorse the use of ECG in the screening of athletes (Corrado et al., 2006; Ljungqvist et al., 2009). These recommendations are supported by studies showing that ECG is more sensitive than history and physical examination alone in identifying athletes with underlying cardiovascular disease, including a 77% greater power to detect hypertrophic cardiomyopathy (Corrado et al., 1998).

Corrado and associates reported results from screening 42,386 athletes over 25 years from the national PPE program in Italy. Disqualification on the basis of a screening protocol using history, physical examination, and ECG produced a tenfold reduction in the incidence of sudden cardiac death in young competitive athletes and an 89% reduction of sudden death from cardiomyopathy (Corrado et al., 2005, 2006). Although only 0.2% of athletes were disqualified for potentially lethal cardiovascular conditions, the study reported a 7% false-positive rate and a 2% overall disqualification rate (Corrado et al., 2005). This raised concerns that adopting such a program in the United States would lead to an unacceptable number of disqualifications in athletes with a low risk of sudden death.

Complex issues regarding feasibility, cost-effectiveness, appropriate physician, and healthy system infrastructure remain before large-scale implementation of ECG screening in the United States can be considered. However, some physicians are using ECG during PPE to improve detection of potentially lethal cardiovascular abnormalities. A large-scale study of 32,561 United States high school students performed by cardiologists, administrators, and volunteers who all underwent specialized training and quality review demonstrated an abnormal ECG rate of 2.5% (Marek et al., 2011). When used, ECG interpretation must be based on modern criteria to distinguish abnormal findings from physiologic alterations in athletes to ensure acceptable

Table 29-2 The Seattle Criteria: Abnormal Electrocardiographic Findings in Athletes* (see Table 29-3)

Abnormal ECG Finding	Definition
T-wave inversion	>1 mm in depth in two or more leads: V2-V6, II and aVF or I and aVL (excludes III, aVR, and V1)
ST segment depression	≥0.5 mm in depth in two or more leads
Pathologic Q waves	>3 mm in depth or >40 msec in duration in two or more leads (except III and aVR)
Complete left bundle branch block	QRS ≥120 msec, predominantly negative QRS complex in lead V1 (QS or rS), and upright monophasic R wave in leads I and V6
Intraventricular conduction delay	Any QRS duration ≥140 msec
Left axis deviation	−30 to −90 degrees
Left atrial enlargement	Prolonged P wave duration of >120 msec in leads I or II with negative portion of the P wave ≥1 mm in depth and ≥40 msec in duration in lead V1
Right ventricular hypertrophy pattern	R-V ₁ + S-V ₅ > 10.5 mm and right-axis deviation >120 degrees
Ventricular preexcitation	PR interval <120 msec with a delta wave (slurred upstroke in the QRS complex) and wide QRS (>120 msec)
Long QT interval [†]	QTc ≥470 msec (male) QTc ≥480 msec (female) QTc ≥500 msec (marked QT prolongation)
Short QT interval [†]	QTc ≤320 msec
Brugada-like ECG pattern	High take-off and downsloping ST segment elevation followed by a negative T wave in ≥2 leads in V1-V3
Profound sinus bradycardia	<30 beats/min or sinus pauses ≥3 sec
Mobitz type II second-degree AV block	Intermittently nonconducted P waves not preceded by PR prolongation and not followed by PR shortening
3-degree AV block	Complete heart block
Atrial tachyarrhythmias	Supraventricular tachycardia, atrial fibrillation, atrial-flutter
Premature ventricular contractions (PVCs)	≥2 PVCs per 10 second tracing
Ventricular arrhythmias	Couplets, triplets, and nonsustained ventricular tachycardia

*These electrocardiographic (ECG) findings are unrelated to regular training or expected physiologic adaptation to exercise, may suggest the presence of pathologic cardiovascular disease, and require further diagnostic evaluation.

[†]The QT interval corrected for heart rate is ideally measured with heart rates of 60 to 90 beats/min. Consider repeating the ECG after mild aerobic activity for borderline or abnormal QTc values with a heart rate less than 50 beats/min.

AV, Atrioventricular.

accuracy and a low false-positive rate (Drezner, 2008). In a study of 2720 competitive athletes and physically active schoolchildren, a U.K. study reported a false-positive rate of 3.7% using history, physical examination, and ECG, with only 1.9% of false-positive results determined by ECG alone (Wilson et al., 2008). Nine athletes (0.3% of those screened) were found to have a cardiovascular condition known to cause sudden cardiac death in young persons, and all athletes were detected by ECG, not by history or physical examination. Physicians interpreting ECGs in athletes should be familiar with common training-related ECG alterations that are normal variants. In contrast, training-unrelated ECG changes suggest the possibility of underlying pathology, require further diagnostic workup, and should be considered abnormal. Current recommendations for ECG interpretation in athletes to distinguish pathologic ECG abnormalities from physiologic ECG alterations have been recently published (Corrado et al., 2009, 2010; Drezner et al., 2013a, 2013b, 2013c). In 2012, a summit of international experts in Sports Cardiology and Sports Medicine convened in Seattle to define contemporary standards in the interpretation of ECGs in athletes. The “Seattle criteria” were developed and subsequently used to develop an online training module for physicians to acquire a common foundation in ECG interpretation in athletes (Tables 29-2 and 29-3). This online training module is available at no cost to any physician worldwide (see Web Resources).

Table 29-3 The Seattle Criteria: Normal Electrocardiographic Findings in Athletes* (see Table 29-2)

1. Sinus bradycardia (≥30 beats/min)
2. Sinus arrhythmia
3. Ectopic atrial rhythm
4. Junctional escape rhythm
5. First-degree AV block (PR interval >200 msec)
6. Mobitz type I (Wenckebach) second-degree AV block
7. Incomplete RBBB
8. Isolated QRS voltage criteria for LVH
Except: QRS voltage criteria for LVH occurring with any nonvoltage criteria for LVH such as left atrial enlargement, left axis deviation, ST segment depression, T-wave inversion, or pathologic Q waves
9. Early repolarization (ST elevation, J-point elevation, J-waves, or terminal QRS slurring)
10. Convex (“domed”) ST segment elevation combined with T-wave inversion in leads V1-V4 in black or African athletes

*These common training-related electrocardiographic alterations are physiological adaptations to regular exercise, considered normal variants in athletes, and do not require further evaluation in asymptomatic athletes.

AV, Atrioventricular; LVH, left ventricular hypertrophy; RBBB, right bundle branch block.

Cardiac Disorders in Athletes

Key Points

- Bradyarrhythmias caused by increased resting vagal tone are common in athletes and include sinus bradycardia, sinus arrhythmia, first-degree atrioventricular block, and Wenckebach (Mobitz I) second-degree atrioventricular (AV) block.
- Mobitz II second-degree and complete third-degree AV blocks are always pathologic and warrant cardiologic evaluation.
- Supraventricular tachyarrhythmias in athletes are abnormal and require further evaluation and treatment, often with radiofrequency (RF) ablation, before participation in strenuous exercise.
- Ventricular arrhythmias are life-threatening events and usually occur in the presence of structural heart disease or ion channel disorders.
- Hypertrophic cardiomyopathy, coronary artery anomalies, and commotio cordis are the most common causes of sudden cardiac death in young U.S. athletes.

ARRHYTHMIAS

Cardiac arrhythmias in athletes range from benign to life threatening. Bradyarrhythmias are more common in athletes than in the general population because of an increase in resting vagal tone as a response to regular strenuous exercise. Common bradyarrhythmias include sinus bradycardia, sinus arrhythmia, first-degree AV block, and Wenckebach (or Mobitz I) second-degree AV block (Huston et al., 1985; Link et al., 2001). These bradyarrhythmias are usually asymptomatic and should resolve during exercise by the withdrawal of vagal tone and associated catecholamine influx.

Athletes with symptomatic Wenckebach block, such as presyncope or syncope during exertion, require further evaluation by a cardiologist and often placement of a permanent pacemaker and restriction of activities. Higher degrees of heart block, such as Mobitz II second-degree and complete third-degree AV blocks, are always pathologic in any individual, including athletes (Figure 29-2). Mobitz II and complete heart blocks signify marked disease in the His-Purkinje system and are generally accepted as a class I indication for permanent pacemaker placement even in the absence of symptoms (Link et al., 2001).

Tachyarrhythmias in athletes are abnormal and require further evaluation and treatment before participation in strenuous exercise. The treatment of many supraventricular tachyarrhythmias has been greatly advanced by the use

Figure 29-2 Mobitz II second-degree atrioventricular block. Note that every alternate P wave is blocked. (From Goldberger E. *Treatment of cardiac emergencies*, 5th ed. Philadelphia: Saunders; 1990.)

of RF ablation, which might offer an actual cure and obviate the need for lifelong pharmacologic treatment.

The most common tachyarrhythmia in athletes is *atrial fibrillation* (AF). Studies have suggested that AF occurs more frequently in athletes than in the general population (Furlanello et al., 1998; Huston et al., 1985). This might be a consequence of increased vagal tone and bradycardia in athletes, which allows dispersion of atrial repolarization and results in a higher susceptibility to AF. RF ablation is curative in most cases of paroxysmal AF (Link et al., 2001). If pharmacologic treatment is needed, rate control can be accomplished with β -adrenergic blockers or calcium channel blockers, and anticoagulation should be considered with aspirin, warfarin, or possibly the newer factor Xa inhibitors (rivaroxaban, apixaban) and direct thrombin inhibitors (dabigatran), depending on the frequency of AF and other risk factors for thromboembolism. However, any athlete receiving anticoagulation therapy with warfarin should be restricted from sports involving collision or bodily contact.

Atrioventricular nodal reentrant tachycardia (AVNRT) is characterized by abrupt onset and termination of symptoms, a narrow QRS complex, and no evidence of atrial activity on the ECG during the tachycardia. AVNRT caused by an accessory bypass tract, known as Wolff-Parkinson-White (WPW) syndrome, may be evident on the ECG by the characteristic delta wave (slurred upstroke of QRS complex), short PR interval, and prolonged QRS complex (Figure 29-3). Athletes with WPW may be at risk of sudden death and should be strongly considered for RF ablation. RF ablation for both AVNRT and WPW offers cure rates higher than 95% (Link et al., 2001; Manolis et al., 1994).

Atrial flutter is an unusual arrhythmia in trained athletes and typically results from an underlying cardiomyopathy.

Ventricular tachyarrhythmias in athletes are life threatening and usually the result of structural heart disease such as hypertrophic cardiomyopathy, anomalous coronary artery, dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia (ARVD), or atherosclerotic coronary artery disease (CAD). Ventricular arrhythmias and sudden death may also occur in individuals with structurally normal hearts. This may occur from ion channel disorders, such as long QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), and Brugada syndrome or from commotio cordis. Long QT syndrome is characterized by a prolonged QTc interval, and Brugada syndrome is suggested by an incomplete right bundle branch block and ST segment elevation in the precordial leads. Exercise may provoke ventricular arrhythmias because of high catecholamine levels and make ventricular fibrillation more difficult to terminate. Athletes who experience a resuscitated sudden death should undergo an extensive workup and treatment with an implantable cardioverter-defibrillator (Link et al., 2001).

SUDDEN CARDIAC DEATH

Sudden cardiac death in athletes is a catastrophic event and the leading cause of death in exercising young athletes (Maron et al., 2009). The exact incidence of sudden cardiac deaths per year in the United States is not known. Reported ranges of sudden cardiac death in the United States is

Figure 29-3 Atrioventricular nodal reentrant tachycardia. Notice the characteristic triad of the Wolff-Parkinson-White (WPW) pattern: wide QRS complexes, short PR intervals, and delta waves (arrows) that are negative in some leads (e.g., II, III, aVR) and positive in others (aVL and V₂ to V₆). The Q waves in leads II, III, and aVR are the result of abnormal ventricular conduction (negative delta waves) rather than an inferior myocardial infarction. This pattern is consistent with a bypass tract inserting into the posterior wall of the left ventricle. (From Goldberger AL. *Clinical electrocardiography: a simplified approach*. 7th ed. Philadelphia: Saunders; 2006.)

between 0.6 and 13 deaths per 100,000 (Atkins et al., 2009; Drezner et al., 2009; Eckart et al., 2004; Maron et al., 2009). These studies are limited by the lack of a mandatory reporting system for juvenile sudden death and their reliance on electronic databases and media reports to identify cases of sudden death. Thus, current reports likely underestimate the true incidence of sudden cardiac death in athletes.

The cause of sudden cardiac death in young athletes (younger than 35 years of age) is usually a structural cardiac abnormality, with hypertrophic cardiomyopathy and coronary artery anomalies representing 36% and 17% of U.S. cases, respectively (Table 29-4) (Maron et al., 2009). *Commotio cordis*, involving a blunt, nonpenetrating blow to the chest that leads to a ventricular arrhythmia, accounts for approximately 3% of cases. *Commotio cordis* is most common in younger athletes (mean age, 13 years) with compliant chest walls (Maron et al., 2002). *Commotio cordis* occurs most often in sports using a firm projectile, such as baseball, softball, hockey, and lacrosse, but can also occur from contact with stationary field equipment, the ground, or another player. In older athletes (older than 35 years of age), atherosclerotic CAD accounts for more than 75% of cases of sudden cardiac death.

AUTOMATED EXTERNAL DEFIBRILLATORS IN ATHLETIC MEDICINE

Limitations of the cardiovascular screening process, the overwhelming desire to protect young athletes from a tragic event, and the success of early defibrillation programs (Caffrey et al., 2002; Page et al., 2000; Valenzuela et al., 2000) using accessible automated external defibrillators (AEDs) have propelled the placement of AEDs into the

Table 29-4 Causes of Sudden Cardiac Death in Young Athletes

Structural	Hypertrophic cardiomyopathy* Coronary artery anomalies Aortic rupture or Marfan syndrome* Dilated cardiomyopathy* Myocarditis Left ventricular outflow tract obstruction Mitral valve prolapse Coronary artery (atherosclerotic) disease* Arrhythmogenic right ventricular cardiomyopathy* Postoperative congenital heart disease

Other	Drugs and stimulants <i>Commotio cordis</i> Primary pulmonary hypertension*

*Familial or genetic etiology.

athletic setting (Drezner et al., 2005). Recent research suggests an improved survival rate for young athletes with sudden cardiac arrest if early defibrillation is achieved. A retrospective cohort of 1710 U.S. high schools with onsite AED programs found 14 cases of sudden cardiac arrest in high school student-athletes and a 64% survival rate if early cardiopulmonary resuscitation (CPR) and prompt defibrillation with an AED were provided (Drezner et al., 2009).

Comprehensive emergency response planning is needed to ensure an efficient and structured response to sudden

cardiac arrest in the athletic setting. This includes establishing a communication system to activate the emergency medical services system and alert any onsite response team, training of anticipated responders (e.g., coaches) in CPR and AED use, access to an AED, and practice and review of the response plan. High suspicion of sudden cardiac death should be maintained in any collapsed and unresponsive athlete, with application of an AED as soon as possible for rhythm analysis and defibrillation if indicated (Drezner et al., 2007, 2009).

KEY TREATMENT

- High suspicion of sudden cardiac arrest should be maintained in any collapsed and unresponsive athlete, with application of an AED as soon as possible for rhythm analysis and defibrillation if indicated (Drezner et al., 2007, 2009) (SOR: B).

Concussion in Sports

Key Points

- Concussion is defined as a traumatically induced transient disturbance of brain function and involves a complex pathophysiologic process. Concussion is a subset of traumatic brain injury that is generally self-limited (Harmon et al., 2013).
- Animal and human studies support the concept of postconcussive vulnerability, showing that a second blow before the brain has recovered results in worsening metabolic changes (Barkhoudarian et al., 2011; Prins et al., 2010; Shrey et al., 2011).
- Concussion remains a clinical diagnosis ideally made by a health care provider familiar with the athlete and knowledgeable in the recognition and evaluation of concussion (Harmon et al., 2013).
- Initial assessment of concussion should be guided by a symptom checklist, cognitive evaluation, balance tests, and further neurologic physical examination (McCrorry et al., 2013).
- Although standardized sideline tests are a useful framework for examination, the sensitivity, specificity, validity, and reliability of these tests among different age groups, cultural groups, and settings is largely undefined. Their practical usefulness with or without an individual baseline test is also largely unknown (Harmon et al., 2013).
- Neuropsychological (NP) tests are an objective measure of brain–behavior relationships and are more sensitive for subtle cognitive impairment than clinical examination (Elleberg et al., 2009; Van Kampen et al., 2006).
- Most concussions can be managed appropriately without the use of NP testing (Harmon et al., 2013; McCrorry et al., 2009).
- A player should never return to play while symptomatic from a concussion.
- When asymptomatic, athletes should follow a stepwise and graded exercise program before return to play (Harmon et al., 2013; McCrorry et al., 2009).

In 1966, the Congress of Neurological Surgeons proposed a consensus definition of concussion. Since then, both the definition and our understanding of concussion have been and are continuing to evolve. *Concussion* is defined as a traumatically induced transient disturbance of brain function and involves a complex pathophysiologic process. Concussion is a subset of traumatic brain injury and is generally self-limited (Harmon et al., 2013). There has been increased attention to concussion and brain injury spurred by concern in the NFL and the military. In addition to this concern, there has been increased public awareness, beginning in 2009 with the passage of the Zackery Lystedt Law in Washington State. Nearly every state in the union has passed concussion-related legislation in the past 5 years.

SYMPTOMS AND INCIDENCE

A concussion usually results in the rapid onset of brief neurologic impairment that resolves spontaneously. Symptoms of concussion include loss of consciousness, amnesia, confusion, headache, vision problems, nausea, and balance problems (Table 29-5). A concussion may or may not be associated with a loss of consciousness. More than 90% of concussions are not associated with a loss of consciousness, and unconsciousness is not a marker of the severity of the injury (Lovell et al., 1999). *Amnesia* can include loss of memory of the events before (retrograde amnesia) or after (posttraumatic amnesia) the concussion, or both, and amnesia appears to be the best predictor of severity in athletic concussion (Collins et al., 2003). Conventional imaging studies such as computed tomography (CT) and magnetic resonance imaging (MRI) are normal in concussion. Research protocols show changes related to concussive injury, but no imaging studies are available for clinical use. It is estimated that as many as 3.8 million concussions occur in the United States per year during competitive sports and recreational activities; however, as many as 50% of concussions may go unreported (Centers for Disease Control and Prevention, 1997). In high school football, there are 40,000 concussions per year, with a 3% to 5%

Table 29-5 Signs and Symptoms of Concussion

Disorientation
Confusion
Amnesia
Loss of consciousness
Headache
Dizziness
Balance problems
Poor coordination, gait
Nausea or vomiting
Visual problems (flashing lights)
Hearing problems (tinnitus)
Feeling “foggy” or “dazed”
Inability to focus
Difficulty concentrating
Irritability
Emotional lability
Excessive drowsiness
Delayed verbal or motor response
Vacant, “glassy” stare
Slurred, incoherent speech
Decreased playing performance
Seizure (rare)

incidence (Powell and Barber-Foss, 1999a, 1999b). High-risk sports include contact and collision sports such as football; ice hockey; rugby; wrestling; and to a lesser extent, soccer and basketball. Women appear to be more prone to concussion in some sports (Tierney et al., 2005) for unclear reasons, with further research needed. Younger players also may be more prone to concussion. Concussions in children and younger adolescents appear to have a more prolonged course of recovery (Field et al., 2003; Moser et al. 2005; Zuckerman et al., 2012).

SIDELINE MANAGEMENT

When attending to an athlete with a suspected concussion on the field, attention must first be given to basic first aid. Airway, breathing, and circulation (ABCs) and level of consciousness should be initially assessed followed by an evaluation for potential cervical spine injuries. If loss of consciousness has occurred, the duration of unconsciousness should be determined. A brief loss of consciousness is generally defined as less than 30 to 60 seconds. If a player is unconscious for more than 30 to 60 seconds or still unconscious by the time a medical provider reaches the athlete on the field, most would consider this “prolonged.” Patients with concussions involving prolonged loss of consciousness, suspected cervical spine injuries, or gross neurologic impairment should be stabilized and transported to a hospital for further evaluation (see “Catastrophic Cervical Spine Injuries: On-the-Field Assessment” later in this chapter).

After it is determined that the athlete is stable and safe to be moved, further assessment can take place on the sideline. Physical examination should include evaluation of cranial nerves, pupillary dilation and reactivity, balance and coordination, motor strength, and cognitive function (McCreary et al., 1997). Several sideline assessment tools exist to aid medical professionals in the evaluation of an athlete with concussion. The most recent consensus conference on concussion recommended a sideline tool called the Sport Concussion Assessment Tool (SCAT3; <http://bjsm.bmj.com/content/47/5/259.full.pdf>) (McCroory et al., 2013). This is a modification of earlier versions and consists of several validated measures for concussion. This includes a symptom scale, standard cognitive assessment, and guided physical examination. Such standardized examinations are useful for serial follow-up and if different medical personnel will be evaluating the athlete. It is important to reassess concussed athletes frequently to monitor for resolution of symptoms or signs of deterioration.

RETURN TO PLAY

Return-to-play decisions are driven by the concern of preventing potential complications, primarily second-impact syndrome and permanent neurologic deficit. *Second-impact syndrome* occurs when a player returns to play after a first concussion before the symptoms have completely resolved, and a second, often minor, blow to the head is sustained, which leads to diffuse cerebral swelling, brainstem herniation, and death (Cantu, 1998). The risk for catastrophic injury in athletes returned to play while still symptomatic is of particular concern in children and adolescents.

There is increasing concern that head impact exposure and recurrent concussions contribute to long-term

Table 29-6 Graded Return to Play after Concussion

1. Rest until asymptomatic
2. Light aerobic exercise (stationary cycling, slow jogging)
3. More strenuous aerobic training (running, sprinting)
4. Sport-specific training
5. Noncontact drills
6. Full contact drills
7. Return to competition

neurologic sequelae, including chronic traumatic encephalopathy (CTE). CTE is characterized by the accumulation of tau protein in specific areas of the brain and results in executive dysfunction, memory impairment, depression, and poor impulse control (Baugh et al., 2012). CTE is a diagnosis made only after death with confirmatory histopathology, although imaging techniques are being developed to diagnose it before death. The prevalence of this condition is unknown; however, given the large number of athletes participating in contact or collision sports and the small number of cases described, it is likely that other factors such as genetic predisposition and lifestyle choices play a role in its development.

Current recommendations suggest that management of concussion be based on symptoms and severity. The mildest concussion is one that involves transient symptoms that resolve quickly. More severe concussions involve persistent or prolonged symptoms and cognitive deficits on NP testing. Management of concussion includes both physical and mental rest until all symptoms have cleared followed by a graded and stepwise program of exertion before return to sport (Table 29-6). *Repetitive concussions*, which take longer to return to baseline or that occur with progressively less trauma, are also considered of greater severity (Guskiewicz et al., 2003). Complex or recurrent concussions with persistent cognitive impairment, neurologic findings on examination, or prolonged symptoms may warrant advanced imaging and formal NP testing and should be managed by physicians with specific expertise in sports-related concussion.

Neuropsychological testing in concussion is becoming more common, particularly computerized NP tests. NP tests are a quantitative measure of brain-behavior relationships and are more sensitive to changes secondary to concussion than standard office testing. They can be used both with and without a baseline test. The interpretation of computerized NP testing requires an understanding of the sensitivity, specificity, and reliable change index of the tests used and should be done by someone with training and understanding in this area. These tests should never be used as a sole indicator as readiness to return to play; rather, they should be viewed as one piece of information to be included in the larger clinical picture. Concussions can be properly managed without the use of NP testing. NP testing is sometimes helpful in athletes with prolonged symptoms and those who may not be forthcoming.

Concussion is a common injury in sports. Athletes sustaining a concussion should be medically evaluated by a health care professional with specific training and experience in the management of concussion. No symptomatic athlete should be allowed to return to play, and an athlete should not be allowed to return to play in the same game or practice during which an injury has occurred. When asymptomatic, athletes should follow a graded program

before return to play. Referral should be considered in complex or complicated concussions. Further research is needed to provide more information regarding accurate diagnosis, prevention, evidenced-based return-to-play guidelines and long-term sequelae.

KEY TREATMENT

- A player with a concussion who is still symptomatic should be held from practice and competition and should not return to the field of play (SOR: C) (McCroory et al., 2013).
- When asymptomatic, athletes should follow a stepwise and graded exercise program before a return to sport. (SOR: C) (McCroory et al., 2013).

Cervical Spine Injuries

Key Point

- “Stingers” result from a blow to the neck and shoulders with transient unilateral upper extremity pain and paresthesias resolving in minutes.

STRAINS AND SPRAINS

Most sports-related neck injuries are mild and self-limiting. Patients with muscle strains and ligament sprains typically present with minor complaints and no neurologic symptoms. More significant injury should be suspected in the presence of significant cervical muscle spasm, tentative active ROM, severe pain, or abnormal neurologic signs. Evaluation includes active cervical ROM and strength testing of the neck and upper extremities. Manual compression and axial loading to the cervical spine (Spurling maneuver) should not cause pain or radicular symptoms and is helpful in ruling out more significant injury (Magee, 1997). Return to play should be considered when full, pain-free ROM and normal strength of the cervical spine are restored.

STINGERS

Stingers or “burners” are characterized by transient unilateral upper extremity pain and paresthesias resulting from a blow to the neck and shoulders. Stingers are common in American football and have been reported in up to 50% to 65% of college players (Clancy et al., 1977; Sallis et al., 1992). Stingers are peripheral nerve injuries and are considered a transient neurapraxia of the cervical nerve roots, usually involving the upper trunk of the brachial plexus (C5-C6). Stingers typically manifest with dysesthesia (burning pain) that begins in the shoulder and radiates down the arm. They often are associated with transient numbness or weakness, and all symptoms typically resolve in minutes.

Stingers can occur from a tensile or compression overload (Watkins, 1986). In most high school athletes, the mechanism of injury involves a tensile or traction injury when the involved arm and the neck are stretched in opposite

directions. This occurs when the neck is forcibly flexed away while the shoulder is depressed. In college and professional athletes, who have a higher likelihood of degenerative changes of the cervical spine, a compression mechanism is more likely. This involves a pinch of the cervical nerve root within the neural foramen as the neck is forcibly extended in a posterolateral direction (Levitz et al., 1997).

Stingers are always unilateral, a distinguishing feature from spinal cord injuries, which involve symptoms in multiple limbs. Athletes are safe to return to play when symptoms have fully resolved and the athlete can demonstrate full cervical ROM and normal neurologic examination results.

Radiography and MRI should be considered in athletes with recurrent stingers to evaluate for cervical degenerative disk disease (Levitz et al., 1997). Rarely, more significant nerve injury involving *axonotmesis* (axon disruption) occurs, causing persistent weakness. Athletes with significant weakness 24 to 48 hours after injury may benefit from treatment with a short burst of oral corticosteroids. If weakness persists, electromyography performed 2 weeks or more after the injury will assess the distribution and degree of injury. Fortunately, most patients with axonotmesis recover within 1 year (Clancy et al., 1977).

CERVICAL CORD NEURAPRAXIA

Cervical cord neurapraxia is characterized by an acute, transient sensory or motor change, or both, to more than one extremity. Symptoms include burning pain, numbness, and tingling with or without paresis or complete paralysis. *Transient quadriplegia* is a type of neurapraxia characterized by temporary paralysis and loss of motor function in all four limbs (Torg et al., 1986). *Burning hands syndrome* is characterized by burning dysesthesias of the hands and associated upper extremity weakness (Maroon, 1977). Episodes of cervical cord neurapraxia usually resolve within 10 to 15 minutes, although gradual resolution may take more than 24 to 48 hours.

Congenital or degenerative narrowing of the anteroposterior (AP) diameter of the cervical spinal canal is an established risk factor for cervical cord neurapraxia (Torg et al., 1997). Athletes with an episode of cord neurapraxia should be held from competition and undergo radiographic evaluation and MRI. Return to play after an episode of cervical cord neurapraxia is a highly controversial area in sports medicine. Several cases of permanent neurologic injury after cervical cord neurapraxia associated with cervical spinal stenosis have been reported (Brigham and Adamson, 2003; Cantu, 1993, 2000). Functional spinal stenosis on advanced imaging in an athlete with a history of cervical cord neurapraxia is an absolute contraindication to return to play in contact and collision sports (Cantu, 2000).

CATASTROPHIC CERVICAL SPINE INJURY

Injury to the spinal cord resulting in temporary or permanent neurologic injury is a rare but potentially catastrophic event during sports competition. Cervical spine trauma is most common in contact and collision sports such as American football, rugby, ice hockey, gymnastics, skiing, wrestling, and diving (Carvell et al., 1983; Cantu and

Mueller, 1999; Tator and Edmonds, 1984; Wu and Lewis, 1985). Cervical spinal cord injuries are the most common catastrophic injury in American football and the second leading cause of death attributable to football. The National Center for Catastrophic Sports Injury Research reported that the incidence of cervical spinal cord injury in American football between 1977 and 2001 was 0.52, 1.55, and 14 per 100,000 participants in high school, college, and professional football, respectively (Cantu and Mueller, 2003). However, the incidence of catastrophic cervical spinal cord injuries in American football between September 1989 and June 2002 was 1.10 and 4.72 per 100,000 participants in high school and college football, respectively (Boden et al., 2006).

Axial loading is the most common mechanism for catastrophic injury to the cervical spine during sports competition (Torg et al., 1979, 1990). Axial loading occurs when a player strikes another player with the top of the head as the point of initial contact (“spear tackling”). In athletes with cervical spinal stenosis, axial loading followed by forced hyperextension or hyperflexion can further narrow the AP diameter of the spinal canal, resulting in compression of the spinal cord and transient or permanent neurologic changes (Eismont et al., 1984; Penning, 1962; Torg et al., 1993).

Recognition of the axial load mechanism as the major cause of catastrophic cervical spine injury in American football resulted in rule changes that banned “spearing,” defined as intentionally striking an opponent with the crown of the helmet, as well as other tackling techniques in which the helmet is used as the initial point of contact. In 1976, the incidence of quadriplegia was 2.24 and 10.66 per 100,000 in high school and college athletes, respectively. In 1977, only 1 year after rule changes that banned spear tackling, the incidence decreased to 1.30 and 2.66 per 100,000 in high school and college athletes (Torg et al., 2002). Most recently, the incidence was shown to have decreased even further to 0.50 and 0.82 per 100,000 high school and college athletes (Boden et al., 2006).

On-the-Field Assessment

Medical providers at sporting events must be prepared to assess, stabilize, and transport athletes with suspected cervical spine injuries. Adequate preparation, including the anticipation of required personnel and equipment plus a well designed emergency response plan, are critical to the management of catastrophic neck and spine injuries. In general, any athlete with significant neck or spine pain, diminished level of consciousness, or significant neurologic deficits should be immobilized and prepared for transport.

Guidelines for the prehospital care of spine-injured athletes were established by the *Inter-Association Task Force for Appropriate Care of the Spine-Injured Athlete* (2001). The initial assessment of an injured athlete begins with a basic assessment of the ABCs and level of consciousness. Unconscious athletes are presumed to have unstable spine injuries until proven otherwise.

The face mask of a protective helmet should be removed as soon as possible regardless of respiratory status (*Inter-Association Task Force, 2001*). In football, the face mask can be removed with screwdrivers or the loop straps cut with various cutting tools such as pruning shears or a

Trainer’s Angel (Knox and Kleiner, 1997). Football helmets and chin straps should be left in place. If the helmet is removed from a downed player wearing shoulder pads, the athlete’s head will hyperextend, which may result in secondary injury to the cervical spine. If the athlete is not breathing, an adequate airway can be established by the jaw thrust maneuver, which allows opening the airway while maintaining the cervical spine in a stable position. Rarely, assisted ventilation may be necessary.

If transport is indicated, the athlete should be immobilized to a spine board. A supine athlete can be transferred to a spine board using a six-plus person lift technique, with one person responsible for stabilization of the head and neck (*Inter-Association Task Force, 2001*). To transfer an athlete who is face down, a logrolling technique is recommended. Transport of a spine-injured athlete should be directed to a trauma center or medical facility with diagnostic and surgical capabilities for spinal injury.

KEY TREATMENT

- Axial loading is the most common mechanism for catastrophic injury to the cervical spine during sports competition (SOR: C) (Torg, 1979, 1990).
- Any athlete with significant neck or spine pain, diminished level of consciousness, or significant neurologic deficits should be immobilized and prepared for transport (SOR: C) (*Inter-Association Task Force, 2001*).
- Unconscious athletes are presumed to have unstable spine injuries until proven otherwise (SOR: C) (*Inter-Association Task Force, 2001*).
- The football helmet in a downed player wearing shoulder pads should not be removed to avoid hyperextension of the neck and secondary injury to the cervical spine (SOR: C) (*Inter-Association Task Force, 2001*).
- Athletes with an episode of cervical cord neurapraxia involving sensory or motor changes (or both) to more than one extremity should be held from competition and undergo radiographic evaluation and MRI to rule out functional spinal stenosis. (SOR: C) (Cantu, 2000; *Inter-Association Task Force, 2001*).
- In an athlete with a history of cervical cord neurapraxia, functional spinal stenosis on advanced imaging is an absolute contraindication to return to play in contact and collision sports. (SOR: C) (Cantu, 2000; *Inter-Association Task Force, 2001*).

Environmental Influences

EXERTIONAL HEAT ILLNESS

Key Points

- Hydration sufficient to replace fluid lost in sweat is essential to prevent heat stroke.
- Athletes exercising in the heat who exhibit mental status changes must be immediately removed from competition and cooled.
- Ice-water immersion produces the most rapid decrease in core body temperature.

Heat stroke is the third leading cause of death in high school athletes (Lee-Chiong and Stitt, 1995). Athletes are at the greatest risk during the month of August. High school football poses the greatest risk of heat illness, tenfold that of any other sport (Centers for Disease Control and Prevention, 2010). This is tragic because these deaths are largely avoidable.

An exercising human is an engine operating at about 25% efficiency, resulting in 3 W of heat production for every watt of work, and requires a biologic radiator to avoid overheating. Humans dissipate heat through convection, conduction, radiation, and evaporation, with evaporative sweat loss being the most significant. Higher temperatures limit heat dissipation from convection and conduction, warm sunny days elevate body temperature through radiant heating, and higher humidity decreases evaporative cooling. Thus, the combination of high ambient temperature, radiant heat from the sun, and high humidity works synergistically to create dangerous playing conditions that promote the development of heat illness.

The wet bulb globe temperature (WBGT) index incorporates ambient temperature, relative humidity, and the amount of radiant heat coming from the sun to provide a measure of the risk of overheating. The American College of Sports Medicine Inter-Association Task Force on Exertional Heat Illnesses Consensus Statement (2006) recommends that WBGT readings from 18° to 23°C (64.4°-73.4°F) result in moderate risk, 23° to 28°C (73.4°-82.4°F) in high risk and more than 28°C (82.4°F) in extreme risk. The cumulative effect of successive days of exercise in the heat must also be considered. In a U.S. Marine Corps study, investigators demonstrated that the risk of exertional heat illness was best predicted by considering the current and the previous day's WBGT index (Wallace et al., 2005).

Because evaporative cooling is the primary mechanism for heat dissipation, adequate hydration is essential to keep the biologic radiator functioning. Losses of 2% to 3% of

body weight are common with high-intensity exercise in the heat (Galloway, 1999). Below 5% fluid losses, performance and thermoregulation are impaired, and thirst is an inconsistent stimulus to rehydrate, so regular, planned fluid consumption is essential. Fluid recommendations vary, but experts have suggested about 500 mL of fluid intake 2 hours or less before exercise and then about 250 mL every 20 minutes during exercise (Convertino et al., 1996). Because of differences in sweat rate, acclimatization, intensity of exercise, clothing, protective equipment, and environmental factors, individual fluid requirements vary. Thus, recording an athlete's nude weight in the morning and evening is an effective method of determining adequate rehydration. If athletes are losing more than 2% to 3% of their body weight with training, they need to consume more fluids during training. If they cannot regain the lost weight before the next morning's training, they need to consume additional fluids after training and during recovery time. For every kilogram of body weight lost, 1 L of fluid should be consumed. Cooler, flavored fluids are recommended to increase palatability and absorption.

Heat illness is classified as heat edema, heat cramps, heat syncope, heat exhaustion, and heat stroke (Table 29-7) (Binkley et al., 2002; Eichner, 1998). Heat stroke is of the greatest concern, with hallmark features of an elevated core temperature higher than 40.5°C (105°F) and associated mental status changes. Any athlete exhibiting mental status changes and participating in an environment conducive to heat illness requires immediate removal from participation and active cooling. An ice-water tub should be prepared in advance if rapid cooling may be necessary in high-risk events, and an affected athlete should be fully submerged, with only the head above water (Smith, 2005). Other methods of cooling, such as applying ice bags to the neck, axilla, and groin, or using a cold-water spray combined with fanning, can be effective, but the rate of core body temperature loss is slower than in ice-water

Table 29-7 Exertional Heat Illness

	Definition	Management	Prevention
Heat edema	Dependent edema usually occurring before acclimation	Elevation of swollen extremity, rest, cooling Diuretics contraindicated	Gradual acclimation to heat
Heat (exercise-associated) muscle cramps	Painful spasms of single or multiple muscles Likely sodium deficiency and salty sweaters most prone	Rest, stretching, cooling, oral hydration with hypertonic sodium drink IV fluids (normal saline) if oral treatment limited or to expedite recovery	Maintain hydration and increase salt intake Add salt to fluids, especially for those with predisposition based on past history
Heat syncope	Orthostatic dizziness at cessation of exercise, with prolonged standing, or after assuming upright posture	Rest, cooling, place supine with legs elevated, monitor vital signs, and mental status Oral fluid hydration	Adequate hydration and acclimation; if occurs during exercise, requires cardiovascular evaluation
Heat exhaustion	Inability to continue exercise in heat Symptoms: weakness, fainting, dizziness, headache, nausea, vomiting, cramps, dehydration with low urine output Minimal mental status symptoms; core temperature <40°C	Immediate rest, rapid cooling (ice bath), close monitoring of mental status, vital signs (e.g., core temperature) Serum sodium if hyponatremia considered Oral fluid hydration with IV fluids (normal saline) if hypotension present	Adequate acclimation, monitor hydration, adjust training to climate, follow player's weight, and close monitoring for symptoms of heat illness
Heat stroke	Heat exhaustion with core temperature >40°C and mental status alteration or central nervous system collapse	As for heat exhaustion, with hospitalization as soon as possible	As for heat exhaustion, be prepared with ice baths, monitoring equipment, and access to emergency medical services

IV, Intravenous.

immersion. Close monitoring of mental status and vital signs (e.g., core temperature) is indicated, and athletes should be transported to the hospital if they do not exhibit improving mental status with normalization of vital signs. The National Athletic Trainers' Association Exertional Heat Illness Position Statement is an excellent reference regarding proper preparedness for heat illness (Binkley et al., 2002).

EXERTIONAL HYPONATREMIA

Key Points

- Life-threatening hyponatremia develops when excessive hypotonic fluid is consumed, with concomitant sodium sweat loss.
- Exertional hyponatremia most often occurs in women completing endurance races in more than 4 hours who drink copiously throughout the race.
- Symptoms of exertional hyponatremia include mental status changes and peripheral edema without significant elevation in core temperature.

Exertional hyponatremia (serum sodium <130 mmol/L), once considered a rare complication of exercise in the heat, is now recognized as more common and responsible for a number of exercise-related deaths (Almond et al., 2005). Controversy surrounds the exact pathophysiology, but the condition develops in the setting of excessive hypotonic fluid replacement while sodium is progressively lost in sweat (Levine and Thompson, 2005; Noakes, 2002). Typical victims are relatively inexperienced female marathon runners who tend to be light sweaters, finish in more than 4 hours, and drink copiously throughout the race. Nonsteroidal antiinflammatory drugs (NSAIDs) taken before the race may be a contributing factor (Hsieh, 2004). Athletes with a history of exercise-induced hyponatremia do not seem to be predisposed to water overload at rest, although there may be some physiologic mechanism beyond pure water overload that accounts for the condition in some susceptible individuals (Speedy et al., 2001). Symptoms are similar to those of heat exhaustion, including weakness, dizziness, headache, nausea, vomiting, and cramping, but the headache is more prominent and progressively severe, extremity swelling may be noted, and progressive mental status changes occur despite a core temperature lower than 40°C (104°F). Cerebral edema underlies the mental status changes, and pulmonary edema may also occur.

The serum sodium level must be assessed in athletes in whom the diagnosis is suspected to differentiate hyponatremia from heat stroke. Intravenous (IV) fluids, often indicated in heat stroke, can actually worsen hyponatremia if related to excessive hypotonic fluid intake. Prompt hospitalization is indicated for any athlete with mental status changes or persistently altered vital signs after the diagnosis of hyponatremia has been established. Exertional hyponatremic encephalopathy is treated with 3% hypertonic saline boluses (100 mL) (Hew-Butler et al., 2008). Prevention includes following an athlete's weight change with exercise to understand the fluid requirements more precisely, not

deviating from established fluid intake on race day to avoid overhydration, incorporating sodium- and electrolyte-containing fluids, and limiting fluid intake to 1 L/hr unless higher fluid requirements have been established (Gardner, 2002).

KEY TREATMENT

- Any athlete exhibiting mental status changes and participating in an environment conducive to heat illness requires immediate removal from participation and active cooling (American College of Sports Medicine, 2006) (SOR: B).
- Patients with exertional hyponatremic encephalopathy are treated with 3% hypertonic saline boluses (100 mL) (Hew-Butler et al., 2008) (SOR: B).

COLD INJURY

Key Points

- Cold-weather exercise requires proper layering of synthetic clothing with a waterproof, breathable outer layer to maintain body temperature, but excessive sweating and environmental dampness should be avoided.
- Hypothermia victims should be sheltered, dried, and warmed, and resuscitation attempts should continue until body temperature is higher than 32°C.

Outdoor sports participation, particularly winter sports, places athletes at risk for cold-induced injury. Two problems commonly encountered are frostbite and hypothermia.

Frostbite most frequently affects the toes, fingers, and exposed skin of the face. As tissue cools, a progressive cell membrane leak results initially in increased extracellular fluid, with progression to extracellular ice crystal formation and then ischemic necrosis. Prevention includes dry layering of clothing that is not constricting; avoidance of skin exposure, especially in windy, cold conditions; and maintaining the core temperature because hypothermic shunting of blood centrally promotes distal extremity freezing. Treatment involves warming, although this is not recommended until the victim has been safely evacuated; warming and then refreezing is more damaging. Antibiotics, tissue debridement, and possibly amputation may be required, depending on the extent of injury. Sallis and Chassay (1999) provide a more in-depth discussion of frostbite and other cold-induced injuries.

Hypothermia is defined as a core temperature at or below 32°C (90°F). Lower ambient temperatures and longer exposure times increase the risk for hypothermia, but *moisture* is the most dangerous variable that must be controlled. Wet clothing results in significant increases in conductive heat loss, which is made worse in the wind. Prevention of hypothermia requires proper clothing for outdoor exercise in the cold. Clothing should be layered so that with increased exertion and endogenous heat production, layers can be removed to avoid excessive sweating. Underlayers should consist of breathable wicking fabrics that move sweat

moisture away from the skin. Outer layers should be wind-proof, waterproof, and breathable. Midlayers, which can be added depending on the temperature and exertion level, should provide loft (synthetic pile or down) to trap air; this provides a temperature gradient between the warm underlayers and cold outer layers similar to the blubber on a marine mammal. Heat loss from the head is significant, so a hat or hood that wicks moisture is necessary, and mittens are warmer than gloves for very cold weather. Dehydration must be avoided because low plasma volume results in peripheral vasoconstriction and increases the risk of frostbite.

Treatment of mild hypothermia involves finding warm shelter away from the wind, removing wet outer layers, and covering with dry blankets. Sharing a sleeping bag with a warm climbing partner can be lifesaving in a desperate situation. In the setting of severe hypothermia, warm IV fluid (40°C), warm humidified oxygen, and warming lamps are indicated, if available. The adage “one is not dead until warm and dead” applies, and ventricular fibrillation or asystole in the setting of hypothermia should be treated with advanced cardiac life support (ACLS) protocols until the patient has a core temperature above 32°C (Sallis and Chassay, 1999; Tom et al., 1994).

ALTITUDE ILLNESS

High-altitude medicine, once the preoccupation of research pulmonologists and physicians practicing at high altitudes and caring for climbers, has become essential for many primary care providers because of increasing numbers of recreational athletes engaging in skiing, hiking, trekking, and other high-altitude pursuits.

Acute mountain sickness (AMS) and its two most significant manifestations, high-altitude pulmonary edema and high-altitude cerebral edema, are complications of travel to higher altitudes with insufficient acclimatization. Symptoms of AMS include headache; sleep difficulty; and GI upset, including loss of appetite, nausea, and vomiting. Symptoms occur a few hours after rapid ascent in 25% of individuals at as low as 8500 feet (Harris et al., 1998), with a higher percentage being affected at higher altitudes. Individuals vary in their susceptibility to AMS, and a high level of physical fitness is not protective. Gradual ascent, allowing acclimatization, prevents symptoms. If symptoms occur, delaying any further ascent with relative rest for 1 to 3 days usually results in improvement. More significant symptoms respond to decreasing altitude. Individuals with a history of AMS are likely to have it recur when they return to a higher altitude. Planning time for acclimatization and avoiding excessive exercise when first arriving at a higher altitude are helpful. Nocturnal periodic breathing probably contributes to worsening hypoxia and subsequent AMS symptoms, so avoiding alcohol and other sedatives is also helpful. Acetazolamide, 125 to 250 mg twice daily, started the day of initial ascent and continuing for 48 hours, has been shown to decrease AMS symptoms and hasten acclimatization, possibly by decreasing nocturnal periodic breathing (Bartsch et al., 2004).

High-altitude cerebral edema (HACE) is defined as a progression of AMS symptoms to include ataxia, mental status changes, lassitude, and eventual coma. HACE is fatal if

untreated. Treatment requires immediate descent of at least 2000 feet. Hyperbaric treatment can be lifesaving if immediate descent is not possible; portable hyperbaric chambers are available for mountaineering expeditions. In addition to immediate descent, treatment includes oxygen at 2 to 4 L/min to keep O₂ saturations greater than 90% and dexamethasone, 4 to 8 mg orally followed by 4 mg every 6 hours (Rodway et al., 2003).

High-altitude pulmonary edema (HAPE) is the development of pulmonary edema, dyspnea, and hypoxemia in the setting of AMS. Rapid descent of at least 1000 m is also the primary treatment. The administration of supplemental oxygen, 4 to 6 L/min to maintain O₂ saturations greater than 90%, and nifedipine, 30 mg of sustained-release nifedipine every 12 to 24 hours, is helpful if immediate descent is not possible (Hackett, 2013; Pennardt, 2013).

KEY TREATMENT

- Hypothermia victims should be sheltered, dried, and warmed and resuscitation attempts continued until body temperature is higher than 32°C (90°F) (Sallis and Chassay, 1999; Tom et al., 1994) (SOR: B).
- Pharmacologic prophylaxis can be helpful, but definitive treatment of HAPE or HACE requires descent to lower altitude as rapidly as possible (Pennardt, 2013; Rodway et al., 2003) (SOR: B).

Sports Trauma to the Teeth, Face, and Eyes

Key Points

- Dental trauma is common in many sports and can be largely prevented with a custom-molded mouth guard.
- Avulsed teeth or tooth fragments should be wrapped in saline-soaked gauze, with urgent transport to a dentist and luxated teeth repositioned if possible.
- Facial and nasal injuries requiring immediate referral include those with prolonged loss of consciousness, visual abnormalities suggesting orbital fracture, malocclusion of the teeth suggesting maxillary or mandibular fracture, facial paresthesias suggesting infraorbital nerve injury, open or significantly displaced nasal fractures, and uncontrollable epistaxis.
- Acute auricular hematomas should be fully evacuated to avoid chronic fibrosis and deformity (cauliflower ear).
- Eye trauma is usually preventable using appropriate eye protection.
- Loss of visual acuity, evidence of globe rupture or leaking aqueous humor, limitation or asymmetry of extraocular movements, persisting pupil abnormalities, and evidence of hyphema all require urgent ophthalmologic consultation.

DENTAL TRAUMA

Dental trauma is common, with one third of all dental injuries in the United States occurring with sports activities

(Honsik, 2004). Mouth guards are recommended by the American Dental Association for participation in all collision and contact sports as well as weightlifting, skydiving, skateboarding, gymnastics, racquetball, squash, and skiing. Dental injury is especially common in sports combining collision and a hard ball or puck, such as ice hockey or field hockey. A study of college basketball players found a significant decrease in tooth injuries in participants using custom-fitted mouth guards; however, there was no decrease in oral soft tissue injury or concussion (Labella et al., 2002). Sports physicians and dental professionals agree that although off-the-shelf molded mouthpieces are less expensive and more readily available, they do not protect teeth as effectively as a custom mouthpiece (Honsik, 2004).

Teeth rest in a bony socket, each with a neurovascular root connected to the socket by a periodontal ligament. Above the gum the tooth consists of three layers, dentin, pulp, and superficial enamel. Injuries involve fracture of the tooth or some degree of luxation. *Fractures* range from an enamel chip to those involving the deeper components. *Luxation* can result in a normally positioned loose tooth or a displaced tooth still positioned in the socket. Injury can also result in complete tooth avulsion.

After injury, tooth fragments or avulsed teeth should always be recovered, if possible, and transported to a dentist in saline-soaked gauze. Fractures involving only enamel and dentin can be managed by dental evaluation within 48 hours. Pulp involvement (visible pink or blood in center of the tooth) mandates urgent dental referral, and medical-grade cyanoacrylate (Super Glue) can be placed on the tooth acutely for pain and to prevent infection. Luxation without impaction can be reduced if jaw fracture is not suspected, and return to play with a custom mouth guard can be considered, depending on successful reduction, level of pain, and level of competition. If the tooth is easily repositioned, dental consultation can be delayed 24 hours. Players with impacted luxation or teeth that cannot be repositioned should not return to play, and dental consultation should be sought immediately. Avulsed teeth should be rinsed with sterile saline and replaced, if possible, taking care not to handle or damage the root followed by immediate dental consultation (Honsik, 2004).

FACIAL TRAUMA

Nasal injuries are frequently encountered in sports. The higher the impact velocity, the higher the probability of concomitant injury requiring urgent referral. Situations requiring emergency department (ED) evaluation include associated prolonged loss of consciousness, vision abnormalities suggesting orbital fracture, malocclusion of the teeth suggesting maxillary or mandibular fracture, facial paresthesias suggesting infraorbital nerve injury, open or significantly displaced nasal fractures, and uncontrollable epistaxis. Examination findings prompting early referral include clear rhinorrhea suggesting cribriform plate injury with cerebrospinal fluid leak and impaired extraocular movements, especially unilateral limited upward gaze, which suggests an orbital fracture with inferior oblique, rectus muscle entrapment, or both. Patients with nasal septal hematoma should be referred to an otolaryngologist expeditiously for incision and drainage. If left untreated,

subsequent cartilage degeneration can result in a nasal saddle deformity (Stackhouse, 1998).

If the initial assessment does not mandate immediate referral, subsequent management requires assessing the extent of deformity and controlling epistaxis. In the first few days, swelling can make assessment for bony deformity difficult, but close follow-up is helpful. Any persistent obstruction of the nares or cosmetic abnormality unacceptable to the patient should be referred to an otolaryngologist within 5 days because reduction is best performed within 10 days of injury. Epistaxis is best managed with a topical decongestant such as oxymetazoline nasal 0.05% (Afrin) and compression of the anterior plexus by pinching the nose for 15 minutes. A short nasal tampon soaked with oxymetazoline can be placed into the bleeding nostril to assist with hemostasis and return to play, but anterior packing should only be performed with appropriate visualization to avoid further injury.

Ear trauma in sports can result in auricular hematomas or injury to the tympanic membrane. *Auricular hematomas* mainly occur in wrestling, rugby, and boxing and result in hemorrhage between the perichondrium and the underlying cartilage. Failure to evacuate the hematoma can lead to fibrosis, necrosis, and a chronic deformity known as *cauliflower ear*. An acute auricular hematoma should be drained by needle aspiration under aseptic conditions, and a pressure dressing (using cotton wool soaked in collodion or a silicone splint) carefully applied against the contours of the outer ear and reexamined daily. Occasionally, incision and drainage are required.

Blows across the side of the head can also result in *tympanic membrane rupture*, marked by pain, bleeding, fluid drainage, and impaired hearing. Tympanic membrane ruptures usually heal spontaneously over 4 to 6 weeks. Antibiotic prophylaxis in the first week should be considered, especially if the rupture occurred in a contaminated environment. The ear canal should be kept clean and dry, and a cotton ball coated with petroleum jelly and placed gently into the ear canal can be helpful while showering.

EYE TRAUMA

Ocular injury is common in sports and largely preventable if athletes wear appropriate eye protection. The highest risk sports are those in which intentional injury can occur (e.g., boxing and combative martial arts) and those in which hard projectiles, sticks, or fingers are likely to encounter the eye. High-risk sports include basketball, baseball, softball, cricket, lacrosse, squash, racquetball, fencing, and all varieties of hockey. Squash and racquetball are particularly concerning because of the high likelihood of severe injury. Athletes with preexisting monocular visual impairment must understand the importance of protecting the good eye, and preparticipation visual acuity assessment of binocular and monocular vision is essential. The American Society for Testing and Materials (ASTM) is the primary U.S. organization for certifying eyewear for sports, and experts have provided recommendations for eye protection for different sports (Vinger, 2000).

Common sports-related eye injuries include presence of a foreign body and corneal abrasion. More significant impact results in possible iris injury, posttraumatic iritis,

hyphema, or globe perforation or rupture. Athletes presenting with eye pain should be removed from participation and have a thorough eye examination, as follows:

1. Assessment and documentation of visual acuity
2. Inspection for evidence of globe rupture or leaking aqueous humor
3. Assessment of extraocular movements, limitation, or asymmetry suggesting orbital fracture
4. Assessment of pupil reactivity (a dilated, constricted, or sluggish pupil can be transient secondary to iris trauma or may indicate hyphema or globe injury)
5. Inspection of anterior chamber for blood indicating hyphema

Abnormalities identified on this initial examination require consultation with an ophthalmologist. If the examination result is normal, eyelid inversion should be performed, inspecting for a foreign body, with slit-lamp evaluation using fluorescein staining to assess for corneal abrasions. Anesthetic eyedrops may be required to facilitate the examination and for initial pain management but should not be used to allow return to play or for ongoing pain management (Moeller and Rifat, 2003).

Corneal abrasions are treated with antibiotic eyedrops to prevent infection, and topical NSAIDs are given for pain if necessary (Weaver and Terrell, 2003). When they are pain free, with a normal follow-up examination, athletes might return to play. After an ocular injury, an athlete is often more receptive to counseling on protective eyewear.

Infectious Disease

Key Points

- Upper respiratory infections are more common in heavily training athletes, and team physicians must consider both infection control measures and avoiding banned substances when treating high-level athletes.
- Infectious mononucleosis is associated with splenomegaly and a risk of splenic rupture. It requires that athletes avoid heavy exertion and contact sports until the spleen is of normal size, usually within 4 weeks.

Upper respiratory tract infection (URI) is a common complaint in primary care sports medicine. Regular, moderate exercise may decrease the risk for contracting a URI, but acute bouts of heavy exercise, such as running a marathon, and prolonged heavy training increase the risk for URI (Nieman, 2003). Treatment of URI is symptomatic, but health care providers of competitive athletes must consider which substances are banned by the governing body overseeing their sport. Banned substances are subject to change, and physicians must be aware of current regulations. For example, the World Anti-Doping Agency (WADA), responsible for drug regulation for many international sports organizations, bans stimulants and many sympathomimetics. Ephedrine and pseudoephedrine are banned by the WADA above urine concentration thresholds, but

caffeine is not currently banned. The National Collegiate Athletic Association (NCAA) does not ban pseudoephedrine but does ban caffeine above a high urinary threshold. Most governing bodies, such as the World Anti-Doping Agency (WADA) and the NCAA, have websites posting current banned substances (see [Web Resources](#)). The WADA also has a smartphone app, which is a convenient resource for both athletes and physicians. These sites should be consulted before prescribing or recommending any medication for athletes subject to drug testing.

Physicians caring for teams must also consider infection control measures. URI, viral gastroenteritis, skin infection, and mononucleosis are of particular concern. Vectors that must be considered include common source spread (enteroviruses), person-to-person spread from sharing secretions (viral, fungal, bacterial skin infection), and airborne droplet spread (picornaviruses). Sharing of water dispensers, bottles, and towels should be eliminated. Handwashing must be encouraged and antibacterial soap or alcohol-based hand sanitizers provided. Shared equipment must be disinfected. Simple infection control measures are often not practiced in the setting of team sports, and educating athletes, coaches, and training staff is the responsibility of the team physician.

MONONUCLEOSIS

Infectious mononucleosis (mono), which is caused by Epstein-Barr virus (EBV) or occasionally by cytomegalovirus (CMV), deserves special mention. Splenomegaly and spleen fragility are often associated with mononucleosis and are a concern for team physicians because of the risk of splenic rupture. The prolonged fatigue accompanying mononucleosis is also especially difficult for athletes trying to return to training as soon as possible.

Epstein-Barr virus is prevalent and shed in saliva. Transmission requires intimate contact with saliva and does not occur via airborne spread, thus mononucleosis's reputation as the "kissing disease." About 50% of the U.S. population seroconverts by age 5 years, with a mild viral syndrome or asymptotically. If an individual reaches college age (18-22 years) without infection, seroconversion results in a 35% to 50% incidence of mononucleosis. The incubation period is 4 to 6 weeks. Symptoms include 1 week of significant flulike symptoms with anterior and often significant posterior cervical lymphadenopathy and exudative pharyngitis. Splenomegaly occurs in 50% of cases during weeks 2 to 3 of illness and usually resolves by weeks 4 to 6. Splenomegaly is difficult to confirm on examination alone and should be suspected in all athletes with mononucleosis. Significant fatigue is often prevalent, and although most symptoms resolve by 4 weeks, fatigue can last 12 weeks or longer (Rea et al., 2001).

When it is suspected, the diagnosis of mononucleosis should be confirmed because of the risk of splenic rupture and implications for withholding sports participation. The diagnosis can be confirmed by a positive EBV heterophile antibody (Monospot) with 90% sensitivity by 3 weeks. False-negative results are common in the first 2 weeks, with a positive test result in only 40% of those infected during the first week of illness. Therefore, an initially negative Monospot test result in a suspicious case should be repeated

1 week later. An EBV or CMV viral capsid antigen (VCA) immunoglobulin M (IgM) assay can also provide evidence of acute infection, with 90% sensitivity at the onset of symptoms (Cohen, 1998). IgM to VCA usually disappears by 6 weeks, making it a good marker for acute infection, and antibodies to EBV nuclear antigen (EBNA) generally appear after 2 to 4 months of illness and persist for life. Absent IgM in the presence of EBNA is more consistent with prior infection, and acute illness in the presence of both antibodies suggests reactivation (<http://www.cdc.gov/epstein-barr/laboratory-testing.html>).

Treatment is supportive. Significant tonsillar hypertrophy can be improved with a short course of oral prednisone. There is no clear evidence-based answer for when an athlete with mononucleosis can safely return to sports. The risk of splenic rupture associated with sporting activity occurs almost exclusively in the first 3 weeks of illness (Kinderknecht, 2002). Many authorities recommend restriction from noncontact sports for at least 3 weeks until symptoms have largely resolved and the spleen is not palpable. Returning athletes to contact sports can be considered after 4 weeks of illness, when all symptoms have resolved and splenomegaly is absent (Auwaerter, 2004). The range for normal spleen size varies significantly, and splenic ultrasonography is not necessary in most cases but can be considered before returning an athlete to contact sports. Larger-than-normal ranges for splenic size have been described for taller athletes (Spielmann et al., 2005).

KEY TREATMENT

- For athletes with confirmed mononucleosis, return to sport can be considered after 3 weeks for noncontact sports and after 4 weeks for collision sports after symptoms have largely resolved and the spleen is not palpable (Auwaerter, 2004) (SOR: C).

Sports Dermatology

Key Points

- Fungal, viral, and bacterial skin infections are usually transmitted through person-to-person contact in sports activities.
- Management requires a high index of suspicion, prompt treatment, restriction of participation for contagious athletes, covering lesions when appropriate to allow participation, and appropriate prophylaxis and treatment.
- Skin problems are usually caused by laceration or abrasion, environmental exposure, inflammation, or infection.

FUNGAL INFECTIONS

Tinea (ringworm) is one of the most common fungal infections. Tinea pedis is frequently seen in athletes secondary to group showering, and it can be prevented to some extent by having athletes regularly change socks and use wicking

materials in socks to keep their feet dry, drying powders (many of which contain prophylactic topical antifungals), and shower shoes. Treatment with topical antifungals and oral therapy for severe cases are effective.

Fungal infections are spread directly from person to person through contact sports, with the type seen in wrestlers (tinea corporis gladiatorum) being the most problematic. Tinea tonsurans occurs most often, with infection rates in high school wrestlers of 24% to 75% (Adams, 2000; Beller and Gessner, 1994). Infection is caused by contact with an infected opponent and usually occurs on the arms, neck, or head. The lesions often appear initially as annular plaques with raised erythematous borders and may progress without the central clearing often appreciated with ringworm (Adams, 2002). Microscopic evaluation of skin scrapings with potassium hydroxide (KOH) may reveal fungal elements. Topical treatment with azole agents and oral treatment have been studied. A randomized prospective study of topical clotrimazole 1% cream twice daily versus oral fluconazole, 200 mg weekly, showed equal symptomatic improvement after 10 days and a similar 50% lesion reduction at 17 days. However, 50% culture eradication took 11 days with oral treatment and 22 days with topical treatment, leading to the conclusion that weekly fluconazole should be first-line treatment (Kohl et al., 1999). For multiple lesions, a 3-week treatment course with an oral antifungal is recommended.

Return-to-play recommendations after tinea corporis gladiatorum infection vary. The NCAA requires 72 hours of topical therapy for skin lesions and 2 weeks of oral therapy for scalp lesions and stipulates that athletes may participate with an active lesion provided it is covered entirely by an adhesive nonpermeable dressing (NCAA, 2013). The National Federation of State High School Associations does not allow participation with communicable lesions even if they lesions are covered (Landry and Chang, 2004). Prophylaxis using oral itraconazole every other week and oral fluconazole weekly has been shown to be effective (Hazen and Weil, 1997; Kohl et al., 2000), but the potential for exposure and time loss morbidity of an active infection must be weighed against the cost and potential side effects.

VIRAL INFECTIONS

Herpes gladiatorum, caused by herpes simplex virus (HSV), is highly contagious and spread by person-to-person contact, with a predilection for the face, arms, and upper trunk. As the name suggests, herpes gladiatorum is common in wrestling, although epidemics are also reported in other sports, such as rugby (Adams, 2002) (Figure 29-4). Because herpes lacks definitive treatment, it is considered more serious than tinea. Herpes gladiatorum has a prevalence as high as 40% in collegiate wrestlers (Anderson, 1999). Outbreaks generally occur 2 to 5 days after exposure. Lesions typically manifest with prodromal pain or itching followed by clear vesicles on an erythematous base. Primary infections may cause systemic flulike symptoms, and recurrent infections occur in the same dermatome. Often, the vesicles have been traumatized before evaluation, making the rash appear nonspecific, although the prodromal symptoms or history of previous outbreak in the same location suggests herpes. Traditionally, diagnosis was confirmed

Figure 29-4 Herpes gladiatorum. Lesions may be numerous in wrestlers and involve a wide area of the skin surface. (From Habib T. *Clinical dermatology*. 5th ed. Philadelphia: Elsevier; 2009.)

with Tzanck testing or culture, but the direct fluorescent antibody test or polymerase chain reaction assays provides rapid detection of HSV in specimens with greater sensitivity than traditional methods.

The natural history of a herpes outbreak is to resolve and possibly recur, with the frequency and severity dependent on both host and environmental factors. Treatment with oral antiviral agents can shorten the duration of the outbreak, decrease contagion, and prevent recurrent infection. No one agent has proved superior. The most cost-effective regimen is acyclovir, 400 mg three times daily for 10 days for primary infections and for 5 days for recurrent infections. Treatment is most effective when started at the first sign of infection. Prophylaxis with valacyclovir (500–1000 mg/day) limited herpes gladiatorum recurrence (Anderson, 1999), and acyclovir (400 mg twice daily) has demonstrated effectiveness comparable with valacyclovir, limiting recurrent genital herpes (Reitano et al., 1998) and herpes outbreak among those being treated for cancer (Glenny et al., 2009). Research using antivirals for primary prevention is lacking, but entire teams may be placed on prophylactic doses if a team member or opposing team member has an outbreak. Some team physicians offer prophylactic treatment to the squad before large tournaments or for the entire competitive season.

Return to play after herpes infection is more conservative than with tinea infection. The NCAA requires that wrestlers be free of any systemic symptoms, have no new blisters for 72 hours, have all lesions crusted over, and have taken treatment doses of antiviral medication for 120 hours before competition (NCAA, 2013).

BACTERIAL INFECTIONS

Bacterial infections are common in sports, and treatment is similar for both athletes and nonathletes. Bacterial infections of the skin generally manifest as furuncles, carbuncles, impetigo, cellulitis, or erysipelas. Staphylococcal and streptococcal infections are most common, but community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA), first reported in the late 1990s, has become a significant problem in athletic training facilities (Lindenmigher et al., 1998; Nguyen et al., 2005) and the leading cause of training room skin infection based on a

literature review of published reports from 2005 to 2010 (Collins and O'Connell, 2012).

Sports activities provide a favorable environment for the acquisition and spread of bacterial skin infection. Abrasive surfaces such as artificial turf can harbor bacteria and become a source of infection. Shared equipment, improperly laundered practice gear, person-to-person contact, and inadequate showering facilities without antibacterial soap have all been implicated in the spread of bacterial skin infections in athletes.

Controlling infection in athletes involves prevention; good surveillance; and prompt, appropriate treatment. Shared equipment requires regular cleaning with antibacterial disinfectant. Athletes should shower with antibacterial soap after practice and competition. Abrasions should be addressed expeditiously; scrubbed with antibacterial wash; and covered with sterile dressings, which are changed regularly. Athletes must be instructed to report suspected infections as soon as identified. Topical antibiotics are appropriate for mild infections, with oral or IV antibiotics required for more severe infections. Any significant abscess should have incision and drainage with bacterial culture, including MRSA. Thus far, most CA-MRSA infections in athletes have shown sensitivity to trimethoprim-sulfamethoxazole, with some isolates sensitive to macrolides and quinolones (Arnold and Wojda, 2005). The resistance patterns are susceptible to rapid change, however, making routine culture of these wounds essential. It has been recommended that athletes with recurrent MRSA infections be assessed by nasal culture for colonization with MRSA and treated with topical mupirocin ointment if positive. The role of colonization in infection has been questioned recently, and in a recent study of college athletes, nasal carriage varied through the year and was not associated with infection (Creech et al., 2010).

Pulmonary Problems

Key Points

- Exercise-induced bronchospasm (EIB) is the transient narrowing of the airways in response to exercise.
- Symptoms of EIB include wheezing, coughing, dyspnea, and chest tightness.
- The diagnosis should be confirmed by spirometry testing before and after exercise showing a 10% to 15% reduction in forced expiratory volume in 1 second (FEV₁).

EXERCISE-INDUCED BRONCHOSPASM

Exercise-induced asthma or, more accurately, EIB is a transient narrowing of the airways following vigorous exercise. Ninety percent of known asthmatics and 40% of patients with allergic rhinitis have bronchoconstriction caused or worsened by exercise (Feinstein et al., 1996). In some patients, the only manifestation of airway hyperresponsiveness is EIB, with up to 50% of athletes having EIB in some high-risk sports (Langdeau and Boulet, 2001).

The pathophysiology of EIB involves mucosal drying secondary to large volumes of dry (often cool) air, which causes changes in mucosal pH, osmolarity, and temperature and triggers the release of inflammatory mediators, leading to bronchoconstriction (Hallstrand et al., 2005). This osmotic hypothesis explains the relationship between the intensity and duration of exercise to EIB; the role of inflammation and bronchoconstriction in EIB; and the increased prevalence of EIB in outdoor winter sports, such as cross-country skiing. A refractory period typically follows EIB in which the patient has fewer symptoms on reexercise. This probably occurs because of increased bronchial blood flow after exercise, which enhances water delivery to airway mucosa and makes it more resistant to osmotic changes. The mechanism of EIB in swimmers may be different and related to exposure to direct bronchial irritants, such as chlorine.

Symptoms of EIB include exercise-related wheezing, coughing, dyspnea, and chest tightness. The diagnosis of EIB, however, is difficult, and screening by medical history and physical examination alone is often inaccurate. In a study of 256 adolescent athletes participating in organized sports, 39.5% reported symptoms or a previous diagnosis suggestive of EIB, although only 9.4% were found to have EIB based on an exercise challenge test and serial spirometry (Hallstrand et al., 2002). Thus, any athlete with suspected EIB should be tested with an exercise challenge test, in which pre- and post-exercise spirometry is performed. A decrease in FEV₁ greater than 10% to 15% is indicative of EIB.

Management of EIB involves both nonpharmacologic and pharmacologic methods. Nonpharmacologic treatment includes emphasis on a good warm-up to precipitate the refractory period, exercising in warm and humid environments, and covering the mouth and nose during cold weather. The goal of pharmacologic therapy is for the athlete to be asymptomatic during exercise. First-line pharmacologic treatment involves the use of an inhaled β_2 -agonist (e.g., albuterol metered-dose inhaler, 2 puffs) 15 to 30 minutes before exercise. If the athlete is still symptomatic, the addition of a leukotriene modifier (e.g., montelukast, 10 mg) taken at least 1 hour before exercise can provide additional relief (Coreno et al., 2000). Another treatment alternative is an inhaled mast cell stabilizer (e.g., cromolyn) before exercise. Inhaled corticosteroids are not as useful for acute prophylaxis because of their delayed onset of action but can be very useful in patients with chronic persistent asthma and EIB. Any underlying chronic asthma or allergic rhinitis should also be optimally controlled.

PNEUMOTHORAX

Spontaneous and traumatic pneumothorax can occur in the setting of sports. Spontaneous pneumothorax should be suspected in tall, thin male athletes with the acute onset of dyspnea, pleuritic chest pain, and shortness of breath. Traumatic pneumothorax should be considered when an athlete is short of breath after sustaining a blow to the chest, particularly if a rib fracture is suspected (Partridge et al., 1997). The diagnosis is confirmed by chest radiograph, and treatment depends on the amount of lung involved. If the patient is stable and there is less than 15%

to 20% volume loss, this can generally be treated with observation. Return to play after a pneumothorax can usually occur safely in 3 to 4 weeks (Putukian, 2004).

KEY TREATMENT

- Treatment of exercise-induced bronchoconstriction involves an adequate warm-up and use of an inhaled β_2 -agonist 15 to 30 minutes before exercise, with the addition of montelukast or cromolyn, if needed (Coreno et al., 2000; Hallstrand et al., 2005) (SOR: B).

Hematologic Problems

Key Points

- Sports anemia is a dilutional anemia caused by the expansion of plasma volume in trained athletes.
- Exertional hemolysis occurs from increased destruction of red blood cells (RBCs), and the diagnosis is confirmed by a low hemoglobin (Hb) or hematocrit (Hct) and low haptoglobin level.
- Low iron stores, even in the absence of anemia, can adversely affect performance in endurance athletes.
- Athletes with sickle cell trait, especially if poorly hydrated, exercising in hot conditions, at a high altitude, or unconditioned, have a higher risk of exertional rhabdomyolysis and sudden death; screening at-risk populations should be considered.

Several hematologic issues are specific to athletes. This section reviews dilutional pseudoanemia or sports anemia, exertional hemolysis, iron-deficiency anemia and low iron stores without anemia, and special considerations regarding athletes who are sickle cell trait positive.

SPORTS ANEMIA

Sports anemia is not representative of true pathology. Rather, it represents an adaptive response to strenuous training and is caused by an expanded plasma volume. The degree of anemia typically correlates with the intensity of training. Plasma volume can expand by 5% to 20%. This adaptive response begins a few days after starting or intensifying training. Moderate exercisers may see a decrease in Hb of 0.5 g/dL, and elite athletes may have an apparent Hb decrease of 1 g/dL. Athletes with low Hb or Hct value and a characteristic history should be checked for iron deficiency. A normal ferritin level, iron level, and total iron-binding capacity confirm the diagnosis of dilutional anemia, or sports anemia, which does not need to be treated (Eichner, 1992; Shaskey and Green, 2000).

EXERTIONAL HEMOLYSIS

Exertional, or “foot strike,” hemolysis is another problem often encountered in athletes. Exertional hemolysis was initially described in endurance runners but is also seen

in swimmers, rowers, and weightlifters. Hypothesized mechanisms for red RBC destruction include trauma secondary to impact, turbulence in the blood vessel, acidosis, and elevated temperature encountered in working muscles. The diagnosis is made with an elevated mean corpuscular volume and reticulocyte count and a low haptoglobin level. Treatment consists of mitigating impact by having the athlete run in biomechanically correct shoes and on cushioned surfaces and by recommending slow, incremental increases in training (Telford et al., 2003).

IRON-DEFICIENCY ANEMIA

As in the general population, iron-deficiency anemia is common in athletes, especially among female athletes. This is typically caused by low intake of dietary iron, but it can also be caused by exertional GI or genitourinary bleeding or GI bleeding related to NSAID use. Iron requirements of athletes, particularly endurance athletes, may also be higher than for sedentary individuals (Beard and Tobin, 2000). The diagnosis of iron-deficiency anemia is made by a low Hb or Hct level and a low ferritin or iron level. Treatment consists of increasing dietary iron, iron supplementation, and treating the underlying cause if present.

LOW FERRITIN LEVELS IN NONANEMIC ATHLETES

The common belief among coaches and endurance athletes is that a low ferritin level can cause fatigue, poor recovery, and poor performance. The ferritin level generally reflects total body iron, and 82% of female endurance athletes have low ferritin levels (Shaskey and Green, 2000). Many studies have examined whether improvements in performance seen in nonanemic athletes are caused by small increases in Hb level (from a normal to a higher normal Hb level) or by an increase in iron alone (Garza et al., 1997). A review of eight randomized, controlled trials indicates that iron has a positive effect on performance in iron-deficient athletes without anemia, independent of Hb increases (Fogelholm et al., 1992; Friedmann et al., 2001; Hinton et al., 2000; Klingshirn et al., 1992; LaManca and Haymes, 1993; Newhouse et al., 1989; Rowland et al., 1988; Zhu and Haas, 1998).

SICKLE CELL TRAIT AND SUDDEN DEATH

Sickle cell trait occurs in 6% to 8% of the African American population (Kerle and Nishimura, 1996). Among black military recruits, the likelihood of sudden death is 28-fold higher in individuals with sickle cell trait than in those without (Kark et al., 1987) and among college football athletes, those with SCT have a 37-fold increased risk of death (Harmon et al., 2012). Most of these deaths are thought to be associated with exertional rhabdomyolysis. This typically occurs when an athlete is poorly hydrated, exercising in hot conditions, at a high altitude, or unconditioned. Athletes with sickle cell trait are generally not restricted from competition; however, consideration should be given to screening high-risk populations, with special precautions taken to ameliorate risk.

Gastrointestinal Problems

Key Points

- Gastroesophageal reflux can be worsened by exercise; treatment with dietary modifications and proton pump inhibitors is usually successful.
- Exercise-induced diarrhea is common in endurance sports; treatment focuses on dietary manipulation before competition and antidiarrheal medications such as loperamide in refractory cases.
- GI bleeding in athletes ranges from microscopic blood loss to ischemic hemorrhagic gastritis or colitis, but pathologic causes of bleeding should be ruled out.

Gastrointestinal problems are common in the general population and in exercising individuals. Although the diagnosis and treatment of many of these issues are similar, exercise may make some issues worse or may present special treatment challenges. See eAppendix 29-1 online for discussions on gastroesophageal reflux, exercise-induced diarrhea, and GI bleeding.

Genitourinary Problems

Hematuria and proteinuria are also common findings in athletes. They may be caused by repetitive mechanical trauma to the bladder or by exercise-related changes in renal physiology. The initial workup is to rule out infection, refrain from exercising for 48 to 72 hours, and retest. If hematuria or proteinuria persists, a full evaluation should be performed (Abarbanel et al., 1990).

Genitourinary problems in male cyclists are particularly common. Pressure from the bicycle saddle can cause compression neuropathies (pudendal nerve), impotence, urethritis, or prostatitis (Leibovitch and Mor, 2005). Pudendal neuropathy manifests with numbness or tingling in the scrotum or penile shaft. Treatment involves relieving pressure by changing the seat type, proper bicycle fitting, and wearing padded shorts.

Low Back Pain

See Chapter 31 and eAppendix 29-2 online.

Spondylolysis

Spondylolysis, a stress fracture of the pars interarticularis, is a common cause of LBP in athletes and is the most common cause of athletic LBP in adolescents (Standaert and Herring, 2000; Standaert et al., 2000) (Figure 29-5). Athletes who participate in sports involving repeated and forceful hyperextension of the spine (e.g., gymnastics, American football) are more likely to develop spondylolysis from the cumulative effect of repetitive loading of the bone imposed by physical activity. Athletes generally have an

Gastroesophageal Reflux

As in the general population, gastroesophageal reflux (GER) is a common problem in athletes; 65% have had heartburn, and 24% have had symptoms for more than 1 year (Shawdon, 1995). GER often worsens with exercise, probably because of an exercise-associated decrease in lower esophageal sphincter tone, and is most common in endurance and high-intensity exercise. Treatment consists of avoiding aggravating foods, a reduction in the level of exertion followed by a gradual increase, adequate fluid intake, and avoiding solid food 3 hours before exercise (Housner and Green, 1997). If this is insufficient, proton pump inhibitors are effective and do not affect performance (Parmelee-Peters and Moeller, 2004).

Exercise-Induced Diarrhea

Exercise-induced diarrhea has a reported prevalence of 8% to 60% and is primarily associated with running sports (Moses, 1990). Typical signs and symptoms include increased stool frequency and volume, loose or explosive stools, urges to defecate, abdominal cramping, and rectal bleeding. There is an increased risk in those with underlying bowel pathology, dehydration, or increased exercise intensity in untrained participants and after meals rich in fat, protein, and fiber before exercise. Treatment ranges from

symptomatic measures such as staying well hydrated and avoiding caffeine to changing the timing and composition of precompetition meals. Pharmacologic treatment with opioid (diphenoxylate)–atropine combinations can adversely affect performance, may involve the use of banned substances or cause hyperthermia, and should be avoided. Loperamide works by decreasing intestinal motility, and side effects are rare; it should be taken 30 minutes before exercise in refractory cases (Simons and Kennedy, 2004). Diarrhea that persists despite treatment or also occurs outside the setting of exercise should be fully evaluated for other causes, including infection and inflammatory bowel disease.

Gastrointestinal Bleeding

Gastrointestinal bleeding in athletes is common. Up to 55% of college runners have heme-positive stool during a season, and the source of bleeding is usually not identified (Housner and Green, 1997). Blood flow to the gut is reduced by up to 80% with exercise and worsened by dehydration and hyperthermia, and cases of ischemic hemorrhagic gastritis and colitis have been reported in endurance runners (Moses, 1990). Another common cause of gastrointestinal (GI) bleeding in athletes is the use of NSAIDs. Exercise-related GI bleeding is a diagnosis of exclusion, and other causes of pathology should be ruled out.

29-2 Low Back Pain

Key Points

- Low back pain (LBP) recurs in up to 80% of patients over 1 year, emphasizing the need for adequate functional rehabilitation.
- Lumbar strain and mechanical LBP are frequently used diagnoses that characterize isolated LBP without clear neurologic or complicating features.
- Comprehensive rehabilitation includes a core lumbar stabilization program involving conditioning of the multifidus and transversus abdominis muscles, correction of muscle inflexibilities, strengthening of the kinetic chain, and correction of faulty biomechanics.

Low back pain is common in both athletes and nonathletes and is one of the most frequent reasons to visit a primary care physician. The lifetime prevalence of LBP ranges from 60% to 90%, with a 5% annual incidence (Frymoyer, 1988). The single best predictor of low back injury during athletic activity is a history of a previous injury, emphasizing the need for improved treatment and rehabilitative strategies. Several competitive sports, including gymnastics, American football, weightlifting, and rowing, have a higher incidence of low back injury (Herring and Weinstein, 1995).

Traditional medical education teaches that 90% of LBP resolves spontaneously within 6 to 12 weeks without specific medical intervention (Weinstein et al., 1998). However, longitudinal studies have suggested that LBP is usually a recurrent condition and that chronic phases of back pain occur more frequently than previously thought (Von Korff, 1994). Investigators analyzed short- and long-term outcomes for courses of LBP in primary care using a review of all available outcome studies (Von Korff and Saunders, 1996). At 1-month follow-up, only 25% to 33% of patients were completely pain free, 33% of patients reported continuing pain of at least moderate intensity, and 20% to 25% reported substantial activity limitations caused by LBP. At 1-year follow-up, 33% of patients had moderate pain, 15% of patients had severe pain, and 20% to 25% of patients still had substantial activity limitations. Up to 86% of patients reported at least one recurrence of their back pain during a 1-year period, and more than 25% of patients experienced *chronic* LBP, defined as back pain present more than 50% of the time during a 1-year period.

The causes of LBP in athletes are diverse, and precise identification of the anatomic site of injury and pain generation is often difficult. LBP can result from mechanical or chemical irritation of nociceptive nerve fibers located in

several areas of the lumbar spine, including the musculoligamentous supporting structures, outer third of intervertebral disk, facet joint capsule, anterior and posterior longitudinal ligaments, and existing nerve roots (Kaul and Haring, 1998).

Anatomy and Mechanism of Injury

The muscular support system of the lumbar spine contains a superficial, a middle, and a deep layer. The superficial layer is the largest paraspinal muscle group and consists of long polysegmental muscles called the *erector spinae*, which are the chief extensors of the spinal column. The middle layer consists of short polysegmental muscles (multifidi), and the deep layer consists of small, intersegmental muscles. The basic motion segment of the spine is the three-joint complex, consisting of one intervertebral disk situated between adjacent vertebrae and two zygoapophyseal (facet) joints located posteriorly. Disk degeneration leads to transfer of weight-bearing and rotational loads to the facet joints and might lead to facet joint arthropathy and a degenerative cascade in the lumbar spine (Weinstein et al., 1998).

Injury to the lumbar spine can occur from a single traumatic event or from repetitive overload. Combined movements of the lumbar spine (e.g., forward flexion, rotation) carry the highest injury potential. Repetitive movements common in sports can fatigue the supporting structures of the lumbar spine, causing muscle strains, or can overwhelm the viscoelastic protective mechanisms of the intervertebral disks and ligaments (Hainline, 1995). The lumbar spine also functions as the link between the lower extremities and the torso and is responsible for the coordinated transfer of power through the body in most sports (kinetic chain). Poor conditioning of the extremities may cause compensatory movements at the lumbar spine, placing the athlete at higher risk of injury.

Assessment

Examination of a patient with LBP includes an assessment of lumbar ROM and of the degree of movement permitted without pain. A lower extremity neurologic examination should also be performed, including specific tests for neural tension, such as the straight leg raising test and slump test (sitting neural tension test) (Magee, 1997).

Diagnostic imaging and other tests are seldom needed in the acute setting. Imaging studies should be considered in

children and adolescents to rule out serious medical conditions, in adults older than age 50 years to rule out malignancy, when traumatic fracture is suspected, and when back pain fails to improve with conservative treatment. Abnormal imaging findings, however, must be carefully correlated with a patient's pain because disk abnormalities have been demonstrated in 20% to 25% of asymptomatic individuals on MRI (Boden et al., 1990).

Patients with LBP must also be screened for warning signs of a serious medical problem requiring more urgent workup or intervention. Fever, malaise, and systemic symptoms suggest dangerous conditions such as diskitis, osteomyelitis, or malignancy. Bowel or bladder dysfunction, saddle anesthesia, and progressive neurologic deficits indicate cauda equina or nerve root compromise and the need for urgent lumbar decompression.

Lumbar Strain

Athletes with lumbar strain present with unilateral or bilateral LBP, often with painful paraspinal muscle spasm. Muscles involved in producing or controlling movements of the lumbar spine, such as the erector spinae and multifidi, are most often involved. Local tenderness and muscle spasm, limited range of motion, and a normal neurologic examination results are usual findings, and pain radiation is unusual. Lumbar strain or sprain and mechanical LBP are frequently used diagnoses that characterize LBP without clear neurologic or complicating features. Pain radiation to the buttocks or lower extremities, associated motor or sensory symptoms, and a prior history of recurrent or chronic LBP make a deeper structural abnormality such as disk degeneration or facet arthropathy more likely. Treatment and rehabilitation of low back injuries are described later.

Discogenic Low Back Pain

Injury to the intervertebral disks is a common source of LBP in athletes. Disk injuries can result from many distinct anatomic abnormalities, including a tear in the annulus fibrosus, disk degeneration or desiccation, disk protrusion (disk bulge without extrusion of the nucleus pulposus), and disk herniation (extrusion of the nucleus pulposus). An annular tear or a small-disk protrusion may cause isolated LBP with a normal neurologic examination and is often difficult to differentiate from a lumbar strain. Subtle signs of a discogenic origin of the pain include pain radiation to the buttocks or proximal posterior thigh and increased pain with prolonged sitting, coughing, sneezing, or a Valsalva maneuver. Disk herniations typically cause mechanical or chemical irritation of a nerve root (or both) with corresponding radicular symptoms of numbness, tingling, or weakness.

Initial management and rehabilitation of LBP are described later. Patients with clear radicular symptoms or motor findings may benefit from a short burst of oral corticosteroids. Prolonged symptoms may benefit from an epidural corticosteroid injection or selective nerve root block performed by a physiatrist or pain management specialist (Lutz et al., 1998; Slipman and Chow, 2002).

Treatment and Rehabilitation

The high incidence of recurrent and chronic LBP emphasizes the need for appropriate rehabilitation after low back injury. Treatment of acute LBP begins with control of pain and inflammation. Decreasing pain and inflammation with NSAIDs or muscle relaxants or with judicious use of narcotics can permit early and more rapid rehabilitation. Bed rest should be limited to no more than 2 days for nonspecific LBP because prolonged inactivity has deleterious effects, including decreases in muscle strength, flexibility, cardiovascular fitness, and disk nutrition (Convertino et al., 1997).

The overall goal of rehabilitation is to restore normal lumbar spine function and promote safe and independent return to activity. Long-term rehabilitation beyond the resolution of symptoms and return to sports activity is important to prevent recurrence. No single treatment or exercise regimen is effective for all patients with LBP, and a customized rehabilitation program optimizes the chance for a successful outcome. Spine stabilization exercises strengthen the muscles around the lumbar spine while maintaining a neutral spine position. Studies have suggested that core stabilization programs conditioning the multifidus and transversus abdominis muscles are effective in reducing pain and decreasing recurrence (Hides et al., 2001; Hodges and Richardson, 1998; O'Sullivan et al., 1997).

Lower extremity muscle tightness found in association with LBP must also be addressed to allow normal lumbar motion. Two patterns of muscle inflexibility are common in patients with LBP. First, tight hip flexors (iliopsoas and rectus femoris) result in excessive anterior pelvic tilt and increased lumbar lordosis and place the hip extensors (gluteus maximus and hamstrings) at a mechanical disadvantage, causing early recruitment of the lumbar extensor muscles. Treatment includes stretching the hip flexors and strengthening the hip extensors. The second pattern involves tight hamstring muscles, which result in excessive posterior pelvic tilt and decreased lumbar lordosis, placing the back extensors at a mechanical disadvantage and making the spine less resilient to axial loads. Treatment is directed at stretching the hamstring muscles and strengthening the back extensors (Drezner and Herring, 2001; Kaul and Herring, 1998).

Correction of predisposing factors, such as poor posture while sitting or standing, faulty lifting or playing techniques, and abnormal biomechanics, is also essential in the treatment of LBP. Normal lumbar spine function and the absence of significant symptoms after sports-specific activity usually mark a successful return to competitive athletics.

KEY TREATMENT

- Comprehensive rehabilitation for LBP includes a core lumbar stabilization program involving conditioning of the multifidus and transversus abdominis muscles, correction of muscle inflexibilities, strengthening of the kinetic chain, and correction of faulty biomechanics (Drezner and Herring, 2001; Hides et al., 2001; Hodges and Richardson, 1998; O'Sullivan et al., 1997) (SOR: B).

Figure 29-5 Spondylolysis. **A**, Sagittal T1-weighted image. **B**, Axial T1-weighted image. (Used with permission from Czervionke LF, Fenton DS. *Imaging painful spine disorders*. Mayo Foundation for Medical Education and Research Published by Saunders, an imprint of Elsevier Inc, 2011.)

insidious history of increasing focal back pain reproduced by lumbar extension.

Spondylolysis can be identified by plain radiography in approximately 5% of the general population, but the vast majority of these lesions occur without associated symptoms. Identification of spondylolysis on radiographs in an athlete with LBP must be correlated with the clinical presentation and advanced imaging. Single-photon emission CT, high-resolution (thin-slice) CT, and MRI are helpful to determine the metabolic activity of the stress fracture, the acuity of the lesion, and potential for fracture healing and to exclude other spinal pathology that may be present.

Conservative treatment is usually successful in controlling symptoms and restoring function. Treatment requires activity restriction and temporary discontinuation of the aggravating sport or activity. Some patients may require lumbosacral bracing to achieve treatment goals, and only a small percentage of patients require surgical intervention for pain or progressive spondylolisthesis (Standaert and Herring, 2000; Standaert et al., 2000).

Muscle and Tendon Injuries

Key Points

- Eccentric loading produced when the muscle is contracting and lengthening is a common mechanism for muscle and tendon injuries.
- Tendinosis is the predominant pathologic feature in painful overuse tendinopathies.

MECHANISM OF INJURY

Muscle and tendon injuries occur from repetitive micro-trauma or a single traumatic event that causes overload to the tensile strength of the myotendinous unit or muscle

fiber itself. *Eccentric loads*, produced when the muscle is contracting and lengthening at the same time, are a common mechanism of injury and can produce higher forces compared with concentric contractions (Stanton and Purdam, 1989). Sports activities with repetitive eccentric demands place the athlete at higher risk of injury. In sprinters, for example, hamstring muscle strains typically occur during the late swing phase of the running cycle as the hamstring muscle contracts while lengthening in an attempt to decelerate the lower leg in preparation for foot strike (Stanton and Purdam, 1989). Achilles tendinopathy and patellar tendinopathy (jumper's knee) also result from repetitive eccentric loading of the tendons during running and jumping.

HISTOPATHOLOGY

Acute muscle injuries go through a predictable cycle of healing and repair. Exercise-induced muscle injury first causes fiber disruption and local microhemorrhage followed by extravasation of inflammatory cells and a phagocytic phase to remove injured tissue and finally a regenerative phase of muscle fiber healing occurs (Armstrong et al., 1991). Limiting overall inflammation decreases pain and minimizes secondary tissue injury caused by hypoxia and inflammatory mediators. However, some amount of inflammation is required in the healing process to remove necrotic muscle fibers and allow scar tissue to bridge the defect (Almekinders and Gilbert, 1986).

In contrast to acute muscle injuries, the pathologic findings in most tendon injuries are consistent with tendinosis, a degenerative condition of the tendon, and not a tendinitis involving inflammation, as was formerly believed (Khan et al., 2000). Healthy tendon contains parallel bundles of tightly packed collagen fibers, with little extracellular matrix (ground substance) and no fibroblasts or myofibroblasts. In contrast, symptomatic tendons contain disorganized collagen fibers, increased mucoid ground substance, prominent capillary proliferation, and increased

numbers of fibroblasts and myofibroblasts (Khan et al., 1999). Histopathologic examination is notably devoid of inflammatory cells. Animal models have also suggested that inflammatory cells are absent by 1 week after induced overuse injury (Zamora and Marini, 1988). These findings are present in the most common tendon injuries, including the patella, Achilles, rotator cuff, and extensor carpi radialis brevis tendons, and have important implications in the treatment of tendon disorders (Khan et al., 1999). Use of the term *tendinopathy*, rather than *tendinitis*, is recommended to describe a painful tendon condition.

The generation of pain in chronic tendon injuries appears to involve more than just inflammation. A biochemical hypothesis to explain tendon pain states that biochemical agents are leaked from a degenerated tendon and irritate nociceptors (pain receptors) on adjacent structures (Khan and Cook, 2000). In patellar tendinopathy, higher levels of glycosaminoglycans have been found in the infrapatellar fat pad (Khan et al., 1996), and in patients with partial rotator cuff tears, higher levels of substance P were found in the adjacent subacromial bursa and were significantly associated with pain (Gotoh et al., 1998).

MUSCLE STRAINS

Muscle injuries can be classified as *mild* (grade 1, strain), *moderate* (grade 2, partial tear of myotendinous units), or *severe* (grade 3, complete tear of myotendinous units). Mild injuries are tender and painful with active use but cause minimal strength loss. Moderate injuries demonstrate clear *weakness* with resisted muscle testing and *pain* with passive stretching. Severe injuries cause significant functional and strength deficits and may show ecchymosis and a palpable defect on examination.

In running and sprinting athletes, hamstring muscle strains are the most common muscle injury (Lysholm and Wiklander, 1987; Meeuwisse et al., 2000; Orchard and Seward, 2002). Other common muscle strains include those of the quadriceps (especially the rectus femoris) and the gastrocnemius. The most significant risk factor for a muscle strain is a recent or past history of that same injury, and incomplete rehabilitation may also contribute to recurrent injuries (Ekstrand and Gillquist, 1983; Orchard, 2001). Other risk factors for muscle injury include poor warm-up, muscle fatigue, and muscle imbalance (Agre, 1985; Croisier et al., 2002; Garrett, 1996; Safran et al., 1989).

Initial treatment of an acute muscle strain involves ice application to limit pain and swelling and relative rest to protect the muscle from more significant injury. A short 3- to 5-day course of NSAIDs can help limit overall inflammation and pain in acute muscle injuries. Gentle stretching to restore flexibility should begin when pain allows, and rehabilitation should progress through isometric, concentric, and finally eccentric strengthening exercises before returning to sports-specific activities.

TENDINOPATHY

Tendon injuries can involve acute overuse tendinopathy, chronic tendinosis, partial-thickness tears, or complete rupture of the tendon. The exact role of NSAIDs in the treatment of tendinopathy remains uncertain. NSAIDs are

potentially helpful initially after acute tendon injury, when inflammation is most likely to be present. For tendinopathy of longer duration, use of NSAIDs, although an adjunct to pain control, does not contribute to tendon healing. The exact mechanism of action of corticosteroid injections, such as in the treatment of lateral epicondylitis and rotator cuff tendinopathies, is also unclear. Corticosteroid injections bathe the region of tendinosis, alter the chemical composition of the matrix, and may modify nociceptors on nearby structures (Khan and Cook, 2000). NSAIDs and corticosteroids also may have an effect on other biochemical irritants (yet to be defined) that play a role in the generation of tendon pain.

The use of therapeutic methods to stimulate collagen repair is also a major focus in the treatment of tendinopathy. Common strategies to induce collagen remodeling include manual therapies such as deep-friction massage, eccentric conditioning of the tendon, tenotomy (needling a degenerated tendon), and injection of autologous growth factors. Eccentric strengthening programs have shown favorable results for patients with chronic Achilles tendinopathy as well as for athletes with chronic patellar tendinopathy (Alfredson et al., 1998; Purdam et al., 2004). When conservative treatments such as physical therapy fail, treatment options are limited and often lead to either the discontinuation of exercise or surgery. In competitive athletics, chronic tendon injuries can lead to persistent pain, lost time from participation, and suboptimal performance. In occupational injuries, chronic tendon trauma leads to significant cost and morbidity.

With a better understanding of the pathogenesis of tendon injury and healing, newer therapies strive to stimulate the failed healing response in tendinopathies, including percutaneous tenotomy with or without injection of autologous blood or growth factor into the degenerative tendon (Housner et al., 2009; McShane et al., 2006). The most common form of autologous growth factor therapy is platelet-rich plasma (PRP) and is increasingly used to treat tendinosis. Although a relatively novel option for sports-related injuries, PRP has been used in other medical conditions for 2 decades. The use of PRP migrated to orthopedic procedures, in which it has been used effectively to augment bone and soft tissue healing in the operating room, especially in poorly healing fractures and those at high risk for nonunion. Most recently, PRP has been used in the outpatient setting for a variety of sports-related soft tissue injuries, including the treatment of chronic tendinopathies, as well as moderate to severe acute ligament, muscle, and tendon injuries. Autologous growth factor therapy in the treatment of chronic tendinosis can initiate a stalled or failed healing response, leading to a healthier and less symptomatic tendon. There are now many studies, including four randomized controlled studies, that suggest the effectiveness of PRP in tendon healing (de Vos et al., 2010; Filardo et al., 2010; Gaweda et al., 2010; Gosens et al., 2011, 2012; Hechtman et al., 2011; Kon et al., 2009, 2010; Mishra and Pavelko 2006; Peerbooms et al., 2010; Vetrano et al., 2013; Volpi, 2007). In the setting of acute soft tissue injury, it is hypothesized that PRP augments the healing response, leading to faster healing, more rapid recovery, and earlier return to sport or activity. In a series of acute muscle injuries in elite soccer players, PRP therapy

was found to significantly shorten the time to return to play (Sánchez et al., 2009).

Although research is still needed to understand the optimal indications and treatment protocols for autologous growth factor therapies, initial findings provide optimism that a new, minimally invasive therapeutic option is available in the management of chronic tendinopathies.

KEY TREATMENT

- Treatment of an acute muscle strain involves ice application to limit pain and swelling; relative rest and protection from more significant injury; gentle stretching to restore flexibility; and progressive rehabilitation through isometric, concentric, and finally eccentric strengthening exercises before returning to sports-specific activities (SOR: C).
- Eccentric strengthening programs can be effective for patients with chronic Achilles or patellar tendinopathy (Alfredson et al., 1998; Purdam et al., 2004) (SOR: B).
- Novel therapies using autologous growth factor injections (platelet-rich plasma) show favorable results in the treatment of chronic tendinopathy (Mishra and Pavelko, 2006; Sánchez et al., 2009) (SOR: C).

Shin Pain

Key Points

- Medial tibial stress syndrome is the most common cause of lower leg pain in running athletes.
- Chronic exertional compartment syndrome is characterized by cramping or burning lower leg pain or numbness, which may radiate to the foot and ankle and resolves within minutes of rest.

MEDIAL TIBIAL STRESS SYNDROME

Exercise-related lower leg pain is an extremely common condition among athletes. The most common presentation is shin pain exacerbated by exercise and diminished with rest. *Shin splints* is a nonspecific term used to describe shin pain in running athletes from almost any cause. *Medial tibial stress syndrome* (MTSS) is the most widely accepted term to describe pain along the medial border of the tibia experienced by running athletes and is considered to be the most common cause of athletic lower leg pain (Kortebein et al., 2000).

The pathogenesis of MTSS is not fully understood. Some support the concept of a traction periostitis along the posteromedial border of the tibia at the origin of the soleus, flexor digitorum longus, and posterior tibialis muscles (Beck and Osternig, 1994; Michael and Holder, 1985). Scintigraphic and biopsy studies, however, have not consistently shown an inflammatory process of the periosteum to support periostitis as the pathogenesis of shin pain. Others suggest that MTSS is caused by a traction fasciitis (involving the crural fascia) or possibly a bony stress reaction and precursor to stress fracture (Batt, 1995). Bone scan and

MRI studies indicate that MTSS is part of a continuum of stress response in bone. Investigation of runners with medial tibial pain demonstrated a spectrum of bone injury, beginning with periosteal edema, progressive marrow edema, and finally frank cortical defects (Fredericson et al., 1995). The mechanism of injury in MTSS probably involves bony overload from the pull of muscle contraction and the impact forces with running.

Athletes with MTSS complain of shin pain that is aggravated with running. Examination reveals tenderness in a broad distribution along the medial border of the tibia, usually spanning the middle and distal thirds of the tibia. In contrast, tibial stress fractures manifest with a focal area of tenderness. Management of MTSS includes rest, activity modification, ice, and antiinflammatory medications. Correction of biomechanical abnormalities is also helpful. Poor hip abductor and external rotator muscle function may contribute to internal femoral rotation and excessive stress on the medial tibia during running. Extreme foot types, both pes planus and pes cavus, may also contribute to impaired shock absorption and force distribution to the tibia and may improve with orthotic devices.

CHRONIC EXERTIONAL COMPARTMENT SYNDROME

Chronic exertional compartment syndrome (CECS) is another cause of athletic lower leg pain. Patients with CECS complain of cramping, burning, or aching lower leg pain with pain or numbness that may radiate to the foot and ankle. The pain is clearly associated with exertion. Pain onset is characteristically at a fixed point in the patient's activity, with progressively increasing pain if the exercise continues and a dramatic reduction in pain within minutes of rest. The pathophysiology of CECS involves elevated intracompartmental pressure, which causes relative ischemia of the involved muscles and pressure on neurovascular structures. The diagnosis of CECS can be confirmed by compartment pressure testing after exercise demonstrating increased intracompartmental pressure correlated with symptom reproduction. Patients with CECS should be questioned about the use of nutritional supplements, such as creatine, that may increase muscle water content and overall muscle mass and contribute to the development of CECS. Surgical treatment by fasciotomy provides good functional improvement and symptomatic cure in a high proportion of cases (Blackman, 2000).

Stress Fractures

Key Points

- Stress fractures typically occur weeks after an abrupt increase in activity level, running distance, or training frequency.
- Navicular stress fractures, anterior tibial stress fractures with a "dreaded black line," and femoral neck stress fractures are high-risk stress fractures for nonunion or progression to a complete fracture and should be referred to an orthopedic specialist.

Stress fractures result from a failure of bone to adapt successfully to repetitive loads encountered during running. Wolff's law of adaptation suggests that a bone responds to external stress by mechanical remodeling. Bone strain may become excessive as a result of increases in load magnitude, rate of loading, or number of loading cycles (Crossley et al., 1999). Advances in imaging techniques and understanding of bone pathophysiology indicate that stress injury to bone occurs on a continuum, ranging from normal bone remodeling to bone strain, to stress reaction, to stress fracture, to frank cortical fracture (Fredericson et al., 1995).

A stress fracture, or *fatigue fracture*, occurs when abnormal stress is applied to normal bone. In contrast, an *insufficiency fracture* occurs when normal or physiologic stress is applied to abnormal bone. Female athletes with premature osteoporosis, as seen in the female athlete triad, may have stress fractures resulting from abnormal stress applied to abnormal bone (Callahan, 2000).

Most stress fractures occur in the lower extremities because of impact forces produced from weight bearing during exercise. Common locations for stress fractures include the metatarsals, navicular, tibia, fibula, femoral shaft, femoral neck, and sacrum. The tibia is the most common site of stress fractures in running and jumping athletes and represents about 50% of all cases (Matheson et al., 1987). Less frequently, stress fractures can occur in the upper extremities, ribs, and clavicle from repetitive activity such as throwing, rowing, or weightlifting.

Lower baseline conditioning and training errors are usually involved in the development of stress fractures. A careful history will often reveal an abrupt increase in activity level, running distance, or training frequency within the 2 or 3 months before symptom onset. Many studies have analyzed bone geometry as a risk factor for stress fracture. In male military recruits and runners, studies have demonstrated that a narrower tibia in combination with a smaller tibial cross-sectional area is a risk factor for tibial stress fractures (Beck et al., 1996; Crossley et al., 1999; Giladi et al., 1987).

Female athletes with a history of eating disorders, oligomenorrhea or amenorrhea, and delayed menarche are more likely to develop stress fractures (Arendt, 2000; Bennell et al., 1995). Inadequate caloric intake relative to energy expenditure, also known as a negative energy balance, has been implicated as the primary cause of menstrual dysfunction in young female athletes and is thought to be responsible in part for bone density changes.

Pain from a stress fracture begins with mild pain during activity that resolves with rest. As the stress fracture progresses, pain increases during activity and continues for hours afterward, usually forcing the athlete to stop exercising. With further progression, pain is present with walking and sometimes at rest. On examination, there is local tenderness at the site of the stress fracture. The hop test (asking the patient to hop on one leg) is a useful functional test for suspected lower extremity stress fractures. If a stress fracture is present, the athlete either is reluctant to hop or will have pain reproduction with hopping. Stress fractures may be seen on radiographs as an area of cortical thickening (periosteal reaction) and may have a linear fracture line visible. Radiographs are positive in only about 50% of cases,

and an advanced imaging study such as MRI or bone scanning is often needed to confirm the diagnosis.

Stress fractures are treated with rest, activity modification, and avoidance of aggravating activities. Ambulation must be pain free to allow for fracture healing. If the athlete cannot achieve pain-free ambulation, a period of non-weight bearing on crutches is indicated. Foot stress fractures may benefit from the use of a rigid walking boot, and tibial stress fractures may benefit from a compressive pneumatic leg brace (Swenson et al., 1997). The time for healing of a stress fracture can vary (range, 4-12 weeks), depending on the site and severity. To maintain overall conditioning, athletes can engage in nonimpact cross-training activities, such as swimming or cycling, assuming that the activity is performed without pain. Athletes with two or more stress fractures should be screened for osteopenia or osteoporosis with a bone density scan. Low bone density requires further investigation to rule out secondary causes of osteoporosis, such as vitamin D deficiency or thyroid abnormalities. Menstrual irregularities, disordered eating, and a negative energy balance in female athletes should also be corrected.

Some stress fractures are at higher risk for nonunion or progression to a complete fracture. High-risk stress fractures include navicular, anterior tibial (diagnosed by the "dreaded black line" on lateral radiograph), and femoral neck stress fractures (Figure 29-6). Athletes with a confirmed or suspected high-risk stress fracture should be made non-weight bearing and referred to a sports medicine or orthopedic specialist.

Figure 29-6 Stress fracture. Lateral tibial radiograph shows the "dreaded black line" (arrow). Note cortical disruption on the anterior cortex. (From Delee, Drez's and Miller orthopaedic sports medicine. 3rd ed. Philadelphia: Elsevier; 2009.)

KEY TREATMENT

- Treatment of lower extremity stress fractures include rest, avoidance of aggravating activities, and pain-free ambulation with use of crutches or immobilizing walking boots if needed (SOR: C).

Pediatric Athletes

Key Points

- Children are not “little adults.” Sports competition and training must be age appropriate to prevent injury to developing bone and soft tissue and prevent psychological trauma, which could lead to an aversion to physical activity.
- Overuse injuries common in pediatric athletes include articular cartilage injuries (osteochondritis dissecans [OCD]), chronic physeal injuries, and apophysitis.

Pediatric sports injuries are increasing in frequency secondary to increased sports participation, prolonged and overlapping seasons, and children being subjected to adult levels of training and competition prematurely. Although the benefits of exercise and sports participation for children are well recognized, overtraining can have adverse physiologic and psychological consequences. In a review of age-appropriate sports participation from a neurodevelopmental and psychological perspective, [Patel and colleagues \(2002\)](#) suggested that children are not prepared for full competitive participation in complex sports before age 12 years. Children obtain the developmental tools to accomplish complex sports tasks at different ages, and future athletic talent cannot be predicted by childhood performance. Children subjected to age-inappropriate levels of competition or sports-specific skill development are likely to stop participating and create negative associations with sports and exercise, an unfortunate outcome that may affect them adversely for life. Primary care physicians must counsel

parents to recognize these issues and not make physical activity and sports participation a negative experience for children.

PHYSEAL AND APOPHYSIAL INJURIES

The adage that “children are not little adults” applies when considering sports injuries. Open physes in long bones and apophyses at tendon attachments to bone provide weak links through which acute and repetitive overuse injury can occur. These growth centers usually close within defined age ranges throughout adolescence, but significant variation among individuals exists. Thus, physeal and apophyseal injury must always be considered when evaluating children or adolescents with musculoskeletal complaints.

Physeal fractures are common and must not be missed because growth arrest can occur if they are not recognized and treated appropriately. The diagnosis of an ankle or knee sprain in a young adolescent with open physes should only be considered after physeal injury has been ruled out. Acute physeal injuries and the Salter-Harris classification system are addressed in greater detail in [Chapter 30](#).

Overuse injuries are increasing in frequency in pediatric athletes, with the most common being articular cartilage injuries (OCD), chronic physeal injury, and apophysitis. OCD involves a focal loss of cartilage and the underlying bone fragment and may be idiopathic or associated with overuse activities. Apophysitis is the pediatric equivalent of tendinopathy in adults. The growth center at the tendon–bone interface is susceptible to injury similar to that sustained by the physes of long bones. Risk factors contributing to the development of pediatric overuse injuries include overtraining; strength and flexibility deficits somewhat inherent in bone and soft tissue development; prior injury with inadequate rehabilitation; faulty technique, often resulting from poor coaching; and excessive pressure from adults to train and perform. The diagnosis is usually straightforward and requires a familiarity with the demands and common overuse injuries of that sport ([Lord and Winell, 2004](#); [Thordarson and Shean, 2005](#)). [Table 29-8](#) lists common apophyseal injuries in pediatric athletes.

Table 29-8 Common Apophyseal Injuries in Pediatric Athletes

Eponym/Common Injury	Body Part and Pathophysiology	Common Sports or Activities
Little League shoulder	Proximal humeral epiphysiolysis from repetitive microtrauma	Overhead sports: baseball, softball, tennis, swimming, volleyball
Little League elbow	Medial epicondylar apophysitis from traction to ulnar collateral ligament	Baseball (especially pitchers)
Lateral Little League elbow/osteochondritis dissecans (OCD)	OCD of capitellum or less likely radial head from repetitive compression-rotation forces	Baseball, gymnastics, overhead throwing and arm weight-bearing sports
Osgood-Schlatter disease	Traction apophysitis of tibial tubercle	Soccer, basketball, running and jumping sports
Sinding-Larsen-Johansson disease	Traction apophysitis to distal patella	Soccer, basketball, running and jumping sports
Sever disease	Calcaneal apophysitis from traction on Achilles insertion	Soccer, basketball, running and jumping sports
Pelvis-ASIS apophysitis	Traction from sartorius origin	Sprinting, kicking, jumping, hurtling
Pelvis-AIIS apophysitis	Traction from rectus femoris origin	Sprinting, kicking, jumping, hurtling
Buttock-ischial apophysitis	Traction from hamstring origin	Sprinting, kicking, jumping, hurtling
Spondylolysis	Stress fracture of vertebral pars interarticularis	Gymnastics, figure skating, football linemen, sports with spine loading in extension

AIIS, Anterior inferior iliac spine; ASIS, anterior superior iliac spine.

The treatment of OCD varies according to location, but the offending activity should be stopped immediately and the upper extremity joint immobilized or the lower extremity joint made non-weight bearing. The patient should be referred to an orthopedist for further management, which may involve prolonged rest with radiographic follow-up, reattachment of loose fragments, or removal of fragments with drilling or grafting of joint surfaces.

The treatment for chronic physeal injury or apophysitis consists of initial rest followed by rehabilitation directed at improving flexibility and strength and then a gradual return to activity. Parents and young athletes should be counseled that low-level recurring symptoms can be expected until growth plates have closed but that escalating symptoms should be managed with rest and physician follow-up. The most challenging aspects of treatment are ensuring proper coaching, educating parents regarding appropriate levels of participation and competition for children, and having adults accept reasonable limits for childhood participation in sports.

Special Concerns for Female Athletes

Key Points

- An energy deficit is the primary cause of amenorrhea in athletic women, and treatment should focus on the restoration of a normal energy balance.
- Menstrual dysfunction or hypothalamic-pituitary axis suppression caused by an energy deficit in exercising women is a diagnosis of exclusion, and the workup should include evaluation for medical causes of amenorrhea, including a pregnancy test and determination of prolactin, follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone (TSH), dehydroepiandrosterone (DHEA), and testosterone levels.
- Bone mineral density is adversely affected by menstrual dysfunction and, although treatment with hormone replacement (e.g., oral contraceptives) should be considered, this does not fully address the mechanisms of bone loss.

Exercise results in many benefits for both male and female athletes. In female athletes, however, exercise coupled with low energy intake can lead to a spectrum of disorders, culminating in the *female athlete triad*, strictly defined as the presence of an eating disorder, amenorrhea, and osteoporosis. It is important to recognize the precursors to the development of the female athlete triad when they may be more amenable to treatment, resulting in less severe long-term sequelae.

The menstrual cycle in the female athlete represents a complex and delicate interplay of hormones. The array of menstrual function seen in athletes ranges from normal ovulatory cycles to luteal-phase defects, to anovulation, to oligomenorrhea, and to amenorrhea. Menstrual dysfunction can exist even in women with normal cycle length, and

various types of cycles are common in an individual athlete (De Souza and Williams, 2004).

Athletic amenorrhea is caused by hypothalamic-pituitary axis suppression and is a diagnosis of exclusion. Other causes of amenorrhea must be ruled out, including pregnancy, hyperthyroidism, hyperprolactinemia, primary deficiency of gonadotropin-releasing hormone, and hyperandrogenic anovulatory syndrome (polycystic ovarian syndrome) (Ahima, 2004). When amenorrhea occurs in the setting of exercise or weight loss and initial hormonal test results are normal, a diagnosis of athletic amenorrhea can be made. Recent research has established that energy deficit is the primary cause of amenorrhea in athletic women (De Souza and Williams, 2004). Strenuous exercise alone in the setting of adequate energy intake does not disrupt the menstrual cycle. An energy deficit results in low concentrations of leptin and in changes in the neuroendocrine axis, including low levels of reproductive hormones, thyroid, and insulin-like growth factor-1 (IGF-1), and an increase in cortisol and growth hormone levels. Similar changes can be seen with psychogenic stress in sedentary women, and stress-induced changes may also contribute to menstrual dysfunction in both normal and underweight female athletes (Ahima, 2004).

The attainment of peak bone mineral density is adversely affected in both the short term and the long term by menstrual dysfunction (Keen and Drinkwater, 1997). The degree of menstrual dysfunction is related to the severity of osteopenia or osteoporosis (Hartard et al., 2004). Initially, the low estrogen state associated with athletic amenorrhea was thought to be solely responsible for bone density problems similar to those seen in postmenopausal women. More recent research has indicated that micronutrient deficiency and low levels of leptin, IGF-1, and other bone trophic factors also contribute to bone mineral deficits (Chan and Mantzoros, 2005).

Treatment of menstrual dysfunction and low bone density has traditionally consisted of hormone replacement therapy, most often with oral contraceptives. Oral contraceptives are not associated with complete bone recovery, most likely because of the multifactorial nature of bone metabolism. Bisphosphonates can increase bone density in adolescents with anorexia but not as effectively as weight restoration (Golden et al., 2005). Bisphosphonates have extremely long half-lives and remain in the skeleton for many years. Because of concern about potential teratogenicity, bisphosphonates should not be used in young women of childbearing age until further studies on their long-term safety.

The primary treatment for athletic amenorrhea should be restoration of a normal energy balance. Disordered eating patterns must be addressed. Anorexia nervosa and bulimia nervosa are common in women, particularly those competing in sports in which there is an emphasis on leanness or appearance, such as gymnastics, figure skating, and cross-country running. Eating disorders are best addressed with an interdisciplinary management team that includes both psychological and nutritional counseling (Otis et al., 1997).

Menstrual dysfunction, although common in female athletes, should prompt evaluation for medical causes and eating disorders. It is never normal or desirable for a female

athlete to cease menstrual function, and this should not be seen as a marker of adequate training. Exercise alone should not be blamed for menstrual dysfunction. Treatment should focus on the restoration of energy balance and a safe continuation of activity.

KEY TREATMENT

- The primary treatment for athletic amenorrhea should be restoration of a normal energy balance by addressing disordered eating and training patterns (Otis et al., 1997) (SOR: C).
