Enhanced eBooks for medical professionals

Compatible with PC, Mac®, most mobile devices, and eReaders, Expert Consult allows you to browse, search, and interact with this title – online *and* offline. Redeem your PIN at expertconsult.com today!

PIN REDEMPTION INSTRUCTIONS

Start using these innovative features today:

- Seamless, real-time integration between devices
- Straightforward navigation and search
- Notes and highlights sharing with other users through social media
- Enhanced images with annotations, labels, and hot spots for zooming on specific details *
- Live streaming video and animations *
- Self-assessment tools such as questions embedded within the text and multiple-format quizzes *

** some features vary by title*

1. Login or Sign Up at ExpertConsult.com
2. Scratch off your PIN code below
3. Enter PIN into the “Redeem a Book Code” box
4. Click “Redeem”
5. Go to “My Library”

Use of the current edition of the electronic version of this book (eBook) is subject to the terms of the nontransferable, limited license granted on ExpertConsult.com. Access to the eBook is limited to the first individual who redeems the PIN, located on the inside cover of this book, at ExpertConsult.com and may not be transferred to another party by resale, lending, or other means.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Although he is the founder and main editor of this text, I would like to dedicate my contribution as co-editor to my father, mentor, and friend, Robert Rakel. He started this text in 1971 when he perceived a need to give the generalist guidance on how to specialize in the whole person and family. Now in its 9th edition, his legacy continues within these pages and within more than 50 other texts he has authored and edited. The science has evolved, but the mission remains, which is to facilitate health with the patients and communities we are privileged to serve. I am grateful to have had the opportunity to learn from his artistry as a clinician, teacher, and father. We are truly lucky souls to be able to do this work together.

David P. Rakel

Contributors

Syed M. Ahmed, MD, MPH, DrPH

Senior Associate Dean for Community Engagement,
Professor, Family & Community Medicine, Medical
College of Wisconsin, Milwaukee, Wisconsin

Preface

The first edition of *Textbook of Family Medicine* was published in 1973, just after the specialty of family practice, now family medicine, was approved by the American Board of Medical Specialties.

Although the practice of medicine has changed considerably since that first edition, the content of the specialty remains essentially the same. Our goal is to provide in one text the information essential to our discipline. While some family physicians, especially those in urban areas, no longer deliver babies, the breadth of knowledge required to practice comprehensive primary care remains unchanged. Because of the great deficit of primary care physicians in the United States, those trained in other specialties are often called upon to provide primary care. They may benefit significantly from the breadth of material presented here.

The entire content of this edition is available electronically and can be accessed by iPad, iPhone, PC, and Mac. In order to limit the size (and weight) of the book, some material (such as references) is available only online. Also available online are 38 videos from Elsevier's Procedures Consult. Videos range from how to repair a wound with tissue glue to performing a vasectomy. See the *Video Contents* for the full list.

This text is designed to be a resource for family physicians to help them remain current with advances in medicine.

It is especially valuable to those preparing for certification or recertification by the American Board of Family Medicine.

Following the policy we established in the first edition, most of the authors of this text are family physicians. The clinical chapters combine a family physician with an authority in the field to ensure that the material is current and relevant to the needs of the family physician.

This edition continues an evidence-based approach, giving the Strength of Recommendation (SOR) taxonomy in the Key Treatment boxes, focusing on Grade A recommendations. More than 1000 tables and color illustrations facilitate the rapid retrieval of essential information and are used to present in-depth data conveniently.

Although this text focuses on problems most frequently encountered in the primary care setting, significant attention is also given to potentially serious problems that would be dangerous if missed. Diagnosing a problem in its early, undifferentiated stage is much more difficult than after symptoms have progressed to the point that the diagnosis is evident.

Our thanks to the staff at Elsevier for their high publishing standards and insistence on quality.

Key Points

- The rewards in family medicine come from knowing patients intimately over time and from sharing their trust, respect, and friendship, as well as from the variety of problems encountered in practice that keep the family physician professionally stimulated and challenged.
- The American Board of Family Practice was established in 1969 and changed its name to the American Board of Family Medicine in 2004. It was the first specialty board to require recertification every 7 years to ensure ongoing competence of its diplomates.
- The American Academy of Family Physicians (AAFP) began as the American Academy of General Practice in 1947 and was renamed in 1971.
- Primary care is the provision of continuing, comprehensive care to a population undifferentiated by age, gender, disease, or organ system.
- The most challenging diagnoses are those for diseases or disorders in their early, undifferentiated stage, when there are often only subtle differences between serious disease and minor ailments.
- The family physician is the conductor, orchestrating the skills of a variety of health professionals who may be involved in the care of a seriously ill patient.
- The most cost-effective health care systems depend on a strong primary care base. The United States has the most expensive health care system in the world but ranks among the worst in overall quality of care because of its weak primary care base.
- The greater the number of primary care physicians in a country, the lower the mortality rate and the lower the cost.

The family physician provides continuing, comprehensive care in a personalized manner to patients of all ages, regardless of the presence of disease or the nature of the presenting complaint. Family physicians accept responsibility for managing an individual's total health needs while maintaining an intimate, confidential relationship with the patient.

Family medicine emphasizes continuing responsibility for total health care—from the first contact and initial assessment through the ongoing care of chronic problems. Prevention and early recognition of disease are essential features of the discipline. Coordination and integration of all necessary health services (minimizing fragmentation) and the skills to manage most medical problems allow family physicians to provide cost-effective health care.

Family medicine is a specialty that shares many areas of content with other clinical disciplines, incorporating this shared knowledge and using it uniquely to deliver primary medical care. In addition to sharing content with other medical specialties, family medicine's foundation remains

clinical, with the primary focus on the medical care of people who are ill.

The curriculum for training family physicians is designed to represent realistically the skills and body of knowledge that the physicians will require in practice. This curriculum is based on an analysis of the problems seen and the skills used by family physicians in their practice. The randomly educated primary physician has been replaced by one specifically prepared to address the types of problems likely to be encountered in practice. For this reason, the "model office" is an essential component of all family medicine residency programs.

The Joy of Family Practice

If you cannot work with love but only with distaste, it is better that you should leave your work and sit at the

gate of the temple and take alms from those who work with joy.

KAHLIL GIBRAN (1883-1931)

The rewards in family medicine come largely from knowing patients intimately over time and from sharing their trust, respect, and friendship. The thrill is the close bond (friendship) that develops with patients. This bond is strengthened with each physical or emotional crisis in a person's life, when he or she turns to the family physician for help. It is a pleasure going to the office every day and a privilege to work closely with people who value and respect our efforts.

The practice of family medicine involves the joy of greeting old friends in every examining room, and the variety of problems encountered keeps the physician professionally stimulated and perpetually challenged. In contrast, physicians practicing in narrow specialties often lose their enthusiasm for medicine after seeing the same problems every day. The variety in family medicine sustains the excitement and precludes boredom. Our greatest days in practice are when we are fully focused on our patients, enjoying to the fullest the experience of working with others.

PATIENT SATISFACTION

Attributes considered most important for patient satisfaction are listed in [Table 1-1](#) ([Stock Keister et al., 2004a](#)). Overall, people want their primary care doctor to meet five basic criteria: “to be in their insurance plan, to be in a location that is convenient, to be able to schedule an appointment within a reasonable period of time, to have good communication skills, and to have a reasonable amount of experience in practice.” They especially want “a physician who listens to them, who takes the time to explain things to them, and who is able to effectively integrate their care” ([Stock Keister et al., 2004b](#), p. 2312).

PHYSICIAN SATISFACTION

Physician satisfaction is associated with quality of care, particularly as measured by patient satisfaction. The strongest factors associated with physician satisfaction are not personal income but rather the ability to provide

Table 1-1 What Patients Want in a Physician

Does not judge.
Understands and supports me.
Is always honest and direct.
Acts as a partner in maintaining my health.
Treats serious and nonserious conditions.
Attends to my emotional as well as physical health.
Truly listens to me.
Encourages me to lead a healthier lifestyle.
Tries to get to know me.
Can help with any problem.
Is someone I can stay with as I grow older.

Modified from Stock Keister MC, Green LA, Kahn NB, et al. What people want from their family physician. *Am Fam Physician.* 2004a;69:2310.

high-quality care to patients. Physicians are most satisfied with their practices when they can have an ongoing relationship with their patients, the freedom to make clinical decisions without financial conflicts of interest, adequate time with patients, and sufficient communication with specialists ([DeVoe et al., 2002](#)). [Landon and colleagues \(2003\)](#) found that rather than declining income, the strongest predictor of decreasing satisfaction in practice is loss of clinical autonomy. This includes the inability to obtain services for their patients, the inability to control their time with patients, and the freedom to provide high-quality care.

In an analysis of 33 specialties, [Leigh and associates \(2002\)](#) found that physicians in high-income “procedural” specialties, such as obstetrics-gynecology, otolaryngology, ophthalmology, and orthopedics, were the most dissatisfied. Physicians in these specialties and those in internal medicine were more likely than family physicians to be dissatisfied with their careers. Among the specialty areas most satisfying was geriatrics. Because the population older than 65 years in the United States has doubled since 1960 and will double again by 2030, it is important that we have sufficient primary care physicians to care for them. The need for and the rewards of this type of practice must be communicated to students before they decide how to spend the rest of their professional lives.

A study of medical students ([Clinite et al., 2013](#)) showed that most of them say that enjoying their work is the most important factor in selecting a specialty. Students who ranked primary care as their first choice ranked time with family, work/life balance, and personal time outside work high, and salary and prestige low. In comparison, students who were least interested in primary care ranked salary and prestige highest. It is clear what changes must be made if we are to increase the number of students entering primary care.

Development of the Specialty

As long ago as 1923, Francis Peabody commented that the swing of the pendulum toward specialization had reached its apex and that modern medicine had fragmented the health care delivery system too greatly. He called for a rapid return of the generalist physician who would give comprehensive, personalized care.

Dr. Peabody's declaration proved to be premature; neither the medical establishment nor society was ready for such a proclamation. The trend toward specialization gained momentum through the 1950s, and fewer physicians entered general practice. In the early 1960s, leaders in the field of general practice began advocating a seemingly paradoxical solution to reverse the trend and correct the scarcity of general practitioners—the creation of still another specialty. These physicians envisioned a specialty that embodied the knowledge, skills, and ideals they knew as primary care. In 1966, the concept of a new specialty in primary care received official recognition in two separate reports published 1 month apart. The first was the report of the Citizens' Commission on Medical Education of the American Medical Association, also known as the Millis Commission Report. The second report came from the Ad Hoc Committee on Education for Family Practice of the Council of Medical

Education of the American Medical Association, also called the [Willard Committee \(1966\)](#). Three years later, in 1969, the American Board of Family Practice (ABFP) became the 20th medical specialty board. The name of the specialty board was changed in 2004 to the *American Board of Family Medicine* (ABFM).

Much of the impetus for the Millis and Willard reports came from the American Academy of General Practice, which was renamed the *American Academy of Family Physicians* (AAFP) in 1971. The name change reflected a desire to increase emphasis on family-oriented health care and to gain academic acceptance for the new specialty of family practice.

SPECIALTY CERTIFICATION

The ABFM has distinguished itself by being the first specialty board to require recertification (now called *maintenance of certification*) every 7 years to ensure the ongoing competence of its members. Certification was achieved initially only by examination, with no “grandfathering” as had been the practice when other specialties were established. Recertification required the attainment of a specified amount of continuing medical education; a full, valid, and unrestricted license; the completion of an audit of office records; and successful performance on a recertification examination. These “firsts” raised the bar for specialty certification in the United States and established the ABFM as a leader and innovator among specialty boards. The logic of the ABFM’s emphasis on continuing education to maintain required knowledge and skills has been adopted by other specialties and state medical societies. All specialty boards are now committed to the concept of recertification to ensure that their diplomates remain current with advances in medicine.

The maintenance of certification now requires that all diplomates comply with the ABFM policy on professionalism, licensure, and personal conduct; complete a combination of self-assessment modules and performance in practice activities every 3 years; accumulate at least 50 continuing medical education credits per year; and successfully pass the maintenance of certification examination every 10 years.

In 2003, the ABFM began transitioning diplomates from its old recertification paradigm into its new process, termed Maintenance of Certification for Family Physicians. By the end of 2009, this transition was complete, and the ABFM became the first specialty board to have all of its diplomates enrolled and participating in maintenance of certification.

The ABFM also offers subspecialty *certificates of added qualifications* in five areas: adolescent medicine, geriatric medicine, hospice and palliative medicine, sleep medicine, and sports medicine. In addition, a special pathway within the maintenance of certification pathway, Recognition of Focused Practice in Hospital Medicine, is offered to family physicians who primarily practice in the hospital setting. Combined residency programs are available and are offered conjointly by ABFM and the appropriate specialty board. These provide training in family medicine and preventive medicine (six programs), family medicine and psychiatry (five programs), family medicine and emergency medicine

(two programs), and family medicine and internal medicine (two programs). These combined residencies make candidates eligible for certification by both specialty boards with 1 year less training than that required for two separate residencies through appropriate overlap of training requirements.

Definitions

FAMILY MEDICINE

Family medicine is the medical specialty that provides continuing and comprehensive health care for the individual and the family. It is the specialty in breadth that integrates the biologic, clinical, and behavioral sciences. The scope of family medicine encompasses all ages, both genders, each organ system, and every disease entity.

In many countries, the term *general practice* is synonymous with *family medicine*. The Royal New Zealand College of General Practitioners emphasizes that a general practitioner provides care that is “anticipatory as well as responsive and is not limited by the age, sex, race, religion, or social circumstances of patients, nor by their physical or mental states.” The general practitioner must be the patient’s advocate; must be competent, caring, and compassionate; must be able to live with uncertainty; and must be willing to recognize limitations and refer when necessary ([Richards, 1997](#)).

FAMILY PHYSICIAN

The family physician is a physician who is educated and trained in the discipline of family medicine. Family physicians possess distinct attitudes, skills, and knowledge that qualify them to provide continuing and comprehensive medical care, health maintenance, and preventive services to each member of a family regardless of gender, age, or type of problem (i.e., biologic, behavioral, or social). These specialists, because of their background and interactions with the family, are best qualified to serve as each patient’s advocate in all health-related matters, including the appropriate use of consultants, health services, and community resources.

The World Organization of Family Doctors (World Organization of National Colleges, Academies and Academic Associations of General Practitioners/Family Physicians [WONCA]) defines the “family doctor” in part as the physician who is primarily responsible for providing comprehensive health care to every individual seeking medical care and arranging for other health personnel to provide services when necessary. Whereas the family physician functions as a generalist who accepts everyone seeking care, other health providers limit access to their services on the basis of age, gender, or diagnosis ([WONCA, 1991](#), p. 2).

PRIMARY CARE

Primary care is health care that is accessible, comprehensive, coordinated, and continuing. It is provided by physicians specifically trained for and skilled in comprehensive first-contact and continuing care for ill persons or those

with an undiagnosed sign, symptom, or health concern (i.e., the “undifferentiated” patient) and is not limited by problem origin (i.e., biologic, behavioral, or social), organ system, or gender.

It is “the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community” (WONCA, 2013).

In addition to diagnosis and treatment of acute and chronic illnesses, primary care includes health promotion, disease prevention, health maintenance, counseling, and patient education in a variety of health care settings (e.g., office, inpatient, critical care, long-term care, home care). Primary care is performed and managed by a personal physician using other health professionals for consultation or referral as appropriate.

Primary care is the backbone of the health care system and encompasses the following functions:

1. It is *first-contact care*, serving as a point of entry for the patient into the health care system.
2. It includes *continuity* by virtue of caring for patients in sickness and in health over some period.
3. It is *comprehensive care*, drawing from all the traditional major disciplines for its functional content.
4. It serves a *coordinative function* for all the health care needs of the patient.
5. It assumes *continuing responsibility* for individual patient follow-up and community health problems.
6. It is a highly *personalized* type of care.

In a 2008 report, *Primary Health Care—Now More Than Ever*, the World Health Organization (WHO) emphasizes that primary care is the best way of coping with the illnesses of the 21st century and that better use of existing preventive measures could reduce the global burden of disease by as much as 70%. Rather than drifting from one short-term priority to another, countries should make prevention equally important as cure and focus on the rise in chronic diseases that require long-term care and strong community support. Furthermore, at the 62nd World Health Assembly in 2009, the WHO strongly reaffirmed the values and principles of primary health care as the basis for strengthening health care systems worldwide (WONCA, 2013).

PRIMARY CARE PHYSICIAN

A primary care physician is a generalist physician who provides definitive care to the undifferentiated patient at the point of first contact and takes continuing responsibility for providing the patient’s care. Primary care physicians devote most of their practice to providing primary care services to a defined population of patients. The style of primary care practice is such that the personal primary care physician serves as the entry point for substantially all the patient’s medical and health care needs. Primary care physicians are advocates for the patient in coordinating the use of the entire health care system to benefit the patient.

Patients want a physician who is attentive to their needs and skilled at addressing them and with whom they can establish a lifelong relationship. They want a physician who

can guide them through the evolving, complex U.S. health care system.

The ABFM and the American Board of Internal Medicine have agreed on a definition of the generalist physician, and they believe that “providing optimal generalist care requires broad and comprehensive training that cannot be gained in brief and uncoordinated educational experiences” (Kimball and Young, 1994, p. 316).

The Council on Graduate Medical Education (COGME) and the Association of American Medical Colleges (AAMC) define generalist physicians as those who have completed 3-year training programs in family medicine, internal medicine, or pediatrics and who do not subspecialize. COGME emphasizes that this definition should be “based on an objective analysis of training requirements in disciplines that provide graduates with broad capabilities for primary care practice.”

Although the number of medical students entering family medicine is far below the number needed in the United States for an effective health care system, things appear to be improving. The percentage of medical school graduates choosing family medicine residencies jumped nearly 10% between 2008 and 2013.

For the seventh consecutive year, the demand for family physicians outpaced the demand for other specialists. A 2013 survey noted more searches for family physicians (624) than for other specialists such as internal medicine (194) and psychiatrists (198). As a result, salaries for family physicians increased 6% from 2011 to 2012 (www.aafp.org/news-now/practice-professional-issues/20130916recruitingstudy.html).

Physicians who provide primary care should be trained specifically to manage the problems encountered in a primary care practice. Rivo and associates (1994) identified the common conditions and diagnoses that generalist physicians should be competent to manage in a primary care practice and compared these with the training of the various “generalist” specialties. They recommended that the training of generalist physicians include at least 90% of the key diagnoses they identified. By comparing the content of residency programs, they found that this goal was met by family medicine (95% of the time), internal medicine (91% of the time), and pediatrics (91% of the time) but that obstetrics-gynecology (47% of the time) and emergency medicine (42% of the time) fell far short of this goal.

Personalized Care

It is much more important to know what sort of patient has a disease than what sort of disease a patient has.

SIR WILLIAM OSLER (1904)

In the 12th century, Maimonides said, “May I never see in the patient anything but a fellow creature in pain. May I never consider him merely a vessel of disease” (Friedenwald, 1917). If an intimate relationship with patients remains the primary concern of physicians, high-quality medical care will persist, regardless of the way it is organized and financed. For this reason, family medicine emphasizes

consideration of the individual patient in the full context of her or his life rather than the episodic care of a presenting complaint.

Family physicians assess the illnesses and complaints presented to them, dealing personally with most and arranging special assistance for a few. The family physician serves as the patients' advocate, explaining the causes and implications of illness to patients and families, and serves as an advisor and confidant to the family. The family physician receives great intellectual satisfaction from this practice, but the greatest reward arises from the depth of human understanding and personal satisfaction inherent in family medicine.

Patients have adjusted somewhat to a more impersonal form of health care delivery and frequently look to institutions rather than to individuals for their health care; however, their need for personalized concern and compassion remains. [Tumulty \(1970\)](#) found that patients believe a good physician is one who shows genuine interest in them; who thoroughly evaluates their problem; who demonstrates compassion, understanding, and warmth; and who provides clear insight into what is wrong and what must be done to correct it.

[Ludmerer \(1999a\)](#) focused on the problems facing medical education in this environment:

Some managed care organizations have even urged that physicians be taught to act in part as advocates of the insurance payer rather than the patients for whom they care. ... Medical educators would do well to ponder the potential long-term consequences of educating the nation's physicians in today's commercial atmosphere in which the good visit is a short visit, patients are "consumers," and institutional officials speak more often of the financial balance sheet than of service and the relief of patients' suffering (pp. 881–882).

[Cranshaw and colleagues \(1995\)](#) discussed the ethics of the medical profession:

Our first obligation must be to serve the good of those persons who seek our help and trust us to provide it. Physicians, as physicians, are not, and must never be, commercial entrepreneurs, gate closers, or agents of fiscal policy that runs counter to our trust. Any defection from primacy of the patient's well-being places the patient at risk by treatment that may compromise quality of or access to medical care. ... Only by caring and advocating for the patient can the integrity of our profession be affirmed (p. 1553).

CARING

Caring without science is well-intentioned kindness, but not medicine. On the other hand, science without caring

Figure 1-1 *The Doctor* by Sir Luke Fildes, 1891. (© Tate, London, 2005.)

empties medicine of healing and negates the great potential of an ancient profession. The two complement and are essential to the art of doctoring.

B. LOWN (1996, p. 223)

Family physicians do not just treat patients; they also care for people. This caring function of family medicine emphasizes the personalized approach to understanding the patient as a person, respecting the person as an individual, and showing compassion for his or her discomfort. The best illustration of a caring and compassionate physician is *The Doctor* by Sir Luke Fildes ([Figure 1-1](#)). The painting shows a physician at the bedside of an ill child in the preantibiotic era. The physician in the painting is Dr. Murray, who cared for Sir Luke Fildes's son, who died Christmas morning, 1877. The painting has become the symbol for medicine as a caring profession.

COMPASSION

The treatment of a disease may be entirely impersonal; the care of a patient must be completely personal.

FRANCIS PEABODY (1930)

Compassion means co-suffering and reflects the physician's willingness somehow to share the patient's anguish and understand what the sickness means to that person. Compassion is an attempt to feel along with the patient. [Pellegrino \(1979\)](#) said, "We can never feel with another person when we pass judgment as a superior, only when we see our own frailties as well as his" (p. 161). A compassionate authority figure is effective only when others can receive the "orders" without being humiliated. The physician must not "put down" the patients but must be ever ready, in Galileo's words, "to pronounce that wise, ingenuous, and

modest statement—"I don't know." Compassion, practiced in these terms in each patient encounter, obtunds the inherent dehumanizing tendencies of the current highly institutionalized and technologically oriented patterns of patient care.

The family physician's relationship with each patient should reflect compassion, understanding, and patience combined with a high degree of intellectual honesty. The physician must be thorough in approaching problems but also possess a sense of humor. He or she must be capable of encouraging in each patient the optimism, courage, insight, and self-discipline necessary for recovery.

Bulger (1998, p. 106) addressed the threats to scientific compassionate care in the managed-care environment:

With health care time inordinately rationed today in the interest of economy, Americans could organize themselves right out of compassion. ... It would be a tragedy, just when we have so many scientific therapies at hand, for scientists to negotiate away the element of compassion, leaving this crucial dimension of healing to nonscientific healers.

Time for patient care is becoming increasingly threatened. Bulger (1998, p. 106) described a study involving a "good Samaritan" principle, showing that the decision of whether or not to stop and care for a person in distress is predominantly a function of having the time to do so. Even those with the best intentions require time to be of help to a suffering person.

Characteristics and Functions of the Family Physician

The ideal family physician is an explorer, driven by a persistent curiosity and the desire to know more (Table 1-2).

CONTINUING RESPONSIBILITY

One of the essential functions of the family physician is the willingness to accept ongoing responsibility for managing a patient's medical care. After a patient or a family has been accepted into the physician's practice, the responsibility for care is total and continuing. The Millis Commission chose the term "primary physician" to emphasize the concept of primary responsibility for the patient's welfare; however, the term *primary care physician* is more popular and refers to any physician who provides first-contact care and is essentially that person's personal physician.

The family physician's commitment to patients does not cease at the end of illness but is a continuing responsibility, regardless of the patient's state of health or the disease process. There is no need to identify the beginning or end point of treatment because care of a problem can be reopened at any time—even though a later visit may be primarily for another problem. This prevents the family physician from focusing too narrowly on one problem and helps maintain a perspective on the total patient in her or

Table 1-2 Attributes of a Family Physician*

A strong sense of responsibility for the total, ongoing care of the individual and the family during health, illness, and rehabilitation
Compassion and empathy with a sincere interest in the patient and the family
A curious and constantly inquisitive attitude
Enthusiasm for the undifferentiated medical problem and its resolution
Interest in the broad spectrum of clinical medicine
The ability to deal comfortably with multiple problems occurring simultaneously in a patient
Desire for frequent and varied intellectual and technical challenges
The ability to support children during growth and development and in their adjustment to family and society
The ability to assist patients in coping with everyday problems and in maintaining stability in the family and community
The capacity to act as coordinator of all health resources needed in the care of a patient
Enthusiasm for learning and for the satisfaction that comes from maintaining current medical knowledge through continuing medical education
The ability to maintain composure in times of stress and to respond quickly with logic, effectiveness, and compassion
A desire to identify problems at the earliest possible stage or to prevent disease entirely
A strong wish to maintain maximum patient satisfaction, recognizing the need for continuing patient rapport
The skills necessary to manage chronic illness and to ensure maximal rehabilitation after acute illness
Appreciation for the complex mix of physical, emotional, and social elements in personalized patient care
A feeling of personal satisfaction derived from intimate relationships with patients that naturally develop over long periods of continuous care, as opposed to the short-term pleasures gained from treating episodic illnesses
Skills for and a commitment to educating patients and families about disease processes and the principles of good health
A commitment to place the interests of the patient above those of self

* These characteristics are desirable for all physicians but are of greatest importance for family physicians.

his environment. Peabody (1930) believed that much patient dissatisfaction resulted from the physician's neglecting to assume personal responsibility for supervision of the patient's care: "For some reason or other, no one physician has seen the case through from beginning to end, and the patient may be suffering from the very multitude of his counselors" (p. 8).

Continuity of care is a core attribute of family medicine, transcending multiple illness episodes, and it includes responsibility for preventive care and care coordination. "This longitudinal relationship evolves into a strong bond between physician and patient characterized by trust, loyalty, and a sense of responsibility" (Saultz, 2003, p. 134). Trust grows stronger as the physician-patient relationship continues and provides the patient a sense of confidence that care will always be in his or her best interest. It also facilitates improved quality of care the longer the relationship continues.

The greater the degree of continuing involvement with a patient, the more capable the physician is in detecting early signs and symptoms of organic disease and differentiating it from a functional problem. Patients with problems arising

from emotional and social conflicts can be managed most effectively by a physician who has intimate knowledge of the individual and his or her family and community background. This knowledge comes only from insight gained by observing the patient's long-term patterns of behavior and responses to changing stressful situations. This longitudinal view is particularly useful in the care of children and allows the physician to be more effective in assisting children to reach their full potential. The closeness that develops between physicians and young patients increases a physician's ability to aid the patients with problems later in life, such as adjustment to puberty, problems with employment, or marriage and changing social pressures. As the family physician maintains this continuing involvement with successive generations within a family, the ability to manage intercurrent problems increases with knowledge of the total family background.

By virtue of this ongoing involvement and intimate association with the family, the family physician develops a perceptive awareness of a family's nature and style of operation. This ability to observe families over time allows valuable insight that improves the quality of medical care provided to an individual patient. A major challenge in family medicine is the need to be alert to the changing stresses, transitions, and expectations of family members over time, as well as the effect that these and other family interactions have on the health of individual patients.

Although the family is the family physician's primary concern, his or her skills are equally applicable to the individual living alone or to people in other varieties of family living. Individuals with alternative forms of family living interact with others who have a significant effect on their lives. The principles of group dynamics and interpersonal relationships that affect health are equally applicable to everyone.

The family physician must assess an individual's personality so that presenting symptoms can be appropriately evaluated and given the proper degree of attention and emphasis. A complaint of abdominal pain may be treated lightly in one patient who frequently presents with minor problems, but the same complaint would be investigated immediately and in depth in another patient who has a more stoic personality. The decision regarding which studies to perform and when is influenced by knowledge of the patient's lifestyle, personality, and previous response pattern. The greater the degree of knowledge and insight into the patient's background, as gained through years of ongoing contact, the more capable is the physician in making an appropriate early and rapid assessment of the presenting complaint. The less background information the physician has to rely on, the greater the need to depend on costly laboratory studies, and overreaction to the presenting symptom is more likely.

Families receiving continuing comprehensive care have a decreased incidence of hospitalization, fewer operations, and fewer physician visits for illnesses compared with those having no regular physician. This results from the physician's knowledge of the patients, seeing them earlier for acute problems and therefore preventing complications that would require hospitalization, being available by telephone or by e-mail, and seeing them more frequently in the office for health supervision. Care is also less

expensive because there is less need to rely on radiographic and laboratory procedures and visits to emergency departments.

Continuity of care improves quality of care, especially for those with chronic conditions such as asthma and diabetes (Cabana and Jee, 2004). Because about 90% of patients with diabetes in the United States receive care from a primary care physician, continuity of care can be especially important. Parchman and associates (2002) found that for adults with type 2 diabetes, continuing care from the same primary care provider was associated with lower Hb_{A1c} values, regardless of how long the patient had diabetes. Having a regular source of primary care helped these adults manage their diet and improve glucose control.

Collusion of Anonymity

The need for a primary physician who accepts continuing responsibility for patient care was emphasized by Michael Balint (1965) in his concept of *collusion of anonymity*. In this situation, the patient is seen by a variety of physicians, not one of whom is willing to accept total management of the problem. Important decisions are made—some good, some poor—but without anyone feeling fully responsible for them. Both the patient and family often wonder who is in charge.

Francis Peabody (1930) examined the futility of a patient's making the rounds from one specialist to another without finding relief because the patient:

... lacked the guidance of a sound general practitioner who understood his physical condition, his nervous temperament and knew the details of his daily life. And many a patient who on his own initiative has sought out specialists, has had minor defects accentuated so that they assume a needless importance, and has even undergone operations that might well have been avoided. Those who are particularly blessed with this world's goods, who want the best regardless of the cost and imagine that they are getting it because they can afford to consult as many renowned specialists as they wish, are often pathetically tragic figures as they veer from one course of treatment to another. Like ships that lack a guiding hand upon the helm, they swing from tack to tack with each new gust of wind but get no nearer to the Port of Health because there is no pilot to set the general direction of their course (pp. 21-22).

Chronic Illness

The family physician must also be committed to managing the common chronic illnesses that have no known cure but for which continuing management by a personal physician is all the more necessary to maintain an optimal state of health for the patient. It is a difficult and often trying job to manage these unresolvable and progressively disabling problems, control of which requires a remodeling of the lifestyle of the entire family.

About 45% of Americans have a chronic condition. The costs to individuals and to the health care system are enormous. In 2000, care of chronic illness consumed 75 cents of every health care dollar spent in the United States (Robert Wood Johnson Foundation Annual Report, 2002).

Comorbidity, the coincident occurrence of coexisting and apparently unrelated disorders, is increasing as the population ages. Those age 60 years or older have an average of 2.2 chronic conditions, and physicians in primary care provide most of this care (Bayliss et al., 2003).

Diabetes is one of the most rapidly increasing chronic conditions. Quality of life is enhanced when care of patients with diabetes is provided in a primary care setting without compromising quality of care (Collins et al., 2009).

Quality of Care

Primary care provided by physicians specifically trained to care for the problems presenting to personal physicians, who know their patients over time, is of higher quality than care provided by other physicians. This has been confirmed by a variety of studies comparing the care given by physicians in different specialties. When hospitalized patients with pneumonia are cared for by family physicians or full-time specialist hospitalists, the quality of care is comparable, but the hospitalists incur higher hospital charges and longer lengths of stay and use more resources (Smith et al., 2002).

In the United States, a 20% increase in the number of primary care physicians is associated with a 5% decrease in mortality (40 fewer deaths per 100,000 population), but the benefit is even greater if the primary care physician is a family physician. Adding one more family physician per 10,000 people is associated with 70 fewer deaths per 100,000 population, which is a 9% reduction in mortality rate. Specialists practicing outside their area have increased mortality rates for patients with acquired pneumonia, acute myocardial infarction, congestive heart failure, and upper gastrointestinal hemorrhage. A study of the major determinants of health outcomes in all 50 U.S. states found that when the number of specialty physicians increases, outcomes are worse, but mortality rates are lower where there are more primary care physicians (Starfield et al., 2005).

Veerappa and colleagues (2011) found that increasing the number of family physicians practicing in the community is associated with reduced hospital readmissions and substantial cost savings. Thirty-day hospital readmission rates for pneumonia, heart attack, and heart failure decrease as the number of family physicians in the community increases. Conversely, increased numbers of physicians in all other major specialties (including general internal medicine) are associated with increased risk of readmission (Figure 1-2).

A comparison of family physicians and obstetrician-gynecologists in the management of low-risk pregnancies showed no difference with respect to neonatal outcomes. However, women cared for by family physicians had fewer cesarean sections and episiotomies and were less likely to receive epidural anesthesia (Hueston et al., 1995).

Patients of subspecialists practicing outside their specialty have longer lengths of hospital stay and higher mortality rates than patients of subspecialists practicing within their specialty (Weingarten et al., 2002). The quality of the U.S. health care system is being eroded by physicians being

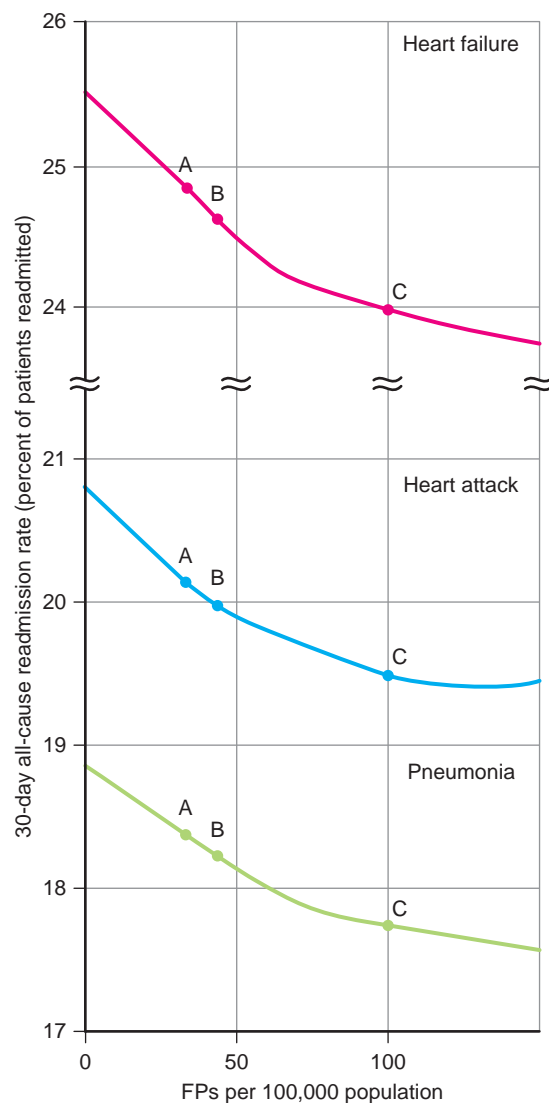

Figure 1-2 Actual and estimated 30-day hospital readmission rates in 2005 per county density of family physicians (FPs). **A**, Actual readmissions in 2005. **B**, Estimated readmissions with 46 FPs per 100,000 population. **C**, Estimated readmissions with 100 FPs per 100,000 population. (From Veerappa K, Culpepper L, Phillips RL, et al. FPs lower hospital readmission rates and costs. *Am Fam Physician*. 2011;83(9):1054.)

extensively trained, at great expense, to practice in one area and instead practicing in another area, such as surgeons practicing as generalists. Primary care, to be done well, requires extensive training specifically tailored to problems frequently seen in primary care.

As much-needed changes in the U.S. medical system are implemented, it would be wise to keep some perspective on the situation regarding physician distribution. Beeson (1974) commented:

I have no doubt at all that a good family doctor can deal with the great majority of medical episodes quickly and competently. A specialist, on the other hand, feels that he must be thorough, not only because of his training but also because he has a reputation to protect. He, therefore, spends more time with each patient and orders more

laboratory work. The result is a waste of doctors' time and patients' money. This not only inflates the national health bill, but also creates an illusion of doctor shortage when the only real need is to have the existing doctors doing the right things (p. 48).

Cost-Effective Care

A physician who is well acquainted with a patient provides more personal and humane medical care and does so more economically than a physician involved in only episodic care. A physician who knows his or her patients well can assess the nature of their problems more rapidly and accurately.

The United States has the most expensive health care system in the world. In 1965, the cost of health care in the United States was just under 6% of the gross domestic product (GDP). It shot up to 16% of GDP in 2008 and continues to increase, with predictions it will reach 20% by 2015. Despite the most expensive health care, however, among industrialized nations, the United States ranks 29th in infant mortality, 48th in life expectancy, and 19th (of 19) in preventable deaths.

Although the rhetoric suggests it is worth this cost to have the best health care system in the world, the truth is that we are far from that goal. The WHO ranks the quality of health care in the United States at 37th in the world, well behind Morocco and Colombia. (For the standing of all countries, see the World Health Organization's ranking of the world's health systems under <http://geographic.org/countries/countries.html>). In a comparison of the quality of health care in 13 developed countries using 16 different health indicators, the United States ranked 12th, second from the bottom. Evidence indicates that quality of health care is associated with primary care performance. Of the seven countries at the top of the average health ranking, five have strong primary care infrastructures. As Starfield (2000) states, "The higher the primary care physician-to-population ratio, the better most health outcomes are" (p. 485).

Similarly, the greater the number of primary care physicians practicing in a country, the lower is the cost of health care. Figure 1-3 shows that in the United Kingdom, Canada,

Figure 1-3 Inverse relationship between number of generalists and cost of health care in the United Kingdom, Canada, and the United States. GDP, Gross domestic product. (From Henry J. Kaiser Family Foundation. *Snapshots: Health Care Spending in the United States & Selected OECD Countries*, April 12, 2011. Available at kff.org/health-costs/issue-brief/snapshots-health-care-spending-in-the-united-states-selected-oecd-countries/)

and the United States, the cost of health care is almost inversely proportional to the percentage of generalists practicing in that country. Great Britain has twice the percentage of family physicians but about half the cost. Administration and profit (31%) of U.S. health care account for a major part of the high overhead cost (Woolhandler et al., 2003). For the same number of physicians, Canada has one "billing clerk" for every 17 in the United States (Lundberg, 2002).

Countries with strong primary care have lower overall health care costs, improved health outcomes, and healthier populations (Phillips and Starfield, 2004; Starfield, 2001). In comparing 11 features of primary care in 11 Western countries, the United States ranked lowest in terms of primary care ranking and highest in per-capita health care expenditures. The United States also performed poorly on public satisfaction, health indicators, and the use of medication (Starfield, 1994).

In the United States, the greater the number of primary care physicians, the lower the mortality rate, and conversely, the higher the specialist/population ratio, the greater the mortality rate. Adding one family physician per 10,000 people would result in 35 fewer deaths. Increasing the number of specialists, a process that continues in the United States, is associated with higher mortality rates and increasing cost. One third of the excessive cost is attributed to performance of unnecessary procedures (Starfield et al., 2005).

Uninsured Persons

Before the Affordable Care Act, the number of Americans without health insurance had been increasing by 1 million per year. In 2008, the number of uninsured persons was 16% of the U.S. population. The number of people who were *underinsured* was growing even more rapidly. Contrary to widespread belief, the problem is not confined simply to unemployed or poor persons. More than half of uninsured persons had annual incomes greater than \$75,000, and 8 of 10 were in working families. In 2013, medical expenses were responsible for 62% of bankruptcies in the United States. This will certainly change with the Affordable Care Act, but the amount of change remains to be seen because many of those filing for bankruptcy already had medical insurance but were still overwhelmed by medical bills.

The United States is the only developed country that does not have universal health care coverage for all its citizens. According to Geyman (2002), "Today's nonsystem is in chaos. A large part of health care has been taken over by for-profit corporations whose interests are motivated more by return on investment to shareholders than by quality of care for patients" (p. 407).

The United Nations passed a resolution encouraging all governments to move toward providing universal access to affordable and quality health care. In 2013, the WHO published a World Health Report, "Research for Universal Health Coverage," that focused on the need for more research to assist countries in establishing universal health care.

The Institute of Medicine (IOM) report on the uninsured population, *Insuring America's Health: Principles and Recommendations*, called for "health care coverage by 2010 that is universal, continuous, affordable, sustainable, and enhancing of high-quality care that is effective, efficient,

safe, timely, patient centered, and equitable. ... While stopping short of advocating a specific approach, the IOM's Committee on the Consequences of Uninsurance acknowledges that the single payer model is the most effective in ensuring continuous universal coverage that would remain affordable for individuals and for society" (Geyman, 2004, p. 635).

Family physicians account for a larger proportion of office visits to U.S. physicians than any other specialty. However, Geyman (2004, p. 631) observed problems:

The country's health care (non) system has undergone a major transformation to a market-based system largely dominated by corporate interests and a business ethic. The goal envisioned in the 1960s of rebuilding the U.S. health care system on a generalist base, with all Americans having ready access to comprehensive health care through a personal physician, has not been achieved. Overspecialization was a problem as long as 4000 years ago, when Herodotus in 2000 BC noted that "The art of medicine is thus divided: each physician applies himself to one disease only and not more."

Comprehensive Care

The term *comprehensive medical care* spans the entire spectrum of medicine. The effectiveness with which a physician delivers primary care depends on the degree of involvement attained during training and practice. The family physician must be trained comprehensively to acquire all the medical skills necessary to care for most problems. The greater the number of skills omitted from the family physician's training and practice, the more frequent is the need to refer minor problems to another physician. A truly comprehensive primary care physician adequately manages acute infections, biopsies skin and other lesions, repairs lacerations, treats musculoskeletal sprains and minor fractures, removes foreign bodies, treats vaginitis, provides obstetric care and care for newborn infants, gives supportive psychotherapy, and supervises diagnostic procedures. The needs of a family physician's patient range from a routine physical examination, when the patient feels well and wants to identify potential risk factors, to a problem that calls for referral to one or more narrowly specialized physicians with highly developed technical skills. The family physician must be aware of the variety and complexity of skills and facilities available to help manage patients and must match these to the individual's specific needs, giving full consideration to the patient's personality and expectations.

Comprehensive care includes complementary and alternative techniques that are of value in managing problems encountered in primary care (see [Chapter 12](#)). The book *Integrative Medicine* (Rakel, 2012) focuses on techniques that can be of value to the family physician but also identifies those that can be harmful or ineffective.

Management of an illness involves much more than a diagnosis and an outline for treatment. It also requires an awareness of all the factors that may aid or hinder an

individual's recovery from illness. This approach requires consideration of religious beliefs; social, economic, or cultural problems; personal expectations; and heredity. An outstanding clinician recognizes the effects that spiritual, intellectual, emotional, social, and economic factors have on a patient's illness.

A family physician's ability to confront relatively large numbers of unselected patients with undifferentiated conditions and carry on a therapeutic relationship over time is a unique primary care skill. A skilled family physician has a higher level of tolerance for the uncertain than her or his consultant colleagues.

Society benefits more from a surgeon who has a sufficient volume of surgery to maintain proficiency through frequent use of well-honed skills than from one who has a low volume of surgery and serves also as a primary care physician. The early identification of disease while it is in its undifferentiated stage requires specific training; it is not a skill that can be automatically assumed by someone whose training has been mostly in hospital intensive care units.

Interpersonal Skills

One of the foremost skills of family physicians is the ability to use effectively the knowledge of interpersonal relations in the management of patients. This powerful element of clinical medicine may be the specialty's most useful tool. Physicians too often are seen as lacking personal concern and as being unskilled in understanding personal anxiety and feelings. There is a need to nourish the seed of compassion and concern for sick people that motivates students as they enter medical school.

Family medicine emphasizes the integration of compassion, empathy, and personalized concern. Some of the earnest solicitude of the "old country doctor" and his or her untiring compassion for people must be incorporated as effective but impersonal modern medical procedures are applied. The patient should be viewed compassionately as a person in distress who needs to be treated with concern, dignity, and personal consideration. The patient has a right to be given some insight into his or her problems; a reasonable appraisal of the potential outcome; and a realistic picture of the emotional, financial, and occupational expenses involved in his or her care. The greatest deterrents to filing malpractice claims are patient satisfaction, good patient rapport, and active patient participation in the health care process.

To relate well to patients, a physician must develop compassion and courtesy, the ability to establish rapport and to communicate effectively, the ability to gather information rapidly and to organize it logically, the skills required to identify all significant patient problems and to manage these problems appropriately, the ability to listen, the skills necessary to motivate people, and the ability to observe and detect nonverbal clues (see [Chapter 13](#)).

Accessibility

The mere availability of the physician is therapeutic. The feeling of security that the patient gains just by knowing he or she can "touch" the physician, in person or by phone, is therapeutic and has a comforting and calming influence. Accessibility is an essential feature of primary care. Services must be available when needed and should be within

geographic proximity. When primary care is not available, many individuals turn to hospital emergency departments. Emergency department care is fine for emergencies, but it is no substitute for the personalized, long-term, comprehensive care a family physician can provide.

Many practices are instituting open-access scheduling, in which patients can be seen the day they call. This tells patients that they are the highest priority and that their problems will be handled immediately. It also is more efficient for the physician who cares for a problem early, before it progresses in severity and becomes complicated, requiring more physician time and greater patient disability.

Some physicians have turned to concierge medicine (also called boutique medicine, retainer-based medicine, and enhanced medical care for an annual fee) in which, for a monthly or annual fee, the physician promises to be available 24/7.

DIAGNOSTIC SKILLS: UNDIFFERENTIATED PROBLEMS

The family physician must be an outstanding diagnostician. Skills in this area must be honed to perfection because problems are usually seen in their early, undifferentiated state and without the degree of resolution that is usually present by the time patients are referred to consulting specialists. This is a unique feature of family medicine because symptoms seen at this stage are often vague and nondescript, with signs being minimal or absent. Unlike the consulting specialist, the family physician does not evaluate the case after it has been preselected by another physician, and the diagnostic procedures used by the family physician must be selected from the entire spectrum of medicine.

At this stage of disease, there are often only subtle differences between the early symptoms of serious disease and those of self-limiting, minor ailments. To an inexperienced person, the clinical pictures may appear identical, but to an astute and experienced family physician, one symptom is more suspicious than another because of the greater probability that it signals a potentially serious illness. Diagnoses are frequently made on the basis of probability, and the likelihood that a specific disease is present frequently depends on the incidence of the disease relative to the symptom seen in the physician's community during a given time of year. Many patients will never be assigned a final, definitive diagnosis because a presenting symptom or a complaint will resolve before a specific diagnosis can be made. Pragmatically, this is an efficient method that is less costly and achieves high patient satisfaction even though it may be disquieting to the purist physician who believes a thorough workup and specific diagnosis always should be obtained. Similarly, family physicians are more likely to use a therapeutic trial to confirm the diagnosis.

The family physician is an expert in the rapid assessment of a problem presented for the first time. He or she evaluates its potential significance, often making a diagnosis by exclusion rather than by inclusion, after making certain the symptoms are not those of a serious problem. Once assured, some time is allowed to elapse. Time is used as an efficient diagnostic aid. Follow-up visits are scheduled at appropriate intervals to watch for subtle changes in the presenting symptoms. The physician usually identifies the symptom

that has the greatest discriminatory value and watches it more closely than the others. The most significant clue to the true nature of the illness may depend on subtle changes in this key symptom. The family physician's effectiveness is often determined by his or her knack for perceiving the hidden or subtle dimensions of illness and following them closely.

The maxim that "an accurate history is the most important factor in arriving at an accurate diagnosis" is especially appropriate to family medicine because symptoms may be the only obvious feature of an illness at the time it is presented. Further inquiry into the nature of the symptoms, time of onset, extenuating factors, and other unique subjective features may provide the only diagnostic clues available at such an early stage.

The family physician must be a perceptive humanist, alert to early identification of new problems. Arriving at an early diagnosis may be of less importance than determining the real reason the patient came to the physician. The symptoms may be the result of a self-limiting or acute problem, but anxiety or fear may be the true precipitating factor. Although the symptom may be hoarseness that has resulted from postnasal drainage accompanying an upper respiratory tract infection, the patient may fear it is caused by a laryngeal carcinoma similar to that recently found in a friend. Clinical evaluation must rule out the possibility of laryngeal carcinoma, but the patient's fears and apprehension regarding this possibility must also be allayed.

Every physical problem has an emotional component, and although this factor is usually minimal, it can be significant. A patient's personality, fears, and anxieties play a role in every illness and are important factors in primary care.

THE FAMILY PHYSICIAN AS COORDINATOR

Francis Peabody (1930), a professor of medicine at Harvard Medical School from 1921 to 1927, was ahead of his time. His comments remain appropriate today:

Never was the public in need of wise, broadly trained advisors so much as it needs them today to guide them through the complicated maze of modern medicine. The extraordinary development of medical science, with its consequent diversity of medical specialism and the increasing limitations in the extent of special fields—the very factors that are creating specialists—in themselves create a new demand, not for men who are experts along narrow lines, but for men who are in touch with many lines (p. 20).

The family physician, by virtue of his or her breadth of training in a wide variety of medical disciplines, has unique insights into the skills possessed by physicians in the more limited specialties. The family physician is best prepared to select specialists whose skills can be applied most appropriately to a given case, as well as to coordinate the activities of each, so that they are not counterproductive.

As medicine becomes more specialized and complex, the family physician's role as the integrator of health services

becomes increasingly important. The family physician facilitates the patient's access to the whole health care system and interprets the activities of this system to the patient, explaining the nature of the illness, the implication of the treatment, and the effect of both on the patient's way of life. The following statement from the Millis Commission Report ([Citizens' Commission, 1966](#)) concerning expectations of the patient is especially appropriate:

The patient wants, and should have, someone of high competence and good judgment to take charge of the total situation, someone who can serve as coordinator of all the medical resources that can help solve his problem. He wants a company president who will make proper use of his skills and knowledge of more specialized members of the firm. He wants a quarterback who will diagnose the constantly changing situation, coordinate the whole team, and call on each member for the particular contributions that he is best able to make to the team effort (p. 39).

Such breadth of vision is important for a coordinating physician. She or he must have a realistic overview of the problem and an awareness of the many alternative routes to select the one that is most appropriate. As [Pellegrino \(1966\)](#) stated:

It should be clear, too, that no simple addition of specialties can equal the generalist function. To build a wall, one needs more than the aimless piling up of bricks, one needs an architect. Every operation which analyzes some part of the human mechanism requires it to be balanced by another which synthesizes and coordinates (p. 542).

The complexity of modern medicine frequently involves a variety of health professionals, each with highly developed skills in a particular area. In planning the patient's care, the family physician, having established rapport with a patient and family and having knowledge of the patient's background, personality, fears, and expectations, is best able to select and coordinate the activities of appropriate individuals from the large variety of medical disciplines. He or she can maintain effective communication among those involved, as well as function as the patient's advocate and interpret to the patient and family the many unfamiliar and complicated procedures being used. This prevents any one consulting physician, unfamiliar with the concepts or actions of all others involved, from ordering a test or medication that would conflict with other treatment. [Dunphy \(1964\)](#) described the value of the surgeon and the family physician working closely as a team:

It is impossible to provide high quality surgical care without that knowledge of the whole patient, which only a family physician can supply. When their mutual

decisions ... bring hope, comfort and ultimately, health to a gravely ill human being, the total experience is the essence and the joy of medicine (p. 12).

The ability to orchestrate the knowledge and skills of diverse professionals is a skill to be learned during training and cultivated in practice. It is not an automatic attribute of all physicians or merely the result of exposure to a large number of professionals. These coordinator skills extend beyond the traditional medical disciplines into the many community agencies and allied health professions as well. Because of his or her close involvement with the community, the family physician is ideally suited to be the integrator of the patient's care, coordinating the skills of consultants when appropriate and involving community nurses, social agencies, the clergy, or other family members when needed. Knowledge of community health resources and a personal involvement with the community can be used to maximum benefit for diagnostic and therapeutic purposes and to achieve the best possible level of rehabilitation.

Only 5% of visits to family physicians lead to a referral, and more than 50% are for consultation rather than direct intervention. Surgical specialists are sent the largest share of referrals at 45.4% followed by medical specialists at 31% and obstetrician-gynecologists at 4.6%. Physicians consulted most frequently are orthopedic surgeons followed by general surgeons, otolaryngologists, and gastroenterologists. Psychiatrists are consulted the least ([Forrest et al., 2002](#); [Starfield et al., 2002](#)).

The Family Physician in Practice

The advent of family medicine has led to a renaissance in medical education involving a reassessment of the traditional medical education environment in a teaching hospital. It is now considered more realistic to train a physician in a community atmosphere, providing exposure to the diseases and problems most closely approximating those she or he will encounter during practice. The ambulatory care skills and knowledge that most medical graduates will need cannot be taught totally within a tertiary medical center. The specialty of family medicine emphasizes training in ambulatory care skills in an appropriately realistic environment using patients representing a cross-section of a community and incorporating those problems most frequently encountered by physicians practicing primary care. For this reason, the model office is integral to training in family medicine because it imitates realistically the environment and kind of problems the student and resident will encounter in practice.

The lack of relevance in the referral medical center also applies to the hospitalized patient. [Figure 1-4](#) places the health problems of an average community in perspective. In any given month, 800 people experience at least one symptom. Most of these people are managed by self-treatment, but 217 consult a physician. Of these, eight are hospitalized, but only one goes to an academic medical center. Patients seen in the medical center (with most cases used for teaching) represent atypical samples of illness occurring within the community. Students exposed to

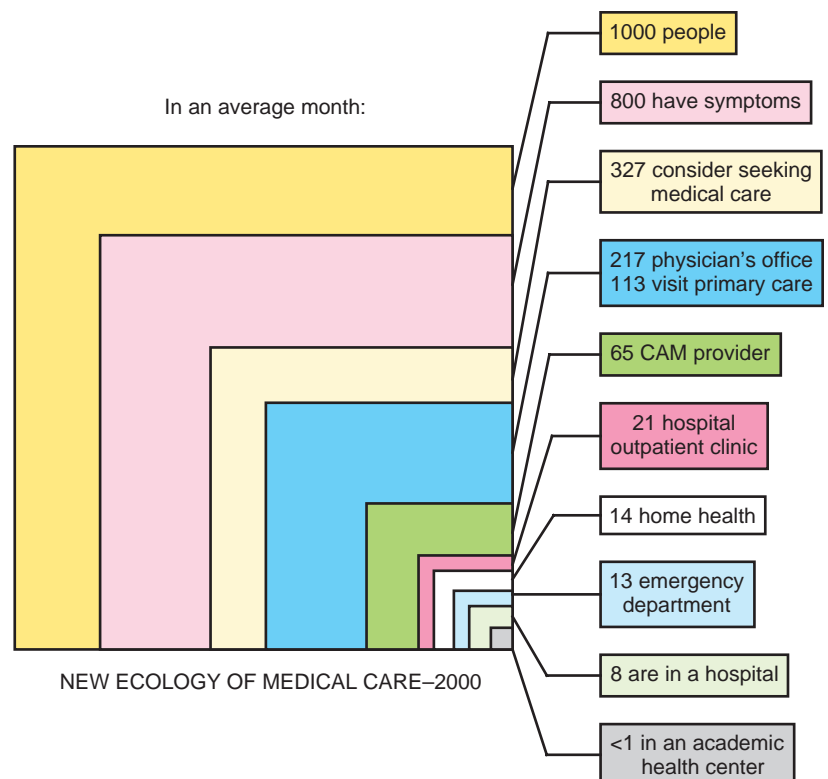

Figure 1-4 Number of persons experiencing an illness during an average month per 1000 people. CAM, Complementary and alternative medicine. (From Green LA, Fryer GE Jr, Yawn BP, et al. The ecology of medical care revisited. *N Engl J Med.* 2001;344:2021-2025.)

patients in only this manner develop an unrealistic concept of the types of medical problems prevalent in society and particularly those composing primary care. It focuses their training on knowledge and skills of limited usefulness in later practice.

PRACTICE CONTENT

Since 1975, the National Ambulatory Medical Care Survey conducted by the National Center for Health Statistics (NCHS) of the U.S. Department of Health and Human Services has annually reported the problems seen by office-based physicians (in all specialties) in the United States. The 20 most common diagnoses seen by physicians in their offices are shown in [Table 1-3](#). Note that arthritis is fourth and diabetes mellitus sixth, reflecting the prominence of chronic diseases in practice. For those who think primary care is little more than caring for acute pharyngitis, note that it is ranked 19th. When only chronic conditions are listed ([Table 1-4](#)), arthritis is second and diabetes fourth.

Although hypertension is the most common problem encountered in offices (see [Table 1-3](#)), primary care physicians checked the blood pressure at 60% of the visits compared with only 20% of surgical specialists and 40% of visits to medical specialists ([Woodwell and Cherry, 2002](#)).

Available data concerning primary care indicate that more people use this type of medical service than any other and that, contrary to popular opinion, sophisticated medical technology is not normally either required or over-used in basic primary care encounters. Most primary care visits arise from patients requesting care for relatively

uncomplicated problems, many of which are self-limiting but which cause the patients concern or discomfort. Treatment is often symptomatic, consisting of pain relief or anxiety reduction rather than a “cure.” The greatest cost-efficiency results when these patients’ needs are satisfied while the self-limiting course of the disease is recognized, without incurring unnecessary costs for additional tests.

Patient-Centered Medical Home

The patient-centered medical home (PCMH; see [Chapter 2](#)) has been proposed as an enhanced model of primary care by four medical organizations (family medicine, pediatrics, internal medicine, osteopathy) and is focused on reducing fragmentation of care and overcoming the reliance on specialty rather than primary care ([Berenson et al., 2008](#); [Rogers, 2008](#)).

Primary care was encouraged to expand beyond its restrictive role as a provider of care to one that analyzes the needs of a community and focuses on those at risk of disease. This process was first described in the 1950s by Sydney Karf, who looked at the needs of his community in South Africa, whether or not they were his patients ([Karf and Cassel, 1952](#); [WONCA, 2013](#)). The process involves identifying the health problems of a community, such as diabetes or obesity, developing a program to prevent the disease and care for people in the early stage, and then evaluating the effectiveness of the program ([Longlett et al., 2001](#)).

Looking toward the Future

The pace of medical progress may result in tomorrow's innovations exceeding today's fantasies. Family medicine in the future will be different as a result of technology. Every patient and physician is computer literate, with patients having access to the same sources of information as

physicians. Patients are likely to have their own home page that contains their medical information and gives them access to whatever services they need ([Scherger, 2005](#)). Although the Internet is an excellent tool for consumers to access information about their health and for disseminating health care information, it will never be a substitute for a face-to-face discussion and physical examination. It cannot convey the worry in a voice or the subtle, nonverbal clues to the real reason for the patient's distress. However, the Internet does allow the individual patient to be more active and involved in his or her own care.

The electronic medical record allows the family physician to incorporate the latest evidence-based recommendations into an individual's care, write electronic prescriptions, and be alerted to drug interactions while seeing a patient. Internet-based textbooks such as this one will provide immediate access to information during patient visits.

Payment Models for the Health Home, 24

Conclusion, 24

Key Points

- Continuous, healing-oriented relationships are the foundation on which the medical home, or “health home,” is built. This is the interpersonal environment.
- The patient-centered medical home brings together health professionals to work collectively toward the health needs of the community through the creation of health teams.
- A continuous self-reflective process is required for the physician-leader to prevent burnout, maintain joy in her or his work, and create an optimal healing environment (OHE). This is the inner environment.
- The health home can have the greatest impact on community health by proactive incorporation of positive lifestyle behaviors. This is the behavioral environment.
- Patient empowerment involves providing accurate information in a manner that is understandable to the individual and creating a context that supports the patient’s ability to make decisions.
- Infusing the elements of an OHE (including inner, interpersonal, behavioral, and external) within the medical home will encourage patient and team empowerment and enhance change toward positive health.

The intuitive mind is a sacred gift, and the rational mind is a faithful servant. We have created a society in which we honor the servant and have forgotten the gift.

ALBERT EINSTEIN

History

The concept of the “medical home” was first described in *Standards of Child Care* by the [American Academy of Pediatrics \(AAP\) Council on Pediatrics Practice in 1967](#). It defined “ideal care” for children with disabilities as a practice that provided care that was accessible, coordinated, family-centered, and culturally effective.

The American Academy of Family Physicians (AAFP) used this concept to expand the characteristics based on discussions defining the future of family medicine. These characteristics described the “personal” medical home, which focused on bringing attention to the importance of continuous, relationship-centered, whole-system, comprehensive care for communities ([Martin et al., 2004](#)). In 2007, the AAP, AAFP, American College of Physicians (ACP), and American Osteopathic Association (AOA)

collaborated to define further the foundational principles of the patient-centered medical home (PCMH; [Table 2-1](#)). The goal of the medical home is to emphasize the importance of primary care in maximizing quality of care, health outcomes, and the patient experience, with improved cost efficiency, called “the “triple aim” by the [Institute for Healthcare Improvement \(IHI, 2014\)](#).

However, the ingredients of the medical home (or “health home”) continue to be defined and modified based on the needs of the clinicians and communities that implement them. These ingredients and how they are delivered are key to the achievement of the lofty goals of the medical home and family medicine in general. This chapter discusses the most important ingredients for the medical home and the actions that the family physician can take to create one.

Healing, Curing, and the Goals of the Medical Home

Medicine in general and primary care in particular involve constant tension between the diagnosis and elimination of disease (cure) on one hand and the alleviation of suffering (healing) on the other. In this context, *healing* means

Table 2-1 Principles of a Patient-Centered Medical Home

1. Access to care based on an ongoing relationship with a personal physician who is able to provide first-contact, continuous, and comprehensive care
2. Care provided by a physician-led team of individuals within the practice who collectively take responsibility for the ongoing needs of patients
3. Care based on a whole-person (holistic) orientation in which the practice team takes responsibility for either providing care that encompasses all patient needs or arranges for the care to be done by other qualified professionals
4. Care coordinated and integrated across all elements of the complex health care system and the patient's community
5. Care facilitated by the use of office practice systems (e.g., registries, information technology, health information exchange) to ensure that patients receive the indicated care when and where they need and want it in a culturally and linguistically appropriate manner
6. Reimbursement structure that supports and encourages this model of care

Modified from American College of Physicians. *Joint Principles of the Patient-Centered Medical Home*, March 2007. http://www.acponline.org/advocacy/where_we_stand/medical_home/approve_jp.pdf.

optimizing patients' responses to treatments and helping them cope emotionally and practically with whatever condition they face, even when cure is not possible.

In *The Nature of Suffering and the Goals of Medicine*, Cassell (2004) elegantly describes this tension and the continual erosion of healing practices under the pressure to apply more specific, technologic cures. In *A Time to Heal*, Ludmerer (1999) documents how, despite decades of efforts in curriculum change, these core values of healing in medical education have failed to gain significant traction under the forces driving the payment for cure-seeking behaviors.

Thus, physicians seeking to create a medical home that balances cure and healing face considerable challenges, especially in the delivery of healing. What are the essential components of such a health care home? How can they be delivered in the current medical context? What actions must a family physician take to create not only a practice that treats disease but an optimal healing environment (OHE) as well?

BALANCING TREATMENT OF DISEASE AND PROMOTION OF HEALTH AND HEALING

Health is largely a result of positive lifestyle behaviors that are often challenging to implement. Addressing issues such as smoking, obesity, substance abuse, and inactivity can reduce premature death by 40% (McGinnis et al., 2002; Schroeder, 2007). Positive lifestyle behaviors not only prevent premature death but also extend the average life expectancy by 14 years (Khaw et al., 2008). Currently, approximately 4 cents of every dollar spent for health care goes toward prevention and public health, with 96% spent on treating established disease (Lambrew, 2007). Two thirds of chronic disease is behavior-related and could be eliminated or mitigated by working interprofessionally to help guide patients toward healthy choices (McGinnis et al., 2002).

Behaviors that have the greatest impact on preventing chronic disease and its progression are (1) reducing exposure to toxic substances (tobacco, alcohol, drugs, pollution),

Figure 2-1 Profit in the current U.S. health care system is obtained focusing on the right of the curve. Investment toward the left of the curve will reduce disease burden and cost over time.

(2) movement and exercise, (3) healthy diet, (4) psychosocial integration and stress management, and (5) early disease detection and intervention (Jonas, 2009; McGinnis, 2003). For these behaviors to have an impact, the health home needs to be both designed and financially supported with the goal of health as its primary focus. This requires new models for funding that go beyond the disease-focused, payment-by-episode, high-throughput model of payment that currently dominates medicine. A primary care clinic that only works from this model will encourage shorter office visits while promoting reliance on expensive technologies that modify symptoms without addressing the cause of disease. The PCMH needs to push the curve in Figure 2-1 to the left by involving professionals who specialize in health promotion and flatten the disease progression curve and reduce the need for emergency and tertiary care.

ESTABLISHING AN OPTIMAL HEALING ENVIRONMENT

An OHE involves changes in the delivery and context of medical treatment rather than a specific treatment itself. Its goal is to infuse healing processes (salutogenesis) into any disease treatment. This means optimizing the effects of "meaning and context" in care process rather than ignoring or dismissing them as "placebo" effects (Jonas 2011). An OHE involves attending to three primary domains of care delivery: (1) the "inner" personal environment of the team and patient; (2) the "inter" personal or relationship environment of care delivery; and (3) the "external" behavioral and physical environment of the medical home (Chez and Jonas, 2005; Jonas et al., 2014).

The "treatment" itself is given the most credit in medicine when often it should not be so. A prescribed medication is valued for its "specific" medical influence, as deemed beneficial by randomized (placebo-) controlled trials (RCTs). This research focuses on the effects of the drug and attempts to control the context to reduce "nonspecific" (placebo) effects that may compromise the results. This helps physicians understand the specific effects of the drugs they prescribe, but it does not value those nonspecific effects that surround the prescribing of a medication. It is impossible, even undesirable, to remove all nonspecific effects from the patient encounter (Moerman and Jonas, 2002). "Meaning" and "context" effects are rooted in relationship-centered care, including empathy, trust, empowerment, and hope (Walach

Table 2-2 Optimal Healing Environments**Inner Environment to the Outer Environment**

Healing Intention	Personal Wholeness	Healing Relationships	Healing Organizations	Healthy Lifestyles	Integrative Collaborative Medicine	Healing Spaces
Expectation	Mind	Compassion	Leadership	Diet	Person oriented	Nature

Surround the individual with elements that facilitate the innate healing process.

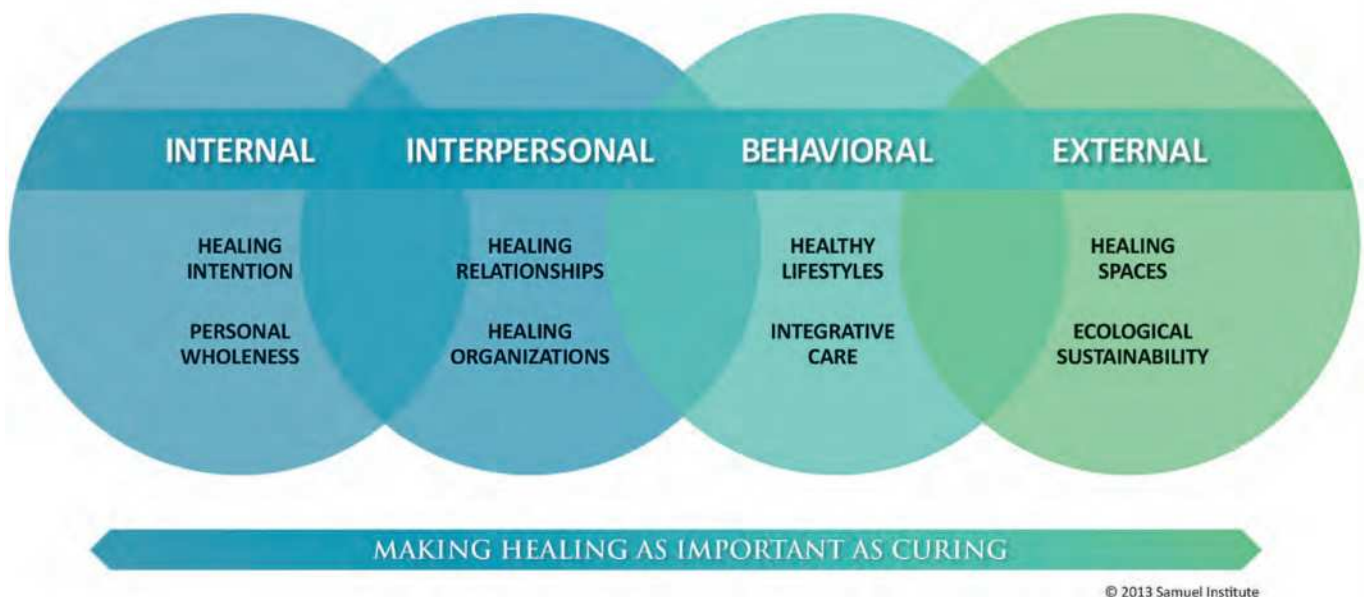

Figure 2-2 Optimal healing environments. (Used with permission from Samueli Institute, www.SamueliInstitute.org.)

and Jonas, 2004) Research on one of the most frequently prescribed drugs in primary care, selective serotonin reuptake inhibitors (SSRIs), shows that these work only about 6% to 9% better than placebos for mild to moderate depression (Kirsch et al., 2002; Turner et al., 2008). Both placebos and drugs work well and are often almost 60% effective. Therefore, if the drug only accounts for 9% of this effect, which factor accounts for the majority of the healing influence? Maybe researchers are not giving enough credit to the clinician and the nonspecific variables that surround the prescribing of the pill. Maybe it is simply the act of listening to people who are suffering and giving them a sense of understanding that there is something they can do to overcome the suffering. Maybe it is the interaction between two people before the medicine is prescribed that has the greatest healing effect. Psychiatrists gifted at developing a trusting relationship were found to have better effects with placebo in treating depression than their colleagues less talented at developing relationships who used active drugs (McKay et al., 2006). Acupuncture delivered with an enhanced clinical human encounter produces better effects

than the same points treated by clinicians who do not form a therapeutic relationship (Kaptchuk et al., 2008; Kelley et al., 2009).

Family physicians do not need to wait for further research to create an OHE for patient care. Physicians already know that the factors summarized in Table 2-2 and Figure 2-2 help encourage the healthy unfolding of complex systems no matter what the disease or treatment. The most important part in influencing healing in others is focused on the left side of the table and starts with a self-reflective, internal process. Family physicians first need to understand the importance of continuously exploring their own awareness and health so they are prepared to do the same for their patients.

THE IMPORTANCE OF SELF-CARE

To care deeply for others, we must know how to care for ourselves. As Cassell (2004) says, "... virtually all the doctor's healing power flows from the doctor's self-mastery." True primary care, therefore, also includes what we do for

ourselves. Up to 60% of practicing physicians report symptoms of “burnout” (Shanafelt et al., 2003; Spickard et al., 2002) with a higher incidence in primary care (Shanafelt, et al., 2012). This is associated with emotional exhaustion, depersonalization (seeing patients as objects), reduced empathy, and the loss of meaning in work. (See Chapter 6, Care of the Self.)

The characteristics lost in burnout are important ingredients in facilitating health and healing in others. If the health team physician leader is “burning out,” the health home will not be healthy. When physicians practice healthy lifestyle behaviors, they are more likely to educate patients on the importance of these behaviors (Lewis et al., 1991) and to become more motivating to their patients toward positive change (Frank et al., 2000; Lobelo et al., 2009). Family physicians benefit from a self-reflective inquiry about personal balance toward health. This behavior will constantly be challenged and will require attention and “mastery.”

Most primary care physicians are attracted to the field to make a difference in people’s lives through continuous healing relationships. When the demands of the working environment tax the sense of control to maintain these relationships, stress and potential burnout can ensue. One remedy for this is to use the patient encounter to allow *meaning* to flow through the work. The healing-oriented primary care approach recognizes each patient as a unique individual with specific needs in the physical, emotional, and spiritual domains and sets aside both mental space and physical time to deal with those needs. To be aware of these personal needs requires a mindful practice in which the physician is fully present in the moment with the patient, where each is able to reduce suffering in the other (Epstein, 1999). This “mindfulness” approach has been found to enhance well-being and physician attitudes in patient-centered care (Krasner et al., 2009) and reduce stress, anxiety, and depression in primary care clinicians (Fortney, et al., 2013). It requires that physicians create physical time in the health home to sit and listen to patient stories (Rakel, 2008).

INVESTING IN RELATIONSHIP

The medical home is just that, a “home” where someone feels welcome, known, and part of a community. The ongoing relationship with patients provides insight into the complexity of their health care needs and honors the interactions among multiple health perspectives. It allows the clinician to use evidence-based guidelines while realizing that variability is the norm. The best care for one individual may not be best for another. Patient-centered care recognizes that care should be focused on the needs of the individual patient, not simply on a disease state. Ideally, the goal should be “relationship centered,” encouraging attention to the unique needs of the patient to be well. Thus, creating healing relationships is a core goal of an effective medical home (Chez and Jonas, 2005).

The evidence for the benefits of continuous, relationship-centered primary care is solid and growing (Neumann et al., 2010). It has been found to improve quality of care (Starfield, 1991), reduce expenditures on diagnostic testing (Epstein et al., 2005), reduce hospital admissions (Gill and Mainous,

1998), and lower total health care costs (De Maeseneer et al., 2003). Having continuous, ongoing relationships with patients is often cited as the most rewarding aspect of being a family physician (Fairhurst and May, 2006). A systematic review of controlled trials on effective “team care,” in which relationship-centered factors are formalized in the care process, has demonstrated reduced mortality and morbidity, improved morale of health care workers, and reduced costs of health care (Safran et al., 2006). Patients with diabetes who are cared for by physicians who rate high in empathy have lower Hgb A1C and low-density lipoprotein cholesterol levels (Hojat et al., 2011).

One health care system that restructured its whole organization around establishing long-term, trusting, accountable relationships in the community is the Southcentral Foundation Alaska Native Health Care model (Eby, 2007). This was the main request of the leaders of native Alaskans when they were asked what they wanted most in their public-owned health care system. Above all else, they valued the relationship with their physician, someone who “listens to them and takes time to explain things and who is able to coordinate effectively their overall care” (Gottlieb, 2007). The system made this its primary objective. This focus not only delivered a better patient experience, but it also improved clinical outcomes. After transforming their health model in 1999, urgent care and emergency department utilization decreased by 40%, specialist utilization by 50%, and hospitalization days by 30%. Customer satisfaction surveys showed that 91% rated their overall care as “favorable” (Gottlieb et al., 2008).

EMPOWERMENT

The greatest amount of suffering, disability, and cost occurs when the individual becomes more dependent on tertiary health care. The goal of the primary health team is to reduce this need. This requires that physicians empower individuals, families, and communities to understand what they can do to reduce the risk of disease and move the acuity curve in Figure 2-3 to the left. This will increase control of health by the individual, family, and community, with less dependence on the health care industry. To understand how best to work toward this goal, it is important to understand the process of empowerment.

Empowerment does not mean that patients do what is asked of them; this is *compliance*. Noncompliance is two people working toward different goals. Empowerment is a way of interacting in which accurate information is provided in a manner understandable to the individual that both respects and promotes patients’ ability to make decisions for themselves. A patient’s decision making occurs in the “inner,” personal environment, influenced by external issues such as culture, family, peer group, work, and payment for care. Anderson and Funnell (2009) describe this well in their research on empowerment and diabetes care, reporting that 98% of diabetes care is “patient directed.” When a patient is told to act a certain way, it is successful less than 5% of the time.

Empowerment is both a process and an outcome. The *process* requires that a health care partner recognizes individuals’ unique needs and helps them think critically to make informed decisions on which they choose to act. This

results in an *outcome* that individuals decide is best for them and their current situations. Health care practitioners cannot control their patients' decisions and thus cannot own the outcome. The clinician can recognize the psychosocial and emotional underpinnings that allow positive change to take place and then gradually and supportively work with the patient toward positive behaviors. As the

health guide of the community, the relationship-centered health home requires the development of health teams to facilitate this change.

Health Teams

Patient-centered, healing-focused care requires that primary care physicians evolve beyond "physician-centered care" that is restricted by the dwindling access of the one-on-one physician visit. The family physician of the future can be a leader in the creation of a team of health professionals who provide multiple paths to access care (Figure 2-4) (Grumbach and Bodenheimer, 2004). This may involve group visits, phone contact, e-mail, Facebook, Twitter, photo and video access, and other use of information technology. The goal should be a proactive, collaborative team effort that is not restricted to the in-office encounter and continuously moving toward meeting patient goals, not just expecting adherence to treatment guidelines (Nutting et al., 2009). Healing-oriented teams include the most appropriate clinicians for the health needs of the community. This process may be physician-led but not necessarily physician-dominant and may include nurses and nurse practitioners, physician assistants, psychologists and counselors, allied health practitioners, complementary and alternative practitioners, health coaches, and others to provide more effective care while reducing the threat of a physician shortage (Bodenheimer and Smith, 2013). Administrative office

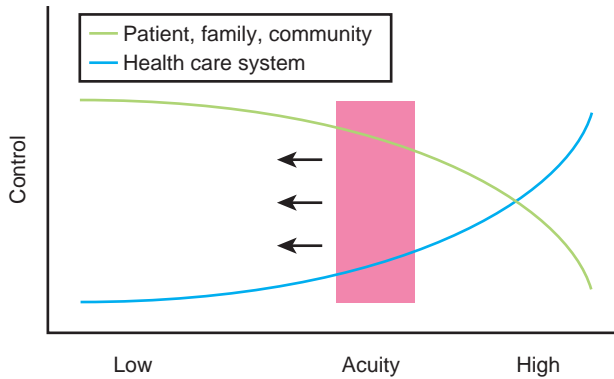

Figure 2-3 The Alaska Native Health Care model moved the slashed lines to the left, reducing dependence on the health care system and increasing control of the family. The goal is to flatten the curves to the right. The health care system should empower the family and community to maintain control of their health and make people less dependent on the "health rescue." (Modified from Gottlieb K, Sylvester I, Eby D. Transforming your practice: what matters most. *Fam Pract Manag.* 2008;15:32-38.)

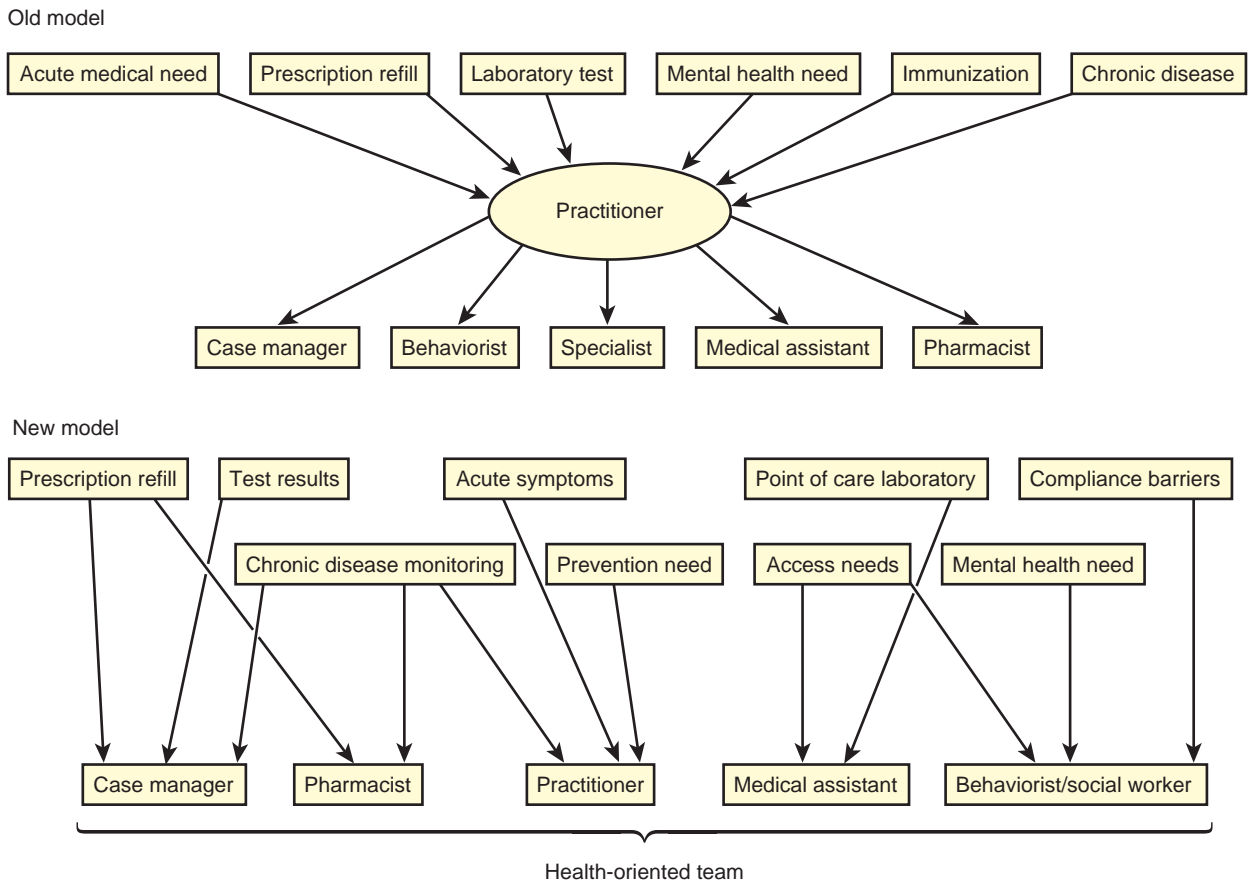

Figure 2-4 Traditional model versus new model of care showing multiple ways to access the health home (medical home).

Table 2-3 Defining Disciplinary Teams

Term	Definition
Multidisciplinary team	Additive. Composed of “more than two professionals from different health care disciplines who work with the same patient, set of patients, or clinical condition, but provide care independently of each other” (Choi and Pak, 2006) (interdisciplinary team building). For example, a patient may have visits with both a primary care practitioner (PCP) and physical therapist (PT). Although the PCP may view clinical notes or a report from the PT, the practitioners from the two disciplines usually do not interact.
Interdisciplinary team	Interactive. An ongoing and integrated care team of one patient, set of patients, or clinical condition. Team members develop collegial relationships with shared goals and joint decision making. They interact, supporting as well as questioning each other’s opinions, and negotiate to develop health strategies based on the needs of the individual.
Transdisciplinary team	Holistic. Professionals learn from each other and in the process transcend traditional disciplinary boundaries, which may result in new knowledge. Often, the greater the difference between professions (epistemologic distance; e.g., engineering and humanities), the more likely insight will develop toward the creation of a new way to solve a problem.

staff, with their frequent patient interactions, are also key members of the healing team, and, of course, the patient and his or her family, friends, caregivers, and community members frequently participate in important ways.

In 2003, the Robert Wood Johnson Foundation supported research to bring behavior change initiatives into primary care to address inactivity, unhealthy eating, smoking, and risky drinking (Cifuentes et al., 2005). Lessons learned from 17 practice-based research networks showed that health behavior change resources are enthusiastically received by practices and patients (Cohen et al., 2005; Woolf et al., 2005), and that practices that use multifaceted team-based interventions are more effective in promoting healthy behaviors than those providing isolated therapy (Goldstein et al., 2004; Prada, 2006; Solberg et al., 2000; Woolf et al., 2005).

When working within teams, it is important to understand the difference among multidisciplinary, interdisciplinary, and transdisciplinary team models (Table 2-3). Traditional *multidisciplinary* teams are often focused on disease states and are limited to specific organ systems. In multidisciplinary teams, clinicians work in isolation, with limited communication and collaboration. These models tend to focus on body parts or systems in isolation, not recognizing their interdependency. Developing a common

goal of health facilitation allows professionals to come together to develop *interdisciplinary* teams that encourage insight toward new ways of problem solving not previously in the group’s consciousness. When a new insight develops, the interdisciplinary team becomes a *transdisciplinary* team as its members develop novel ways to create (or promote) health that transcend the “siloed” model of care (Choi and Pak, 2006; Soklaridis et al., 2007).

Accountable care organizations (ACOs) are an example of *interdisciplinary* communication and coordination of care to eliminate waste while improving care for specific disease-based conditions such as congestive heart failure (Berwick and Hackbarth, 2012). Although ACOs will benefit from patient-centered medical homes, they continue to focus within a disease-care paradigm and thus are not an example of *transdisciplinary* care. *Transdisciplinary* care will require teams that partner with patients and help them achieve their health goals. This transcendence asks the patient, “What do you want your health for?” The answer will direct the energy of the team, and the disease will often improve as a consequence.

WHO SHOULD COMPRISE THE HEALTH TEAM?

The family physician knows the population of the community served and their specific health care needs. This insight will define the professionals who will be of most benefit for health creation (promotion). For example, obesity is a significant health threat in many locales. A team of professionals working together toward sustained optimal weight for patients might include a registered dietician, an exercise physiologist, and a psychologist or mind–body practitioner to understand the interplay between stress and eating. The process to develop a health-oriented team for musculoskeletal health (back pain) is summarized in Table 2-4.

The health team may look different from a disease team, but there will be obvious overlap. For example, a health home may include a nutritionist or health coach who works with patients who have diabetes. This team member can also provide counseling for prediabetic persons and overweight youths to prevent the expression of a disease that is influenced by lifestyle choices.

HEALTH TEAM MODELS

There are many ways to develop health-oriented teams. The approach will depend on the needs of patients, the population served, the availability of team members, the size of the clinic, strategic needs, and the support of administration and clinic staff. Teams can be initiated in all sizes of clinics, from large, complex institutions to small, rural settings, and may take many forms. For example, a team may include only the family physician and two health coaches or medical assistants. This “teamlet” model extends the office visit to include communication before, during, and after the visit (Bodenheimer and Laing, 2007). The teamlet uses these opportunities to address patient needs and develops appropriate strategies. The health team’s common mission is working toward the greatest improvement in the patient’s quality of life.

The team members do not need to share the same space as long as they maintain communication and build

Table 2-4 Health-Oriented Team Creation Worksheet (Example: Achieving Optimal Back Health)

Task	Action
Health need of my community	Achieving optimal back health
Identify professionals to address health need.	1. Manual practitioner 2. Physical therapist 3. Psychologist or “mindfulness” instructor 4. Health coach
Delineate the team-focused goal/mission.	To empower patients to learn how to achieve their ideal back function and health
Name the health-oriented program.	“Back to Health” program
Create relationships among team members.	Team members to meet initially to develop program goal or mission and methods of interacting; periodic meetings as needed for team building and interactions around patient issues
Agree on team communication method.	Fax or e-mail will be sent to the team for referrals, findings, and discussion.
Follow up and promote sustainability.	Patient will meet periodically with health coach or nurse at the medical home to sustain lifestyle behaviors.

intermember relationships. This helps clinicians learn of each other’s interests and talents in relation to common goals, fostering mutual understanding, trust, and respect. Without the team concept, there will simply be separate therapies and professionals working in isolation, causing fragmentation of care.

The most important ingredient in effective teams is trust—trust that each team member will play his or her particular part in care delivery and process improvement (Sargeant et al., 2008). Changing to an effective team approach takes humility and time and requires constant fine tuning and quality improvement. Miller and Crabtree (2005) have developed a comprehensive model of team care operations and describe effective techniques to build effective team processes. However, the physician can begin in any domain that fits the readiness of the practice (see Table 2-4), and the effects will often spread to other domains. The following checklist provides some places to start in a practice assessment format.

The Health Home Checklist

- Create a “home” where those who enter feel known and welcome. Patients will remember how they *felt* in a health home longer than what they are told. This starts with how they are greeted when they come in.
- Create a common mission supported by all health home members; for example, “To invest in a continuous healing relationship for the well-being of the community we serve.”
- Provide multiple ways to access care from the most appropriate health professional, including using technology to provide interaction outside the office encounter (see Figure 2-4).
- Provide a variety of encounter visits that complement the one-on-one office visit. These may include group visits, e-mail, video access, support groups, and health promotion or disease-focused programs.
- Create relationships through open communication with a team of health professionals who are configured specifically for each patient to positively influence lifestyle behaviors or address specific disease states and management needs.
- Provide a way for the consumers (patients) to have input into what health-related programs or services are implemented based on their perceived needs and explicit goals.
- Provide an opportunity to understand the most important areas that patients believe need to be addressed for their long-term health. (See eBox 2-1, health agreement document online.)
- Learn to provide rapid and evidence-based information on lifestyle and conventional and complementary medicine in each team encounter.
- Review the space of the practice and develop a plan to make it less stress-inducing and more comfortable and conducive to communication and operations for the patient and team members.
- Make sure the health home resonates with that which gives family physicians meaning and purpose in their work. This will translate across the medical home, encouraging team acceptance while reducing the risk of burnout.

Lessons from Early Adaptors

A national demonstration project was launched in 2006 to implement and study the patient-centered medical home model. The findings of this project confirmed that this can be done, but change is slow and should recognize the unique aspects of each individual health team and the needs of its community. A strategy that may be successful for one health home will be different for another (Crabtree et al., 2010). In fact, many of the challenges that were encountered in shifting a culture from a throughput disease model to one of patient empowerment and population management are similar to the challenges seen in facilitating health in complex systems (Bitton et al., 2012). The characteristics of effective PCMH were found to include:

Interpersonal autonomy. Physicians needed to learn to work with teams, and the teams needed to understand and identify with their new roles (Cronholm et al., 2013).

Uniqueness. Every site had its own underlying story that influenced the projects they would work on. The talents and expertise of the team often directed projects that resulted in the most success (Alexander et al., 2013).

Leadership engagement. Success requires commitment from system leaders to provide resources needed for sustainability (True et al., 2013).

Communication. Invest in a communication plan that may include regular meetings and access to patients and team members through electronic health records for ongoing coordination of care and interprofessional collaboration.

Health Agreement

Welcome to the Odana Atrium Clinic! Our focus is your health, but to succeed, we need your help. We may only spend a few hours together each year, setting the stage for how you can optimize health and well-being the rest of the time. We can guide you along the way, but all healing is really self-healing. You choose how you spend your time. We are here to walk the path with you, but it is your path!

Although it is vital to keep your parts working and to fix them as needed, we also want to focus on you as a *whole person*. That means paying attention to emotions, thoughts, beliefs, culture, relationships—all the things that make you who you are. If you do this, you will be sick less often, need fewer drugs and procedures, and have a better quality of life. Please join us in committing to your wellness.

I, _____, will do my best to promote my own health. I acknowledge that the following areas are beneficial to my well-being:

1. **Movement and exercise.** I will try to do some form of vigorous movement or exercise most days of the week.
2. **A healthy diet.** I will try to eat at least 7 servings (*1 serving size = the size of the palm of your hand*) of fresh fruits and vegetables daily. Whenever possible, I will use organic and locally produced food, including multicolored whole foods that were recently alive. I will try to limit foods that are processed or have many difficult-to-pronounce artificial ingredients.
3. **Rest.** I acknowledge that my body and mind need rest to heal and restore. I will try to get enough sleep each night, and I will take short naps during the day if needed.
4. **A healthy weight.** I will do my best to move toward and maintain a weight that is healthy for me.
5. **Avoiding harmful substances.** If there are substances that are harmful to me and that I would have trouble giving up,

such as certain foods, caffeine, tobacco, alcohol, and drugs, I will seek help in reducing or giving them up.

6. **Healthy relationships.** I will focus on having healthy family ties, friendships, sexual connections, and other types of relationships. I understand that caring for others and being cared for are good for my community and me.
7. **Managing stress.** I understand that the body and mind are one. When one suffers, the other is also affected. I will mindfully pay attention to where and how I feel stress in my body and explore paths to ease.
8. **Connecting with nature.** I acknowledge that the environment influences my health, and I will do my best to help protect it. Being in nature is healing, and I will spend time exploring it.
9. **Spiritual connection.** Spirituality is something that I define for myself. I recognize that being helpful and kind to others is good for me. I will reflect on what gives my life meaning and purpose, and I will do my best to help it grow and share it with others.
10. **Maintaining balance.** I acknowledge that time for myself, with others, and for play is just as important as work and finances. I will do my best to find balance in my life.

I will do my best to practice these healthful lifestyle habits. I feel I should start with number(s) _____.

Health Partner

Date

As your health care practitioner, I will help you work toward these goals. I will do my best to provide health care that is easily accessible, compassionate, continuous, and grounded in good science. I will do my best to assist your own capacity to heal.

Healthcare Practitioner

Modified from the Odana Atrium Clinic at the University of Wisconsin Department of Family Medicine, Wis.

Payment. It is difficult to sustain new payment models if there is no support for non-face-to-face work that is required to improve access and value. Be an advocate for policy change that pays for coordinated team-based care and the health outcomes the team has as their priority.

Patience. Creating patient-centered medical homes cannot be done in isolation because they are a foundational ingredient of a larger health care system that takes time to change. Celebrate each small step toward this cultural transformation.

Payment Models for the Health Home

In the past several years, it has become clear that a simple, office visit only, episode-based, disease treatment model alone will not allow for the optimal delivery of the patient-centered medical home. Although several elements of the Affordable Care Act favor the PCMH, transition to an effective payment model will be essential of those elements to work. Recently, the AAFP has embarked on a rethinking of how to align payment models for the “health home” (Family Medicine 2.0), examining everything from bundled capitated, per patient, per month models to blended models that still optimize preventive and postvisit care. Primary care is at the center of our health care delivery system and affects the functioning of both downstream care (tertiary, hospital, and emergency department care) and upstream care (prevention and population health). Family physicians can be the leaders in these efforts by pushing for the widespread adoption of global payment models as soon as possible even if they currently do not rely on those models for payment. The time for adequate investment in primary care has come.

Conclusion

Creating OHEs with health-oriented teams honors the concepts of the medical home as primary care physicians transition from medical care to health creation as a critical focus (see [Table 2-2](#) and [Figure 2-2](#)). This is an exciting opportunity for professionals from varied disciplines to come together to work toward a common goal. The family physician’s expertise in understanding the interplay of biopsychosocial systems makes this profession uniquely qualified to lead the implementation of these models of care.

The gift of primary care is the human connection that occurs within continuous healing relationships. Family physicians will succeed in providing efficient, cost-effective quality care if they invest in ingredients that are the most valuable yet most difficult to measure, the most important one being that nonquantifiable bond of intention, trust, and communication between the practitioner and patient in which both are transformed ([Scott et al., 2008](#)).

EVIDENCE-BASED SUMMARY

- Positive lifestyle behaviors have the largest effect on reducing morbidity and mortality for chronic disease ([Khaw et al., 2008](#); [McGinnis et al., 2002](#); [Schroeder, 2007](#)) (SOR: A).
- Team-based interventions are more effective in promoting healthy behaviors than are those that provide isolated therapy ([Safran et al., 2006](#); [Woolf et al., 2005](#)) (SOR: B).
- Relationship-centered care improves quality of care and clinical outcomes ([Starfield, 1991](#)) (SOR: B).
- Relationship-centered care reduces health care costs ([De Maeseneer et al., 2003](#); [Epstein et al., 2005](#)) (SOR: B).

Psychosocial Influences on Health

SYED M. AHMED, PAUL J. HERSHBERGER, and JEANNE PARR LEMKAU

CHAPTER OUTLINE

Conceptual Models, 26
Integration of Psychosocial Issues in Clinical Practice, 30

Evidence-Based Practice, 32
The Patient-Centered Medical Home, 32
Conclusion, 33

Key Points

- Factors that influence health include age, gender, and sexual orientation.
- Religious, ethnic, and cultural groups affect individual functioning.
- Individuals are affected by family composition, structure, and functioning.
- The health of an individual is influenced by work and school status.
- Individuals are affected by their social support network and significant others.
- Financial resources, including health insurance status, affect health status.
- Personal and family history of major loss, trauma, or illness should be integrated into the assessment of a patient's health status.
- Psychological functioning, including personality, defensive style, and current mental status, warrants evaluation.
- Self-control is a limited resource that can be replenished with healthy food, sleep, and practice.
- Data about the patient's physical environment, including home, neighborhood, and environmental hazards, are essential.
- The physician should elicit an account of recent stressors and changes in the patient's life.
- A collaborative physician–patient relationship that emphasizes physician listening is the foundation for sensitive psychosocial care.

- An overweight 11-year-old boy with abnormal lipids tells his family physician that his favorite activity is playing online video games.
- A middle-aged woman emphatically asserts that her blood pressure is elevated only when she has it taken in a medical setting.
- A single mother with a part-time job but no health insurance tells her doctor that she can only take medications that have low co-pays.

Psychosocial factors influence health. Assessing and treating patients in a manner that integrates psychosocial and biologic aspects of care is the essence of excellent family medicine and its greatest challenge. The following example is illustrative.

Mr. Ramirez is a 52-year-old man who lost his well-paying job as a software engineer several years ago. After 8 months of unemployment, he took a less satisfying job for less money. Mr. Ramirez has type II diabetes, diagnosed when he was 45 years old and well-controlled before he lost his job. He has taken diabetes education classes and can accurately describe what he must do to maintain good glucose control. Reluctantly, Mr. Ramirez acknowledges to his physician that he does not follow his diet as closely as he

once did and more frequently eats fast food. He also misses the exercise facility at his former workplace and struggles with motivation to exercise. His marriage “isn't as good as it used to be,” and he reports decreased interest in sex. When the physician asks him about feelings of depression, Mr. Ramirez says that he never thought he was a weak person, but he just does not enjoy things as he once did. His physician summarizes the changes Mr. Ramirez has experienced in the past few years and acknowledges the emotional toll of such stress. She briefly describes how stress and depression make diabetes more difficult to control and how she and Mr. Ramirez can collaboratively work on strategies to improve his health and quality of life.

This case highlights the following three imperatives for providing care that is appropriately responsive to psychosocial issues:

1. The physician sees the person first, conceptualizing symptoms and behaviors in his social and psychological context and responding with sensitivity to the patient's experience and priorities.
2. The physician understands the interactive nature of multiple biopsychosocial variables and communicates this effectively to the patient.

Table 3-1 Psychosocial Influences: Conceptual Models

Biopsychosocial model
Systems approach
Stress and coping model
Life span perspective
Ethnomedical cultural model

- The physician fosters a supportive and empathic physician–patient relationship to provide the foundation for gathering information and intervening effectively.

As the case illustrates, biomedical factors may be only a small part of what patients bring to their physicians. The biomedical model, based on the assumptions of mind–body dualism, biologic reductionism, and linear causality, has resulted in miraculous achievements of high-technology medicine, but primary care physicians who restrict their attention to purely medical considerations are of limited use to their patients. Nevertheless, the shift from a biomedical to a biopsychosocial paradigm has been a major challenge to modern medicine.

In 1977, psychiatrist George Engel proposed a biopsychosocial model that included social and psychological variables as crucial determinants of disease and illness. According to his new framework, the subsystems of the body interact to produce successively more complex biologic systems, which are simultaneously affected by social and psychological factors. The organism is thus conceptualized in terms of complex interacting systems of biologic, psychological, and social forces, and neither disease nor illness is seen as understandable only in terms of smaller and smaller biologic components. Engel (1980) believed that systemic interactions of biopsychosocial factors were relevant to all disease processes and to the individual's experience of illness. Accordingly, understanding a person's response to a disease requires consideration of such interacting factors as the social and cultural environment, the individual's psychological resources, and the biochemistry and genetics of the disorder in the population (Brody, 1999).

In the following section, we present a number of conceptual models and perspectives that emphasize different but overlapping psychosocial dimensions that influence health (Table 3-1). These models can aid practicing physicians in thinking about their patients in psychosocial context and conceptualizing potentially helpful interventions. Subsequently, we elaborate on practical strategies for gathering and using psychosocial information in clinical practice and discuss a pragmatic approach to addressing psychosocial considerations in primary care. We conclude with brief discussions of evidence-based practice and how current challenges and trends in the health care system may affect the practice of family medicine.

Conceptual Models

THE BIOPSYCHOSOCIAL MODEL

As previously noted, the biopsychosocial model was proposed as a scientific paradigm by Engel (1977), who encouraged the clinician to observe biochemical and morphologic

Table 3-2 Five-Factor Model of Personality

- Openness to experience: tendency to be curious and appreciative of a variety of experiences
- Conscientiousness: proclivity to be self-disciplined, to plan, and to direct behavior toward achieving goals
- Extraversion: preference for being around other people and to be enthusiastic and socially energetic
- Agreeableness: inclination to be cooperative with others; strongly preferring harmony over disagreement
- Neuroticism: propensity to experience negative emotions on an ongoing and regular basis

changes in relation to a patient's emotional patterns, life goals, attitudes toward illness, and social environment. Engel proposed that the brain and peripheral organs were linked in complex, mutually adjusting relationships, affected by changes in social as well as physical stimuli. Within this model, environmental and psychological stress is seen as potentially pathogenic for the individual. Emotions may serve as the organism's bridge between the meaning (or significance) of stressful events and the changes in physiologic function (Zegans, 1983). Engel urged physicians to evaluate the patient on biologic, psychological, and social factors to understand and manage clinical problems effectively (Wise, 1997). For example, a workplace accident could be seen as resulting from poorly designed equipment (social) and inattentiveness (psychological) brought about by low blood sugar (biologic). Similarly, the accident could result in damage to internal organs (biologic), distress (psychological), and lost income (social), any or all of which may become the focus of physician intervention.

Comprehensive evaluation of biopsychosocial dimensions would assess the following:

- Biologic factors, including genetics, medical history, and environmental factors that affect physiologic functioning (e.g., those causing cancer)
- Psychological factors, including affective, cognitive, and behavioral components, such as feelings, beliefs, expectations, personality, coping style, and health behaviors (e.g., exercise, diet, smoking) that contribute to patients' experience of health and illness
- Social factors, including access to health care, quality of available health care, social systems (e.g., family, school, work, church, government), social values, customs, and social support

Further discussion of biologic influences on health is beyond the scope of this chapter. Psychological and social factors known to affect health are discussed next.

Psychological Factors

Numerous psychological factors affect health. We discuss here a common approach to personality, the five-factor model, and an essential psychological resource for healthy behavior, self-control. We also review key findings from the literature on the relationship between emotions and health.

The most prominent approach to personality at present is the five-factor model (Goldberg, 1993). The five broad personality domains of this model, for which OCEAN is an acronym, are openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (Table 3-2). Research on the relationship of these factors to health

Table 3-3 Self-Control

Self-control is a limited resource, like a muscle. It can be replenished.

Self-control is used to:

- Regulate emotions
- Control thoughts
- Manage impulses
- Direct performance
- Make decisions

Self-control is replenished or strengthened through:

- Fuel (healthy food at regular intervals)
- Sleep
- Practice

People high in self-control tend to plan and adjust their schedules or environments to reduce demands on willpower (desired behaviors are more automatic, and temptations are minimized).

variables has generated several findings. Whereas conscientiousness has been associated with longevity among healthy individuals and better functional status in those with physical illnesses or impairments, neuroticism is consistently found to be negatively correlated with health (Bogg and Roberts, 2013; Goodwin and Friedman, 2006; Smith and Mackenzie, 2006). Agreeableness, extraversion, and openness to experience generally tend to have weaker associations with health.

Because personality style tends to be quite stable across the life span, physician focus on changing personality for health reasons is not a sensible pursuit. However, an understanding of a particular patient's personality can help guide the physician toward interventions that are more likely to be effective.

Because health behaviors are a major factor in the development of, management of, and morbidity from chronic illnesses, self-control or willpower is a critical psychological resource. Children with more self-control have been found to have better health as adults. Adults with more self-control have healthier behaviors. Research indicates that willpower operates like a muscle; it is a resource that people have in limited supply, and it can be exhausted (Baumeister and Tierney, 2011). Fortunately, it can also be replenished. Importantly, various demands for willpower draw from the same common resource. Willpower is used to control thoughts, regulate emotions, manage impulses (the task most commonly associated with willpower), and direct performance. Making decisions uses willpower. Numerous studies have demonstrated that tasks requiring willpower deplete the self-control resource, so that performance declines on subsequent tasks requiring willpower. Interestingly, when there are competing demands for the self-control resource, managing negative emotions predictably takes precedence over other demands. Given the multiple emotional and behavioral challenges associated with the management of chronic illness, a patient with excessive demands on the limited self-control resource is particularly vulnerable to worsening health. See Table 3-3 for a summary of key factors about self-control, including how it can be replenished.

The ongoing experience of chronic negative emotions (depression, anxiety, and anger) tends to be associated with poorer health. There is an extensive research literature linking negative affectivity and pessimism to adverse

health outcomes (Peterson et al., 1988; Salovey et al., 2000). Although the experience of negative emotions is a natural part of the human experience, effective management of such emotions through cognitive strategies, active coping, and social support can be learned, and medications can be a helpful adjunct when negative emotional states are prolonged or severe.

Likewise, a large body of research indicates that positive emotional states are associated with better health and longevity. Happiness, optimism, and positive attitudes toward aging have been associated with 7 more years of life (Danner et al., 2001; Levy et al., 2002). Almost three decades of research have shown that an optimistic outlook has a positive effect on coping and on mental and physical health outcomes (Peterson and Steen, 2002). Family physicians have long recognized the importance of mobilizing and maintaining patient hopefulness through encouraging words that foster positive expectations of medical treatment. The demonstrated efficacy of placebos affirms the importance of this approach (Sobel, 1991).

Social Factors

A gradient between socioeconomic status (SES) and health is consistently found in epidemiologic studies (Marmot, 2004). Persons with less education and income tend to have poorer health than their better educated and richer counterparts. A recent analysis indicates that in the year 2000 in the United States, 245,000 deaths could be attributed to low education, 176,000 to racial segregation, 162,000 to low social support, and 133,000 to poverty (Galea et al., 2011). Interestingly, subjective SES (i.e., individuals' perceptions of where they view themselves on the social ladder) has an even stronger relationship to health than objective SES (Singh-Manoux et al., 2005). Negative affect, stress, pessimism, and a decreased sense of control are among the factors thought to contribute to the relationship between lower subjective SES and poorer health (Operario et al., 2004).

In general, social support reduces stress and contributes to more positive health outcomes. Social support refers to the process by which a social network provides psychological and material resources to enhance an individual's ability to cope with stress (Cohen, 2004). Both quantity and quality of support are important, and sources of support include spouses, lovers, friends, family, coworkers, and health care professionals. A person who has many friends but no confidant may have inadequate social support in a time of need. Some people report high levels of satisfaction with just a few close friends, but others require larger social networks.

There are several varieties of social support (Cohen, 2004). Emotional support involves the expression of caring, concern, and empathy toward the person and typically involves opportunities for the recipient to express emotions. Instrumental support involves providing some type of direct assistance, which might include financial resources, transportation, or help with daily tasks. Informational support involves giving advice or information relevant to an individual's situation.

Social support appears to undergird health by buffering the person against negative effects of stress, perhaps by affecting the cognitive appraisal of stress. When people

encounter a strong stressor, such as a major financial crisis, individuals with high levels of social support may appraise the situation as less stressful than will those with low levels of support. Social support may further buffer the stress by modifying people's response to a stressor as they turn to friends for advice, reassurance, or material aid. Social integration, or participating in a broad range of social relationships, benefits health and well-being by enhancing self-esteem and fostering positive health behaviors in people who believe that others count on them. Social integration is beneficial, whether or not an individual is experiencing stress (Cohen, 2004).

Relationships also can involve significant negative social exchange and be harmful to health; negative interactions in troubled marriages have adverse effects on cardiovascular, endocrine, and immune system function (Robles and Kiecolt-Glaser, 2003). Recent research has found specific links between negativity in relationships and cellular aging, such as shortening telomere length (Uchino et al., 2012).

Misconceptions

Polan (1993) identified and addressed two common misconceptions about the biopsychosocial model. First, contrary to popular belief, a physician who is "humanistic" is not necessarily practicing biopsychosocial medicine. A physician can be ethical and caring but still neglect scientific knowledge from the social and behavioral sciences and relevant data from the patient's life. For example, compassion by itself is of limited usefulness to a physician who needs an effective treatment plan for a patient with asthma who smokes. Interventions should be informed by knowledge of the social environment and the individual psychology of the patient.

The second misconception is that people can be reduced to distinct biologic, psychological, and social categories or that their problems can then be expressed as a set of scientific principles from which diagnosis and treatment can be neatly derived. In fact, use of the biopsychosocial model increases rather than decreases the level of complexity required to understand patient status, introducing multiple avenues for intervention. Interpreting the biopsychosocial model as a new opportunity for reductionist thinking diminishes its power to inform more holistic treatment. Borrell-Carrio and colleagues (2004) proposed a biopsychosocially oriented clinical practice based on self-awareness, active cultivation of trust, an emotional style characterized by empathic curiosity, self-calibration to reduce bias, cultivation of emotional sensitivity to assist with diagnosis and therapeutic relationships, use of informed intuition, and communication of clinical evidence to foster dialogue.

Another important misconception is that educating patients about important biologic, psychological, social, or environmental factors will necessarily change behavior. Much of human behavior is automatic, cued by environmental or situational factors. Health behaviors are frequently less a product of thoughtful choices than of non-conscious factors (Sheeran et al., 2013). Although intention and motivation affect adherence to treatment regimens and health behavior recommendations, multiple other factors (e.g., depletion of self-control, media and peer influences, physical environment) play important roles.

THE SYSTEMS APPROACH

Humans are infinitely complex. Adequately conceptualizing a person in health or illness requires a systems approach that encompasses this complexity. The concept of systems was first developed by von Bertalanffy (1968) to refer to the dynamic interrelationships of various components. A systems approach rejects the notion of linear causality in favor of multidimensional and multidirectional models.

The systems approach has strongly influenced conceptualizations of family functioning. Smilkstein (1978) developed one of the first applications of "family systems" thinking for family medicine. Physician attention is important in the systemic interactions of family members and the impact of crisis, coping styles, and resources on family functioning. He incorporated these components into the "family APGAR" (adaptation, partnership, growth, affection, and resolve), a simple instrument and mnemonic device for assessing the functioning of a family system in health and illness (not to be confused with the newborn Apgar score).

THE STRESS AND COPING MODEL

General relationships among life stresses, coping resources, and health outcomes are presented schematically in Figure 3-1. This approach represents another example of the application of a systems model. In this model, health outcomes are impacted by how life stresses affect the individual. The effect of stress is moderated by the individual's appraisal and coping responses, personality, and the person's available social resources. Although the complex synergistic interactions that characterize these relationships are beyond the scope of this chapter, the major variables provide a basis for considering physician interventions.

Definitions of Stress

Stress has been variously defined as an environmental event, a response to an event or circumstance, and a process. One approach defines stress in terms of life events—as a stimulus—circumstances or events that require the person to adapt produce feelings of tension. These stressors may be major catastrophic events (e.g., natural disaster), major life events (e.g., death of a loved one), or recurrent daily hassles (e.g., need to manage a chronic medical condition).

Stress can also be seen as a response. For example, a person with a social phobia feels stressed at a party, experiencing a psychological state of nervousness with associated physical symptoms of dry mouth, palpitations, and sweating. This physiologic and psychological response to a stressor is often called *strain*.

A third approach emphasizes stress as a process in which "environmental demands tax or exceed the adaptive capacity of an organism, resulting in psychological and biologic changes that may place persons at risk for disease" (Cohen et al., 1995). Within this approach, stress includes stressors and strains along with the relationship between the person and the environment. The process involves transactions between the person and the environment, with each affecting and being affected by the other (Sarafino, 1990). "Adaptive capacity" is operationalized in terms of resilience and vulnerability; within this model, the physician considers aspects of a person's psychological makeup

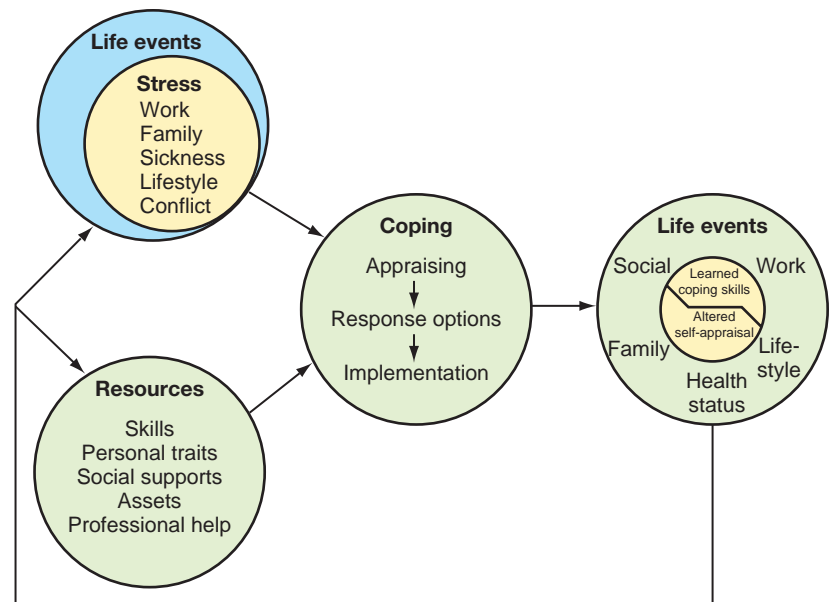

Figure 3-1 Stress, life events, and coping. (From Tunks E, Bellissimo A. *Behavioral Medicine: Concepts and Procedures*. Boston, Pergamon Press. Copyright 1991 Pergamon Press.)

and social world that may render the patient more susceptible or more resilient (Step toe, 1998).

Stress Appraisal and Coping

Every family physician sees patients under stress who present with a wide spectrum of stress-related symptoms and coping responses. How the individual interprets and copes with stress are as significant as the stressor itself. Cognitive appraisal of a stressor, rather than severity or duration alone, determines physiologic and behavioral responses (Epel et al., 1998).

Coping refers to how individuals manage the real or imagined discrepancy between environmental demands and their resources for addressing the stressful situation. According to Lazarus and Folkman (1984), adaptation to stress is mediated by appraisal (i.e., personal meaning of a stressor and one's sense of resources for dealing with it) and coping (i.e., thoughts and behaviors used to manage stress). Whereas with emotion-focused coping, a person directs energy to regulating internal feeling states, with problem-focused coping, a person directs attention to reducing the stressor or expanding resources for dealing with it (Sarafino, 1990). The effect of stressful life events on health is determined by many factors related to coping, including cognitive style, personality characteristics, and social and behavioral tendencies.

Personal Control

An individual's perception of the extent of his or her control in a stressful circumstance is a critical component of the appraisal process in coping. This includes control over the stressor as well as control over one's responses, whether problem-focused or emotion-focused. How a person deals with the loss of control precipitated by stressful life events can affect health outcomes.

Personal control can be defined as the feeling that one can make decisions and take effective action to produce desirable outcomes and avoid undesirable ones (Rodin,

1986). Mobilizing a strong sense of personal control can significantly reduce the impact of stressors on the individual, particularly when the response is appropriate to the circumstance. Sarafino (1990) classified personal control into the following five types:

1. Behavioral control involves the ability to take concrete action to reduce the impact of a stressor. For example, using a special breathing technique may help reduce pain.
2. Cognitive control involves the ability to use thought processes or strategies to modify the impact of a stressor. For example, focusing on a pleasant thought during suturing of a laceration may decrease the pain sensation.
3. Decisional control involves the opportunity to choose among alternative procedures or courses of action. For example, a victim of domestic violence may benefit from considering various options for when and how she will leave her abuser.
4. Informational control involves the opportunity to obtain knowledge about a stressful event, what will happen, why, and what consequences are likely. For example, a patient may feel less anxious about upcoming surgery upon learning more about managing discomfort from the procedure.
5. Retrospective control involves beliefs about causation of a stressful event after it has occurred. The attribution that the person makes about the adversity can affect future perspective and behavior. For example, attributing misfortune to factors that are temporary and specific leaves an individual feeling more optimistic than when misfortune is attributed to stable and global factors (Seligman, 1990).

Life stresses affect health outcomes. These effects are moderated not only by individual differences in genetics and pathophysiology but also by psychosocial factors. Psychosocial influences include appraisal and coping, personality traits, cognitive style, and such resources as social support.

THE LIFE SPAN PERSPECTIVE

The life span perspective emphasizes the importance of an individual's place on his or her personal developmental trajectory. Past development, current status, and anticipated developmental changes and challenges are taken into account. On the biologic level, changes in cellular functions occur from infancy through old age; decline in physical stamina is one manifestation of this dynamic change. On the psychological level, personality interacts with ongoing changes that occur across the life span (e.g., becoming a parent), and each developmental stage brings its own psychosocial challenges. Erikson's eight stages of development highlight the importance of trust issues in infancy, autonomy issues in early childhood, and issues of generativity and meaning in old age (Erickson, 1959). On the social level, family and peer relationships change throughout life, with significant implications for health, which may be either positive or negative. For example, the typical adolescent's shift toward greater reliance on peer relationships may lead to behaviors that endanger health, such as smoking or substance abuse. The death of a husband who has been physically abusive may lead to improved well-being for the surviving wife. The primary care physician needs to keep the life span model in mind and assist patients in addressing psychosocial factors that facilitate or block health and development.

THE ETHNOMEDICAL CULTURAL MODEL

Every encounter between a patient and a physician is a cross-cultural transaction. Each person brings to the physician–patient relationship a unique mix of culturally embedded attitudes, knowledge, and beliefs. Ethnicity, gender, religion, language, education, and personal history shape expectations and behavior on both sides of the relationship. A physician's cultural proficiency is instrumental in establishing rapport and gathering information for accurate and comprehensive diagnosis and treatment (Carrillo et al., 1999). The patient's acculturation status and cultural background are important to understand, and physicians should become familiar with the dominant cultural groups they serve.

The ethnomedical cultural model emphasizes cultural concepts relevant to health and illness (Kleinman et al., 1978), including patient beliefs and expectations about the body, illness, and treatment. Berlin and Fowkes (1983) operationalize this model in clinical encounters with their LEARN acronym, exhorting physicians to do the following:

- Listen with empathy and understanding to the patient's perception of the problem by eliciting the patient's explanatory model for the illness.
- Explain your perceptions or explanatory model in language the patient can understand.
- Acknowledge the differences and similarities between your explanatory model and that of the patient and discuss any significant discrepancies.
- Recommend treatment that you decide is optimal within your explanatory model.
- Negotiate treatment with the patient, seeking a compromise that is acceptable to the patient, is consistent with

your ethical standards, and uses the patient's social network when necessary.

The ethnomedical cultural model highlights cross-cultural elements in all physician–patient interactions.

Integration of Psychosocial Issues in Clinical Practice

Wynne (2003) states, "In the 'real' world of health care, systems thinking is more needed than ever before, but its increased complexity challenges both clinicians and researchers to the depths of their resources." Knowledge, attitudes, beliefs, emotions, behaviors, relationships, and social/environmental factors interact to affect the experience of illness or well-being. Accordingly, physicians' ability to promote health and relieve suffering depends on their ability to engage effectively in this complex web of interrelationships. This is a daunting task that depends on fostering a quality relationship over time, gathering sufficient biopsychosocial data about each patient, and integrating data with theoretic understanding to inform interventions.

The challenge for even the most astute physician is to assess and address psychosocially important issues within the limited time available for each patient. In a 10- to 15-minute period, a detailed evaluation of all relevant psychosocial factors is an impractical goal. Using a pragmatic approach that balances this goal with time constraints, a physician can maintain awareness of psychosocial cues and information in all patient encounters while restricting direct inquiry, depending on the specific situation. A physician may not need to elicit a detailed psychosocial assessment with every patient who presents with an upper respiratory infection, but knowing if the patient smokes would be useful, leading to further inquiry and potential smoking intervention.

Following pragmatic considerations, a physician should work collaboratively with patients to identify problems of highest priority and to address less pressing issues in subsequent encounters. For example, in the case of domestic violence, immediate needs for patient safety must be addressed. Addressing long-standing issues, such as dysfunctional means of coping with stress, must be a secondary concern in the face of the primary need to achieve safety. Similarly, every physician learns to place high priority on patient complaints of chest pain, adjusting questioning depending on the patient's age, gender, family history of coronary heart disease, and patient medical history. Nevertheless, the physician must look for psychosocial clues, evaluate stressors, and be aware of factors that suggest an anxiety or somatization disorder. These secondary factors can be addressed in more depth when the physician is assured that a cardiac crisis is not imminent.

COLLECTION OF PSYCHOSOCIAL DATA

In family practice settings, the most common and natural approach to gathering psychosocial data is interviewing the patient over time. Freud suggested that the major

achievements of healthy development were the abilities “to work and to love,” and this is often a good place to start. Where does this patient work, and how does he or she feel about the job, school, or household responsibilities? Who is “family” for this patient, and what is the nature of the support system? Detailed inquiries about work and love made in the context of the ongoing physician–patient relationship result in significant accretion of knowledge over time and make it easy to flag stressful changes in these important arenas.

Other important areas of inquiry include the patient’s physical and social environment. Factors such as the quality of housing, neighborhood, food, and financial resources all affect patient safety, health care use, family stress, and physical health. Understanding the ethnic, religious, and political culture of a patient and family is important for guiding culturally appropriate care. Personal and family history, usually gathered gradually over time, can alert the physician to important family coping patterns, strengths, and liabilities. Of special importance is information on major personal family “dislocations,” including losses, illness, and trauma. Knowledge of any traumatic encounters with previous health professionals or with previous medical procedures may help the physician anticipate and manage potential crisis situations.

Information from patient dialogue can be supplemented by standard measures such as health questionnaires (e.g., Short Form 36); screening inventories (e.g., Beck Depression Inventory); and stress, coping, and social support tools. Other means of gathering relevant data include informal interviews with family members, structured assessments (e.g., family APGAR), review of existing records (e.g., school records), consultation with nonmedical colleagues (e.g., psychologist, occupational therapist), observation of the patient’s environment through home visits, and consultation with cultural informants and translators. Perhaps most important is the ongoing use of open-ended questions, so that important psychosocial data are elicited from the patient in the patient’s own words.

INTERVENTIONS USING PSYCHOSOCIAL DATA

A comprehensive review of interventions addressing psychosocial influences in health is beyond the scope of this chapter and would require discussions of clinical psychology, social work, nursing, occupational therapy, and public health. Even in optimal circumstances, competency can be achieved only within a limited range. Realistically, family physicians should pursue basic proficiency in selected interventional strategies and additional training in areas of interest relevant to their specific practice needs and the population they serve. Here we discuss pragmatic interventions for practicing physicians based on the general model of stress, life events, coping, and health discussed earlier.

Because health outcomes are affected by stressful life events, coping (e.g., stress appraisal), and resources (e.g., personality, social support), addressing any of these dimensions can have a positive effect on functioning. As stress increases relative to available support and coping capacities, disequilibrium results. Put simply, interventions that decrease stress or enhance support tend to improve well-being. Physician attention to factors that exacerbate or

mitigate is always valuable. For example, because a new medical diagnosis is stressful but a loving partnership is a source of support, assuring the presence of a loving family member when bad news is to be shared with a patient may lessen its negative impact. Some life events, such as the death of a supportive partner, affect several elements in the model, as the bereaved partner confronts a major loss (stress) without the person who had previously offered comfort in such times (decreased support). Not surprisingly, persons who are grieving are at higher risk for experiencing health problems (Rogers and Reich, 1988), and a focus on their support systems and coping strategies is almost always warranted.

Interventions that should be part of the standard repertoire for family physicians are those that do no harm, usually help, and use traditional skills. Specifically, physicians can work with patients directly to reduce stress, to enhance or mobilize social support resources, and to reinforce or model positive stress appraisal and coping. Direct approaches to stress reduction may include intervening in the patient’s environment (e.g., arranging respite care for an older patient to relieve stress on his middle-aged daughter) and allaying a patient’s unrealistic fears about an illness. Social support can be enhanced directly through the provision of more contact with the physician or indirectly through mobilizing the patient to increase contact with family or friends. Physicians can support positive coping through instilling hope, modeling optimism, and encouraging patients who adapt. Reminding patients of personal strengths previously used to confront crises is also helpful. The physician often can implement these strategies by asking questions that allow the patient to respond in a broader perspective (e.g., “What do you remember doing to help you cope with the death of your good friend several years ago?”). Especially when behavior change is indicated, collaborating in discussing options rather than giving advice is more likely to be effective. One collaborative approach that has demonstrated efficacy is motivational interviewing (Rollnick et al., 2008; Rubac et al., 2005).

In the provision of care within a biopsychosocial model, interdisciplinary teams, rather than solo practitioners, have the advantage, and physicians can have more positive impact on their patients’ lives when they harness the wisdom of colleagues from other fields through referral or consultation. Depending on physician training, interest, and time, these basic categories of intervention can be supplemented by a wide range of psychosocial interventions, from family therapy to behavior modification.

IMPORTANT TIMES FOR PSYCHOSOCIAL INTERVENTIONS

Interventions that attend to psychosocial issues are especially important at specific times in the provision of family medical care. Natural transitions in the family life cycle, such as the birth of a child or the death of a spouse, call on the physician to provide empathic support, assess the patient’s support system, normalize emotional reactions, and provide anticipatory guidance as patients confront changing family roles and functioning.

When adherence or lifestyle issues impinge on health, interventions that focus on biologic mechanisms alone are

likely to be ineffective. The health effects of substance abuse, domestic violence, poverty, or inactivity are often best addressed through attention to social environment and psychological concerns.

A dramatic change in patient symptoms also indicates consideration of psychosocial factors. A psychosocial crisis can provoke an exacerbation of a chronic condition (e.g., rheumatoid arthritis), a new manifestation of illness (e.g., myocardial infarction), or emotional-psychiatric symptoms (e.g., anxiety, trouble sleeping) best treated through stress reduction and symptomatic care.

A significant medical diagnosis may precipitate emotional distress or psychosocial upheaval and requires physician attention to the context of the patient's life. Effective physician intervention may involve anticipating the nature of the potential family crisis, including family members in discussions with the patient, and addressing family needs for support. Timely provision of accurate information can enhance a patient's sense of control. Direct support by the physician during the initial adjustment phase can minimize more serious emotional disruption.

Patients living with chronic illness require sensitive psychosocial care. Managing a chronic health problem challenges a person's ability to adhere to medical recommendations and to cope with other life stressors. Patients often cope in highly idiosyncratic ways. Pollin (1995) identified eight emotionally charged issues that patients with chronic illnesses inevitably confront: control, self-image, dependency, stigma, abandonment, anger, isolation, and death. These issues can often be effectively addressed within the physician-patient relationship and through judicious referral to support groups for chronically ill patients. As elaborated by Pollin, each issue can be met by an appropriate and helpful professional stance. In response to control issues, for example, professionals should help patients express their feelings of loss of control and identify areas where they may feel powerless. Normalizing the patient's feelings and fears is the first step in helping address control issues. The goal of intervening in regard to the issue of loss of control is to reinforce the patient's confidence in being able to cope with the demands of the medical condition.

Evidence-Based Practice

Increasingly, high-quality data are available that support the therapeutic efficiency of a variety of general and specific behavioral interventions relevant to primary care practice (Trask et al., 2002). A systematic review by Di Blasi and colleagues (2002) on the consequences of nonspecific effects of the physician-patient relationship found that providing information and emotional support contributed to recovery or improvement from physical illness. Because coping with stress and managing chronic illness often involve behavior change, physicians may use "motivational interviewing" approaches to assist these patients (Rollnick et al., 2008).

Much research demonstrates the efficacy of psychosocial interventions in diseases that have been historically viewed as purely medical, including cancer (Anderson et al., 2007; Edwards et al., 2008; Rehse and Pukrop, 2003; Spiegel et al., 1989) and diabetes (Bogner et al., 2007), and the

efficacy of behavioral interventions such as exercise for cardiovascular disease (Taylor et al., 2004). Online resources are available to search for study results (see Web Resources at end of chapter).

Given the time constraints primary care physicians face and the expertise required to use behavioral interventions effectively, the physician should know behavioral health providers in the community and refer to them promptly and often. The evidence base for effective behavioral interventions in numerous psychiatric and psychosocial problems, as well as medical problems, continues to expand (e.g., mood and anxiety disorders, trauma victims). Highly effective treatments are underused when physicians underrefer to mental health professionals with specialized training and overrely on the use of psychotropic medicines alone. Unfortunately, even when guidelines are available that physicians could follow themselves, resistance to change impedes their implementation (Torrey et al., 2001).

KEY TREATMENT

- Providing information and emotional support contributes to the improvement and recovery from physical illness (SOR: A; Di Blasi et al., 2002).
- Negative emotions such as anger, anxiety, and depression are associated with poor health (SOR: B; Salovey et al., 2000).
- Positive emotions such as happiness, optimism, and a positive attitude have been shown to add 7 years to life (SOR: B; Danner et al., 2001; Levy et al., 2002).
- "Motivational interviewing" outperforms advice-giving in addressing a broad range of behavioral problems (SOR: A; Rubac et al., 2005).
- Exercise-based rehabilitation for patients with cardiovascular disease is associated with reduced cardiovascular and all-cause mortality (SOR: A; Taylor et al., 2004).
- Treating depression in older patients with diabetes reduces mortality (SOR: A; Bogner et al., 2007).

The Patient-Centered Medical Home

Health care spending currently represents approximately 18% of the U.S. gross domestic product and is projected to surpass 20% within a decade (Sisko et al., 2009). There is ongoing concern about the number of uninsured and underinsured persons, although new legislation to expand insurance coverage took effect in 2014.

Numerous perspectives exist on how the health care system needs to change, but a consensus is emerging that focuses on the importance of primary care medicine and on managing chronic disease in the context of a high-quality physician-patient relationship (Bein, 2009). This consensus reflects the accumulating evidence that higher quality health care at lower cost is achieved when primary care is emphasized (Starfield et al., 2005).

The concept of the patient-centered medical home (PCMH) embodies this emerging emphasis. As discussed in Chapter 2, the numerous components of a PCMH (or "health home") include the use of an electronic health

record, better access and scheduling processes, use of evidence-based medicine, more point-of-care services (e.g., multidisciplinary teams, group visits), and ongoing emphasis on quality improvement. Some argue that incremental change in this regard is insufficient and that transformation of practices is necessary (Nutting et al., 2009). Such transformation would include a broad, population-based approach to preventive services and chronic care beyond a “single patient at a time” approach. However, even within such a model, services would need to be individualized based on the patient’s goals and unique situation, including attention to the psychosocial factors that affect chronic disease prevention and management.

These trends represent an opportunity for family medicine to take a leadership role in health care reform, with an emphasis on psychosocial aspects. The PCMH philosophy is consistent with family medicine’s long-standing emphasis on whole-person care in the context of a high-quality physician–patient relationship. Ideally, the family physician in a PCMH will address the psychosocial needs of patients in collaboration with ancillary providers as needed.

Conclusion

To practice in a way that sensitively integrates psychosocial concerns, a physician needs to have a solid knowledge base in the social and behavioral sciences (Cuff and Vanselow, 2004). This general knowledge base complements specific knowledge of self, patients, practice, and community. Self-knowledge entails an honest assessment of the physician’s knowledge base, skills, and attitudes relevant to comprehensive care. Acknowledging limitations in dealing with psychosocial issues in primary care is vital and can serve as an impetus for further training and the development of collaborative relationships with other

professionals. A responsible physician feigns neither knowledge nor empathy but relies on an interdisciplinary network of professional and community resources to complement personal limitations.

As Osler (1904) emphasized, knowing what kind of person has a disease is as important as knowing the disease. Knowledge of each patient is requisite to the provision of sensitive psychosocial care, with attention to life stresses, coping, personality, and social resources. Furthermore, the physician needs to know details about the population he or she serves, including demographic, socioeconomic, cultural, and epidemiologic dimensions. Addressing psychosocial issues in a practice that serves an ethnically diverse, indigent population presents different challenges than addressing the needs of an affluent population from a familiar ethnic and cultural background. Understanding the practice also entails knowing the health care economics and current systems of care, which inevitably introduce challenges to comprehensive care.

Care of the Elderly Patient

MELISSA STILES and KATHLEEN WALSH

CHAPTER OUTLINE

Geriatric Assessment, 34
Falls, 37
Elder Abuse, 41
Pressure Ulcers, 42

Rational Drug Prescribing for Elderly Patients, 45
Urinary Incontinence, 48

Family physicians are responsible for the care of increasing numbers of elderly patients and their unique and complex primary care needs. Older patients often have comorbidities; “polypharmacy”; and psychological, social, and functional impairments. These can lead to variability in presentation of health problems and make diagnosis and treatment challenging for the family physician.

This chapter discusses common geriatric syndromes and outlines a process by which family physicians can effectively and efficiently care for elderly patients. The main goal is to assist elderly persons to maintain function and quality of life with self-respect, preserving their lifestyle as much as possible. The chapter addresses functional assessment, falls, elder abuse, pressure ulcers, rational drug prescribing, and incontinence; geriatric conditions such as dementia, delirium, and depression are discussed in other chapters.

Geriatric Assessment

Key Points

- A comprehensive geriatric assessment includes a systematic approach assessing medical, functional, psychological, and social domains.
- A medication review is an essential component of a geriatric assessment.
- A multidisciplinary approach is used to identify intervention and management strategies.
- A questionnaire targeted to the geriatric assessment domains will expedite the patient visit.
- The goals of the geriatric assessment are to maintain function and preserve quality of life.

Longer life spans and aging “baby boomers” will double the population of Americans age 65 years and older over the next 25 years. The dramatic increase in life expectancy in the United States is the result of improved medical care and prevention efforts. In 2006, persons 65 years or older numbered 37.3 million and represented 12.4% of the U.S. population, about one in every eight Americans. The population 65 years of age and older increased from 35 million in 2000 to about 40 million in 2010, a 15% increase, and

will increase to 55 million in 2020, a 36% increase for that decade. According to the Centers for Disease Control and Prevention (CDC, 2007), by 2030 there will be about 71.5 million older persons, more than twice their number in 2000 and about 20% of the U.S. population (Table 4-1).

There has been a significant shift in the leading causes of death for all groups from infectious disease and acute illnesses to chronic diseases and degenerative illnesses. Of the elderly population, approximately 8% experience severe cognitive impairment, 20% have chronic disabilities and vision problems, and 33% have restrictions in mobility and hearing loss (Freedman et al., 2002). There are also the predictable age-related structural and physiologic changes that occur with aging. External factors such as diet, occupation, social support, and access to health care can significantly influence the extent and speed of the physiologic decline (Sarma and Peddigrew, 2008; Tourlouki et al., 2009).

America’s aging population is also marked by a more racially and ethnically diverse group of individuals. Simultaneously, the health status of racial and ethnic minorities lags far behind that of nonminority populations. The burden of many chronic diseases and conditions, such as hypertension, diabetes, and cancer, varies widely by race and ethnicity. Data from the 1997 to 2009 National Health Interview Survey (NHIS) indicated that 70.2% of non-Hispanic white adults aged 65 years or older reported very good or excellent health compared with 57% of non-Hispanic blacks and 58.8% of Hispanics (CDC, 2009).

There is a strong economic incentive for action. The cost of providing health care for an older American is three to five times greater than the cost for someone younger than 65 years of age. As a result, by 2030, the nation’s health care spending is projected to increase by 25% because of these demographic shifts (CDC, 2009).

A comprehensive geriatric assessment is a systematic approach to the collection of patient data. The approach varies greatly, from single-physician evaluation with referral as needed to full teams of professionals evaluating all patients. The geriatric assessment can assist in developing an individualized approach to each patient (Table 4-2). It is imperative to recognize the unique “blueprint” of what characterizes each elderly patient, including age, ethnicity, education, religious or spiritual beliefs, traditions, diet, interests and hobbies, daily routines, medical illness and

Table 4-1 Population by Age and Gender, 2010*

Age	Both Sexes		Male	Female
	Number	Percent	Number	Number
All ages	310,233	100.0	152,753	157,459
55-59 years	19,517	6.3	9,450	10,067
60-64 years	16,758	5.4	8,024	8,733
65-69 years	12,261	4.0	5,747	6,514
70-74 years	9,202	3.0	4,191	5,011
75-79 years	7,282	2.5	3,159	4,123
80-84 years	5,733	1.8	2,302	3,431
85 years and older	5,751	1.9	1,893	3,859

*Numbers in thousands.

Table 4-2 Goals of Geriatric Assessment

1. Focus on preventive medicine rather than acute medicine.
2. Focus on improving or maintaining functional ability and not necessarily a “cure.”
3. Provide a long-term solution for “difficult to manage” patients with multiple physicians, recurrent emergency department visits, and hospital admissions with poor follow-up.
4. Aid in the diagnosis of health-related problems.
5. Develop plans for treatment and follow-up care.
6. Establish plans for coordination of care.
7. Determine the need and site of long-term care as appropriate.
8. Determine optimal use of health care resources.
9. Prevent readmission into the hospital.

disabilities, language barriers, functional status, marital status, sexual orientation, family and social support, occupation, life experiences, and socioeconomic position.

The geriatric assessment can be divided into four categories: medical, functional, psychological, and social. Within each of these categories are a number of approaches, including use of office-based instruments that can aid in the collection of information and streamline the plan of care.

MEDICAL ASSESSMENT

The medical assessment includes a review of the patient’s medical record, medication history (past and present), and a nutritional evaluation. On average, elderly patients have four to six diagnosable disorders, which may require the use of several medications. One disorder can affect another, and in turn a collective deterioration of both can lead to overall poor outcomes. Review of the patient’s medical record should focus on conditions that are more common in elderly adults (geriatric syndromes) and in particular their risk factors.

Four shared risk factors—older age, baseline cognitive impairment, baseline functional impairment, and impaired mobility—have been identified within the five most common geriatric syndromes: pressure ulcers, incontinence, falls, functional decline, and delirium (Inouye et al., 2007). It is important that health care providers familiarize themselves with the common geriatric body area or system disorders that can directly influence these risk factors. Understanding the basic mechanisms involved in geriatric syndromes is essential to targeting therapeutic options.

During the medical assessment, the review of systems should be completed with special emphasis on sensory impairment, dentition, mood, memory, urinary symptoms, falls, nutrition, and pain. However, the U.S. Preventive Services Task Force (2013) recommends routine screening for visual and hearing impairment in older adults.

Hearing loss is the third most prevalent chronic condition in elderly people, after hypertension and arthritis, and its prevalence and severity increase with age. In persons age 65 to 75 years, the prevalence of hearing loss ranges from 20% to 40% (Cruikshanks et al., 1998; Rahko et al., 1985; Reuben et al., 1998), but in those older than age 75, it ranges from 40% to 66% (Ciurlia-Guy et al., 1993; Parving et al., 1997).

Screening for hearing loss can be accomplished using two office-based methods: the audioscope (objective) and a validated short questionnaire (subjective) (Ventry, 1982). The audioscope is a handheld instrument that functions as an otoscope and audiometer and can be used to visualize the ear canal and eardrum and remove cerumen if necessary. The audioscope is easy to use, with 87% to 96% sensitivity and 70% to 90% specificity (Abyad, 1997; Mulrow and Lichtenstein, 1991). The Hearing Handicap Inventory for the Elderly—Short Version (HHIE-S) is a subjective, 10-item, 5-minute questionnaire with an overall accuracy of 75% in identifying hearing loss (Mulrow et al., 1990).

A formal audiologic evaluation should be offered to any patient who fails a hearing screening. The evaluation can assist in determining the need for further testing or management, including hearing aid, medical treatment, or surgical intervention.

Review of the patient’s current medication list, including over-the-counter (OTC) medications, as well as any drug allergies or previous adverse drug reactions (ADRs), is a necessary component of the geriatric assessment. ADRs (also called adverse drug events [ADEs]) are a significant public health issue, especially in the elderly population (Thomsen et al., 2007). Polypharmacy is defined as taking more than four medications and is an independent risk factor for both delirium and falls (Inouye, 2000; Moylan and Binder, 2007).

Patients or family members should be asked to bring in all the patient’s prescription medications and supplements at the initial visit and periodically thereafter. Clinicians can make sure patients have the prescribed drugs, but possession of these drugs does not guarantee adherence. Patients should be asked to demonstrate their ability to read labels (often printed in small type), open containers (especially the child-resistant type), and recognize their medications. Pill boxes may be helpful in organizing the patient’s medications by the week or month.

Nutritional evaluation is an integral part of the geriatric assessment. The type, quantity, and frequency of food eaten should be determined. Malnutrition and undernutrition can lead to health problems, including delayed healing and longer hospital stays. A reliable marker of nutritional problems is weight loss, specifically, more than 5% in the past month and 10% or greater in the last 6 months (Huffman, 2002). Clinicians should ask about any special diets (e.g., low carbohydrate, vegetarian, low salt) or self-prescribed “fad” diets. A nutritional screen can aid in further assessment of the patient’s nutritional health and help guide

Directions: Read the statements below. Circle the number in the YES column if it applies to you or the person you are completing the questionnaire for. Add the circled numbers for the total.

	YES
I have an illness or condition that made me change the kind or amount of food I eat.	2
I eat fewer than two meals per day.	3
I eat few fruits or vegetables or milk products.	2
I have three or more drinks of beer, liquor, or wine almost every day.	2
I have tooth or mouth problems that make it hard for me to eat.	2
I don't always have enough money to buy the food I need.	4
I eat alone most of the time.	1
I take three or more different prescribed or over-the-counter drugs a day.	1
Without wanting to, I have lost or gained 10 lb in the last 6 months.	2
I am not always physically able to shop, cook, or feed myself.	2
TOTAL	

Total

- 0–2 Good! Recheck your nutritional score in 6 months.
- 3–5 You are at moderate nutritional risk. See what can be done to improve your eating habits and lifestyle. Your office on aging, senior nutrition program, senior citizens center, or health department can help. Recheck your nutritional score in three months.
- 6 or more You are at high nutritional risk. Bring this checklist next time you see your doctor, dietitian, or other qualified health or service professional. Talk with them about any problems you may have. Ask for help to improve your nutritional health.

Figure 4-1 Nutrition questionnaires such as this (Determine Your Nutritional Health) can help in the assessment of the elderly patient's nutritional health. (Courtesy Nutrition Screening Initiative, Washington, DC, 2007. The Nutrition Screening Initiative is funded in part by a grant from Ross Products Division of Abbott Laboratories, Inc.)

interventions (Figure 4-1). Additional questioning should include weight loss and change of fit in clothing, amount of money spent on food, and accessibility of grocers with a variety of fresh foods.

The ability to chew and swallow should also be evaluated. It may be impaired by xerostomia (dryness of mouth), which is common in elderly persons. Decreased taste or smell may reduce the pleasure of eating, so patients may eat less. Patients with decreased vision, arthritis, immobility, or tremors may have difficulty preparing meals and may injure or burn themselves when cooking. Patients worried about urinary incontinence may reduce their fluid intake and thus may eat less food.

FUNCTIONAL ASSESSMENT

A primary goal of the geriatric assessment is to identify interventions to help patients maintain function and stay at home in independent living situations. The functional assessment focuses on activities of daily living (ADLs) and risk screening for falls. The basic ADLs include eating, dressing, bathing, transferring, and toileting. The instrumental ADLs (IADLs) consist of shopping, managing money, driving, using the telephone, housekeeping, laundry, meal preparation, and managing medications (Katz, 1983). Home health and social services referral should be considered for patients who have difficulty with the ADLs. A simple method of screening patients for gait and mobility problems

is to ask, "Have you fallen all the way to the ground in the past 12 months?" A positive screen should lead to a more thorough evaluation and consideration of a physical therapy referral (Ganz et al., 2007) (see "Falls Assessment" later in this chapter).

PSYCHOLOGICAL ASSESSMENT

The psychological assessment screens for cognitive impairment and depression, two conditions that significantly impact both the patient and the family. The most studied test to screen for cognition is the Mini-Mental State Examination, which is best for identifying patients with moderate or severe dementia. Depression can be readily screened with shorter versions of the original 30-item Yesavage Geriatric Depression Scale (GDS) (Yesavage et al., 1983). The five-item version of the GDS asks the following:

1. Are you basically satisfied with your life?
2. Do you often feel bored?
3. Do you often feel helpless?
4. Do you prefer to stay home rather than going out and doing new things?
5. Do you feel pretty worthless the way you are now?

A score of greater than two positive answers is positive (97% sensitivity, 85% specificity) (Rinalde et al., 2003). The Yale Depression Screen ("Do you often feel sad or

depressed?") is a validated one-item GDS screening tool (Mahoney et al., 1994).

SOCIAL ASSESSMENT

It is important to assess the patient's living situation and social support when performing a geriatric assessment. The living situation should be evaluated for potential hazards, especially if the patient is identified as being at risk of falling. The social assessment also includes questions about financial stressors and caregiver concerns. Advance planning is a key component of the assessment and includes clarifying the patient's values and setting goals for care in case of future incapacity, including identifying the patient's "power of attorney" for health care.

SUMMARY

A geriatric assessment can identify frequent problems, thus leading to earlier interventions for the common medical and social concerns of the elderly population. It is important to remember, however, that patients may underreport medical problems because they worry about losing their independence. Patients may also be reluctant to repeat their health concerns to their primary care physician because they fear being perceived as having an emotional or psychiatric illness. Often, older patients rationalize their symptoms as being a "normal" component of aging.

The key to a successful geriatric assessment is to establish trust and effective communication between the patient and the physician. Allotting for adequate time during appointments and, if needed, scheduling frequent office visits are essential to the gathering of information. Inquiring about recent socioeconomic changes, functional losses, or life transitions is also important. The physician should obtain the patient's medical records before the first visit. A questionnaire targeted to the geriatric assessment domains should be completed by the patient, with family assistance if needed (Figure 4-2). Language, education, social support, economic status, and cultural and ethnic factors play a vital role in the patient's health care outcome. A multidisciplinary approach is used in interventions and management. Preserving function and maintaining quality of life are the primary goals of the geriatric assessment (Miller et al., 2000).

Falls

Key Points

- Falls result in significant morbidity, mortality, and functional decline.
- Patients should be asked about their history of falls and balance issues.
- Medication review is a key component of falls assessment.
- Multifactorial interventions can reduce the rate of falls.
- Exercise programs that focus on strength and balance training are most effective in preventing falls.

EPIDEMIOLOGY

Falls result in significant morbidity and mortality as well as an increased rate of nursing home placement. Each year, approximately 30% of persons older than age 65 years fall at least once, and the incidence increases with age. Up to 10% of falls result in serious injury. Falls are the leading cause of injury-related deaths in people older than 65 years (CDC, 2013). In the United States, hip fractures currently account for more than 300,000 hospitalizations, with a 1-year mortality rate of up to 33% (Sattin, 1992; Tinetti et al., 1988). By 2050, it is estimated that the worldwide number of hip fractures will rise to 6.26 million. Direct medical costs related to falls in adults age 65 years of age or older exceeded \$19 billion in 2000 (Stevens et al., 2006).

Falls also cause functional limitations by both direct injury and indirect psychological consequences. Postfall anxiety leads to loss of self-confidence in ambulation and self-imposed limitations in activity. Postfall anxiety syndrome can also result in depression, social isolation, and increased risk of falls from deconditioning. Because the cause of falls is often multifactorial, the assessment and interventions target several areas (Nevitt et al., 1989).

RISK FACTORS

The multiple risk factors for falling can be categorized as intrinsic or extrinsic. Intrinsic risk factors include age-related physiologic changes and diseases that affect the risk of falling (Table 4-3). Extrinsic risk factors include medications and environmental obstacles. The risk of falling increases significantly in people with multiple risk factors. A prospective study found that 19% of older patients with one risk factor have a fall in a given year compared with 60% of older patients with three risk factors (Tinetti et al., 1988).

Taking four or more prescription drugs is itself a risk factor for falling. Also, several medication classes have a higher potential to cause falls, including tricyclic antidepressants, neuroleptic agents, serotonin reuptake inhibitors, benzodiazepines, and class 1A antiarrhythmic medications. Narcotic analgesics, antihistamines, and anti-convulsants are also associated with increased risk for falls (Ensrud et al., 2002; Rubenstein and Josephson, 2002).

Physical restraints have been used in an attempt to reduce falling. Although the focus here is on community-dwelling elderly persons, it is worth noting that use of physical restraints in nursing home and hospital settings does not reduce the risk of falling and is instead associated with an increased risk of injury (Neufeld et al., 1999). Since the 1980s, the use of physical restraints has been appropriately and dramatically reduced.

SCREENING

At present, no one screening test can be recommended to identify potential fallers (Gates et al., 2008). The two best predictors of falls are a history of falls and a reported abnormality in gait or balance (Ganz et al., 2007). "Have you had any falls in the past year?" is a simple screening question that can be answered by the patient or caregiver in a previsit

GERIATRIC HEALTH QUESTIONNAIRE

Date: _____ Birthdate: _____ Hosp #: _____
 Name: _____ Address: _____

INSTRUCTIONS: PLEASE CIRCLE ANSWERS.

1. **General health:** In general, would you say your health is:
 Excellent / Very good / Good / Fair / Poor
- How much bodily pain have you had during the past 4 weeks?
 None / Very mild / Mild / Moderate / Severe / Very severe

2. **Activities of daily living:** Are you (I) independent (can do by myself); (A) require assistance (need help from another person); or (D) dependent (cannot do at all) with each of the following tasks?

Walking	I	A	D	Using telephone	I	A	D
Dressing	I	A	D	Shopping	I	A	D
Bathing	I	A	D	Preparing meals	I	A	D
Eating	I	A	D	Housework	I	A	D
Toileting	I	A	D	Taking medications	I	A	D
Driving	I	A	D	Managing finances	I	A	D

3. **Geriatric review of systems:**
- a. Do you have difficulty driving, watching TV, or reading because of poor eyesight? Yes / No
 - b. Can you hear normal conversational voice? Yes / No
 - Do you use hearing aids? Yes / No
 - c. Do you have problems with your memory? Yes / No
 - d. Do you often feel sad or depressed? Yes / No
 - e. Have you unintentionally lost weight in the past 6 months? Yes / No
 - f. Do you have trouble with control of your bladder? Yes / No
 - Do you have trouble with control of your bowels? Yes / No
 - g. How many falls have you had in the past year? _____
 - h. Do you drink alcohol? Yes / No
 - If yes, how many drinks per week? _____
4. Do you live with anyone? Yes / No
 If yes, who? Spouse / Child / Other / Relative / Friend
 Who would help you in an emergency? _____
 Who would help you with health care decisions if you were not able to communicate your wishes?

5. How many medicines do you take, including prescribed, over the counter, and vitamins? _____
 What is your system for taking your medications? Pill box / Family help / List or chart / None
6. Are you sexually active? Yes / No
7. Has anyone intentionally tried to harm you? Yes / No
8. Have you had a shot to prevent pneumonia? Yes / No
9. Please draw the face of a clock with all the numbers and the hands set to indicate 10 minutes after 11 o'clock.

Memory: 3 item recall after 1 minute (pen, dog, watch) # recalled _____

Figure 4-2 Geriatric health questionnaires assist in gathering pertinent information regarding the functioning of the elderly patient. (From Jogerst GJ, Wilbur JK. Care of the elderly. In RakeI RE, ed. *Principles of Family Practice*, 7th ed. Philadelphia: WB Saunders; 2007:67-105.)

Table 4-3 Intrinsic Risk Factors for Falls

Age-related changes in vision, hearing, or proprioception
Decreased blood pressure response to postural changes
Delayed compensatory muscle response to postural changes
Age older than 80 years
Cognitive impairment
Depression
Functional impairment
History of falls
Visual impairment
Gait or balance impairment
Use of assistive device
Arthritis
Leg weakness

Table 4-4 Initial Evaluation of Falls

History	Circumstances of fall Presence of risk factors Medical conditions Medication review Functional abilities
Physical examination	Postural blood pressure CV examination focusing on rhythm and murmurs Visual acuity Neurological examination: strength, proprioception, cognition Musculoskeletal examination: ROM, joint abnormalities Gait and balance assessment
Diagnostic studies	None required routinely

CV, Cardiovascular; ROM, range of motion.

questionnaire. For patients who have not fallen, the pretest probability of a fall in the upcoming year ranges from 19% to 36%. Also, asking the patient, “Have you noticed any problems with gait, balance, or mobility?” is another simple screening question. Answering “yes” to either screening question warrants further assessment (Tinetti, 2003).

FALLS ASSESSMENT

Falls assessment should include a multifactorial evaluation beginning with the circumstances surrounding the fall(s), associated symptoms, risk factor assessment, and medication history (Table 4-4). The physician should ask about the environment (e.g., indoors or outdoors, dark or well lighted, time of day), environmental obstacles (e.g., throw rugs, door thresholds, stairs), and footwear worn at the time. The history should also include questions about prodromal symptoms (e.g., lightheadedness, dizziness) if there was a loss of consciousness or other symptoms of arrhythmias (i.e., palpitations). If available, information should be obtained from a witness. The evaluation should also include questions about risk factors, functional abilities, and medication history (American Geriatrics Society [AGS] et al., 2010).

Postural blood pressure and pulse are important assessments in the examination. Up to 30% of older persons have orthostatic hypotension, and although some may be asymptomatic, others become lightheaded and dizzy (Luukinen et al., 1999). The musculoskeletal examination should focus on range of motion in the legs, inflammatory or degenerative conditions of the leg joints, kyphosis, and abnormalities of the feet. The neurologic examination should include proprioception, coordination, muscle strength, and cognition. The cardiovascular examination should focus on detecting potential causes of falls (e.g., arrhythmias, aortic stenosis). Visual acuity and hearing should be assessed. Disturbances in gait and balance can be identified through the patient or caregiver’s direct report or a simple office-based assessment, such as the “get up and go” test (Podsiadlo and Richardson, 1991). This test may be scored, timed, or used as an overall assessment of the patient’s gait, stability, balance, and strength. The patient is asked to stand from a seated position, walk about 10 feet (3 m), turn around, walk back, and sit down again. If the patient needs to push off the chair or rock back-and-forth several times to arise, leg strength is diminished. The task should be completed within 10 seconds. Gait abnormalities, such as poor step height, decreased stride length, and shuffling, may be observed. A wide-based stance and slow, multiple-point turning may reveal poor balance.

Laboratory evaluation and imaging are based on the history and clinical findings. If an underlying metabolic abnormality is suspected (e.g., diabetes, anemia, dehydration), appropriate blood tests may assist in the diagnosis. If a patient is suspected of having syncope, cardiac rhythm monitoring (e.g., Holter or event monitor) is appropriate. An echocardiogram may be necessary for evaluation of a murmur. Neuroimaging with magnetic resonance imaging (MRI) or computed tomography (CT) is indicated for the evaluation of focal findings on neurologic examination.

MANAGEMENT

Evidence has demonstrated that a multifactorial approach and intervention strategy is needed to reduce the rate of falling in older patients (Figure 4-3). Because one of the most modifiable risk factors is medication use, medication review is a key component of management (Hanlon et al., 1997). The review should focus on decreasing the dose or discontinuing sedating medications. If orthostasis is present, adjustment of diuretics and antihypertensive medications should be considered. The role of vitamin D in fall prevention is questionable. Although it probably does not decrease the risk of falls, except in patients with low levels of vitamin D, supplementation should be started in patients with osteopenia or osteoporosis (Gillespie et al., 2012).

Supervised exercise programs should be considered for patients at high risk for falls; exercise can reduce the physical risk factors (Rose, 2008). Specifically, programs that focus on two of three exercise components (strengthening, balance training, and aerobic or endurance training) for a minimum of 12 weeks have shown the most benefit (Costello and Edelstein, 2008). Finally, home hazard evaluation and intervention is an essential component in the assessment of falls in elderly (AGS, 2010; Gillespie et al., 2012).

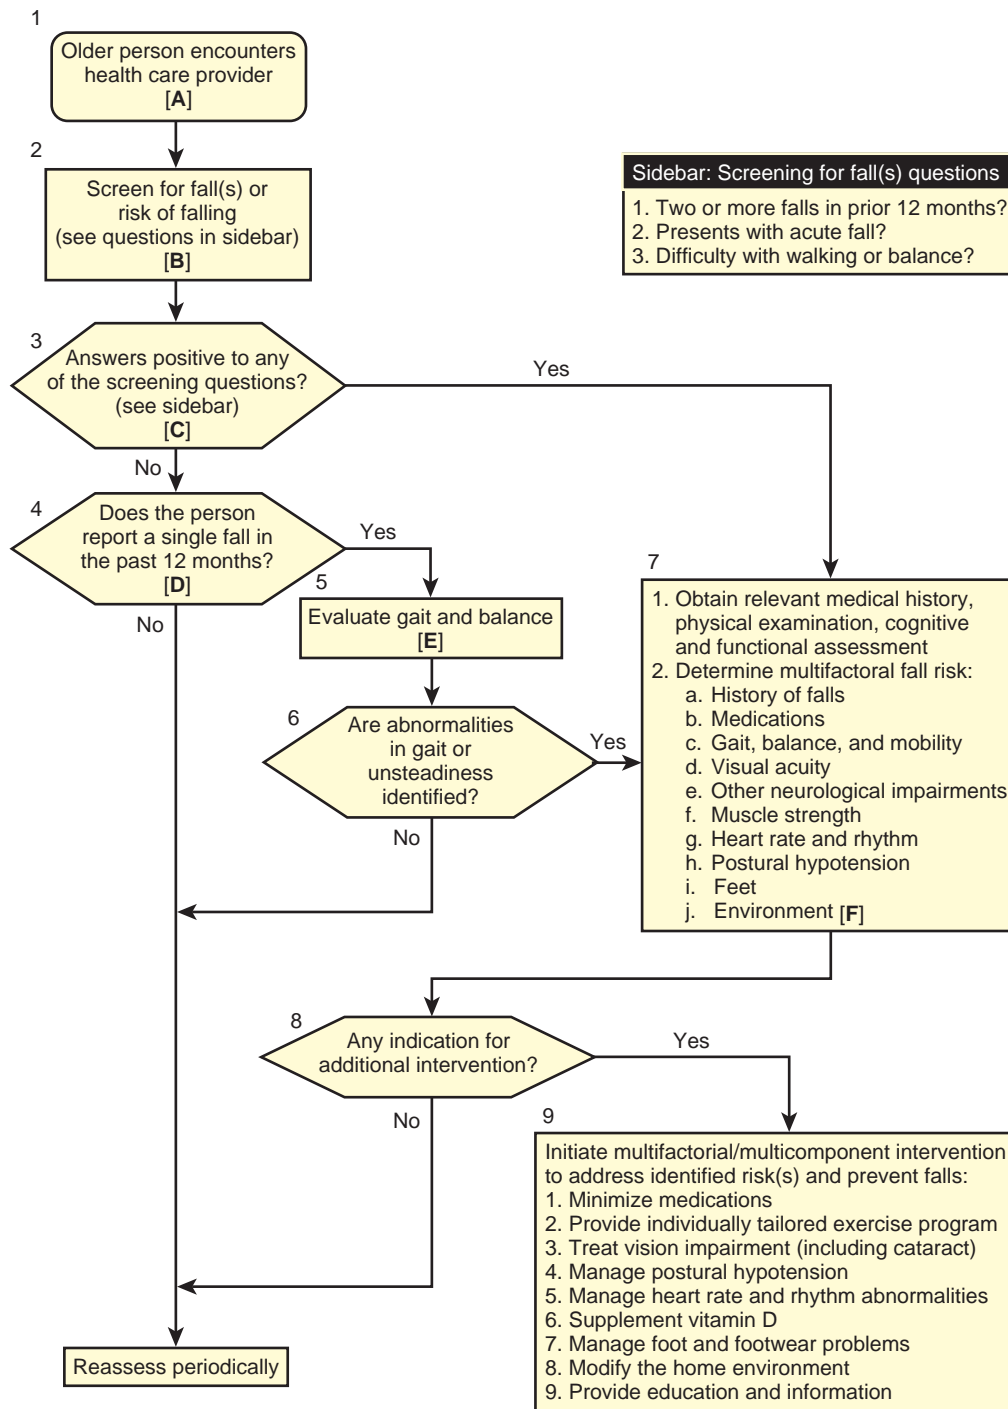

Figure 4-3 Practice guideline for the prevention of falls in older persons. (From American Geriatrics Society, British Geriatrics Society, and American Academy of Orthopedic Surgeons Panel on Falls Prevention: Guideline for the prevention of falls in older persons. *J Am Geriatr Soc.* 2001;49:664-672.)

KEY TREATMENT

- Risk factor assessment and multifactorial intervention reduce the rate of falls (SOR: A; Gillespie et al., 2012).
- Exercise programs that target more than two components reduce the rate of falls (SOR: A; Gillespie et al., 2012).
- Community-living elderly patients who have fallen or who have risk factors for falling should have their homes assessed for safety by occupational therapists (SOR: A; Gillespie et al., 2012).
- All older individuals should be asked at least once yearly about falls (SOR: C; AGS et al., 2010; Tinetti, 2003).

Elder Abuse

Key Points

- Elder abuse is underreported.
- Direct questioning for elder abuse is recommended.
- Physicians should recognize the physical and behavioral signs of abuse.
- A positive screening result for elder abuse should be followed by a safety assessment.
- Physician reporting requirements regarding elder abuse vary by state.

Elder abuse is a significant public health issue that physicians need to identify and address in both outpatient and inpatient settings. The prevalence of elder abuse is difficult to determine because its definition varies across U.S. states and other countries, and research is still limited in this area (Erlingsson, 2007). In a systematic review of international literature, estimates ranged from 3.2% to 27.5% based on population studies. More than 6% of the general population had reported abuse in the prior month (Cooper et al., 2008).

In the United States, the number of people age 65 years and older who have been victims of elder abuse ranges between 1 and 2 million. In 2000, adult protective services (APS) departments received approximately 470,000 reports. Of the types of abuse, elder “self-neglect” is most often reported. A prospective, population-based cohort study found that elder self-neglect was associated with a 5.82 times increased risk for mortality in the year after a report of self-neglect (Dong et al., 2009). From incidence studies, it is estimated that for every case reported, about five go underreported (National Elder Abuse Incidence Study, 1998). Underreporting stems from both patient issues (familial secrecy, denial, fear, shame) and provider issues (lack of awareness) (Kahan and Paris, 2003). Primary care physicians have the opportunity to detect early signs of elder abuse in patients with whom they have well-established relationships (Stiles et al., 2002).

DEFINITION

The National Center on Elder Abuse (2013) defines elder abuse as “a term referring to any knowing, intentional, or negligent act by a caregiver or any other person that causes harm or a serious risk of harm to a vulnerable adult.” Although terms vary across states, elder abuse can be generally categorized into several types: physical abuse, emotional abuse, sexual abuse, exploitation, neglect, self-neglect, and abandonment (Table 4-5). Elder abuse is also classified by its setting. Domestic abuse occurs in the home of the victim. Institutional abuse occurs in a nursing home, hospital, assisted living center, or group home.

RISK FACTORS

Awareness of risk factors for abuse can increase the chance of identification and early intervention. Although research is ongoing, several characteristics of both the victim and

Table 4-5 National Center on Elder Abuse Definitions

Physical abuse	Inflicting or threatening to inflict physical pain or injury on a vulnerable elder or depriving him or her of a basic need
Emotional abuse	Inflicting mental pain, anguish, or distress on an elder person through verbal or nonverbal acts
Sexual abuse	Nonconsensual sexual contact of any kind
Exploitation	Illegal taking, misuse, or concealment of funds, property, or assets of a vulnerable elder
Neglect	Refusal or failure by those responsible to provide food, shelter, health care, or protection for a vulnerable elder
Abandonment	Desertion of a vulnerable elder by anyone who has assumed the responsibility for care or custody of that person
Self-neglect	Characterized as the behavior of an elderly person that threatens his or her own health or safety

From National Center on Elder Abuse. <http://www.ncea.aoa.gov/faq/index.aspx>.

Table 4-6 Screening Questions for Elder Abuse

Are you afraid of anyone at home?
Are you alone a lot?
Has anyone at home ever hurt you?
Has anyone taken anything that was yours without asking?
Does anyone at home make you uncomfortable or afraid?
Has anyone ever forced you to sign a document that you did not understand?
Are you kept isolated from friends or relatives?

the abuser should trigger further screening questions. Risk factors associated with the victim include shared living situations, history of dementia, and social isolation. Perpetrator risk factors include a history of mental illness (specifically depression), alcohol abuse, and financial dependency (Lachs and Pillemer, 2004).

SCREENING

There is no consensus that asymptomatic patients should be screened for elder abuse. The American Medical Association (AMA, 1992) suggests that all outpatients be screened for family violence, but the U.S. Preventive Services Task Force (2013) concluded that there was insufficient evidence for or against screening for older adults or their caregivers for elder abuse. Patients should be screened if there is a suspicion of elder abuse. The questions should be open ended, nonthreatening, and asked in a variety of ways to assess for the different forms of elder abuse (Table 4-6). A positive response should be followed by more direct questions as to the nature of the abuse. Direct questioning by physicians has been shown to increase reporting (Oswald et al., 2004).

CLINICAL MANIFESTATIONS

Certain behavioral and physical signs should raise suspicion for elder abuse. Behavioral signs in the caregiver

Table 4-7 Physical Signs of Elder Abuse

General	Weight loss, dehydration, and poor hygiene
HEENT	Traumatic alopecia; poor oral hygiene; absent hearing aids, dentures, or eyeglasses; subconjunctival or vitreous hemorrhage
Skin	Hematomas, welts, burns, bites, bruises, pressure sores
Genitorectal	Inguinal rash, fecal impaction
Musculoskeletal	Fractures, contractures

HEENT, Head, ears, eyes, nose, throat.

include answering for the patient, insisting on being present for the entire visit, failing to offer assistance, and displaying indifference or anger. Behavioral signs in an elderly patient include poor eye contact, hesitation to talk openly, or fearfulness toward the caregiver. Other indicators of possible abuse include confusion, paranoia, anxiety, anger, and low self-esteem. Physical signs that may signal neglect include poor hygiene, malnutrition, dehydration, pressure ulcers, and injuries (Table 4-7). Medication nonadherence may also be a warning sign of abuse.

ASSESSMENT

In suspected cases of abuse, the assessment includes a thorough history; physical examination; and functional, cognitive, and mental health assessments. The patient and the caregiver should be interviewed alone and separately (Abbey, 2009). Documentation begins with the description of the abusive or neglectful event, using the patient's words whenever possible. The duration, frequency, and severity of the abuse should be recorded. If injuries are present, a detailed description of the injuries and photographs, if available, should be documented. Whereas assessment of functional dependence can be helpful in recommending resources, evaluation of cognitive impairment is important in assessing both risk and capacity. The assessment should also include a mental health screening, with particular attention to depression, anxiety, insomnia, and alcohol abuse.

The elderly patient's caregiver should be assessed for caregiver stress and for risk factors for elder abuse, including alcohol abuse, depression, and financial dependency.

MANAGEMENT

Because the cause of elder abuse is often multifactorial, management involves a multidisciplinary approach with social workers and legal, financial, and APS representatives. The immediate management is determined by the safety and capacity assessments. Is the patient in any immediate danger? If so, acute hospitalization, safe home placement, and a protective court order may be indicated. If the patient lacks capacity, the physician should work with APS on options, including guardianship, financial management resources, and order of protection if indicated. In other cases, management should focus on using community resources to maintain the patient in the least restrictive environment. The emphasis is to decrease social isolation and caregiver stress. Interventions can include respite care,

home health or custodial services, counseling, and drug or alcohol rehabilitation.

REPORTING REQUIREMENT

All 50 states have laws authorizing APS departments to intervene in cases of elder abuse. It is important for primary care physicians to know their state's requirements on mandatory reporting for elder abuse and which type of abuse (e.g., physical, emotional, sexual, financial) requires reporting. Higher rates of abuse have been documented in states that require public education regarding elder abuse and states that require mandatory reporting (Jogerst et al., 2003). Mandatory reporting laws in 42 states are controversial because they conflict with a competent elder's autonomy and with the physician–patient relationship. In such cases, physicians should explain their legal obligation to report and emphasize that the goal of reporting is to develop a care plan to assist the patient.

KEY TREATMENT

- Direct questioning by physicians for elder abuse increases the rate of reporting (Oswald et al., 2004) (SOR: B).
- Older individuals should be screened for elder abuse (AMA, 1992) (SOR: C).

Pressure Ulcers

Key Points

- Preventive measures can reduce the incidence of pressure ulcers in elderly patients.
- Classification is only one aspect of wound assessment.
- Assessment of pressure ulcers includes identification of risk factors.
- Pain assessment is an essential component of management.
- Risk factor modification is the key to management of pressure ulcers.

Pressure ulcers are a common and serious public health issue, especially in the elderly population. The reported incidence is as high as 22% in the nursing home population and ranges from 4.7% to 9% up to 32% in the hospitalized population (Allman, 1997; Allman et al., 1995; Coleman et al., 2002; Kaltenthaler et al., 2001). The treatment costs related to pressure ulcers exceed an estimated \$5 billion annually in the United States (Xakellis et al., 1995). Prevention is paramount and can reduce the incidence of pressure ulcers by 50%. A thorough assessment of the wound and potential risk factors is the key to management.

CLASSIFICATION

Wound assessment begins with classification, as initially proposed in 1989 by the National Pressure Ulcer Advisory Panel (NPUAP) and then adopted for the Agency for Health

Care Policy and Research (AHCPR) Pressure Ulcer Clinical Practice Guidelines (1992 and 1994). The NPUAP revised the stage I classification in 1998 and added two stages in 2007, suspected deep tissue injury and unstageable. The six classifications are as follows:

Suspected deep tissue injury: Purple or maroon, localized area of discolored skin or blood-filled blister caused by damage to underlying soft tissue from pressure and shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, and warmer or cooler compared with adjacent tissue.

Stage I: Intact skin with nonblanchable redness of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, and warmer or cooler compared with adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones.

Stage II: Partial-thickness skin loss involving the epidermis, the dermis, or both. The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater, without slough.

Stage III: Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.

Stage IV: Full-thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendons, joint capsules). Slough or eschar may be present on some parts of the wound bed, often with undermining and tunneling.

Unstageable: Full-thickness tissue loss in which the base of the ulcer is covered with slough (yellow, tan, gray, green, or brown) or eschar in the wound bed.

A wound cannot be accurately staged if eschar or slough is present. The staging system is useful only for initial classification because wounds do not heal predictably (Ferrell, 1997). Thus, it is important to include other factors when describing the wound to help assess treatment over time. These factors include size, type of exudate, and a description of the predominant tissue type. Size can be assessed by measuring the two largest diameters at right angles. The type and amount of exudate should be recorded. Exudate types include serous (clear or amber), sanguineous (bloody), or purulent (thick, yellow, or odiferous). The predominant tissue types are epithelial, granulation, necrotic, and eschar (AHCPR, 1992; Ferrell, 1997; Maklebust, 1997; NPUAP, 2007).

RISK FACTORS

An understanding of risk factors for pressure sore development is the key to prevention and management. Risk factors can be divided into extrinsic and intrinsic categories (Table 4-8).

Extrinsic Risk Factors

Extrinsic factors include direct pressure, shearing forces, friction, and moisture. Direct pressure results in hypoperfusion of the affected tissue, which can lead to hypoxia;

Table 4-8 Risk Factors for Pressure Sore Development

Extrinsic Factors	Intrinsic Factors
Pressure	Age
Shearing forces	Impaired mobility
Friction	Malnutrition
Moisture	Sensory impairment

acidosis; and, if prolonged, tissue death and necrosis. Pressure sores most frequently occur over bony prominences below the waist, including the sacrum, greater trochanter, malleolus, heel, ischial tuberosity, and fibular head. Of note, the heels are the second most common site for pressure ulcer development. As the prevalence of pressure ulcers at other sites has decreased or remained the same, the prevalence of heel pressure ulcers has increased.

Shearing forces result from traction on the skin, which causes a relative displacement of the underlying structures. This usually occurs when patients are positioned in bed more than 30 degrees or seated and then slide down. In these patients, the underlying sacrum is at risk for pressure sore development. Friction between the skin and a stationary source such as bedclothes or sheets is another factor. Care must be taken to avoid friction, especially during transfers in and out of bed. Excessive moisture can lead to skin maceration and subsequent skin breakdown. Common causes include incontinence, diarrhea, and excessive perspiration (AHCPR, 1994; Patterson and Bennett, 1995).

Intrinsic Risk Factors

Intrinsic risk factors for pressure ulcer development include age, conditions that impair mobility, malnutrition, and sensory impairment. Skin changes associated with aging (e.g., epidermal thinning, diminished vascularity) increase the susceptibility of older persons to shearing forces, pressure, and friction. Immobility can cause infrequent position changes, thus exposing an older person to prolonged pressure. Malnutrition, specifically an inadequate intake of calories or protein, has been associated with the development of pressure sores (Thomas, 2001). The AHCPR (1994) defines clinically significant malnutrition as a serum albumin level of less than 3.5 mg/dL, a total lymphocyte count of less than 1800 cells/mm³, or body weight less than 80% of ideal weight. Supplementation of micronutrients involved in skin healing, such as ascorbic acid and zinc, has not been shown to prevent pressure sores or improve rates of healing. Sensory impairment, such as in diabetic neuropathy, can prevent an individual from responding appropriately to pressure-related discomfort (Patterson and Bennett, 1995; Reddy et al., 2006; Thomas, 1997, 2001).

Risk Factor Assessment Tools

The AHCPR's guidelines recommend that individuals with limited mobility be assessed on admission to hospitals, nursing homes, and home care programs for risk factors for pressure sore development. The most common assessment tool is the Braden scale (Pancorbo-Hidalgo et al., 2006). Risk factor identification and subsequent intervention are integral components of pressure sore prevention and management.

Table 4-9 Pressure Sore Risk Factor Modification

Implement	Avoid
Support devices to reduce pressure	Donut-type devices
Frequent repositioning	Massage over bony prominences
Positioning devices such as pillows	Raising head of bed above 30 degrees
Lifting devices such as a trapeze	Dragging the patient during transfers

MANAGEMENT

The principles of pressure sore management include modification of risk factors, nutritional support, maintaining a wound environment optimal for healing, and pain control.

Risk Factor Modification

The primary goal is to reduce pressure, shear, and friction over high-risk bony prominences (Table 4-9). This can be accomplished by frequent turning and repositioning while the patient is in bed (every 2 hours); frequent repositioning while sitting (every hour); and use of a support device to lower surface pressure, such as a foam, static air, alternating air, gel, or water mattress. Positioning devices such as pillows or foam wedges should be used to keep bony prominences (e.g., knees, ankles) from touching each other and high-risk areas from contacting the bed (e.g., heels). Donut-type devices should be avoided because the tissue within the ring can become necrotic from increased venous congestion.

Massage should be avoided over bony prominences because it can lead to deep tissue trauma. When positioning on the side, avoid pressure directly on the trochanter. To decrease the effect of shear forces, maintain the head of the bed at the lowest degree of elevation. To decrease the effect of friction lubricants, use protective films, dressings, or padding. Also, lifting devices such as a trapeze can be used to assist patients with limited mobility in transfers and repositioning (AHCPR, 1994; Bergstrom, 1997; Bluestein and Javaher, 2008; Reddy et al., 2006; Remsburg and Bennett, 1997).

Nutritional Support

Nutritional support emphasizing adequate protein and calorie intake is another key component of pressure sore management. Protein intake should be 1.0 to 1.5 g/kg/day. Caloric intake should be 30 to 35 kcal/kg/day. Some experts recommend supplementation with vitamin C and zinc, although evidence that either enhances wound healing is limited (AHCPR, 1994; Langer et al., 2003; Reddy et al., 2006; Thomas, 2001).

Debridement

Wound healing requires a moist environment, free of necrotic tissue and infection, which allows for granulation and reepithelialization. Debridement is often needed to remove necrotic tissue, slough, and eschar, which can be accomplished by sharp, mechanical, enzymatic, or autolytic techniques. The technique used depends on the patient's

condition, location, clinical urgency, and overall goals for patient care. Debridement is not recommended for heel ulcers that have stable, dry eschar without edema or signs of infection (AHCPR, 1994; NPUAP, 2007).

Sharp debridement is appropriate for removing areas of thick eschar and necrotic tissue in extensive ulcers. Care must be taken to control pain when using this technique. Also, surgical debridement may cause transient bacteremia, and prophylactic antibiotics may be needed for high-risk patients.

Mechanical debridement includes wet-to-dry dressings; hydrotherapy; wound irrigation; and dextranomers, which are small beads of highly hydrophilic dextran polymers (e.g., Debrisan). Wet-to-dry dressings may be painful when changed and need to be discontinued when the wound bed is clean to avoid desiccation (Ovington, 2001). Hydrotherapy is appropriate for pressure sores with thick exudate or necrotic tissue. Care must be taken not to place the wound too close to the jets. Irrigation pressures need to be high enough to adequately cleanse the wound but not too high to potentially cause tissue trauma. Safe and effective pressures are between 4 and 15 pounds per square inch (psi). Examples of safe irrigation devices include 35-mL syringe with 19-gauge needle or angiocatheter, water-jet device at the lowest setting, and saline squeeze bottle (250 mL) with irrigation cap.

Enzymatic debridement is accomplished by products that have proteolytic enzymes such as papain and urea (e.g., Accuzyme, Panafil) and collagenase. Typically used once daily, these products may damage healthy tissue and should not be used if infection is present. Thus, special care is needed in application, and use should be limited to short periods (<2 weeks).

Autolytic debridement involves the use of occlusive synthetic dressings that allow enzymes normally present within wounds to self-digest necrotic tissue. Occlusive dressings should not be used if the wound is infected or if there is a moderate amount of exudate (AHCPR, 1994; Cervo et al., 2000; Goode and Thomas, 1997).

Infection Control

In the majority of cases, infection can be prevented by adequate debridement and cleansing. Wounds should be cleansed daily and with dressing changes. Normal saline is the most appropriate solution for cleansing. Avoid skin cleansers and antiseptics that are cytotoxic, such as povidone-iodine, hydrogen peroxide, and acetic acid. Signs of a wound infection include delayed healing, increasing wound size, purulent exudate, pain, and foul odor. Initially, consider a trial of topical antibiotics, such as silver sulfadiazine cream (Silvadene), for 2 weeks. Superficial cultures of the wound are not helpful because they detect only the surface colonization. Ideally, bacterial tissue cultures should be performed to guide antibiotic coverage. Systemic antibiotics are reserved for patients with cellulitis, osteomyelitis, bacteremia, or sepsis (AHCPR, 1994).

Dressing Selection

Wound dressings provide a physiologically moist wound environment shown to enhance healing, reduce pain, debride necrotic tissue, and decrease infection rates in pressure sores. Dressing selection depends on the stage,

Table 4-10 Wound Dressing Properties

Wound Dressings	Absorbent Quality*	Debriding Action	Frequency of Dressing Change	Stage
Polyurethane films	None	None	Every 7 days or less	I, II
Amorphous hydrogels	Minimal to moderate	Autolysis	Every 7 days or less	II, III, IV
Hydrogel sheets	Minimal to moderate	Autolysis	Every 7 days or less	II, III
Hydrocolloids	Minimal to large	Autolysis	Every 7 days or less	II, III, IV
Polyurethane foams	Minimal to moderate	None	Every 7 days or less	II, III, IV
Foamed gels	Minimal to large	Autolysis	Every 7 days or less	II, III, IV
Alginates	Minimal to large	Autolysis	Daily to every 3 days	II, III, IV
Hydrocolloid–alginate	Minimal to large	Autolysis	Every 3 to 5 days	III, IV

*None, minimal, moderate, or large.

amount of exudate, size, site, and condition of surrounding skin. No moist-dressing type has proved superior to the others (Bouza et al., 2005). The main categories of modern dressings are polyurethane films, hydrocolloids, amorphous hydrogels, hydrogel sheets, polyurethane foams, foamed gels, alginates, and hydrocolloid–alginate combinations (Table 4-10).

For deep, stage III and stage IV pressure sores, packing is often needed to eliminate dead space. This can be accomplished with saline-moistened gauze, calcium alginates, gels, and dextranomers. After packing, the wound is covered with an occlusive or semiocclusive dressing. If excessive exudate is present, the dressing must have absorptive properties to control exudate without drying the wound bed. Examples include saline-moistened gauze, alginates, and combination hydrocolloid–alginate dressings.

Pressure sores should be evaluated weekly by a health care professional. Reevaluation of the treatment plan should be considered if there are not signs of healing within 2 weeks of treatment (Ferrell, 1997; Goode and Thomas, 1997).

Pain Control

The overall management of a patient with a pressure sore includes pain assessment and control. Patients should be assessed for pain related to the pressure sore. Management includes the appropriate use of analgesics and eliminating or modifying the source of the pain. This can be accomplished by repositioning, using support surfaces, and using wound dressings shown to reduce pain. Pain should be anticipated before dressing changes and debridement. Appropriate analgesia should be provided as needed.

Adjunctive Therapy

Numerous modalities have been attempted to expedite the wound healing process, but their role remains unclear. Examples include electrical stimulation, hyperbaric oxygen, ultrasonography, and hydrotherapy (Baba-Akbari et al., 2006; Kranke et al., 2004; Olyaei Manesh et al., 2006). Negative-pressure wound therapy has shown promise in the management of stage III and IV pressure ulcer (Banwell and Teot, 2003; Mendez-Eastman, 2004). Further research is needed to establish efficacy of adjunctive therapy for wound healing.

KEY TREATMENT

- Assess all support surfaces and patient factors for increased pressure and modify appropriately (AH CPR, 1994, Reddy et al., 2006) (SOR: A).
- Assess and manage the patient's nutritional status (AH CPR, 1994; Langer et al., 2003; Thomas, 2001) (SOR: B).
- Assess all patients for pain related to the pressure ulcer treatment or its treatment (AH CPR, 1994; NPUAP, 2007) (SOR: C).

Rational Drug Prescribing for Elderly Patients

Key Points

- Adverse drug events result in significant morbidity and a high rate of hospital admissions.
- Medications should be adjusted for the individual patient's renal function.
- Medication lists of elderly patients should be periodically reviewed, focusing on indications and side effects.
- One drug should not be used to treat the side effects of another medication.
- Pharmacists' recommendations should be incorporated in a rational drug-prescribing plan.
- The primary care physician plays an important role in addressing an array of pharmaceutical issues and concerns for elderly patients, including polypharmacy, adverse drug reactions, adherence, and undertreatment of certain conditions.

Medication use is common in the elderly population and increases with age. A population-based survey showed that 44% of men and 57% of women older than age 65 years used five or more medications weekly (Kaufmann et al., 2002). Although persons older than 65 years represent only 13% of the general population, they account for more than 30% of U.S. drug expenditures, totaling more than \$73 billion in 2006 (Medical Expenditure Panel Survey, 2006). Polypharmacy is a major risk factor for ADEs. Up to 10% of emergency department visits and 10%

Table 4-11 Pharmacokinetic Changes in Older Persons

Absorption generally does not change
Longer half-life of lipophilic drugs
Increased amount of water soluble and free (active) drug
Decreased excretion

to 17% of hospital admissions are the result of ADEs (Hayes et al., 2007).

PHARMACOKINETICS AND PHARMACODYNAMICS

Knowledge of the physiologic changes that occur with aging is essential when prescribing medications to elderly patients. Changes in pharmacokinetics and pharmacodynamics can result in increased or decreased amounts of medication and drug-drug interactions (Table 4-11).

Pharmacokinetics refers to the body's response to the drug and includes absorption, distribution, metabolism, and elimination (excretion). Age-related gastrointestinal and skin changes have minimal effect on drug absorption, except for drugs that require active gastrointestinal transport (vitamins, minerals), which decreases with aging. The volume of distribution (Vd) is determined by degree of plasma protein binding and body composition. The changes in protein binding are not clinically significant, unless a condition (e.g., acute illness, malnutrition) is causing a marked decline in albumin. Water composition and lean body mass decrease with aging. Fat composition increases, resulting in a larger Vd of lipid-soluble drugs, such as benzodiazepines. Although liver function tests are unchanged, liver size and blood flow are somewhat reduced. The clinical significance is difficult to determine because there is such wide interindividual variation in hepatic metabolism. Drug elimination is mainly affected by a decrease in creatinine clearance. Also, decreased muscle mass causes a decrease in serum creatinine. Because serum creatinine may appear normal even when significant renal impairment exists, it is important to calculate clearance and adjust medication dosages accordingly (Cusak, 2004). The Cockcroft-Gault (1976) formula can be used to estimate creatinine clearance (eCcr).

$$\text{Cr clearance} = (140 - \text{Age [yr]}) \times (\text{Actual body weight [kg]} / (72 \times \text{Serum Cr [mg/dL]}))$$

For women, multiply the result by 0.85. Of note, this formula is less accurate in extremely ill patients and those with moderate to severe renal insufficiency.

Pharmacodynamics refers to the end-organ response to a drug. Although not as well understood as pharmacokinetic changes, pharmacodynamic changes can lead to changes in receptor binding, a decrease in receptor number, and altered translation of response to a receptor. One clinical example involves β -adrenergic blockers and β -adrenergic agonists. With aging, there is a reduction in β -adrenergic activity in the cardiovascular and respiratory systems that can result in less responsiveness to β -blockers and β -agonists (Cooney and Pascuzzi, 2009).

COMMON PRESCRIBING ISSUES

Prescribing problems that can lead to ADEs include a failure to monitor medications appropriately, to prescribe clinically indicated medications, to educate patients, or to maintain continuity (Higashi et al., 2004). One well-researched problem is the use of inappropriate medications in elderly patients. In 1991, based on ADEs in the nursing home, an expert panel developed a list of drugs that should generally be avoided in the elderly population (Beers et al., 1991). The Beers criteria were updated in 2002 to include ambulatory and nursing facility populations (Fick et al., 2003/2004) and further updated in 2012 (AGS, 2012). Medications on the list are generally ineffective in elderly patients, have a higher risk for ADEs, or have safer alternatives (Table 4-12). The list also includes recommendations regarding medication dosages that generally should not be exceeded and medications to avoid in certain comorbid conditions. It is important to note that this list is only a guideline; if a patient has been taking one of the medications without adverse effects, it may not need to be discontinued.

On the other end of the spectrum is failure to prescribe clinically appropriate medications. Common oversights include a failure to prescribe a β -blocker for a patient with congestive heart failure or with a history of a myocardial infarction, aspirin in a patient with known coronary heart disease, or angiotensin-converting enzyme inhibitors for a patient with diabetes and proteinuria (Rosen et al., 2004; Sloane et al., 2004).

PRINCIPLES OF PRESCRIBING

With patients seeing multiple providers across different clinical settings, it is essential that the medication list remain updated. In one prospective observational study, 74% of patients were taking at least one medication of which their primary physician was unaware (Bikowski et al., 2001).

At least once yearly, ask your older patients to bring in all their medications, including over-the-counter medications. Use a checklist to review each medication (Table 4-13). With each medication, first and foremost, review the indication. Educating the patient about the indication can decrease ADEs and increase adherence (Garcia, 2006). Is the medication effective? Medications are often started for good clinical reasons but never revisited as to their efficacy. Are there side effects? Medications should be discontinued if there are intolerable side effects, and always consider an ADE as a cause of any new patient symptom. Avoid the "prescribing cascade," in which medications are started to treat an ADE. Does the medication require any laboratory monitoring? This may include direct drug levels (e.g., digoxin) or monitoring for side effects (e.g., electrolytes in patient taking hydrochlorothiazide).

Is the patient taking the medication? Medication nonadherence is a common and complex issue with both physician and patient factors. Depending on the definition, "nonadherence" ranges from 14% to 70% (DeSmet et al., 2007). Adherence is associated with the number of medications, cost, frequency of dosing, and patient's knowledge of the condition. It is important to obtain the patient's

Table 4-12 Drugs to Avoid or Limit in the General Elderly Population

Pharmacologic Agents	Comments
Drug Classes to Avoid	
Antihistamines	Nonsedating antihistamines (e.g., fexofenadine, loratadine) are considered safer
Antispasmodics	May result in anticholinergic side effects, sedation, and generalized weakness
Barbiturates	Highly addictive with many side effects; numerous other agents for sedation are preferred
GI antispasmodic drugs (e.g., dicyclomine, hyoscyamine)	Highly anticholinergic
Long-acting benzodiazepines (e.g., chlordiazepoxide, diazepam)	Short- or medium-acting agents are preferred; start with smaller doses
Muscle relaxants	May result in anticholinergic side effects, sedation, and generalized weakness
Specific Drugs to Avoid	
Amitriptyline	Highly anticholinergic; use newer antidepressants or less anticholinergic tricyclics
Chlorpropamide	Long half-life leads to increased risk of hypoglycemia; newer insulin secretagogues are preferred
Dipyridamole	May cause dizziness and hypotension
Disopyramide	Anticholinergic and negative inotropic properties
Doxepin	Highly anticholinergic; use newer antidepressants or less anticholinergic tricyclics
Indomethacin	Compared with other NSAIDs, risk of CNS, GI, and renal side effects is greater
Meperidine	Active metabolite normeperidine may accumulate and cause CNS stimulation and seizures
Meprobamate	Highly addictive; may worsen depression; other anxiolytics preferred
Methyl dopa	Common side effects include depression, sedation, and edema; multiple antihypertensive options are available
Pentazocine	Mixed narcotic agonist-antagonist with potent CNS effects
Phenylbutazone	May cause severe bone marrow suppression; other NSAIDs are preferred
Propoxyphene	Weak narcotic pain reliever (probably no better than acetaminophen alone) but has same side profile as other narcotics
Reserpine	CNS side effects include sedation and depression; multiple antihypertensive options are available
Ticlopidine	More toxic effects than aspirin or clopidogrel
Trimethoprim	May cause extrapyramidal side effects; numerous alternative antiemetics are available
Drugs to Limit	
Digoxin	Limit to <0.125 mg/day in most elderly patients
Ferrous sulfate	Limit to <325 mg/day in most elderly patients
Spironolactone	>50 mg; avoid in patients with heart failure or creatinine clearance <30 mL/min

CNS, Central nervous system; GI, gastrointestinal; NSAID, nonsteroidal antiinflammatory drug.

Is the patient taking the medication routinely?
Does the medication need laboratory monitoring?
Is it still needed?

perspective and concerns about medications in a nonjudgmental manner (Eric Medication Errors Research Group, 2009). Methods to increase adherence have focused on educational interventions and external cognitive aids. For short-term therapies, written information, counseling about the medication's indication and potential side effects, and personal phone calls increased adherence. The same effect was not seen for patients taking long-term medications (Haynes et al., 2008; McDonald et al., 2002).

Finally, the checklist should include asking if the medication is still needed. Has the patient's condition changed to

where you can stop unnecessary drugs, such as preventive medications in a hospice patient?

Continuity of pharmacists is as important as continuity of physicians in decreasing medication errors. Encourage patients to use one pharmacy and inform the pharmacist of any medication changes. Seeking input from the pharmacist can reduce inappropriate prescribing (Garcia, 2006). With inpatient settings, pharmacists obtain more accurate medication histories from patients, reducing the rate and severity of ADEs (Carter et al., 2006; Reeder and Mutnick, 2008). Simplify the medication regimen by using once-daily dosing and generic drugs, if possible. Discontinue medications that have no indication or benefit (Carlson, 1996). When initiating medications, start one at a time at the lowest dose possible (Table 4-14).

The decision to prescribe a drug depends on many factors besides age, including the patient's functional status, comorbidities, other medications, and personal preferences and values. Physicians must be extremely vigilant in prescribing, especially for frail, elderly patients, carefully weighing the risks and benefits of any new medication. Periodic review of patients' medication list is essential for

 Start one medication at a time.

monitoring adverse effects, potentially inappropriate drugs, drug–drug interactions, and drug–disease interactions.

KEY TREATMENT

- Current methods of improving medication adherence for chronic health problems are not predictably effective (Haynes et al., 2008; McDonald et al., 2002) (SOR: B).
- Certain drugs should be avoided or limited in the elderly patient (AGS, 2012) (SOR: C).
- Obtain local pharmacists' recommendations to reduce inappropriate prescribing and ADEs (Garcia, 2006) (SOR: B).
- Reviewing a medication list regularly can reduce polypharmacy and inappropriate prescribing (SOR: B).

Urinary Incontinence

Key Points

- Incontinence is a common medical problem in the elderly population, affecting up to 30% of women and 15% of men.
- Older women are more likely to have urge and stress incontinence, and older men are more likely to experience overflow and urge incontinence.
- Acute episodes of incontinence are more likely the result of underlying medical conditions (e.g., infection, hyperglycemia) or new medications (e.g., diuretics).
- Specific health risks, including depression and falls, have been linked to urinary incontinence in elderly patients.
- History, physical examination, urinalysis, and postvoid residual assessment are the key elements in categorization of incontinence.
- In the majority of patients, incontinence can be diagnosed and treated by the primary care provider.
- Treatment options for incontinence include behavior modification, pelvic floor exercises, pharmacologic agents, vaginal pessaries, urethral inserts, condom catheters, penile clamps, and surgical procedures.
- Systemic hormone replacement therapy may exacerbate incontinence.

Urinary incontinence, defined as involuntary leakage of urine, affects 25% to 30% of all adults in their lifetime. Although women report incontinence more often than men, both sexes are affected equally after the age of 80 years. The estimated prevalence of urinary incontinence

in people older than 65 years of age ranges from 35% in community-dwelling individuals to more than 60% for those who reside in long-term care facilities (Goode et al., 2008; Song and Bae, 2007; Tennstedt et al., 2008). Incontinence not only increases in prevalence with age but also is considered part of a geriatric syndrome. Within the younger population, a specific condition of the lower urinary tract or its neurologic control is often the cause of urinary incontinence. In older persons, however, incontinence is often secondary to physiologic age-related changes, comorbidities, medications, and functional impairments.

Women spend almost \$750 annually out of pocket for incontinence management, have significantly decreased quality of life, and are willing to pay almost \$1400 per year for a cure. The annual costs of incontinence care are greater than annual direct costs for breast, ovarian, cervical, and uterine cancer treatments combined (Subak et al., 2006, 2008; Wilson et al., 2001).

Urinary incontinence is associated with increased morbidity and mortality. Studies have demonstrated an association between urinary incontinence and worsening in overall function. Health-related quality of life measurements have been found to decline in individuals with urinary incontinence (DuBeau et al., 2009; Ko et al., 2005; Teunissen et al., 2006). This decline has been seen in those living independently, in assisted living facilities, and in long-term care environments (DuBeau et al., 2006).

Specific health risks linked to urinary incontinence include depression, social isolation, urinary tract infections (UTIs), pressure ulcers, falls and fractures, decreased sexual activity, sleep deprivation, and increased caregiver stress (Brown et al., 2000; Griebing, 2006; Ory et al., 1986; Spector, 1994). Urinary incontinence is also found to be a common reason for institutionalization of elderly patients (Holroyd-Leduc et al., 2004).

AGE-RELATED CHANGES IN URINARY SYSTEM

Specific age-related changes in the urinary system can directly influence urinary continence. The pelvic floor muscles can lose tone and predispose women to uterine, bladder, and rectal prolapse, causing secondary urge incontinence. Overall bladder capacity also tends to decrease, limiting total volume and therefore increasing urge to urinate. Prostatic hypertrophy predisposes older men to increases in postvoid residual volumes. Older incontinent persons may also experience increased involuntary bladder contractions, exacerbating the problem.

PRESENTATION

Urinary incontinence presentations can be divided into acute (“transient”) or chronic. Sudden onset of incontinence by potentially reversible and treatable conditions is referred to as acute urinary incontinence. Conditions contributing to acute incontinence include lower urinary tract conditions, stool impaction, delirium, fluid imbalance, impaired mobility, and medications (Table 4-15). These conditions not only precipitate acute urinary incontinence but can also contribute to chronic incontinence.

Chronic incontinence can be divided into five types: urge, stress, overflow, functional, and mixed (Table 4-16).

Table 4-15 Medications That Can Cause or Contribute to Geriatric Urinary Incontinence

Class	Mechanism of Action
Pain relievers Opioids	Urinary retention, fecal impaction, sedation, delirium, overflow incontinence
Antiinflammatories; COX-2 inhibitors	Increase fluid retention, nocturnal diuresis, functional incontinence
Skeletal muscle relaxants	Inhibit bladder contractions causing retention and overflow incontinence
Psychotherapeutics	Urinary retention, overflow incontinence
Antidepressants, antipsychotics sedatives and hypnotics	Sedation, delirium, immobility causing functional and overflow incontinence
Pain relievers NSAIDs, COX-2 inhibitors	Increased fluid retention, nocturnal diuresis and functional incontinence
Opioids Skeletal muscle relaxants	Bladder relaxation, fecal impaction, sedation, retention, overflow incontinence
Others Anticholinergics, antihistamines Alcohol, caffeine	Inhibit bladder contractions, sedation, retention, and overflow incontinence Lead to diuretic effect, depressed central inhibition, urge and overflow incontinence

COX, Cyclooxygenase; NSAID, nonsteroidal antiinflammatory drug.

Urge Incontinence

Urge incontinence is the most common type of incontinence identified in older ambulatory patients. It is defined as an abrupt, urgent sensation to urinate and results in loss of urine, with both large and small amounts. Urinary frequency and nocturia are often associated with urge incontinence. Detrusor overactivity is also associated, caused by age-related smooth muscle changes, central inhibitory pathway lesions, history of pelvic irradiation, and bladder sensory or motor innervation deficits. Urge incontinence with an elevated postvoid residual volume can occur when detrusor overactivity and impaired detrusor contractility occur simultaneously. Urinary frequency and retention are common in these patients, particularly those receiving anticholinergic medications.

Stress Incontinence

Stress incontinence is the unintentional loss of urine. It is most often associated with weakening of the pelvic floor muscles and subsequent hypermobility of the bladder outlet and urethra. Stress incontinence occurs with physical movement or activity, such as coughing, sneezing, laughing, or heavy lifting. Stress incontinence is often seen in older women with previous vaginal deliveries or pelvic surgery. It is also associated with lack of estrogen in the menopausal woman. Obesity can exacerbate the symptoms of stress incontinence.

Overflow Incontinence

Symptoms of overflow incontinence include a weak urine stream, dribbling, urinary hesitancy, frequency, and

nocturia. These symptoms may overlap with other types of incontinence, influencing the diagnosis. The etiology of overflow incontinence includes detrusor muscle weakness, bladder outlet obstruction, or both. Medications such as narcotics, anticholinergics, and α -adrenergic blockers can contribute to overflow incontinence.

Functional Incontinence

Functional incontinence refers to leakage of urine caused by factors not directly associated with the bladder. Cognitive impairment (e.g., dementia), mobility disorders (e.g., Parkinson's disease), and inaccessible bathrooms are the most common contributing factors in functional incontinence. Factors may be temporary, as in a patient with a lower extremity fracture who is not able to transfer independently on and off the toilet.

Mixed Incontinence

Mixed urinary incontinence is the combination of two types of incontinence simultaneously, typically stress and urge incontinence. Mixed incontinence is the most common type in women, and the causes of the two forms may or may not be related. Detrusor hyperactivity with impaired contractility is a form of mixed incontinence specific to older adults. Symptoms include urinary frequency and urgency caused by uninhibited contractions of the detrusor smooth muscle. When patients try to void, the bladder does not contract sufficiently, and emptying is incomplete, leading to overflow incontinence.

EVALUATION

The initial step in the clinical evaluation is the identification of patients with urinary incontinence. Many older patients do not complain about incontinence to their health care providers because they are embarrassed or believe their symptoms are just part of normal aging. Direct questioning during the review of systems can help identify urinary incontinence: Do you have trouble with your bladder? Do you lose urine when you do not want to? Do you find that you have to wear pads or adult diapers for protection? (Fantl et al., 1996; Kane et al., 2004).

A thorough history and physical examination are important in the clinical evaluation of older patients with urinary incontinence. The main objectives of the workup are to diagnose and treat reversible causes, establish the principal type of urinary incontinence to help guide treatment, identify patients who may need subspecialty referral, and improve overall quality of life for the patient. After urinary incontinence has been identified, the evaluation should continue with a detailed incontinence history, including the type of leakage, frequency, duration, inciting factors, previous treatments, and overall treatment goals. The physical examination should include abdominal, genitopelvic, rectal, and neurologic evaluation. Health care providers need to be aware of the specific "red flags" to refer a patient for further urologic, gynecologic, or urodynamic evaluation (Table 4-17).

A urinalysis should be obtained in all patients to assess for UTIs, hematuria, or other medical conditions that may be associated with urinary incontinence. Persistent hematuria should prompt additional evaluation, including upper

Table 4-16 Basic Types, Causes, and Treatments of Persistent Urinary Incontinence

Types	Symptoms	History	Common Causes	Primary Treatment
Stress	Involuntary loss of urine with increases in intraabdominal pressure (e.g., cough laugh, exercise)	Patient can usually predict which activities cause leakage of urine	Urethral hypermobility Sphincteric dysfunction Radical prostatectomy	Scheduled voiding Pelvic muscle exercises (Kegel) Females: pessary, tampon during exercise; surgical bladder neck suspension or sling; urethral bulking agent Males: condom catheter, penile clamp; synthetic sling, artificial urinary sphincter
Urge	Leakage of urine because of inability to delay voiding after sensation of bladder fullness is perceived	Loss of urine may vary from minimal to complete emptying of bladder (if full) Urinary frequency and nocturia are common	Detrusor overactivity Neurologic disorders Spinal cord injury	Bladder training (including pelvic muscle exercises) Antimuscarinic therapy Topical estrogen (for severe vaginal atrophy or atrophic vaginitis)
Mixed	Combination of urge and stress symptoms	Variable; patient will usually identify which symptom is more bothersome	Combination of above causes	One or a combination of above, targeting most bothersome symptom(s) first
Overflow	Leakage of urine resulting from mechanical forces on an overdistended bladder, or from other effects of urinary retention on bladder and sphincter function	Usually does not occur unless bladder emptying is impaired Usually see postvoid residual volumes >200-300 mL	Detrusor failure Neurologic disorders Spinal cord injury Diabetes Anatomic obstruction	Bladder retraining; Surgical removal of obstruction Intermittent catheterization Indwelling catheterization
Functional	Urinary accidents associated with inability to toilet because of impairment of cognitive or physical functioning, psychological unwillingness, or environmental barriers	Physical or cognitive impairment May have lower urinary tract deficits	Mobility Impairment Cognitive Impairment	Behavioral interventions with toileting assistance Environmental adaptations Undergarments and pads

urinary tract imaging and cystoscopy. A postvoid residual volume (with ultrasound or catheterization) helps to exclude overflow incontinence. In clinical practice, a postvoid volume of less than 50 mL is regarded as normal, and in general, residual volumes greater than 200 mL are considered abnormal (Pantl et al., 1996).

Voiding (bladder) diaries can provide valuable information for the clinician and patient. The diary includes documentation of each urination episode and any associated symptoms of incontinence for three 24-hour periods. If possible, the patient can also record the amount of fluid intake and output (Abrams and Klevmark, 1996). Several patterns of abnormality can emerge from the voiding diary. For example, frequent small volumes can occur in patients with overactive bladder syndrome, detrusor overactivity, and some painful bladder conditions (e.g., cancer). Frequent large-volume voids are associated with polyuria, as seen in patients with excessive fluid intake and conditions causing polyuria (e.g., diabetes, hypercalcemia). Obstructive sleep apnea, physiologic aging, congestive heart failure, and medications can all cause nocturnal polyuria (Bryan and Chapple, 2004). A simple office tool that can help detect stress incontinence is the cough test. The patient is asked to produce a forceful cough with a comfortably full bladder to determine any urine leakage and potential stress incontinence.

TREATMENT

Several therapeutic options exist to help manage the different types of urinary incontinence. Many older adults prefer

to start with conservative therapies such as behavioral modification techniques before considering medications or surgery. In many cases, several small behavioral changes together may lead to significant improvement in symptoms.

Behavioral Interventions

Particular beverages can aggravate the lower urinary tract symptoms in older adults. Alcohol, caffeine, and highly acidic citrus fruits and drinks are considered direct bladder irritants and may worsen incontinence symptoms. Alcohol has diuretic properties, causing increased urinary frequency. Weight loss may be beneficial for some patients, in particular women with stress incontinence. Nocturia is a common complaint for many elderly patients with multifactorial causes (Sugaya et al., 2008). Minimizing late-afternoon and evening fluid intake may decrease nocturnal episodes for some patients. Reduced production of antidiuretic hormone has been seen in patients with obstructive sleep apnea. Treatment of the sleep apnea may help reduce nocturia symptoms (Kujuba and Aboseif, 2008).

In older patients with symptoms of urinary urgency, timed voiding is often suggested. Many patients experience symptoms only when the bladder is full, so voiding more frequently will reduce the amount of bladder distention and the sense of urinary urgency. Older patients with cognitive or mobility impairments will often need assisted-toileting programs. Providing physical assistance in going to the toilet on a regular basis can reduce incontinence episodes (van Houten et al., 2007). Some patients benefit from bladder retraining, in which they are taught to delay voiding

Table 4-17 “Red Flag” Criteria to Refer an Older Patient with Incontinence to a Subspecialist

Significant uterine, bladder, or rectal prolapse
Surgery or radiation involving the lower urinary tract within the past 6 months
Two or more symptomatic urinary infections within the past 6 months
Greater than 5 red blood cells per high-power field on repeated urinalysis in the absence of infection
Postvoid residual volume >200 mL
Marked prostatic enlargement, prominent asymmetry, or induration of the lobes
Persistent symptoms after appropriate trials of behavioral or drug therapy

at progressively longer intervals (Wallace et al., 2004). Bladder retraining can take months and has the most benefit for patients with urge incontinence and those with mixed incontinence when combined with pelvic floor exercises (Teunissen et al., 2004). The patient is encouraged to focus on the sensations in the pelvis, complete pelvic floor contractions, and wait until the urgency sensation subsides before proceeding to the toilet.

Pelvic floor muscle (Kegel) exercises remain one of the mainstays of behavioral therapy in the treatment of urinary incontinence. The exercises involve repetitive contractions and relaxations of the pelvic floor muscles. They have been found effective in stress, urge, and mixed incontinence (Hay-Smith and Dumoulin, 2006). A simple way to teach women to identify and isolate the pelvic floor muscles is by having the patient squeeze the examiner’s finger during vaginal examination. Squeezing the examiner’s finger by contracting the anal sphincter during a rectal examination can help both men and women isolate the pelvic floor muscles.

Management with Devices

There are two main device options for women with primarily stress incontinence: pessaries and urethral inserts. Pessaries come in many different forms and sizes and have been used for hundreds of years for the treatment of pelvic organ prolapse and urinary incontinence in women. The support offered by the pessary helps in correcting the angles and contacts between adjacent organs, thus minimizing bladder irritation and spontaneous contractions that lead to incontinence. Women need to have pessaries fitted individually by a health care provider. Routine cleaning and care by either the patient or, in many cases, a health care provider is required. Urethral inserts are short silicone single-use tubes. The tube is placed in the urethra by the woman and held in place by a mineral oil-filled bulbous sheath that is located in the bladder neck. In a 2-year follow-up study of 150 women using the insert, mild urethral trauma (6.7%) and UTIs (31.3%) occurred (Sirls et al., 2002). The urethral insert has not seen as widespread use as the pessary.

Men with incontinence have a few device options, including condom catheters and body-worn urinal and penile clamps. A condom catheter is a well-known external collection device and is much safer than indwelling catheters, which have been associated with UTIs and patient

discomfort (Saint et al., 2006). Several condom catheter brands and sizes are available, and most are latex free.

Another similar device is the body-worn urinal. Body-worn urinals consist of a rubber cone (into which the penis fits) and a flange (with a central hole through which the penis passes) that fits around the base of the penis. Body-worn urinals are secured in place by straps or specially designed support underwear as opposed to adhesive. The final male-specific option is the penile clamp. It is a device that is applied to the pendulous part of the penis, preventing urinary leakage, and is used primarily for stress incontinence. The clamps carry a risk of penile edema, urethral erosion, pain, and skin breakdown. Use over a short period of time and by cognitively intact men provides for an excellent discreet device option for male incontinence (Saint et al., 2006).

Absorbent Pads. Many older adults with urinary incontinence use some type of pad or undergarment to help with their urinary incontinence. Although these products play an important role in the management of incontinence symptoms, patients should be encouraged to seek other types of treatment if appropriate. The cost of these products can be significant and is not covered by Medicare or most other insurance plans. However, it is important to realize that these absorbent products can help older adults maintain their functional independence and participate in their preferred activities.

Pharmacologic Therapies

Various medications have been used to treat the different forms of urinary incontinence. However, most current medications are used for urge or mixed incontinence because there is little evidence that adrenergic agonists help stress incontinence (Alhasso et al., 2005) (Table 4-18). The anticholinergic, antimuscarinic medications prescribed for urge incontinence work by blocking cholinergic receptors in the bladder, which in turn diminishes bladder contractility. This class of medications is effective but has adverse side effects (e.g., dry mouth, constipation) related to the cross-reactivity with muscarinic receptors in the salivary glands and colon (Alhasso et al., 2006). Additional side effects include dry eyes, blurry vision, and risk of urinary retention. Anticholinergics can also worsen cognitive function in elderly patients or cause drug-induced delirium, mimicking dementia. Newer medications (e.g., Sanctura) that are theoretically more uroselective and preferentially bind to the muscarinic receptors in the bladder may be associated with fewer adverse side effects. Incontinence medications should not be prescribed to those patients with untreated closed-angle glaucoma and in memory-impaired patients already taking cholinesterase inhibitors to prevent further deterioration of memory function. The anticholinergic agents and cholinesterase inhibitors work in direct opposition and, if taken together, can lead to rapid loss of cognitive function (Sink et al., 2008).

α -Adrenergic antagonists are helpful in treating urge incontinence in men with benign prostatic hypertrophy (BPH). Hypotension is a common side effect with traditional α agents. The newer agents (e.g., Tamsulosin) have fewer adverse side effects and should be used in older men who have low blood pressure or episodes of dizziness. The

Table 4-18 Drug Treatment for Urinary Incontinence

Generic Drugs (Trade Name)	Dosages	Mechanisms of Action	Type of Incontinence
Antimuscarinic			
Darifenacin (Enablex)	7.5-15 mg QD	Lessen involuntary bladder contractions and increasing bladder capacity	Urge or mixed
Oxybutynin (Ditropan) (Ditropan XL) (Oxytrol) transdermal	2.5-5 mg TID 5-30 mg QD (extended-release XL) 3.9- mg patch Q4 days	Lessen involuntary bladder contractions and increasing bladder capacity	Urge or mixed
Solifenacin (Vesicare)	5-10 mg QD	Lessen involuntary bladder contractions and increasing bladder capacity	Urge or mixed
Tolterodine (Detrol) (Detrol XL)	1-2 mg BID 2-4 mg QD (extended-release XL)	Lessen involuntary bladder contractions and increasing bladder capacity	Urge or mixed
Trospium (Sanctura) (Santura XR)	20 mg BID 60 mg QD (extended-release XR)	Lessen involuntary bladder contractions and increasing bladder capacity	Urge or mixed
Estrogen			
Topical estrogen Topical cream	0.5-1.0 g/day for 2 wk; then twice weekly	Strengthen periurethral tissues	Urge associated with severe vaginal atrophy or atrophic vaginitis
Vaginal ring	One ring Q3 months	Increase periurethral blood flow	
Vaginal tablets	One 25- μ g tablet QD for 2 wk; then twice weekly		
Cholinergic Agonists			
Bethanechol (Urecholine)	10-30 mg TID	Stimulates bladder contraction	Overflow incontinence with atonic bladder
α-Adrenergic Antagonists			
Alfuzosin (UroXatral)	10 mg QD	Relax smooth muscle or urethra and prostate capsule	Urge and symptoms associated with BPH
Tamsulosin (Flomax)	0.4 mg QD		
Terazosin (Hytrin)	1 to 10 mg QHS		

BID, Twice daily; BPH, benign prostatic hypertrophy; Q, every; QD, every day, QHS, every night at bedtime; TID, three times daily.

addition of an antimuscarinic drug can be considered in men who are still symptomatic on α -antagonist therapy. For long-term treatment of overflow incontinence in men, 5 α -reductase inhibitors alone or in combination have been shown to reduce the voiding symptoms from BPH as well as the incidence of urinary retention (McConnell et al., 2003).

Currently, no medications are approved by the Food and Drug Administration for the treatment of stress incontinence. Estrogen has been prescribed in the past for stress incontinence because it was thought to improve urethral thickness and vascularity and sensitize α -adrenergic receptors in the bladder neck musculature. However, a Cochrane review failed to demonstrate improvement in stress incontinence while patients were taking estrogen, and the incontinence may actually worsen with oral agents. Conversely, combination estrogen–progestin oral hormone therapy has been associated with increased frequency of incontinence. Topical estrogen in the same Cochrane review was mildly effective when prescribed for older women with urge incontinence related to atrophic vaginitis or severe vaginal atrophy (Cody et al., 2009; Grady et al., 2001; Rossouw et al., 2002).

Surgical Treatment

The sling procedure is the primary form of open surgical treatment in women with stress incontinence. Several variations of the procedure exist with relation to the exact location of the sling and the nature of the graft material used to make the sling. The principal function of the sling is to increase the outlet resistance and thus prevent urine leakage during periods of increased intraabdominal pressure. Initial success rates for the sling procedure range from 80% to 90% but decrease with time. Some women respond to other forms of therapy or elect to undergo another sling procedure (Anger et al., 2007).

Periurethral injection of bulking agents can be an effective treatment in some elderly women with stress incontinence. The procedure is minimally invasive and can be performed in the outpatient setting with rapid recovery and immediate results. To date, there is limited evidence that this can relieve stress incontinence in women (Keegan et al., 2007). One disadvantage is that treatment usually needs to be repeated with time. Injection therapy may be particularly useful in elderly women who are unable to undergo the more invasive sling procedure or who are

symptomatic after a previous sling procedure. Older men with mild postprostatectomy stress incontinence may benefit from periurethral injection of bulking agents (Fantl et al., 1996).

KEY TREATMENT

- Pelvic floor exercises help with all types of urinary incontinence in women (Hay-Smith and Dumoulin, 2006) (SOR: A).
- Anticholinergic drugs are effective for overactive bladder syndrome but are associated with common side effects (Alhasso et al., 2006) (SOR: A).
- There is limited evidence that periurethral injection helps women with stress incontinence (Keegan et al., 2007) (SOR: A).

Medical education and our professional attitude regarding patient care are oriented primarily toward sustaining life and curing disease. This is reasonable because not long ago, the major causes of death were infectious diseases, which usually attacked young people, who died before experiencing life. With the advent of antibiotics, it was possible to triumph over these diseases and prevent untimely death. Patients had a high probability of complete recovery. It is no surprise, therefore, that the medical profession emphasized preserving life at all costs and became preoccupied with the advancing technology that made such triumphs possible. Today, most people no longer die of acute illness but rather from chronic disease for which there is no cure. This calls for medicine to focus on improving the *quality* rather than the *quantity* of life and to recognize that the relief from suffering is superior to attempts to cure when there is limited likelihood of success. Patients with chronic diseases and those who are terminally ill benefit most from supportive therapy.

In previous centuries, it was assumed that life should be lived so that one would be able to "die well," but contemporary American culture has refused to accept death as a normal occurrence. Children and young adults have been conditioned to consider death from the viewpoint of the observer or disinterested third party. An individual's attitude toward his or her own death depends largely on experiences in dealing with the deaths of relatives or friends. Rather than a time of despair, sickness may be used as an opportunity for reflection. For some patients, it may be the first time they have faced their own mortality. Too often, however, this natural personal encounter has been depersonalized by removing the dying patient to an institutional setting.

Care of a terminally ill patient typically focuses on the disease, neglecting the patient as a whole person. The value of treatment must be interpreted on the basis of its net value to the individual. When additional treatments no longer provide benefits, the patient needs someone who provides personalized care with attention to the patient's emotional as well as physical comfort. The dying person often is isolated physically and emotionally from familiar

surroundings and placed in a social setting that gives very low priority to an individual's personality, fears, and past experiences. Informed physicians, family, and friends can do much to help the terminal patient die with integrity and dignity. However, if dying is really to be accepted as a normal component of the life cycle, reintegration of the dying patient into the routine course of living is necessary.

The concept of quality care does not always demand that death be regarded as an enemy to be fought with every weapon at a physician's disposal. The technology of today makes it possible to keep people alive indefinitely, often without consideration for their quality of life. An obsession with quantity of life can adversely affect its quality; at times, a graceful death with dignity is preferable to lingering torment (LORAN Commission, 1989). Many people consider quality of life more important than quantity and want to leave while they still have something to say about it. The goal is to "respect the experience of living while supporting the process of dying" (Berlinger et al., 2013, p. 13).

The Physician's Attitude

Fewer than 10% of people die suddenly; more than 90% experience a protracted, life-threatening illness (Emanuel et al., 2003). Terminal illness is more taxing on the physician than sudden and unexpected death. Not surprisingly, an empathic family physician with a long patient relationship may be uncomfortable in dealing with the patient's impending death. Physicians are most uncomfortable when they feel helpless. Unfortunately, this leads to withdrawal from the patient who is terminally ill because the physician inappropriately feels helpless and impotent, when in fact a great deal of comfort and help can be provided. "Even the busiest doctor owes [the patient] courtesy and compassion" (Lieberman, 2013, p. 136).

While expressing concern and compassion for a terminal patient, the family physician still must maintain composure and objectivity to remain effective. Osler (1904) referred to this as "calm equanimity" and added, "Our equanimity is chiefly exercised in enabling us to bear with composure the

misfortunes of our neighbors” (p. 8). Medicine long has emphasized the need for physicians to remain objective and deal with problems factually; if a physician is unable to do so effectively, attempts to hide emotion may lead the physician to adopt a facade that appears unsympathetic and insensitive to the patient’s needs. A son reported that “with the worsening of my father’s condition, the physician stopped being friendly and warm; his visits became rare and brief; his manner became quite detached, almost angry” (Seravalli, 1988, p. 1729).

Physicians sometimes lose enthusiasm for care when an illness has been recognized as incurable. If this occurs, interaction with the patient diminishes at the very time emotional support is needed most. Time-motion studies indicate that nurses and other ward personnel also spend less time with terminally ill patients when giving baths and providing routine care. Using videotape surveillance of terminally ill patients’ rooms in a university hospital, Sulmasy and Rahn (2001) found that the average patient spent more than 10 hours alone while awake per day. Because abandonment is a major fear of terminally ill patients, we must remain aware of the need to reduce the time patients spend without human interaction by physicians, nurses, or family.

Compassion fatigue is a form of emotional exhaustion and diminished empathy more common in health professionals caring for dying patients. Symptoms parallel those of post-traumatic stress disorder—that is, hyperarousal in the form of disturbed sleep and irritability, avoidance of the patient, and intrusive thoughts or dreams relating to the provider’s work with dying patients (Kearney et al., 2009).

During the terminal stages of a fatal illness, it is vital to the dying patient that the family physician maintain a warm and caring relationship and, through the strength of the doctor–patient bond, provide support for the patient.

A physician who is uncomfortable discussing impending death can discourage conversation in many subtle ways. Hospital rounds are made rapidly, perhaps in a superficial, lighthearted manner, never pausing long enough to give the patient an opportunity to express fears and concerns. Comments such as “everything will be all right” effectively close lines of communication with an intelligent patient who is fully aware of the seriousness of the situation. When the physician tells a patient, “Don’t worry,” the patient interprets this as, “Don’t bother me.” Patients are unlikely to initiate discussions regarding their fears of death or feelings of helplessness under such circumstances and remain silent or avoid these issues unless they think the physician is interested and will listen. The physician easily can squelch such conversation, but a slight indication of willingness to discuss the problems disturbing the patient often results in frank conversations, which relieve much of the patient’s anxiety and reveal concerns that can be shared only with the physician.

THE “RIGHT TIME” TO DIE

Simpson (1976) described the “how dare you die on me” syndrome in which the patient has the “effrontery” to die before medical and nursing staff have used all the treatments in their repertoire. The patient is supposed to die “at the right time”—neither before all potential effective therapies have been tried nor too long after all palliative

procedures have been used. Health professionals often need to believe that everything possible was done for the patient before death. These attitudes have developed because the health care process too often focuses more on professional expectations than patient needs.

We might consider what we have done to a patient who dies in the isolation of a laminar flow room without having been able to touch another person’s hand during his last few weeks of life. Such treatment is a *false-positive*, a treatment inappropriate to the real needs of the patient (Saunders, 1976).

However, it is impossible for physicians to provide adequate support during this difficult time unless they have come to grips with their own mortality. Studies by the Group for the Advancement of Psychiatry have revealed that physicians are afraid of death in greater proportion than patient control participants (Aring, 1971). What better defense against death than to make one’s full-time vocation fighting it?

Patients are often more willing to accept death than the physicians who treat them, and many fear that they will receive more aggressive treatment than they want. Based on interviews with seriously ill patients, 60% preferred that treatment focus on comfort even if it meant shortening their lives. The other 40% wanted life-extending care. Of those preferring comfort care, only 41% reported that treatment matched their wishes (Teno et al., 2002). In another study, more than half of physicians interviewed admitted they had provided overly aggressive care to patients (Solomon et al., 1993).

Many, if not most, patients will choose toxic chemotherapy even if there is only a slight chance of cure or even if it would prolong their life by only a few months. The concern is that they may choose this route on the advice of their physician even though they will be miserable for those remaining months. It is important to have a straightforward discussion with the patient about the quality and quantity of life with and without chemotherapy. More than 20% of Medicare patients with metastatic cancer had a new chemotherapy treatment regimen started in the 2 weeks before death (Earle et al., 2004).

Unfortunately, chemotherapy is better compensated than are discussions as to its need and potential side effects. It is no surprise that oncologists prefer third- or fourth-line chemotherapy to discussing hospice care. One patient received intrathecal chemotherapy 6 days before his death at a cost of \$3400 (Harrington and Smith, 2008).

Communication

WHEN TO TELL THE PATIENT

The issue today is not so much whether to tell patients they have a terminal illness but rather how to share this information with them—because most patients know the nature of their disease process to some degree. Because they know their patients well, family physicians should be able to gauge patients’ desire to be told and their capacity to withstand the shock of disclosure. When a terminal state of cancer is inevitable, most patients prefer to discuss such issues with their family physician rather than with their oncologist.

Key Points

- Abandonment is a major fear of dying patients, who spend an average of 10 awake hours alone per day.
- Listening and allowing patients to express their fears and concerns is of great therapeutic benefit.
- Touch and sitting with the patient convey support and compassion.
- Frequent assessment of the patient and family's desire for information must be accompanied by honest answers.
- Patients should be allowed as much control as possible to avoid fear of the unknown.
- When cure is not possible, much benefit can be derived from attention to daily symptom control.
- Avoid giving false hope but remember that hope and humor can be therapeutic.

Patients who have end-of-life conversations with their family physician have lower health care costs during the final week of life. Better communication results in better quality of life and quality of death as well as lower cost (Zhang et al., 2009). End-of-life care is often fragmented among providers, leading to a lack of continuity of care and impeding the ability to provide high-quality, interdisciplinary care. A family conference to discuss a plan of care, which would include the patient if he or she were still capable of participating, is often initiated after the patient's functional decline (Berlinger et al., 2013). Enhanced communication among patients, families, and providers is crucial to high-quality end-of-life care (National Institutes of Health, 2004).

A frank discussion of death or how long the patient is expected to live may not be necessary or even indicated. A good understanding between the physician and patient may make open disclosure unnecessary. The physician's role may be primarily one of supporting patients during the progressive, terminal course of their illness. However, the physician who is uncomfortable with the subject of death should not use such a situation as an excuse to avoid discussing the issue. The family physician's primary responsibility is to take the time to evaluate the situation, make sure the patient's true desires have been assessed correctly, and provide whatever support is needed based on the patient's concepts and needs rather than those of the physician (Table 5-1). An institution's policies should recognize that, on occasion, a health care professional may choose to withdraw from a patient on religious or other moral grounds as a conscientious objection. The institutions should accommodate for this request without compromising standards of professional care and the rights of the patients. The physician should maintain the duty of care until the patient is transferred to another professional (Berlinger et al., 2013).

A physician who can deal with death honestly is able to focus more attention on the patient and can determine the patient's level of awareness by listening and observing non-verbal cues. Clues to the patient's wish to discuss the condition may simply be a deep sigh, a tear, or a shaky voice. The physician must be alert during busy hospital rounds for these or similar signs. The physician can pause to sit and

Table 5-1 Useful Questions in Determining a Terminally Ill Patient's Needs and Wishes

What do you fear most?
What would you like to accomplish in the time left?
What is your highest priority?
How can I help you achieve this?
What has been most difficult about this illness for you?
How is your family (e.g., wife, husband, child) dealing with your illness?
Is religion important to you?

encourage conversation if time permits or return later when more time is available. Whenever possible, however, the response should be at that moment because the patient is more likely to communicate freely in a spontaneous situation. Physicians who are uncomfortable in this situation may insulate themselves from the issue during hospital rounds by checking the bedside monitoring equipment or otherwise directing attention away from the patient, effectively ignoring overt as well as subtle clues to the patient's needs.

Talking with patients about their death can be difficult, but end-of-life discussions with patients do not result in greater emotional or psychological stress. On the contrary, worse outcomes are found in those who do not have these conversations. Such discussions result in less aggressive medical care near death and earlier hospice referrals. Wright and colleagues (2008) showed that quality of life deteriorates with a greater number of aggressive end-of-life interventions and improves with longer hospice care. Even if a patient has a short hospice stay of hours to days, the patient may still benefit from a higher quality of life because of better symptom management and spiritual support for both the patient and the family (Waldrop et al., 2009). A key benefit of hospice is bereavement support for the patient's family up to 13 months after the patient has died. When the patient is ready to discuss her or his impending death, the physician and patient are probably past the most difficult stage, and the physician needs merely to listen, accept the patient's feelings, and respond to questions honestly. Most patients raise questions that indicate how much they wish to know, provided the physician gives them the opportunity. The most supportive and facilitative act the physician can provide is to sit and ask the patient, "Do you have any questions?" When asked in a sincere manner, patients who are ready to talk about their death will take advantage of the opportunity, but they may be reluctant under other, more hurried circumstances.

Patients usually will indicate their desire to discuss their prognosis, as well as when they want to avoid the subject and focus on other topics. Even patients who fully accept their terminal process cannot remain constantly focused on that subject and must attend to more satisfying issues. Physicians should honor and respond to this need, just as they would respond to a desire to discuss pain or other problems.

What physicians say to dying patients is not nearly as important as their willingness to listen. One of the most comforting steps physicians can take in caring for the dying is to allow them to talk about their fears, frustrations, hopes,

needs, and desires. *Talking about problems can be very therapeutic.* Patients who are permitted to examine and discuss their feelings about death and dying are grateful for the opportunity and usually become less anxious, experience less pain, and accept their situation more easily. If they are denied this opportunity, especially when the terminal process is obvious, they may be convinced that the time remaining is too terrible to be discussed, and their anxiety will be significantly increased. Often, terminally ill patients are more fearful of the manner in which death will occur (e.g., painful, alone and abandoned, weak and helpless) than they are of death itself.

Do all patients want to be told of their fatal illness, however? Surveys indicate that 80% to 90% of patients say they wish to be told, but many physicians prefer not to tell a patient that he or she is dying. Ward (1974) found that family physicians are more likely to discuss a fatal diagnosis with women than with men (22% vs. 7.5%) and more often with patients in the upper social class than the lower social class (24% vs. 5% for men; 30% vs. 26% for women). Physicians often wait until the patient is close to death before initiating end-of-life discussions with patients and their families. Patients with cancer often receive a more comprehensive discussion about end-of-life issues than patients with noncancer diagnoses (Abarshi et al., 2011). Promoting earlier discussion about end-of-life decisions helps patients and their families to better prepare for the changes to come. Medical students must be trained more adequately to assist their future patients with how to cope with the dying process. Allowing space to patients and family is beneficial for all participants in the discussion, combined with communication that includes active listening tailored to each patient's needs (Mazzi et al., 2013).

Most physicians tell a patient that he or she has terminal cancer if the patient asks a direct question but otherwise evade the issue and discuss it openly only with the family. In many cases, this is the most appropriate course of action; some patients clearly indicate that they cannot and do not wish to face the fact that they have an incurable disease. It is essential, however, that the physician evaluate the true nature of the patient's desire in the matter and neither avoid the issue when the patient wishes to discuss it nor force a discussion on an unwilling individual. "When the task of telling a patient about an onerous diagnosis is too easy, the doctor has become callous. When it is too difficult, he needs to examine his own guilt or anxiety" (Weisman and Brettell, 1978, p. 251).

Patients should be given adequate time to absorb the knowledge of the terminal nature of their illness and the opportunity to react appropriately before death intervenes. This is not possible if the physician procrastinates or rationalizes that it is better not to inform the patient. The process should not be allowed to advance to such a final a stage that inadequate time remains for individuals to react appropriately and put their affairs in order.

HOW TO TELL THE PATIENT

There is no need to answer questions the patient has not yet asked. One way to approach the subject is to ask patients what they think the problem is or how sick they think they really are. The response may be straightforward ("I think I

have cancer"), or the patient may indicate a wish to avoid the issue by saying, "I hope it's nothing serious." The patient's condition can be revealed gradually or in stages, such as telling the patient after surgery that there is a suspicion of cancer but that further information will have to wait for the pathology report. The physician should observe the patient's response to this initial suspicion and, based on that reaction, choose a method for presenting subsequent information. Tumulty (1973) supported the concept of *gradualism* in informing a patient and the family of the terminal nature of the illness: "The total truth is revealed in small doses as the illness unfolds, affording the family the opportunity to get its feet under itself before another blow falls. ... The patient and the family need to be eased into the truth ... not slugged with it" (pp. 180-181).

Such a gradual disclosure is likely to lead to acceptance, but a harsh, sudden, or abrupt disclosure is likely to result in denial or severe depression. If the patient appears reluctant to accept the information, do not push the issue; merely make sure that openings for discussion are made available periodically and further information is provided when the patient is ready.

One statement is never appropriate: "There is nothing more that we can do." Such statements tell patients they are being abandoned and increase their feelings of isolation and vulnerability. There is *always* something the family physician can do to provide compassionate, comforting care to the patient and family even if it is only sitting at the bedside so the patient does not feel abandoned. *Distress* can take many forms: physical, emotional, and spiritual, as well as anticipating symptoms that may arise, such as pain, constipation, anxiety, depression, and nausea. Family physicians also can help by stopping or avoiding treatments and diagnostic procedures that hold little promise of improving the patient's quality of life, such as taking vital signs or turning patients in bed when they are trying to sleep. If a test will not lead to a change in treatment, the test is not indicated.

Delivering "Bad News"

When giving "bad news" to a patient, do so privately and without interruption (see eTable 5-1). Use language the patient can understand, allow the patient to be emotional, offer to help break the news to the patient's family and employer, and be sure that care providers know what the patient has been told (Field and Cassel, 1997).

Health care professionals caring for patients at the end of life should assess the patient's readiness to engage in the discussion and appreciate their level of understanding about the situation and how much they want to know. When physicians know the patient's preferences, they can tailor the discussion appropriately, checking periodically for the patient's level of comprehension and desire for more information. It is best to provide small amounts of information at a time, frequently assessing the patient's desire to continue. Also, besides comprehension, what are the patient's expectations?

When sharing information regarding a fatal diagnosis with a patient, eye contact, touch, and personal closeness are important. If possible, sit with the patient and hold his or her hand or touch the forearm. Such gestures convey a sense of support, closeness, and compassion, reinforcing

eTable 5-1 Delivering “Bad News” to Patients

- Choose a private, quiet place.
- Avoid delivering bad news over the telephone because there is no way to know what the reaction is or if a support system is available.
- Allow adequate uninterrupted time; turn off cell phone or beeper.
- Have a family member or friend (another “set of ears”) present because the patient may hear nothing after the word “cancer.”
- If the family is present, acknowledge everyone and ask their relationship to the patient.
- Ask the patient and family what they already know and determine how much they want to know.
- Be honest but not blunt and assure continued honesty.
- Present information in a few sentences and ensure understanding by those present.
- Watch your body language; convey concern; sit, touch, and look the patient in the eye.
- Let the news sink in; give the information and then pause and wait for a reaction. Encourage the patient to express his or her feelings, fears, and desires.
- Assure the patient that treatment will allow as normal a lifestyle as possible.
- Assure the patient that you will do everything possible to make his or her days pain free and comfortable and that you will be available and will provide continued support.
- Schedule a follow-up visit with family members soon to answer questions and correct misconceptions.
- Communication is an ongoing process determined by the patient’s coping mechanisms and desire to know more.
- Do not underestimate the amount of information the patient wants. Talk less about diagnosis and treatment and more about the disease’s impact on the patient and family.
- Do not avoid discussing prognosis; lack of information increases anxiety.

Table 5-2 Positive Language to Use with Dying Patients

I will keep you as comfortable as possible.
 I will focus on maintaining your quality of life.
 I want to help you live meaningfully in the time you have left.
 I will do everything I can to help you maintain your independence.
 Maintaining your independence and dignity will be my top priority.
 I will do my best to fulfill your wish to remain at home.

Modified from Stone MJ. Goals of care at the end of life. *Proc (Bayl Univ Med Cent)*. 2001;14:134-137.

verbal assurance that the patient will not be abandoned during the difficult time remaining. Be positive whenever possible (Table 5-2).

Sitting with the patient on the bed or at the bedside rather than standing puts the physician on the same level and conveys in a clear, nonverbal manner a willingness to talk and listen. In one study, physicians visited with hospitalized patients for exactly 3 minutes. Half the visits they sat down, and the other half they remained standing, a little removed from the bed. “Every one of the patients [with whom] the physician had sat down thought the physician had stayed at least 10 minutes. None of the ones [with whom] the physician remained standing estimated that it was as long” (Kübler-Ross, 1975, p. 20).

PROGNOSTICATING

One of the most difficult tasks in medicine is predicting how long someone with a terminal illness will live. People enjoy repeating stories of patients who survived long after the date their doctor predicted. In most cases, however, physicians tend to be overly optimistic, and short estimates are more accurate than longer ones (Evans and McCarthy, 1985).

In fact, physicians overestimate survival more than 60% of the time and underestimate it only 17% of the time (Christakis and Lamont, 2000). In addition to physicians overestimating prognosis, many patients believe their treatment at the end of their life (e.g., radiation) is intended to be curative, when in reality it is palliative. The better that physicians know their patients, the more they overestimate survival, probably hoping the best for patients they know well. The longer the physician has been in practice, the more accurate the prognosis. Most patients want optimistic physicians, but at some point, this optimism may delay palliative treatment.

Attempts have been made to develop indexes (e.g., Karnofsky score) to assist the physician in making objective estimates that correlate with actual survival. However, no accurate method is currently available, largely because of the multiple variables that influence when a patient dies. A good policy is to provide a conservative estimate. It is better to have the patient and family proud that they “beat the odds” or exceeded the physician’s prediction than to have the patient die earlier than anticipated.

CONSPIRACY OF SILENCE

Honesty with the terminal patient will provide the greatest benefits. However, the physician frequently is torn between

patient and family, with the patient saying, “Don’t tell my wife because she can’t handle it,” while the wife is saying, “Don’t tell my husband because he can’t handle it.” Although the wishes and desires of the family must be considered when deciding how to care for a dying patient, the physician’s primary obligation is to the patient. The method of management must be based on the physician’s knowledge of the patient and insight into the patient’s desires, feelings, and approach to life. Despite all efforts at deception, the patient knows or will soon learn about his or her condition.

By cooperating with the family in a conspiracy of silence, information that really belongs to the patient is withheld. Only if the physician believes that the patient is not yet ready to cope with the information or sincerely wishes not to be told should the information be withheld; however, this is more often the exception than the rule. One patient said, “I knew it was cancer from the moment they started lying to me” (Lamerton, 1976, p. 28). Simpson (1976) described a 63-year-old woman whose family insisted she knew nothing of her inoperable gastric carcinoma. When visited by the physician, “She gave a dry chuckle: ‘Only a little ulcer ... and my relatives down from Wales to see me for the first time in 15 years, and the priest here at 6 in the morning?’” (p. 193). When such a charade continues, terminally ill patients become increasingly more isolated because they are unable to communicate their concerns and fears honestly and openly with those closest to them. The elaborate schemes some families and physicians develop to “protect” the patient lead to great tension within the family, as everyone attempts to perpetuate the lie while continuing to interact with the patient.

Similarly, failure to provide the information to the patient’s family can lead to a decrease in the quality of their relationship in the time remaining because the patient’s tensions and fears are not understood by family members and friends. Dunphy (1976) described a patient with terminal cancer who asked that his wife not be told. He then quickly planned a world cruise, which they had wanted to take for some time. The wife, unaware of the reason for the hasty departure, was unhappy and complaining throughout the trip, while the husband saw himself as a silent martyr, trying to provide a final measure of happiness for his wife. Only after returning home and reminiscing on this miserable cruise did he tell his wife the truth and the reason for the precipitous departure. Had she been told earlier, their final days together could have been a pleasant and memorable experience. At a time when the terminally ill patient most needs closeness, a lie may serve to push them apart.

Denial

Most patients tend to deny the reality of their situation after being made aware of the terminal nature of their illness. Denial is one way of coping with or protecting oneself against overwhelming anxiety, which otherwise could be incapacitating. This reaction is more marked in a patient who is told abruptly without adequate preparation. Although denial is noted primarily when the patient first learns of impending death, it can appear in different degrees

at different times. Even patients who have accepted the terminal nature of their illness will need to use denial periodically to avoid feelings of hopelessness. The mental burden of impending death is too heavy to carry all the time, and periodic relief is necessary to carry on customary activities and enjoy the limited time left. As Aring (1971) noted, La Rochefoucauld said, “Neither the sun nor death can be looked at steadily.”

Patients who avoid asking about their illness or prognosis when the physician offers every opportunity usually are experiencing denial. Excessive denial usually means that the patient subconsciously knows the truth but wants to avoid facing it consciously. Even when repeatedly given the accurate diagnosis, some patients deny ever having been told. This denial provides constant emotional protection until the patient is ready to face the truth.

“Watch with Me”

The greatest fear of the dying patient is that of suffering alone and being deserted. There is less fear of a painful death than of the loneliness and alienation that may accompany it. A patient particularly dreads being abandoned by the physician in the face of death and may need increasing levels of professional support as the illness progresses. This is particularly true if family and friends are not able to cope with the deteriorating condition and begin to avoid contact, thus contributing further to the patient’s feelings of loneliness and abandonment. If the patient believes that no one is available to discuss the situation openly and honestly, despair is likely to ensue. The patient’s fear of the unknown is easier to cope with if his or her apprehension can be shared with a caring physician who provides comfort, support, encouragement, and even a modicum of hope.

Each new problem of the dying patient should be viewed as a nuisance requiring relief or removal and approached with the vigor that one would devote to an acute, short-term illness. When a fresh complaint arises, the patient should be reexamined and attempts made to relieve the symptom so the patient will not feel unworthy of further attention. If everyday nuisances can be controlled or lessened, the patient will believe that there is sincere concern for making her or his remaining life pleasant. The physician should give attention to details such as improving the taste of food by fixing or replacing dentures or stimulating the patient’s appetite, eliminating foul odors, and suggesting occupational therapy to avoid boredom.

The physician should take advantage of every opportunity to touch and examine the patient rather than standing apart. Gentle palpation of areas of pain or merely taking a pulse can convey a sense of concern and warmth and provide comfort for an apprehensive and lonely patient. The physician and other health professionals can provide much support merely through conversation. The tendency to withdraw and reduce conversation contributes to the patient’s sense of loneliness. Silence is an enemy of dying patients and increases their separation from society. Conversation is a social bond that affirms life and reduces anxiety by providing a means of catharsis. Saunders (1976) summed up the needs of a dying patient with the words of one patient: “Watch with me,” asking that he not be

abandoned in his final days. The readiness to listen and personal, caring contact are comforts that cannot be matched by modern “wonder drugs” and procedures.

When dying patients notice that people are avoiding them, they may interpret it as rejection because their condition has not improved or as the loss of love from family and friends, which is particularly traumatic because it tends to negate long-cherished relationships; the joys of a rewarding life can suddenly lose their value. The dying patient’s contentment depends on maintaining warm relationships with loved ones as well as continuing other satisfying interpersonal relationships, including with the physician. If physicians and others withdraw from interaction with the terminally ill patient, much of the motivation for living disappears and is replaced by despair or terminal depression. The following plea to fellow health professionals is from a young student nurse who was terminally ill (Kübler-Ross, 1975):

I know you feel insecure, don't know what to say, don't know what to do. But please believe me, if you care, you can't go wrong. Just admit that you care. ... All I want to know is that there will be someone to hold my hand when I need it. I am afraid. Death may get to be a routine to you, but it is new to me. You may not see me as unique! .. If only we could be honest, both admit of our fears, touch one another. If you really care, would you lose so much of your valuable professionalism if you even cried with me? Just person to person? Then, it might not be so hard to die—in a hospital—with friends close by (p. 26).

Patient Control

We need to provide options to patients so they can actively participate in their care and feel a sense of control.

Terminally ill patients have a need to believe that they are still in control of their affairs as much as possible even though they have lost control of their bodies. They should be given the freedom to make choices and assume responsibility over as many aspects of their existence as possible. For many individuals, this is an essential part of living, and its loss may destroy their motivation to live. A terminally ill patient should be helped to focus on and cope with the realities of daily living because these problems remain very real and can serve as a diversion from constant preoccupation with the prospect of death. When patients have understanding and insight into the treatment and believe they still have some control over the decision-making process regarding their lives, they are more likely to cooperate with prescribed treatment regimens.

It is often fear of the unknown that makes a patient suspicious and resistant to therapy. Patients also should be given the opportunity to settle their affairs. Studies have shown that 40% of terminally ill patients are most concerned about being a burden to their family and friends and that 40% of the families of cancer patients become impoverished

as a result of providing care for a family member (Emanuel et al., 2003). Concentration on financial business and putting the house in order is a pragmatic approach to active participation in the decision-making process. Some patients may have a burning desire to complete a cherished project, reconcile an estranged relationship, or visit particular places before they die. Positive motivation can be maintained by assisting them to focus on and deal with these issues.

A sense of control is more possible for the patient if pain is controlled and the patient is made comfortable. Sleep should not be forced with medication because some patients resist going to sleep, fearing they may never awaken, and others frequently have terrifying dreams.

The Importance of Hope

Hope is one of the essential ingredients of human existence, without which life is dark, cold, and frustrating. It maintains strength and gives substance to courage. In the presence of hope, suffering of all sorts still has some positive qualities. In its absence, suffering is a completely negative experience (Tumulty, 1973).

Hope allows patients to face the shortness of their lives constructively. Twycross (1986) defined hope as having “an expectation greater than zero of achieving a desired goal.” Hope can also be defined as the patient believing in what is still possible. Anything that contributes to a sense of meaning or purpose in life fosters hope. Thus, belief in God or a higher being provides hope and may give a sense of meaning to suffering for some patients.

The physician should not raise false hopes or be overaggressive in treating a terminal illness to help the patient maintain hope. Some patients find it best to plan for a little time and hope for more. A false sense of hope may deflect the patient and family from finding final meaning and value in their remaining lives together.

Even patients with advanced cancer can maintain a positive outlook on life. The physician can help direct a patient toward an achievable goal, such as pain relief, support for the family from a hospice service, or making a trip to visit relatives.

Even laughter can contribute to hope. One patient said, “I may not have much control over the nearness of death, but I do have the power to joke about it.” Also, recalling uplifting moments such as vacations or looking at old photograph albums can support hope. Memories of the past can serve to enrich the present (Herth, 1990).

Whereas having one’s individuality accepted, honored, and acknowledged fosters hope, devaluation of personhood and a feeling of abandonment and isolation interfere with hope. Hope is also hindered by uncontrollable pain and discomfort. The continuation of pain after attempts to control it have failed contributes to the loss of hope (Herth, 1990).

Even when death is near, the patient can hope for a measure of happiness during the amount of time he or she has remaining. The physician can support the patient’s hope for a good quality of life in the remaining time, for spiritual healing, and for a final phase of life that has integrity and dignity.

Hope is a potent force for patients to deal with their illness and to have a confiding relationship with a physician, spouse, or close friend, which can also help prevent depression. Every physician–patient encounter should leave the dying patient emotionally more able to deal with end-of-life issues. Always promote the patient’s sense of hope (Ngo-Metzger et al., 2008).

DISCUSSING RELIGIOUS AND SPIRITUAL ISSUES

As patients approach the end of life and grapple with their mortality, their spiritual and religious concerns may be awakened or intensified. Although some physicians may be uncomfortable discussing a patient’s spiritual and religious concerns, they can listen respectfully without judgment or discussion of religious views. Patients who believe that the physician really understands their concerns no longer feel isolated or alone in their final days (Low et al., 2002).

One way to approach this issue is to ask the patient, “Is faith or religion important to you in this illness?” In a study of patients with advanced cancer, 88% reported that religion and spirituality were important factors in adjusting to their illness (Balboni et al., 2007). Although religious coping can offer patients a sense of meaning and comfort when facing a life-threatening illness, it is somewhat surprising that a high level of religiousness is associated with preference for aggressive end-of-life care such as mechanical ventilation. These patients may have a greater trust that God will heal them through the treatment even when near death (Phelps et al., 2009).

Prolonging Living or Prolonging Dying?

It has been a long time since pneumonia was accepted as “the old man’s friend.” As one organic system after another slowed to a halt, the aged person was released from nausea, pain, delirium, and the degradation of lingering deterioration by finally developing pneumonia and dying. The family doctor merely showed concern and support; before antibiotics, there was not much to do but stand by and “let nature take its course.” With improved medical care, however, a dying process that might have taken only a few days in previous years now may drag out for months (Veatch, 1972). Modern technology allows improved medical care to be taken to unrealistic extremes; one person was kept alive in a vegetative state for more than 37 years (LORAN Commission, 1989).

Protraction of the dying process is a modern epidemic. Some physicians seem to forget that their primary responsibility is to relieve suffering, not prolong it. Greater clinical skill often is required to provide daily supportive care than to cure acute illness. Tenderness and caring must be included in the protocols of terminally ill patients so that the ravaged patient is allowed to die peacefully, without tubing and respirators. Patients should be allowed “to experience those waning moments unencumbered by high-tech devices that serve only to impede their capacity for human interaction. Here it is the patient’s comfort, not the

caregiver's need 'to do something,' that should prevail" (LORAN Commission, 1989, p. 29).

In some situations, therapeutic restraint is necessary to permit a patient to die with dignity. When a cure is no longer possible, care should focus on the comfort of patient and family. At St. Christopher's Hospice in London, feeding is provided by human hands instead of nasogastric or intravenous tubes; "even if the patient does not get enough physical nourishment, he or she gets what is more important—the personal nourishment of someone who cares enough to sit by the bed several hours each day" (Nelson and Rohricht, 1984, p. 174).

Management of Symptoms

When fewer therapeutic options are available, the physician's involvement should increase. Even when no cure is possible, much can still be done to relieve pain and suffering. The family physician can help alleviate the fear, symptoms, and family stress that often make this a distressing time, keeping the patient as comfortable as possible and avoiding any impression of abandonment. A good death means being free of pain and unpleasant symptoms yet having the ability to make clear decisions and prepare for death.

Care of a dying patient can be one of the most rewarding aspects of the family physician's practice. Too often, however, the physician's discomfort with this stage of life contributes to the isolation and discouragement of the terminally ill patient. Unwarranted fears of respiratory depression, addiction, or tolerance prevent the prescribing of adequate amounts of analgesics. The resulting uncontrolled pain makes those final weeks a nightmare for all. Families may disintegrate as a result of the sleepless nights, fears, and guilt that come from trying to cope with uncontrolled symptoms.

Table 5-3 shows symptoms most often encountered in seriously ill hospitalized patients; some are predictable, and all are manageable to some extent. Rarely is a single symptom present, and most patients have two or more. Symptom severity can be decreased if anticipated and treated early. Eliciting and addressing the patient's concerns about anticipated suffering can often be as important as managing the symptoms. Good control of pain, nausea, and dyspnea can enable patients to die in the place of their

Table 5-3 Common Symptoms in Seriously Ill Hospitalized Patients

Symptom	Percentage of Total Patients	
	At Any Time	Severe and Frequent
Pain	51	23
Dyspnea	49	23
Anxiety	47	16
Depression	45	14
Nausea	34	6

choosing with comfort and dignity. A study of patients in inpatient palliative care units showed that the quality of dying was associated with adequate symptom management and communication of the expected outcome to the family members (Choi et al., 2013).

The keys to symptom control, as in all areas of medicine, are a careful history and physical examination to determine the various causes of discomfort, as well as a broad knowledge of the therapeutic agents available.

PAIN CONTROL

Key Points

- Analgesics should be given regularly and in adequate doses. When titrated appropriately, analgesics do not cause addiction or respiratory depression.
- Oral morphine is the drug of choice for severe pain.
- Nonsteroidal antiinflammatory drugs (NSAIDs) are recommended for bone or joint pain, antidepressants or anticonvulsants for neuropathic pain, anticholinergics for cramping abdominal pain or bladder spasms, and antipsychotics for restlessness and confusion.
- Prevention and treatment of constipation is required for all patients receiving opioids.

Pain can be physical, psychological, emotional, or spiritual. It can also be a combination of chronic, somatic, visceral, and neuropathic pain. *Somatic* and *visceral* pain account for about two thirds of patients with pain and respond to conventional opioids. About 35% of patients have some degree of *neuropathic* pain, a shooting or stabbing, electric shock–like pain. *Chronic* pain is influenced by memories of past pain and the anticipation of future pain. The fear of worsening pain may distort the patient's perception of current discomfort. Frustration and anxiety may accentuate the pain. All these factors can lower the patient's pain threshold and greatly magnify even minor disturbances (Twycross, 1993).

Failure to treat the whole person often results in inadequate pain control for patients with terminal cancer. Fatigue, insomnia, anxiety, boredom, and anger all contribute to a lower threshold for pain. Rest, sleep, diversion, and companionship all help to increase the patient's tolerance for pain.

Analgesics should be given in adequate amounts to provide comfort. Giving analgesic doses both regularly and on an as-needed basis is ideal for pain management. Using only as-needed doses for moderate to severe pain is suboptimal because it contributes to a lower pain threshold and a need for increasing doses to relieve the pain. When medication is given regularly in adequate doses, the anxiety and fear that accentuate pain are avoided, and lower doses of the drug are effective because the patient no longer fears recurrent or "breakthrough" pain.

Nonpharmacologic Techniques

Nonpharmacologic pain management techniques include transcutaneous electrical nerve stimulation (TENS), exercise, heat, cold, acupuncture, cognitive therapies (relaxation, imagery, hypnosis, biofeedback), behavioral therapy,

Table 5-4 Guidelines for Dosing Data for Opioid Analgesics (see Table 5-5)

1	Evaluate pain for all patients using a 0-10 scale: A. Mild pain: 1-3 B. Moderate pain: 4-7 C. Severe pain: 8-10
2	For chronic moderate or severe pain, do the following: A. Give baseline medication around the clock. B. Order 10% of the total daily dose for PRN administration given every 1 to 2 hours for the PO route or every 30 to 60 minutes for the SC or IV route. C. For continuous infusion, PRN administration can be the hourly rate every 15 minutes or 10% of the total daily dose every 30 to 60 minutes. D. Adjust the baseline upward daily in an amount roughly equivalent to the total amount used for PRN. E. Negotiate with the patient the target level of relief, usually achieving a level at least <4.
3	In general, the PO route is preferable, then the transcutaneous, SC, and IV routes.
4	When converting from one opioid to another, some experts recommend reducing the equianalgesic dose by one third to half and then titrating as in guideline 2.
5	Elderly patients or those with severe renal or liver disease should start on half of the usual initial dose.
6	If parenteral medication is needed for mild to moderate pain, use half of the usual starting dose of morphine or an equivalent.
7	Refer to the <i>Physicians' Desk Reference</i> for additional fentanyl guidelines.
8	Naloxone (Narcan) should be used only in emergencies: Dilute 0.4 mg of naloxone with 9 mL of normal saline; give 0.1 mg (2.5 mL) by slow IVP until effect; and monitor patient every 15 minutes. It may be necessary to repeat naloxone again in 30 to 60 minutes.
9	Short-acting preparations should be used in the initial period and postoperatively. Switch to long-acting preparations when the pain is chronic and after the total daily dose is determined.

IV, Intravenous; IVP, intravenous push; PO, oral; PRN, as needed; SC, subcutaneous.

psychotherapy, music therapy, and massage. Cold works especially well for neuropathic pain; heat works well for muscle spasm.

Opioids

A symptom-oriented history and careful examination may reveal a number of different sources of pain. Oral candidiasis, decubitus ulcers, constipation, and infected wounds all have specific remedies. Most patients with pain from cancer (and many with pain from non-neoplastic illnesses) require an opioid analgesic. Opioids are often the safest analgesics available, usually causing only temporary sedation and an increased need for laxatives. Opioid toxicity may manifest as myoclonus or nightmares; the patient may exhibit spontaneous jerking or pull the hand away when touched, which can be misinterpreted by others, making them reluctant to touch the patient. Morphine taken orally gives good relief for cancer pain but has some unwanted side effects, mainly constipation and nausea.

High doses of opioids may be necessary to obtain initial pain control in a patient with severe pain. Psychological dependence is rarely a problem in patients who receive appropriate opioid doses for chronic, severe cancer pain. When medication is given before the recurrence of pain, craving for medication does not occur. Physical dependence does occur with routine use, but withdrawal symptoms can be avoided by reducing a dose no more than 20% in any 2-day period.

In the past, physicians feared scrutiny by the U.S. Drug Enforcement Administration for using high doses of morphine to control pain. However, failure to use adequate doses of morphine may be a greater concern now because a physician was successfully sued for undertreatment of pain in a terminally ill patient. The proper combination of

pain medications can relieve pain without clouding the mind or suppressing the spirit.

Concerns about addiction, respiratory depression, and tolerance usually are unwarranted in patients with severe pain (Twycross, 1993). If the dose is titrated carefully, the patient's pain (or dyspnea) usually can be controlled completely. Patients can still be alert and mentally clear even when they receive hundreds of milligrams of oral morphine every 4 hours (Bruera et al., 1990).

A number of effective oral opioid preparations are available (Tables 5-4 and 5-5). Start with oral morphine solution 2 mg every hour as needed for pain. If four or more doses are given in 24 hours, divide the total milligrams into every-4-hour doses the following day. Use breakthrough doses every hour as needed between scheduled doses. Do the same for each subsequent day. Titrate the morphine dose upward until analgesia lasts the full 4 hours even if large doses are required. Hydromorphone is a good alternative.

The particular drug used is less important than the method of administration. To prevent pain and end the cycle of uncontrolled pain followed by oversedation, an oral narcotic should be administered on a regular schedule around the clock. "Breakthrough" doses equal to about half the regular 4-hour dose can be used as needed for breakthrough pain.

Long-acting drugs such as methadone (half-life 48 to 72 hours) can be prescribed every 8 to 12 hours but are often unsuitable for booster doses. They accumulate over several days and are difficult to titrate, especially in patients who have fluctuating levels of pain or deteriorating renal or hepatic function. Methadone is a synthetic that has no cross-allergenicity with morphine. It is available in oral and injectable forms and has been successfully used via other

Table 5-5 Dosing Data for Opioid Analgesics

Medication	Equianalgesic Dose (for chronic dosing)			Usual Starting Doses Adult > 50 kg; for opioid-naïve patients (♦ ½ dose for elderly or severe renal or liver disease)			Comments	Half-Life (hours)	Duration (hours)
	IM/IV	PO	PO	Parenteral	PO	PO			
Morphine	10 mg	30 mg		2.5-5 mg SC/IV q3-4h (♦ 1.23-2.5 mg)	5-15 mg q3-4h (IR or oral solution) (♦ 2.5-7.5 mg)		IR tablets (15, 30 mg) oral sol. (2 mg/ml, 4 mg/ml) Conc. (20 mg/ml) can give buccally Morphine ER tablets (15, 30, 60, 100, 200 mg) q8-12h Kadian ER pellets (10, 20, 30, 50, 60, 80, 100, 200 mg) q12-24h Avinza ER pellets (30, 60, 90, 120 mg) q24h Rectal suppositories (5, 10, 20, 30 mg) Not recommended in renal failure.	1.5-2	3-7
Oxycodone	Not available	20 mg		Not available	5-10 mg q3-4h (♦ 2.5 mg)		OxylR capsule (5 mg); IR tablet (5, 10, 15, 0, 30 mg); Conc. sol (20 mg/ml) Oxycontin (10, 15, 20, 30, 40, 60, 80 mg)— due to high cost and potential for abuse, use only if failure or contraindication to morphine ER. Combos available with APAP or ibuprofen (generally not recommended). Not enough literature regarding dosing in renal failure. Use caution.	3-4	4-6
Hydromorphone	1.5 mg	7.5 mg		0.2-0.6 mg SC/IV q2-3h (♦ 0.2 mg)	1-2 mg q3-4h (♦ 0.5-1 mg)		Tablet (2, 4, 8 mg); oral liquid (1 mg/ml); Suppository (3 mg) Use carefully in renal failure.	2-3	4-5
Methadone (see text for dosing conversions)	½ oral dose 2 mg PO methadone = 1 mg parenteral methadone	24 hour oral morphine < 30 mg 31-99 mg 100-299 mg 200-499 mg 500-999 mg 1000-1200 mg > 1200 mg		1.25-2.5 mg q8h (♦ 1.25 mg)	2.5-5 mg q8h (♦ 1.25-2.5 mg)	Oral morphine: methadone ratio 2:1 4:1 8:1 12:1 15:1 20:1 Consider consult	Tablet (5, 10 mg); solution (1 mg/ml, 2 mg/ml, and concentrated 10 mg/ml) Usually q12h or q8h; long variable T1/2 Acceptable with renal disease; small dose change makes big difference. Tends to accumulate with higher doses; always advise "hold for sedation." Because of long half-life, do not use methadone pm unless experienced. When converting from oral to parenteral, cut dose in half for safety. When converting from parenteral to oral, keep dose the same.	15-190 (N.B. Huge variation)	6-12

Table 5-6 Dosing Data for Coanalgesics

Pain Source	Pain Character	Drug Class	Examples	Comments
Bones or soft tissue	Tenderness over bone or joint pain on movement	NSAIDs	Ibuprofen, 400 mg q4hr Sulindac (Clinoril), 200 mg q12hr Naproxen (Naprosyn susp, 125 mg/5 mL), 15 mL q8hr Indomethacin (Indocin, 50-mg caps or susp), q8hr Piroxicam (Feldene, 20-mg caps), qD Choline magnesium trisalicylate (Trilisate susp, 500 mg/5 mL), 15 mL q12hr Celecoxib (Celebrex), 100 mg q12hr Dexamethasone 4-8 mg at 8 AM and 2 PM daily	Inexpensive; large pills Well tolerated; preferred in renal impairment Liquid preparation Suppository; more gastritis? Easiest to swallow; more gastritis? No platelet dysfunction; less problem with gastritis; less effective Less GI toxicity; high cost Liquid available Insomnia, vivid dreams possible
		Steroid		
Nerve damage or dysesthesia	Burning or shooting pain radiating from plexus or spinal root	Tricyclic antidepressant	Amitriptyline (Elavil), 10-50 mg HS Doxepin (Sinequan), 10-50 mg HS Trazodone (Desyrel), 25-150 mg HS	Best studied; sedating; start with low dose 10 mg/mL susp available Less anticholinergic effect; one third as potent as amitriptyline
		Anticonvulsant	Carbamazepine (Tegretol), 200 mg q6-12hr Valproic acid (Depakene), 250 mg q8-12hr Gabapentin (Neurontin), 100-400 mg qd to qid	Absorbed from rectum, unlike phenytoin Liquid available; can be absorbed rectally Often effective but expensive
		Steroid	Dexamethasone 4-8 mg at 8 AM and 2 PM daily	Liquid available Insomnia, vivid dreams possible
Smooth muscle spasms	Colic: cramping, abdominal pain, bladder spasms	Anticholinergic	Glycopyrrolate 0.4 mg q 1hr PRN Dicyclomine (Bentyl), 10 mg q4-8hr Oxybutynin (Ditropan), 5-10 mg q8hr Hyoscyamine (Levsin), 0.125 mg q4-8hr Glycopyrrolate (Robinul), 2 mg q8hr 0.2 mg/mL IV or IM q4h PRN	Oral or parenteral Capsules Tablets Sublingual available

Cap, capsule; GI, gastrointestinal; HS, at bedtime; IM, intramuscular; IV, intravenous; NSAID, nonsteroidal antiinflammatory drug; PRN, as needed; q, every; qd, every day; qid, four times a day; susp, suspension.

routes. It is metabolized in the liver and has no active metabolites, making it especially useful in patients with renal insufficiency (Toombs and Kral, 2005). The cost of methadone, especially in the parenteral form, has recently skyrocketed, making it cost prohibitive in many settings. The availability of parenteral methadone is limited.

Slow-release morphine preparations such as MS Contin and Oramorph SR can provide excellent analgesia for 8 to 12 hours, and Kadian and Avinza last 12 to 24 hours. The shorter-acting, slow-release tablets may be given rectally when the patient cannot swallow (Wilkinson et al., 1992). Small, soluble tablets or concentrated solutions of morphine or hydromorphone can be given sublingually when the patient is too weak to swallow and can be used for both 4-hour and booster doses.

Fentanyl, a synthetic opioid, is available for use as a transdermal patch (Duragesic) in 12.5-, 25-, 50-, 75-, and 100- μ g/hr strengths or a transmucosal lozenge on a stick (Actiq) in 200- to 1600- μ g strengths. Because these products are expensive and deliver a wide variation of plasma levels (25- μ g patch = 4 to 11 mg of oral morphine every 4 hours), they should be reserved for patients who cannot receive drugs by the oral or subcutaneous routes. However, the patches may not work in thin, malnourished elderly patients because they need a subcutaneous fat reservoir to work. There is no need to use injections when an adequate dose by mouth will work effectively.

Two opioid agents that are available orally are not recommended for cancer pain. Meperidine (Demerol) has a very low oral potency, a short duration of action, and a toxic metabolite that can cause tremors or even seizures (Kaiko

et al., 1983). Pentazocine (Talwin, Talacen) is an agonist-antagonist agent that is no more potent than aspirin with codeine and has a high incidence of psychotomimetic effects (hallucinations, confusion) in cancer patients.

Co-analgesics

Co-analgesics are drugs that potentiate the analgesic effects of opioids for particular types of pain (Table 5-6).

Bone Pain

Nonsteroidal antiinflammatory drugs are quite helpful in the alleviation of pain from lesions in bones or skeletal muscles. The nonacetylated salicylates (e.g., salsalate [Disalcid], choline magnesium trisalicylate [Trilisate]) are less toxic to the gastric mucosa and do not inhibit platelet function (Zucker and Rothwell, 1978) but are less potent analgesics. The newer nonsalicylate NSAIDs are more potent, more convenient, more expensive, and less toxic than aspirin. Although no single agent has been shown to be consistently more efficacious, particular patients do seem to favor one drug over another. If swallowing large tablets becomes a problem, piroxicam (Feldene) capsules, naproxen (Naprosyn) suspension, or indomethacin (Indocin) rectal suppositories may be used. The cyclooxygenase-2 (COX-2) inhibitor celecoxib (Celebrex) offers comparable analgesia and less gastrointestinal toxicity but at a higher risk of stroke or heart attack (which may not be an issue in the final weeks of life) and a higher cost. Steroids may also be a helpful adjuvant for bone pain. The steroid side effect of insomnia or vivid dreams may arise. Administering the doses of steroids earlier in the day,

such as dexamethasone 4 mg at 8 AM and 2 PM daily, can prevent negative side effects.

Neuropathic Pain

For the burning, stabbing, or shooting pain caused by nerve damage, an anticonvulsant such as gabapentin (Neurontin), 100 to 400 mg orally one to four times a day, or pregabalin (Lyrica), 50 to 100 mg orally three times a day, may be a useful addition (Rosenberg et al., 1997). Amitriptyline or nortriptyline, in doses smaller than those used to treat depression (10-50 mg at bedtime), are often effective, but newer agents such as venlafaxine (Effexor) or duloxetine (Cymbalta) may be effective for neuropathic pain and have fewer side effects. If swallowing problems arise and a tricyclic drug is needed, doxepin (Sinequan) solution may be used. The addition of carbamazepine (200 mg three times daily) or valproate (Depakene, 250 mg three times daily) should be considered if the tricyclic agent alone is not adequate. Both doxepin and carbamazepine can be administered rectally in gelatin capsules (Storey and Trumble, 1992). Steroids are helpful in treating neuropathic pain.

Visceral Pain and Smooth Muscle Spasm

If smooth muscle spasms are not caused by a treatable condition, such as urinary tract infection from a nonessential Foley catheter, these are best treated with an anticholinergic agent such as dicyclomine (Bentyl) or oxybutynin (Ditropan). For severe cases, 0.6 to 1.6 mg of glycopyrrolate (Robinul) subcutaneously may be used (Storey et al., 1990). The physician must be alert for side effects such as dry mouth, constipation, and delirium.

ANXIETY AND DEPRESSION

If anxiety is severe enough to require drug therapy, a benzodiazepine such as lorazepam (Ativan), 0.5 to 1 mg two or three times a day, may be effective. Antidepressants such as nortriptyline (Pamelor), desipramine (Norpramin), and doxepin in low doses (25-75 mg at bedtime) have analgesic properties and can help with insomnia and agitation. Selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) may also be effective. Mirtazapine may provide the advantage of improved sleep and appetite. Psychostimulants such as methylphenidate (Ritalin), 2.5 to 10 mg orally at 9 AM and 12 noon, take effect quickly and can relieve depression and pain in some terminally ill patients, especially when the prognosis is limited (Block, 2000). Quetiapine (Seroquel), an atypical antipsychotic beneficial for addressing bipolar disorder and schizophrenia, can also be used as an adjuvant antidepressant.

Grief and depression may appear similarly. The key to their differentiation is whether the patient is able to function. For example, a grieving patient will still function by taking his or her children to school or going to work and will temporarily improve on seeing his or her grandchildren, but depressed patients will not function appropriately.

In family members, *complicated grief*, also called “unresolved grief,” is grief persisting more than 6 months and occurring at least 6 months after death. Normally, grief

symptoms fade over time, but those of complicated grief linger or worsen, resulting in a chronic state of mourning. Although complicated grief can lead to depression, it may be distinct and associated with long-term functional impairment (Prigerson et al., 1995). Parents who have not successfully worked through their grief are at increased risk of mental and physical problems 4 to 9 years later (Lannen et al., 2008).

DELIRIUM OR AGITATION

Delirium or agitation is often seen in dying patients. It may result from the disinhibition of the nervous system that takes place. It is often concerning for family members because personality changes are associated with the delirium. This can result in the patient’s attempting to get out of bed, when he or she is significantly weaker, increasing the risk of falling or harming caregivers. Haloperidol (Haldol) is an antipsychotic that is beneficial for restlessness or confusion. It can be administered orally, rectally, intravenously, or subcutaneously. It is reasonable to start with 0.5 or 1 mg every hour as needed for breakthrough restlessness and monitor over an initial 24 hours. If the patient requires three or more doses in a day, adding the total haloperidol, dividing evenly and scheduling the haloperidol regularly may be beneficial. Chlorpromazine (Thorazine) is an antipsychotic that is more sedating than haloperidol; the patient’s family members may desire this sedating effect at a certain point in the patient’s disease progression. Escalating the dose of the chlorpromazine may be necessary to treat progressively worsening agitated delirium (Bascom et al., 2013). Chlorpromazine, given subcutaneously, may cause more irritation to the injection site than haloperidol. Atypical antipsychotics may be used when there is a longer prognosis of weeks to months to decrease the side effects of extrapyramidal symptoms and tardive dyskinesia. Quetiapine (Seroquel) is favored over other atypical antipsychotics for patients with Parkinson disease or parkinsonian features because it improves delirium without worsening motor function (Friedman, 2011). When symptoms of anxiety and restlessness are both present, benzodiazepines are effective in treating these symptoms, as listed in the previous section on anxiety.

DYSPNEA

As with pain, dyspnea can have many causes. When anemia, bronchospasm, and heart failure have been excluded or treated, the focus should be on symptom control. Oxygen has been shown to be helpful for controlling dyspnea in patients with hypoxia but may be less convenient and more expensive than opioids. When the dose of opioid is titrated carefully to control the pain and is administered on a regular schedule, with additional doses available for breakthrough dyspnea, the patient can obtain excellent relief without significant respiratory depression (Bruera et al., 1990).

Evidence from 13 studies shows a valuable effect of morphine for dyspnea in advanced lung disease and terminal cancer. However, using nebulized versus oral opioids showed no additional benefit. Good-quality evidence shows that long-acting β -agonists are beneficial in the treatment of

dyspnea in patients with chronic obstructive pulmonary disease (Qaseem et al., 2008).

Albuterol nebulizer treatments every 4 hours while the patient is awake may help relax the bronchospasms that often result in dyspnea and loosen the secretions that become more cumbersome as the respiratory muscles become weaker.

It may also be helpful to provide cool, moving air (open window, fan) and keep an unobstructed line of sight between the patient and the outside. Careful consideration should be given to the use of antibiotics for pneumonia in terminally ill patients. Because dyspnea can be controlled well without antibiotics, the physician must decide whether the antibiotics will improve the quality of life or just prolong the dying.

CONSTIPATION

Constipation can be more easily prevented than treated. When mobility and oral intake decrease and opioid analgesics are required, virtually every patient will require regular doses of laxatives to avoid distressing constipation. The laxative should be given once or twice every day and the amount increased to get a soft bowel movement every 1 to 2 days. Bulk laxatives are tolerated poorly and rarely are adequate for these patients. If docusate (Colace), 100 to 200 mg twice daily, is not effective, senna (Senokot), 1 to 4 tablets twice daily, should be added. Sorbitol 70% may be added in doses of 15 to 45 mL two or three times per day if the tablets are inadequate or if dysphagia causes aspiration risk when taking tablets. If a patient has gone several days without a bowel movement or is having small, frequent, liquid stools, an impaction may require manual removal. Bisacodyl (Dulcolax) 10-mg suppositories or sodium phosphate (Fleet) enemas may be needed occasionally until an effective oral regimen is found. Impaction may cause delirium, which can mimic pain. In these patients, the delirium may be improved with a simple enema.

NAUSEA AND VOMITING

In patients with nausea and vomiting, the physician should first look for a reversible cause such as constipation or gastritis from NSAIDs. If increased intracranial pressure is the cause, the patient may require steroids. Overfeeding may be the problem if a nasogastric or gastrostomy tube is in place. Metoclopramide (Reglan) is the agent of choice when an enormous liver limits gastric emptying or slow motility is causing early satiety. Many patients whose nausea and vomiting have not responded to prochlorperazine (Compazine) or promethazine (Phenergan) will be relieved by haloperidol (Haldol), 0.5 to 2 mg orally or subcutaneously every 4 to 8 hours. Effective and expensive preparations (usually unnecessary for hospice patients) that are approved for the treatment of nausea associated with chemotherapy include ondansetron (Zofran), granisetron (Kytril), dolasetron (Anzemet), and palonosetron (Aloxi). Parenteral fluids administered subcutaneously may provide some relief from the nausea. Either D5 ½ normal saline or normal saline is often effective, given about 1 L/day or 40 cc/hr. It can be administered as a rapid drip, if time is limited, so that the patient does not have to have a cumbersome fluid bag

all day. If the patient develops worsening respiratory secretions, increasing abdominal girth, or worsening extremity edema, it would be necessary to decrease or stop the parenteral fluids because it demonstrates that the patient's body is not able to process the fluid.

As with persistent pain, persistent nausea should be treated with regularly scheduled antiemetics. Combinations of antiemetics that have different modes of action may be needed. A combination of haloperidol with metoclopramide or dexamethasone may be effective. When oral antiemetics cannot be tolerated, rectal suppositories can be tried but rarely provide adequate control for persistent nausea and vomiting unless they are compounded from the potent agents just mentioned. Continuous subcutaneous infusions of metoclopramide, haloperidol, and the required opioid are more effective (Baines, 1988). Discontinuation of metoclopramide is recommended for complete bowel obstruction because this can worsen abdominal pain, nausea, and vomiting (Doyle et al., 2004). Even vomiting associated with complete bowel obstruction can be controlled without a nasogastric tube or gastrostomy with a continuous subcutaneous infusion of opioids, antiemetics, and anticholinergic agents (Baines et al., 1985). Octreotide (Sandostatin) has also been extremely effective.

HICCUPS

Persistent hiccups can be caused by any lesion affecting the phrenic nerve and by gastric distention or systemic problems, such as uremia. Oral treatment may include baclofen (Lioresal), 10 mg every 8 hours as needed; chlorpromazine (Thorazine), 25 to 50 mg every 4 to 6 hours as needed; metoclopramide, 10 to 20 mg every 6 to 8 hours as needed; or haloperidol, 1 to 2 mg every 4 to 6 hours as needed.

SUBCUTANEOUS ROUTE

When oral opioids or antiemetics cannot be tolerated because of nausea, vomiting, stupor, or extreme weakness, parenteral medications may be needed. Frequent intramuscular injections or frequent restarting of intravenous infusions can be painful and difficult to manage at home. In these cases, medications can be administered subcutaneously, either by intermittent bolus or by continuous infusion. At least 50 mL of medication per day can be infused through a small-gauge butterfly needle under the skin of the upper chest, arms, abdomen, or thighs using a portable pump. Morphine and hydromorphone have been shown to be safe and effective when administered by this route (Bruera et al., 1988). Methadone, metoclopramide, haloperidol, lorazepam, dexamethasone, glycopyrrolate, and parenteral fluids can also be administered subcutaneously (Destro et al., 2012).

Nutrition

Although uncontrolled pain is the principal complaint of many patients, the family's primary concern is often the patient not eating well. The causes of cancer cachexia are still poorly understood. Because patients seem to stop eating, lose weight, and eventually die, the natural

assumption has been that even if physicians cannot effectively treat the cancer, they can at least treat malnutrition and thereby delay death.

The problem is that more harm than good can come from tube feedings or pushing multiple cans of supplement each day. The family may feel responsible if the patient loses weight and may feel guilty when the person dies. Unfortunately, the patient's final weeks become a struggle with the family over how much the person has eaten. One patient said, "Tell her to stop pushing that spoon into my face; I don't want any more!" This can be carried to extremes, such as inserting nasogastric tubes in patients who "do not cooperate." If they tug on the tube, their hands may be tied to the bed rails. A study of tube feedings in elderly patients revealed that within 2 weeks, 67% of patients with nasogastric tubes had attempted self-extubation, and 43% had aspiration pneumonia. Gastric or jejunal tubes had a lower self-extubation rate (44%), but 56% of the patients had aspiration pneumonia, 31% had a leak or infection at the insertion site, and 50% had a clogged or kinked tube (Ciocon et al., 1988). Another comprehensive analysis found evidence of many risks and no benefits from tube feeding in patients with advanced dementia (Finucane et al., 1999). Large volumes of supplemental feeding can cause painful gastric distention, nausea, diarrhea, and copious pulmonary secretions. Routinely checking residuals of gastric content before each tube feeding is beneficial. This can be done by gently pulling back on the syringe attached to the tube used for feeding to measure any fluid left in the stomach. If residuals are more than approximately 60 cc, then the patient may not be processing the tube feeding, so that the patient or family can see why decreasing or stopping the tube feeding would be in the patient's best interest.

There is no evidence that forced feeding of cancer or dementia patients prolongs life. Careful metabolic studies on force-fed cancer patients at the National Institutes of Health showed irreversibly increased metabolic rates from forced feeding. It was speculated that tumor growth was accelerated (Terepka and Waterhouse, 1956). Animal experiments have shown that growth rates of a variety of different cancers are nutrient dependent; the growth rate slows down with fasting or protein-free diets and speeds up with total parenteral nutrition (TPN) (Buzby et al., 1980; Stragand et al., 1979). In several trials, patients who received TPN plus chemotherapy were compared with those receiving chemotherapy alone. The TPN group died faster, especially patients with lung adenocarcinoma (Jordan et al., 1981), colorectal cancer (Nixon et al., 1981), and small-cell lung cancer (Shike et al., 1984). Pooling data on TPN and cancer through 1985, Klein and associates (1986) found that infections were more common in patients receiving TPN and that these patients were less responsive to chemotherapy and had shortened survival times. After reviewing all the clinical trials of parenteral nutrition in patients receiving cancer chemotherapy, the American College of Physicians (1989) concluded, "The evidence suggests that parenteral nutritional support was associated with net harm, and no conditions could be defined in which such treatment appeared to be of benefit. Thus, the routine use of parenteral nutrition for patients undergoing chemotherapy should be strongly discouraged."

What should be done to relieve the anorexia of patients with advanced cancer? eTable 5-2 lists a number of treatable causes of anorexia. Uncontrolled pain blunts any person's appetite and can be alleviated. Low-level nausea, oral candidiasis, and constipation can interfere with eating and can be treated effectively. Families can be taught to relieve xerostomia (dry mouth) using a small syringe filled with water or juice and to prepare soft foods. Corticosteroids and megestrol have been beneficial to some but can cause side effects. The most important service the family physician can provide is to allay guilt. An appropriate statement would be: "I do *not* believe that how much time your husband has or how comfortable he is depends on how much he eats." Family members can be counseled about offering pleasure feedings, not for nutrition but to bring back the pleasant memories of food that was enjoyable. Offering small amounts, about a handful at a time, can keep the portions from being overwhelming. Allowing the patient to take as much or as little as desired is best.

Where to Die

Death with dignity is easiest to accomplish when the patient dies amid the surroundings that gave meaning to his or her life and in the company of those whose companionship provided most of the rewards of living. Physicians too often deny this, however, in the medically conditioned struggle to prolong life. Medical technology has advanced to the point that too few patients are permitted to die at home even though improved diagnostic techniques identify the irreversible nature of a terminal process at an earlier stage. A sorry commentary, reflecting the abuse of technology, is the case of a man who had built his house with his own hands and wanted to die there but was prevented from doing so while physicians exhausted their therapeutic armamentarium in an attempt to prolong his life a few days or weeks. The family physician must remain in charge as the patient's advocate when the consultants want to continue aggressive therapy yet all the patient wants to do is be comfortable. The family physician must have the courage to discontinue aggressive therapy when the evidence points to its futility.

Charles Lindbergh is an excellent example of an individual who insisted on designing his final days in a manner that would preserve dignity and allow him to die as comfortably as possible. When dying of lymphoma, he refused to remain in a medical center on the East Coast and returned to his home in Hawaii, where he made final arrangements regarding his estate and discussed with friends and family the details of his memorial service and burial site. His death was as he preferred—quiet, dignified, private, and in the company of family and friends—a striking contrast to what it would have been had he not insisted on leaving the medical center.

Although 70% of Americans still die in institutions (39% in hospitals and 31% in nursing homes), polls show that 80% of them say they would rather die at home (Farber et al., 2002). Jacqueline Onassis is an example of a prominent person whose wish to die at home was respected. Similarly, Richard Nixon's wishes were respected when his physicians and family knew that he wanted no extraordinary means taken to keep him alive if he developed

eTable 5-2 Management of Anorexia

Treat "anorexia":
Aches and pains
Nausea
Oral candidiasis
Reactive depression
Evacuation problems (constipation)
Xerostomia (dry mouth)
Iatrogenic problems (from chemotherapy or radiation therapy)
Acid problems (gastric ulcers)
Teach the family to prepare soft, easy-to-swallow foods.
Consider steroids.
Avoid nasogastric or gastrostomy tubes and hyperalimentation.
Allay guilt.

an illness that left him seriously debilitated, particularly intellectually.

Some patients do not want to be a burden to their families and pride themselves on being able to afford hospitalization or nursing home care. For some of these patients, the gradual withdrawal from family may be an emotional “letting go” that is necessary for all concerned in their particular family and circumstances. In other cases, the spouse simply may not be equipped physically or psychologically to deal with the loved one dying in the house over time. The important aspect is a network of support for all concerned, with no arbitrary judgment about the best approach. The family physician will be sensitive to the style of living and the style of dying that seem most appropriate in a given case after the options have been explained to the patient and family.

Hospice Care

Key Points

- Hospice care is intended for patients with a prognosis of 6 months or less.
- Most patients are referred too late, with a reported median survival time of only 3 weeks.
- A primary goal of a hospice is to support the patient’s wish to die at home.
- The hospice team gives around-the-clock support to the family, relieves them at times to prevent burnout, and provides follow-up bereavement care for up to 1 year.

“Hospice” originally meant a way station for pilgrims and travelers, where they could be replenished, refreshed, and cared for if needed. The Irish Sisters of Charity viewed death as one stage of a journey. They opened hospices for dying patients in Dublin in 1879 and in London in 1905. These were places where dying people could be cared for when such care could not be managed at home.

Cicely Saunders was trained as a nurse and social worker in London in the 1940s. She cared for a dying cancer patient who made a £500 donation to “be a window” in the special home for the dying they both knew was needed. Saunders went to medical school and then worked in St. Joseph’s Hospice in London from 1958 to 1965. She discovered the effectiveness of interdisciplinary team support, scheduled doses of oral opioids, and other methods to relieve the symptoms and stresses of her patients and their families. She opened St. Christopher’s Hospice in south London in 1967, and the modern hospice movement was born. In 2008, there were almost 5000 hospices in the United States alone.

The hospice concept can benefit patients and families wherever death takes place. A hospice program consists of palliative and supportive services that provide physical, psychological, social, and spiritual care for dying persons and their families. Services are provided by a medically supervised interdisciplinary team of professionals and volunteers and are available both in the home and in an inpatient setting. Home care is provided as necessary: on a part-time, intermittent, regularly scheduled, or around-the-clock on-call basis. The hospice concept is directed toward

providing compassionate care for people facing life-limiting illnesses or injuries. Hospice and palliative care involve a team-oriented approach to expert medical care, pain management, and emotional and spiritual support expressly tailored to the patient’s needs and wishes. Support is provided to the patient’s loved ones as well. At the center of hospice and palliative care is the belief that everyone has the right to die pain free and with dignity and that patients’ families will receive the necessary support to allow them to do so (www.nhpco.org, 2009).

The principal requirement for hospice admission is a life-limiting illness with a prognosis of 6 months or less, if the disease runs its normal course, as certified by the patient’s physician and the hospice physician. eTable 5-3 lists the standards of a hospice program as developed by the National Hospice and Palliative Care Organization (NHPCO).

The interdisciplinary hospice team consists of a patient care coordinator, a nurse, a physician, a counselor, a volunteer coordinator, and spiritual support. Medical services are on call 24 hours a day, 7 days a week. Continuity of care by the same group of team members provides a familiarity that is comforting to the patient. Volunteers are an integral part of the program and provide many helpful services. Hospice services are covered by Medicare, Medicaid, and most insurance companies to some extent. Some hospices are able to provide charity care.

To qualify for hospice under the Medicare Hospice Benefit, a patient should have a life expectancy of less than 6 months. Again, however, referrals are usually made much too late. A study of five hospice programs in Chicago showed that the median survival time after referral was only 24 days (Stone, 2001). In fact, 7% of patients referred to hospice die within hours of admission. This may be because survival estimates by physicians at admission are accurate only 20% of the time, 63% being optimistic and 17% pessimistic. The longer the physician had cared for the patient, the more optimistic the prediction. In 2011, the median (50th percentile) length of stay in a hospice was only about 19.1 days, and the average length of service was 69.1 days, with 35.8% enrolling in the last week of life (NHPCO, 2013). Family physicians should discuss hospice care when options are still available, not at the end of life.

SUPPORT FOR THE FAMILY

Families and close friends of the dying patient also suffer and should be supported. A good policy is for the physician not only to be sensitive to the needs of family members before death but to also follow up with the family after the patient dies with a phone call, letter, or home visit.

Hospice care is not focused only on the patient; the unit of care is the patient and family. The physical, psychological, and interpersonal needs of both the patient and the family are addressed. After a patient’s death, family members may experience increased morbidity and mortality, emphasizing the need for greater family support from the physician. Unfortunately, most physicians do not routinely contact the family after a patient’s death, so this need often goes unrecognized.

The “widower effect” is the likelihood that the surviving spouse will die shortly after the death of the partner. However, spouses of partners who received hospice care live

eTable 5-3 Principles of Hospice Care

1. Hospice offers palliative care to all terminally ill people and their families, regardless of age, gender, nationality, race, creed, sexual orientation, disability, diagnosis, availability of a primary caregiver, or ability to pay.
2. The unit of care in hospice is the patient and family.
3. A highly qualified, specially trained team of hospice professionals and volunteers works to meet the physiological, psychological, social, spiritual, and economic needs of patients and families facing terminal illness and bereavement.
4. The hospice interdisciplinary team collaborates continuously with the patient's attending physician to develop and maintain a patient-directed, individualized plan of care.
5. Hospice offers a safe, coordinated program of palliative and supportive care in a variety of appropriate settings from the time of admission through bereavement, with the focus on keeping terminally ill patients in their own homes as long as possible.
6. Hospice care is available 24 hours a day, 7 days a week, and services continue without interruption if the patient care setting changes.
7. Hospice is accountable for the appropriate allocation and utilization of its resources to provide optimal care consistent with patient and family needs.
8. Hospice maintains a comprehensive and accurate record of services provided in all care settings for each patient and family.
9. Hospice has an organized governing body that has complete and ultimate responsibility for the organization.
10. The hospice governing body entrusts the hospice administrator with overall management responsibility for operating the hospice, including planning, organizing, staffing, and evaluating the organization and its services.
11. Hospice is committed to continuous assessment and improvement of the quality and efficiency of its services.

From National Hospice Organization. *Standards of a Hospice Program of Care*. Arlington, VA: National Hospice Organization; 1993.

longer than those whose spouses died without the benefit of hospice care, probably because hospice patients impose less stress on the family (Christakis and Iwashyna, 2003).

The hospice team provides follow-up bereavement care to the family up to 1 year after the patient's death. Family members who experience grief after the death of a loved one are more vulnerable to physical and other emotional disturbances than at any other time in their lives. They need help dealing with the grief, guilt, and symptoms associated with this emotional turmoil. The bereavement services of a hospice team can minimize these problems and can help family members cope with the pain of memories that arise from time to time, especially at holidays, birthdays, and other stressful occasions.

A man dying of cancer did not tell his family or friends in order to spare them. After his death, some admired his ability to suffer in silence, but many were angry and hurt, believing he did not think they were strong enough to suffer with him. The survivors not only were angry because he did not appear to need them but also were hurt because he did not even say good-bye (*New Age Hospice Horizons*, 1989).

The most remarkable contribution of the hospice movement is not that it provides a special and compassionate setting in which terminally ill persons can die without heroic measures but that the family becomes involved and comfortable in caring for the ill member. With the rapid increase of scientific and technologic competence in the field of medicine, families feel increasingly incompetent about the dying process. The hospice movement has reversed this trend and helps family members work with community support services to provide home care for many of these patients. When symptoms cannot be controlled at home, the hospice inpatient unit can provide medical and nursing expertise in a homelike setting.

SELECTING A HOSPICE

Most cities now have more than one hospice. Some organizations consist of volunteers with little or no medical expertise. Others have freestanding inpatient units and their own medical staffs. The questions in eTable 5-4 will help in the selection of a hospice.

Some patients and their families resist entering hospice for fear that their care will be taken over by a stranger and their personal physician will no longer be involved. That fear should be addressed directly by the family physician (Jemal et al., 2009). Many hospices employ a physician board certified in hospice and palliative medicine who can help with particularly difficult symptom problems. (See www.abhpm.org for a list of certified physicians in each area.)

SOCIAL SUPPORT AND RESOURCES IN THE COMMUNITY

See eAppendix 5-1 at www.expertconsult.com.

Advance Directives

An advance directive is a legal document that allows competent adults to express their intentions regarding medical

Key Points

- An advance directive is a legal document expressing a person's preferences regarding care in the event the person becomes unable to make decisions regarding care.
- The most important item is the appointment of a health care surrogate as the patient's proxy.
- Advance directives vary from simple to complex but still cannot cover every possibility.
- A variety of state-specific advance care-planning documents are available on the Internet.

treatment in the event that they lose decision-making capacity because of a terminal illness. Types of advance directives are as follows:

- **Living will:** A form regarding the limitation of life-sustaining medical treatment in the face of a life-threatening illness.
- **Health care surrogate:** The appointment of a person to serve as the health care proxy (or medical power of attorney) to make medical decisions for an incapacitated patient. Ideally, these medical decisions would be based on the patient's preferences expressed in earlier discussions with the health care proxy.
- **Durable power of attorney:** Designates a person to make health, financial, and legal decisions if the patient is unable to do so.
- **"Do not resuscitate" (DNR) order, also known as Allow Natural Death (AND):** Determined by the physician and patient or the patient's health care surrogate or power of attorney.
- **Physician Orders for Life-Sustaining Treatment (POLST):** A set of medical orders based on the patient's wishes, as discussed with the patient's physician. This assures that health care professionals provide only the medical treatment that the patient desires to receive. This is currently endorsed with legislative support in 14 states, and it is in development in several other states.

If a person has only one action to take, it should be to appoint a health care surrogate as the person's proxy. Family physicians should encourage every patient to name a substitute decision maker, proxy, or surrogate who can represent the patient's wishes when needed. One problem is that often the surrogates named in the advance directive are not present to make decisions or are too emotionally overwrought to offer guidance.

Each state has its own laws governing advance directives, available at www.caringinfo.org.

Another site for useful advance directive information is:

www.familycaregiversonline.net/legal-resources

The Patient Self-Determination Act of 1991 requires hospitals and other health care institutions that receive Medicare or Medicaid funds to inform patients of their right to formulate advance directives. The purpose is to encourage greater awareness and use of advance directives so that situations of ambiguity can be avoided (Field and Cassel, 1997). The act requires hospitals to provide written information to all patients concerning their rights under state

eTable 5-4 Questions to Ask When Selecting a Hospice

Patient's needs and wishes	1. How does the hospice staff, working with the patient and loved ones, honor the patient's wishes?
Family involvement and support	<ol style="list-style-type: none"> 1. Are family caregivers given the information and training they need to care for the patient at home? 2. What services does the hospice offer to help the patient and loved ones deal with grief and loss? 3. Is respite care (i.e., relief for the caregiver), including inpatient care, available? 4. Are loved ones told what to expect in the dying process, and what happens after the patient's death? 5. What bereavement services are available after the patient dies?
Physician's role	<ol style="list-style-type: none"> 1. What is the role of the patient's physician after hospice care begins? 2. How will the hospice physician oversee the patient's care and work with the patient's doctor?
Staffing	1. How many patients at any one time are assigned to each hospice staff member who will be caring for the patient?
Volunteers	<ol style="list-style-type: none"> 1. What services do volunteers offer? 2. What screening and types of training do hospice volunteers receive before they are placed with patients and families?
Comfort and pain management	<ol style="list-style-type: none"> 1. Does the hospice staff regularly discuss and routinely evaluate pain control and symptom management with patients and families? 2. Does the hospice staff respond immediately to requests for additional pain medication? 3. What specialty or expanded programs does hospice offer? 4. How does the hospice meet the spiritual and emotional needs of the patient and family?

SOCIAL SUPPORT AND RESOURCES IN THE COMMUNITY

In addition to the extended family, other resources that the family physician can use in the care of the dying patient include the visiting nurse or public health nurse. Most county social service departments have some form of homemaker service. Social workers from both public and private agencies can assist the patient and family in dealing with negative feelings, hostile relationships, economic planning, and financial assistance programs. The social worker is often the key to obtaining tangible assistance such as wheelchairs, walkers, and hospital beds and adapting the home for patients with disabilities.

For sensorially deprived patients, talking books, tape cassettes, and other aids are available from local public libraries and the library of the State Commission for the Blind. Chronically and terminally ill children of school age can have teachers for the homebound to keep up with the child's peers, making every day count in as positive a manner as possible. The patient avoids the burden of feeling rejected because of having the stigma of dying. In-home assistance also increases the number of natural interpersonal relationships, avoiding further isolation of a person who already is limited in locomotion and outreach.

Some persons have built close relationships through membership in churches or synagogues, service clubs, choirs, prayer groups, athletic teams, professional associations, hobby clubs, and so on. If these friends and associates

do not show up, it may be, as Orville Kelly found before he organized Make Today Count, that they are embarrassed and insecure in the face of this impending death of a friend or that they hesitate to intrude. The family physician does not have time to be a social coordinator, but a brief call to a minister, social worker, or family member usually can start the wheels of social interaction moving again. The physician is simply the catalyst.

Every religion pays special attention to dying persons. Support comes from the priest, minister, or rabbi, who can help the patient work through basic issues of the meaning of life. The question of "why?" and the confusion of guilt that plagues some patients may be addressed best by a religious counselor. Even if a particular unresolved issue is not related directly to the illness, its resolution provides relief for the patient, whether through confession, sacramental absolution, restitution, or reconciliation with a significant other. This can be as important as medication in the care of the whole person. Bereavement on the part of family members or friends also is eased when issues are "made right."

The priest, minister, or rabbi not only serves as a symbol of a community of faith that cares about the sick and dying but also represents a belief system that nurtures hope and trust. The task of the minister (or priest or rabbi) is to sustain and nurture hope through the dying process and to help the dying person surrender the unrealistic forms of hope in favor of more appropriate forms as death draws near (Paterson, 1981).

Example of Medical Power of Attorney

I, _____, appoint _____ as my agent to make any and all health care decisions for me, except to the extent I state otherwise in this document. This Medical Power of Attorney takes effect if I become unable to make my own health care decisions and my physician certifies this fact in writing.

I sign my name to this Medical Power of Attorney on _____ (date).

Signature _____

Printed Name _____

Witnesses

Signature _____	Signature _____
Printed Name _____	Printed Name _____

Figure 5-1 Example of a living will.

law to refuse or accept treatment and to complete advance directives.

Almost 90% of Americans say that they would not want extraordinary steps taken to prolong their lives if they were dying, but only 20% have put that wish in writing in the form of a “living will.” The version of the living will shown in [Figure 5-1](#) has several advantages over others. It clarifies the person’s preferences, and instead of locking elements arbitrarily in place, it leaves two witnesses as guardians of the individual’s wishes and intentions, with discretion to use their judgment in the specific circumstances. This statement presumes goodwill on all sides and should be helpful to all concerned.

There is no one-size-fits-all approach to advance care planning. Some people prefer a simple approach, and others choose a more comprehensive, step-by-step process. The simple approach prevents support measures from being undertaken that should never have been initiated. It is best to have a patient both complete a living will and designate a health care surrogate to ensure that the person receives the desired medical care.

Although advance directives are not guarantees that the patient’s wishes will be followed, without them, these wishes probably will not be followed. Since the case of Terri Schiavo, a 41-year-old woman whose feeding tube was removed in 2005 after a legal battle and political storm, patients are much more aware of the need to declare their feelings about life-sustaining treatment. The Schiavo case illustrates the importance of advance care planning to save both families and physicians considerable anguish.

Unfortunately, the legal restrictions arising out of the Schiavo case may be counterproductive. Courts in several states have now ruled that life-sustaining interventions must be continued in the absence of *clear and convincing evidence* that the patient would not want them. Despite efforts to make advance directives address a greater variety of terminal situations, it is almost impossible to state accurately the patient’s wishes in every scenario. Advance directives are poorly equipped to cope with the complex clinical situations that often arise, emphasizing the need to appoint a health care surrogate.

In the past, end-of-life decisions were usually limited to deciding whether or not to use cardiopulmonary

resuscitation (CPR). Now the range includes feeding tubes, hydration, hospitalization, antibiotic use, and terminal sedation. The more the family can focus on what the patient would want instead of what makes the family members feel most comfortable, the better will be the final decision ([Lang and Quill, 2004](#)). CPR can be lifesaving in some cases, but in most terminally ill patients, it is extremely unlikely to result in return of satisfactory cardiopulmonary function, survival to discharge from the hospital, or ability to live outside an institution. In a large multi-institutional study, physicians did no better than chance in identifying their seriously ill hospitalized patients’ wishes to forgo CPR, and such wishes, even when known, rarely were respected when the physician believed that another course was more appropriate ([Connors et al., 1995](#)).

A relatively simple Advance Care Plan Document is available from Project GRACE (Guidelines for Resuscitation and Care at End-of-life) at www.projectgrace.org. A document that attempts to address a variety of clinical situations that may arise is the Medical Directive site at www.medicaldirective.org. This permits patients and physicians to download a scenario-based living will that includes six different scenarios to cover a variety of situations, plus a personal statement and a health care proxy. See [Web Resources](#) for additional sites and more information.

CARDIOVASCULAR IMPLANTABLE ELECTRONIC DEVICES

Many patients with end-stage cardiac disease have implantable electronic devices, such as pacemakers and implantable cardioverter-defibrillators (ICDs). To better prepare patients and their families, the family physician can discuss the risks and benefits of having or discontinuing these devices before an event in which the patient has a significant decline or hospitalization. Pacemakers are considered to neither prolong nor shorten the end of life. Discontinuing a pacemaker may result in angina or dyspnea, so continuing a pacemaker at the end of life is recommended. On the other hand, ICDs cause pain with shocks and are considered to be comparable to resuscitation efforts. At the end of life, when the goal is comfort only, discontinuing the ICD is indicated ([Manaouil et al., 2012](#)). The company that

manufactures the device can assist with discontinuing the ICD. Also, placing a magnet the size of the ICD on the chest over the device can deactivate the ICD temporarily while the magnet is in place. ICD deactivation should be explicitly addressed in advanced care planning and at the end of life (Hastings, 2013, p. 167).

EUTHANASIA AND ASSISTED SUICIDE

Virtually all dying patients think about suicide, and many ask their physicians to help them. The greatest difficulties in the care of the dying sometimes are seen in patients who linger much longer than expected—so-called postmature deaths. How should a caring physician respond to such situations?

In any area where medicine intersects with moral codes, there are diverse opinions and heated debate. The distinctions between euthanasia, assisted suicide, and withdrawing unwanted life-prolonging treatments should be kept in mind. *Euthanasia* involves the purposeful administration of drugs to end life; it is common practice in Holland but unlawful in the United States. Withdrawing or withholding drugs or other treatments that the patient (or surrogate) no longer wants and permitting the disease to run its course are ethical and legal in all states. *Assisted suicide* involves the prescribing of large quantities of drugs for the purpose of empowering patients to take their own lives, which is now legal in certain circumstances in some states.

Most physicians are uncomfortable managing the suffering of a dying patient. It has been proposed that the physician's wish to be released from such a painful clinical relationship may be a factor influencing the patient's suicidal decision. A patient's suicide can have a profound effect on the physician, especially younger physicians. "By some measures, the distress equals in intensity, if not duration, that caused by the death of a parent. Patients' suicides engender anger, guilt, and loss of self-esteem on the part of treating physicians" (Miles, 1994, p. 1787). The emotional strain on some Dutch physicians who had assisted suicide left them "disinclined to repeat the act" (Diekstra, 1993).

The principal reason that most patients requested assisted suicide in Oregon was not uncontrolled pain but rather the loss of control or intolerable debilitation. However, much can be done to relieve patients' fears, and support systems can be devised to provide the necessary care for an incapacitated patient. The physician can almost always find an effective pain-control regimen that does not hasten death. One experience of being thanked for *not* agreeing to assist in suicide by a patient whose previously intolerable pain is now well controlled makes any physician hesitate about participating in assisted suicide. Permanent solutions to temporary problems should be avoided. However, a few patients will have symptoms that are difficult to control in their final days, and physicians should explore "options of last resort," such as palliative sedation, with their hospice and hospital ethics committees.

The idea that any treatable complication of a terminal illness *must* be treated because it *can* be treated is also wrong. Most patients do not want to die, but they are just as concerned about the *quality* of their time remaining as they are about the *quantity*. The physician may rescue a patient with advanced cancer from one potentially lethal complication, only to find that another, which may cause much worse suffering, will end the person's life. Hippocrates' admonition *primum non nocere* ("first, do not harm") also may apply to treatments that under other circumstances might be helpful.

Well-informed and competent adults have the right to refuse medical treatment even if refusal is likely to result in

death. Many are willing to sacrifice some quantity of life in exchange for maintaining quality of life. In one study, 60% of seriously ill patients preferred that their treatment focus on comfort and quality of life even if it meant shortening their lives (Teno et al., 2002).

KEY TREATMENT

- Regularly assess patients for pain, dyspnea, and depression at the end of life (SOR: B; Lindqvist et al., 2013; Qaseem et al., 2008).
- Use therapies of proven effectiveness to manage pain at end of life, including NSAIDs and opioids (SOR: A; King et al., 2011; Lindqvist et al., 2013; Qaseem et al., 2008; McNicol et al., 2005; Nicholson, 2007; Quigley, 2007; Wiffen and McQuay, 2007).
- Use therapies of proven effectiveness to manage dyspnea at end of life, including opioids and oxygen (SOR: B; Cranston et al., 2008; Jennings et al., 2001; Lindqvist et al., 2013; Qaseem et al., 2008).
- Use therapies of proven effectiveness to manage depression at end of life, including tricyclic antidepressants, SSRIs, or SNRIs (SOR: B; Qaseem et al., 2008; Widera and Block, 2012).
- Ensure that advance care planning, including completion of advance directives, occurs for all patients with serious illness (SOR: C; Michael et al., 2014; Northouse et al., 2012; Qaseem et al., 2008).
- Use anticonvulsant drugs as adjuvants in management of pain (SOR: B; Bennett, 2011; Wiffen et al., 2005a, 2005b, 2005c).
- Use antidepressants as adjuvants in management of neuropathic pain (SOR: B; Bennett, 2011; Saarto and Wiffen, 2007).
- Treat anxiety at end of life (SOR: C; Lindqvist et al., 2013; Jackson and Lipman, 2004).
- Treat constipation at end of life with laxatives (SOR: B; Miles et al., 2006; Strassels et al., 2010).
- Use therapies of proven effectiveness to manage nausea and vomiting at end of life (SOR: C; Lindqvist et al., 2013; Perkins and Dorman, 2009).
- For patients receiving palliative radiotherapy, if pressure symptoms occur in the beginning of treatment or if symptoms are expected during therapy, start steroid therapy (e.g., dexamethasone, 3-10 mg × 1-3 times orally or parenterally) (SOR: A; Finnish Medical Society Duodecim, 2003).
- Opioids are effective in the treatment of dyspnea; starting dose with morphine solution is 12 to 20 mg; starting dose with long-acting morphine is 10 to 30 mg; and dose is increased by 20% to 30% (up to 50%) (SOR: A; Finnish Medical Society Duodecim, 2003).

Care of the Self

LUKE W. FORTNEY

CHAPTER OUTLINE

The Burnout Trap, 73

A Roadmap to Health and Wellness, 76

Summary, 80

Key Points

- Professional burnout is common among physicians and is considered an occupational hazard that significantly impacts patient care.
- Burnout is dynamic and changes along a spectrum depending on both the duration and degree of work-related stress.
- For many physicians, burnout starts as early as medical school but appears to be most significant mid-career, with primary care specialties being at greatest risk.
- Treatment and prevention of professional burnout involves a general, well-balanced approach to physical and mental health.
- Simple but persistent efforts using “The Formula for Good Health” and other tools are an effective evidenced-based approach to achieving wellness.
- Mindfulness is one form of mind-body medicine that is helpful for both burnout prevention and health promotion.
- A regular mind-body practice such as mindfulness can help physicians work through hard times and avoid being overwhelmed by stress.

The Burnout Trap

THE PHYSICIAN PREDICAMENT

Societies of the world have long recognized the fragile and challenging role that healers have played. Although highly regarded in most cultures, healers have also been charged by their communities to oversee and manage the inevitable afflictions of old age, sickness, and death. A culture’s medicine-person is and has always been committed to a life of addressing suffering in an endless pursuit to restore and preserve health and balance in the body and mind. Prior to relatively recent advances in science and medical technologies, this endeavor has historically often been unsuccessful (Rakel and Weil, 2012).

Although the landscape, culture, technologies, and beliefs surrounding healing continue to evolve, the predicament has not. Every clinical encounter includes five general patient expectations: trust, compassion, accuracy, safety, and relief. No matter the location or situation, every patient seeks a physician who will establish a trusting therapeutic

and compassionate partnership to accurately diagnose the problem and offer safe and effective treatment options that empower the patient. Unfortunately, mistakes, neglect, and bad luck will always be a part of medical practice. It can be very challenging dealing with the blame, guilt, remorse, grief, fear, and anger that come with the loss and injury that occasionally occur in medical practice.

The practice of modern medicine can be called a high-pressure, high-expectation, high-stakes profession that involves the persistent stress of navigating life-threatening issues on a regular basis, but often in a random and unanticipated way. Early psychology research showed that inescapable electric shocks administered to dogs leads to strong emotional stress, learned helplessness, and depression. Just like this classical conditioning experiment where repeated inescapable stress results in depression-like symptoms and learned helplessness (Seligman, 1972), similar effects are also observed among physicians who are subject to the continued, unrelenting, and unpredictable stresses of medical emergencies, overwhelming patient care duties, and beeping pager alerts in on-call situations (Arora et al., 2013). Over time these and other factors can have negative effects on health and quality of life for physicians (Sonneck and Wagner, 1996).

The modern physician predicament incorporates a wide range of stressors and influencing factors. Patient satisfaction scores are now commonly used in part to determine a physician’s success and reimbursement, which can pose considerable strain, especially in treating conditions such as addiction, working with demanding patients with unrealistic demands, and managing U.S. Drug Enforcement Administration (DEA) schedule II and III medications, among many others. Furthermore, many physician roles involve not only patient care in clinic and hospital settings, but also teaching, oversight of advanced practitioners, and managerial responsibilities with increasing expectations for excellence (Nedrow et al., 2013).

The advent of electronic health records (EHRs) along with changes in billing, coding, documentation, and electronic patient communication pose new opportunities and challenges in a rapidly changing landscape of insurance coverage and prior authorization processes (Howard et al., 2013). What’s more, physicians are independently accountable and licensed professionals who are finding themselves more and more as employees in large health care corporations. Nonetheless, physicians continue to be individually

responsible for staying current with advances in medical research as it applies to patient care. In large corporate hospital environments, physicians must also skillfully navigate personal and professional boundaries with staff, administration, patients, and home life (Chen et al., 2013).

At times the conflicting interests of altruistic expectations from patients and the personal need for rest and limits on work-hour responsibilities can be overwhelming and exacerbate the underlying strain that comes from working with sick patients in an endless stream of crises (Sonneck and Wagner, 1996). In short, physicians are being asked more and more to be everything to everyone in every way all the time (Merton, 1966). It is important to also realize that all of these factors are stressors that come *in addition* to remaining proficient with medical skills in various areas of expertise. Add strain from one's personal life—family, home, and financial disruption—and it is easy to understand why today's physician will at times experience significant professional burnout.

To allow oneself to be carried away by a multitude of conflicting concerns, to surrender to too many demands, to commit oneself to too many projects, to want to help everyone in everything, is to succumb to violence. The frenzy neutralizes our work for peace. It destroys our own inner capacity for peace because it kills the root of inner wisdom which makes work fruitful.

—THOMAS MERTON

BURNOUT AMONG PHYSICIANS

Professional burnout is characterized as a loss of emotional, mental, and physical energy caused by continued job-related stress. It results from ongoing, unrelenting work stress without adequate time away from professional work duties for rest and recreation. The Maslach Burnout Inventory (MBI) is used worldwide and has been validated in samples of various professions, including health care workers (Maslach and Jackson, 1996). It is used to investigate job satisfaction using self-report measures that score three aspects of professional burnout syndrome: emotional exhaustion, depersonalization, and lack of personal accomplishment. A high degree of burnout is one in which a respondent has high scores on the Emotional Exhaustion and Depersonalization subscales and a low score on the Personal Accomplishment subscale (Maslach and Jackson, 1996). Among these, research suggests that emotional exhaustion represents the core burnout dimension among physicians (Lee et al., 2013), which is caused in large part by working long hours with significant off-duty personal-time intrusion (Chen et al., 2013).

Burnout appears to be more common among physicians than other professional groups, with primary care and emergency medicine specialties being at greatest risk (Fortney et al., 2013; Shanafelt et al., 2012; Sonneck and Wagner, 1996) (Figure 6-1). However, research comparing inpatient- to outpatient-based care does not support the

belief that burnout is more frequent among hospitalists compared to clinic-based physicians (Roberts et al., 2013). Furthermore, compared with physicians in the early and late stages of their careers, middle career physicians appear to be particularly at risk (Dyrbye et al., 2013).

In general, there are three risk factors recognized as being independently associated with burnout for physicians: hours worked per week, experience of recent work or home conflict, and how that conflict was addressed or resolved (Dyrbye et al., 2011). Overall, up to 60% of all physicians report having experienced burnout at some point in their careers (McCray et al., 2008), with more than 40% experiencing burnout at any single point in time (Wallace et al., 2009). Perhaps the most concerning aspect of physician burnout is that it starts early, with up to 45% of medical students and 80% of medical residents reporting significant work-related burnout (McCray et al., 2008). A cross-sectional survey administered to senior medical students in New York found that 71% met criteria for burnout (Mazurkiewicz et al., 2012).

BURNOUT CAUSES

There are several factors that contribute to burnout (Table 6-1). Increasing workload is significant in primary care. In the United States, implementation of the Affordable Care Act is estimated to enroll 32 million previously uninsured citizens, which will increase demand for primary care services (Mann, 2011). In addition, an expanding elderly population, insufficient supply of new primary care physicians, increased physician attrition, low medical student interest in primary care specialties, and lower primary care services reimbursements compared with other medical specialties add further strain (Baron, 2010; Bell et al., 2002; Dyrbye et al., 2008; Dyrbye and Shanafelt, 2011).

There is a saying that the cobbler always wears the worst shoes. It has been observed that physicians, while striving to deliver high quality care to their patients, tend to give themselves suboptimal care and are less attentive to their own wellness (Wallace et al., 2009). An increasingly bureaucratic health care system also creates the higher likelihood of feeling alienated and depersonalized (Bell et al., 2002; McKinlay and Marceau, 2011). Furthermore, certain personality traits—for example, being highly driven, a strong sense of perfectionism, being strongly empathetic, feeling inadequate, having low self-esteem, and being the classic “type A” workaholic—may add greater risk to burnout syndrome (Table 6-1) (Vicentic et al., 2013).

Other personal factors that correlate with professional burnout (see Table 6-1) include the lack of coping skills for stress (Epstein, 1999; Nedrow et al., 2013), unhealthy habits such as smoking and alcohol abuse, and poor relationships with colleagues. Lack of time for self-care and feeling that there is not enough time in the day to complete necessary work tasks are other common physician concerns—while for some, regret of specialty choice can be a significant cause of burnout (Eckleberry-Hunt et al., 2009). From a medical practice perspective, increasing clinical demands, caring for a difficult or sociomedically complex patient panel, mounting productivity pressures, business or insurance concerns, keeping up with rapidly advancing technology and EHRs, lack of control over office

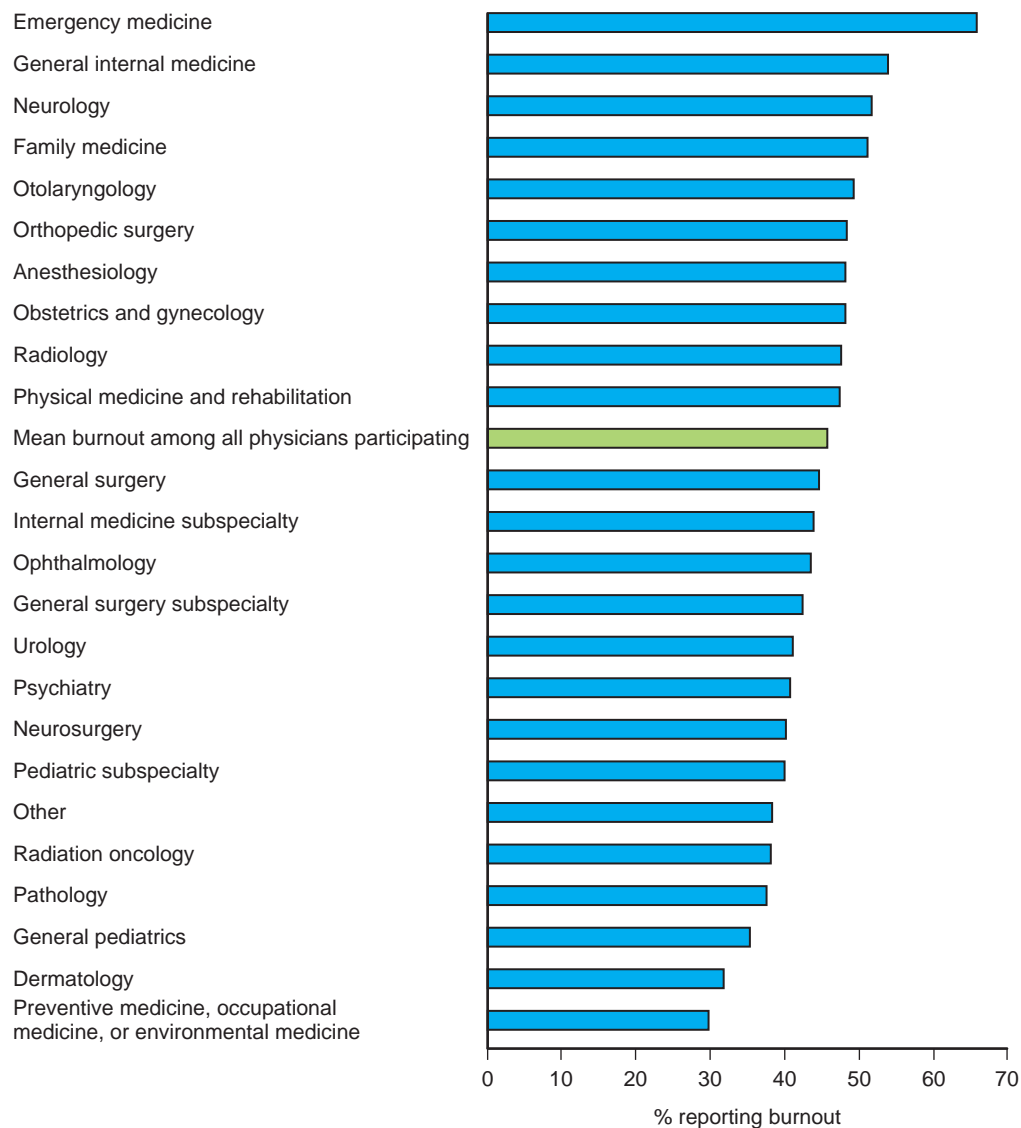

Figure 6-1 Burnout prevalence by medical specialty. (From Shanafelt TD, Bradley KA, Wipf JE, et al. Burnout and self-reported patient care in an internal medicine residency program. *Ann Intern Med.* 2002;136(5):358-367.)

Table 6-1 Risk Factors for Burnout

1. Highly driven, “workaholic,” perfectionistic personality
2. Low self-esteem, feeling inadequate
3. Continued unabated work stress and long work hours
4. Poor relationships with colleagues
5. Difficulty resolving home and work relationship conflicts
6. Poor coping skills for stress (smoking, alcohol abuse, drug use, avoidance, confrontational)
7. Lack of time for self-care
8. Feeling there is not enough time in the day to complete work tasks
9. Regret of specialty choice
10. Lack of control over clinic schedule or office processes
11. Rapidly advancing electronic health records, changing insurance landscape
12. Increasing bureaucratization of health care
13. Complex and challenging patient panels

processes and one’s schedule are additional physician concerns (Shanafelt et al., 2002). Finally, studies have also identified difficulty in resolving home and work conflicts as a major contributor to physician burnout (McCray et al., 2008; Dyrbye et al., 2014).

BURNOUT EFFECTS

Considerable evidence suggests that burnout negatively affects quality of patient care (Durning et al., 2013), with profound personal implications for physicians, including depression and suicidal ideation (Center et al., 2003; Devi, 2011; Dyrbye et al., 2008; Sonneck and Wagner, 1996). Furthermore, physician attrition because of burnout is both disruptive to continuity of patient care and costly to health care organizations (Scott, 1998). Once burnout is present, absenteeism increases, physician turnover increases, and overall job satisfaction decreases; but perhaps

Figure 6-2 Burnout spectrum. (Adapted from West CP, Shanafelt TD. Physician well-being and professionalism. *Minn Med.* 2007;90(8):44-46.)

most concerning is that physicians self-report increased suboptimal patient care and medical errors (McCray et al., 2008). Physician surveys also suggest that 50% of all physicians with professional burnout are also depressed and at risk for alcohol abuse (Brown et al., 2009; Shanafelt et al., 2002). This is especially concerning given that many aspects of patient care—physician self-reported medical error, lower empathy, early retirement, and lower patient satisfaction—are directly affected by physician burnout (Dyrbye and Shanafelt, 2011).

BURNOUT SPECTRUM

On one end of the burnout spectrum is wellness, well-being, and balance in one's personal and professional life (West and Shanafelt, 2007). However as stress increases and persists over time, scores of depersonalization and emotional exhaustion increase, while personal accomplishment measures decrease. The extreme end of the burnout spectrum includes substance abuse, depression, anxiety, and suicidal ideation (Figure 6-2). Death by suicide is considered a major occupational hazard for physicians (Center et al., 2003; Devi, 2011; Sonneck and Wagner, 1996). Among medical students, suicidal ideation is nearly double that of the general population (Dyrbye et al., 2008).

BURNOUT PROTECTION

Certain personal attitudes and perspectives appear to be protective against burnout (Table 6-2). Having a healthy temperament and sense of humor, along with being self-aware, reflective, and attuned to personal needs appears to be helpful. Additionally, having meaningful core values with an optimistic philosophy of life have also been identified as important protective traits (Jensen et al., 2008). Healthy, happy, and well-adjusted physicians also display nonjudgmental and forgiving attitudes, as well as a compassionate acceptance of self and others. Perhaps most importantly, feeling that one is making a difference in one's profession carries significant protection from burnout (Jensen et al., 2008). Fortunately, these skills can be learned and supported.

Finally, as the mind goes, so follows the body and vice versa. This fundamental truth of health was recognized long ago when Plato wrote, "The great error of our day is that physicians separate treatment of psyche from treatment of the body." Even today, this is more commonly recognized. For example, there have been more than 1000 trials that have examined the link between exercise and depression and anxiety (Kirby, 2005), with more than 80 meta-analyses showing significant benefit (North et al.,

Table 6-2 Attributes That Protect Against Burnout

1. Having a healthy temperament and sense of humor
2. Being self-aware, reflective, and attuned to personal needs
3. Having meaningful core values
4. Having an optimistic philosophy of life and work
5. Having a nonjudgmental and forgiving attitude
6. Being compassionate and accepting of self and others
7. Feeling that one is making a difference in one's work
8. Having healthy boundaries and knowing when to say no or step away
9. Maintaining work and life balance with regular restorative time away from work
10. Having supportive and caring friends, family, and colleagues
11. Maintaining a balanced lifestyle of healthy diet, regular exercise, and attention to mind-body needs

1990). One study concluded that moderate regular exercise should be included as a viable means of treating depression, anxiety, and improving mental well-being (Fox, 1999). As the saying goes, "we have yet to find a disease that exercise does not help." When it comes to burnout, the importance of regular physical activity as it pertains to wellness cannot be overstated.

A Roadmap to Health and Wellness

The true healer knows that health can only be achieved by promoting a balance of body, emotions, mind, and spirit...first in oneself and then in one's patients.

—HOWARD SILVERMAN, MD

The effects of professional burnout go beyond depersonalization, emotional exhaustion, and low sense of accomplishment. In a ripple effect of consequences, continued unabated work stress can quickly move from health, well-being, and balance on one end of the spectrum and eventually lead to depression, anxiety, substance abuse, and various chronic diseases on the other end. Just as the burnout spectrum is dynamic and shifting from time to time, so is health and well-being, which must be cultivated and supported.

In general, health can be defined as decreased morbidity and mortality. The first rule of health, therefore, is to remove the obstacles to healing. From this perspective, unnecessary early death and suffering are overwhelmingly caused by tobacco use, poor diet, and lack of physical activity alone (Katz, 2013). Just these three adverse health behaviors are directly responsible for 8 out of every 10 deaths in the United States every year (McGinnis and Foege, 1993; Mokdad et al., 2004). Expanding on this, the Centers for Disease Control and Prevention (CDC) has identified four modifiable health risk behaviors—tobacco use, lack of physical activity, poor nutrition, and obesity—that are overwhelmingly responsible for most of the unnecessary illness, suffering, and early death in the United States every year (CDC, 2014; Katz, 2013).

At the same time, positive change in these four main modifiable health risk behaviors is at the root of preventing

unnecessary suffering, while empowering patients and physicians alike to take direct personal action toward wellness in their own lives using straightforward and simple strategies that have dramatic effects on improving longevity and happiness (Kopes-Kerr, 2010; Formula for Good Health). One representative study from the large corpus of literature showing the profound benefits of healthy lifestyle behaviors found that by getting 3.5 hours of exercise per week, eating a healthy diet, not smoking, and having a body mass index (BMI) of less than 30 kg/m² reduced the risk of myocardial infarction (MI) by 81%, stroke by 50%, type 2 diabetes by 93%, and cancer by 36% over nearly 8 years. Adhering to all four of these health factors reduced overall risk of death and serious disease by 78% (Ford et al., 2009).

AVOID UNNECESSARY SUFFERING

A basic evidence-based strategy to reduce the risk of developing chronic disease and early death is comprised of the following five elements (www.meriter.com/wellness; Kopes-Kerr, 2010):

1. Increase physical activity.
2. Eat healthier foods.
3. Avoid tobacco.
4. Consume moderate or no alcohol.
5. Acknowledge and address stress and the mind-body connection.

THE BASIC TENANTS OF WELLNESS: MIND-BODY CONNECTION

There are three main pillars to prevention and health: (1) what we put into the body (e.g., nutrition, medications, supplements, vitamins), (2) how we move the body (e.g., exercise, manual therapies, procedures), and (3) how we perceive the world (e.g., mind-body connection) (Figure 6-3). Mind-body awareness and practice, which are those things that address subjective areas such as emotions, the heart, meaning and purpose, and connection with others, may be the least recognized but most essential aspect of good health. For example, the INTERHEART study, which was a study of risk factors for first MI in more than 24,000 adults from 52 countries, found that psychosocial stress

STATE OF HEALTH, BALANCE, AND WELLBEING

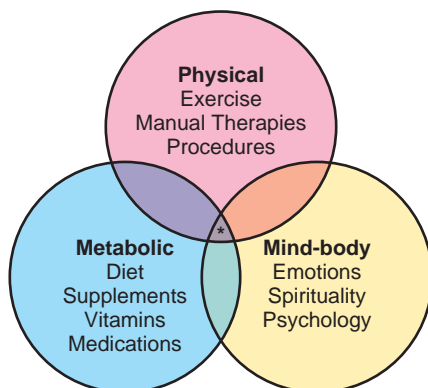

Figure 6-3 Three pillars of health.

was the second most significant risk factor for acute MI, behind smoking, but above hypertension and obesity (Rosengren et al., 2004). Another study found that severe emotional stress was the cause of 19 cases of reversible cardiomyopathy as demonstrated by objective measures such as decreased ejection fraction, prolonged QT interval electrocardiogram (ECG) findings, increased inflammatory monocyte infiltration, and elevated serum troponin and catecholamine levels, despite the fact that 95% of cases had normal cardiac arteries when visualized on catheterization (Wittstein et al., 2005). Yet another study found an inverse association between sense of humor and coronary heart disease. Of 150 participants who were given humorous manuscripts to read, those with existing heart disease were 45% less likely to laugh. Those who did laugh were less likely to have heart disease and hostility overall (Clark et al., 2001). Specific to professional burnout, research shows that there is an increased risk of cardiovascular disease, including metabolic syndrome, hypertension, overall poor health, and increased meta-inflammation, among chronically stressed mid-career physicians (Melamed et al., 2006; Spickard et al., 2002).

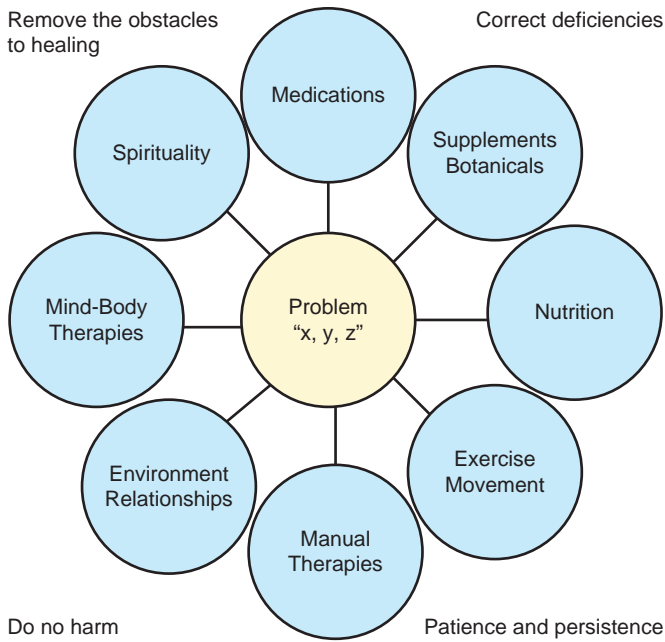

MINDFULNESS IN A MEDICAL CONTEXT

From these three main generalized areas of health (see Figure 6-3) are derived more specific aspects of healing that help guide decisions about what therapies and approaches are best suited from person to person for both illness and wellness (Figure 6-4). But before any therapeutic action can happen, it is essential to start with pausing, being present, and taking an objective inventory of one's current work and life situation before proceeding (Figure 6-5) (Rakel and Fortney, 2012).

The practice of mindfulness is a fundamental dimension of the mind-body connection that addresses every aspect of health. Mindfulness in a medical setting is considered a form of awareness training (Figure 6-6) that enables one to attend to aspects of experience in a nonjudgmental, nonreactive way, which in turn helps cultivate clear thinking, equanimity, compassion, and open-heartedness (Ludwig and Kabat-Zinn, 2008). The goal of mindfulness is compassionate informed action in the world, using a wide array of data, making correct decisions, better understanding the patient and oneself, and ultimately relieving suffering (Epstein, 1999). In this sense, mindfulness aims to maintain open awareness in one's experience in a way that generates a greater sense of emotional balance and well-being. Through the practice of mindfulness, unhelpful habitual thoughts and behaviors can be recognized, allowing for new and creative ways of responding.

MINDFULNESS AND BURNOUT

Growing research shows that the practice of mindfulness can have significant health benefits (Fortney and Taylor, 2010). Among physicians, mindfulness is helpful in both preventing and treating professional burnout. In practical terms, mindfulness operationalizes the notion that increased awareness leads to insight, which in turn leads to increased clarity in making healthy personal choices in any given moment (Epstein, 1999). A study published in *The Journal*

General approach to health and wellness:

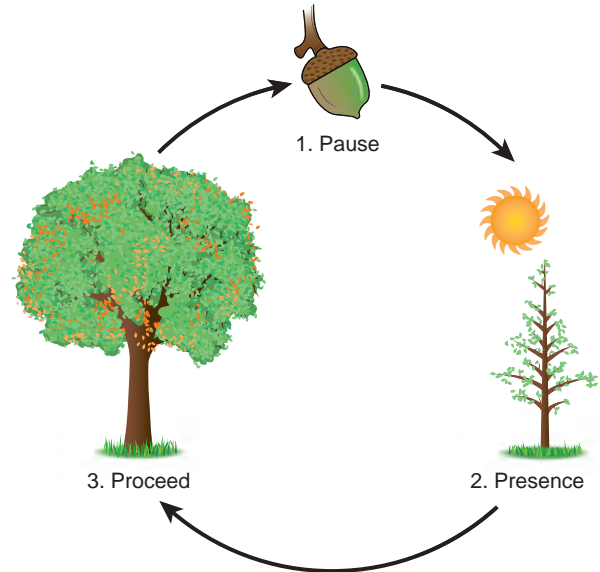

1. Awareness of the factors influencing burnout
2. Action steps toward wellness

Peripheral lifestyle factors: (1) Remove obstacles to health, such as smoking, overeating, sleep deprivation, and those lifestyle factors that are in direct competition to well-being. (2) Identify and correct obvious deficiencies (hypothyroidism, anemia, malnutrition, etc.). (3) Choose strategies that are not harmful and have low risk for harm. (4) Encourage patience and persistence with lifestyle changes.

Eight integrated approaches to addressing burnout and any health concern: (1) medications (non-habit-forming options for sleep, mood support, etc.); (2) OTC nutraceuticals that have evidence for safety and efficacy; (3) improving nutrition to include transition to a general healthy, antiinflammatory, whole-foods-based diet; (4) encouragement to increase movement, activity, exercise in any capacity; (5) manual therapies such as massage, acupuncture, etc.; (6) environment and relationships are those external factors that influence health such as air pollution, abusive relationships, toxic work/home settings, etc.; (7) mind-body therapies address internal factors such as emotions, beliefs, thoughts, and memory; (8) spirituality defined as that which gives meaning and purpose and/or is valuable, which may or may not be religious.

Figure 6-4 Integrated eight-wheel approach to health and wellness. OTC, over-the-counter. (Used with permission from Fortney L, Rakel D, Rindfleisch A, et al. Introduction to the integrative primary care: the health-oriented clinic. *Prim Care*. 2010;37(1):1-12.)

of the American Medical Association demonstrated that mindfulness education for primary care physicians over 12 months was helpful in addressing burnout by improving mood and emotional stability. Another study then went on to demonstrate that even an abbreviated course in mindfulness adapted to the professional needs of primary care physicians significantly improved burnout, depression, anxiety, and stress. These positive effects were maintained and generally trended toward further improvements over the length of the 9-month study despite there being no booster sessions or formal follow-up trainings (Fortney et al., 2013).

A 3-step exploration of health: practice in your practice

1. Pause: stop, take a breath, drop in, notice this moment
2. Presence: noticing thoughts, body sensations, and emotions without reactivity
3. Proceed: mindfully responding to whatever needs attention in this moment

Figure 6-5 Mindfulness in medicine: practice in your practice. (Used with permission from University of Wisconsin Integrative Medicine (<http://www.fammed.wisc.edu/MINDFULNESS>))

Practice:

1. In this moment, what is happening?
2. How does the experience change from moment to moment?

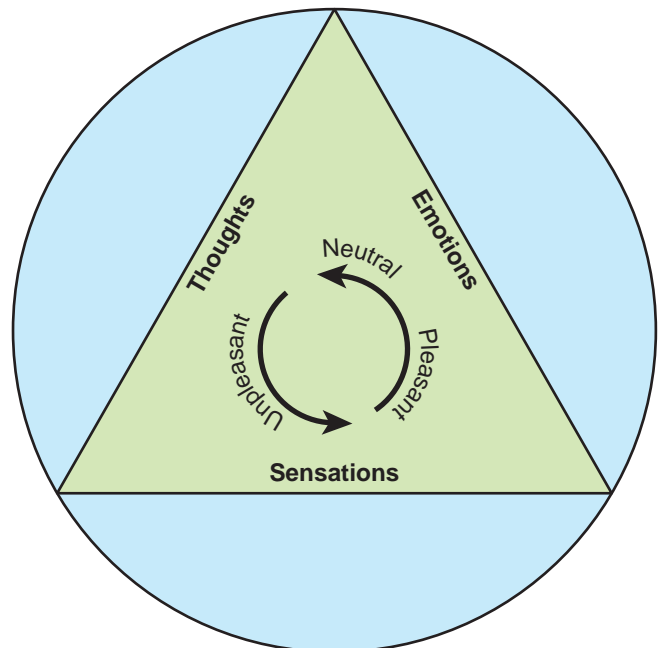

Figure 6-6 Triangle of awareness: becoming aware of things as they are, so as to inform choices for change. (From Fortney L. Chapter 98: Recommending meditation. In: Rakel D, ed. *Integrative Medicine*. 3rd ed. Philadelphia: Elsevier; 2012.)

This study helped show that mindfulness—even relatively brief training—for busy primary care physicians was sufficient in teaching meaningful mindfulness skills that led to significant improvements in burnout that persisted over a relatively long period of time. Similar to exercise, it appears that any amount of mindfulness training and practice is better than none at all when it comes to burnout, stress, health, and well-being (Podein, 2013). These and other findings further support growing evidence that suggests increased emotional awareness among physicians is associated with less burnout, higher work satisfaction, and higher patient satisfaction overall (Jensen et al., 2008; Weng et al., 2011).

MINDFULNESS IN MEDICINE:

Increased research and familiarization with mindfulness in the fields of neuroscience, psychology, and medicine have led to an increased understanding of consciousness and improved treatment for many health conditions, including burnout and stress. Practicing mindfulness (see Figures 6-5 and 6-6) can elicit physical ease and mental stability, which can provide a foundation for health and wellness as they directly influence one's ability to meet the challenges resulting from stress, burnout, and illness for patients and practitioners alike (Rakel et al., 2011). According to experienced meditation teacher Charlotte Joko Beck, the practice of mindfulness “provides a skill that affords a greater sense of self-determination—the ability to cultivate and draw upon inner resources to help meet all circumstances with equanimity and clarity.”

Basic mindfulness practice addresses burnout by offering a simple yet effective tool to help ease many of the challenges, both personal and academic, encountered throughout medical training and practice. Medical students who participated in an 8-week mindfulness course showed reduced anxiety, reduced distress and depression, and increased levels of empathy (Shapiro et al., 1998). There is growing evidence that heightened present-moment awareness gained through mindfulness training improves attention and memory as well (Jha et al., 2007). Furthermore, research suggests that mindfulness meditation can help foster present-moment awareness that may reduce medical error and improve patient care by addressing faulty thinking such as snap judgments, distracted attention, inadvertent stereotyping, and other cognitive traps that lead to critical mistakes in patient care (Groopman, 2007). This line of thinking is contrary to previous conventional thinking that medical errors are derived from lack of knowledge. These cognitive processing errors can be avoided by paying attention to the process of thinking by the metacognitive practice of mindfulness (Epstein, 1999).

Research also shows that practitioners who themselves exhibit healthy habits are more effective in motivating patients to make significant positive change for health (Fortney et al., 2010; Frank et al., 2000). In a randomized controlled trial of 124 psychiatric inpatients managed by 18 psychology residents, patients of interns who received mindfulness training did significantly better than those patients treated by interns who did not receive mindfulness training (Grepmaier et al., 2007).

CREATE YOUR OWN HEALTH PLAN

Preventive research widely shows the benefits of healthy behaviors, for both avoiding chronic disease and promoting good health. Within the three main areas of wellness (see Figure 6-3), it is clear that even very basic minimal efforts in exercise, nutrition, and mind-body care can have profound health benefits that can lead to reduced mortality and morbidity in the long run (Kopes-Kerr, 2010; Mokdad et al., 2004). In approaching both disease and wellness, the process starts with awareness of those factors that either directly contribute to poor health or create obstacles that interfere with healing and well-being (Fortney, 2010). Heavy alcohol use, smoking, and overindulgence of unhealthy foods are the most common things that inhibit the body's ability to heal and recover. Having a plan to guide the process of wellness can be helpful, and there are simple tools that can facilitate this (Table 6-3; see Figure 6-4) (see the Web Resources).

For busy primary care physicians, knowing when to step away, turn off the pager, and intentionally limit work responsibilities can be very challenging. The practice of “letting go,” being more mindful, and living a balanced lifestyle may even seem impossible. However, the effect of burnout on patient care can have negative consequences, as well as negatively affect home life and relationships if a balance of rest, physical health, and work is not

Table 6-3 Strategies That Help Reduce Burnout

Cultivating balance, the “In’s and Out’s” of personal needs. In any given moment, ask, “What do I need?” Different things are needed in different situations from the perspective of physical, psychological, emotional, and spiritual aspects of life.

Physical	<p>Energy out: Unburdening—to release tension and overstimulation in the body. Examples: Movement, exercise, physical activity.</p> <p>Energy in: Restorative—to increase energy when physically depleted. Examples: Rest, sleep, food, water.</p>
Psychological	<p>Energy out: Unburdening—actively seeking answers and resolving confusion. Examples: Analysis, insight, problem-solving, research, learning.</p> <p>Energy in: Restorative—taking in peace and equanimity, letting go of mental clutter and chatter. Examples: Meditation, silence, stillness, mental rest.</p>
Emotional	<p>Energy out: Unburdening—cathartic, get it out. Examples: Emotional expression such as journaling, singing, talking with a counselor, “shouting” technique.</p> <p>Energy in: Restorative—receiving emotional support and care. Examples: Love, laughter, kindness, positive touch.</p>
Spiritual	<p>Being aware and acknowledging what is personally meaningful in life, what provides a sense of wonder and awe, being connected to something and someone(s) beyond oneself—this may or may not be religious for each person. Examples: Cultivating connection with loved ones, being in nature, recognizing and expressing love, offering service and kindness to others, practicing prayer or meditation, experiencing joy, and pursuing an experience of being alive.</p>

maintained. One study found that doctors who were more mindful with their patients were more upbeat, better listeners, and showed more empathy while remaining efficient in their daily work tasks (Beach et al., 2013). Another study from the University of Warwick found that happier people are more motivated to work harder and overall are more productive (Oswald et al., 2014). As the saying goes, “you can’t give what you don’t have.” Resilience, however, is a dynamic, evolving process of healthy attitudes, mindful awareness, and constructive action steps toward good health (Fortney, 2012; Jensen et al., 2008) (see Figures 6-3 and 6-4).

Summary

It is important to remember that burnout is not static, but rather a dynamic process that changes over time along the burnout spectrum depending on various degrees and duration of work-life stressors (West and Shanafelt, 2007). Nonetheless, the absence of disease—in this case anxiety, depression, and stress—does not automatically imply the presence of health and well-being (WHO, n.d.). The full importance of the impact of happy, healthy clinicians on patient care cannot be overstated (Dyrbye, 2008; Wallace et al., 2009). The path to health and wellness among physicians and for patients starts with self-reflection, personal awareness, and small action steps that incorporate regular physical activity, a reasonably healthy diet, avoidance of substance abuse, and other work-life changes that may be appropriate from person to person (Ford et al., 2009) (see Table 6-3).

KEY TREATMENT

- Professional burnout is a significant occupational hazard for physicians, which has a negative effect on patient care and quality of personal and professional life (SOR: B) (Arora et al., 2013; Brown et al., 2009; Center et al., 2003; Chen et al., 2013; Devi 2011; Durning et al., 2013; Dyrbye et al., 2008; Dyrbye and Shanafelt, 2011; Eckleberry-Hunt et al., 2009; Fortney et al., 2013; Lee et al., 2013; McCray et al., 2008; Melamed et al., 2006; Scott, 1998; Shanafelt et al., 2002; Shanafelt et al.,

2012; Sonneck and Wagner, 1996; Spickard et al., 2002; Wallace et al., 2009).

- Emotional exhaustion and emotional awareness are the two most important aspects in recognizing and addressing burnout (SOR: B) (Dyrbye et al., 2013; Epstein, 1999; Jensen et al., 2008; Lee et al., 2013; McCray et al., 2008; Nedrow et al., 2013; Shapiro et al., 1998; Weng et al., 2011).
- Mindfulness training has been shown to reduce stress and burnout among medical professionals (SOR: B) (Beach et al., 2013; Epstein, 1999; Fortney et al., 2013; Krasner et al., 2009).
- Stress, poor diet, lack of exercise, and substance abuse are four modifiable risk factors that contribute to early mortality and morbidity (SOR: A) (CDC, 2014; Kopes-Kerr, 2010; McGinnis and Foege, 1993; Mokdad et al., 2004; Rosengren et al., 2004).
- Stress reduction, eating a healthy diet, getting a minimum of 2.5 hours of exercise a week, avoiding tobacco products, and drinking no to moderate alcohol significantly reduces the risk of chronic lifestyle-related disease and early death (SOR: A) (Ford et al., 2009; Fox, 1999; Katz, 2013; Kopes-Kerr, 2010; Mokdad et al., 2004).

The Family Physician as the Foundation of the Public Health System, 97
Intergenerational Aspects of Prevention in the Family, 99
Genomics and Prevention, 99
Office Systems as an Aid to Prevention, 100

Key Points

- Preventive interventions should be supported by high-level evidence of effectiveness and safety.
- Of all organizations and committees that make prevention recommendations, the U.S. Preventive Services Task Force (USPSTF) uses the most robust, evidence-based methodology.
- Other groups that make recommendations pertinent to prevention in the primary care and community setting are the Advisory Committee on Immunization Practices (ACIP) and the Community Preventive Services Task Force, both supported by the Centers for Disease Control and Prevention (CDC).
- Screening tests should be assessed for accuracy, safety, and effectiveness. Effectiveness means that screening results in an outcome that is better than occurs when the condition presents naturally and that the benefit gained exceeds harms caused.
- Screening tests can appear effective when they are not because of lead time and length biases.
- In low-prevalence conditions, even with accurate tests, the positive predictive value of the test will be low.
- One of the harms that can arise from screening is overdiagnosis, finding and treating disease, with the associated harms from diagnosis and treatment, when the condition would have resolved on its own or never progressed.
- Some behaviors that lead to bad health can be modified by brief interventions in a clinical encounter, others need more intensive interventions.
- A four-step approach of considering risk assessment, risk reduction, screening, and immunizations can assist family physicians in remembering to address prevention with each patient.
- Reducing “risks” for specific diseases found in observational studies should be tested in controlled clinical trials to see if risk reduction lowers the incidence of the disease.
- Tools available for risk reduction include behavior modification and chemoprevention.
- Physicians should offer to patients screening tests that have an A or B recommendation from the USPSTF.
- Physicians should offer and encourage patients to accept immunizations recommended by the ACIP.
- Preventive services offering the most benefit and those most acceptable to the patient should be prioritized.
- Smoking is the leading cause of preventable mortality and morbidity. Any patient who smokes should be encouraged to cease smoking and be offered nicotine replacement, medications, and support group referral.
- Accurately diagnosing and treating diseases of public health importance, such as sexually transmitted infections, influenza, and tuberculosis, helps control these diseases and prevent drug resistance.
- Family physicians can minimize the effects of communicable diseases in the community by providing recommended treatment for family members and other contacts of those with infectious diseases either with expedited partner therapy or by referring them to the public health department.
- Infection control practices should be enforced in the clinical setting.
- Physicians should report infectious diseases, cancers, and other reportable conditions as required by state and local reporting requirements.
- Clinic staff should be vaccinated as recommended by the CDC.
- Avoiding unnecessary or harmful testing and treatments and their associated harms should be considered part of the preventive practices of family physicians.
- Genomic and genetic testing holds promise for enhancing clinical prevention, but only a few tests have been proven effective at this time, and genetic risk profiling for chronic disease risk has not proven to be beneficial.
- Making prevention interventions routine, as part of the clinical system, helps to ensure a high level of performance.

Family Medicine and Prevention

Prevention is a large part of family medicine. Family physicians provide preventive health care on a daily basis and are frequently consulted by patients on how to stay healthy and avoid disease. Family physicians are also a part of the foundation of the nation's public health system, being the first contact for patients with illnesses of public health importance, a source of surveillance for disease prevalence, and a resource for dissemination of information that can protect the health of the public. This chapter will discuss all these roles and describe how to maximize the effectiveness of preventive services delivered.

Definitions of Prevention

Prevention can be divided into three categories: primary, secondary, and tertiary. Family physicians should consider how all three categories may benefit each patient.

Primary prevention results in the prevention of a disease or condition from occurring. Examples include vaccinations, which prevent an array of infectious diseases, and smoking cessation, which prevents myriad illnesses that result from sustained tobacco use. Primary prevention can be, but is not always, cost saving for society (more money is saved than spent). It often involves community-wide intervention (clean water and sanitation), and the benefits are often unseen and unappreciated by the public.

Secondary prevention involves screening asymptomatic individuals for a disease to detect it early, and with early intervention achieve a better outcome than with later detection and treatment. When testing is performed in those who are symptomatic, to diagnose or rule out a suspected condition, this is not screening, it is diagnostic testing. Screening applies only to those who are asymptomatic. Many disagreements over the value of screening result from not understanding this fundamental difference between screening and diagnostic testing.

Contrary to common belief, secondary prevention does not save money. It can lower morbidity and mortality and usually compares favorably in cost-benefit analyses to medical interventions such as cardiac bypass surgery, but it does not result in more money saved than spent. It can be, however, money well spent.

Tertiary prevention involves interventions that occur after a disease or condition is evident, in an attempt to make the affected person healthier and improve quality of life. An example is cardiac rehabilitation after myocardial infarction. Tertiary prevention also is not cost saving. Because tertiary prevention can prevent a repeat event, such as a second heart attack, it is frequently, although incorrectly, referred to as secondary prevention.

Evidence as the Foundation of Prevention

Solid evidence supporting the effectiveness and safety of an intervention is important. Family physicians are busy and

need to use their time effectively, concentrating on providing services that actually result in improvements for their patients. In addition, with primary and secondary prevention, the interventions involve healthy, asymptomatic people. The physician does well to remember that it is hard to improve on the healthy, asymptomatic patient. It can be done, but in attempting to make someone healthier we should ensure that not only are we being effective, we are also being safe and not causing harm in the process.

For this reason the evidence threshold for action should be higher for prevention than for therapy. If a patient has a serious illness, the therapeutic imperative provides a rationale for using treatments that might be supported only by moderate quality studies and intermediate outcomes, if that is the best evidence that exists. For prevention, if the safety and effectiveness of the intervention is not based on high-quality evidence, it is better to wait for better evidence and concentrate on the many interventions available that are backed by strong evidence. It is difficult enough to fit all the proven interventions into a tight clinical schedule without spending time on those we are not sure make a difference.

Figure 7-1 illustrates the pyramid of evidence that is found in the medical literature. At the top of the pyramid, and providing the highest quality evidence, are high-quality systematic reviews and meta-analyses. Next come randomized controlled trials, followed by lesser quality-controlled trials. Below that are observational studies, which are much more subject to bias. Among observational studies, cohort and case-control studies provide more reliable information than cross-sectional studies. Correlational (ecological) studies and case reports are at the base, providing interesting information that should not be used as proof of effectiveness or causation but are useful for generating questions and providing direction for more in-depth research. A description of each type of study is provided in Chapter 9.

Accepted practice should not be altered based on a single observational study and rarely on a single randomized, controlled trial. Single studies are frequently cited to support one view or another, and this practice is called “cherry picking.” The astute family physician will want to know that results are reproducible, will realize that more than one study on the topic probably exists, and will ask, “What does the totality of the evidence show?”

There are well-developed methods for assessing the quality of individual studies and for assessing the totality of the evidence. The individual family physician does not need to possess these skills and certainly does not possess the time necessary to properly research each possible prevention intervention; there are organizations and authoritative groups that perform these functions. However, the family physician should know what makes for a high-quality, truly evidence-based recommendation, and know which organizations can reliably be depended on to produce them.

The Institute of Medicine (IOM) has published guidance on how to conduct a high-quality systematic review (IOM, 2011c) and how to produce a high-quality, dependable guideline (IOM, 2011a). A high-quality guideline is based on a high-quality systematic review, preferably conducted by a noninterested, independent party. A high-quality systematic review should involve methods of finding all the

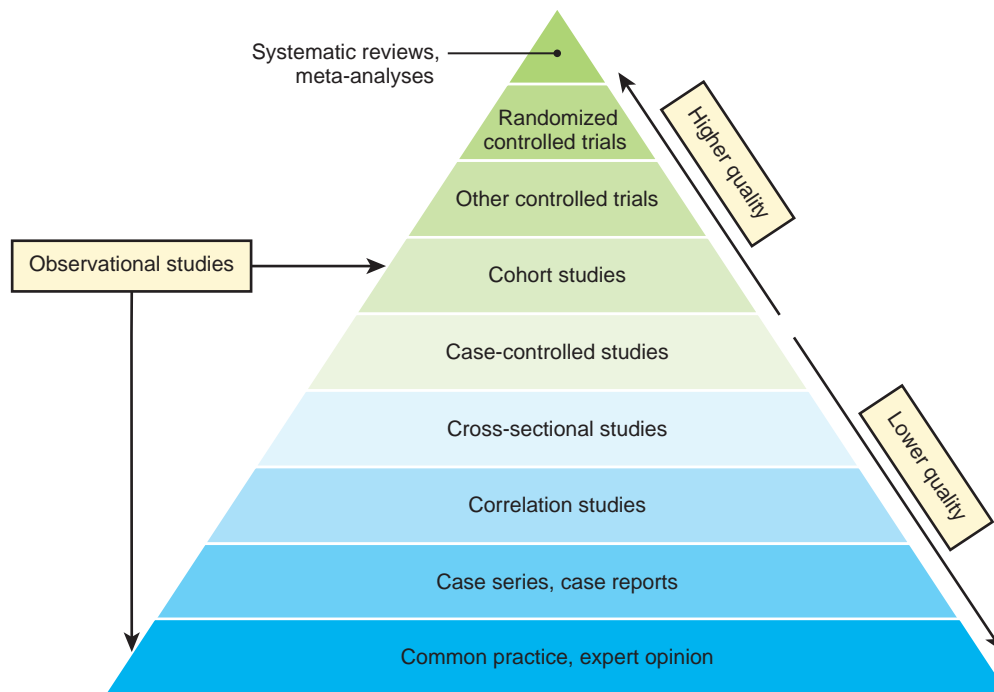

Figure 7-1 The pyramid of evidence.

existing evidence on the issue with clearly defined inclusion and exclusion criteria; a clear and accepted method of assessing each study and for summarizing and ranking all of the evidence; and several reviewers doing the assessment, using defined methods of resolving differences of opinion.

High-quality guidelines also involve a panel of experts with an array of skills, including how to assess the medical literature; conflict of interest policies that minimize and manage potential as well as real conflicts of interest; a methodology that assigns a strength of recommendation that reflects the best available evidence behind it; a limited number of clearly worded, unambiguous recommendations; an emphasis on patient-oriented outcomes, as well as options that allow for patient preferences; a consideration of potential harms as well as benefits; tools that assist with implementation, if they are available; and plans for periodic updating.

As described in the [IOM report \(2011a\)](#), many guidelines and recommendations currently do not meet these standards. This places family physicians in an awkward position, as poor-quality guidelines produced by specialty societies and special interest groups can be perceived as the gold standard because they come from the specialists who are seen as the experts in a particular topic. Some specialty societies produce high-quality guidelines, others do not. Specialist-dominated panels can be conflicted (setting out to defend current practices and justify payments), often do not consider potential harms, frequently are not prevention oriented, and may lack the members with the skills needed to assess the medical literature. This has resulted in the American Academy of Family Physicians (AAFP) developing its own prevention recommendations. These can be found on the AAFP website (www.aafp.org/patient-care/clinical-recommendations/cps.html).

THE UNITED STATES PREVENTIVE SERVICES TASK FORCE

The U.S. Preventive Services Task Force (USPSTF) was first created in 1984 as an independent panel of experts to provide guidance to physicians on the use of clinical preventive services. In 1998, it was placed under the sponsorship of the Agency for Healthcare Research and Quality (AHRQ), while maintaining its independent status, and provided with support to conduct scientific evidence reviews of a broad array of clinical preventive services and develop recommendations. The topics the task force addresses include screening tests, counseling, and preventive medications.

The USPSTF uses a rigorous and strict methodology of considering evidence and making recommendations after balancing documented benefits and harms ([USPSTF, 2014](#)). The task force does not consider the costs of the services being assessed or cost-benefit analyses. The interventions evaluated are often already in common use and frequently recommended by specialty and advocacy organizations before they have been thoroughly assessed for effectiveness and safety.

The USPSTF recommendations are separated into four categories: Level A recommendations are reserved for interventions with a clear predominance of benefits over harms backed by high-quality evidence. If evidence is not as robust, or the benefit/harm differential not as great but still in favor of benefits, a B recommendation is given. When benefits and harms are balanced, or overall benefit is minimal, it is assigned a C. Level D (a recommendation against) is assigned when no benefit exists or harms exceed benefits. If insufficient evidence exists to judge the balance of benefits and harms, the USPSTF is not compelled to make a practice recommendation and will assign it an I. Each recommendation made by the task force is accompanied by

a description of the natural history of the condition, the types of interventions available, and the level of evidence that exists on their effectiveness and harms, as well as how the task force recommendation either agrees with or differs from those of other organizations. All USPSTF recommendations are found on their website (www.uspreventiveservicestaskforce.org/recommendations.htm).

The process used by the USPSTF is scientifically robust and is considered the gold standard for assessing evidence and making recommendations. The result, however, often leads to recommendations that are at odds with other organizations and advocacy groups, which tend to adopt new technologies before they are fully tested for effectiveness or safety. In addition, because of a reluctance to make a recommendation without strong evidence, the wording of USPSTF recommendations is often vague about the frequency of testing or screening, because the relative effectiveness of different screening frequencies has not been assessed.

THE CENTERS FOR DISEASE CONTROL AND PREVENTION ADVISORY COMMITTEE ON IMMUNIZATION PRACTICES

The Advisory Committee on Immunization Practices (ACIP) was created in 1964 to provide expert external advice and guidance to the director of the Centers for Disease Control and Prevention (CDC) and the Secretary of the U.S. Department of Health and Human Services (DHHS) on use of vaccines. The ACIP is an official federal advisory committee and is governed by the Federal Advisory Committee Act, which has strict requirements for public notification of meetings, allowing for public comment, and publication of minutes.

The ACIP recently adopted a new system for developing evidence-based recommendations that is based on a modification of the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) approach (Guyatt et al., 2011). Key factors considered in the development of their recommendations include the balance of benefits and harms, type of evidence, values and preferences of the people affected, and health economic analyses. There are two categories of recommendations: category A (either for or against) applies to all persons in an age- or risk-factor-based group, while category B is a recommendation that is not meant to be universal but recognizes that a vaccination may be found to be appropriate for an individual within the context of a clinician-patient encounter. Evidence tables are used to summarize the benefits and harms and the strengths and limitations of the body of evidence. This new process brings the ACIP more in line with contemporary evidence-based processes (Ahmed et al., 2011).

THE NATIONAL HEART, LUNG, AND BLOOD INSTITUTE

The National Heart, Lung, and Blood Institute (NHLBI) in the National Institutes of Health produces guidelines on prevention and control of the major risks for cardiovascular diseases in adults, including two influential clinical guidelines; one on cholesterol and one on high blood pressure

(NHLBI, 2001, 2004). These and other guidelines regarding cardiovascular diseases can be found on their website (www.nhlbi.nih.gov/guidelines). The NHLBI, unfortunately, does not use methodology as strong as the USPSTF to produce their guidelines. Many of the recommendations are based on expert opinion, and the strength of the evidence supporting each recommendation is not readily apparent. They are, however, widely viewed as the standard of care. Both the cholesterol and high blood pressure guidelines are in the process of revision as this chapter is being written.

THE AMERICAN ACADEMY OF FAMILY PHYSICIANS

Clinical prevention recommendations to guide family physicians are made by the AAFP Commission on the Health of the Public and Science, and their recommendations are considered and approved by the AAFP Board of Directors. The AAFP has taken a strong evidence-based approach and tends to endorse the recommendations from the USPSTF and the ACIP, although not always. The AAFP approach to child preventive services is more conservative than that of the American Academy of Pediatrics (AAP), and it does not endorse AAP recommendations if they differ from those of the USPSTF or if they are not evidence based. The AAFP recommendations for clinical preventive services are listed at their website (www.aafp.org/patient-care/clinical-recommendations/cps.html).

THE AMERICAN ACADEMY OF PEDIATRICS AND BRIGHT FUTURES

The AAP endorses a set of periodic visits and clinical guidelines for children starting at birth and continuing to age 21 years. This set of recommendations is called *Bright Futures* and can be found on the AAP website <http://www.aap.org/en-us/professional-resources/practice-support/Pages/PeriodicitySchedule.aspx>. There is a set of recommended screening tests, developmental assessments, immunizations, and anticipatory guidance recommended for each visit. Due to a scarcity of research on the effectiveness of preventive services in infants and children, many of these recommendations are not based on high-quality evidence. The AAP acknowledges this by calling these recommendations “evidence informed.” The AAFP has not endorsed the Bright Futures guidelines. They are, however, the basis for Medicaid preventive services for children and some quality-improvement programs use them as performance measures of quality in child preventive care.

THE COMMUNITY PREVENTIVE SERVICES TASK FORCE

The Community Preventive Services Task Force (CPSTF) was formed in 1996 and consists of 15 members appointed by the director of the CDC. They are tasked to make recommendations and develop guidance on which community-based health promotion and disease-prevention interventions work and which do not work, based on available scientific evidence. The CDC provides the CPSTF with technical and administrative support. This task force uses a

strong evidence-based methodology that consists of systematic reviews of the evidence and tying recommendations to the strength of the evidence.

A challenge for the CPSTF is that community-wide recommendations are rarely subjected to controlled clinical trials so that methods of assessing and ranking other forms of evidence are required. The methods used by the CPSTF are described on their website (www.thecommunityguide.org/index.html). The recommendations made are contained in the Guide to Community Preventive Services, often called *The Community Guide*, which is also available on the website.

The Community Guide also provides evidence-based recommendations for increasing the use of preventive services in the clinical setting.

Paying for Preventive Services

The Patient Protection and Affordable Care Act (PPACA), Public Law 111-148, passed on March 23, 2010, established that a set of preventive health services shall be included without cost sharing by group health plans and health insurers offering group or individual health insurance. These services include:

- Those recommended with an A or B rating by the USPSTF.
- Immunizations that are recommended by the ACIP.
- Preventive services for infants, children, and adolescents that are included in guidelines supported by the Health Resources and Services Administration (HRSA), which in effect are those described in the Bright Futures initiative of the AAP.
- Additional services for women as provided for by guidelines supported by the HRSA. The HRSA contracted the task of developing this list to the IOM (2011b).

The intent of this provision in the PPACA is to provide an incentive to Americans to obtain evidence-based (or at least evidence-informed) preventive services to promote health and prevent disease. While on the surface it appears to provide an array of free preventive services, family physicians and patients need to appreciate that unanticipated expenses can occur from these services. As an example,

while colonoscopy screening for colorectal cancer every 10 years should be available without patient cost sharing (it is a level A recommendation by the USPSTF), a polypectomy performed during the procedure and follow-up testing are not covered by this PPACA provision and can result in significant out-of-pocket expenses.

Assessing Screening Tests

Many physicians and much of the public believe that screening and finding disease early is always beneficial. Many single-issue advocacy groups view screening as a key element in the control of their condition of concern. Family physicians simply do not have time to screen for every condition advocated, and should not screen for all of them, even if they did have time. Screening should only be conducted when the outcome of screening (finding the condition early and treating it) provides an outcome that is superior to waiting for the condition to become symptomatic. Additionally, the benefits provided by the screening test should outweigh any harms it causes.

Assessing the effectiveness of screening tests is not easy. Let us take an imaginary example. If screening for a cancer, labeled cancer of organ A, is detected by screening and then treated, life expectancy is 8 years. If the disease is detected by the presence of symptoms and then treated, life expectancy is 2 years. Does this prove that screening is effective? Many will answer that it does, including many practicing physicians (Wegwarth et al., 2012), but it does not. There are two biases in observational studies of this type that can affect the results: lead time bias and length bias (Figure 7-2). *Lead time bias* means that the disease is detected earlier, but the outcome is not changed. The point of death is not moved back; the disease was simply detected earlier making it seem that life expectancy is improved. *Length bias* comes from the fact that screening is more likely to find less aggressive disease. Cancers can have more aggressive and less aggressive forms. Aggressive forms leave little time from onset to symptoms to be detected by screening. Less aggressive forms exist in an asymptomatic state for an extended period and are more likely to be detected by screening, again leading to perceived increase in life expectancy.

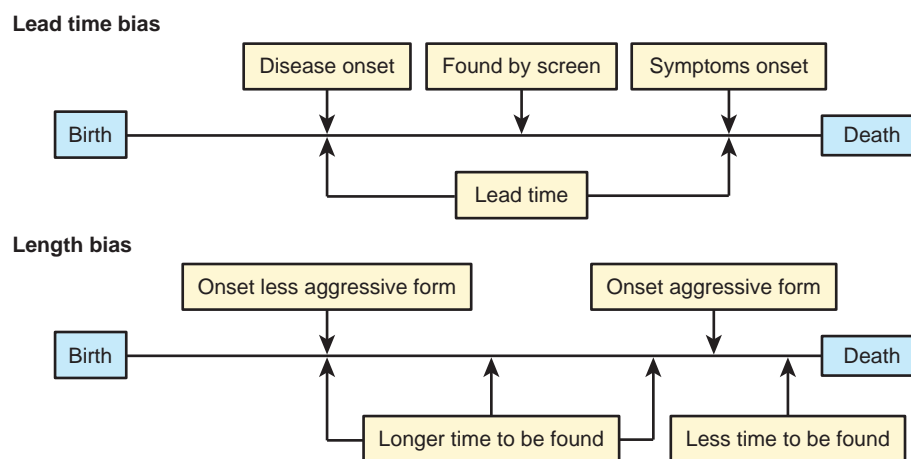

Figure 7-2 Lead-time bias and length bias.

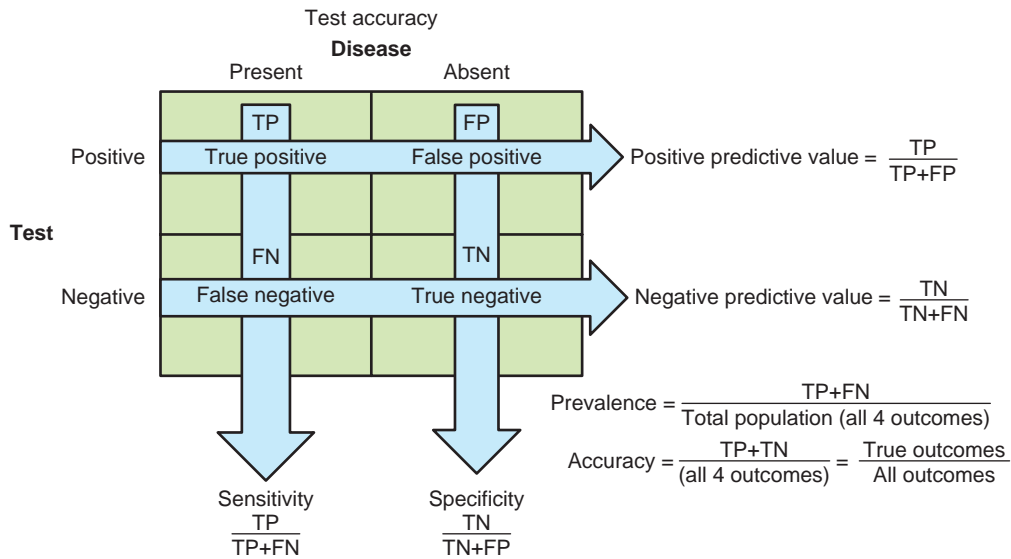

Figure 7-3 Measures of accuracy in screening tests.

Table 7-1 How Positive Predictive Value Changes with Prevalence*

Prevalence	1/100,000	1/10,000	1/1000	1/100 (10/1000)	1/10 (100/1000)
Number of true positives (TP)	1	1	1	10	99
Number of false-positives (FP)	100	10	1	1	1
Positive predictive value (TP/all positives)	1/101	1/11	1/2	10/11	99/100

*This example involves a test with a sensitivity of 99% and a specificity of 99.9% (false-positive rate of 1/1000) and the number tested equal to the denominator of the prevalence.

The only sure way to prove that screening is effective is to perform a controlled clinical trial in which a large number of people are randomly assigned to one of two groups: screening and no screening. They then need to be followed over time to determine the age-adjusted cancer A-specific death rates (using the previous example). If screening is effective in preventing death from cancer A, the death rate in the screened group should be lower than the unscreened group. In addition, the overall death rate should be lower. If both conditions are not met, the screening test is of questionable value. Very few screening tests have been evaluated with such rigor, and we are often left with making decisions about effectiveness on lower quality observational studies. However, a recommendation can still be made without a controlled clinical trial if the observational evidence is strong enough. This requires that there be a large difference between those screened and unscreened, and that the difference is found consistently in multiple studies in which potential biases have been controlled for.

Other factors that should be considered when assessing a screening test should include characteristics of the condition and the screening test. The condition should be serious (causing major mortality or morbidity) with a natural history that includes a lengthy asymptomatic period, and there should be an effective treatment for the condition or an intervention that prevents spread of the condition to others. The screening test should be readily available, relatively inexpensive, acceptable, and, above all, safe. This is because most of those being screened will not have the condition being screened for, and it is important not to cause them harm with screening.

In addition, the test should be accurate. Accuracy is measured by sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). These terms and how they are determined are illustrated in Figure 7-3. Sensitivity is the proportion of those with the condition who are detected by the test. Specificity is the proportion of those without the condition who are labeled as negative. Generally, as a test’s sensitivity improves, specificity worsens and vice versa. PPV is the proportion of those with a positive test who actually have the condition, whereas NPV is the proportion of those who test negative who are condition free. While sensitivity and specificity are frequently reported as the most important statistic, from a physician and patient perspective, the predictive values are more critical.

It is possible to have a test with a very good sensitivity and specificity but a poor PPV. This occurs when the prevalence of the condition in the screened population (the pretest probability) is low. With rare conditions, even with very accurate tests, a positive test is more likely to be a false-positive than a true positive (i.e., it has a poor PPV). The effect of prevalence on PPV is illustrated in Table 7-1. This concept is very important for assessing screening tests because false-positives can cause harm.

Another statistical concept one must understand to assess screening tests is the difference between relative risk reduction and absolute risk reduction. Using another hypothetical example, if a screening test and early treatment result in a 50% reduction in mortality, this looks pretty impressive. But what if the reduction in mortality is from a rate of 2 per 100,000 to 1 per 100,000? That is a relative reduction of 50% but an absolute reduction of only 1 per

100,000. In this example, it is necessary to screen 100,000 people to save one life or, stated another way, the number needed to screen (NNS) is 100,000.

When assessing a screening test, it is important to ask about all these variables: sensitivity, specificity, PPV, NPV, NNS, and number needed to harm (NNH). It also is necessary to compare the benefits from testing to the harms caused by testing. Benefits can include improved outcomes resulting from early detection as well as, with infectious diseases, prevention of spread to others. Harm can result from both false-positive and false-negative results, complications that can result from further testing when the test is positive, and complications from the treatment for the condition.

It is increasingly appreciated that additional harm can occur from testing, called *overdiagnosis*. This occurs because not all disease detected by screening is destined to progress and cause morbidity and mortality. Sometimes the condition regresses or does not progress, or progresses so slowly that other conditions cause death first. An example of this is prostate cancer. Many prostate cancers detected by screening would never cause a man any problems. It would have gone unnoticed if the screening had not been performed. But almost all these men will undergo further diagnostic testing and then treatment, with significant resulting morbidity and even mortality caused by complications of these interventions. There is now an appreciation that overdiagnosis occurs as a result of cancer screening much more frequently than was previously known (Kalager et al., 2012).

Assessing Physician Counseling

Changing patients' behavior is difficult. An in-depth discussion on effective counseling and behavioral modification methods is in Chapter 8. While there are many behaviors that place a person at risk for current and future adverse health, not all of them are conducive to being modified by counseling in a clinical encounter. Since family physicians do not have time to counsel regarding all potential risky behaviors, it is important to focus on the ones that have the greatest effect on health and for which evidence of the effectiveness of counseling exists. The USPSTF provides guidance on this topic but frequently finds that evidence is insufficient to judge whether physician advice and counseling actually change behavior. This does not mean that a family physician should not provide counseling when insufficient evidence exists, but they should be aware that evidence is lacking about the effectiveness of counseling in that situation and that time might be better spent on interventions supported by stronger evidence.

Putting Prevention into Practice

There are many barriers to practicing preventive medicine in a family medicine clinical setting. These include time pressures, inadequate reimbursement, and lack of interest from the patient. These barriers can be overcome with a systematic and organized approach to prevention that is part of each patient encounter. A complete set of preventive

Table 7-2 Four-Step Approach to Prevention in a Clinical Encounter

Step 1: Risk assessment based on:	Age Gender Family history Medical history Occupation Socioeconomics Environment Behaviors: <ul style="list-style-type: none"> ■ Diet ■ Physical activity ■ Sexual practices ■ Alcohol, tobacco, and drug use ■ Risk taking
Step 2: Risk reduction including:	Counseling and behavior modification Chemoprevention

Step 4: Immunizations	Immunizations recommended by the ACIP

ACIP, Advisory Committee on Immunization Practices; USPSTF, U.S. Preventive Services Task Force.

services can be provided as part of a periodic health assessment and wellness examination, which for most people does not need to be performed annually. They can also be approached incrementally, with the physician addressing a limited number of them at each visit. Neither approach has been proven superior to the other. Continuity of care is the family physician's ally in providing comprehensive preventive care, in that a little bit of prevention can be achieved at each visit and important prevention messages can be reinforced. With either approach, a four-step process (Table 7-2) can be used to consider

1. Risk assessment
2. Risk reduction
3. Screening
4. Immunizations

RISK ASSESSMENT

Each patient has a set of risks that can affect his or her health in the near or long term. These risks are based on age, gender, family history, medical history, current chronic diseases, occupation, socioeconomic factors, environment, and behaviors (diet; physical activity; sexual practices; alcohol, tobacco, and drug use; and risk taking). Some of these risks are modifiable; others are not. This information can be obtained at the first encounter or shortly thereafter, but it needs to be updated periodically. Knowing a patient's risks helps to focus risk reduction advice where it will have the greatest impact.

Table 7-3 lists the leading causes of death in the United States. The two leading causes of death are cardiovascular diseases and cancer. Figure 7-4 shows the time trends in these leading causes of mortality and demonstrates that age-adjusted death rates for cardiovascular diseases are declining while those for cancer and injuries are remaining relatively stable. Cancer will soon be the leading cause of death, and unintentional injuries has replaced cerebral vascular disease as the third leading cause. These data show that the largest improvements in population mortality can

Figure 7-4 Time trends in the leading causes of death. ICD, International Classification of Diseases. (From Murphy SL, Xu J, Kochanek KD. Deaths: final data for 2010. *Natl Vital Stat Rep.* 2013;61:67.)

Table 7-3 Leading Causes of Death, United States, 2010

Cause	Number of Deaths	Percent of All Deaths	Rate per 100,000
Heart disease	307,384	24.9	202.5
Cancer	301,037	24.4	198.3
Unintentional injuries	75,921	6.2	50.0
Chronic lung disease	65,423	5.3	43.1
Stroke	52,367	4.2	34.5
Diabetes	35,490	2.9	23.4
Suicide	30,277	2.5	19.9
Alzheimer disease	25,364	2.1	16.7
Kidney disease	24,865	2.0	16.4
Influenza and pneumonia	23,615	1.9	15.6

From Heron M. Deaths: leading causes for 2010. *Natl Vital Stat Rep.* 2013;62(6):1-96. http://www.cdc.gov/nchs/data/nvsr/nvsr62/nvsr62_06.pdf.

be achieved by concentrating on the causes of cardiovascular diseases, cancer, and injuries.

The actual causes of death in the United States are listed in **Table 7-4** and include unhealthy behaviors, most notably tobacco use, poor diets, lack of physical activity, and misuse of alcohol. **Table 7-5** lists the risk factors for the leading causes of death and the number of deaths attributed to each. These behaviors and risk factors are prime targets for preventive interventions in the clinical setting.

Figure 7-5 demonstrates that the leading causes of death are quite different in younger age groups than older. In addition, race/ethnicity and socioeconomic factors change the magnitude of these causes. Family physicians knowing the epidemiology of disease and risks in their communities can focus in on the risks that have the greatest impact on their patients.

When assessing the risks linked to each of these leading causes of death and disability, it is important to remember that a “risk factor” identified in an observational study may not translate into reduced disease if that risk is eliminated.

Table 7-4 Actual Causes of Death, United States, 2000

Actual Cause	Number (%)
Tobacco	435,000 (18.1)
Poor diet and physical inactivity	400,000 (16.6)
Alcohol	85,000 (3.5)
Infectious diseases	75,000 (3.1)
Toxic agents	55,000 (2.3)
Motor vehicles	43,000 (1.8)
Guns	29,000 (1.2)
Sexual behavior	20,000 (0.8)
Illicit drug use	17,000 (0.7)

Data from Mokdad AH, Marks JS, Stroup DF, Gerberding JL. Actual causes of death in the United States 2000. *JAMA.* 2004;291:1238-1245.

Table 7-5 Deaths Attributable to Risk Factors, United States, 2009

Rank	Risk	Number of Deaths
1	Smoking	467,000
2	High blood pressure	395,000
3	Overweight and obesity	216,000
4	Physical inactivity	191,000
5	High blood glucose	190,000
6	High cholesterol	113,000
7	High dietary salt	102,000
8	Low omega-3 fatty acid intake	84,000
9	High trans fat intake	82,000
10	Alcohol intake	64,000

Data from Danaei G, Mozaffarian D, Taylor, et al. The preventable cause of death in the United States: comparative risk assessment of dietary, lifestyle and metabolic risk factors. *PLoS Med.* 2009;6(4):e1000058. doi:10.1371/journal.pmed.1000058. <http://www.plosmedicine.org/article/info:doi/10.1371/journal.pmed.1000058>.

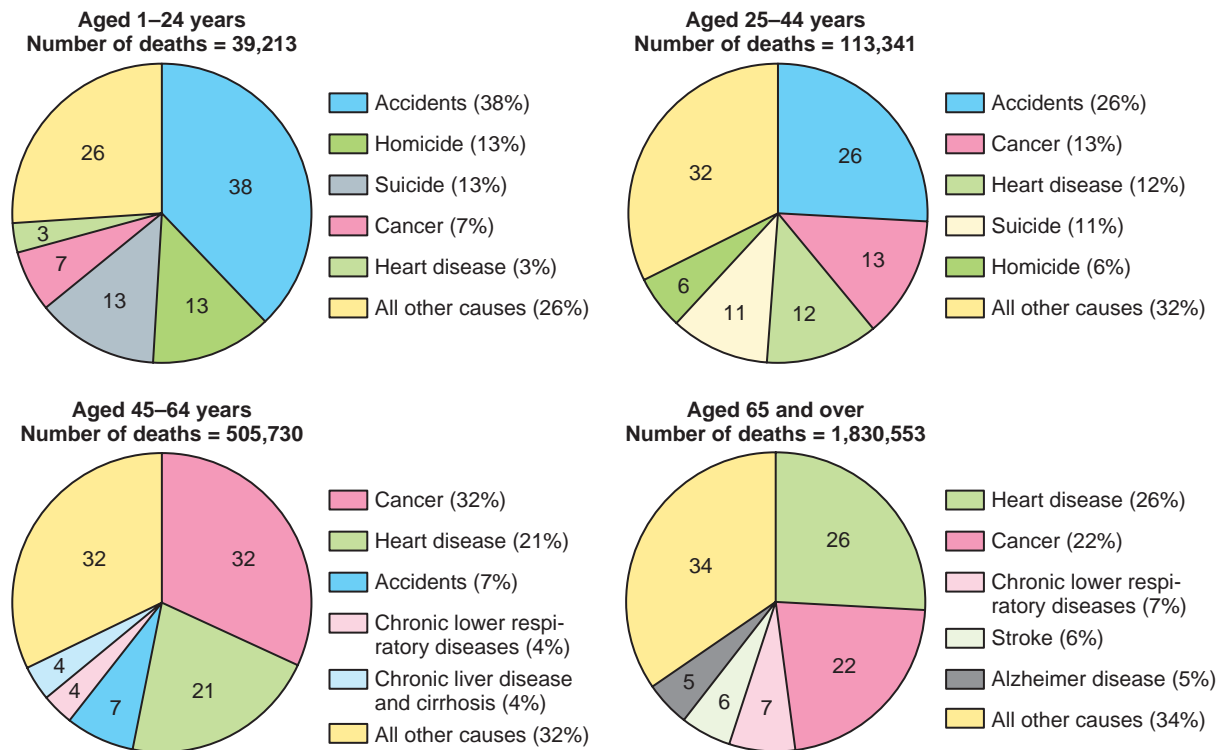

Figure 7-5 Leading causes of death by age. (From Minino AM. Death in the United States, 2011. *NCHS Data Brief*. 2013;115:1-8.)

Controlled clinical trials are needed to provide proof of improved outcomes from risk reduction. An example of a risk reduction intervention for which evidence exists is blood pressure control. It was shown in observational studies that hypertension is a risk for coronary heart disease and cerebral vascular disease. Following that discovery, controlled clinical trials showed that controlling blood pressure resulted in a reduction in these conditions. An example of a risk reduction effort that did not pan out is the use of antioxidants to prevent cancer. Observational studies indicated that lower intake of certain vitamins with antioxidant properties was associated with higher rates of certain cancers. However, controlled clinical trials of increased antioxidant intake failed to demonstrate reduced cancer rates (Boffetta et al., 2010; Gasiano et al., 2009; Zhang, 2008). Looking back at Table 7-5, there is good evidence that reducing risks 1 through 6 and 10 result in improved health outcomes. The evidence of benefit from reducing risks 7 through 9 is not as strong.

RISK REDUCTION

Once a patient's short and long-term health risks are known, the family physician can concentrate on reducing these risks. Time and effort is best spent on risk reduction that evidence demonstrates will result in improved outcomes. There are two major tools for reducing patients' risks for disease—behavioral change counseling and chemoprevention. Both can be applied as primary or tertiary prevention.

Information on how to provide effective behavioral change counseling is provided in Chapter 8. Because the leading causes of death are chronic diseases affected by

behavior, with the harmful effects building up over a number of years, convincing younger adults to change unhealthy behaviors is challenging as is altering habits that have been practiced for long periods. We should keep in mind, however, that if behavior change is achieved in only a small percentage of patients, this can add up, on a population level, if all physicians applied the most effective counseling and behavior modification methods.

Some behaviors can be changed by brief counseling that can be provided in a clinical encounter. Table 7-6 lists those that are recommended by the USPSTF. Other behaviors are more difficult to change and require more intensive and multicomponent interventions. Table 7-7 lists behaviors in this category and the more intensive interventions needed to change them that are recommended by the USPSTF. In these instances the family physician can provide more intensive counseling themselves or defer to other health care professionals who have more time and training in this area.

Chemoprevention can be utilized as either a primary or tertiary prevention intervention. Those in Table 7-8 are primary interventions that are recommended by the USPSTF. Table 7-9 includes examples of other uses of medications for prevention in specific circumstances. These include those that are used commonly, such as medications to control high blood pressure and hypercholesterolemia, which can prevent cardiovascular disease, and medications to improve hyperglycemia in those with diabetes, which can prevent the microvascular complications of this chronic condition. Others are less common and need to be kept in mind when patients present after an event that places them at risk for a recurrence or have had an exposure to an infectious agent.

SCREENING

Secondary prevention, or screening for early detection of asymptomatic disease, is an important component of clinical prevention. As described previously, the USPSTF and the AAFP list screening tests that family physicians should offer to patients. The USPSTF offers a user-friendly electronic version of their recommendations called the Electronic Preventive Services Selector (ePSS). It can be downloaded to all types of electronic devices and used to search for recommended screening tests by age and gender (see <http://epss.ahrq.gov/PDA/index.jsp>). If the screening test is recommended only for certain risk groups, there is an attached tool to assist in measuring risk.

Table 7-6 Conditions That Can Be Affected by Brief Counseling in a Clinical Encounter

Condition	Counseling	For Whom
Alcohol misuse	Brief behavioral counseling interventions to reduce alcohol misuse	Adults age 18 years and older engaged in risky or hazardous drinking
Skin cancer	Counseling about minimizing exposure to ultraviolet radiation to reduce risk for skin cancer	Children, adolescents, and young adults ages 10-24 years who have fair skin
Tobacco use	Tobacco cessation interventions	All those who use tobacco products
Tobacco use	Interventions, including education or brief counseling, to prevent initiation of tobacco use	School-aged children and adolescents

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

Family physicians should, over time, ensure that their patients have been offered screening tests with A or B recommendations. **Table 7-10** lists screening tests recommended by the USPSTF for adults, and **Table 7-11** lists screening tests and other preventive interventions the

Table 7-7 Behaviors That Require Intensive Counseling or Referral

Condition	Intensive Counseling or Referral	For Whom
Fall prevention	Counseling about exercise or physical therapy	Community-dwelling adults age 65 years and older who are at increased risk for falls
Cardiovascular disease risk reduction	Health diet counseling	Adult patients with hyperlipidemia and other known risk factors for cardiovascular and diet-related chronic disease
Intimate partner violence	Intervention services	Women of childbearing age who screen positive for intimate partner violence
Obesity, improvement in weight status	Intensive, multicomponent behavioral interventions	Obese adults and children
Sexually transmitted infections	High-intensity behavioral counseling to prevent sexually transmitted infections (STIs)	Sexually active adolescents and adults at increased risk for STIs

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

Table 7-8 Chemoprevention Recommended by the U.S. Preventive Services Task Force

Chemoprevention	Condition to Prevent	When to Use	A or B Recommendation	Risk Group
Aspirin	Myocardial infarction	When the potential benefit due to a reduction in myocardial infarctions outweighs the potential harm due to an increase in gastrointestinal hemorrhage	A	Men ages 45-79 years
Aspirin	Ischemic stroke	When the potential benefit outweighs the potential harm of an increase in gastrointestinal hemorrhage	A	Women ages 55-79 years
Erythromycin ophthalmic ointment	Gonococcal ophthalmia neonatorum	All newborns	A	Newborns
Fluoride supplementation	Dental caries	When the primary water source is deficient in fluoride	B	Preschool children older than 6 months
Folic acid daily supplement containing 0.4-0.8 mg (400-800 µg)	Neural tube defects	All women	A	Women planning or capable of pregnancy
Iron supplementation	Iron deficiency	When at increased risk for iron deficiency	B	Children ages 6-12 months
Tamoxifen or Raloxifene	Breast cancer	Discuss chemoprevention and the potential benefits and harms of chemoprevention	B	Women at high risk for breast cancer and at low risk for adverse effects of chemoprevention
Vitamin D supplementation	Falls in the elderly	When at increased risk for falls	B	Community-dwelling adults age 65 years and older

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

Table 7-9 Examples of Chemoprevention Not Addressed by the U.S. Preventive Services Task Force

- Isoniazid (INH) for treatment of latent tuberculosis (TB) and prevention of active TB
- Antivirals for influenza prevention in high-risk, exposed individuals
- Postexposure prophylaxis for human immunodeficiency virus (HIV) exposure from sexual contact or work-site exposure
- Antibiotics in contacts and household members of those with meningococcal and *Haemophilus influenzae* type B meningitis
- Anticoagulants in those with atrial fibrillation and post deep vein thrombosis or pulmonary embolus
- Antibiotic prophylaxis in those with heart valves undergoing invasive procedures
- Postexposure prophylaxis after exposure to syphilis, gonorrhea, and chlamydia
- Treatment for high blood pressure, high cholesterol, diabetes control

Table 7-10 Screening Tests for Adults Recommended by the U.S. Preventive Services Task Force

Condition	Screening Test	A or B	For Whom
Abdominal aortic aneurysm	One-time screening for abdominal aortic aneurysm by ultrasonography	B	Men ages 65-75 who have ever smoked
Alcohol misuse	Screen for alcohol misuse	B	All age 18 years and older
High blood pressure	Screen for high blood pressure	A	All age 18 years and older
Breast cancer gene	Referral for genetic counseling and evaluation for <i>BRCA</i> testing	B	Women whose family history is associated with an increased risk for deleterious mutations in <i>BRCA1</i> or <i>BRCA2</i> genes
Breast cancer	Mammography every 2 years	B	Women 50-74 years
Cervical cancer	Screen with cytology (Pap smear) every 3 years or, for women ages 30-65 years who want to lengthen the screening interval, screening with a combination of cytology and human papillomavirus (HPV) testing every 5 years	A	Women 21-65 years
Chlamydia	Screen for chlamydia infection	A	Sexually active women age 24 and younger, older women at risk
Cholesterol abnormalities	Screen for lipid disorders	A	All men age 35 years and older and women age 45 and older if at increased risk of coronary heart disease
Cholesterol abnormalities	Screen for lipid disorders	B	All men ages 20-35 years and women ages 20-45 years if they are at increased risk for coronary heart disease
Colorectal cancer	Screen for colorectal cancer using fecal occult blood testing, sigmoidoscopy, or colonoscopy	A	All age 50-75 years
Depression	Screen for major depressive disorder when systems are in place to ensure accurate diagnosis, psychotherapy (cognitive-behavioral or interpersonal), and follow-up	B	All adults
Diabetes	Screen for type 2 diabetes	B	Asymptomatic adults with sustained blood pressure (either treated or untreated) greater than 135/80 mm Hg
Gonorrhea	Screen for gonorrhea infection	B	Sexually active women, if they are at increased risk for infection
Hepatitis C virus (HCV)	Screen for HCV	B	Adults at high risk for infection, including a one-time screening for adults born between 1945 and 1965
Human Immunodeficiency Virus (HIV)	Screen for HIV	A	All adults through age 65 years and older adults who are at increased risk
Intimate partner violence	Screen for intimate partner violence, such as domestic violence, and provide or refer women who screen positive to intervention services	B	Women of childbearing age
Obesity	Screen for obesity	B	All adults
Osteoporosis	Screen for osteoporosis	B	Women age 65 years and older and younger women whose fracture risk is equal to or greater than that of a 65-year-old white woman who has no additional risk factors
Syphilis	Screen for syphilis infection	A	Those at increased risk for syphilis infection
Tobacco use	Ask about tobacco use and provide tobacco cessation interventions for those who use tobacco products	A	All adults

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

Table 7-11 Screening Tests and Other Interventions for Infants, Children, and Adolescents Recommended by the U.S. Preventive Services Task Force

Condition	Screening Test/Intervention	A or B Recommendation
Chlamydia infection	Screen for chlamydia infection in females if sexually active	A
Gonorrhea infection	Screen for gonorrhea infection if sexually active	B
Gonococcal ophthalmia neonatorum	Ocular topical medication for newborns	A
Hearing loss	Screen for hearing loss in newborns	B
Hemoglobinopathies	Screen for sickle cell disease in newborns	A
Human immunodeficiency virus (HIV) infection	Screen for HIV infection age 15 and older, younger if at risk*	A
Hypothyroidism	Screen for congenital hypothyroidism in newborns	A
Intimate partner violence	Screen for intimate partner violence, such as domestic violence, in women of childbearing age [†]	B
Iron deficiency	Iron supplementation for asymptomatic children ages 6-12 months who are at increased risk for iron deficiency anemia	B
Obesity	Screen children age 6 years and older for obesity	B
Phenylketonuria	Screen for phenylketonuria in newborns	A
Sexually transmitted infections	High-intensity behavioral counseling to prevent sexually transmitted infections (STIs) in all sexually active adolescents	B
Skin cancer	Counsel children, adolescents, and young adults ages 10-24 years who have fair skin about minimizing their exposure to ultraviolet radiation to reduce risk for skin cancer	B
Tobacco use	Provide interventions, including education or brief counseling, to prevent initiation of tobacco use in school-aged children and adolescents	B
Syphilis	Screen those at increased risk for syphilis infection	A
Vision	Vision screening for all children at least once between the ages of 3 and 5 years to detect the presence of amblyopia or its risk factors	B

*The American Academy of Family Physicians (AAFP) recommends routine screening starting at age 18 and screening at younger ages for those at risk.

[†]Reproductive age is considered to start at age 14. If an adolescent has an intimate partner relationship, screening is recommended.

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

USPSTF recommends for infants, children, and adolescents. It is equally important not to provide screening tests that are not effective and/or are harmful, such as those given a D rating by the USPSTF (Table 7-12). These tables describing USPSTF recommendations were developed at the time of the writing of this chapter and reflect the USPSTF recommendations as of that time. Keeping up to date on screening recommendations is challenging. The USPSTF makes a new recommendation or updates an old recommendation about once a month. Physicians can sign up for periodic updates at the USPSTF website (www.uspreventiveservicestaskforce.org/announcements.htm).

IMMUNIZATIONS

One of the most effective forms of primary interventions available to family physicians is vaccines. The ACIP publishes updated immunization schedules annually. These include routinely recommended immunizations for infants, children, and adolescents (Figure 7-6), routinely recommended immunizations for adults starting at age 19 years (Figure 7-7), and catch-up recommendations for these two age groups (all can be found at www.cdc.gov/vaccines/schedules/index.html). The catch-up schedules are useful in determining what vaccines to provide to someone who is not completely vaccinated with recommended vaccines at the time of the clinical encounter.

Family physicians should take every opportunity and use systematic approaches to ensure that patients are completely protected from vaccine-preventable diseases. This can involve assigning a clinical team member to be a vaccine advocate, implementing standing orders for nurses and others to administer vaccines, sending electronic reminders when vaccines are due, and taking advantage of each clinical encounter to provide recommended vaccines unless a valid contraindication exists (Community Preventive Services Task Force, *Increasing Appropriate Immunizations*).

PRIORITIZING PREVENTIVE SERVICES

Given the large number of possible preventive interventions that can be implemented, it is often necessary to prioritize them and address the most important ones first and the others as time and continuity allow. Patient preferences are important to consider. Difficult choices are sometimes necessary when patients have multiple risks and comorbid conditions. Chronic diseases often occur concurrently, and the guidelines for each often are written from the assumption that only one disease is present. Research is being conducted on what preventive interventions will yield the greatest gains to patients with multiple chronic conditions and risks (Taksler et al., 2013). Family physicians and patients should prioritize together.

Table 7-12 U.S. Preventive Services Task Force D Recommendations (Screening Tests That Should Not Be Performed)

Infants, children, and adolescents	<ul style="list-style-type: none"> Screening of asymptomatic adolescents for idiopathic scoliosis Screening for elevated blood lead levels in asymptomatic children age 1-5 years who are at average risk
Pregnant women	<ul style="list-style-type: none"> Screening for bacterial vaginosis in asymptomatic pregnant women at low risk for preterm delivery Screening for elevated blood lead levels in asymptomatic pregnant women
Adults: chemoprevention	<ul style="list-style-type: none"> Use of aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) to prevent colorectal cancer in persons at average risk for colorectal cancer Routine use of medications, such as tamoxifen or raloxifene, for risk reduction of primary breast cancer in women who are not at increased risk for breast cancer Use of aspirin for stroke prevention in women younger than age 55 years and for myocardial infarction prevention in men younger than age 45 years Use of β-carotene supplements, either alone or in combination, for the prevention of cancer or cardiovascular disease Use of combined estrogen and progestin for the prevention of chronic conditions in postmenopausal women Use of estrogen for the prevention of chronic conditions in postmenopausal women who have had a hysterectomy Daily supplementation with 400 IU or less of vitamin D₃ and 1000 mg or less of calcium for the primary prevention of fractures in noninstitutionalized postmenopausal women
Adults: screening	<p>Cancer</p> <ul style="list-style-type: none"> Routine referral for genetic counseling or routine breast cancer susceptibility gene (<i>BRCA</i>) testing for women whose family history is not associated with an increased risk for deleterious mutations in breast cancer susceptibility gene 1 (<i>BRCA1</i>) or breast cancer susceptibility gene 2 (<i>BRCA2</i>) Teaching breast self-examination (BSE) Screening for cervical cancer in women younger than age 21 years Screening for cervical cancer in women older than age 65 years who have had adequate prior screening and are not otherwise at high risk for cervical cancer Screening for cervical cancer in women who have had a hysterectomy with removal of the cervix and who do not have a history of a high-grade precancerous lesion (i.e., cervical intraepithelial neoplasia [CIN] grade 2 or 3) or cervical cancer Screening for cervical cancer with human papillomavirus (HPV) testing, alone or in combination with cytology, in women younger than age 30 years Screening for testicular cancer in adolescent or adult males Screening for colorectal cancer in adults older than age 85 years Screening for ovarian cancer in women Screening for pancreatic cancer in asymptomatic adults using abdominal palpation, ultrasonography, or serologic Prostate-specific antigen (PSA)-based screening for prostate cancer <p>Cardiovascular and Lung Disease</p> <ul style="list-style-type: none"> Screening for abdominal aortic aneurism in women Screening for asymptomatic carotid artery stenosis in the general adult population Screening adults for chronic obstructive pulmonary disease (COPD) using spirometry Screening with resting or exercise electrocardiography (ECG) for the prediction of coronary heart disease (CHD) events in asymptomatic adults at low risk for CHD events Routine genetic screening for hereditary hemochromatosis in the asymptomatic general population <p>Infectious Disease</p> <ul style="list-style-type: none"> Screening for asymptomatic bacteriuria in men and nonpregnant women Screening for gonorrhea infection in men and women who are at low risk for infection Screening the general asymptomatic population for chronic hepatitis B virus infection Serological screening for herpes simplex virus (HSV) in asymptomatic pregnant women at any time during pregnancy to prevent neonatal HSV infection Serological screening for HSV in asymptomatic adolescents and adults Screening of asymptomatic persons who are not at increased risk for syphilis infection

Data from U.S. Preventive Services Task Force. <http://www.uspreventiveservicestaskforce.org/index.html>.

Examples of Putting the Four-Step Approach into Practice

EXAMPLE 1, YOUNG ADULT MALE

A 28-year-old male visits the clinic in October with a complaint of abdominal pain. The pain occurs after nights when he parties with friends, consuming 6 to 7 alcohol-containing drinks. He drinks some alcohol almost every day. He admits to occasionally driving home after these parties, but feels like he is not impaired, although he was cited for driving under the influence several months ago. He also admits to being in bar fights once or twice the past year. He smokes

less than one pack of cigarettes per day and started at the age of 17 years and states he would like to quit. He denies any use of illicit drugs except occasionally smoking marijuana. He is an only child and both parents are alive with no health problems. There is no known history of cancer or early heart disease in his family. He currently takes no medications and has no chronic health problems. He has sex only with women, has had eight partners in the past year, and uses condoms irregularly. He works as an insurance adjuster in an office, exercises three to four times a week at the gym, lifting weights. He eats mostly fast food for convenience. He believes he has had all childhood vaccines but is not sure. His last tetanus shot was at age 22 years after a laceration. He is 5 ft 11 in tall and weighs 180 lb (body mass

Vaccine	Birth	1 mo	2 mo	4 mo	6 mo	9 mo	12 mo	15 mo	18 mo	19–23 mo	2–3 yr	4–6 yr	7–10 yr	11–12 yr	13–15 yr	16–18 yr
Hepatitis B ¹ (HepB)	1 st dose	← 2 nd dose →			← 3 rd dose →											
Rotavirus ² (RV) RV1 (2-dose series); RV5 (3-dose series)			1 st dose	2 nd dose	See footnote 2											
Diphtheria, tetanus, and acellular pertussis ³ (DTaP; <7 yrs)			1 st dose	2 nd dose	3 rd dose			← 4 th dose →				5 th dose				
Tetanus, diphtheria, & acellular pertussis ⁴ (Tdap; ≥7 yrs)														(Tdap)		
<i>Haemophilus influenzae</i> type b ⁵ (Hib)			1 st dose	2 nd dose	See footnote 5			← 3 rd or 4 th dose → See footnote 5								
Pneumococcal conjugate ⁶ (PCV13)			1 st dose	2 nd dose	3 rd dose			← 4 th dose →								
Pneumococcal polysaccharide ⁶ (PPSV23)																
Inactivated poliovirus ⁷ (IPV) (<18 yrs)			1 st dose	2 nd dose	← 3 rd dose →							4 th dose				
Influenza ⁸ (IIV; LAIV) 2 doses for some ⁹					Annual vaccination (IIV only)						Annual vaccination (IIV or LAIV)					
Measles, mumps, rubella ⁹ (MMR)							← 1 st dose →					2 nd dose				
Varicella ¹⁰ (VAR)							← 1 st dose →					2 nd dose				
Hepatitis A ¹¹ (HepA)							← 2-dose series, See footnote 11 →									
Human papillomavirus ¹² (HPV2; females only; HPV4; males and females)														(3-dose series)		
Meningococcal ¹³ (Hib-Men-CY ≥ 6 weeks; MenACWY-D ≥ 9 mos; MenACWY-CRM ≥ 2 mos)			See footnote 13											1 st dose		Booster

Range of recommended ages for all children
 Range of recommended ages for catch-up immunization
 Range of recommended ages for certain high-risk groups
 Range of recommended ages during which catch-up is encouraged and for certain high-risk groups
 Not routinely recommended

This schedule includes recommendations in effect as of January 1, 2014. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at <http://www.cdc.gov/vaccines/hcp/acip-recs/index.html>. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (<http://www.vaers.hhs.gov>) or by telephone (800-822-7967). Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (<http://www.cdc.gov/vaccines/recs/vac-admin/contraindications.htm>) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (<http://www.cdc.gov/vaccines/acip>), the American Academy of Pediatrics (<http://www.aap.org>), the American Academy of Family Physicians (<http://www.aafp.org>), and the American Congress of Obstetricians and Gynecologists (<http://www.acog.org>).

Figure 7-6 Infant, child and adolescent immunization schedule. **These recommendations must be read with the footnotes shown on the Centers for Disease Control and Prevention (CDC) website.** For those patients who fall behind schedule or start late, see the Catch-Up Schedule from CDC website. (From CDC. *Recommended Immunization Schedule for Persons Aged 0 through 18 years—United States, 2014*. <http://www.cdc.gov/vaccines/schedules/downloads/child/0-18yrs-schedule.pdf>.)

index [BMI] 20.9 kg/m²). He is well developed and muscular. His blood pressure is 125/75 mm Hg.

Because he presents out of concern for his abdominal pain, this problem needs to be addressed first. However, doing a quick assessment (Step 1), it can be determined that his major health risks are smoking, alcohol misuse (which is likely contributing to his abdominal pain), unsafe sex, and risk-taking behavior. You can mention each of these to him quickly and focus on smoking, strongly advising him to quit, offering nicotine replacement, and providing information on smoking cessation support groups. You make a note to address the other two risks, which are related, at the follow-up visit. You advise a healthier diet and the addition of aerobic exercise to his weight lifting, even though the value of this advice in changing behavior is uncertain (Step 2).

Using the USPSTF ePSS you determine the recommended screening tests are human immunodeficiency virus (HIV), syphilis (although this may not be indicated if the rate of heterosexual syphilis in the community is low), lipid disorders (since he is at higher risk for cardiovascular disease due to his smoking), high blood pressure (done at this first visit and to be repeated at each follow-up visit), obesity (done with the initial height and weight measurement), and

depression (which can be deferred to a future visit). HIV testing and a nonfasting cholesterol and high-density lipoprotein (HDL) cholesterol level can be performed on a blood sample taken in the office, in addition to any diagnostic blood tests needed (Step 3).

You can ask him to try to find his childhood vaccine record at his parent's house to bring to the next visit and offer him influenza vaccine and tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap) today (Step 4).

EXAMPLE 2, OLDER ADULT MALE

A 61-year-old male is in the clinic for a routine visit for several medical conditions including hypertension, hypercholesterolemia, obesity, and osteoarthritis of his right knee. His medications include lovastatin, hydrochlorothiazide, enalapril, and acetaminophen. He has had no recent hospitalizations or surgery. He smoked in the past but quit 15 years ago, currently drinks a glass of wine several times a week, uses no illicit drugs and denies past use, has been married to his wife for 35 years, and has no extramarital sexual partners. He has three children, all grown and out of the house, and three grandchildren, one of them

Recommended adult immunization schedule, by vaccine and age group¹

VACCINE ▼	AGE GROUP ▶	19–21 years	22–26 years	27–49 years	50–59 years	60–64 years	≥ 65 years
Influenza ^{2,*}		1 dose annually					
Tetanus, diphtheria, pertussis (Td/Tdap) ^{3,*}		Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs					
Varicella ^{4,*}		2 doses					
Human papillomavirus (HPV) Female ^{5,*}		3 doses					
Human papillomavirus (HPV) Male ^{5,*}		3 doses					
Zoster ⁶						1 dose	
Measles, mumps, rubella (MMR) ^{7,*}		1 or 2 doses					
Pneumococcal 13-valent conjugate (PCV13) ^{8,*}		1 dose					
Pneumococcal polysaccharide (PPSV23) ^{9,10}		1 or 2 doses					
Meningococcal ^{11,*}		1 or more doses					
Hepatitis A ^{12,*}		2 doses					
Hepatitis B ^{13,*}		3 doses					
<i>Haemophilus influenzae</i> type b (Hib) ^{14,*}		1 or 3 doses					

*Covered by the Vaccine Injury Compensation Program

- For all persons in this category who meet the age requirements and who lack documentation of vaccination or have no evidence of previous infection; zoster vaccine recommended regardless of prior episode of zoster
- Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indication)
- No recommendation

Report all clinically significant postvaccination reactions to the Vaccine Adverse Event Reporting System (VAERS). Reporting forms and instructions on filing a VAERS report are available at www.vaers.hhs.gov or by telephone, 800-822-7967.

Information on how to file a Vaccine Injury Compensation Program claim is available at www.hrsa.gov/vaccinecompensation or by telephone, 800-338-2382. To file a claim for vaccine injury, contact the U.S. Court of Federal Claims, 717 Madison Place, N.W., Washington, D.C. 20005; telephone, 202-357-6400.

Additional information about the vaccines in this schedule, extent of available data, and contraindications for vaccination is also available at www.cdc.gov/vaccines or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 8:00 a.m. to 8:00 p.m. Eastern Time, Monday to Friday, excluding holidays.

Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

The recommendations in this schedule were approved by the Centers for Disease Control and Prevention's (CDC) Advisory Committee on Immunization Practices (ACIP), the American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), the American Congress of Obstetricians and Gynecologists (ACOG), and the American College of Nurse-Midwives (ACNM).

A

Vaccines that might be indicated for adults based on medical and other indications¹

VACCINE ▼	INDICATION ▶	Pregnancy	Immuno-compromising conditions (excluding human immunodeficiency virus [HIV]) ^{4,6,7,8,15}	HIV infection CD4+ T lymphocyte count ^{4,8,7,8,15}	Men who have sex with men (MSM)	Kidney failure, end-stage renal disease, receipt of hemodialysis	Heart disease, chronic lung disease, chronic alcoholism	Asplenia (including elective splenectomy and persistent complement component deficiencies) ^{8,14}	Chronic liver disease	Diabetes	Healthcare personnel
Influenza ^{2,*}		1 dose IIV annually		< 200 cells/ μ L	≥ 200 cells/ μ L	1 dose IIV or LAIV annually	1 dose IIV annually				1 dose IIV or LAIV annually
Tetanus, diphtheria, pertussis (Td/Tdap) ^{3,*}		1 dose Tdap each pregnancy	Substitute 1-time dose of Tdap for Td booster; then boost with Td every 10 yrs								
Varicella ^{4,*}		Contraindicated		2 doses							
Human papillomavirus (HPV) Female ^{5,*}		3 doses through age 26 yrs		3 doses through age 26 yrs							
Human papillomavirus (HPV) Male ^{5,*}		3 doses through age 26 yrs		3 doses through age 21 yrs							
Zoster ⁶		Contraindicated		1 dose							
Measles, mumps, rubella (MMR) ^{7,*}		Contraindicated		1 or 2 doses							
Pneumococcal 13-valent conjugate (PCV13) ^{8,*}						1 dose					
Pneumococcal polysaccharide (PPSV23) ^{9,10}						1 or 2 doses					
Meningococcal ^{11,*}						1 or more doses					
Hepatitis A ^{12,*}						2 doses					
Hepatitis B ^{13,*}						3 doses					
<i>Haemophilus influenzae</i> type b (Hib) ^{14,*}		post-HSCT recipients only					1 or 3 doses				

*Covered by the Vaccine Injury Compensation Program

For all persons in this category who meet the age requirements and who lack documentation of vaccination or have no evidence of previous infection; zoster vaccine recommended regardless of prior episode of zoster

Recommended if some other risk factor is present (e.g., on the basis of medical, occupational, lifestyle, or other indications)

No recommendation

U.S. Department of Health and Human Services
Centers for Disease Control and Prevention

These schedules indicate the recommended age groups and medical indications for which administration of currently licensed vaccines is commonly indicated for adults ages 19 years and older, as of February 1, 2014. For all vaccines being recommended on the Adult Immunization Schedule: a vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Licensed combination vaccines may be used whenever any components of the combination are indicated and when the vaccine's other components are not contraindicated. For detailed recommendations on all vaccines, including those used primarily for travelers or that are issued during the year, consult the manufacturers' package inserts and the complete statements from the Advisory Committee on Immunization Practices (www.cdc.gov/vaccines/hcp/acip-recs/index.html). Use of trade names and commercial sources is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services.

B

Figure 7-7 Adult immunization schedule. These recommendations must be read with the footnotes shown on Centers for Disease Control and Prevention (CDC) website. (From CDC. *Recommended Adult Immunization Schedule—United States, 2014*. <http://www.cdc.gov/vaccines/schedules/downloads/adult/adult-schedule.pdf>.)

born just 3 weeks ago. Both parents are still alive at ages 89 and 90 years. He does not exercise regularly. He had a tetanus shot an uncertain number of years ago and has never had a flu shot. His current height is 5 ft 10 in. and weight is 250 lb (BMI 35.9 kg/m²). His blood pressure in the clinic is 130/75 mm Hg (using a large cuff) and he reports a similar reading when he checks it at home. His fasting labs, obtained a week before the clinic visit, demonstrate normal renal functions, a cholesterol level of 155 mg/dL, an HDL cholesterol level of 35 mg/dL, and glucose level of 95 mg/dL.

His risks include obesity, hypertension (controlled on medication), and hypercholesterolemia (also being treated with medication but not optimally controlled). Using the NHLBI cardiovascular disease (CVD) risk calculator (<http://cvdrisk.nhlbi.nih.gov/calculator.asp>), his risk of a myocardial infarction in the next 10 years is 12%.

Risk reduction could include obesity intensive educational interventions. To be effective in assisting him to lose weight, this will need to consist of setting weight loss goals, improving diet and increasing physical activity, addressing barriers to change, self-weight monitoring regularly, and setting strategies to maintain lifestyle changes. Today you can ask him to go online and assess his diet and obtain advice on how to improve his diet at the DHHS website (www.healthfinder.gov/HealthTopics/Category/health-conditions-and-diseases/diabetes/eat-healthy). A plan for regular follow-up and monitoring should be established.

Recommended chemoprevention includes continued treatment for hypertension and hypercholesterolemia to reduce risks of cardiovascular disease. If he has no history of bleeding disorders, he might benefit from daily low-dose aspirin, and this can be discussed. At age 61, with a 12% risk of a heart attack, daily aspirin will prevent about four heart attacks per 100 men over 10 years (see www.uspreventiveservicestaskforce.org/uspstf09/aspirincvd/aspcvdrs2.htm).

Recommended screening includes being tested for colorectal cancer (with colonoscopy, sigmoidoscopy, or fecal occult blood testing), HIV and hepatitis C virus, hyperlipidemia (not applicable since he is on treatment), high blood pressure (not applicable since he is on treatment), obesity (done), depression using one of the scales linked on the USPSTF website (www.integration.samhsa.gov/images/res/PHQ%20-%20Questions.pdf), and type 2 diabetes (done with the preclinic laboratory work). He does not meet the criteria to screen for syphilis (men who have sex with men, commercial sex workers, persons who exchange sex for drugs, and those in adult correctional facilities).

Immunizations that are recommended include influenza vaccine annually, herpes zoster, and Tdap. Tdap and influenza vaccine are especially important if he is going to be in contact with his 3-week-old grandchild. You should mention that Tdap and influenza are also recommended for his wife for the same reason.

EXAMPLE 3, EARLY ADOLESCENT FEMALE

A 12-year-old African American female visits the clinic with her mother because the mother felt it was time for her

daughter to have a checkup. The patient is seen at first with the mother and then alone. The patient is well, with no acute or chronic medical problems. She started having her menses 6 months previously and states she is not sexually active or considering it. She is active in sports, and her mother feeds her lots of fruits and vegetables and minimizes consumption of fast foods and sweetened drinks. The mother provides an immunization record that shows the patient has received all recommended childhood vaccines except for a single dose of varicella vaccine. The patient is 5 ft 4 in. tall and weighs 120 lb (75th percentile for both height and weight; BMI 20.6 kg/m²). Her mother is 45 years old and was diagnosed with breast cancer earlier in the year.

Risk factor assessment shows that injuries from a motor vehicle crash are the most likely cause of death in this age group. A more detailed family history is important to see if she has a high-risk family history for breast cancer. You can request that the mother gather this information to present at a future visit.

Risk reduction should include counseling about tobacco avoidance. Skin cancer behavioral counseling is recommended only for those with fair skin color, not African Americans and others with dark skin.

Recommended screening includes tests for depression, which can be performed using one of the tools on the USPSTF website, and obesity (done).

Recommended immunizations include Tdap, meningococcal conjugate vaccine (MCV4), human papillomavirus (HPV) first dose of a three-dose schedule, varicella dose 2 (catch up), and annual influenza vaccine.

Bright Future recommendations for this age group include measuring blood pressure, checking vision, performing a psychosocial and behavioral assessment, and providing anticipatory guidance focused on substance abuse and safety. The USPSTF states that the evidence is insufficient to recommend for or against these interventions.

EXAMPLE 4, ELDERLY FEMALE

An 85-year-old female visits the clinic for her annual examination to have her migraine medication refilled. She has occasional migraine headaches that are relieved by sumatriptan. She lives alone, walks 2 miles daily, and reports no health problems. She has no problem getting out of a chair. Her height is 5 ft 10 in. and weight is 165 lb (BMI 23.7 kg/m²). Her family history shows no cancer or cardiovascular risks. She is 30 years post menopause, and other than a multivitamin each day, takes no medicine. She received a pneumococcal shot at age 65, a Tdap 4 years ago, and a zoster vaccine 5 years ago. She receives a flu shot each year. All of her children (4) and grandchildren (8, the youngest being age 5 years) live in the local area. Her blood pressure has never been high and today is 125/75 mm Hg.

Influenza and pneumonia are risks for this patient since she is around her school-age grandchildren, and the influenza vaccine has low effectiveness in those age 85 years old.

Risk reduction can best be achieved in this woman through advising influenza and pneumococcal vaccines for

her children and grandchildren and avoiding unnecessary screening tests. The only screening tests recommended for her are for osteoporosis, obesity (done), high blood pressure (done), and depression (which she refuses). She is current on all other recommended vaccines.

This woman is best left alone, other than the screening for osteoporosis to prevent iatrogenic illnesses.

The Family Physician as the Foundation of the Public Health System

Although applied prevention in the clinical setting is important for individualized health and wellness, family physicians should realize that the largest improvements in the health of the public at large come from community-wide, public health interventions. [Table 7-13](#) lists just some of the important public health interventions of the last century that have led to significant decreases in morbidity and mortality.

Each state and local political jurisdiction has some kind of official public health presence. At the local level, these are referred to as *local health departments*, which are subunits of city, county, or other regional government jurisdictions. All states have state public health departments, and the major public health department at the national level is the CDC, although important public health functions are also carried out by other federal agencies. The major roles and functions of local, state, and national health departments include disease surveillance and reporting, infectious disease control, infectious disease outbreak response, emergency preparedness and response, and chronic disease prevention.

The public health infrastructure, however, provides minimal direct clinical care, and depends on family physicians and other primary care providers to fulfill vital public health functions that contribute to improved community health. These functions are listed in [Table 7-14](#). Screening tests, immunizations, and risk reduction have already been discussed in this chapter. Other important functions include

accurately diagnosing and treating diseases of public health importance, such as sexually transmitted infections, influenza, and tuberculosis; providing recommended treatment for family members and other contacts to infectious diseases or referring them to the public health department; reporting of infectious diseases, cancers, and other reportable conditions as required by state and local reporting requirements; enforcing infection control practices in the clinical setting; and providing advice to infectious patients on how to avoid spreading disease. Avoiding unnecessary or harmful testing and treatments should also be considered part of the prevention package offered by family physicians.

Family physicians should be continually aware of the epidemiology of disease in their communities, which diseases are endemic, which ones are not, and which infectious diseases are occurring at increased rates as part of an epidemic or seasonal increase. Local and state health departments as well as the CDC provide routinely updated epidemiological information through a variety of communication outlets. This knowledge assists physicians in making more accurate clinical diagnoses and providing appropriate treatments. The CDC and state health departments provide recommendations on how to diagnose and treat infectious diseases such as sexually transmitted infections, influenza, tuberculosis, and many others. A list of the most commonly used recommendations and their location on the CDC website is contained in [Table 7-15](#). Following these official guidelines assists in providing accurate surveillance data, helps control infectious disease outbreaks, and assists in preventing antibiotic resistance.

When an infectious disease is discovered in a patient, the family physician should think about the implications of this for the family and the community. Family members may benefit from immunizations and/or chemoprevention depending on the disease. Some states allow treatment of sexually transmitted infections and other infectious diseases for contacts of patients, without directly examining the contact. This is called expedited partner therapy (EPT), and it not only benefits the contact but can also prevent reinfection of the patient. Examples of when EPT can be

Table 7-13 Major Public Health Achievements of the Past Century

- Vaccination
- Motor-vehicle safety
- Safer workplaces
- Control of infectious diseases
- Prevention of deaths from coronary heart disease and stroke through risk factor reduction
- Safer and healthier foods
- Maternal and child health programs
- Family planning
- Fluoridation of drinking water
- Tobacco use prevention

Centers for Disease Control and Prevention (CDC). Ten great public health achievements—United States 1900-1999. *MMWR Morb Mortal Wkly Rep.* 1999;48(12):241-243.

Table 7-14 Important Public Health Functions of Family Physicians

- Provide and promote recommend immunizations
- Provide screening tests recommended by the U.S. Preventive Services Task Force (USPSTF)
- Avoid providing unproven and/or harmful screening tests
- Use effective methods to modify risky behaviors
- Accurately diagnose and treat diseases of public health importance, such as sexually transmitted infections, influenza, and tuberculosis
- Either provide treatment for exposed family members and other contacts of infectious diseases or refer to the public health department
- Adhere to reporting requirements for infectious diseases, cancers, and other reportable conditions
- Enforce infection control practices in the clinical setting
- Provide advice to infectious patients on how to avoid spreading disease
- Avoid unnecessary and harmful testing and treatments

Table 7-15 Commonly Referenced Guidelines on Diseases of Public Health Importance

Diseases	Guideline Location
Sexually Transmitted Diseases <ul style="list-style-type: none"> ■ Treatment guidelines and updates 	http://www.cdc.gov/std/treatment/2010/default.htm
Tuberculosis <ul style="list-style-type: none"> ■ Diagnosis, treatment of active and latent tuberculosis 	http://www.cdc.gov/tb/publications/guidelines/Treatment.htm#treatment
Influenza <ul style="list-style-type: none"> ■ Vaccinations ■ Diagnosis and treatment ■ Outbreak control ■ Pre- and postexposure chemoprevention 	http://www.cdc.gov/flu/professionals/index.htm

useful include chlamydia and trichomonas infections. Family physicians who live in states where EPT is not legal and those who are not comfortable providing EPT should either recommend the exposed contact see a physician for assessment and treatment or refer the patient to the local health department. A current catalogue of the legal status of EPT by state can be found at the CDC Expedited Partner Therapy web page (www.cdc.gov/std/ept/default.htm/).

Much of the public health surveillance system depends on reports that come from clinical settings. Hospitals, physicians, and other providers are required to report to the local health department occurrences of specific infectious diseases. In some locations, new diagnoses of cancers are also required. Family physicians should be aware of what the reporting requirements are in the locale of their practice. These requirements usually specify that individual cases should be reported; however, in some instances, the requirement applies only to suspected outbreaks or multiple cases. Anytime family physicians detect an infectious disease that is out of the ordinary, with potential to spread in the community, they should consult with a public health department, either local or state.

Most of the required reports request information about the patient that includes name, address of residence, and phone number. If this information is required, it is exempt from the requirements of the Health Insurance Portability and Accountability Act (HIPAA), and the patient's consent to report is not required. The public health department uses this information for a variety of purposes, including detailed surveillance, contact notification, and implementation of preventive measures.

A clinical setting can be the source of spread of infectious disease in the community. Sick, infectious patients visit physician offices and clinics, and measures need to be taken to insure that spread of disease does not occur in these settings, to other patients as well as to physicians and staff. Measures that can be taken fall into five categories: policies on respiratory hygiene, policies on hand hygiene, immunization of staff, triage policies, and use of personal protective equipment (PPE). Policies on all these areas should be in place and enforced. A checklist of what the CDC considers minimum expectations for the prevention of infections in the outpatient setting can be found at its

Table 7-16 Policies for Respiratory Hygiene in Health Care Settings

- Signs at entrances asking patients to inform office staff if they have symptoms of a respiratory infection
- Signs describing expectations regarding respiratory hygiene and demonstrating the correct way to cover the mouth and nose with a tissue when coughing or sneezing; proper disposal of tissue and hand cleansing after contact with respiratory secretions
- Offering masks to those who are coughing and not practicing respiratory hygiene
- Providing readily available tissues and hand sanitizer and no-touch receptacles for tissue disposal

Healthcare-associated Infections web page (www.cdc.gov/HAI/settings/outpatient/checklist/outpatient-care-checklist.html).

Respiratory hygiene means covering the nose and mouth with a disposable tissue when coughing and sneezing. This should be an expectation for patients and staff. Measures that can be taken to encourage and enforce respiratory hygiene are listed in [Table 7-16](#). Health care personnel should wash or sanitize their hands after every patient encounter. Patients should be instructed to use frequent hand washing when sick. Hand sanitizer should be readily available in clinical areas and waiting rooms.

Office design and triage policy can assist in physically and temporally separating sick, infectious patients from others. Potentially infectious patients can be placed in a separate waiting area and/or asked to come in during specified time periods. However, if respiratory and hand washing policies are adhered to, having those with common respiratory infections use common waiting areas and examination rooms is acceptable. Other infectious diseases require more stringent measures. Fever accompanied by rash is particularly problematic. Measles, rubella, and varicella can all present this way and are highly infectious. Those presenting with rash and fever can be placed into a designated "rash room" and kept confined there until the diagnosis is clarified. If a highly infectious disease is suspected or confirmed, the room should not be used for other patient encounters for a time period as determined by the public health department.

Physicians and other health care personnel are at increased risk of exposure to infectious diseases and should take measures to protect themselves and thereby also protect their patients and families. All health care personnel should be vaccinated according to CDC recommendations ([Table 7-17](#)). Having unvaccinated personnel in a clinical setting causes a risk to them, their families, and patients. They are also a liability risk to the practice. PPE should be used any time an exposure to a potentially infectious body fluid occurs. Details on the proper use of PPE are on the CDC web page, Healthcare-associated Infections (www.cdc.gov/HAI/prevent/ppe.html).

When a family physician detects an infectious disease in a patient, advice should be given on how to prevent the spread of the disease to the patient's family, friends, and the community. A list of advice that can be provided is in [Table 7-18](#).

As noted earlier, the last important role for family physicians in practicing optimal preventive medicine is to avoid

Table 7-17 Vaccines for Health Care Personnel

Vaccines	Recommendations in Brief
Hepatitis B	If you do not have documented evidence of a complete hepatitis B vaccine series, or if you do not have an up-to-date blood test that shows you are immune to hepatitis B (i.e., no serologic evidence of immunity or prior vaccination), then you should: <ul style="list-style-type: none"> ■ Get the 3-dose series (dose #1 now, #2 in 1 month, #3 approximately 5 months after #2). ■ Get anti-hepatitis B surface antigen (HBs) serologic tested 1-2 months after dose #3.
Flu (Influenza)	Get 1 dose of influenza vaccine annually.
MMR (Measles, Mumps, and Rubella)	If you were born in 1957 or later and have not had the MMR vaccine, or if you do not have an up-to-date blood test that shows you are immune to measles, mumps, and rubella (i.e., no serologic evidence of immunity or prior vaccination), get 2 doses of MMR, 4 weeks apart. For health care workers (HCWs) born before 1957, see the Advisory Committee on Immunization Practices (ACIP) recommendations.
Varicella (Chickenpox)	If you have not had chickenpox (varicella), if you have not had varicella vaccine, or if you do not have an up-to-date blood test that shows you are immune to varicella (i.e., no serologic evidence of immunity or prior vaccination), get 2 doses of varicella vaccine, 4 weeks apart.
Tdap (Tetanus, Diphtheria, Pertussis)	Get a one-time dose of Tdap as soon as possible if you have not received Tdap previously (regardless of when previous dose of Td was received). Get Td boosters every 10 years thereafter. Pregnant HCWs need to get a dose of Tdap during each pregnancy.
Meningococcal	Those who are routinely exposed to isolates of <i>Neisseria meningitidis</i> should get 1 dose.

From the Centers for Disease Control and Prevention (CDC). *Recommended Vaccines for Healthcare Workers*. <http://www.cdc.gov/vaccines/adults/rec-vac/hcw.html>.

Table 7-18 Advice to Patients to Prevent Spread of Infectious Disease

- The patient should stay at home while most infectious to avoid infecting others. If patients have to leave the home, they should strictly follow respiratory hygiene.
- At home, place patients in a separate room or separate them physically from other household members as much as possible.
- Limit the number of household members having contact with the patient.
- Follow hand hygiene after contact with the patient or the patient environment and waste products. This includes handwashing with soap and water or use of an alcohol-based hand rub.
- Consider having the patient wear a surgical mask.
- Immunize household members if appropriate.
- Wash dishes, utensils, and laundry in warm water and soap.
- Consider chemoprophylaxis for household members if it is available and recommended.
- Household members should watch for symptoms and seek care at their first appearance.
- Nonhousehold members should not enter the home. If nonhousehold members need to enter the home, they should avoid close contact with the patient.

unnecessary and harmful testing and treatments. This at first glance seems clear cut, but there is good evidence that in daily medical practice many tests and treatments provided are not necessary and result in harm (Kale et al., 2013; Korenstein et al., 2012). Antibiotics for upper respiratory infections is one example. The AAFP and other specialty organizations have joined forces in an initiative called “Choosing Wisely.” Each organization has developed a list of testing or interventions that should not be performed, or done only in specific circumstances. The AAFP list of 15 such interventions is contained in Table 7-19. Unnecessary testing and treatments are costly and harmful, and avoiding them is good preventive medicine.

Intergenerational Aspects of Prevention in the Family

Family physicians have the opportunity to appreciate and achieve intergenerational benefits of preventive interventions within families and households. Influenza and pneumococcal vaccines in infants and children provide added protection to elderly family members—who are at the highest risk of morbidity and mortality from these respiratory infections—through herd immunity and reduced disease transmission. Pertussis immunization of adolescents and adults of all ages provides a cocoon of protection around infants who have high rates of serious complications from pertussis and are not fully protected by the vaccine until they have received a full primary series. Other infectious diseases can spread among family members, and ways to minimize this have already been discussed in this chapter.

In addition, chronic diseases tend to be common among family members because of common genes and common environments, and interventions to prevent these conditions can spread their effects through the household. For example, smoking cessation helps prevent disease not only in the smoker but also in the whole family by preventing exposure to secondhand smoke. Improved diets and increased physical activity can be family activities, which lead to improved health for those with obesity and diabetes and contribute to a reduced risk for everyone else in the household.

Genomics and Prevention

The human genome project has led to a better understanding of the genomic basis of responses to specific

Table 7-19 American Academy of Family Physicians “Choosing Wisely” List

1. Do not do imaging for low back pain within the first 6 weeks unless red flags are present.
2. Do not routinely prescribe antibiotics for acute mild-to-moderate sinusitis unless symptoms last for 7 or more days or symptoms worsen after initial clinical improvement.
3. Do not use dual-energy x-ray absorptiometry (DEXA) screening for osteoporosis in women younger than 65 or men younger than 70 with no risk factors.
4. Do not order annual electrocardiograms (ECGs) or any other cardiac screening for low-risk patients without symptoms.
5. Do not perform Pap smears on women younger than 21 years of age or who have had a hysterectomy for noncancer disease.
6. Do not schedule elective, nonmedically indicated induction of labor or cesarean deliveries before 39 weeks, 0 days gestational age.
7. Avoid elective, nonmedically indicated inductions of labor between 29 weeks, 0 days and 41 weeks, 0 days, unless the cervix is deemed favorable.
8. Do not screen for carotid artery stenosis in asymptomatic adult patients.
9. Do not screen women older than 65 years of age for cervical cancer who have had adequate prior screening and are not otherwise at high risk for cervical cancer.
10. Do not screen women younger than 30 years of age for cervical cancer with human papillomavirus (HPV) testing alone or in combination with cytology.
11. Do not prescribe antibiotics for otitis media in children ages 2 to 12 years of age with nonsevere symptoms when the observation option is reasonable.
12. Do not perform voiding cystourethrograms routinely in first febrile urinary tract infection in children ages 2 to 24 months.
13. Do not routinely screen for prostate cancer using a prostate-specific antigen (PSA) test or digital rectal examination.
14. Do not screen adolescents for scoliosis.
15. Do not require a pelvic examination or other physical examination to prescribe oral contraceptive medications.

From American Academy of Family Physicians. *Fifteen Things Physicians and Patients Should Question*. http://www.aafp.org/dam/AAFP/documents/about_us/initiatives/choosing-wisely-fifteen-questions.pdf.

medications, adverse drug reactions, and the underlying inheritability of many conditions. Rapidly evolving scientific advances in genomics, along with reduced costs of genomic tests, holds the promise of one day each person knowing their whole genome. While theoretically this will lead to more accurate targeting of drug therapy, fewer adverse drug reactions, and targeted risk reduction activities, the full translation of this new science into useful and effective clinical interventions is pending the demonstration of clinical utility and improved clinical outcomes.

Genomic tests should be evaluated for effectiveness just as should other screening tests. So far, evidence-based groups that have assessed genetic and genomic tests used for predicting risk for chronic diseases, such as diabetes, coronary heart disease, and obesity, have not endorsed their use because they have not proven to be clinically useful; they do not provide much information beyond that obtained from a family history and traditional risk factors (EGAPP Working Group, 2010, 2013). In addition, it is not clear

that people will take any action to improve their health or risks based on this information.

However, testing for two conditions that cause higher risks for cancer have been found to result in improved outcomes: breast cancer genes and Lynch syndrome. The USPSTF recommends that women with high-risk family histories for breast and uterine cancer be counseled about the *BRCA* gene test (USPSTE, n.d.). Patients who have a *BRCA* gene can reduce their chances of breast and ovarian cancer with bilateral mastectomy and oophorectomy. First-degree relatives of those with Lynch syndrome, discovered to be the cause of colon cancer, can be tested to see if they carry the same mutation, and if they do, they can benefit from earlier and more frequent colonoscopy. This has led to a recommendation to test all of those with newly diagnosed colon cancer for Lynch syndrome and counseling of first-degree relatives of those with this inherited disorder (EGAPP Working Group, 2009).

Family physicians will need to stay current with advances in genomics and use discretion when deciding when to use genomic tests and genomic-based interventions, adopt them when the evidence merits it, and avoid unnecessary and potentially harmful testing.

Office Systems as an Aid to Prevention

In a busy clinical setting, prevention can easily be relegated to the back bench. It takes effort to adhere to recommendations for counseling, chemoprevention, screening, and vaccines. Reporting of infectious diseases to the health department can be overlooked. Making prevention interventions routine, as part of the clinical system, helps ensure a high level of performance. Examples of systemization that can occur include electronic health record reminders to providers of recommended preventive services for each patient; flagging of infectious diseases that need to be reported; standing orders for immunizations; alerts when targets such as blood pressure and blood glucose levels are exceeded; and automatically generated reminders for patients that can be sent using electronic media. Other system-wide interventions with good evidence of effectiveness include group education sessions for diabetes self-management and increasing breast cancer screening; team-based approaches to assist patients in managing chronic conditions such as high blood pressure, diabetes, and high cholesterol; and periodic assessment and feedback to providers on performance on prevention measures (Community Preventive Services Task Force, *Cardiovascular Disease Prevention, Diabetes Prevention and Control, and Obesity Prevention and Control*). Individual team members can be charged with specific responsibilities such as assessing each patient's vaccine status or ensuring that hand sanitizers and tissues are readily available. Immunization schedule wall charts can be posted in waiting areas and examination rooms, and prevention-oriented patient education materials can be placed so they are easily seen and obtained. The key is making all aspects of prevention a priority and finding ways to make it happen.

Behavioral Change and Patient Empowerment

CHARLES W. SMITH and J. CHRIS RULE

CHAPTER OUTLINE

Traditional Physician Role, 102
Evolution of the Care Model, 102
The Participatory Medical Model, 103
The Birth of the “e-Patient Revolution,” 103
Patient- and Family-Centered Care, 104
Patient Engagement, 104

The Patient-Centered Medical Home, 104
Patient/Provider Collaboration, 105
Information Technology and Participatory Medicine, 105
Health Behavior Change and Motivational Interviewing, 105

Key Points

- Patients are responsible for their own health.
- Patient engagement and shared decision-making is more likely to result in better patient outcomes.
- Motivational interviewing can help patients make important changes.

Although most people find it very difficult to change behavior, they often do so in the interest of achieving positive health outcomes. This chapter introduces you to the concept of “participatory medicine” and challenges you to think of patient relationships in a new way, as a partnership, and to facilitate the notion that patients are, in fact, responsible for their own health. Patients will never achieve meaningful, lasting behavior change unless the decision is their own. And, they will not feel empowered to make change unless they have access to enabling tools and methods. Motivational interviewing (MI) is one technique that can be used by providers to help patients initiate and implement important change processes. This approach is presented later in this chapter.

Traditional Physician Role

Physician training often involves techniques and advice about how to “lead” or “direct” the patient to change, whether the goal is adherence to treatment recommendations, smoking cessation, or dietary changes to achieve weight loss. As a result of taking on this provider-centric, directive role, physicians often mistakenly assume responsibility for patient outcomes. This can foster paternalistic interaction, cause frustration, and contribute to provider burnout. Embracing the notions of shared decision-making, patient engagement, and patient empowerment frees both patient and provider to form a more equal relationship and allows the patient to receive appropriate guidance and

advice. This type of relationship is more likely to result in the patient taking responsibility for making the necessary changes to achieve optimal health (Stewart et al., 2000). Examples that support this approach can be seen in the Kaiser Permanente HealthConnect Collaborative Cardiac Care Case Study, which reported that patient engagement resulted in prevention of 135 deaths and 260 costly emergencies and increased achievement of patient’s cholesterol goals from 26% to 73%; and it resulted in the percent of patients screened for cholesterol levels increasing from 55% to 97% (Munro, 2013).

Evolution of the Care Model

The dominant care model in Western medicine has been the biomedical model. The traditional provider role places the physician in an illness/disease paradigm. This model has sustained the health care system for more than a century and has resulted in much success. Yet the system cries out for change, in part because of the perceived negative consequences on patient health outcomes. An alternative approach, the patient-centered, participatory, patient-engagement paradigm, focuses more on health promotion and maintenance of a healthy lifestyle. One of the early “disruptive” forces that led to the evolution of the traditional medical model was Michael Balint, who used his dual training in medicine and psychiatry to explore the way emotions affect symptoms. He also emphasized the importance of the role of the physician himself and the doctor-patient relationship (Balint, 1957). Engel (1977), building on the works of general systems theorists, first proposed the biopsychosocial model, which embraces the complexities of genetics, physiology, family history, family dynamics, environmental stress, and stress-related illness, as well as social and cultural factors. It also takes into account that many deeply personal factors affect the expression of symptoms and one’s response to, and recovery from, illness.

The “medical model” focuses on making a diagnosis and providing treatment to eliminate the disease, and it has been largely successful. Yet the obdurate rate of change for

certain chronic diseases illustrates that this model has significant limitations. Likewise, while the biopsychosocial model and Balint's blend of the medical/psychosocial approach to care are helpful in understanding patient behavior, they do not provide readily applicable practice approaches that help doctors and patients achieve optimum health outcomes. Nevertheless, these pioneers provided the background and basis for an exciting new approach by encouraging patients to be active participants in narrating their stories to their physicians (Engel, 1997). This may provide a more effective approach, namely, participatory medicine.

The Participatory Medical Model

The medical and biopsychosocial models describe how providers view their patients. But in the realm of interaction and the doctor-patient relationship, patients and providers alike are calling for a new model of care in which the provider assumes a new, less authoritative role that seeks to engage the patient more actively in the care process. This participatory model assumes that patients will actively learn about their condition, prepare questions for provider visits, collaborate with other patients with similar conditions, and take an active role in making lifestyle changes to improve health and manage their own conditions.

The participatory health model goes hand in hand with the introduction of the Internet and mobile technology. And it embraces the enormous impact the Internet is having on health care. (Reynolds, 2013). But these changes also complicate the doctor-patient relationship, bringing to light multiple, potentially conflicting sources of information from online journals, websites, and blogs that must be reconciled. So then, how can this reconciliation best take place and how will we, as providers, facilitate the role of patients within the participatory model of care?

In this new model of care, patients will receive guidance, tools, and information that foster active participation in their care and effective collaboration with providers. In addition to engaging in research about their health and their medical conditions, patients will network with online communities to discover which treatments, providers, and facilities work best. Through the network effect of communicating with other engaged patients, they will become more aware of their responsibilities for maintaining health. This approach will be even more effective as home monitoring devices become routinely available (Kruse et al., 2013).

As providers increasingly adopt electronic communication options, clinical care will shift to a "care anywhere" model. Office visits will become much less important and less frequent. Most routine follow-up, medication refills, review of blood pressure, adjustment of medications, and other former office-based interactions will be conducted online. Office visits will only take place when a hands-on examination, interaction, or procedure is needed. This new care model will be less costly, more patient-centered, more convenient, and will lower barriers to accessing care. These electronic methods of communication may include e-mail, web-based secure messaging, videoconferencing, mobile phone conversations, text messaging, and instant messaging (Epstein and Street, 2011).

But, as with most things, these sweeping changes are not without risk and potential negative outcomes. Increasing dependence on online communication removes the valuable role of face-to-face communication and nonverbal communication. Thus it will risk missing subtle clinical clues that may otherwise be detected within an office setting. Further, it is difficult to be certain that someone other than the assumed patient is communicating online, so there is also a risk of fraudulent activity occurring. And state medical regulations generally limit the extent to which a provider may give online advice or prescription medications without a previously established doctor-patient relationship or an in-office evaluation before communicating online. So this, appropriately in most cases, limits the breadth of online provider-patient communication.

The Birth of the "e-Patient Revolution"

"e-Patients: How They Can Help Us Heal Healthcare," a Robert Wood Johnson white paper, articulated this emerging change in health care and introduced the participatory model for U.S. health care (Ferguson et al., 2007). More recently, the Affordable Care Act, with its emphasis on patient-centered medical homes and accountable care organizations (ACOs), is in the early stages of implementation. The effectiveness of these health reforms will depend to a great extent on how successful we are in activating and engaging patients to become participatory partners. Ferguson also noted that people provide their own care 80% to 98% of the time and thus self-care is actually the predominant care mode (Figure 8-1). He also noted that, with the advent of the Internet and the accompanying massive access to information, the triangle is becoming "flipped"; that is, self-care is now more encouraged, more routine, and more accepted than previously (Figure 8-2). Ferguson believed that patients are now more knowledgeable about their health and in a better position to use health professionals in a coequal, consultative mode (participatory model) than to continue to function as passive patients.

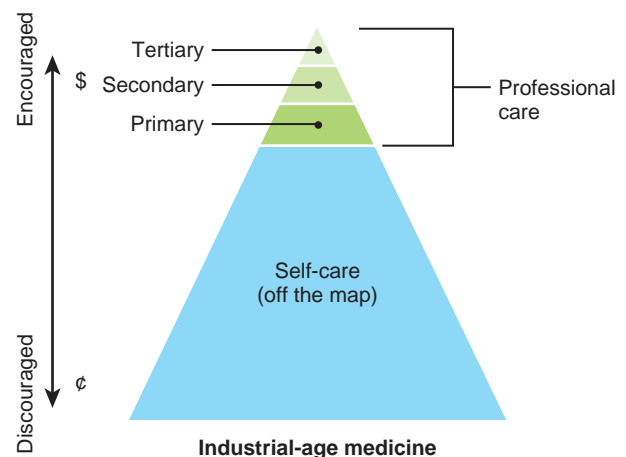

Figure 8-1 Importance of self-care. (From Ferguson T. Consumer health informatics. *Healthc Forum J.* 1995;38(1):28-33.)

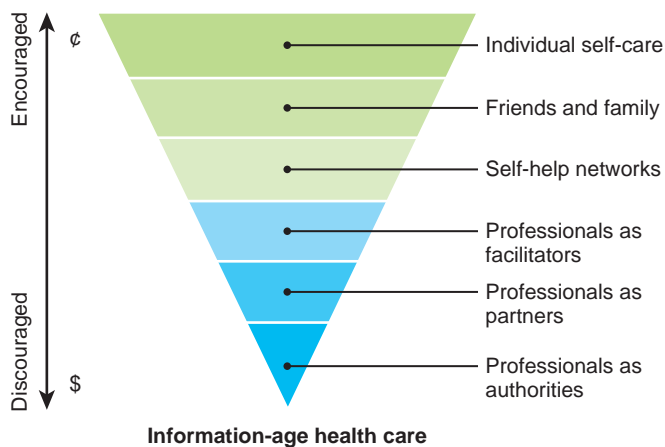

Figure 8-2 Emergence of individual self-care. (From Ferguson T. Consumer health informatics. *Healthc Forum J.* 1995;38(1):28-33.)

Patient- and Family-Centered Care

Medical teachers have emphasized the preeminent role of the provider in making the diagnosis, giving staff and patients “orders” to be carried out, and performing follow-up checks. The picture is one of the providers as “all knowing” and as “captains of the ship” who must remain in control within the medical setting. This focuses all of the pressure on the provider to perform well and places the patient in a passive role that often results in suboptimal outcomes.

In recent years, the patient-centered care movement has gained in popularity. Practicing patient-centered care embodies a number actions and strategies, including shared decision-making, open communication between physician and patient through patient portals, text messaging, e-mails and social media, MI, and being available and responsive during regular hours and after hours (Bergeson and Dean, 2006). Hospitals have encouraged and embraced this movement by building online portals that allow patients to review laboratory and radiography reports, request or make appointments, and communicate with clinical staff. Hospitals have also engaged individuals to serve in patient and family advocacy roles, including formation of patient advisory committees. Many institutions have also begun to add patients to hospital committees, boards, and work groups. This patient participation in the governance of health care organizations is a necessary addition if we are going to effectively bring the patient’s voice and perspective into the way these entities function (Luxford et al., 2011).

Patient Engagement

The term “patient engagement” has become a “hot buzz” phrase recently and is variably interpreted and very difficult to measure. Munro notes that the search phrase returns more than 500,000 results and is a lead topic for speakers and conferences (Munro, 2013). He also notes that it is important to use metrics, not just words and platitudes, to measure how providers and institutions move into patient engagement programs. Kernisan (2013) defines patient engagement as fostering a fruitful collaboration in which patients and clinicians work together to help the patient

progress toward mutually agreed-on health goals. It requires providers to work collaboratively with patients to determine which health outcomes are important, which ones to pursue, and how they should be pursued. This allows us to engage in meaningful partnerships with patients. Allowing patients to make these choices will be a very different mindset for many providers.

The Patient-Centered Medical Home

The patient-centered medical home (PCMH) concept has been embraced by many organizations and policy groups and is widely regarded as a key tool to reform health care. It involves a team approach to care and describes a wide variety of services to provide high-quality care to patients with chronic illnesses (Robert Graham Center, 2007). It also appeals to healthy patients who want to prevent illness and maintain optimum health.

Utilizing the principles of the PCMH is a practical way to shift physicians’ attitudes and practices toward the participatory medicine model. It points to new roles for both patients and providers. It requires physicians to become more involved in and supportive of patient education. It involves a multidisciplinary team approach to care, with each member of the team practicing “at the top of their license.” These teams often include mental health professionals, nutritionists, pharmacists, and other professional providers. And it will profoundly alter the provider business model, with widespread adoption and expansion of information technology (IT) capabilities, more accessible and more frequent modes of communication, and reconfigured incentives and rewards for all stakeholders. Many believe that it will ultimately bring an end to the fee-for-service reimbursement method of paying for medical services (NCQA, 2011).

This approach has profound implications for patient and provider interaction. No longer will the care system be based primarily on an “office visit” model. Physicians will be reimbursed for “monitoring” their overall practice population and will receive incentive payments for agreed-on, desired outcomes. Because payment to providers will not be based solely on office visit charges, there will be greater incentives to communicate in other ways, including phone, e-mail, text messages, and social media.

The National Committee for Quality Assurance (NCQA) created a certification standard for PCMH that was modified in 2011 (Peek and Oftedahl, 2010). This list comprises the six basic standards:

1. Enhance access and continuity.
2. Manage population.
3. Plan and manage care.
4. Provide self-care support using community resources.
5. Track and coordinate care.
6. Measure and improve performance.

Meeting these standards involves a significant redesign of the primary care physician office team, including utilization of nurse care managers, greatly expanding access to care, and involving patients in goal-setting and self-management. It also involves a commitment to evaluation of the patient experience and making appropriate modifications. And it

involves significant additional investments in personnel, IT systems, and training. Thus if this model is to be sustainable, payers of health care services will need to take these additional costs into consideration in their reimbursement for this care.

Patient/Provider Collaboration

Adopting and following the principles outlined for the PCMH moves providers from traditional means of communication between doctor and patient. No longer does the provider supply “doctor’s orders,” but the paradigm has evolved toward the patient and provider conducting collaborative conversations and exchanging ideas. Providers will engage patients to participate in their care and will encourage them to be actively involved. Providers will also invite the patient to provide feedback about the care received. This feedback will include identification of, and reporting, medical errors (Allen, 2012; Pear, 2012).

Physicians and patients will find new ways to use social media to communicate with patient groups who have similar conditions (e.g., Association of Cancer Online Resources at www.acor.org). Physicians will commonly prescribe “information therapy” to give patients the material they need to manage their own health care. Similarly, patients will provide physicians with insights they have gleaned from their own experience and from their social network (Reinders et al., 2011). Most physicians will have interactive practice websites and an electronic portal through which patients can request an answer to a clinical question or renewal of a prescription.

Information Technology and Participatory Medicine

The use of electronic medical records (EMRs) and other technology tools will play a major role in this new model of health care. There will be easy mechanisms within the EMR for follow-up after every encounter (Smith and Graedon, 2012). Physicians will send communication to the patient electronically or give printed information, depending on patient preference and technical access, generated from the EMR. Laboratory and imaging results will be shared, along with interpretative comments and any necessary instructions. Physicians and patients will use e-mail or secure messaging to discuss changes in status, provide progress reports, or communicate other important information. Rather than establishing fixed intervals for when follow-up will occur, there will be an ongoing dialogue made possible by these online tools.

Access to health applications (apps) currently available on smartphones and tablets will play a central role in the future of health care. Patients will use apps to help guide weight loss, promote exercise programs, and monitor chronic conditions (Lim, 2013). Patients with cardiac problems will be able to obtain and transmit an electrocardiogram to their providers (Seppala, 2013). Touch-sensitive devices will be used to monitor pulse, respiratory rate, and oxygen saturation (Bloom, 2013). Patients with diabetes will measure their glucose on a connected glucometer and

transmit the results directly from their devices, allowing consultation and medication adjustments to be made without the necessity of an office visit.

Health Behavior Change and Motivational Interviewing

Key Points

- Health behavior change and MI are patient-centered approaches that promote change, empower patients to address ambivalence, and improve patient engagement in their health care.
- Brief MI and health behavior change (HBC) interventions in clinical settings are more effective than no treatment and are generally equal to other viable treatments of longer duration and cost.

BACKGROUND AND KEY PRINCIPLES

Motivational interviewing is one good way to engage the patient in the process of positive change. Developed by Miller (1983) as a promising way to treat alcoholism, MI has most recently been defined as “a collaborative person-centered form of guiding to elicit and strengthen motivation for change” (Miller and Rollnick, 2009, p. 137). Often described by its creators as more than a series of techniques and skills, MI is a way of being with patients that empowers them to improve their own health, addresses resistance and barriers to change, and fortifies their ability to maintain these changes over time. Miller and Rollnick (1991) adapted and expanded MI to work with various patient populations in substance abuse treatment settings (see Miller and Rose, 2009, for an extensive background on the development of the method). In the past two decades, a strengthening evidence base has demonstrated that MI can be adapted to many different patient health problems in a wide variety of settings. Rollnick and colleagues (2008), in their book *Motivational Interviewing in Health Care*, identify four guiding principles of MI. These are captured in the mnemonic **RULE**:

1. **Resist** the “righting reflex”—recognize that correcting the patient can produce a paradoxical effect (i.e., “Don’t try to fix it, and don’t give advice”).
2. **Understand** your patient’s motivations—the desire for change and the goals to achieve must come from the patient not the provider.
3. **Listen** to your patient—use empathic, active listening; this changes the mindset that the provider has all the answers.
4. **Empower** your patient—understand that the outcomes will be better when patients are active participants in their own care and take responsibility for the change process.

Prochaska and DiClemente (1984) developed their transtheoretical model, also known as the stages of change theory, to provide a structure that providers can use to track a patient’s progress through health behavior change. This

Table 8-1 Stages of Change Theory

1. Precontemplation: not yet considering change
2. Contemplation: evaluating reasons for and against change
3. Preparation: planning for change
4. Action: making the identified change
5. Maintenance: working to sustain changes
6. Relapse: backsliding into old behavior patterns

model has five key stages that are used to identify where a patient is in the process and tailor the appropriate intervention to this change. These can be used as a way to open the dialogue about change behaviors with the patient, and the provider can use the process to monitor treatment. The stages are listed in [Table 8-1](#).

The sixth step or stage that is commonly seen in clinical settings is “backsliding” or relapse (see [Table 8-1](#)). This part of the transtheoretical process can occur at almost any level and is central to understanding how patients’ health behavior is often cyclical as they move back and forth in their decision-making and maintenance of healthier behaviors. This model can serve as a complement to MI in clinical practice. There are several guiding philosophies that undergird MI, which make it an excellent approach within the PCMH model. MI specifically, and health behavior change (HBC) more broadly, are becoming essential tools in clinical practice and support providers’ shift to the patient engagement movement and to practicing more patient-centered medicine. With a patient-centered approach, the patient works in collaboration with the provider to set the agenda for treatment; this contrasts with a provider-centered approach in which the physician or other health care team member determines the agenda for the patient and directs treatment. The collaboration between patient and team is seen as essential because the goals must start with what the patient is willing and able to do. This supports patient self-efficacy, autonomy, and expertise, and it creates belief in the patient’s own capacity to change and implement these new healthier behaviors.

Key to the success of applying MI to patient care requires several provider behaviors, some of which fly in the face of the formal instruction that physicians receive. One of these is termed “rolling with resistance” or the denial that the patient may put forward. This keeps the encounter from becoming a confrontation or tug-of-war between patient and provider. Providers also need to be acutely aware of how to enhance a patient’s readiness by helping the patient identify the real or perceived obstacle to change by resolving the patient’s ambivalence. By enhancing patients’ self-efficacy, providers become more active collaborators in their patients’ health.

Empathy for the patient is a key component, as it allows the provider to really “start where the patient is” and promotes a deeper understanding of what it is like to be that patient as they face his or her health challenges. With this empathic stance, both the provider and the patient recognize that the motivation to change comes from the patient. The provider does not have to convince the patient to change or give sage advice about how this should be done. The mnemonic, OARS, is the basis for patient-centered interventions in brief counseling; it is a path that leads to empathic connection with the patient ([Miller and Rollnick,](#)

Table 8-2 OARS for Brief Counseling

- Open-ended questions, e.g., “How are you feeling about your health these days?”
- Affirmation, e.g., “You may not be at your goal yet, but look at how far you’ve come.”
- Reflective listening, e.g., “It sounds as though you don’t feel confident about making this change but you do want to change.”
- Summaries, e.g., “Let me summarize what we’ve just talked about.”

From McAndrews JA, McMullen S, Wilson SL. Four strategies for promoting healthy lifestyles in your practice. *Fam Pract Manag* 18(2):16-20, 2011.

[2002; Table 8-2](#)). These basic microcounseling skills have been shown to work well with all types of patients considering a health behavior change. These interpersonal communication skills help a clinician capture what has been referred to as the “spirit” of MI, and this is often cited by the founders of the model as the most critical aspect of using this method properly ([Miller and Rose, 2009](#)).

EVIDENCE FOR HEALTH BEHAVIOR CHANGE AND MOTIVATIONAL INTERVIEWING

Recent meta-analyses and review articles across a variety of disciplines have further solidified the evidence for MI and other patient-empowering methods to bring about positive health outcomes ([Britt et al., 2004; Burke et al., 2004; Martins and McNeil, 2009; Rubak et al., 2005](#)). Numerous strategies for changing health behaviors have also received attention in recent years ([Martins and McNeil, 2009; Rubak et al., 2005](#)). MI has been shown in dozens of controlled trials to produce significant change in client health behaviors in general and in substance use in particular. Randomized trials showing benefit from MI have been completed with patients with alcohol, tobacco, and substance abuse problems, type 2 diabetes, hypertension, gambling addiction, and weight reduction ([Miller et al., 2004](#)). Given the wide breadth of articles and subjects covered, this section will focus on those studies that address a few of the problems commonly seen in family medicine practice.

HBC and MI complement the approaches being used in the management of a variety of chronic illnesses in health care settings. The “way of being with patients” that is the central aspect of MI and is a component of many chronic disease models being used to address these complex problems helps the provider address the problems in new ways. By dealing with a patient’s feelings and thoughts and ambivalence using MI, there seems to be much less resistance and better adherence to treatments. As with all models, this one is not a panacea, but there are strong indications that MI and HBC approaches can have positive impacts on a wide range of illnesses and effect behavior change in many populations where other standard methods have come up short ([Miller and Rose, 2009](#)).

MOTIVATIONAL INTERVIEWING AS APPLIED TO COMMON PROBLEMS IN FAMILY MEDICINE

Diet Changes, Obesity, and Reducing Body Mass Index

More than three dozen studies have been conducted since 1999 that have investigated the effects of MI on changes in

diet, for weight loss, to reduce body mass index (BMI), and to increase physical activity (see [Martins and McNeil, 2009](#), for a review, and [Armstrong et al., 2011](#)). These studies, mostly randomized controlled clinical trials, have demonstrated moderate to strong support for MI and other HBC interventions. They used several MI methods to achieve their results, including empathic understanding; opened-ended questions to assess for readiness to change; scaling questions for importance and confidence to create discrepancy and to track progress; and multiple sessions of varying number and duration (10-40 minutes). In-person meetings by a variety of providers as well as telephone calls were used as the primary interventions and as follow-up or maintenance interventions. The most robust findings have been in the areas of maintaining dietary and weight loss changes and lowering BMI based on goals agreed on between patient and the provider. A recent review by [Rose and colleagues \(2013\)](#) summarized that provider advice, including some studies in which MI was used, produces a greater level of health behavior change and commitment to weight loss goals. The long-term value of MI in this area seems well established at this point. In the review by [Rubak and colleagues \(2005\)](#), the combined effect estimates of using MI to produce decreases in body mass index indicate that it can and should be used. The growing weight of the evidence supports using these techniques and this style of counseling with overweight and obese patients.

Case Example of a Participatory Encounter

See [Box 8-1](#).

Hyperlipidemia

Several studies have investigated the effect of MI on lowering cholesterol level, and the results have been mixed. [Brug and colleagues \(2007\)](#) found that dietitians trained in using MI with patients with type 2 diabetes attained a significantly larger self-reported change in their saturated fat scores than dietitians who were not trained in MI in newly diagnosed patients. Other risk behaviors for type 2 diabetes such as glycemic control and body mass were no different than the controls. A study that compared two interventions, one of which was MI, for lowering lipid levels and dietary fat intake showed positive results for both interventions, which were sustained for 12 months ([Mhurchu et al., 1998](#)). Additionally, numerous other studies with a wide range of populations, age ranges, and from a broad diversity of cultures have demonstrated that using standard MI interventions to lower serum cholesterol has a strong enough positive effect to suggest its use over other methods ([Martins and McNeil, 2009](#); [Rubak et al., 2005](#)).

Diabetes Care

There have been a large number of studies over the past 15 years investigating the impact of MI and other HBC approaches on patients with diabetes (see [Rubak et al., 2005](#) for a review; [DiLillo and West, 2011](#)). Most of these studies have yielded positive or mixed (positive-neutral) results when comparing MI- or HBC-focused interventions to controls. The most salient changes have been where intervention groups who have received MI have experienced larger reductions in weight, significantly lower hemoglobin A1c values, improved dietary changes, increased activity

levels, an enhanced motivation to learn about their diabetes, and an improved outlook on maintaining behavior change ([Channon et al., 2003, 2007](#); [Rubak et al., 2009](#)). [West and colleagues \(2007\)](#) studying a group of overweight women with type 2 diabetes found that MI enhances patient weight loss at 6 and 18 months, as well as leads to significantly reduced hemoglobin A1c levels. However, this study also found that the motivation to change for African American patients seemed to diminish over time. This observation calls into question the clinical durability of MI with some populations; however, there are promising studies being undertaken with adolescents that combine MI with other treatment strategies ([Stanger et al., 2013](#)). This will be an important area of future research as MI techniques are refined to discover how best to meet the needs of special populations. Team-based care for diabetes management has become the norm, involving physicians, nurses, care managers, social workers, psychologists, support groups, and lay volunteers. HBC and MI help to educate patients, facilitate change, and maintain patient adherence at all levels of care. Given all the available evidence, these techniques have been shown to empower patients to be more engaged with their diabetic care. They have the potential to make the provider's work more efficient and effective in reducing more costly levels of care. With further data, this may be where the greatest benefits of MI are realized.

TRAINING AND GROWTH OF MOTIVATIONAL INTERVIEWING

In the past 30 years since these approaches were conceived, the current widespread use of MI and HBC methods across a variety of disciplines illustrates that they have moved beyond emerging trends. Currently there is a need for expanded training and teaching of these methods and principles across the health care system. Having emerged from the discipline of psychology, these methods are being used in medical residency programs from family medicine to obstetrics/gynecology, and from internal medicine and pediatrics to psychiatry. They are also widely used in colleges of nursing, public health, schools of social work, and other health-related professions. The adoption of MI and HBC as part of standard curricula is in the beginning stages in medical school and other health care fields, so future professionals should have a stronger grounding in HBC and the basics of MI as essential tools. However, this has been helped along by recent reports from the Association of American Medical Colleges (AAMC, 2011) and the Accreditation Council for Graduate Medical Education (ACGME) that place strong emphasis on the physician-patient relationship, the psychosocial aspects of the human condition, the communication skills and advanced interpersonal competencies necessary to provide excellent care, and the importance of methods and techniques as found in MI and the HBC literature. Important support for these efforts could come from the accreditation bodies for PCMH as these methods are increasingly seen as cost-effective approaches that involve the entire health care team, especially the patient.

In the spirit of collaborative care, with provider and patient working together in MI, [Triana and colleagues \(2012\)](#) recently demonstrated how a standardized MI

Box 8-1 Case Example of a Participatory Encounter

Mrs. Smith is 59 years old, is 20 pounds overweight and has an average blood pressure of 145/98 mm Hg and a fasting glucose of 135 mg/dL. Her hemoglobin A1c is 7.2%, indicating that she has previously undiagnosed diabetes mellitus. She complains of bilateral knee pain, which makes it hard to exercise. Radiographs of the knees confirm the diagnosis of moderately severe osteoarthritis. She also has complained of hot flashes, insomnia, and depression.

When Ms. Smith calls the office to arrange for a new patient visit, she is enrolled in the office's patient portal, which allows her to submit her medical history and all of her insurance and demographic information online prior to her visit. When she arrives in the office, she checks in using a computerized kiosk and, because she has been preregistered, the process takes less than 2 minutes. She is brought back to the examination room a little ahead of her scheduled visit.

The doctor uses a questioning method informed by the spirit of motivational interviewing (MI). Open-ended questioning begins the visit, and the doctor actively listens to allow the patient to tell her story in her own way. This empowers the patient to inform the doctor of her concerns and what her most important issues are from her perspective. She expresses concerns about the diabetes diagnosis and her knee pain.

Using another key technique of MI and health behavior change, the doctor might use a scaling question or review with the patient a "confidence/readiness ruler" to assess the patient's confidence and the level of importance she places on making the necessary changes. This could be in a customized, tablet-based handout synced with the clinic electronic medical record (EMR), or it could be administered as a handout by a patient-centered medical home (PCMH) team member (nurse, medical assistant, or diabetes care manager) depending on the patient's health literacy level. The doctor (who has already reviewed her online history) reviews her laboratory results and discusses the medication choices for her to consider. Instead of making hasty decisions, the doctor then uses this information to

- Affirm how the patient is feeling about making these significant changes.
- Resolve any ambivalence she may be having to the recommended changes in her medication regimen, diet, and activity levels.
- Summarize the biomedical and psychosocial aspects of care into an integrated plan that is personalized and fits with the patient's level of readiness to change.

After reaching common ground the follow-up plans flow easily.

Because this MI approach blends client-initiated information with the doctor's medical knowledge and clinical judgment, the process is collaborative and the patient feels empowered to be more involved in the decision-making. The patient and doctor reach common ground on the patient's medications.

In addition to the core concerns, the doctor and patient discuss additional supports that the patient can receive through the PCMH. She is given an appointment with the nutritionist and with the diabetes educator for later that week. She is also given a web address for an online diabetes support group, and several diabetes care apps that the physician is familiar with are recommended for her to track her blood glucose levels and dietary changes.

To address the patient's second agenda item, the doctor and patient repeat the OARS process as detailed in Table 8-2. They reach mutual agreement to use ibuprofen for her knee pain and decide on a referral to a physical therapist who specializes in hydrotherapy for osteoarthritis. The patient also indicated that she is willing to try some alternative methods so she is provided with information about a certified acupuncturist to help treat her arthritis pain. She is referred to a well-respected website that specializes in home remedies and is encouraged to look over the options listed for treatment of arthritis and knee pain and select any that she is comfortable with. She is asked to log her results for later sharing with the care team.

She is encouraged to use the patient portal to provide blood glucose levels, ask questions, and provide feedback about the effectiveness of her medications. She uses a connected glucometer, along with a new mobile application on her smart phone, to upload her blood glucose data directly to her medical team. She is also given an opportunity to join the patient advisory group that the practice is forming, and she is invited to the first meeting 3 days from now. She is given a follow-up appointment with the physician in 3 months but is reminded that scheduling is "open" so she can come back sooner, or anytime she has a need. At the end of the visit, she receives a brief online feedback survey inviting her to give the doctor and his staff feedback about the visit and what suggestions she may have to improve her experience. She notes on this form that the office staff gave her incorrect information about her group diabetes visit and so the outdated information on the patient forms was promptly corrected for future patients.

She is referred to the psychologist who is integrated with the PCMH to help assess and treat her depression. The psychologist uses brief MI along with cognitive behavioral therapy (CBT) interventions to target the depressive symptoms. MI is used at each visit to affirm, support, and encourage the patient as she makes these changes that affect her overall health. In addition, she is given a web address for an online support group for depression, and is encouraged to log on to Psych Central (www.psychcentral.com) to review its array of resources and patient tools.

A couple of days later, she develops an annoying cough and is starting to have abdominal pain, so she logs onto the patient portal and asks the office team about these symptoms. The nurse who is monitoring the portal messages contacts the physician, who decides to switch her medication from the angiotensin-converting enzyme (ACE) inhibitor she is taking to a β -blocker. He also suggests that she stop taking the ibuprofen, try substituting acetaminophen (Tylenol), and take a proton pump inhibitor, omeprazole (Prilosec), for a 2-week trial. She is asked to log on and provide an online update in 48 to 72 hours.

Two days later, her abdominal pain and her cough have resolved. Her blood pressures are in normal range, but her blood glucose levels are still running from 120 to 150 mg/dL. She is urged to continue the current course and check back online after her nutrition visit, her group visit, and her diabetes education visit.

Two weeks later, on the same dose of diabetes medication, with the benefit of her classes and counseling, she logs back in and proudly reports that her glucose levels have come back into the normal range. She returns to the office 3 months later, feeling great, in good control of her health issues, and confident with the PCMH team's approach.

curriculum can be presented as part of an intensive block rotation for family medicine and psychiatry. This study reinforces the crucial need for continued one-on-one coaching and individual feedback as part of MI training, and it recognizes that increasing the self-efficacy of the learner is essential if clinical practice changes are the goal (Miller et al., 2006). Current research is helping establish a common core of MI that includes skills, training in the spirit of MI, eliciting change talk, and rolling with resistance (Söderlund et al., 2011); however, the authors caution that the results are not strong enough in all studies due to methodological issues. A recent study by Seale and colleagues (2013), in which MI-based training was shown to have relatively small effects in residents' behavior, underscores the difficulty of instilling these methods into their clinical communication skills during this stage of their careers. Despite mixed results so far, one of the benefits of MI's application across a variety of clinical settings and its implementation by providers with a variety of professional backgrounds suggests that this approach is well-suited for the PCMH model of care (VanBuskirk and Wetherell, 2013).

With its widespread adoption in primary care settings, MI has the potential to evolve into an essential clinical tool, much like taking a history and physical, with common practice guidelines and interventions that can be taught reliably. The Motivational Interviewing Network of Trainers (MINT) has established an international group of trainers and a set of criteria for certification for MI (<http://www.motivationalinterviewing.org/motivational-interviewing-training>). A series of assessment tools (such as the Motivational Interviewing Treatment Integrity [MITI] scale) are being used to validate the core elements of MI and the gains that are made after training in MI (Moyers et al., 2005).

CHALLENGES AND LIMITATIONS TO MOTIVATIONAL INTERVIEWING

As research progresses and MI continues its wide use in health care settings, there are limitations about which providers should be concerned. As several review articles point out, a number of studies fail to provide enough information on the details of each intervention. The measures and assessment tools for MI are still in initial stages of development and require larger validation studies. Additionally, while strong review studies and meta-analyses in the past 5 to 10 years have illustrated significant results, the efficacy of MI and HBC for producing the desired effects in every health problem being studied is not consistent across the board. As with many methods born out of clinical practice and based on experiential, interpersonal communication, the use and applications of MI and HBC techniques in practice has outpaced the research on their validity.

KEY TREATMENT

- Motivational interviewing (MI) has been shown to have moderate to significant and clinically relevant effects on

a range of health, mental health, and substance use conditions when compared to control groups in randomized trials in recent meta-analyses and reviews (SOR: A) (Lundahl et al., 2010; Martins and McNeil, 2009; Rubak et al., 2005; VanBuskirk and Wetherell, 2013).

- Training practitioners in MI can be cost-effective and seems to work best when accompanied by 1 : 1 coaching and individual feedback to enhance behavioral rehearsal of specific clinical skills (SOR: B) (Lundahl and Burke, 2009; Miller et al., 2006).
- MI lends itself to cross-disciplinary clinical settings such as patient-centered medical homes, which are common to family medicine. (SOR: B)

Interpreting the Medical Literature: Applying Evidence-Based Medicine in Practice

DOUGLAS R. SMUCKER

CHAPTER OUTLINE

Building Clinical Evidence from Published Research, 110

Understanding the Statistical Significance of Study Results, 112

Interpreting Study Results: Statistical and Clinical Significance, 112

Other Keys to Interpreting Clinical Evidence, 113

Using Evidence at the Point of Care, 114

Key Points

- Interpreting the medical literature is a task any physician can do, particularly when using common, evidence-based summaries that are available at low or no cost.
- The studies should report statistically significant results that are applicable to the physician's population of patients and that should evaluate important patient-oriented outcomes, including potential harms.
- When potentially changing practice behavior, the physician should assess whether the evidence is from high-quality studies replicated over time.
- The medical literature is an evolving body of evidence, and each physician should develop a personal plan to keep up with important changes in medicine and strategies to answer more immediately important clinical questions at the point of care.
- Summary measures, such as the number needed to treat, can help physicians interpret research findings in a way that better informs patient care decisions.

Building Clinical Evidence from Published Research

Evidence-based medicine (EBM)—asking clear, relevant clinical questions, finding appropriate studies, critically appraising the literature, and implementing changes in practice behavior—has become an essential part of medical care. Most busy physicians do not have the time nor the background to answer critically the questions that arise in practice. Primary care physicians identify 2.4 clinical questions for every 10 encounters (Barrie and Ward, 1997), but they spend less than 15 minutes on average with each

patient. Evidence about common primary care problems is accumulating at an overwhelming pace, and the broad scope of family medicine presents important challenges. Other barriers to the use of EBM include lack of evidence that is pertinent to an individual patient, quick access to information at the point of care, and potentially negative impacts on the art of medicine (McAllister et al., 1999). How can diligent physicians narrow the gap between their current behaviors and best practices?

In this chapter, hormone replacement therapy (HRT) for postmenopausal women is used as a case example to understand the evolution of medical practice based on the changing landscape of published evidence over time and to review concepts important to interpreting the medical literature. These concepts form the basis for practical EBM tools that family physicians can use to answer important clinical questions.

Evidence that supports interventions such as HRT usually begins with observational studies, including unblinded case series, case-control studies, and cohort studies, and it culminates in randomized controlled trials (RCTs) (Figure 9-1). To better understand how we arrived at the current clinical understanding of HRT and its effects on heart disease, this chapter reviews the progression of research studies and evidence over the past 40 years. A series of observational studies in the 1970s and 1980s led to regular prescribing of HRT to prevent a number of significant health conditions in postmenopausal women. Common types of observational studies are case-control studies and cohort studies.

CASE-CONTROL STUDIES

Case-control studies are often the first step in a progression of building clinical evidence because they are relatively inexpensive and rapid studies to complete. Case-control studies always look backward in time (i.e., they are

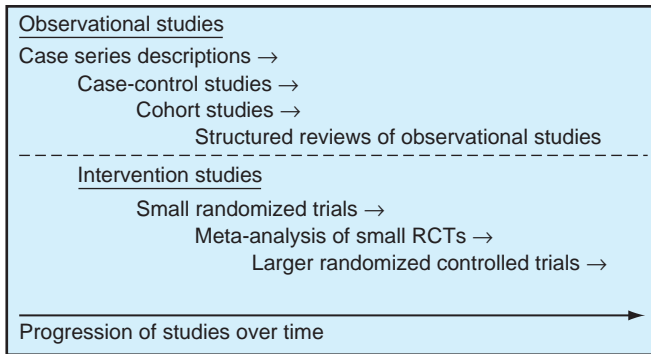

Figure 9-1 Common progression of research in building the strength of evidence. *RCTs*, Randomized controlled trials.

retrospective studies) to determine a statistical association between an exposure and an outcome. To complete a case-control study of the association of HRT and coronary heart disease (CHD), a researcher would identify a group of cases (i.e., women with CHD) and a group of controls (i.e., women without CHD) and look back in time to determine how many women in each group had taken HRT. The association between exposure (i.e., HRT) and outcome (i.e., CHD) in a case-control study is typically summarized by a statistical measure called an *odds ratio*. An odds ratio is an estimation of the true relative risk for the outcome in question. A common form of bias in a case-control study is recall bias: errors in accurately determining whether cases and controls had exposure to HRT in the past.

COHORT STUDIES

Cohort studies are often the next step in building the strength of evidence regarding an association between an exposure and an outcome. Cohort studies typically look forward in time (i.e., they are prospective studies) and are generally more expensive and take longer to complete than case-control studies. However, compared with case-control studies, they provide a more accurate estimate of the relative risk for women who take HRT and those who do not. A cohort study is also an observational study—one that observes outcomes in groups but does not assign participants to a particular exposure or treatment. In a cohort study of HRT and CHD, a researcher would identify a group of women taking HRT and a similar group of women who have chosen not to take HRT, and the researcher would then follow them over time and count the number of CHD events. Because outcome events may be uncommon in each group and may take many months to occur, cohort studies often require large numbers of participants and long follow-up periods to show significant differences between groups.

The primary statistical measure from a cohort study is relative risk. This is a ratio of the rate of CHD events among women who choose to take HRT divided by the rate among women who choose not to take HRT. A common form of bias in cohort studies related to prevention is the healthy user bias, when participants who choose one preventive measure (e.g., HRT) also tend to make healthier lifestyle decisions (e.g., diet, exercise) that may also prevent the measured outcome (i.e., CHD).

Beginning with case-control studies and then using larger cohort studies, early observational research showed that HRT might reduce the incidence of CHD, fractures, and colorectal cancer. These observational studies also suggested that the same therapy might cause harm, with a slightly increased risk of breast cancer, stroke, and venous thromboembolism. On balance, however, even a small positive impact of HRT on preventing CHD was thought to far outweigh the potential adverse effects of HRT.

STRUCTURED REVIEWS AND META-ANALYSIS

After a number of studies are completed, whether cohort studies or initial small RCTs, these are often reviewed and summarized in publications called *structured reviews*. Occasionally, data from a series of studies are combined using a statistical technique called *meta-analysis*, which allows increased statistical power to determine the weight of evidence from a series of studies. The use of HRT was greatly increased during the 1990s based on a number of case-control and cohort studies and on three meta-analysis studies that further suggested that HRT was protective against CHD (Pettiti, 1998).

In 1991, an editorial in the *New England Journal of Medicine* concluded that “a consensus of epidemiologic reports has demonstrated that women who are given postmenopausal estrogen therapy have a reduction of about 40% to 50% in the risk of ischemic heart disease as compared with women who do not receive such therapy” (Goldman and Tosteson, 1991). Prescribing HRT for disease prevention became a de facto standard for postmenopausal women through the 1990s.

THE POWER OF RANDOMIZED CONTROLLED TRIALS

In RCTs, study participants are randomly allocated to two or more groups and then assigned to receive an intervention such as HRT or to receive no active treatment (i.e., placebo or to continue with their usual care). RCTs greatly add to the confidence of measured results because the structure of an RCT helps to eliminate many of the inherent biases that are common in observational studies. Because participants in an RCT are randomly assigned to treatment and control groups, they are less likely to have differences in other factors that might also prevent or promote heart disease.

The decreased likelihood of systematic bias in an RCT may explain why HRT appeared to be protective in cohort studies but later proved to be harmful in large RCTs. Because RCTs have this inherent ability to decrease many important potential forms of bias (but are not immune to biases themselves), they are considered the strongest form of evidence for measuring the true association between the HRT treatment and CHD outcomes (Ebell et al., 2004). Despite decades of work, dozens of observational studies, and structured reviews that strongly suggested a protective effect of HRT for CHD, a single, large RCT trumped them all and caused a sudden reversal in physicians’ prescribing behavior.

The results of the Women’s Health Initiative (WHI) study, released in 2002, sent a shock wave through the medical

community (WHI Writing Group, 2002). For the first time, a large, randomized trial showed that HRT—given to otherwise fairly healthy postmenopausal women—caused a statistically significant increase in CHD events. Within days of the release of the WHI primary results, many women called their physicians to decide whether they should continue with HRT. Many physicians drastically changed their prescription of HRT based on the WHI; within 9 months, prescriptions of the most popular formulation of HRT decreased by as much as 61% (Majumdar et al., 2004). Perhaps more than any other single study in modern medical history, the WHI report dramatically changed a widespread, common medical practice.

Understanding the Statistical Significance of Study Results

Reports from RCTs such as the WHI study frequently include relative risk as a summary measure of differences between the treatment and placebo groups (Table 9-1). To arrive at the relative risk, the researcher first measures the incidence rate of an outcome in each of the two study groups (i.e., treatment and placebo). The incidence rate for each group is a ratio of the number of new outcome events, such as CHD events, divided by the number of patients at risk for the outcome in that group over a specific period. In multi-year studies, the average annual incidence rate is often reported as a summary measure. In a placebo-controlled RCT, the relative risk is then calculated as a ratio of the incidence rate for the treatment group divided by the incidence rate for the placebo group (see Table 9-1).

How can a physician determine whether the reported relative risk from a study is significant enough to influence clinical decisions? Typically, the statistical significance of the summary measure is reported, which in this case is relative risk. Statistical significance is usually summarized in published studies by a p value for a given summary measure. The p value describes the statistical probability that the observed difference between the groups could have happened simply by chance alone. A p value of less than 0.05 is the arbitrary cutoff most often used for “statistical significance.” A $p < 0.05$ means that there is less than a 1 in 20 (5%) probability that a difference as large as that observed would have occurred by chance alone; a $p = 0.04$ means a

1 in 25 (4%) probability; a $p = 0.06$ means a 1 in 16 probability (6%).

Although frequently used, p values provide only limited information: the chance that any difference found is caused by chance, or random error. A p value alone gives no indication of the clinical significance of a finding and provides no information regarding the likelihood that a finding of “no difference” is caused by chance or random error.

Confidence intervals are more informative than p values when interpreting the clinical value of study results. When relative risk is reported as the summary result of a study, the 95% confidence interval (CI) is often used to give an indication of the precision of the estimated relative risk. The 95% CI describes the range within which there is a 95% probability that the true relative risk (RR) is in that range. An RR of 1.0 indicates no difference. For example, if a study reported an RR of 2.5 with a 95% CI of 2.3 to 2.7, we could be reasonably certain (95% certain) that the true RR was no less than 2.3 and no greater than 2.7. Our conclusion would be that the estimated RR of 2.5 is fairly precise. However, if RR was reported as 2.5 with a 95% CI of 1.1 to 5.0, the true RR could be as low as 1.1 (almost no difference) or as high as 5.0 (a fivefold difference), a more imprecise estimate of the RR.

Confidence intervals also provide a better measure than p values of the precision for concluding that there is no difference in an RR. Any 95% CI that includes RR = 1.0 indicates that there may be no difference. However, an RR of 1.05 with a 95% CI of 0.99 to 1.11 is almost certainly a finding of no difference (i.e., a narrow CI), whereas an estimated RR = 1.4 with a 95% CI interval of 0.99 to 1.7 is much less precise (i.e., a wide CI). Even though the 95% CI contains 1.0 in the latter example, there may still be a true difference that was not able to be detected in this study.

Interpreting Study Results: Statistical and Clinical Significance

Although the WHI showed a statistically significant increase in the RR of CHD events among women who were randomly assigned to take HRT, it is important to consider the absolute difference in CHD events between the two groups to understand the strength of the association and to discuss the risk of HRT treatment with individual patients. Calculating absolute risk (in addition to RR) is a helpful way to understand the level of risk that HRT may add for a group of women who are at risk for CHD events (Table 9-2).

In the WHI study, the RR of CHD for participants who took HRT was 1.29, with a 95% CI that did not cross 1.0 (95% CI, 1.02-1.63). This figure (RR = 1.29) can generally be interpreted as HRT being associated with a 29% increase in CHD events. This summary measure was reported widely in medical journals and the mainstream press.

When reported in terms of RR, the weight of the association between HRT and CHD sounds ominous (i.e., a 29% increase). However, in terms of absolute risk attributable to HRT treatment, a less portentous picture emerges (see Table 9-2). In the WHI study, women taking HRT had an average rate of CHD events of 0.37% per year, or 37 events per 10,000 women each year, and those in the placebo

Table 9-1 Understanding Study Results

Typical summary rates from randomized, controlled trials:

$$\text{Incidence rate} = \frac{\text{Number of new cases of disease over a defined period}}{\text{Number of persons at risk during the period}}$$

$$\text{Relative risk (RR)} = \frac{\text{Incidence rate among the treated group}}{\text{Incidence rate among the placebo group}}$$

Summary measures that may be more meaningful for clinicians:

$$\text{Attributable risk (AR), or risk difference} = (\text{Incidence rate among treated group}) - (\text{Incidence rate among placebo group})$$

$$\text{Number needed to treat (NNT) or number needed to harm (NNH)} = \text{Reciprocal of AR, or } 1/\text{AR}$$

Table 9-2 Examples of Summary Rates from the Women's Health Initiative Study

The following equations show how to take a summary rate commonly reported in published studies (i.e., relative risk) and calculate a summary measure (e.g., number needed to treat, number needed to harm) that may be more useful in describing the results to clinicians and patients. The example considers the average annual incidence rates and relative risk for coronary heart disease (CHD) events in the Women's Health Initiative (WHI) study on the effects of hormone replacement therapy (HRT):

$$\begin{aligned} \text{Average annual incidence among HRT-treated women} \\ = 37 \text{ CHD events/year/10,000 women} \end{aligned}$$

$$\begin{aligned} \text{Average annual incidence among placebo-treated women} \\ = 30 \text{ CHD events/year/10,000 women} \end{aligned}$$

$$\text{Relative risk of CHD} = \frac{37 \text{ CHD events/10,000 women}}{30 \text{ CHD events/10,000 women}} = 1.29 \text{ (adjusted)}$$

The relative risk describes a relative 29% increase in CHD events. It may be more useful to consider the absolute difference in incidence rates between the two groups to understand the magnitude of the potential risk for a given patient:

$$\begin{aligned} \text{Attributable risk (AR)} &= \frac{37 \text{ CHD events}}{10,000 \text{ women}} - \frac{30 \text{ CHD events}}{10,000 \text{ women}} \\ &= \frac{7 \text{ additional}}{10,000 \text{ women}} \text{ CHD events} \end{aligned}$$

The number needed to harm (NNH) can be calculated to describe, on average, how many women must be treated for 1 year to cause one additional CHD event attributable to HRT:

$$\text{NNH} = \frac{1}{7 \text{ CHD events/1000 women}} = \frac{10,000}{7} = 1430$$

Data from Women's Health Initiative (WHI) Writing Group: Risks and benefits of estrogen plus progestin in healthy postmenopausal women, *JAMA* 288:321-333, 2002.

group had an annual rate of 0.30%, or 30 events per 10,000 women each year. Although the adjusted RR of CHD is 1.29 (0.37 divided by 0.30), the attributable risk or risk difference between the two groups is 0.07% (0.37 minus 0.30). In other words, approximately seven additional cases of CHD occurred for 10,000 women using HRT during each year over the course of the study. The attributable risk of the treatment group can be summarized as the number needed to harm (NNH) or, if a study reports a beneficial effect, the number needed to treat (NNT). In this case the NNH was approximately 1430; on average, for every 1430 patients treated with HRT, one additional CHD event occurred each year (i.e., the inverse of the risk difference, 0.07, or 10,000 divided by 7) (see [Table 9-2](#)). The NNH or NNT is often a more understandable and useful summary of study outcomes when physicians and patients weigh the risks and benefits of a particular therapy ([Bhandari and Haynes, 2005](#)).

Other Keys to Interpreting Clinical Evidence

One of the major tasks in interpreting whether the results of a study should change practice is to determine whether all relevant patient-oriented outcomes were considered. For example, when considering evidence regarding the

prevention of fractures, it is important to distinguish among studies that measure physiologic outcomes (e.g., serum calcium), intermediate outcomes (e.g., bone density), and patient-oriented outcomes (e.g., fractures). Whenever possible, practice decisions should be based on outcomes patients would deem important. For example, in a trial of HRT for osteoporosis, a decrease in fracture incidence would be a more convincing finding than a change in an intermediate outcome such as bone density. Likewise, all important harms (i.e., risks) and financial end points (i.e., costs and savings) should be reported and considered. In a trial of a new antiresorptive agent, the rate of esophagitis, gastritis, and esophageal perforation, along with such measures as patient satisfaction, costs, and global well-being, should all be considered in balance with any improvement in fracture incidence.

When assessing the benefits and harms of such a new treatment, appropriate competing alternatives (including no treatment at all) should be compared. Typically, such a comparison may take the form of a "balance sheet," a table comparing each intervention in terms of benefits, harms, and economic end points. Many studies are randomized, placebo-controlled trials in which some patients receive an active intervention and others receive a placebo or sham intervention. Alternatively, a study may use an active comparator, an intervention already known to be effective. Each of these approaches has pros and cons, but the most important point to remember is that just because a study shows statistical significance in a single measure, it does not mean that all appropriate patient-oriented outcomes were considered.

When a study shows no effect, the question of power is raised. Put in simple terms, power is the ability to detect the effect of an intervention; it depends on the number of patients in the study, the magnitude of effect of the intervention, and the variability of the effect from one subject to another. For some interventions, even a small effect may be important. For example, many nonpharmacologic treatments for hypertension (e.g., salt restriction) have relatively modest but important effects. Clinicians should generally be skeptical of small studies that show negative results. Examining the confidence intervals is the easiest way to assess whether the study sample was too small and therefore did not have the statistical power to detect a clinically important difference (as reflected by wide confidence intervals).

When a study is positive or shows statistically significant results, it is important to consider whether the findings are clinically significant and applicable to your practice. For example, if a study showed a drug reduces the risk of heart attack by one in a million patients, we would probably be skeptical about its clinical utility, even if the outcome was statistically significant. Likewise, a study showing that daily borscht reduces fractures in a group of Russian dockworkers may not be applicable to patient populations in the United States. Findings of a study done in a controlled research setting may differ from outcomes experienced in real-world practice. An intervention for osteoporosis requiring daily injections may be demonstrated to be efficacious among carefully selected participants in a clinical trial, but in the average practice setting its effectiveness may be more limited.

Table 9-3 Evidence-Based Medicine Skills and Techniques: Online Learning Resources

Online Learning Resource	Description
Evidence-Based Medicine Course; Michigan State University (MSU); http://omerad.msu.edu/ebm/index.html	Developed for the MSU Primary Care Faculty Development Fellowship Program, this free web-based course introduces the basic concepts of evidence-based medicine, information mastery, and critical appraisal of the medical literature.
Introduction to Evidence-Based Practice; Duke University Medical Center Library and the Health Sciences Library at the University of North Carolina at Chapel Hill; http://guides.mclibrary.duke.edu/ebmtutorial	This free online tutorial provides a basic introduction to the principles of evidence-based practice and covers skills in building good clinical questions, strategies for efficient PubMed literature searches, and critical appraisal of studies.
Centre for Evidence-Based Medicine; University of Oxford; www.cebm.net	The Oxford University CEBM offers conferences, workshops, online PowerPoint presentations, and other tools for effective practice and teaching of evidence-based medicine.
KT (Knowledge Translation) Clearinghouse; Funded by the Canadian Institute of Health Research; http://ktclearinghouse.ca	Website materials are provided by a collaborative effort between St. Michael's Hospital Toronto and the University of Toronto, Faculty of Medicine, and offer a wide range of training and tools for learning evidence-based medicine skills.
JAMAevidence; American Medical Association; http://jamaevidence.com	Free online access to content from the JAMA series <i>The User's Guides to the Medical Literature</i> , <i>The Rationale Clinical Examination</i> , and many other resources to learn skills in critical appraisal of the literature and evidence-based medicine techniques.

Clinicians frequently rely on the synthesis of many studies, rather than a single study, to change our practices. Such reviews can be systematic, in which rigorous attempts are made to uncover all studies, published and unpublished, in English and in other relevant languages, or they may be more limited reviews that consider only a portion of the published literature. Some use formal mathematical methods to combine the results of studies (i.e., meta-analysis), and others are qualitative and synthesize data according to an author's overall judgment. Common biases to consider related to published reviews include whether all sources of evidence were considered; how disparate results were combined; whether relevant patient-oriented outcomes were assessed; if there was adequate attention to the quality of the studies and their generalizability; and whether the authors analyzed why differences in outcomes may have occurred based on such factors as study design, population, and intervention. Published reviews, including systematic reviews and clinical guidelines, have become increasingly important tools for the busy clinician.

It is important to understand basic concepts for interpreting and applying research results (Bhandari and Haynes, 2005). Clinicians may move beyond the basic skills in searching the literature and critically appraising individual research studies by using online EBM tools and educational resources or by attending EBM training courses (Table 9-3). The ability to critique original research using a structured approach is facilitated by using widely available worksheets and tools. However, sifting through original research studies can be a tedious, impractical process for busy clinicians.

Using Evidence at the Point of Care

Finding evidence to inform clinical practice no longer requires clinicians to critically appraise individual research studies. Many practical EBM tools are available to help physicians quickly access comprehensive, expert reviews of published studies in the middle of a busy practice. Online searchable databases provide useful summaries of expert analysis of published clinical research for a wide variety of

clinical questions. Certain online resources require a paid subscription but may be available to clinicians through institutional subscriptions at a local hospital medical library or academic health center (Table 9-4). Others are free to access on the web or through applications on handheld digital devices and offer physicians a practical first step for rapidly accessing published evidence as part of daily patient care. Examples of freely available online resources include (see links and descriptions in Table 9-4):

- Systematic reviews and meta-analyses from the Cochrane Database of Systematic Reviews, or by searching PubMed using their Clinical Queries tool.
- Critically appraised topics and clinical guidelines from the National Guideline Clearinghouse.
- The *Trip* database, a clinical search engine that draws on multiple sources for systematic reviews and guidelines.

Once a clinician becomes familiar with searching online databases, identifying and reviewing published evidence can be accomplished quickly and at the point of care (Ebell, 1999). The following case describes examples of relevant information that a busy clinician can access using free online EBM resources described in Table 9-4.

CASE EXAMPLE

A 40-year-old woman sees you because she is experiencing severe vasomotor symptoms (i.e., hot flashes). These symptoms are keeping her awake at night. She had a total abdominal hysterectomy and oophorectomy 6 months ago because of enlarging uterine fibroids. She has a family history of heart disease and she is concerned about cardiovascular risks associated with HRT. What is the current evidence regarding cardiovascular risks of HRT for this patient? How should you counsel this patient?

A free search was performed using the Clinical Queries page in PubMed (www.ncbi.nlm.nih.gov/pubmed/clinical). When typing "HRT" into the Clinical Queries search box, a drop-down list of frequently entered queries automatically appears, and "menopause HRT" was chosen. The first

Table 9-4 Examples of Resources for Identifying Evidence-Based Medicine Information at the Point of Care

Information Source Access	Description	Paid Subscription Required?
DynaMed™; https://dynamed.ebscohost.com	Physician authored, clinically organized evidence summaries and expert opinion, organized in a searchable resource that can be used efficiently at the point of care to answer clinical questions.	Yes. Free trial available.
UpToDate®; www.uptodate.com/home/product	Synthesis of evidence and expert opinion on topics in multiple specialties, organized to provide practical answers to clinical questions at the point of care.	Yes
Cochrane Reviews; www.cochrane.org/cochrane-reviews	The Cochrane Collaboration is an international, nonprofit, independent organization that has produced and disseminated thousands of highly detailed systematic reviews of health care interventions. Seen by many as the gold standard of systemic evidence-based reviews.	Free searches and reviews of abstracts. Access to full reports requires subscription.
Family Physicians Inquiries Network (FPIN); www.fpin.org	Virtual learning community with point-of-care answers to clinical questions using structured, critical reviews of the literature, with a strong focus on topics relevant to family practice and other primary care specialties.	Yes
PubMed Clinical Queries; www.ncbi.nlm.nih.gov/pubmed/clinical	The Clinical Queries section of PubMed, a search engine for MEDLINE provided by the National Library of Medicine, conducts focused searches of published clinical studies and systematic reviews. A free Clinical Queries tutorial is available online.	Free
National Guideline Clearinghouse; www.guideline.gov	This public resource for evidence-based clinical practice guidelines is organized by the U.S. Federal Agency for Healthcare Research and Quality.	Free
Trip Database; www.tripdatabase.com	A meta-search engine that retrieves information from multiple evidence-based resources and databases.	Free

article listed from this simple search was a structured review of HRT and cardiovascular risk, including studies published since the 2002 WHI study (Hodis and Mack, 2014). The search and review of this article took approximately 5 minutes. The authors' conclusions include the following statement:

The totality of the data show that HRT decreases coronary heart disease and overall mortality when started in women who are less than 60 years old and/or less than 10 years post-menopausal, providing a “window-of-opportunity.”

A second search using the free online database Trip (www.tripdatabase.com) with the keywords “hormone replacement therapy menopause” resulted in a list of clinical guidelines. Limiting the search to “Guidelines/USA” and scanning the first few listed titles showed a 2012 guideline and position statement of the North American Menopause Society and a link to a free online copy of the guideline through the National Guideline Clearinghouse (North American Menopause Society, 2012). This systemic review and guideline summarizes both the risks and benefits of HRT. Search of the Trip database and review of this guideline took approximately 4 minutes. Summary recommendations of the guideline include the following statement:

Women experiencing premature menopause are at increased risk of osteoporosis and, possibly, cardiovascular disease, and they often experience more intense symptoms than do women reaching menopause at the median age. Therefore, HRT generally is advised for

these young women until the median age of menopause when treatment should be reassessed.

This case outlines how a physician with access to searchable databases can quickly review an array of clinical evidence and published guidelines. Such resources are based on systematic evaluations of evidence and can provide clinicians with practical guidance at the point of care. EBM, information mastery, and the application of knowledge at the point of care remain works in progress. By developing a basic understanding of these resources and tools, physicians' care for patients can be more effective, safe, and efficient.

Key Points

- Do not assume that statistical significance is the same as clinical significance.
- Do not rely on pharmaceutical representatives or experts who may be biased in their presentation of information.
- Consider the potential harms and economic effects of an intervention.
- Do not assume that results even from a well-done study are applicable to your population of patients.
- Do not fail to use the many comprehensive sources of evidence-based information.

Information Technology

DAVID KUNSTMAN

CHAPTER OUTLINE

Introduction, 116
Electronic Health Records, 116
Mobile Technology, 118

Engaging Patients, 118
Security, 118
Conclusion, 119

Introduction

Information technology in medicine is a topic that has moved from concept and convenience to a critical operational and patient care need. The trend toward this received a big push in 2009 with the introduction of the Health Information Technology for Economic and Clinical Health (HITECH) Act. This act set aside \$27 billion in incentives through Medicare and Medicaid for health care organizations to achieve “meaningful use” in the use of their electronic health records (EHRs).

Health care providers have been challenged to incorporate data entry skills into the patient care visit. They have also reaped benefits from the information and knowledge gained from the analysis of that data. Improvements in device technology, clinical work flows, and interface design are continually improving these efforts.

Patients are now witnessing the effects of this technology revolution from within our formal health care structure and from multiple other sources. The Internet remains a powerful tool for health information, but the introduction of the app store in 2008 and smartphone technology has pushed this into everyday life, including the examination room.

Electronic Health Records

EHRs were first discussed in the 1970s. Since then, there has been an evolution of the electronic storage of patient medical information, and at its heart is structured data. The entry and organization of this data is critical to the success of every process going forward. Each data element has a location, and data obtained from individuals or devices populate values to this location. A strong data governance structure is essential to maintain this order. Without governance, individuals will seek their own solutions, and the downstream benefits of structured data will be lost.

This governance group should look toward the needs of the organization and consumers of data when determining data architecture. Each request for a new data field should come with a discussion about where the data will ultimately be used. Examples of areas to include in this discussion are

coding, compliance, business office, legal, clinic operations, clinical research, and, ultimately, patient needs.

The ability to enter values into the determined fields needs to be reasonable and practical so that individuals will choose to do the right thing. Tools to aid this may include graphical, tabular, or audible entry. Digital imaging and video are also becoming popular methods of entry.

One emerging technology that will aid entry is called *natural language processing*. This has the ability to analyze unstructured data similar to the original progress notes of years past. The notes are then parsed into specific data elements for inclusion in the electronic record.

ELECTRONIC HEALTH RECORD USABILITY

Adoption of the use of EHRs in a large part is affected by usability, or being “user friendly.” Simply defined, this is the effectiveness, efficiency, and satisfaction with which specific users can achieve a specific set of tasks in a particular environment (Schoeffel, 2003). Usability was felt to be a major factor in the slow adoption of EHRs in the United States. In 2009, the Healthcare Information and Management Systems Society (HIMSS) defined a set of key principles behind EHR usability (HIMSS EHR Usability Task Force, 2009).

- **Simplicity of design:** Show the information minimally necessary to accomplish a task.
- **Naturalness:** Allow the ability for the user to be automatically familiar with the application.
- **Consistency:** Enable predictability of behaviors, layouts, and concepts between screens and work flows.
- **Minimizing cognitive load:** Present information needed to make the correct decision and desired outcome easy to perform.
- **Efficient interactions:** Minimize the number of steps it takes to complete the task.
- **Forgiveness and feedback:** Allow the user to explore without fear of bad outcomes through the use of feedback.
- **Effective use of language:** Provide language that is concise and unambiguous.
- **Effective information presentation:** Make good use of data density, color, and readability.

- Preservation of context: Avoid distractions common with screen changes and dialog boxes.

OPTIMIZATION

The complexity of patient care and EHR software make it extremely difficult for all clinical operation processes to be taught effectively on day 1. In addition, software is constantly evolving, and new clinical needs arise on a frequent and sometimes emergent basis. Optimization of EHR use becomes essential maintenance. Users of the system will need regular reminders of software processes, especially those that are infrequently used. New processes will need to be introduced as well. Communication may take several forms. The training team becomes helpful for this, as does the use of advanced users in a train-the-trainer model. Written or electronic materials in a push or pull model may also be needed for those users requiring asynchronous learning.

MEANINGFUL USE

Meaningful Use is a Medicare and Medicaid EHR incentive program to provide financial incentives for “meaningful use” of a certified EHR. As of June 2014, 479,941 eligible professionals and 4741 hospitals (Medicaid and Medicare) have enrolled in the Meaningful Use program. The Meaningful Use program is comprised of three stages as summarized in Table 10-1 (HealthIT.gov, 2014). To receive incentives, attestation to specific criteria needs to begin by 2014, and the payments are made over a number of years (HealthIT.gov, 2014). The last year for incentives in the Medicare group is in 2015 and in 2021 for the Medicaid group.

COMPUTERIZED DECISION SUPPORT

Computerized decision support (CDS) is a key component of the Meaningful Use program. It relies on structured data within the EHR to output knowledge to the organization or consumer. The EHR software analyzes data and applies rules to identify patterns or critical values deserving of attention. A key concept here is that the correct data is

presented to the correct audience in the correct format at the correct time.

An organization does need to be careful and balance the amount of clinical decision support with the operational work flows. Too many alerts, or “alert fatigue,” may counteract the benefits of the intended support. A governance body tasked with monitoring the amount and perceived importance level of support is quite helpful here.

PATIENT PORTALS

Stage II of the Meaningful Use program calls for increased use of patient portals. These portals provide access to things such as messaging to providers, refill requests, appointment requests, notifications, and in some cases, full medical record access. As of 2013, it is estimated that 28% to 40% of patients have access to this technology. There has been concern by providers, but multiple organizations have now started providing patients direct viewing of their entire medical record with good results. The use of these patient portals not only gives patients more information about their health but allows them to participate in their health care. The use of questionnaires and direct entry of medical history is an area that is evolving. Not only may this be done manually, but device makers are starting to incorporate this technology into consumer products such as scales, blood pressure cuffs, and glucometers.

In a multinational study of 9100 patients by Accenture, 41% of U.S. patients said they would be willing to switch doctors to gain access to their records. Eighty-four percent of those patients felt they should have access to their records while only 36% of providers shared this view (Accenture, 2013).

TECHNOLOGY CONSIDERATIONS

With the advance of EHR, electronic means of obtaining data became essential. Equipment that was designed to provide a paper output now needs to also include a method to interface with EHRs. Examples of this technology include cardiac monitoring, radiologic and visible light imaging, audiometric screening, and diabetes monitoring.

Table 10-1 Stages of Meaningful Use Incentive Program

Stage 1: Data Capture and Sharing Meaningful Use Criteria Focus on:	Stage 2: Advance Clinical Processes Meaningful Use Criteria Focus on:	Stage 3: Improve Outcomes Meaningful Use Criteria Focus on:
Electronically capturing health information in a standardized format	More rigorous health information exchange (HIE)	Improving quality, safety, and efficiency, leading to improved health outcomes
Using that information to track key clinical conditions	Increased requirements for e-prescribing and incorporating laboratory results	Decision support for national high-priority conditions
Communicating that information for care coordination processes	Electronic transmission of patient care summaries across multiple settings	Patient access to self-management tools
Initiating the reporting of clinical quality measures and public health information	More patient-controlled data	Access to comprehensive patient data through patient-centered HIE
Using information to engage patients and their families in their care		Improving population health

Adapted from *EHR Incentives & Certification: How to Attain Meaningful Use*. HealthIT.gov; page modified April 10, 2014. <http://www.healthit.gov/providers-professionals/how-attain-meaningful-use>.

In evaluating this equipment, not only is it essential that the interface exists, but that interface must be compatible with EHRs. Cost considerations need to include the device itself, device maintenance fees, estimated years of service, initial interface fees, and maintenance of that interface. A good first step is to inquire with the EHR vendor about device compatibility. A centralized process for coordinating purchases of this equipment is also quite helpful.

Technical teams will also need to consider the storage of this digital information going forward. This consideration will include location, format, size requirements, and ability to review or recover the data. For that technology preceding electronic interfaces, a robust scanning solution must also be included.

Mobile Technology

By some measures, smartphone owners check their phones 150 times/day (Kvedar, 2013). A quarter of Americans in one survey say they would trust a symptom checker website or mobile application as much as they would their doctor (PMLive, 2013). Another study of 2000 patients and covering 20 disease states found that 90% of patients would accept the offer of a mobile app, while only 66% of respondents would accept prescription medicine from their doctor (Royal Philips Electronics, 2012).

Mobile technology applications are largely unregulated. Those applications that either control a regulated medical device or turn a smartphone into a regulated medical device may soon fall under the jurisdiction of the U.S. Food and Drug Administration (FDA). Several websites exist to give guidance to clinicians and patients about these applications (e.g., mobihealthnews at <http://mobihealthnews.com> and iMedicalApps at <http://www.imedicalapps.com>).

A survey conducted by the University of Pennsylvania found that the top eight mobile medical applications for 2012 were

1. Epocrates Essentials
2. MedCalc
3. Medscape Mobile
4. DynaMed
5. VisualDx
6. Micromedex
7. Skyscape
8. Diagnosaurus DDx

These applications are excellent references to clinicians and may also benefit patients. Physicians may consider “prescribing” applications to patients for uses of therapy, reference, or tracking. When considering applications to suggest to patients, consider the patient’s likelihood to use, the developer of the application, and ratings that are often available on the developer or app store site (Table 10-2). It is best practice to try the application yourself when feasible.

Engaging Patients

Stage 2 of the Meaningful Use program will make more of the medical record available directly to the patient in the

form of the problem list. Although the introduction of the computer to the examination room was a recent phenomenon for many, the computer must now become an interactive learning tool. A few considerations for this include:

1. Position the computer between the health care provider and the patient so the patient may view information along with the provider. Pivot arms on monitors will greatly improve this interaction.
2. Keep patients first. Always greet patients before logging in. At the proper time, introduce the computer as a tool in their medical care.
3. Assure patients about the safety of their data and perhaps make specific mention about logging off to protect their data.
4. Position print devices convenient to the patient flow or alternatively encourage the patient to be involved in a patient portal.

Ultimately, patients may interact more directly with their charts and update information. Beginning to educate them about the problem list in the examination room may serve as a good primer for this.

Security

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 ensured individual rights of patients and added specific privacy and security protections. The scope of this was expanded in 2013 along with the breach notification requirements under the HITECH Act of 2009. Providers play an important part in assuring the continued confidentiality of the patient record. Patient information may be shared for the purposes of treatment, but a few key points to be aware of follow:

- Understand what is protected health information (PHI) and what may be disclosed and authorization that may be needed.
- Provide safeguards such as individual passwords, private areas for viewing PHI, and policies and procedures for the release of PHI.
- Access only that information that is required to perform your job.
- Never discuss PHI in public areas or present PHI to individuals who are not involved in the care of the patient.

- Report any suspected breaches of PHI to your privacy officer immediately.

More information about privacy practices may be found at the U.S. Department of Health and Human Services website (www.hhs.gov/ocr/privacy/index.html). The Meaningful Use incentive program also has additional information about Privacy and Security at its website (www.healthit.gov/providers-professionals/ehr-privacy-security).

Conclusion

We are just beginning to see the impact of health information technology as we use the data stored now in EHRs and other databases. Beyond data acquisition, we derive knowledge and ultimately wisdom. The attention to structure and usability becomes essential to maintain integrity and trust.

Usability remains a top priority for health care providers and patients, and we should not forget the critical and

personal interactions we have in the clinical setting. We should strive for seamless acquisition and understanding of data as we move this technology forward.

Finally, data security must guide our behavior and interactions. As health care providers, we are trusted with the most intimate details of our patient's lives and we must not breach that trust.

Clinical Problem Solving

PHILIP M. DILLER and ROBERT T. ELLIS

CHAPTER OUTLINE

Introduction, 120

The Principles of Family Medicine Define the Context for Solving Clinical Problems, 120

Tasks and Steps Used by Family Physicians to Solve Clinical Problems, 121

Challenges to Clinical Problem Solving, 124

Conclusion, 124

Introduction

Practicing family medicine is a continual confrontation of problems besetting the human condition, and a goal for many family physicians is to become a master problem solver. Having a front row seat to the joys and tragedies, the drama and the misery that patients experience through the life cycle provides ample opportunity to gain mastery.

The purpose of this chapter is to outline a systematic approach to problem solving commonly used by family physicians. Before presenting the model for clinical problem solving, we review the context of family medicine practice that shapes problem solving by family physicians. By taking a systematic approach to solve problems and using point-of-care information resources, the physician can minimize or at least control some of the uncertainty common in practice.

There are four primary tasks to solve clinical problems: (1) begin to understand the problem in clinical terms, (2) define and select the problem or problems to address, (3) discuss and create treatment and solution options and eventually selecting an agreed-on management plan, and (4) monitoring response to treatment. The model for clinical problem solving can be used as a guide to improve the process and identify the challenges associated with the process to prevent errors. The intent of this chapter is to describe how to move toward mastery as a problem solver, and in turn, achieve desired patient outcomes of care.

The Principles of Family Medicine Define the Context for Solving Clinical Problems

The principles characterizing family medicine (Green et al., 2004) that shape the context for clinical problem solving include (1) deep understanding of whole person care, (2) provision of comprehensive care, (3) first contact care ensuring patient access, (4) continuity of care, and (5) commitment to team-based care.

WHOLE PERSON CARE

Patient problems presenting to family physicians are legion; anything having to do with the human condition can be encountered by family physicians. The family physician must first be a student of humanity and have a working knowledge of the five dimensions of being human: (1) physical, (2) psychological, (3) social, (4) spiritual, and (5) chronological (life cycle). Each dimension can be problem generating and require a treatment or solution. Some problems can be very simple, such as a sore throat that is easily diagnosed, and have a fairly standard course of treatment. At the other end of the spectrum a patient could come in with a congestive heart failure but then live on the street, have no insurance coverage, and have poorly controlled mental health problems. Thus patients can present with a multiplicity of problems, and these problems often are interactive, making it harder to control any one of them with singular solutions. As a result, family physicians need to have a fairly broad-based approach to solving problems, and this requires a very big search net in seeking to understand the nature of the problems.

COMPREHENSIVE CARE

Applying a taxonomy of visit types can also aid in understanding problems commonly seen in family medicine. Patients can be seen by family physicians for acute, self-limited illness, chronic disease, mental health problems, maternity care, prevention and wellness issues, and administrative needs such as disability evaluations or return-to-work notes. In addition, patients could have end-of-life concerns, including nursing home placement or a need for palliative care or hospice services. Thus the patient problems addressed by family doctors are many because of the multiple human dimensions, but also because of the breadth of comprehensive services offered by family physicians in the health system.

FIRST CONTACT CARE

Family physicians are on the frontlines and are often the entry point for patients who seek care, and as a

result, problems present early in the course of an illness. Patients present with symptoms when the disease is not defined, is undifferentiated, and the illness is yet to be organized for the patient. This aspect of seeing patients in an undifferentiated state, when a physician only has a few facts or objective signs of disease, presents challenges and underscores how widespread uncertainty is when trying to define the problem. Family physicians need to be comfortable with uncertainty and to understand that time is an ally in sorting out patient problems. Family physicians also have to be versed in probabilities and consider likelihood ratios for what signs and symptoms mean. Such information can assist in deciding whether an intervention is needed or if a watch-and-wait approach is appropriate.

The family physician provides access to care in a multitude of settings, including home, office, hospital, nursing home, or even a factory. Each setting brings contextual data into play, and understanding the setting or the limitations of the setting can be helpful in solving patient problems. Resources available to the patient to be included in the solution or treatment plan may be setting-specific.

CONTINUITY OF CARE

Family physicians create longitudinal relationships with patients and as a consequence gain valuable prior knowledge of patients used to individualize problem solving. The accumulated knowledge of patients leads to efficiency in understanding patients' problems and then designing treatment solutions. For example, patients with chronic obstructive pulmonary disease (COPD) may have baseline respiratory distress but having adapted are reasonably comfortable with an oxygen saturation of 89%, and when they come in with a little additional distress, a decision needs to be made to hospitalize or closely watch them as outpatients. Having had prior episodes and knowing exactly how the patient responds and what is necessary, physicians are much more comfortable in that area of uncertainty about what the next steps should be in the care of the patient. Contrast this with an emergency department physician who has no prior knowledge of this patient, discovers an oxygen saturation of 88%, is concerned with how distressed the patient looks, and decides to admit the patient to the hospital. Understanding the problem as well as the context for that unique patient is fundamental to making patient-centered clinical decisions in practice.

TEAM-BASED CARE

Finally, an additional context factor for family physicians is the health system, a complex and evolving health environment in which different treatment options or innovative care models can be put into place. Increasingly, care managers are part of the emerging primary care delivery team included in the patient-centered medical home experience. The family physician also needs to be aware of what resources are in the health system, and the new and emerging innovations in care that can lead to potentially better patient outcomes.

Tasks and Steps Used by Family Physicians to Solve Clinical Problems

Figure 11-1 illustrates a systematic step-by-step approach to problem solving. There are four primary tasks, with each task having specific steps: (1) beginning to understand the problem in clinical terms, (2) defining the problem(s) to address, (3) formulating solutions and treatment, and (4) monitoring the response or testing the solution based on actual results. Family physicians perform these tasks in solving clinical problems. This problem-solving approach encompasses many of the fundamental steps of doctoring, including data gathering, clinical reasoning, defining the diagnosis, considering prognosis, generating a treatment plan, and monitoring the response to treatment.

BEGINNING TO UNDERSTAND PROBLEM(S) IN CLINICAL AND CONTEXTUAL TERMS

The first part of the *data-gathering step* is to take the traditional disease-focused approach: listening to the patient's chief concern or complaint, taking a medical history, doing a physical examination, and requesting needed laboratory or imaging data. This traditional approach is structured to elucidate physical diagnoses. Simultaneously, the family physician is also seeking focused data about the patient as a person, and these data include information of the five human dimensions. Patient-as-person data can be a source of nonphysical problems and influence possible solutions to the problems.

The chronological, or seasons-of-life, dimension is readily appreciated during the encounter and is valuable to note because the cause of the patient's symptoms may be age-related. For example, the causes of constipation in a 4-month-old infant are very different from a middle-age person who has constipation of recent onset. The same symptom is present, but there are very different diagnostic possibilities because of the patient's age.

The psychological dimension includes not just mental health diagnoses but also personality, intelligence, attention, ability to process information, mood, and emotional states such as fear and anxiety that are part of the conversation. Any of these can be source of problems for the patient or influence a solution.

A family physician actively scans the patient's social dimension for potential problems. Social dimension is often divided into five different areas (Berkman and Kawachi, 2000): (1) relationships at the individual level, such as a person's family unit or source of social support; (2) the work environment; (3) social status (e.g., educational level); (4) socioeconomic position (e.g., poverty); and (5) community relationships and norms. All can be a source of problems but can also set the stage for potential solutions. Such information is often critical in creating effective solutions to patient's problems.

The spiritual dimension can also be a source of problems and potential solutions for patients. Patients can attribute diseases as punishment from God or as a struggle with

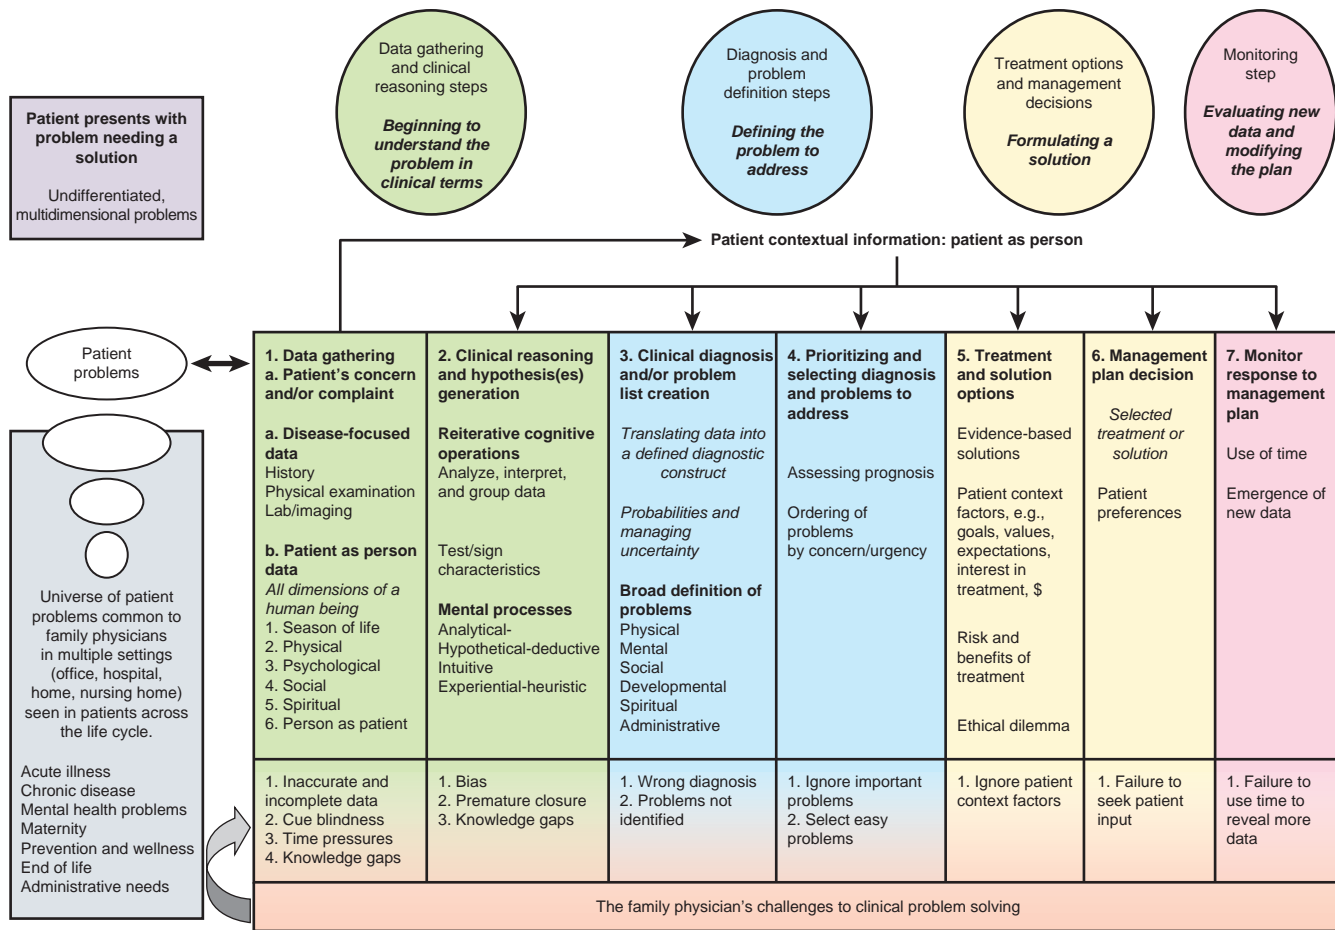

Figure 11-1 Steps family physicians take to define clinical problems and create patient-centered treatment solutions.

purpose and meaning in life. Alternatively, patients may draw on strong spiritual beliefs or a religious community for solace and support.

In addition to these five human dimensions, the role the person plays as patient can also be a source of problems. For example, the ideal patient is expected to follow through on treatment plans, but nonadherence to the plan is a common problem in practice. Trying to understand the factors causing noncompliance become part of the physician's search and demand a solution if patient adherence is to be achieved.

Family physicians elicit and search for "data" related to the physical diagnosis, the various human dimensions, the role of the patient to understand the multitude of problems, and also to generate an active problem list.

The second step after data gathering is *clinical reasoning*. In reality, this goes on simultaneously while gathering the data. The physician conducts specific mental operations that initially include sorting and sifting, analyzing, and interpreting the data. Signs and symptoms have different meanings diagnostically and prognostically (Wilson, 1926). The physician often uses two broad categories of mental operations on the gathered data (Croskerry, 2009). The first is an analytical or a systematic algorithmic approach to hypothesis generation. Questions are ordered sequentially, with the patient's answers directing the next line of questions. In a very systematic way, the physician is sifting and sorting information as it comes forth to get to a likely answer to the hypothesis. The second broad mental operation

category is intuitive processing. Here the physician is using prior experience and pattern recognition to sort information in a much more efficient, rapid manner. Intuitive processing is much quicker, but it also has a higher likelihood of error.

One aspect of sorting and sifting data and hypothesis generation is the value of that information in raising or lowering the likelihood of a specific diagnosis. In clinical practice, knowing likelihood ratios of specific signs (McGee, 2012), symptoms, and tests (or a combinations of these, for example, severity of illness scales) (Kellet, 2008) is valuable in defining the probability of a disease and its outcomes. In addition to the likelihood ratios, family physicians are assisted in defining clinical problems by knowing the prevalence and incidence of a specific disease in the community. Such information may not be readily available, but, for example, based on the season of year, monitoring the emergence of communicable disease (e.g., Centers for Disease Control and Prevention [CDC] flu map website) and hearing of patients with flu in the community, a physician's suspicions for flu are elevated when a patient comes in with runny nose, cough, fever, and diffuse body aches. Such information helps with generating probabilities in the same way Will Pickles' work on the incubation periods of certain infectious diseases (Pickles, 1939) allows a physician encountering a jaundiced patient to increase the likelihood of a diagnosis of infectious hepatitis by knowing when the patient was exposed to another person with that condition.

DEFINING THE PROBLEM(S) TO ADDRESS

The next step includes making a *clinical diagnosis*, *defining the problem(s)*, and *creating a problem list*. Diagnosis is a translation of symptoms and signs into a medical disease category or classification scheme. Diagnosis is the naming of the clinical problem based on the patient's signs and symptoms. Diagnosis is laden with meaning, assigning a pathobiological process responsible for the patient's signs and symptoms. The signs and symptoms understood in pathobiological terms begin to demystify and move the process to a specific prognosis and suggest treatment options.

For the family physician, patient problems do not end with a physical diagnosis. Glenn (1984) reminded us that diagnosis for family physicians is much broader and includes problems of the kind alluded to earlier of psychological, social, and spiritual dimensions of being human. Neglecting these problems in the treatment of disease often leads to poor outcomes because of the interaction of problems that permeate the patient's life. An important aspect of helping a patient is to classify these other problems as well and recognize how they are shaping the experience of disease (illness).

An important part of the discussion in generating an active problem list is to gain agreement with the patient on what the problems are and which ones are the most important. Getting to agreement on patient problems (and their treatment) influences the outcomes of care (Stewart, 1995).

The next step in clinical problem solving is *prioritizing and selecting the diagnosis and the problems to address*. This is really not as simple as it sounds, and it is an important part of the process because in practice, faced with multiple problems, the physicians must decide what to address first and in what order (Balint, 1964). Some solutions or treatments are easy, such as writing for a medication, whereas others require much effort by the patient and physician (e.g., behavior changes). A physician's expertise or comfort level influences what problem a physician or patient may choose.

Another factor is the level of concern or urgency to the problems. The patient with suicidal ideation in crisis needs immediate response to treatment, as opposed to somebody who has a nagging fatigue and back pain due to the repetitive stresses of life who may have depression; the sense of urgency is different. A patient may have strong feelings about what is most important and that influences what problem is addressed first. All are part of the conversation on deciding and prioritizing what problems need to be addressed.

The prognosis of the problem also shapes how the physician orders and prioritizes what problem should be addressed. A new diagnosis of cancer, for example, changes a person's life trajectory in the short term as well as the long term. With a new cancer diagnosis, the focus of attention for that patient carries heightened concern and anxiety about what the diagnosis portends for the future and how the cancer is going to impact his or her ability to function in his or her various work or family roles, and such considerations shape the nature of the treatment plan. Thus knowing the prognosis of specific conditions and what their natural history could be with or without treatment is included in formulating solutions and treatment options.

FORMULATING SOLUTIONS AND TREATMENT OPTIONS

Once the problem is understood, defined, and prioritized and agreement is achieved between the physician and patient, the physician and patient can then begin to explore treatment and solution options. Increasingly the physician takes an evidence-based approach to deciding treatment options (Sackett et al., 1991). Some treatments have a strong evidence base with clear likelihood of response to treatment. In practicing evidence-based medicine, the physician often uses point-of-care resources to help guide care decisions. In addition, there are also patient decision aids (O'Connor, 2001) available to help patients understand the risks and benefits of treatment. A selected set of electronic resources is shown in Table 11-1.

Table 11-1 Point of Care Resources Available to Assist with Clinical Problem Solving

Resource	Description	Type	Free
5-Minute Clinical Consult	Quick and concise clinical reference: not a lot of details but good for a quick overview of medical conditions	App, Web	No
AHRQ ePSS	Easy-to-use USPSTF guidelines: enter patient demographics and get patient-specific recommendations	App, Web	Yes
Epocrates	Popular drug reference	App	Yes
MedCalc	Free reference of more than 300 formulas, scoring, scale, and classification systems	App	Yes
MediMath Medical Calculator	More than 140 of the most important medical calculators and scoring tools	App	No
Mediquations Medical Calculator	More than 230 formulas and scoring systems	App	No
Medscape	Popular decision support tool that includes medical news, clinical information, drug information, procedure videos, and medical calculators	App, Web	Yes
Shots by STFM	Easy-to-use immunization program based on CDC guidelines; includes vaccine info and schedules if using combination shots	App	Yes
Skyscape	Decision-support tool that includes clinical information, drug information, and medical calculators	App	Yes
UpToDate	Comprehensive evidence-based resource; requires a subscription	App, Web	No

AHRQ, Agency for Healthcare Research and Quality; CDC, Centers for Disease Control and Prevention; ePSS, Electronic Preventive Services Selector; STFM, Society of Teachers of Family Medicine; USPSTF, U.S. Preventive Services Task Force.

In addition to knowing the evidence for specific treatments, patient context factors also impact the treatment plan options. Patient expectations, values, and willingness to pursue specific treatment plans come into play (Janz and Becker, 1984). Common to family medicine practice are patients who do not like to take medications and would prefer to use alternative approaches to treat physical problems. Thus, increasingly, family physicians should be knowledgeable of the integrative medicine approaches that can be used to complement some of the medical approaches to create a management plan that patients will accept.

Patient context factors also play into modifying the treatment plan in other ways. Specifically, concern for quality-of-life issues may want the physician to steer away from aggressive treatment plans that actually lead to lower quality of life. Patients have specific goals they want to accomplish in a certain period of time, and they will delay following through on some medical interventions before they have achieved these other goals. Even though there may be a very strong and compelling evidence base for a specific treatment plan, patients make choices based on other values and goals.

In addition, ethical issues arise in practice and shape and influence decisions. If a person is trying to weigh the benefits of treatment versus harm, and if one available treatment option will cause more harm than another, a patient may decide to avoid the harmful approach even if the patient knows there may be increased risk of premature mortality. Family physicians often handle ethical dilemmas that arise in practice as part of any management plan or decisions patients face.

All this information involving the treatment options is used to select the specific management plan on which the physician and patient agree to move forward. Including patient preferences is an important element in selecting that management plan.

MONITORING THE RESPONSE: TESTING THE RESPONSE BASED ON ACTUAL RESULTS

Monitoring the response to treatment is an important part of the problem-solving process because a plan ultimately must produce the desired results—a good outcome. When a patient presents early in the course of an illness, it is often not clear exactly what the problem is, but with the passage of time more data come forth and the physician can better understand the problem and adjust the treatment plan. In a similar way the response to treatment in time may help clarify what the problem actually might be. For example, a patient comes in with dyspepsia and the physician starts a medication for acid disease. In follow-up, the physician can monitor whether the patient responded to treatment and is able to confirm that the diagnosis is acid dyspepsia. That response may lead to evaluate for *Helicobacter pylori* infection and, in turn, offer treatment to eradicate the problem.

In monitoring the response to treatment, the physician and patient begin to gain further understanding of the problem, and the physician specifically gains practical experiential knowledge of what works and what does not. Time will tell if the problem was understood and defined correctly and if the treatment was effective. In this way, monitoring

the response to treatment is a source of learning and helps with future problem solving.

Challenges to Clinical Problem Solving

The data-gathering step can be associated with potential errors that lead to poor problem solving. For example, having inaccurate or incomplete data leads to a limited understanding of the problem and, in turn, to ineffective solutions. Another factor related to data gathering is insufficient clinical knowledge to collect key data and ask important questions. The pressures of practice can limit the time allowed to gather information. As a result, the history may be a little bit briefer, the physical examination may be incomplete, and as a result, important data are not obtained.

Clinical reasoning errors using intuitive processing may lead a physician to prematurely close the search for a diagnosis; quick judgments of the problem based on prior pattern recognition may not be reliable. Knowledge gaps could also impact clinical reasoning abilities with analytical processing. If a physician's knowledge is incomplete, then a very limited algorithmic or analytical approach will be used compared with another physician who has a very detailed knowledge base and can go very deep in questioning to clarify the patient's story. Finally, clinical reasoning can be influenced by faulty assumptions (biases) and, as a consequence, lead to flawed diagnostic impressions and perception of problems.

In prioritizing and selecting problems, it is possible the physician can choose to ignore important problems because they are more difficult to manage than others. The physician may select easy problems rather than tackle those that are more frustrating and difficult to address. For example, changes in behavior to help people to lose weight for hypertension are much harder to accomplish than writing a prescription for hypertension medication. Depending on the degree of difficulty and resources available, patients may choose not to address certain problems.

In designing treatment options and solutions, physicians may ignore patient context factors, such as patient-driven goals or gaining agreement with the plan. Physicians may take a paternalistic approach and exclude patient input in the management plan. Sometimes paternalism is needed, but other times physicians create solutions not acceptable to patients. Patients may simply feign agreement and leave knowing they will not follow through.

Finally, in monitoring response to the management plan the physician may fail to pursue or seek new data and/or not try to understand the problem in a new way. The physician may not recognize how time can help in confirming whether the problems are correct or whether the treatment plan is working.

Conclusion

Effective clinical problem solving occurs when a family physician uses a systematic approach. This chapter offers

a systematic approach to problem solving that outlines the specific tasks and describes specific steps to arrive at effective solutions. Patient involvement is critical throughout the whole process. Family physicians who debrief their problem solving skills and identify areas for improvement in time become master problem solvers, and in turn become trusted advisors to their patients. In the current environment of outcomes-based medicine, becoming a master

clinical problem solver—creating care for the unique patient that leads to positive outcomes—cannot be overly emphasized.

Integrating Complementary and Alternative Medicine into Practice, 134

Conclusion, 139

Key Points

- Terms and definitions that describe complementary and alternative medicine (CAM) are diverse and evolving.
- Integrative medicine combines CAM and conventional medicine.

The level of integration of conventional and CAM therapies is growing. That growth generates the need for tools or frameworks to make decisions about which therapies should be provided or recommended, about which CAM providers to whom conventional medical providers might refer patients, and the organizational structure to be used for the delivery of integrated care. The committee believes that the overarching rubric that should be used to guide the development of these tools should be the goal of providing comprehensive care that is safe and effective, that is collaborative and interdisciplinary, and that respects and joins interventions from all sources. (IOM, 2005)

Many countries now recognize the need to develop a cohesive and integrative approach to health care that allow governments, health care practitioners and, most importantly, those who use health care services, to access T&CM [Traditional & Complementary Medicine] in a safe, respectful, cost-efficient and effective manner. A global strategy to foster its appropriate integration, regulation and supervision will be useful to countries wishing to develop a proactive policy towards this important—and often vibrant and expanding—part of health care. (WHO, 2013)

In these tumultuous times of health care reform, family physicians find themselves on a threshold: a place of great

professional promise as well as uncertainty. Will they step through this historic doorway with newfound meaning and professional identity? Will they create new practice models, new ways of delivering care, and new methods of collaborating across the spectrum of healing practices and health professionals? Work is already underway with initiatives such as patient-centered medical homes (PCMHs) and accountable care organizations (ACOs). In addition, the field of family medicine has taken the lead and is currently pioneering work bringing complementary and alternative medicine (CAM) and integrative medicine into residency training and clinical care (Benn et al., 2009; Lebensohn et al., 2012; Locke et al., 2013).

How will these relatively new and evolving areas of health care optimize and revitalize the practice of family medicine? This chapter describes these new fields, assesses proposals by U.S. medical organizations, and addresses the challenges for practitioners applying current research techniques to these diverse and complex healing approaches and systems. Core principles and specific examples of CAM encountered by the practicing family physician are presented with relevant evidence and helpful tips.

Complementary and alternative medicine is based on multiple healing traditions practiced long before conventional Western medicine. Emerging from diverse cultural traditions worldwide, these approaches to health and healing offer the wisdom of their unique perspective on the human condition. Many traditional practices, including those of conventional medicine, share common roots and philosophies and uphold the sacred call to relieve the suffering of others. Family physicians should keep an open mind as they explore these dimensions of CAM.

What Is Complementary and Alternative Medicine?

Various definitions have been used to describe the array of approaches and philosophies commonly referred to as CAM. As the field has evolved, so has the terminology. Unconventional, unproven, alternative, complementary, holistic, integrative, and integral are some of the most common examples of terms in current use.

Historically, medical pluralism has long existed in the United States (Kaptchuk and Eisenberg, 2001a). Over the past few decades, *alternative medicine* has become a more recognized entity within conventional medicine. Because of the public's growing use of CAM, the National Institutes of Health (NIH) created an Office of Alternative Medicine (OAM) in 1992, with the intention of bringing its scientific expertise "to more adequately explore unconventional medical practices" (NCCAM, 2000). Because of Americans' ongoing and increasing use of CAM, the OAM was expanded to the *National Center for Complementary and Alternative Medicine (NCCAM)* in 1998, guided by the following mission statement (2000, p 17): "We are dedicated to exploring complementary and alternative healing practices in the context of rigorous science, training researchers, and disseminating authoritative information to the public and professional communities." After a decade of work in the field, NCCAM has become a leading resource for helping the public and health professionals better understand this rapidly growing area of medicine. The center's name has led to the more widespread use and recognition of CAM as the defining term for this field. NCCAM's free website contains a wealth of information, including the following definitions (2014):

- **Complementary and alternative medicine** are terms often used to mean the array of health care approaches with a history of use or origins outside of mainstream medicine. NCCAM generally uses the term "complementary health approaches" when discussing the practices and products we study for various health conditions. Although some scientific evidence exists, the list of what is considered to be CAM changes continually as the therapies that are proved to be safe and effective become adopted into conventional health care and as new approaches to health care emerge.
- **Alternative medicine** refers to using a non-mainstream approach **in place** of conventional medicine.
- **Complementary medicine** generally refers to using a non-mainstream approach **together with** conventional medicine.
- **Integrative medicine** and *integrative health care* combine this array of non-mainstream health care approaches together with conventional medicine.

The NCCAM has classified CAM into five categories, or domains (Figure 12-1). Currently NCCAM finds it useful to consider these approaches as falling into one of two subgroups: natural products or mind and body practices. Examples of alternative or whole medical systems include homeopathy, naturopathy, and Ayurveda (eAppendix 12-1 provides a glossary of CAM terms). Although there are a variety of approaches to the complex taxonomy of CAM (Kaptchuk and Eisenberg, 2001b), the NIH system is most often used.

Another term, *holistic medicine*, also describes these practices and philosophy. The American Holistic Medical Association (AHMA), founded in 1978, is a membership organization for physicians and other health professionals seeking to practice a broader form of medicine than that currently taught in allopathic medical schools (Table 12-1). "Holistic medicine is the art and science of healing that addresses care of the whole person—body, mind, and spirit.

Figure 12-1 The National Center for Complementary and Alternative Medicine (NCCAM) groups' complementary and alternative medicine (CAM) practices into five domains, recognizing that there can be some overlap among them. *Biologically based therapies* use substances found in nature, such as herbs, special diets, or vitamins (in doses outside those used in conventional medicine). *Energy therapies* involve the use of energy fields, such as magnetic fields or biofields (i.e., energy fields that some believe surround and penetrate the human body). *Manipulative and body-based methods* are based on manipulation or movement of one or more body parts. *Mind-body medicine* uses a variety of techniques designed to enhance the mind's ability to affect bodily function and symptoms. *Alternative or whole medical systems* are built on complete systems of theory and practice. Often, these systems have evolved apart from and earlier than the conventional medical approach used in the United States.

The practice of holistic medicine integrates conventional and complementary therapies to promote optimal health and to prevent and treat disease by addressing contributing factors" (AHMA, 2014).

In 1981, the nursing profession, guided by a group of nurses dedicated to bringing the concepts of holism to every arena of nursing practice, founded the American Holistic Nursing Association (AHNA). "Holistic nursing is defined as 'all nursing practice that has healing the whole person as its goal' (AHNA, 1998). Holistic nursing is a specialty practice that draws on nursing knowledge, theories, expertise, and intuition to guide nurses in becoming therapeutic partners with people in their care. This practice recognizes the totality of the human being—the interconnectedness of body, mind, emotion, spirit, social/cultural, relationship, context, and environment" (AHNA, 2014).

Integrative medicine, a term brought into popular use by Andrew Weil, MD, founder and director of the innovative University of Arizona Center for Integrative Medicine, describes how CAM and conventional medicine is practiced together (Rakel and Weil, 2003, p 6):

Integrative medicine is healing oriented and emphasizes the centrality of the doctor-patient relationship. It

Table 12-1 Important Events in Complementary and Integrative Medicine

Year	Event
1978	American Holistic Medical Association is founded.
1981	American Holistic Nurses Association is founded.
1992	U.S. Office of Alternative Medicine (OAM) is established.
1996	U.S. Food and Drug Administration (FDA) approves acupuncture needles for use by licensed practitioners.
1998	National Center for Complementary and Alternative Medicine (NCCAM) is established, replacing OAM.
1999	Consortium of Academic Health Centers for Integrative Medicine (CAHCIM) is formed in response to increasing public interest in complementary and alternative medicine (CAM) and grows to 57 members by 2013.
2000	American Board of Medical Acupuncture is established, with a certifying examination for physicians to demonstrate proficiency in the specialty of medical acupuncture.
2000	President Clinton appoints James S. Gordon, MD, to chair the first White House Commission on Complementary and Alternative Medicine Policy (WHCCAMP).
2002	WHCCAMP submits final report with administrative and legislative recommendations for maximizing the benefits of CAM for all Americans.
2005	Institute of Medicine (IOM) releases report on CAM in the United States. NCCAM releases 5-year strategic plan.
2006	CAHCIM sponsors the first North American Research Conference on Complementary and Integrative Medicine.
2009	IOM Summit on Integrative Medicine and the Health of the Public. CAHCIM sponsors a second research conference. NCCAM prepares its third strategic plan.
2011	Veterans Health Administration (VHA) launches a new Office of Patient-Centered Care and Cultural Transformation for “whole health.”
2013	World Health Organization (WHO) Traditional Medicine Strategy 2014-2023 is published to set the course for global traditional and complementary medicine.
2014	American Board of Integrative Medicine offers its first certifying examination.

focuses on the least invasive, least toxic, and least costly methods to help facilitate health by integrating allopathic and complementary therapies. These are based on an understanding of the physical, emotional, psychologic, and spiritual aspects of the individual.

In general, the terms *holistic* and *integrative* seem to best convey the ideal blending of conventional and unconventional medicine “in that both imply a balanced, whole-person-centered approach and involve a synthesis of conventional medicine, CAM modalities, and other traditional medical systems, with the aim of prevention and healing as a basic foundation” (Lee et al., 2004, p 10).

The term *integral* has recently emerged in the literature. First noted several decades ago in the book *Mind, Body and Health: Toward an Integral Medicine* (Gordon et al., 1984), its original use may be traced to the work of Sri Aurobindo, an Indian mystic and political leader. The term has been popularized by contemporary philosopher and transpersonal psychologist Ken Wilber (2005), as applied in the context of his *integral theory*. Many thought leaders in the field of health and healing, including the Institute of Noetic Sciences (IONS), support these concepts and encourage further research into what may be considered the beginnings of a paradigm shift in medicine (Schiltz, 2005). The following excerpt captures the essence of the deep change and transformation that integral medicine calls for (Wilber, 2005, pp xxx-xxxi):

The crucial ingredient in any integral medical practice is not the integral medical bag itself—with all the

conventional pills, and the orthodox surgery, and the subtle energy medicine, and the acupuncture needles—but the holder of that bag. Integrally informed health-care practitioners, the doctors, nurses, and therapists, have opened themselves to an entire spectrum of consciousness—matter to body to mind to soul to spirit—and who have thereby acknowledged what seems to be happening in any event. Body and mind and spirit are operating in self and culture and nature, and thus health and healing, sickness and wholeness, are all bound up in a multidimensional tapestry that cannot be cut into without loss.

Family physicians know this to be true. They practice with the intention to care for the whole patient within the context of a continuous healing relationship while honoring the rich complexity and interplay of family, community, and environment. They acknowledge the personal and interpersonal effects of health and illness and are trained to consider the behavioral and social aspects of a person’s life as well as the biomedical factors.

Now is the time not only to reclaim its roots, but also to move primary care into expanded dimensions and possibilities of health and healing. Family medicine is the ideal discipline to champion this movement and to actualize changes that will begin to heal the failing U.S. health care system. Whether it is called holistic, integrative, or integral, family physicians are collectively evolving toward a more compassionate and sustainable system of care that may ultimately be called *good medicine*.

Complementary and Alternative Medicine Use in the 1990s

Key Points

- Almost 40% of U.S. adults and 12% of children use complementary and alternative medicine (CAM) therapies.
- The number of adult Americans using CAM rose by 38% between 1990 and 1997 and has remained stable between 2002 and 2007.
- CAM is used more by women, by those with higher levels of education and income, and by those who were recently hospitalized.
- Most patients do not disclose CAM use to their physicians.
- Most patients use CAM and conventional care together.

The first major study of CAM use in the United States was conducted in 1990 by David Eisenberg and colleagues (1993), who published a landmark paper in the *New England Journal of Medicine*. Serving as a wake-up call to conventional medicine, the data from this national telephone survey of 1539 English-speaking adults estimated that one of three Americans (34%) had used a CAM therapy in the prior year. The study estimated that those using CAM had made 425 million visits to complementary medicine practitioners—more than all office visits to primary care physicians in that same time frame! The out-of-pocket costs for these CAM services were approximately \$14 billion a year. The striking statistics alerted mainstream medicine and prompted further inquiry into the growing phenomenon of the public's use of CAM.

In 1997, Eisenberg and colleagues conducted a follow-up to the 1990 study, again using a national telephone survey of English-speaking adults (2055). The findings, published in the *Journal of the American Medical Association* in 1998, showed that the number of Americans using CAM rose by 38% (60 to 83 million) and that visits to CAM practitioners increased from an estimated 427 million to 629 million. Overall, 42% of Americans were estimated to be using at least one CAM therapy in the prior 12 months. With regard to costs, conservative estimates put expenditures for CAM professional services at \$21.2 billion, with approximately \$12.2 billion paid as out-of-pocket expenses (Eisenberg et al., 1998).

Most concerning was the finding that although CAM use had increased over the 7-year period, the number of patients informing their doctors of such use had not changed—approximately 60% to 70% of CAM users in 1990 and 1997 did not discuss their use of CAM with their physicians. Lack of communication was noted again in a 2006 NCCAM/American Association of Retired Persons (AARP) survey of adults 50 or older revealing only one-third of CAM users had talked to their physicians about their CAM use (NCCAM/AARP, 2007). Given this fact and the potential for untoward side effects, it is essential that physicians and all other health professionals ask patients about their

Table 12-2 Guidelines for Advising Patients Who Seek Alternative Therapies

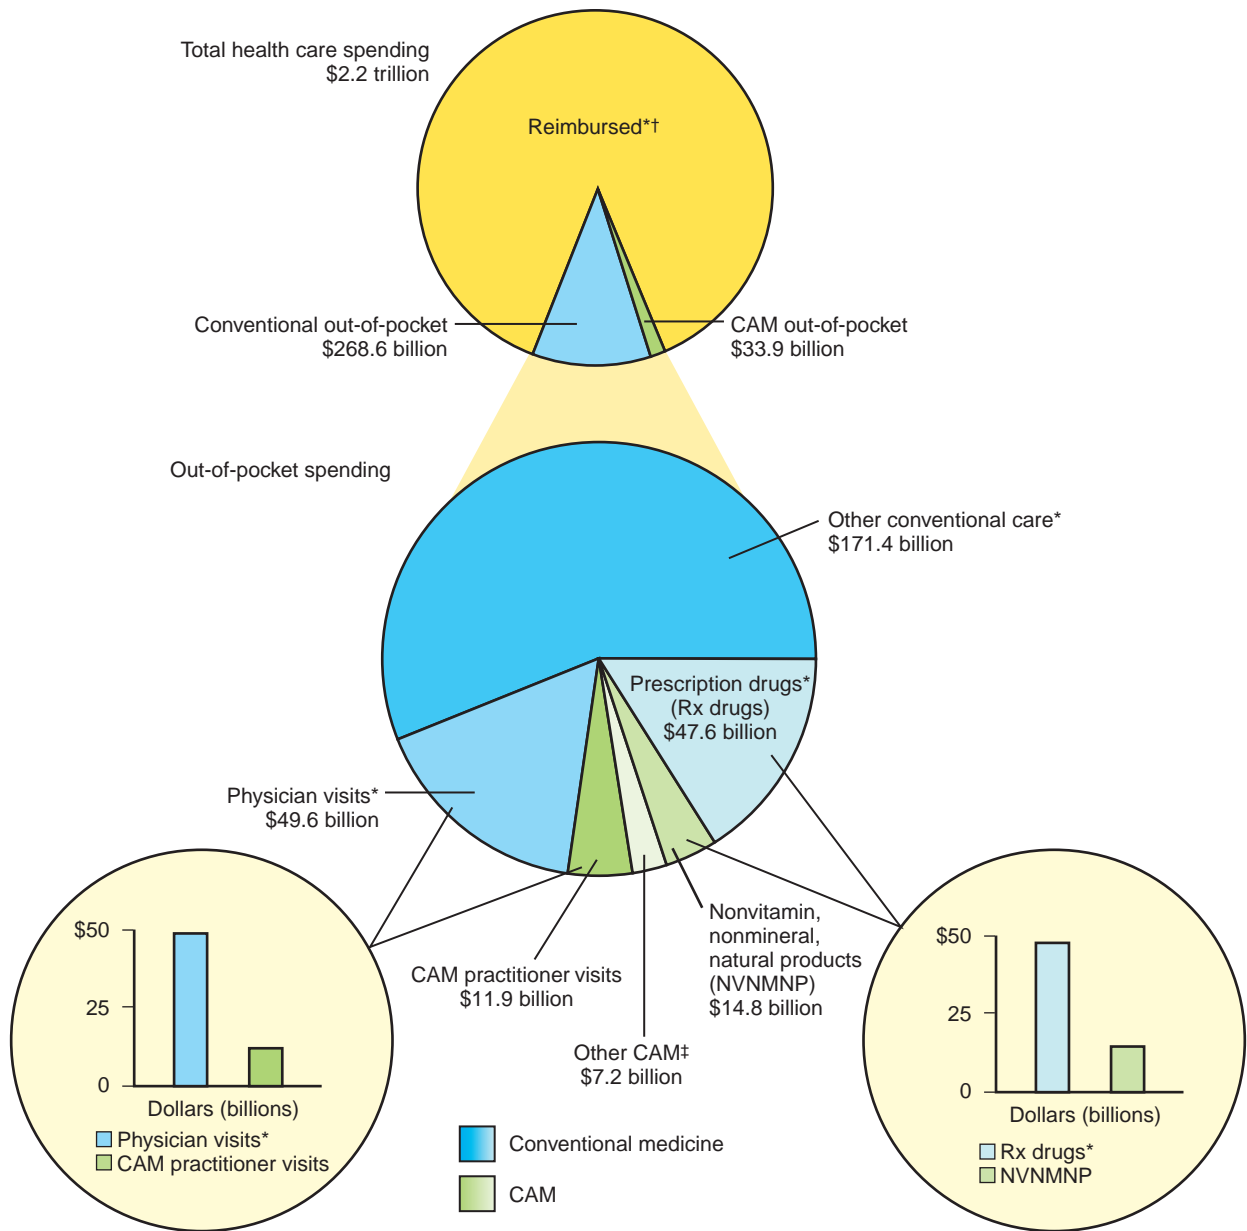

Ask; don't tell.
Be willing to listen and learn.
Communicate and collaborate.
Diagnose.
Explain and explore options and preferences.

use of CAM. In addition to NCCAM's "Time to Talk" campaign, several approaches have been suggested (Eisenberg, 1997); Table 12-2 lists an ABC format especially useful for the busy clinician (Sierpina, 2001).

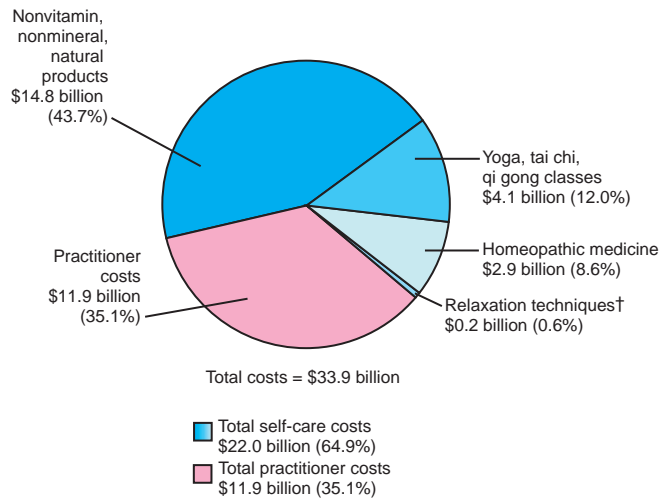

Complementary and Alternative Medicine Use in the 21st Century

Data on the U.S. population's use of CAM was collected in 2002, 2007 (published), and 2012 (publication pending). Considered the most comprehensive and reliable findings on Americans' use of CAM, these studies were conducted by the NCCAM and the National Center for Health Statistics (NCHS), part of the Centers for Disease Control and Prevention (CDC). For the first time, detailed questions regarding CAM were added into the 2002 edition of the NCHS National Health Interview Survey (NHIS), an annual study interviewing tens of thousands of Americans about their health- and illness-related experiences. The 2002 and 2007 studies were completed by approximately 30,000 families through adults 18 years or older who spoke English or Spanish. The study reflected CAM use during the 12 months before the survey. The 2007 survey included expanded questions on 36 types of CAM therapies commonly used in the United States: 10 practitioner-based therapies, such as acupuncture, and 26 other, self-care therapies not requiring a practitioner. CAM therapies included in the surveys are listed in Table 12-3, and the terms are defined in eAppendix 12-1.

As shown in Figure 12-2, CAM use increased from 36% of U.S. adults in 2002 to 38% in 2007, or almost 4 of 10 adults (Barnes et al., 2004, 2008). For the first time, the 2007 survey collected data on CAM use in children (<18 years), showing 12% use, or 1 in 9 children. The top 10 CAM therapies for both adults and children are shown in Figure 12-3. Significant increases in adults' use of deep breathing, meditation, massage, and yoga occurred over the 5 years of the study. Another notable NCCAM/AARP study focused on CAM use in adults older than 50 years. Approximately two-thirds (63%) had used one or more CAM therapies (NCCAM/AARP, 2007). The most common reasons cited for not discussing CAM included: the physician never asked (42%), the patient did not know they should ask (30%), and there was not enough time during the office visit (19%). Of those using CAM, 66% did so to treat a specific condition and 65% for overall wellness. For details on CAM costs in the United States, see eFigures 12-1 to 12-3 online.

eFigure 12-1 Combined total health care spending and out-of-pocket spending for conventional health care costs and complementary and alternative medicine (CAM). *National Health Expenditure Data for 2007. US Department of Health and Human Services, Centers for Medicare and Medicaid Services website. WHO IS MORE LIKELY TO USE COMPLEMENTARY AND ALTERNATIVE MEDICINE AND WHY?

Consistent with data from the 2002 NHIS study, CAM use by adults in 2007 was more prevalent among women; adults age 30 to 69; those with higher education level, not poor, or living in the West; former smokers; and those hospitalized in the prior year ([Barnes et al., 2008](#)). CAM use was positively associated with number of health conditions

Figure 12-2 Complementary and alternative medicine (CAM) use by U.S. adults (2002, 2007) and children (2007). (From Barnes PM, Bloom B, Nahin R. Complementary and alternative medicine use among adults and children: United States, 2007. *Natl Health Stat Rep*. December 2008;(12):1-23.)

and number of physician visits in the previous year. When concerned about cost or unable to pay for conventional care, adults were more likely to use CAM. For children, the 2007 data show no gender difference. For all therapies combined, CAM use was highest among adolescents age 12 to 17 years (16%) versus children age 5 to 11 years (11%) or preschool children age 0 to 4 years (8%). Children's use of CAM increased as their parents' education or income level increased, and when families were unable to afford conventional medical care. Children with a parent or other relative who used CAM were about five times as likely (23%) to use CAM as children whose parent did not (5%).

Figure 12-4 shows the disease or condition for which adults and children are most likely to seek CAM. The 2002 survey also addressed the important question: Why do people use CAM? Previous studies revealed general issues of the overuse of technology and a reductionist approach to care, managed-care time constraints limiting visits and eroding the physician-patient relationship, and the explosion of Internet-based information on CAM. [Astin \(1998\)](#) found that along with being more educated and reporting poor health status, most alternative medicine users were not dissatisfied with conventional medicine but rather found these health care alternatives to be more congruent with their own values, beliefs, and philosophic orientations toward health and life. Only 4.4% reported relying primarily on CAM therapies for their health care. A subsequent study of patients using both CAM and conventional care also found that use of CAM did not primarily reflect dissatisfaction with conventional care ([Eisenberg et al., 2001](#)).

Reasons for CAM use reported in the 2002 NHIS study are shown in **Figure 12-5**, with slightly more than one-half of all respondents believing CAM *combined with* conventional medicine would be helpful.

TRENDS IN COMPLEMENTARY AND ALTERNATIVE MEDICINE USE

The 2002 and 2007 NHIS data show that although the overall prevalence of CAM use by adults had remained relatively stable (36% and 38%, respectively), there have

Figure 12-3 A, Ten most common complementary and alternative medicine (CAM) therapies among adults in 2007. **B**, Ten most common CAM therapies among children in 2007. (From Barnes PM, Bloom B, Nahin R. Complementary and alternative medicine use among adults and children: United States, 2007. *Natl Health Stat Rep*. December 2008;(12):1-23.)

been significant increases in some therapies, including acupuncture, deep-breathing exercises, massage therapy, meditation, naturopathy, and yoga (see Figure 12-3). Several factors may account for this growth, including increasing state licensure of some of the practices and greater public awareness of their use through the press and Internet resources. Characteristics of adult and pediatric CAM users are similar in that education, poverty status,

geographic region, number of health conditions, physician visits in the prior year, and delaying or not receiving conventional care because of cost are all associated with CAM use. Overall reasons for CAM use fall into two equal categories: (1) treating a variety of health problems, especially pain, and (2) promoting general health and wellness. Much of CAM use is “self-care” and is mostly used with conventional care.

Figure 12-4 **A**, Disease or condition for which complementary and alternative medicine (CAM) therapies are most frequently used among adults in 2007. **B**, Disease or condition for which CAM therapies are most frequently used among children in 2007. *ADHD*, Attention-deficit/hyperactivity disorder. Important U.S. Reports

Key Points

- The White House Commission on complementary and alternative medicine (CAM) created a blueprint for public policy and health care transformation in 2002.

- The Institute of Medicine’s 2005 CAM report and 2009 summit called for expanding research, education, and clinical application.
- CAM challenges conventional research methods.
- CAM creates opportunities for innovative studies.
- The National Institutes of Health (NIH) National Center for Complementary and Alternative Medicine 2010 Strategic Plan sets an agenda for more CAM research.

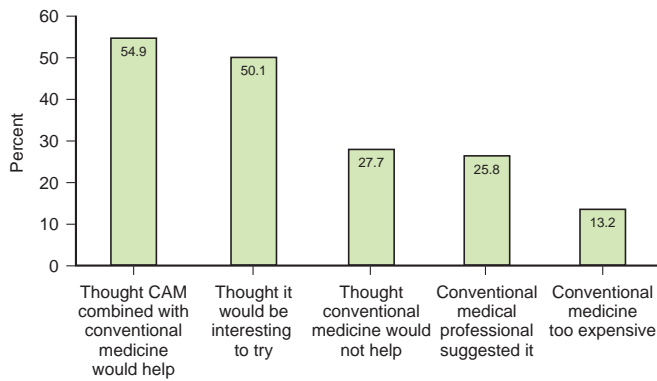

Figure 12-5 Reasons people use complementary and alternative medicine (CAM) therapies. (From Barnes PM, Powell-Griner E, McFann K, Nahin RL. Complementary and alternative medicine use among adults: United States, 2002. *Adv Data*. May 2004;(343):1-19.)

Table 12-4 Guiding Principles: 2002 White House Commission on Complementary and Alternative Medicine Policy

1. A wholeness orientation in health care delivery
2. Evidence of safety and efficacy
3. The healing capacity of the person
4. Respect for individuality
5. The right to choose treatment
6. An emphasis on health promotion and self-care
7. Partnerships are essential for integrated health care
8. Education as a fundamental health care service
9. Dissemination of comprehensive and timely information
10. Integral public involvement

Over the past two decades, several important reports have addressed CAM and integrative medicine in the United States. This section summarizes the major themes and recommendations.

WHITE HOUSE COMMISSION 2002 REPORT

The White House Commission on Complementary and Alternative Medicine Policy ([WHCCAMP](#)) 2002 report was the culmination of 18 months of in-depth work of a committee of 20 appointed commissioners. Their task was to provide the president, through the secretary of Health and Human Services, with a report containing legislative and administrative recommendations that would ensure a public policy that maximized the potential benefits of CAM to all. Specifically, the commission addressed the coordination of research to increase knowledge about CAM products; the education and training of health care practitioners in CAM; the provision of reliable and useful information about CAM practices and products to health care professionals; and guidance regarding appropriate access to and delivery of CAM. [Table 12-4](#) lists the 10 guiding principles the commission endorsed for their process of making recommendations. The final report lists 29 recommendations and more than 100 action steps as a blueprint for shaping future CAM policy.

INSTITUTE OF MEDICINE 2005 REPORT AND 2009 SUMMIT

The Institute of Medicine (IOM) of the National Academy of Sciences acts as a private, nonprofit society of scholars engaged in research dedicated to the promotion of science and technology for the public good. Because of the American public's increasing use of CAM and the many concerns regarding safety, efficacy, and information access, a report was commissioned and a committee charged to explore the emerging scientific, policy, and practice questions. The 300-page report released in 2005 gave specific recommendations in the domains of research, education, and clinical care; new and innovative approaches to research were considered essential. The IOM Committee Chair placed a "call to action" to researchers ([Bondurant and Sox, 2005](#), p 150):

Ignoring CAM is not an option. The widespread use of CAM by patients is a mandate to the scientific community to improve our relatively weak scientific understanding of CAM practices. Moreover, health professionals have a duty to their patients to bring these 2 worlds of contemporary medical practice together. The path to this outcome begins with adopting the same standards of evidence.

In 2009, IOM and the Bravewell Collaborative convened a 3-day summit, Integrative Medicine and the Health of the Public. More than 600 scientists, academic leaders, policy experts, health practitioners, advocates, and other participants from various disciplines examined the practice of integrative medicine, its scientific basis, and its potential for improving health. Note how the recurring themes and shared values listed in [Table 12-5](#) resonate with the principles of family medicine and the foundations of the PCMH. Family physician Victor Sierpina shared a vision for integrative medicine and the physician of the future ([Table 12-6](#)).

NATIONAL CENTER FOR COMPLEMENTARY AND ALTERNATIVE MEDICINE STRATEGIC PLAN 2010

Now in its third cycle of 5-year strategic planning, NCCAM continues to explore CAM healing practices in the context of science, train CAM researchers, and disseminate authoritative information to public and professional communities. NCCAM's course for 2010-2014 is to create priority areas of CAM research to focus efforts that would best serve public need while meeting fiscal realities, as guided by four factors: (1) scientific promise, (2) extent and nature of practice and use, (3) amenability to rigorous scientific inquiry, and (4) potential to change health practices. A recent, new research priority is focused on symptom management, specifically the role of mind-body interventions in managing pain and common chronic disease symptoms. ([Briggs and Killen, 2013](#))

[Nahin and Strauss \(2001\)](#) and [Ahn and Kaptchuk \(2005\)](#) discuss the unique challenges that CAM presents to conventional research approaches in evidence-based medicine.

Table 12-5 Recurring Perspectives from the Institute of Medicine Summit on Integrative Medicine and the Health of the Public

Vision of optimal health	Alignment of individuals and their health care for optimal health and healing across a full life span.
Conceptually inclusive	Seamless engagement of the full range of established health factors—physical, psychological, social, preventive, and therapeutic.
Life span horizon	Integration across the life span to include personal, predictive, preventive, and participatory care.
Person-centered	Integration around, and within, each person.
Prevention-oriented	Prevention and disease minimization as the foundation of integrative health care.
Team-based	Care as a team activity, with the patient as a central team member.
Care integration	Seamless integration of the care processes, across caregivers and institutions.
Caring integration	Person- and relationship-centered care.
Science integration	Integration across approaches to care (e.g., conventional, traditional, alternative, complementary), as the evidence supports.
Policy opportunities	Emphasis on outcomes, elevation of patient insights, consideration of family and social factors, inclusion of team care and supportive follow-up, and contributions to the learning process.

From Institute of Medicine (IOM). *Integrative medicine and the health of the public: summary of the February 2009 summit*. Washington, DC: National Academies Press; 2009, p 5.

Table 12-6 How the Physician of the Future Will Function

The Care Process Is ...	The Doctor's Role Will Be ...
Patient-centered	A navigator
Team based	Part of a multidisciplinary team
High touch, high tech	Grounded in the community
Genomic and personalized	Support of social and environmental policies promoting health
Preventive	
Integrative	
And Supports Patients Through ...	And Will Follow ...
Complementary and alternative practices	Evidence-based, outcome-focused practices
Belief that the body helps heal itself	Principles for creations of healing environments
	The lead of empowered patients

From Institute of Medicine (IOM). *Integrative medicine and the health of the public: summary of the February 2009 summit*. Washington, DC: National Academies Press; 2009, p. 43.

Many CAM study therapies are complex and heterogeneous compared with the more familiar single-drug trial of biomedicine. As such, innovative research strategies, such as those for sham acupuncture, will need to be continually developed. CAM may help the science of medicine to further evolve, as reflected on by [Linde and Jonas \(1999\)](#):

The continuing interface between orthodox and unorthodox medicine today provides the opportunity for new research strategies and methodologies to arise. By purposefully maintaining a creative tension between the established and frontier, we can advance scientific methods and more clearly define the boundaries and purpose of the scientific process for medicine.

Integrating Complementary and Alternative Medicine into Practice

Key Points

- Nutrition, mind-body medicine, and spirituality are core elements of integrative medicine practice.
- Strong evidence supports mind-body medicine for coronary artery disease, low back pain, and headache.
- Acupuncture is a safe and efficacious adjunctive treatment for several musculoskeletal conditions.
- Energy medicine researchers use current technologies to explore the frontiers of CAM.

Because the field of CAM and integrative medicine is so broad and includes so many different approaches and modalities, this section reviews core elements and then explores three common CAM modalities with evidence of efficacy: acupuncture, yoga, and homeopathy. Energy medicine, an important frontier of the CAM field, is also discussed.

CORE ELEMENTS OF INTEGRATIVE MEDICINE

Nutrition, mind-body medicine, and spirituality are considered core elements of an integrative medicine approach and often are applied during patient consultation. These elements also tend to be cost-effective and patient empowering. Considered the foundation of good health and enhanced healing, nutritional principles are key elements in most treatment plans.

The adage “food is medicine” is becoming ever more important as the United States, as well as other world populations, face impending epidemics of diabetes and obesity. Research has shown the health benefits and cost-effectiveness of the Mediterranean diet for primary and secondary prevention of metabolic syndrome ([Kastorini et al., 2011](#)). When the new food pyramid was released by the U.S. federal government (MyPyramid.gov), critics such as Walter Willett commented, “This is a huge lost

Figure 12-6 The Healing Foods Pyramid emphasizes “healing foods,” which are known to have healing benefits or essential nutrients; plant-based choices, which create the base and may be accented by animal foods; variety and balance of color, nutrients, and portions sizes; a healthful environment; and “mindful eating” to savor and focus on the food being eaten. (Courtesy Monica Myklebust, MD, and Jenna Wunder, MPH, RD, University of Michigan Integrative Medicine Clinical Services, Regents of the University of Michigan. <http://med.umich.edu/umim/food-pyramid/index.htm>.)

opportunity to convey information about healthy food choices that could benefit Americans enormously. ... The pyramid tells nothing of healthy food choices” (Mitka, 2005, p 2581).

Other options are considered in the Healing Foods Pyramid (Figure 12-6). While developing the best nutrition advice for the diverse people seen at the University of Michigan’s Integrative Medicine Clinic, family physician Monica Myklebust found various recommendations for the prevention and treatment of obesity, mood disorders, heart disease, diabetes, chronic pain, and inflammation. The result of her work is a user-friendly tool that brings all of these data together. Omega-3 fatty acids, antioxidants, medicinal seasonings, soy, chocolate, and tea are all considered. For example, green tea offers a variety of health benefits, with emerging evidence for prevention of cancer, stroke, and cardiovascular disease (Schneider and Segre,

2009). Health concerns regarding the sources of U.S. food and recommendations for organic and wild food are discussed. The Healing Foods Pyramid is available as a web-based interactive version (<http://med.umich.edu/umim/food-pyramid/index.htm>). The top is left open to be filled in by what individuals feel may complete and customize their pyramid.

A particular aspect of nutrition that has received increasing attention for its value in lessening inflammation is that of fish oil (i.e., omega-6 and omega-3 fatty acids). Omega-3 fatty acids consist of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) and are mostly found in fatty fish, such as herring and salmon. Because inflammation plays a role in several common conditions, such as cardiovascular disease, asthma, arthritis, psoriasis, and inflammatory bowel disease, research has explored the role of omega-3 fatty acids in reducing symptoms and improving outcomes.

Practical applications for recommending fish oil in the primary care setting included the following (Oh, 2005):

1. The American Heart Association recommends 1 gram (g) per day for all patients with documented coronary artery disease through diet or through supplementation.
2. For patients with mild or persistent hypertriglyceridemia, use of 2 to 4 g per day of fish oil may lower levels by 20% to 50% to reach NIH National Heart, Lung, and Blood Institute (NHLBI) Adult Treatment Panel (ATP) III goals.
3. For those with rheumatoid arthritis, doses of 2.6 to 6 g per day for at least 8 to 12 weeks are optimal and may reduce or eliminate nonsteroidal antiinflammatory drug (NSAID) use.

Monitoring for clinical bleeding and for low-density lipoprotein (LDL) cholesterol and glycemic response should be considered for patients taking doses higher than 3 g/day, especially if they are diabetic. Unfortunately, because our waters are polluted with heavy metals, avoiding fish known to have high methyl mercury levels (especially by women who are pregnant and of childbearing age) is an important precaution when discussing fish oil use with patients (Williams, 2005). Along with fish oil consumption, other dietary modifications are also known to help lessen inflammation; Table 12-7 shows guidelines for prescribing an antiinflammatory diet (Rakel, 2003; Rakel and Rindfleisch, 2006).

MIND-BODY MEDICINE

The area of CAM with perhaps the most extensive research base is mind-body medicine, which encompasses a diverse array of practices that overlap many traditions and whole systems of care. Astin and colleagues (2003, p 131) concluded, "There is now considerable evidence that an array of mind-body therapies can be used as effective adjuncts to conventional medical treatment for a number of common clinical conditions." They found strong evidence to support mind-body approaches in the treatment of low back pain, coronary artery disease, headache, insomnia, preparing for surgical procedures, and in the management of disease-related symptoms of cancer, arthritis, and urinary incontinence.

Given the relative ease of learning and employing such techniques, NCCAM has made research into mind-body medicine a priority. Mind-body medicine approaches may enhance healing and optimize health. They may be recommended to most patients for health maintenance and disease management and could easily be incorporated into a PCMH through group visits or health coaches. In addition, a study of 70 primary care physicians who participated in an intensive mindfulness education program over 1 year showed dramatic improvements in mindfulness skills, burnout, mood disturbance, and empathy (Krasner et al., 2009). An accompanying editorial noted that the study "demonstrates that training physicians in the art of mindful practice has the potential to promote physician health *through* work." Also, recognizing and enhancing the meaning derived from the practice of medicine using these skills may "protect against burnout and promote

Table 12-7 Guidelines in Prescribing an Antiinflammatory Diet

1. Omega-3 and omega-6 fatty acids are essential polyunsaturated fatty acids (i.e., they cannot be made by the human body).
2. The ratio of omega-6 to omega-3 fatty acids in the average Western diet has steadily increased in the past 100 years. The standard American diet has a ratio of omega-6 to omega-3 of more than 20:1, but the ideal range is less than 4:1.
3. To follow an antiinflammatory diet, take the following steps:
 - a. Decrease red meat, poultry, and dairy intake.
 - b. Increase the intake of omega-3 fatty acids, such as cold-water fish, flaxseed, walnuts, and green leafy vegetables.
 - c. Even one meal of cold-water fish weekly reduces the risk of cardiac arrest. Consuming fish twice each week is ideal. If this is not possible, fish oil supplements can be taken at a dose of 500-2000 mg twice daily.
 - d. An alternative is ground flax seeds or flaxseed oil. Flax should be freshly ground because it can spoil after exposure to light or heat. Supplementation can be provided with 500-2000 mg of flax oil twice daily.
 - e. Reduce foods that contain omega-6 fatty acids, including the following:
 - (1) Margarine.
 - (2) Oils made from corn, cottonseed, grapeseed, peanut, safflower, sesame, soybean, or sunflower (avoid partially hydrogenated oils).
 - (3) Foods with a long shelf life, such as crackers and chips.
 - f. Cook with monounsaturated oils such as olive or canola oil.
4. Consider this dietary approach to treat the following:
 - a. Heart disease or associated risk factors
 - b. Inflammatory rheumatic disorders
 - c. Autoimmune diseases
 - d. Chronic pain
5. Low-carbohydrate, high-protein diets tend to have high omega-6 fat content and should be used with caution.
6. It may take up to 6 months to see the full clinical effects of an antiinflammatory diet.

From Rakel D, Rindfleisch A. Integrative medicine. In: Rakel RE, ed. *Essential family medicine: fundamentals and case studies*. Philadelphia: Saunders; 2006, pp. 132-141.

patient-centered care for the benefit of both physicians and their patients" (Shanafelt, 2009, p 1340). A recent abbreviated mindfulness intervention adapted for primary care clinicians was associated with reductions in indicators of job burnout, depression, anxiety, and stress (Fortney et al., 2013) and a multicenter study found that clinicians who rate themselves more mindful engage in more patient-centered communication and have more satisfied patients (Beach et al., 2013).

Online **eAppendix 12-2** highlights a well-known and well-studied mind-body technique called *mindfulness-based stress reduction* (MBSR) and includes a short audio sample of mindful breath work for the interested reader to try.

SPIRITUALITY

Another area thought to be integral to a whole-patient integrative medicine approach to care is spirituality. This broad and controversial subject is well reviewed (e.g., Sierpina and Sierpina, 2004); some key issues are considered here. Working definitions and terms from the Samuelli Conference on Definitions and Standards in Healing Research (Dossey, 2003) include the following:

- **Spirituality** encompasses the feelings, thoughts, experiences, and behaviors that arise from a search for that

which is generally considered sacred or holy. Spirituality is usually considered to involve a sense of connection with an absolute, imminent, or transcendent spiritual force, however named, as well as the conviction that meaning, value, direction, and purpose are valid aspects of the universe.

- **Religion** is the codified and ritualized beliefs and behaviors of those involved in spirituality, usually taking place within a community of like-minded individuals.
- **Prayer** is communication with an absolute, imminent, or transcendent spiritual force, however named. Such communication may take a variety of forms and may be theistic or nontheistic in nature, as in some forms of Buddhism. *Intercessory prayer* is an appeal to such a force to influence another person or thing. *Healing prayer* is an appeal to such a force for the healing and recovery of self or others. *Directed prayer* is offered with a specific outcome in mind. *Non-directed prayer* is offered with no specific outcome in mind, such as, “Thy will be done,” or “May the best outcome prevail.”

Given recent statistics on prayer from the 2002 NHIS and Gallup Polls over the past six decades (showing that more than 90% of Americans believe in God or a universal spirit), it is not surprising that proponents and critics have agreed that taking a spiritual history is essential to a comprehensive and culturally sensitive medical consultation. Just as challenging as asking patients about substance abuse, domestic violence, and sexual practices, a spiritual history helps elucidate how spiritual beliefs or religious practices may impact health and health-related choices. Such discussions may be most relevant during times of a new diagnosis, loss of a loved one, onset of depression, or terminal illness. Continuity of care and sensitivity to the biopsychosocial aspects of a patient’s life foster the rapport to facilitate such discussion. Such inquiry may also help engage support systems or identify deep conflicts. Although not all physicians may be comfortable addressing spirituality with their patients, referrals to colleagues in pastoral care and chaplaincy are options to consider.

Interviewing seven physicians recognized as leaders in the field of healing research, Egniew (2005, pp 258 and 255) found that “healing was defined in terms of developing a sense of personal wholeness that involves physical, mental, emotional, social and spiritual aspects of human experience.” The central theme in the responses provided an operational definition of healing: “Healing is the personal experience of the transcendence of suffering.”

Various models have been suggested as guides to taking the spiritual history (Table 12-8) (Anandarajah and Hight, 2001; Kinney, 1999; Puchalski and Romer, 2000).

ACUPUNCTURE, YOGA, AND HOMEOPATHIC REMEDIES

Three areas of CAM are most likely to be encountered in the family physician’s office: acupuncture, yoga, and homeopathic remedies. As shown in Table 12-9, these three areas are components of whole systems or *nonallopathic* medical systems of care: *acupuncture* within traditional Chinese medicine (TCM), *yoga* as a part of Ayurveda, and *homeopathic remedies* as the mainstay of homeopathy. Many family

Table 12-8 Spiritual Assessment Tools

FICA MNEMONIC

F: Faith or belief—What is your faith or belief?

I: Importance and influence—Is it important in your life? How?

C: Community—Are you part of a religious community?

A: Awareness and addressing—What would you want me as your physician to be aware of? How would you like me to address these issues in your care?

HOPE MNEMONIC

H: Hope—What are your sources of hope, meaning, strength, peace, love, and connectedness?

O: Organized—Do you consider yourself part of an organized religion?

P: Personal spirituality and practices—What aspects of your spirituality or spiritual practices do you find most helpful?

E: Effects—How do your beliefs affect the kind of medical care you would like me to provide?

THREE QUESTIONS

1. What helps you get through tough times?
2. Who do you turn to when you need support?
3. What meaning does this experience have for you?

physicians have pursued professional training in these fields and are now integrating new skills and perspectives into their practice. The Society of Teachers of Family Medicine (STFM) *Group on Hospital Medicine and Procedural Training* has proposed that acupuncture become an advanced procedure within the scope of family medicine training (Kelly, 2009).

Although challenging to research, trials have shown acupuncture efficacious as an adjunctive therapy in osteoarthritis of the knee (Berman et al., 2004) and as a complement to standard therapy for the debilitating effect of pelvic girdle pain during pregnancy (Elden et al., 2005). Cochrane reviews have shown that acupuncture benefits patients with chronic low back pain, neck pain, and headache (migraine and tension) (Kelly, 2009). A meta-analysis evaluating 33 randomized controlled trials (RCTs) of acupuncture for acute and chronic low back pain concluded that acupuncture effectively relieves chronic low back pain, although no evidence suggests that it is more effective than other active therapies (Manheimer et al., 2005). A more recent review found acupuncture a reasonable referral option for chronic pain (Vickers et al., 2012).

Excellent reviews of acupuncture’s theory, efficacy, and practice (Kaptchuk, 2002; Nielsen and Hammerschlag, 2004) cite the 1997 NIH Consensus Development Panel findings on acupuncture. After reviewing all available evidence from RCTs up to 1997, the panel concluded that clear evidence shows that acupuncture is efficacious for adult postoperative and chemotherapy nausea and vomiting and for postoperative dental pain. The panel also reported that acupuncture should be considered a useful adjunct for addiction, stroke rehabilitation, osteoarthritis, headache, low back pain, tennis elbow, menstrual cramps, carpal tunnel, and fibromyalgia (NIH, 1998).

Yoga, a widely popular and rapidly increasing CAM practice in the United States, has its roots in ancient India and is a Sanskrit word that means “yoke” or “union.” The original goal of practicing these postures was to purify and

Table 12-9 Nonallopathic Medical Systems**TRADITIONAL CHINESE MEDICINE**

Philosophy: Qi and other substances flow through the body through various channels, or meridians. Yin and yang (i.e., passive and active) and the five elements (i.e., wood, fire, earth, metal, and water) have competing influences on various body parts. Excesses or deficiencies of these cause illness. Pain is blocked qi.

Diagnostics: A specific diagnosis is not needed. Information is gathered by the four kanbing: looking (i.e., observation of posture, coloring, gait, demeanor, appearance of the tongue); asking about the status of the 11 basic areas, including body temperature, sleep, fluid metabolism, pain, and digestion; listening to the body's sounds, including breathing, voice, and peristalsis; and palpation of the affected site and the pulse. The pulse is thought to have three parts that correlate with the status of different parts of the body.

Therapeutics: Acupuncture is the insertion of needles into various points along the qi meridians. Moxibustion is the burning of moxa (*Artemisia vulgaris*) on or near meridian points. Gua sha is pressing the skin with a hard, round-edged instrument to create petechiae. Cupping is the creation of a vacuum in a cup and applying the vacuum pressure to the skin. Tui na is manipulation or massage with specific hand movements. Plum blossom is a cluster of needles that is moved along a meridian. Herbal therapies typically are combinations of multiple herbs mixed specifically for the individual patient.

AYURVEDA

Philosophy: The concept emerged in India 5000 years ago, and it incorporates five elements and three types of energy, or doshas. *Vata* is the dosha associated with movement, *pitta* governs metabolism, and *kapha* maintains structure. Diet, lifestyle, and relationships shape a person's energy and define health status. Ancient texts divide illnesses according to subspecialties, many of which are the same as for biomedicine.

Diagnostics: Factors that may have weakened the person's defenses are considered, such as genetics, trauma, diet, habits, seasonal affects, climate, age, balance of the doshas, emotions, metabolism, and acts of God. A full physical examination includes evaluation of pulses, speech and voice, eyes, tongue, and the appearance of the urine and feces.

Therapeutics: Approaches include prevention, detoxification, reestablishment of one's unique constitutional balance. Foods, emotions, and behaviors are used to adjust dosha levels. Panchakarma is used to remove aggravated doshas and toxins. Components of panchakarma include therapeutic vomiting, use of purgatives or laxatives, nasal administration of medications, blood purification (traditionally by blood-letting, now more often with teas), and therapeutic enemas.

NATUROPATHY

Philosophy: The body is able to heal itself by means of the healing power of nature. Healing occurs through a diet of natural, unrefined foods; adequate exercise; avoidance of environmental toxins; proper elimination of body wastes; and positive thoughts and emotions. Key principles in patient care include doing no harm, taking a preventive approach, and focusing on maintenance of health rather than just on the treatment of disease. The naturopath's goals are to educate, empower, and motivate.

Diagnostics: Methods may draw from any number of approaches, including laboratory testing not commonly performed in a biomedical setting.

Therapeutics: Approaches can include nutrition, botanicals, homeopathy, Chinese medicine, physical medicine (e.g., ultrasound, massage, manipulation), hydrotherapy (e.g., baths, steams, wraps, colonic irrigation), and various detoxification regimens.

HOMEOPATHY

Philosophy: Homeopathy is based on the law of similars, which holds that medicines can produce the same symptoms in healthy people that they cure in those who are ill. Remedies are used in the smallest quantity possible, which can often mean they are diluted to the point that not even a molecule of the original therapeutic substance remains in solution.

Diagnostics: A detailed history is taken relating to the specific nature of symptoms. For example, otitis media is treated differently based on the mood of the child, which ear is sore, the nature of the fever, and the nature of the pain.

Therapeutics: A remedy that has elicited a similar set of symptoms in a healthy patient is given in minute quantity to the ill person. The degree to which a remedy is diluted is given as a Roman numeral. For example, a 6X solution has been diluted to one-tenth of its strength six times (i.e., to 10^{-6} of the original strength), and a 200C solution has been diluted to 1/100 of its original strength 200 subsequent times (i.e., to 10^{-400} of its original strength).

From Rakel D, Rindfleisch A: Integrative medicine. In: Rakel RE, ed. *Essential family medicine: fundamentals and case studies*. Philadelphia: Saunders; 2006, pp 132-141.

prepare the body for higher states of consciousness. *Hatha yoga*, as described in [Table 12-10](#) along with other types of movement therapies, has many different styles and is the most popular form taught and practiced in the United States today. Because most yoga instructors are not medical professionals, it is recommended to refer a patient to a teacher with several years' experience. A study of the efficacy of yoga on pregnancy outcome ($N = 335$) concluded that an integrated approach to yoga during pregnancy was safe and that it improved birth weight and decreased preterm labor and intrauterine growth retardation with no complications ([Narendran et al., 2005](#)). A recent study of 90 patients with chronic low back pain who participated in a 24-week trial of yoga twice a week showed those receiving the yoga intervention experienced decreased levels of pain, functional disability, and depression ([Williams et al., 2009](#)). The International Association of Yoga Therapists (IAYT) is a worldwide organization for yoga teachers, therapists,

and researchers (www.iayt.org). The Yoga Alliance (www.yogaalliance.org), formed in 1999, sets minimum training standards for yoga teachers. Both organizations provide sound resources for professionals and the public.

Perhaps the most controversial of CAM therapies, *homeopathy* seems to defy biomedicine's attempts to decipher its mechanism of action. Particularly perplexing is the concept that the more dilute the remedy, the more potent is its effect. Founded by the German physician Samuel Hahnemann (1755-1843), homeopathy is still widely accepted and practiced in Europe and is now experiencing a renaissance in the United States. A brilliant linguist and scholar, Dr. Hahnemann developed the Principle of Similars, in which "like cures like" based on his medical translation work and personal experience of malaria symptoms after taking *Cinchona* bark, which was then the treatment for the disease. A critical overview of homeopathy by [Jonas and colleagues \(2003\)](#) reviewed the research regarding specific conditions

Table 12-10 Commonly Used Movement Therapies

Therapy*	Description	Research
Hatha yoga	Focuses on the use of postures (asanas) and breathing exercises (pranayama); traditionally used in India to purify the body and maximize the impact of meditation practice; many different schools; must be used with caution by those with glaucoma, retinal detachment, or at high risk for muscle strain or fracture.	Most trials are quite small. Positive benefits likely for musculoskeletal and other types of pain; lowering autonomic nervous system sympathetic tone; decreasing histamine effects of FEV ₁ in asthmatic patients; reducing blood pressure; improving headaches, diabetes, osteoarthritis, rheumatoid arthritis; overall improvement in balance, endurance, and vitality.
Tai chi	Developed more than 5000 years ago; movement and breathing, often associated with specific flowing movement patterns, are used to affect the flow of energy, or qi.	Useful adjunctive therapy for arthritis and cardiovascular disease. Helpful for improving postural stability and decreasing fall risk in older adults.
Qigong (Qi gong)	Part of traditional Chinese medicine; also used to cultivate qi; includes breathing exercises, meditation, and physical movement; used in the martial arts and to generate energy to be used in healing.	Most studies conducted in China. Potentially useful for hypertension, decreasing overall stroke and mortality rates compared with controls, decreasing peripheral vascular resistance, increasing bone density; improvement of blood flow to brain (e.g., adjunctive treatment for memory loss, dizziness, insomnia, vertigo); improvement of cardiac output, ejection fraction, and valve function.
Feldenkrais	Developed by Moshe Feldenkrais in the 1950s; gentle movements and manipulation enlisted to retrain the body with new movement patterns.	Limited randomized trial-based research. Used to promote flexibility and posture, decrease back pain, and improve vocal cord function.

From Rake D, Rindfleisch A. Integrative medicine. In: Rake RE, ed. *Essential Family Medicine: Fundamentals and Case Studies*. Philadelphia: Saunders; 2006, pp 132-141.

FEV₁, Forced expiratory volume in 1 second.

*Other therapies include *Alexander technique*, which uses minimal effort to maximize efficiency of muscle use and alleviate problems associated with poor posture, and *Pilates*, which also uses exercises and other techniques used to strengthen postural muscles.

and the placebo effect. After analyzing systematic reviews of clinical trials, the authors concluded, “Despite skepticism about the plausibility of homeopathy, some randomized, placebo-controlled trials and laboratory research report unexpected effects of homeopathic medicine. However, the evidence on the effectiveness of homeopathy for specific clinical conditions is scant, is of uneven quality, and is generally poorer quality than research done in allopathic medicine” (p 397).

Known for his groundbreaking research showing homeopathic treatment of allergic rhinitis more effective than placebo (Taylor et al., 2000), David Reilly of Glasgow, Scotland, commented on the increasing scientific validation for homeopathy over the past decade. Noting that studies reviewed show positive evidence for overall effect and citing the growing prospective, observational research that indicates beneficial outcomes, Reilly (2005) points out that homeopathy can offer therapeutic options when conventional care has failed or reached a plateau, no conventional treatments exist, conventional treatments are contraindicated, side effects of conventional treatments are not tolerated, and patients are reluctant to accept conventional care. An important distinction clouds other areas of medical research: “The two dimensions of care need to be considered: the direct effects of the remedy and the therapeutic impact of the method of approach on the patient” (p 30). Believing that the homeopathic approach is helping to reintroduce a holistic perspective in medical practice, Reilly concludes, “The evidence mosaic for homeopathy reinforces clinicians’ and patients’ experiential knowledge that this approach can make a valuable contribution to care, especially when applied with a whole person perspective and integrated with conventional knowledge” (p 31).

ENERGY MEDICINE: FRONTIER SCIENCE OF COMPLEMENTARY AND ALTERNATIVE MEDICINE

The practice of CAM presents many challenges to Western science. How does acupuncture work, and what is *qi*? How can dilute homeopathic remedies induce effects on biologic systems? What are the *chakras*, or energy centers, so integral to yoga and Ayurveda? These mysteries present us with opportunities for new discoveries and an expansion of our healing capacities (eAppendix 12-3). Many scientists are showing how research in biophysics and biomagnetism is helping to elucidate the subtle energies of biologic systems, including those of humans. Advanced technologies such as functional magnetic resonance imaging and infrared thermography are demonstrating amazing images that seem to correlate with empiric knowledge (eAppendix 12-4).

Open-minded scientists are helping to bridge the worlds of CAM and conventional medicine by linking research findings to those of clinical practice (Oschman, 2002). “Let us document each of these fascinating clues. We will connect the dots by describing an information system in the body that is the missing link for many phenomena that have seemed hopelessly inexplicable in the past. It is a system that is responsible for extraordinary feats of perception, movement, and healing” (Oschman, 2003, p. xiv).

Conclusion

Complementary and alternative medicine is an evolving area of health care used by approximately 4 in 10 adults and 1 in 9 children in the United States. As a diverse system

Table 12-11 Precautions in Complementary and Alternative Medicine

1. *Primum non nocere* (first, do no harm).
2. Patients may encounter complications if they abandon effective, conventional therapies in favor of complementary and alternative medicine (CAM).
3. Medicolegal issues and certification or qualification requirements of practitioners are important topics, not covered in this chapter.

of varied approaches and philosophies of healing, CAM is usually incorporated into conventional health care as integrative medicine. CAM presents opportunities to expand the current research paradigm to meet the challenges of studying its multidimensional approach to health and healing. Prominent organizations such as the IOM and World Health Organization (WHO) have placed a call to action to the medical community to advance knowledge and clinical applications in this field. Family physicians, specialists in caring for the whole person through a continuous, healing relationship, are in the ideal discipline to advance the integration of safe and effective CAM into their repertoire to optimize the health of their patients (Table 12-11). Ultimately, complex terminology will subside as the essence of integrative medicine becomes good family medicine.

KEY TREATMENT

- Fish oil supplementation can benefit heart health (Bucher et al., 2002; Wang et al., 2004), hypertriglyceridemia (Balk et al., 2004), and rheumatoid arthritis (Fortin et al., 1995; MacLean et al., 2004) (SOR: A).
- Acupuncture should be considered as a treatment option for common painful conditions such as chronic low back pain (Furlan et al., 2005; Yuan et al., 2008), neck pain (Fu et al., 2009; Trinh et al., 2006), and headache (migraine, tension) (Linde et al., 2009a, 2009b) (SOR: A).
- Green tea is associated with decreased risk of stroke and cardiovascular disease (Kuriyama et al., 2006) and may help prevent cancer of the breast (Sun et al., 2006a),

gastrointestinal tract (Sun et al., 2006b), and prostate (Kurahashi et al., 2008) (SOR: B).

- Yoga reduces functional disability, pain, and depression in people with chronic low back pain (Williams et al., 2009) (SOR: B).
- Mindful communication may improve physician well-being and attitudes associated with patient-centered care (Kearney et al., 2009; Krasner et al., 2009) (SOR: C).

Glossary of Complementary and Alternative Medicine (CAM) Terms

Acupuncture Family of procedures involving stimulation of anatomic points on the body by a variety of techniques. American practices of acupuncture incorporate medical traditions from China, Japan, Korea, and other countries. The acupuncture technique that has been most studied scientifically involves penetrating the skin with thin, solid, metallic needles that are manipulated by the hands or by electrical stimulation.

Alexander technique Movement therapy that uses guidance and education on ways to improve posture and movement. The intent is to teach a person how to use muscles more efficiently to improve the overall functioning of the body. Examples of the Alexander technique as CAM are using it to treat low back pain and the symptoms of Parkinson disease.

Alternative provider, alternative practitioner Someone who is knowledgeable about a specific alternative health practice. This person provides care or gives advice about its use and usually receives payment for his or her services. For some practices, the provider may have received formalized training and has been certified by a licensing board or related professional association. For example, a practitioner of biofeedback (biofeedback therapist) usually has received training in psychology and physiology and may be certified by the Biofeedback Certification Institute of America.

Ayurveda System of medicine that originated in India several thousand years ago. In the United States, Ayurveda is considered a type of CAM and a whole medical system. As with other such systems, it is based on theories of health and illness and on ways to prevent, manage, or treat health problems. Ayurveda aims to integrate and balance the body, mind, and spirit (thus some view it as “holistic”). This balance is believed to lead to contentment and health and to help prevent illness. However, Ayurveda also proposes treatments for specific health problems, whether they are physical or mental. A chief aim of Ayurvedic practices is to cleanse the body of substances that can cause disease, and this is believed to help reestablish harmony and balance.

Biofeedback Technique that uses simple electronic devices to teach clients how to consciously regulate bodily functions, such as breathing, heart rate, and blood pressure, to improve overall health. Biofeedback is used to reduce stress, eliminate headaches, recondition injured muscles, control asthmatic attacks, and relieve pain.

Botanica Traditional healer who supplies healing products, sometimes associated with spiritual interventions.

Chelation therapy Chemical process in which a substance is used to bind molecules, such as metals or minerals, and hold them tightly so that they can be removed from a

system, such as the body. In medicine, chelation has been scientifically proven to rid the body of excess or toxic metals. For example, a person who has lead poisoning may be given chelation therapy to bind and remove excess lead from the body before it can cause damage.

Chiropractic care Adjustment of the spine and joints to influence the body’s nervous system and natural defense mechanisms to alleviate pain and improve general health. It is primarily used to treat back problems, headaches, nerve inflammation, muscle spasms, and other injuries and trauma.

Chiropractic manipulation Form of health care that focuses on the relationship between the body’s structure, primarily of the spine, and function. Doctors of chiropractic, who are also called chiropractors or chiropractic physicians, use a type of hands-on therapy called manipulation (or adjustment) as their core clinical procedure.

Complementary and alternative medicine (CAM) Therapies not usually taught in U.S. medical schools or generally available in U.S. hospitals. Also called *integrative*, these therapies include a broad range of practices and beliefs such as acupuncture, chiropractic care, relaxation techniques, massage therapy, and herbal remedies. They are defined by the National Center for Complementary and Alternative Medicine as a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine.

Curandero Type of traditional folk healer. Originally found in Latin America, curanderos specialize in treating illness through the use of supernatural forces, herbal remedies, and other natural medicines.

Deep breathing Slow and deep inhalation through the nose, usually to a count of 10, followed by slow and complete exhalation for a similar count. The process may be repeated 5 to 10 times, several times a day.

Energy healing therapy Channeling of healing energy through the hands of a practitioner into the client’s body to restore a normal energy balance and, therefore, health. Energy healing therapy has been used to treat a wide variety of ailments and health problems and is often used with other alternative and conventional medical treatments.

Espiritista Traditional healer who assesses a patient’s condition and recommends herbs or religious amulets to improve physical or mental health or to help overcome a personal problem.

Feldenkrais Movement therapy that uses a method of education in physical coordination and movement. Practitioners use verbal guidance and light touch to teach the method through one-on-one lessons and group classes. The intent is to help the person become more aware of how

the body moves through space and to improve physical functioning.

Guided imagery Series of relaxation techniques followed by the visualization of detailed images, usually calm and peaceful in nature. If used for treatment, individuals will visualize their body free of the specific problem or condition. Sessions typically are 20 to 30 minutes and may be practiced several times a week.

Hierbero Traditional healer or practitioner with knowledge of the medicinal qualities of plants; also called *yerbera*.

Homeopathy System of medical practices based on the theory that any substance that can produce symptoms of disease or illness in a healthy person can cure those symptoms in a sick person. For example, a person with insomnia may be given a homeopathic dose of coffee. Administered in diluted form, homeopathic remedies are derived from many natural sources, including plants, metals, and minerals.

Hypnosis Altered state of consciousness characterized by increased responsiveness to suggestion. The hypnotic state is attained by first relaxing the body, then shifting attention toward a narrow range of objects or ideas as suggested by the hypnotist or hypnotherapist. The procedure is used to effect positive changes and to treat numerous health conditions, including ulcers, chronic pain, respiratory ailments, stress, and headaches.

Macrobiotic diet Low-fat diet that emphasizes whole grains and vegetables and restricts the intake of fluids; of particular importance is the consumption of fresh, nonprocessed foods.

Massage Manipulation of muscle and connective tissue to enhance function of those tissues and promote relaxation and well-being.

Meditation Group of techniques, most of which started in Eastern religious or spiritual traditions. In meditation, persons learn to focus their attention and suspend the stream of thoughts that normally occupy the mind. This practice is believed to result in a state of greater physical relaxation, mental calmness, and psychological balance. Practicing meditation can change how a person relates to the flow of emotions and thoughts in the mind.

Native American healer Traditional healer who uses information from the “spirit world” to benefit the community; patients especially seek to find relief or a cure from illness or to find spiritual guidance; also called *medicine man*.

Naturopathy Alternative medical system that proposes that a healing power in the body establishes, maintains, and restores health. Practitioners work with patients to support this power through treatments such as nutrition and lifestyle counseling, dietary supplements, medicinal plants, exercise, homeopathy, and treatments from traditional Chinese medicine (TCM).

Nonvitamin, nonmineral, natural products Taken by mouth, these natural products contain a dietary ingredient other than vitamins and minerals, intended to supplement the diet; examples include herbs or herbal medicine (as single herbs or mixtures), other botanical products (e.g., soy or flax products), and dietary substances (e.g., enzymes). Among the most popular are echinacea, *Ginkgo biloba*, ginseng, feverfew, garlic, kava, and saw palmetto; garlic has been used to treat fever, sore throat, digestive ailments, and arteriosclerosis.

Ornish diet High-fiber, low-fat vegetarian diet that promotes weight loss and health by controlling what is eaten, not by restricting the intake of calories. Fruits, beans, grains, and vegetables can be eaten at all meals; nonfat dairy products such as skim milk, nonfat cheeses, and egg whites are consumed in moderation. Products such as oils, avocados, nuts and seeds, and meats are avoided.

Osteopathic manipulation Full-body system of hands-on techniques to alleviate pain, restore function, and promote health and well-being.

Pilates Movement therapy that uses a method of physical exercise to strengthen and build control of muscles, especially those used for posture. Awareness of breathing and precise control of movements are integral components of Pilates. Special equipment, if available, is often used.

Progressive relaxation Technique used to relieve tension and stress by systematically tensing and relaxing successive muscle groups.

Qi gong Ancient Chinese discipline combining the use of gentle physical movements, mental focus, and deep breathing directed toward specific parts of the body. Performed in repetitions, the exercises are normally performed two or more times a week for 30 minutes at a time.

Reiki Energy medicine practice that originated in Japan. The practitioner places the hands on or near the person receiving treatment, with the intent to transmit *ki* (qi), believed to be life-force energy.

Shaman Traditional healer who is said to act as a medium between the invisible spiritual world and the physical world. Most gain knowledge through contact with the spiritual world and use the information to perform divination, influence natural events, and heal sick or injured persons.

Sobador Traditional healer who uses massage and rub techniques to treat patients.

Tai chi Mind-body practice that originated in China as a martial art. The person moves the body slowly and gently while breathing deeply and meditating (tai chi is sometimes called “moving meditation”). Many practitioners believe that tai chi helps the flow throughout the body of a proposed vital energy called *qi*. A person practicing tai chi moves her body in a slow, relaxed, and graceful series of movements. Persons can practice on their own or in a group. The movements make up what are called *forms* (or routines).

Traditional healer Person who employs any of a number of ancient medical practices based on indigenous theories, beliefs, and experiences and handed down from generation to generation. The methods employed by each type of traditional healer have evolved to reflect the different philosophical backgrounds and cultural origins of the healer.

Trager psychophysical integration Movement therapy in which practitioners apply a series of gentle, rhythmic rocking movements to the joints. They also teach physical and mental self-care exercises to reinforce the proper movement of the body. The intent is to release physical tension and increase the body’s range of motion. An example of Trager psychophysical integration as CAM is using it to treat chronic headaches.

Vegetarian diets Vegetarian diets are totally devoid of meat, red or white. There are, however, numerous variations on the nonmeat theme. For example, some vegetarian diets are restricted to plant products only, whereas others

include eggs and dairy products. Another variation limits consumption to raw fruit, sometimes supplemented with nuts and vegetables. Finally, a number of vegetarian diets prohibit alcohol, sugar, caffeine, or processed foods.

Yerbera Practitioner with knowledge of the medicinal qualities of plants; also called *hierbero*.

Yoga A combination of breathing exercises, physical postures, and meditation to calm the nervous system and balance body, mind, and spirit. The sessions last about 45 minutes and usually are performed in classes once a week (or more often).

About the Center for Mindfulness

Directed by Dr. Saki F. Santorelli, the Center for Mindfulness is an innovative leader in mind-body medicine and the integration of mindfulness into key areas of modern life, including mainstream medicine, health care, academic medical and professional education, public and private school education, corporate and nonprofit leadership, and service to broad segments of society.

Established in 1995, the Center emerged as an outgrowth of the acclaimed Stress Reduction Clinic, the oldest and largest academic medical center-based stress reduction program in the world, founded by Dr. Jon Kabat-Zinn in 1979. For more than 30 years, the Center has pursued an active research program that has focused on understanding the potential efficacy of mindfulness and the mechanisms through which mindfulness may work, publishing many peer-reviewed papers as well as scientific abstracts and books. Each year the Center hosts an annual international scientific conference attended by professionals from six continents.

In the course of three decades, more than 20,000 people have completed the Stress Reduction Program. They have

been referred by more than 5000 physicians and, as well, through self-referral. Likewise, more than 9000 health care professionals and educators have participated in training programs through *Oasis*—the Center's institute for mindfulness-based professional education and innovation. In parallel, the Center has developed a range of innovative programs for leaders in business, government, and nonprofit organizations, educators, attorneys and judicial officials, inmates and correctional staff, clergy, and Olympic and professional athletes.

This work has encouraged the creation of more than 250 *mindfulness-based stress reduction* (MBSR) programs worldwide and has inspired researchers across the planet to investigate the potential efficacy of MBSR and other mindfulness-based interventions. The work of the Center has been featured in the PBS Bill Moyers' documentary, *Healing and the Mind*, on NBC *Dateline*, and on ABC's *Evening News* and *Chronicle* programs, as well as on the *Oprah Winfrey Show*.

12-3 Energy Healing Modalities*

Energy Modality	Description and Comments
Meridian-based therapies	Meridians are energy pathways located throughout the body. Points on a given pathway are interconnected and can influence one another. Energy imbalances along the meridians are restored using various methods.
Acupuncture	Needles are inserted at key meridian points.
Acupressure	Pressure is applied at key points.
Electroacupuncture	Electricity is passed through meridian points. Laser light, sound from tuning forks, and other sources of energy also may be used.
Emotional freedom technique, thought field therapy	Tapping of various meridian points is used to release stored negative emotional energy.
Energy field or chakra balancing	The technique is based on concepts of an "energy body." Changes in the energy body can reflect changes in the physical body, or <i>chakras</i> . The seven main chakras are energy vortices that project from the center of the body. Small chakras also exist at various locations. Energy fields surrounding the body (i.e., aura) are said to be influenced by the healer's actions.
Polarity therapy	Based on the work of Randolph Stone, this technique combines diet, exercise, and other techniques to optimize health of the energy field.
Reiki	Japanese in origin, there are now many different schools. Trainees are given a series of "attunements," which allow them to pass universal healing energy to others. Energy is believed to flow to where it is needed most.
Therapeutic touch	Developed in the 1970s by Krieger, a nurse, there are now more than 50,000 practitioners in the health care professions. The hands are used to balance energy flows and chakra function in the body.
Healing touch	Developed in the 1980s by Mentgen, a registered nurse, the technique is based on principles used in therapeutic touch and the work of Brennan, Bruyere, and others. It requires completion of standardized instruction.
Other healers' schools or techniques	Examples include the techniques of Barb Brennan and Rosalyn Bruyere. They focus on energetic healing with more descriptive approaches to energy healing based on the healer's own experiences and systems.
Other Energy Therapies	
Flower essences	Various flower remedies are believed to have different vibrations and health effects.
Eye movement desensitization	Rapid alterations of eye movements from left to right, or alternate tapping motions on the right and reprocessing (EMDR) left sides, are used to release energy imbalances.
Color therapy	Use of various colors influences the energy field.
Music or sound therapy	Sounds that correlate with various energy vibrations are used in healing.
Movement therapies	Tai chi and qi gong enlist various movements to alter energy patterns or the amount of energy the body is able to store.
Correlational therapies	Techniques are based on the idea that a certain part of the body reflects all other parts. Focusing on one specific area, it is possible to provide generalize healing. In <i>reflexology</i> , certain parts of the feet, which are believed to correlate with various body parts, are massaged or treated with essential oils. In <i>iridology</i> , diagnoses are made by looking at parts of the iris, which is believed to reflect the health status of various body parts.
Magnet therapy	Magnets are applied to various body parts.
Shamanic healing	Often classified as a "spiritual" versus an energy modality. The shaman is said to determine intuitively the source of a health problem, then enlists ritual, helpful spirits; journeys to the spirit world; and other techniques to bring about healing.

Modified from Raket D, Rindfleisch A. Integrative medicine. In: Raket RE, ed. *Essential family medicine: fundamentals and case studies*. Philadelphia: Saunders; 2006, pp 132-141.

*This list is not comprehensive. Many complementary and alternative medicine therapies can be considered to be based in part on energy. Overall medical systems, such as Ayurveda, traditional Chinese medicine (TCM), and homeopathy, base their approaches in part on energy. Yoga and various forms of meditation also may involve conscious movement of energy.

12-4 Highlights of Acupuncture Research and Findings

2. Langevin H, Yandow J. The relationship of acupuncture points and meridians to connective tissue planes. *Anat Rec.* 2002;269:257-265.
3. Lagevin M, Churchill D, Cipolla M. Mechanical signaling through connective tissue: a mechanism for the therapeutic effect of acupuncture. *FASEB J.* 2001;15:2275-2282.
4. Cho ZH, Chung SC, Jones JP, et al. New findings of the correlation between acupoints and corresponding brain cortices using functional MRI. *Proc Natl Acad Sci USA.* 1998;95:2670-2673. All images courtesy National Academy of Sciences, USA. This was the first study to report a direct brain-acupoint correlation—that needling a specific acupuncture point on the body has specific effects in the brain. Recent developments of functional magnetic resonance imaging (fMRI), which is sensitive to changes in regional blood oxygenation as an index of neuronal activity, can be used for quantitative study of the correlation between various acupoints and specific functional areas of the brain (eFigure 12-4).

Bladder meridian points on the lateral aspect of the foot (**A** and **B**) affect visual function as predicted by ancient acupuncture literature (eFigure 12-5).

fMRI shows visual stimulation (**A** = light flashed into eye) and acupoint stimulation (**B** = point VA1) compared with non-acupoint stimulation (**C** = control) (eFigure 12-6). Notice that the visual and acupoint stimulation evoke similar fMRI findings compared with non-acupoint stimulation.

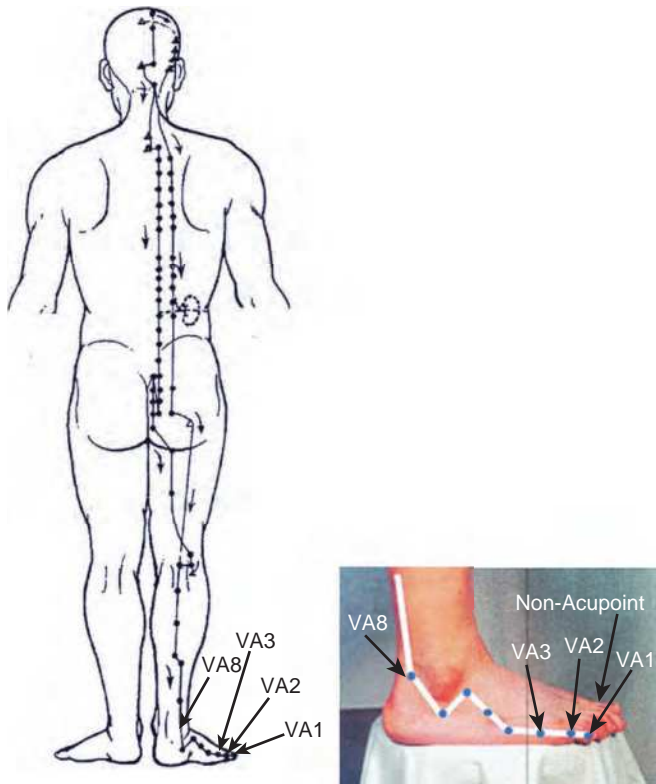

Activated areas resulting from acupoint stimulations of VA1, VA3, and VA8 (see eFigure 12-5) are in the primary visual cortex (i.e., occipital lobe). Results led to the hypothesis that acupuncture stimulates or activates the corresponding brain cortex through the central nervous system, modulating chemical and hormonal release of neurotransmitters to the diseased or disordered organs for treatment.

5. Schlebusch KP, Walburg MO, Popp FA. Biophotonics in the infrared spectral range reveal acupuncture meridian structure of the body. *J Altern Complement Med.* 2005;11:171-173. This study shows, for the first time, evidence of the existence of the acupuncture meridian structure in the human body. After moxibustion (i.e., burning of moxa, the herb *Artemisia vulgaris*, on or near meridian points) or similar light stimulation of the body in the range of 3 to 5 μm , light channels appear on the body. They appear to be identical to what are known as *meridians* in textbooks of traditional Chinese medicine. These findings appear to confirm the existence of acupuncture meridians, and they open a window on understanding the energy transfer dynamics of the human body. It is likely that living matter is not in the ground state, but permanently electronically excited.

The following diagrams of the bladder and stomach meridians are given to help orientation to the infrared thermography that follows them (eFigure 12-7). The stomach meridian runs up front of leg and torso and into facial area bilaterally; only the right side is shown.

The infrared thermography images demonstrate light channels, which appear identical to the corresponding meridians (eFigures 12-8 and 12-9). The meridian structure is revealed after moxibustion. **A**, The heat source is near the patient's left leg. **B**, Changing sides reveals mirror meridian images.

The bladder meridian runs down the back on either side of the spine and down the back of the legs. The left side is shown (eFigure 12-10). Structure along the bladder meridian after moxibustion.

Establishing Rapport

ROBERT E. RAKEL

CHAPTER OUTLINE

Respect 142

Patient Satisfaction 142

Communication 142

Rapport comes from the French *en rapport*, which means “in harmony with.” Rapport is most easily established during the patient’s first visit, and achieving rapport enhances the likelihood that the patient will comply with the treatment plan. When rapport has been established, patients are more likely to forgive a less than perfect experience or an unexpected poor clinical outcome.

Even the most knowledgeable and skilled physician will have limited effectiveness if he or she is unable to develop rapport with patients. Unfortunately, rapport is one of those intangibles that is more than the sum of its parts. Rapport is not analyzed easily within any one body of knowledge. The basis of rapport, however, is the development of communication skills that instill in patients a sense of confidence and trust by conveying sincerity and an interest in their care and well-being. The patient’s satisfaction and compliance with the physician’s instructions (both measures of rapport) depend on the ability of the physician to communicate understanding, compassion, and genuine interest in the patient and to display a thorough approach to solving the patient’s problems. Patient satisfaction also is related to the physician’s efforts in educating patients about the disease process and motivating them to participate in their treatment.

Failure of communication between physician and patient also can affect the outcome of treatment, often as seriously as an error in treatment. More complaints against physicians result from a breakdown of the caring aspect of the doctor-patient relationship than from the technical quality of treatment.

Most complaints against physicians—and those that too frequently lead to legal action—are the result of a lack of communication between physician and patient. The potential for a serious problem always exists when a patient is inadequately informed regarding a diagnostic procedure, treatment, prognosis, or anticipated cost. The misunderstandings that result cause unnecessary expense and grief for both parties.

Similarly, the worries that result from distorted information can jeopardize the physician-patient relationship. When a patient is discussed on hospital rounds or with a colleague in the office, take care that the discussion is not within the patient’s hearing distance or within that of other patients. Patients overhearing the conversation may believe the comments apply to them, or they may know the patient involved and relay the information in a distorted manner. Fragments of such conversations, overheard by the patient

or others, are too easily taken out of context and can become the focus of fearful fantasies that only serve to increase uneasiness and apprehension.

Compassion, interest, and thoroughness are essential components of successful patient care. These features traditionally have been embodied in the term *bedside manner*, which also connotes qualities of concern, kindness, friendliness, wit, and cheerfulness, all of which result in an atmosphere of trust and confidence between physician and patient. The physician with the best bedside manner may be the one who makes no special effort to communicate these feelings but acts in a concerned, natural, and comfortable manner.

[Oliver Wendell Holmes](#) said that to be effective, the physician should “speak softly, be well-dressed, have quiet ways and have eyes that do not wander” (1883, p. 388). Lack of eye contact may be interpreted as a lack of concern. A good first impression is certainly great help in establishing rapport. It takes less than 7 seconds to form a first impression. You do not get a second chance to create a first impression. The physician should approach the patient in an assured, confident manner with a smile and a handshake if the occasion is appropriate.

Personal appearance is a significant part of nonverbal communication. Patients consider house staff who wear white coats with conventional street clothes as more competent than those who wear scrub suits. If white coats are worn, the patient sees only the collar, tie, and shoes, and it is therefore important to keep these items neat.

Posture is also important in conveying an image of confidence and competence. Standing erect, moving briskly with head up and stomach in, is better than slouching. Energetic people seldom slump; they sit upright and appear alert. A listless or lethargic appearance can be interpreted as lack of concern.

Before entering the examining room or hospital room to see a patient, review the record briefly and become familiar with the patient’s name and its proper pronunciation. If the pronunciation is unusual or difficult, place phonetic markings on the chart as a reminder for future use. Repeat the patient’s name when first given it to confirm the pronunciation, and then use the name twice in the first minute to help it register. Review the medical record for particular aspects of the previous visit that should be remembered and commented on, such as the illness treated at that time, family conditions, or other problems. Patients will believe that the well-informed physician is truly interested in them. Additional courtesy, such as opening the door and assisting

patients with their coats (especially elderly patients), shows a consideration that aids in establishing and maintaining rapport.

Respect

Patients should believe that their comments are being listened to, carefully considered, and taken seriously. They must believe that the physician values their comments and opinions before trusting him or her with information of a more personal nature. As long as the physician's attitude toward the patient embodies respect, concern, and kindness and a sincere effort is made to understand the patient's difficulties, the patient will overlook or forgive myriad other problems.

Oliver Wendell Holmes advised patients to "Choose a man who is personally agreeable, for a daily visit from an intelligent, amiable, pleasant, sympathetic person will cost you no more than one from a sloven or a boor, and his presence will do more for you than any prescription the other will order" (1883, p. 391).

A lack of confidence, rather than an excess of it, may lead physicians to appear aloof and unconcerned. Too often, physicians think that a godlike image of omnipotence is necessary for the maintenance of the patient's respect and confidence. It is usually a lack of self-confidence that causes physicians to retreat behind this protective image, which limits their ability to help. Secure physicians are freer to establish close personal relationships with patients without fearing their position will be threatened. A physician with a positive self-image is also willing to recognize and admit the limits of personal competence and feels comfortable seeking help from a colleague when such consultation is of value to the patient's care.

The bond of mutual respect is enhanced if the physician makes positive statements about other people. Patients find it difficult to respect a physician who is regularly detractive, making negative statements about other people or other physicians. Any comments that can be interpreted as "building yourself up by tearing someone else down" merely accomplish the reverse.

The effectiveness of physicians depends on the degree of their insight into the limitations of their personalities and the psychological defenses that distort their perceptions of patients. Physicians must recognize patients or situations that make them unreasonably angry or provoked (e.g., a whining, complaining individual who shows no interest in being rehabilitated, preferring a role of social dependency). The physician's emotions, if they go unrecognized, can serve as a barrier to the development of mutual respect. If the physician is aware of negative feelings toward a patient, an effort can be made to avoid showing signs of irritation or anger. It has been said that clenching of the physician's fist is a clinical sign of a hysterical patient. The physician should attempt to remain objective and analyze the situation for its diagnostic value.

Patients with trivial complaints or somatic manifestations of emotional disease sometimes are given less attention than those with clear-cut organic abnormalities. The frequency with which a physician complains about the triviality and inappropriateness of patients' problems has

been found to be related to the volume of patients seen and the degree to which the physician feels overburdened. The more patients that physicians see and the more overloaded their practices, the more likely they are to describe patients' complaints as trivial, inappropriate, or bothersome. Physicians who have more time or take more time per patient, and who investigate the patient's complaints more thoroughly, frequently uncover significant factors and less often tend to view the complaints as trivial. Respect for patients involves taking their fears and apprehensions seriously and withholding value judgments. Patients who frequently seek help for nonspecific somatic and functional complaints may be depressed (Widmer et al., 1980).

Patient Satisfaction

A close relationship exists between rapport and patient satisfaction, and this chapter deals with the many facets of that relationship. It is important that the physician make an effort to understand what patients are "going through" (not only their pain and discomfort, but also the effect these have on their lives) and communicate this understanding to them.

Most studies indicate that patient satisfaction depends on information and the degree to which the patient understands the illness. Joos and associates (1993) found that patients whose desires for information and attention to emotional and family problems went unmet were significantly less satisfied with their physicians than those whose desires were met. Even patients with chronic diseases who had lived with the problem for years had questions they wanted answered. Their satisfaction was related more strongly to the desire for information and affective support than to whether the physician conducted examinations and tests. The greater the patients' satisfaction, the more likely they are to comply with treatment recommendations.

Although patient satisfaction is strongly associated with the length of the visit, it can be further enhanced by spending some time talking about nonmedical topics. Even brief chatting about the weather or something nonmedical can give the impression that more time was taken with the patient, thereby reducing the feeling of being rushed through the visit (Gross et al., 1998).

PATIENT DISSATISFACTION

In a typical business, only 4% of customers voice their dissatisfaction. The other 96% say nothing, and 91% never return. This has led to many practices conducting regular patient satisfaction surveys so that problems can be identified.

Communication

The patient should be able to gain access to the clinician on the phone, by e-mail, or by an early appointment without having to run an obstacle course created by an overly protective staff. Delay in returning a phone call may result in a patient remaining home all day waiting; if the call is not returned at all, the negative effect on rapport is great.

Unwillingness to make communication convenient for the patient usually results in a spiral of increasingly frequent attempts to reach the physician and mounting frustration for everyone. In contrast, physicians who give a high priority to communicating discover that most patients are considerate and even protective of the physician's time. At the beginning of a practice, patients do a certain amount of testing to determine a physician's accessibility; physicians who pass the test find that they are rarely inconvenienced by unnecessary calls or patient visits.

VERBAL COMMUNICATION

Much of the communication process in the clinical interview centers on verbal interchange. Symptoms, past medical history, family medical history, and psychosocial data are transmitted primarily by verbal means. The chief complaint is extremely important because it explains why patients believe they need the physician's help.

Patients who do not mention a concern and who withhold requests are less satisfied with their care and experience less improvement in their symptoms. [Bell and colleagues \(2001\)](#) found that 9% of patients had one or more unvoiced desires and were most hesitant to ask their physician for referrals and for physical therapy. These patients were also less likely to trust their physician. This is an important reason to be sensitive to subtle clues that the patient may be suppressing something important to them. What the patient does *not* say may be as important as what the patient says.

"Slips of the tongue" or major areas of omission (e.g., a married person who never mentions a spouse) may signify problem areas that, when explored, help establish the interviewer as a perceptive person who understands the underlying issues. The interviewer constantly must consider, "Why is the patient telling me that?" Even simple, casual remarks may be the patient's way of broaching issues of great concern; the man who says, "Oh, by the way, a friend of mine has been having some chest pain when he walks a lot. Do you think that sounds serious?" may actually be talking about his own concern that he is unable to face directly. A child may be brought to the office with a trivial problem so that the mother has a chance to discuss with the physician something that is troubling her; the child is a calling card, signaling the need to open the communication channel. The physician who is sensitive to these subtle clues and encourages the patient to discuss what is actually troublesome will find that the rapport established allows future interviews to be much more open and direct.

HAND-ON-THE-DOORKNOB SYNDROME

The patient's parting phrase is sometimes a clue to the primary reason for the visit, or it may reflect another issue of great concern that is emotionally threatening and could not be voiced until adequate courage was summoned at the moment of departure. It sometimes surfaces as a last, desperate attempt to communicate because, with a hand on door, escape is readily accessible if the physician's reaction is unfavorable. Reasons for this hidden communication by the patient are important and must be recognized and addressed. Because of fear of rejection or humiliation, the

patient may test the physician with minor complaints before mentioning the real reason for the visit ([Quill, 1989](#)). The physician must be alert to any unusual behavior during an interview (e.g., slips of the tongue, unexpected responses, overenthusiastic denials) and should search further for the underlying reason for the visit when a patient presents with a trivial complaint that appears inappropriate. It is a good practice to ask the patient routinely at the end of a visit, "Is there anything we have not covered, or anything else you would like to ask me?"

Patients with a fear of cancer, for example, often are unable to voice their concern to the physician. Instead, they present with somatic complaints or contrived reasons that necessitate a complete examination. They are hopeful that the examination will allay their fears without it being necessary to express them openly. A female patient presenting for a complete physical examination actually may be concerned over the possibility of a carcinoma of the breast, which her elder sister might have had at the same age or for which a friend recently had surgery. Such situations emphasize the need for a complete family history and a discussion of any patient concerns in an effort to allow these feelings to surface. Attention then should be paid to alleviating the anxiety. Apprehension regarding cancer is widespread, and the only cure for this fear often is a therapeutic conversation with the physician.

Physicians in private practice who have established rapport during an ongoing relationship with patients communicate more easily than do physicians seeing a patient for the first time in an emergency department (ED). [Korsch and Negrete \(1972\)](#) showed that ED physicians did more talking than the patients, although their perception was just the opposite. This was attributed to interaction with unfamiliar patients by house staff in a setting where the stress level is high and the orientation therapeutic. However, [Arntson and Philipsborn \(1982\)](#) found that physicians in private practice for 26 years who knew their patients and saw them in a low-stress situation for diagnosis or health maintenance also talked more than the patients (twice as long). One difference in the two settings was a strong, reciprocal affective relationship between physician and patient in the private office. If either made an affective statement, the other would respond similarly, whereas in the ED, patients expressed twice as many affective statements as did the physicians.

VOCABULARY

The use of appropriate vocabulary assists in establishing rapport by ensuring easy and accurate communication. Phrasing questions in simple language appropriate to the patient's level of understanding and avoidance of medical jargon help establish a sense of working together. The patient's cultural background and educational level should be considered, and the physician should avoid using slang or a contrived accent because the patient will detect the artificiality and consider this patronizing.

Patients prefer to be enlightened, and they demand maximum insight into their care. It is best to start all explanations at a basic level and proceed only as rapidly as the patient's understanding permits. An analysis of 1057 audiotaped patient interviews with 59 primary care

physicians and 65 surgeons showed that in 9 of 10 cases, patients did not receive good explanations of proposed treatments or tests (Braddock et al., 1999).

Medical terminology should be avoided unless it is familiar to the patient. For example, some patients have interpreted “lumbar puncture” to mean “an operation to drain the lungs.” No longer does the physician gain a therapeutic advantage by writing prescriptions in Latin or impressing the patient with medical terms.

Metaphors can be harmful and are often used without the physician being aware of the negative connotation, unknowingly raising the patient’s anxiety level. Attempts to coerce a patient into having surgery with phrases such as “you are living on borrowed time” may cause anxiety and increase postoperative morbidity (Bedell et al., 2004).

Physicians should be sure of what patients mean to convey by their word selection and make certain they are operating at a common level of understanding. When the patient says he or she “drinks a little,” inquire further to clarify “a little.” If the patient “spits up blood,” determine whether it is truly spitting or really vomiting. A major barrier to accurate interpersonal communication is the tendency of people to react to a statement from their own points of view, rather than attempting to interpret it from the speaker’s vantage point. If a question exists regarding the clarity of the interpretation, it is best to repeat it to the speaker’s satisfaction. Contract negotiators have found that when parties in a dispute realize that they are being understood and each party sees how the situation appears to the other, there is less need to exaggerate and act defensively. Korsch and Negrete (1972) found that some of the longest interviews between physician and patient were caused by failures in communication; they had to spend considerable time trying to “get on the same wavelength.” An analysis of the conversations revealed that less than 5% of the physician’s conversation was personal or friendly in nature, and that although most of the physicians believed that they had been friendly, fewer than half of patients had this impression.

NONVERBAL COMMUNICATION

Verbal communication occupies so much of daily social interaction that nonverbal communication often is ignored. However, much that is said is unspoken. Communications specialists have demonstrated convincingly that nonverbal messages play a major role in validating or contradicting verbal messages, with great influence as communication symbols in their own right. When there is conflict between the verbal and nonverbal, believe the latter.

Communication between two people is usually one-third nonverbal, although some say communication is 93% nonverbal and 7% verbal (Secrets of Body Language, 2008). What is said verbally often is emphasized nonverbally, and personal attitudes and emotions usually are communicated at the nonverbal level. Nonverbal communicative signals are under less censorship from conscious control than are verbal messages, so they are likely to be more genuine.

Charles Darwin held that there is a unique pattern of nonverbal actions for each emotion. In *Expressions of the Emotions in Man and Animals* (1872), Darwin suggested that emotional expressions are evolutionary remnants of

previous adaptive behavior that persist even though currently useless. Snarling as a sign of aggression is one example. Although recent knowledge indicates that emotional expression is learned and genetically mediated, Darwin’s idea of a unique pattern of actions has been shown for depression and anxiety and is likely in the future to be demonstrated for other emotional states.

PARALANGUAGE

Paralanguage is the voice effect that accompanies or modifies talking and often communicates meaning. It includes velocity of speech (e.g., fast, slow, hesitant), tone and volume of voice, sighs and grunts, pauses, and inflections. Urgency, sincerity, confidence, hesitation, thoughtfulness, gaiety, sadness, and apprehension all are conveyed by qualities of voice. McCaskey (1979) believes that the literal interpretation (i.e., definition) of words accounts for only 10% of communication between two people, whereas facial expression and tone of voice account for up to 90% of the communication.

There is a real difference between verbal and vocal information. The *verbal message* refers to the words literally transmitted. The *vocal message* includes the emotional quality, the tone of voice, and the frequency and length of pauses—information that is lost when the words are written. Tone of voice, for example, can reverse the meaning of words. Sarcasm is a common example of a contradiction between vocal and verbal messages. Comparative studies have shown that when the vocal and verbal messages transmit contradictory information, the vocal is more accurate.

Physicians should be alert to subtle changes of tone, such as when patients ask whether everything will be all right. Are they asking for reassurance, showing fear, or doubting the diagnosis? Rather than concentrating exclusively on *what* patients are saying, the astute physician will concentrate on *how* they are saying it.

In a study of recordings of surgeons who had been sued and those who had not, the sued group could be identified by their tone of voice. They sounded dominant, whereas the nonsued group sounded less dominant and more concerned. “In the end it comes down to a matter of respect, and the simplest way that respect is communicated is through tone of voice” (Gladwell, 2005, p. 43).

TOUCH

A close personal interest in the patient can be communicated by the appropriate use of touch. The most socially acceptable method in this country is a handshake, enabling the physician to establish early contact with the patient (Colgan, 2009). The handshake, properly used, can convey to the patient sincerity and interest as well as security and poise. It is an inoffensive intrusion into the other person’s area of privacy and can be extended under certain circumstances to include the application of the left hand to the lower or upper arm. This technique is often used by politicians to emphasize sincerity and concern (Figure 13-1). A variation of the politician’s handshake is the “double-hander,” which some equate to a miniature hug.

Politicians also “gain the upper hand” by positioning themselves to the right of the other person so that when

Figure 13-1 The politician's handshake.

shaking hands theirs is on top. Another way to show dominance is to make sure they go through a door last, often with a pat on the back. This shows that the one going through the door last is in charge. This was well illustrated when President Clinton welcomed the Israeli and Palestinian leaders into a building and each insisted the other go first. While this would be considered polite in the United States, in the Middle East it reflects a power struggle. The winner (the last one through the door) emphasizes this with a pat on the back as the other enters (*Secrets of Body Language, 2008*).

The handshake as a traditional greeting of friendship began by the raising of exposed hands by two approaching individuals to give evidence that they held no weapons. This proceeded to the grasping of hands or, in the Roman society, the forearms. In the United States, a firm handshake is most acceptable. Usually, the limp or “wet dishrag” handshake indicates lack of interest or insincerity, especially if it is rapidly withdrawn. A moist palm is a sign of nervousness or apprehension, and the “halfway there,” fingers-only handshake indicates reluctance or indecision. However, the handshake continues to be modified culturally, and a person should be extremely wary of misinterpreting another person’s handshake without understanding his or her cultural background.

In the past in China, the Confucian code of etiquette dictated that there should never be a touching of persons, and even today, Chinese officials may appear reluctant to grasp an extended hand; a Chinese man formerly shook his own hand (*Butterfield, 1982*). Some young people in the United States have modified the traditional palm-to-palm handshake to a grasping of the thumb and thenar eminence and continue to develop new variations reminiscent of the secret handshakes of fraternal groups.

Touching can be an effective method for communicating concern or compassion and can break down some of the defensive barriers to communication. Caution should be exercised, however, not to use it excessively or earlier than is socially permissible. If used without adequate

preparation, touch can be interpreted as an invasion of privacy and a forward and inconsiderate act. During the physical examination, it is best to talk before touching by explaining to the patient what will be done next. Studies of primates have shown that touching gestures usually are considered nonaggressive and calming in nature. When used properly by the physician, touch can be facilitative and welcome.

The tremendous symbolic value of touch as a healing power was demonstrated during the Middle Ages, when people sought relief from scrofula (i.e., tuberculous lymphadenitis) through the king’s touch, or royal touch, despite the notoriously low cure rates. This power has been transferred to physicians, and patients often feel better after a routine physical examination. *Friedman (1979)* stated that 85% of patients leaving a physician’s office feel better even if they have not received medication or treatment, and 50% of patients in the waiting room feel better in anticipation of the help they will receive.

Touch, or “laying on of hands,” may promote healing, especially if it is imbued by the patient with a special symbolic value. Franz Mesmer (1734-1815) was among the first to emphasize the medical importance of laying on of hands. Mesmer, however, believed that there was a magnetic power in his hands, which he called “animal magnetism” and which he applied to ailing individuals. His theory was unscientific, and although he became famous for successfully treating a number of hysterical patients, he finally was discredited by a committee that included Benjamin Franklin and Antoine Lavoisier. They found his treatments to be without magnetism and essentially useless. They did agree, however, that he had helped many people and had brought about many cures. They attributed these cures to unknown factors rather than to the animal magnetism he claimed. Mesmerism was the forerunner of hypnosis, initially called “artificial somnambulism,” developed by Puysegur, a disciple of Mesmer.

The magic of touch can be good medicine, especially when combined with concern, support, and reassurance. *Stroking*, a special kind of touching, describes a physical or symbolic recognition of a person’s finer attributes. A stroke may be a kind word, a warm gesture, or a simple touch of the hand. Infants deprived of touch and stroking suffer mental and physical deterioration. Adults also require stroking to maintain a healthy emotional state. Stroking occurs when an interchange between two people leaves one or both with a good or fulfilled feeling.

Lightly touching someone’s elbow for less than 3 seconds can give you up to three times the chance of getting what you want (*Pease and Pease, 2004*). Elbow touching works better in places where touching is not the cultural norm, such as Great Britain and Germany.

BODY LANGUAGE

It is said that body language is the unspoken truth. The astute physician will cultivate observational skills that enable the detection of hidden or subtle clues to diagnosis contained in the patient’s nonverbal behavior. *Kinesics* is the study of nonverbal gestures, or body movements, and their meaning as a form of communication. However, specific gestures and their interpretation are of importance only

when judged in the context of the circumstances surrounding them. Body language alone does not reveal the entire behavioral image any more than verbal language does alone. Just as one word does not make a sentence or even have much meaning without the sentence, a single gesture has clinical relevance only as part of a sequence of actions. Although they have significance, individual signs are not reliable when they stand alone; they are meaningful only when considered in the context of a person's total behavioral pattern.

When there is *congruence* between the verbal and nonverbal message—when the gesture conveys the same message as the spoken word—communication and its meaning are probably in agreement. When a person indicates something different from the other, however, the *nonverbal* message usually is more accurate. Unless body language, tone of voice, and words spoken all match, look more closely for the reason.

Attempts by the patient to mask feelings can be detected readily by observing body behavior. True feelings are more likely to leak through conscious efforts to conceal feelings. Likewise, a physician's attempt at deception will be detected by patients and can destroy confidence and damage rapport. Positive verbal communication (e.g., "You're looking better today") accompanied by negative nonverbal cues will be interpreted by the patient as insincere. For example, a patient who is not told the true nature of a terminal illness usually knows it anyway and may distrust family, friends, and physician if they persist in the charade.

In a medical school commencement address, Alan Alda (star of TV's *M*A*S*H*) challenged new physicians to be able to read a patient's involuntary muscles as well as their radiographic studies. He asked, "Can you see the fear and uncertainty in my face? If I tell you where it hurts, can you hear in my voice where I ache? I show you my body, but I bring you my person. Will you tell me what you are doing and in words I can understand? Will you tell me when you don't know what to do?" (*Time*, May 28, 1979, p. 68). The physician will see the fear and uncertainty in the patient's face only if she or he is looking at the patient rather than the medical record. Alda's statement reflects the concern and compassion that patients desire. By using appropriate body language, the physician can convey this attention and concern in the most effective manner possible.

Body Position

The body position when sitting can show various degrees of tension or relaxation. The tense person sits erect with a fairly rigid posture. A person who is moderately relaxed has a forward lean of approximately 20 degrees and a side lean of up to 10 degrees. A very relaxed position (usually too relaxed for physicians interacting with patients) is a backward lean (i.e., recline) of 20 degrees and a sideways lean of more than 10 degrees.

Higher patient satisfaction is associated with a physician's forward body lean and rotation of the torso toward the patient. Larsen and Smith (1981, p. 487) found that "the patient also responds more favorably to the physician who relaxes his chin in his hands and gazes directly at the patient, rather than a physician who elevates his chin (unsupported) as if to imply a more superior status." Physicians whose communication styles have been

considered patient oriented have been observed to change body position more frequently than physicians whose conversations were physician centered.

An attempt should be made, whenever possible, to sit rather than stand when interviewing a patient. Rapport is improved if the physician does not intimidate the patient by placing him or her in a submissive position. Patients feel more comfortable and less helpless speaking in a sitting position rather than prone. Sitting on the patient's bed is usually not recommended, but for some patients, it is an effective means of establishing closeness and conveying warmth in a relaxed yet attentive manner.

Mirroring

When good rapport exists between two people, each will mirror the other's movements. Some people unconsciously establish rapport with another by mirroring that person's movements or body posture (Key, 1980) (Figure 13-2). Disruptions in this mirroring may signal that one member

Figure 13-2 Joseph Califano (left), Secretary of Health, Education and Welfare, mirrors his boss, President Jimmy Carter, through his posture and gestures. (From Key MR, ed. *The relationship of verbal and nonverbal communication*. New York: Mouton; 1980, p. v.)

Figure 13-3 This woman signals attentiveness and seriousness by holding very still, cocking her head, and looking intently at the speaker. (From Schefflen AE. *Body language and the social order—Communication as behavioral control*. Englewood Cliffs, NJ: Prentice-Hall; 1972.)

disagrees with what the other has said or feels betrayed or insulted but cannot express this idea verbally. If the physician notices this sudden disruption of mirroring activity by the patient, more attention should be focused on the comment that led to the change of position. Renegotiation or further explanation may be indicated. A powerful way to establish rapport is to match intentionally the body language of another.

Head Position

Typically, the head is held forward in anger and back in defiance, anxiety, or fear. It is down or bowed in sadness, submissiveness, shame, or guilt. The head tilted to one side indicates interest and attention (Schefflen, 1972) (Figure 13-3); under certain circumstances, this can be a flirtation. The erect head indicates self-confidence and maturity. It is almost impossible to tilt the head in front of someone who is not trusted or of whom we are afraid.

When listening to a patient, the physician should show interest and concern by an attentive position, which is best illustrated by sitting forward in the chair with an interested, attentive facial expression and the head slightly tilted. Darwin was one of the first to notice that animals assume a head tilt when listening intently.

Face

The human face can create more than 7000 expressions using 44 muscles (Cleese, 2001); some say 10,000 expressions are possible (Ekman, 2003).

Darwin (1872) proposed that cultures throughout the world express similar emotions or states of mind with remarkably uniform body movements. His information was gathered from missionary friends working with aborigines, persons under hypnosis, infants, and patients with mental disease. He also studied blind and deaf persons who, without benefit of learning from others, were observed to raise eyebrows when surprised and shrug their shoulders to indicate helplessness.

Darwin held that the facial expression of emotion, when undisguised, is independent of culture and is identical throughout the world. The facial expressions of joy, sadness, and anger are the same in the Australian aborigine, the American farmer, and the Norwegian fisherman (Ekman, 2006). Various cultures, however, do disguise the facial expression in different ways. In American culture, the mouth is used most often to disguise feelings. A person in a social gathering may be smiling, although inwardly sad or angry. The eyebrows, eyes, and forehead are least affected by these cultural disguises and are the most consistently dependable indicators of emotion. The current popularity of Botox injections, however, may mask these expressions by showing no wrinkling of the forehead. “A 50-year-old person with no wrinkling has almost certainly had some kind of cosmetic procedure or treatment.” (Hartley and Karinch, 2010, p. 88). As Shakespeare wrote, “I saw his heart in his face” (*The Winter’s Tale*, Act I, Scene II).

Ekman and Friesen (1975) found that the facial expressions of fear, disgust, happiness, and anger were the same in countries with widely disparate languages and cultures. They used composite facial photographs to show how each part of the face contributes to the expressions of emotion, especially surprise, fear, disgust, anger, happiness, and sadness. In American culture, when people want to disguise their true feelings and convey a more socially acceptable impression, they do so by smiling. This may be especially true in patients who are sad or depressed. Figure 13-4 is a composite showing sadness in the eyes, brow, and forehead being masked by a smile.

Smile

A genuine smile can be helpful in quickly establishing a friendly atmosphere and developing a warm, interpersonal relationship. A grin can be the physician’s most effective weapon for breaking down resistance or apprehension in patients, especially children or young adults. A number of studies have shown that patients are more positively disposed to physicians who smile. The smile must be genuine, however; patients can easily spot a phony smile.

Smiles are controlled by the zygomatic major muscles that connect to the corners of the mouth and the orbicularis oculi muscles. The latter are not under conscious control and reveal a true smile that involves characteristic creases around the eyes (crow’s feet). A genuine smile lights up the whole face; one that does not is more likely a deception (Ekman et al., 2005). In Figure 13-5, A, the man on the left has a broad nonenjoyment smile whereas on the right there is true enjoyment shown by the eyes. Similarly, in Figure 13-5, B, the genuine smile on the right pulls back both the mouth and the eyes. An excellent overview of facial expressions can be viewed on the DVD *The Human Face* by John Cleese (2001).

Micro-Expressions

Ekman and Friesen (1975) describe micro-expressions as a valuable indication of masking or deception. “Micro-expressions are caused by the face’s all too rapid efficiency in registering inner feelings” (Morris, 1977, p. 110). Most facial expressions last more than 1 second, but micro-expressions last only about one-fifth of a second (Ekman, 2003). This is approximately the time it takes to blink an

Figure 13-4 **A**, The man on the right has a true smile, his eyes are narrower, cheeks are higher and their contour has changed. **B**, Both have a broad smile but the one on the left has a broad, nonenjoyment smile while the one on the right shows true enjoyment. **C**, Compare the insincere smile on the left with a genuine smile on the right that pulls back both the mouth and the eyes. (A and B, From Ekman P. *Emotions revealed: recognizing faces and feelings to improve communication and emotional life*. New York: Henry Holt; 2003, pp. 207, 208; C, From Kuhnke E. *Body Language for Dummies*. Chichester, England: Wiley; 2007, pp. 66-67.)

Figure 13-5 Sadness shown in the eyes and forehead (the mouth is neutral). The importance of the eyelids can be seen because the person on the right (**B**) is obviously sadder than the one on the left (**A**) but differs only in that a sad lower eyelid has been substituted for a neutral lower eyelid. (From Ekman P, Friesen WV. *Unmasking the face: a guide to recognizing emotions from facial clues*. Englewood Cliffs, NJ: Prentice-Hall; 1975.)

eye, and micro-expressions easily can be missed if the physician is not carefully observing the patient. Micro-expressions tend to occur when emotion is concealed unwittingly by repression or deliberately by suppression. They are seen when the patient begins to show a true facial expression, senses this, and immediately neutralizes or masks the expression. Some micro-expressions are complete enough to show the true emotion felt, but most often, they are squelched to such an extent that the physician has only a clue that the patient is concealing some emotion.

Most expressions last about 2 seconds (0.5 to 4 seconds). Surprise is the briefest expression (Ekman, 2003).

Eyes

The eyes are probably the principal organs of expression. They are so important to a person's appearance that when anonymity is desired, only the eyes need to be covered. The eyebrows have been shown to have 40 different positions of expression and the eyelids have 23. Consider the magnitude of possible combinations when all facial elements are involved as indicators of expression. The message conveyed by each position can be further modified by the length of a glance and its intensity.

In most cultures, good rapport is enhanced when one's gaze meets the other's 60% to 70% of the time. When we talk, we maintain eye contact about 40% of the time and 80% when listening. Ninety percent of the gaze will be in a triangular area between the eyes and the mouth (Pease and Pease, 2004). On meeting, two people will scan each other's face for about 3 seconds, then briefly gaze downward. An upward eye break may be disconcerting or convey a lack of interest (Lewis, 1989) (Figure 13-6).

The eyes can give more information for some emotions than others. Knapp (1978) found that the eyes were better than the brow, forehead, or lower face for the accurate portrayal of fear but were less accurate for anger and disgust. Even the lower eyelid alone can convey considerable information. In Figure 13-5, it is apparent that the person in B depicts more sadness than the one in A, but the pictures differ in only one respect: the lower eyelid.

It has long been known that *pupils* dilate when the person sees something pleasant and contract when something unpleasant is viewed. This involuntary signal can be a valuable indication of what is really going on. Asian jade dealers wore dark glasses so that no one could see their pupils dilate when they discovered an especially valuable piece of jade. Likewise, a magician doing card tricks can tell when a pre-selected card is seen by a subject because of the sudden pupil enlargement. In one experiment (Hess, 1975), the pupils of males dilated when the men were shown photographs of nude females and constricted for nude males. Homosexuals demonstrated the opposite. Dilated pupils also can indicate that listeners are interested, whereas constricted pupils suggest that they do not like what is being said (or viewed).

Sincerity is expressed with the eyes. The best method for conveying sincerity is frequent eye contact, a technique most appropriately used when listening to the other person. One trait of good listeners is that they constantly look at the speaker. A listener who does not maintain eye contact but continues to look down or away from the speaker may be shy, depressed, or indicating rejection of the speaker or the comments being made. One patient said, "I had one student doctor who looked at his toes instead of me. If he ever opens

Figure 13-6 Record of eye movements made by a person looking at a photograph of a young girl's face.

a practice, I don't believe I would trust him." Conversely, speakers frequently may break eye contact when talking and are permitted a distant stare when formulating ideas and selecting phrases. However, they still should try to make frequent, although less prolonged and intense, eye contact.

A special form of human-to-human awareness is conveyed by eye contact. Prolonged eye contact, or staring, can be offensive. Monkeys can be provoked to combat by a person staring at them because it represents a threat of aggression. Under other circumstances, however, staring can be flirtatious, emphasizing that the meaning of eye behavior depends on other factors in the situation.

The acceptability of eye contact varies significantly among different cultures. In the United States, focusing the

eyes on the speaker indicates respect and attention, regardless of the age of the individuals involved. However, Mexican Americans tend not to maintain as much eye contact while listening as do other Americans and may look away from the speaker more often. This is not a sign of disrespect or inattention. In Latin American countries, a younger person may be thought disrespectful if his or her eyes meet those of the adult who is speaking. A physician could be considered seductive in that culture if he or she maintained steady eye contact while talking to a patient. In the United States, it is impolite to maintain eye contact with a stranger for more than 3 seconds, but Europeans believe that longer periods of eye contact are normal. The physician needs to consider the patient's cultural background when interpreting the meaning of eye contact behavior. Looking away from the speaker from time to time may be a sign of respect and sensitivity rather than the opposite. At the same time, the physician's failure to look a patient in the eye can be dehumanizing and can cause the patient to feel more like an object than a person. Patients are most comfortable when the physician looks at them approximately 50% of the time and are uncomfortable when eye contact is avoided. Some feel that rapport is improved if a person's gaze is met 60% to 70% of the time (Kuhnke, 2007).

The frequency of eye contact also can provide clues to whether the patient is anxious or depressed. The eyes of anxious patients blink frequently or dart back and forth. They look at the interviewer as frequently as low-anxiety patients but maintain eye contact for less time on each gaze. Similarly, the patient may interpret the physician's lack of eye contact as indicative of anxiety or discomfort, even rejection.

Frequent blinking of the eyes can be a sign of pressure or stress. In a political debate between Senator Bob Dole and President Bill Clinton in 1996, Dole blinked an average of 105 times per minute, showing more pressure than Clinton's 48 times per minute.

Depressed patients maintain eye contact only one-fourth as long as nondepressed patients. Downward contraction of the mouth and a downward angling of the head are also cues to depression. As with the anxious patient, there is no difference in frequency of eye contact in the depressed patient; the difference is only in the duration of contact.

Patients with abdominal pain caused by organic disease are more likely to keep their eyes open during palpation of the abdomen than those with nonspecific pain (Gray et al., 1988). The patient with genuine abdominal tenderness may apprehensively watch the physician's hand as it approaches the tender area.

Hands

The hands will be droopy and flaccid with sadness, fidgety or grasping in anxiety, and clenched in anger. When a speaker joins her or his hands, with fingers extended and fingertips touching, it is called *steeping* and indicates confidence and assurance in the comments being made (Figure 13-7). It can be taken to extremes if held too high and convey arrogance instead of self-assurance (Kuhnke, 2007).

Palms usually are held in the palm-in position. Turning the palms outward can be a subtle courting behavior (usually used by women), but it more likely indicates a warm and friendly greeting (Davis, 1975).

Figure 13-7 Steeping.

The hands of an anxious patient can be observed to shake when holding a pen, to twitch, or to be braced unnaturally. The white-knuckle pose of tightly locked fingers can be an effort to mask anxiety.

Hands can be a subtle indicator of the urge to interrupt. Be alert for this sign in a patient so that important information will not be suppressed, and the patient can be given every opportunity to supply valuable information. Indications of this urge to interrupt are a slight raising of the hand or perhaps the index finger only, pulling at the earlobe, or raising the index finger to the lips. The latter gesture also may indicate an attempt to suppress a comment and should alert the physician to inquire further and elicit the hidden information. A patient listening in “The Thinker” position, with the index finger across the lips or extended along the cheek, or one sitting with elbows on the table and hands clenched in front of the mouth, although listening intently, may not believe or understand the physician’s words (Figure 13-8). The physician should take additional time to amplify the issue or explain the diagnosis or treatment regimen further.

Arms

Although folded arms are found in all cultures, this is considered a discovered action rather than an inborn trait because it is a natural position of comfort that is as easily discovered by the African tribesman as the New York banker. It is the subtle ways in which the arms are held that can give clues to underlying emotions. Crossed arms can be a defensive posture, indicating disagreement with another’s view, or it can be a sign of insecurity. It can also be nothing more than a position of comfort and should, as with all other signs, be considered in the context of the individual’s total behavior.

Figure 13-8 The defensive or “doubting Thomas” position.

Notice the manner in which the arms are crossed. Are they relaxed in the normal position of comfort, or are they in a self-hugging posture, reflecting insecurity or sadness and indicating a need for reassurance? Anger can be seen in clenched fists that are held tightly against the body in a holding-back manner, preventing them from hitting (Figure 13-9). If the patient has assumed a position of resistance or defensiveness, sitting with arms and legs crossed and perhaps with body turned away, search for the reason for this defensiveness and try to eliminate it. Perhaps a recommendation that the patient stop smoking is threatening and difficult to accept. In that case, it is important to make an additional effort to explain the rationale for the recommendation; do not hurry over it with a brief comment or admonition.

Men who are under stress will often cross their hands in front of them as if protecting their genitals, called the fig-leaf position or “protecting the precious.” Women may cross arms over their abdomen referred to as “egg protecting” (Hartley and Karinch, 2010).

Legs

Although crossing the legs is a common position of comfort, it can also indicate a shutting out of or protection against the outside world. If crossed legs in a patient confirm the total kinesic picture of resistance, including crossed arms and other signals discussed earlier (Figure 13-10), make every effort to identify the reason for the resistance and correct it before proceeding further. Likewise, locked ankles can indicate defensiveness. Diagnostic information obtained from a resistant patient is likely to be incomplete, and instructions are unlikely to be followed.

Figure 13-9 The resistant position, suggesting suppressed anger.

Figure 13-10 The defensive position.

When seated, a person's legs are pointed in the direction of interest and if disinterested will point away. Similarly, when legs are crossed, the upper knee dictates the direction of interest.

Notice the position of the feet and their movement. As with fidgety hand movements, anxiety is associated with the fidgety, constantly moving foot. An anxious or scared person may sit forward in the chair with feet placed in the ready-to-run position, with one foot in front of the other. The angry person is more likely to place the feet widely apart in a position of stability, whereas the feet of a sad person tend to move in a slow, circular pattern.

Gestures

The thumbs-up sign in the United States means "good going," but in some Islamic countries, it is the equivalent of an upraised middle finger. Similarly, the extended hand with palm forward means "stop" in the United States, but in West Africa, it is an insult greater than the upraised middle finger.

Joining the thumb and index finger in a circle to indicate "OK" is an insult in many Latin American countries and in France means zero or worthless. In Texas, raising the index and little finger with the middle two fingers folded down is the "Hook 'em Horns" gesture of the University of Texas Longhorns, but in parts of Africa this gesture is a curse and in Italy it means your spouse is unfaithful.

American television and the movies have dulled these differences worldwide, although some still exist. In the 1978 movie *Inglorious Bastards* (remade in 2009) the

American posing as a German was detected because he displayed the number 2 using index and middle fingers, whereas Europeans would hold up the thumb and index finger with the thumb being number 1.

Preening

Preening gestures, such as the male pulling up socks, adjusting a tie, or combing hair and the female adjusting clothing or using a mirror to review makeup, may not necessarily be seductive in nature but can be an attempt to establish rapport and good interpersonal relations. If the preening is intended to be flirtatious, however, the woman may cross her legs, place a hand on her hip, caress her leg, or stroke the arm or thigh in some fashion. The flirtatious male typically uses gaze holding and head tilt to accentuate normal preening gestures or may stretch to make himself look larger. Both genders may use "accidental" touching as a flirting signal. When someone's attention is completely focused on the other, legs, knees, and feet are usually extended in the direction of the other. The physician should remain alert to the accentuation of normal preening gestures into courtship actions to identify the seductive patient and deal with the issue early, before unknowingly encouraging the patient to proceed further along this course.

Respiratory Avoidance Response

The respiratory avoidance response involves a frequent clearing of the throat when no phlegm or mucus is present. All animals exhibit a respiratory avoidance response as a

Figure 13-11 The nose rub, a variation of the respiratory avoidance response.

means of clearing something unpleasant or undesirable from the respiratory tract. This action also can be a nonverbal indication of disgust or rejection. When physicians find themselves doing this, they should observe the accompanying circumstances and notice whether posterior pharyngeal mucus is truly present.

Nose Rub

Another component of the respiratory avoidance response is the nose rub (Figure 13-11). This involves a light or subtle rub of the nose with the index finger and signals rejection of a statement being made by the subject or by another individual. The nose rub to relieve an itch is usually vigorous and involves a repeated series of rubs, whereas that of the respiratory avoidance response is soft and consists of one or two light strokes, often involving nothing more than a light flick of the nose. Morris (1977, p. 111) described the nose flick as “a reflection of the fact that a split is being forced between inner thoughts and outward action.” It can be associated with lying or with the struggle to appear calm while suppressing anger or discomfort. During Bill Clinton’s testimony to the grand jury regarding his affair with Monica Lewinsky, he rarely touched his nose when telling the truth, but when he lied he gave a split-second frown, then touched his nose. During the testimony he touched it 26 times (Pease and Pease, 2004). Variations of the nose rub include pulling at the earlobe, scratching the side of the neck or rubbing one eye. Someone aware of the nose rub will often notice it

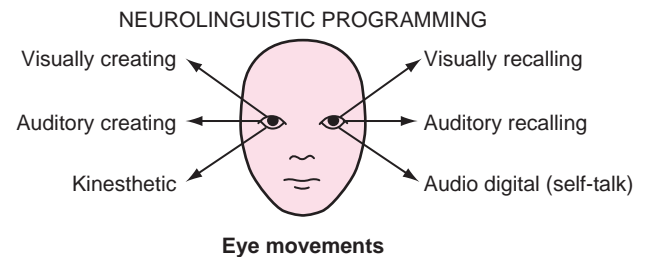

Figure 13-12 Neurolinguistic programming.

in themselves and realize they are uncomfortable with what is being said by themselves or others. Watching for this during interviews on television may indicate the person being interviewed is uncomfortable with the question, or the person asking may realize it is a “testy” point.

This sign can be quite useful in patient interviewing. For example, the physician may ask a patient, “How are things at home?” The patient may answer, “Fine,” but then clears his or her throat and lightly rubs the nose with the index finger. He or she is actually saying, “I don’t like what you are asking me,” or “I feel uncomfortable with my answer; things really aren’t going very well at home.” If there is a cause to pursue the issue further, a simple comment such as “Really?” or “You mean not even an occasional argument?” may lead to a flood of information masked by the previous response.

Verbal-Nonverbal Mismatch

Another indication that what a patient is saying may be in conflict with what is being felt is a verbal-nonverbal mismatch, such as when the patient answers “fine” to “how are things between you and your husband?” while looking sad and avoiding eye contact (Quill, 1989). If the patient answered negatively to the question, “Have you ever had a venereal disease?” and at the same time exhibited a nose rub, this topic should be followed up with a similar inquiry later, perhaps while doing the physical examination, when the patient may feel more comfortable after better rapport has been established.

Other clues that the patient may not be telling the truth or that there are repressed feelings are asymmetric facial expressions and a prolonged smile or expression of amazement. Almost all authentic facial expressions fade after 4 or 5 seconds (Ekman, 1985).

Neurolinguistic Programming

Neurolinguistic programming (NLP) involves the eye movements performed while thinking and depends on whether a person is thinking visually, aurally, or kinesthetically. A right-handed person who is visually oriented will look up and to his or her left when recalling something visually, but up and to the right if creating something visually or, in other words, making it up or lying. Similarly, a right-handed person will look sideways to his or her left when recalling sounds and sideways to the right when imagining sounds (Ritch, 2004). A person who is looking up and to his or her right (i.e., your left) probably is imagining things he or she has never seen before. This technique is used by police investigators when interviewing suspects. A left-handed person will respond in opposite directions (Brooks, 1989; Zellmann, 2004) (Figure 13-12).

Figure 13-13 The “body bubble” surrounding strangers in a queue. (Courtesy Magnum Photos, New York)

DETECTING LYING

In addition to looking up and to the right to create an image or a fact, a person who is lying is also likely to do the following:

- Cover the mouth with hand.
- Rub or flick the nose.
- Scratch the neck.
- Pull at the ear, or rub behind the ear.
- Rub one eye.
- Blink excessively (although absence of blinking is also possible).
- Have a micro-expression indicating something is different than what is said.
- Avoid making eye contact.
- Use arms and hands less.
- Be defensive rather than aggressive.
- Change manner or posture abruptly.

The liar will also rarely touch the other person or point a finger at them or others, and the story will not include negative details (Lieberman, 1998). The liar is not comfortable with silence and may speak more than normal to convince the other. Persons suspected of lying should be encouraged to talk because verbal and nonverbal clues will then be easier to detect (Vrij, 2005). Liars are also likely to slouch, unlike a confident person, who will sit upright. Remember that it takes a combination of verbal and nonverbal clues to detect lying, and no single action is likely to be dependable other than to raise doubt or suspicion.

PROXEMICS: SPATIAL FACTORS

Proxemics is the study of how people unconsciously structure the space around them. This structuring varies with every culture. North Americans, for example, maintain a protective “body bubble” of space about 2 feet in diameter around them when they interact with strangers or casual

acquaintances. Violators of that space are considered intruders and cause the person to become defensive (Figure 13-13). In the Middle East, no such bubble exists, and it is proper to invade this area. In fact, not to do so may be interpreted as unfriendly and aloof. Arabs prefer to stand close enough to touch and smell the other person. Americans, however, if forced to stand close together, as on a crowded subway, will use their eyes (i.e., distant gaze) to maintain a more proper distance. An arm’s length is a good measure of the appropriate personal distance for most people. A wife can stand inside her husband’s bubble, but she will be unhappy if another woman invades this sphere of privacy, and vice versa.

Robert Frost said, “Good fences make good neighbors.” In suburbs and small towns, people are more likely to talk to each other while in their backyards if a fence indicates the boundary than if there is a communal yard (McCaskey, 1979). Marking the boundary helps maintain territoriality and actually brings the neighbors closer together than when there is no fence.

Intimate space has been classified as that ranging from close physical contact to 18 inches, *personal space* from 18 inches to 4 feet, *social space* from 4 feet to 12 feet, and *public space* from 12 feet and beyond (Lambert, 2008). Placing a desk between two people shifts personal space to social space. The office desk also can be a barrier to communication when it is placed between the physician and patient, thereby emphasizing the illusion of the physician’s importance and power. There may be occasions when this is desired, but it usually is not necessary in a family physician’s office. Office furniture should be arranged so that a minimum number of obstacles lie between physician and patient.

Automobiles magnify the size of one’s personal space up to 10 times. Compare the relationship of two people having a conversation with that of “road rage” when one invades the other’s space by cutting in front of them.

HIDDEN OR MASKED COMMUNICATION AND PATIENTS' EXPECTATIONS

Although the average person has a symptom about every 6 days, he or she visits a physician only once every 4 months. Some people visit a physician much more frequently than others for the same symptom. The group who visits more frequently tends to have a higher level of anxiety, fear, grief, or frustration. It is the physician's responsibility to search for, identify, and treat organic disease if it is present, but in about one half of cases, none will be found. It is equally important to identify the reason for these visits—the basis for the heightened concern or increased anxiety. A person may see a minor symptom as a potential catastrophe if she or he thinks it may be a sign of cancer similar to that causing a parent's death. Is the patient really there "just for a blood pressure check," or because of concern about the condition of his or her coronary arteries since a friend recently had an acute myocardial infarction? If the physician deals only with the symptoms, the real concerns may go undetected, and the result will be a dissatisfied and non-compliant patient.

Barsky (1981, p. 492) cautioned, "Patients who express dissatisfaction with their medical care should be questioned about this, as they may be dissatisfied because their real motivation in seeking care has not been illuminated." He also advised the physician to investigate the patient's current life stresses when visits are made if there is no change in clinical status.

Patients may come to a physician because of what they imagine is causing their symptoms rather than because of the symptoms themselves. Identifying what patients hope can be done for them—focusing on their expectations for the visit—often reveals hidden reasons for the visit. The physician should be sure to address the patient's expectations and make certain that the interpretation is correct. Rapport and satisfaction will be enhanced if the physician identifies and satisfies the patient's expectations for the visit. Dissatisfaction results when these expectations go unmet.

LISTENING WELL

A good family physician must be a good listener. Of all the communication skills essential to rapport, the ability to listen well is probably the most important. All the information in the world about body language, vocal messages, and nonverbal cues is of limited value unless it helps the family physician be a better listener.

As Lown (1996) states, "In the brief time available to take a history, the aim is to obtain, in addition to essential facts, insight into the human being. This seems easy, but listening is the most complex and difficult of all the tools in a doctor's repertory. One must be an active listener to hear an unspoken problem" (p. 10). The appearance of readiness to listen is aided by bending forward and maintaining eye contact. The physician can discourage a patient from talking by looking away or writing in the medical record. Well-chosen questions can be rendered useless by inappropriate nonverbal behavior. Even great questions are of no value if you do not know how to listen.

For many people, the opposite of talking is not "listening" but rather "waiting to talk." It is impossible to listen

attentively when you are planning what to say next. Besides, learning to listen is more difficult than learning to ask good questions (Dimitrius and Mazzearella, 1999).

The average listening efficiency of most people is only 25% because we do not concentrate on what is being said. Effective listening requires focus on what is being said and on voice tone, facial expression, and body movements. Hearing what someone says and truly listening to what they are saying is quite different (Zellmann, 2004).

Analyses of physician-patient interviews reveal that, on average, the physician rather than the patient does most of the talking, although when questioned, physicians usually imagine the reverse. In general, the less the physician says during an interview, the more the patient will say.

Boredom is one of the most difficult states to conceal. It is very difficult to appear attentive and interested if you are bored, and it takes considerable effort to appear interested (Dimitrius and Mazzearella, 1999).

SILENCE

Silence can be as effective a means of eliciting further information as direct questions. The timing is important, however, and silence should be used as a technique only when the physician is relatively certain that there is more information to follow the last statement. A shift of position or a nod and a smile, properly timed and coupled with silence, can be more effective than an encouraging comment. Nonverbal encouragement to continue is less distracting and may be more facilitative than the verbal form.

Attorneys use silence in the courtroom to get witnesses to say more than they had intended. They wait silently as if the witness has not given a complete answer, and usually they do receive additional information. Silence can be effective as long as the patient feels more inclined to fill the void than the physician. This is of value, however, only when there is more information to be obtained. It is said that Charles DeGaulle thought that silence was the ultimate power tool, and in his speeches, he gained control by looking at the audience, never breaking eye contact, and saying nothing.

INTERRUPTION

The patient may be following a line of thought and may be about to open up more but must stop and refocus if the physician captures the patient's attention with a question. The physician should interrupt a patient's statement only if it is necessary to change the conversation to a new topic, clarify an issue, elicit information not produced spontaneously, offer reassurance, or reduce patient anxiety.

Physicians usually use closed-ended questions to interrupt the patient and thereby inappropriately control the interview. Beckman and Frankel (1984) found that 69% of patients (52 of 74) had only 18 seconds to complete their initial complaint before being interrupted by their physician. This usually occurred after the patient stated only a single concern, and it effectively halted the further flow of information from the patient. This prematurely terminates opportunities for patients to present their primary concerns. Only one of the 52 patients subsequently returned to and completed the opening statement. In these recorded

office interviews, only 23% of the patients were permitted to complete their list of problems uninterrupted; when they were, the complete statements usually took less than 60 seconds, and none required more than 2.5 minutes.

HUMOR

The art of medicine consists of amusing the patient while nature cures the disease.

—VOLTAIRE

Humor can be helpful in establishing rapport and can strengthen the physician-patient relationship. It can be used to “break the ice” and is most useful if it communicates the feeling that “we are all in this together.” Humor is an effective way for physicians to appear human while supporting and empathizing with their patients. Physicians who score high in empathy also tend to have a good sense of humor (Hampes, 2001). Empathic humor can promote a stronger physician-patient relationship and enhance the effectiveness of other, more traditional as well as nontraditional forms of therapy (Berger et al., 2004).

Care must be taken, however, because humor can be a two-edged sword that can cut either way if used inappropriately. The least risk is when the humor is self-deprecating or focused on neutral topics such as the weather or parking. It can even alienate the patient if they feel the joking around is inappropriate at the very time they want serious attention paid to their problem.

More research is needed on the value of humor in medicine so that we will know when and how to use it effectively. Norman Cousins, former editor of the *Saturday Review*, had ankylosing spondylitis. He received 3 hours of pain relief after watching comedy videotapes of *The Three Stooges* and *Abbott and Costello* but obtained only one-half hour of

pain relief from an oral analgesic. Some physicians write prescriptions for patients to laugh out loud three times each day. In India, more than 600 Laughter Clubs convene for 15 to 20 minutes at the beginning of each day to laugh out loud. Even a fake laugh makes one feel better throughout the day. Laughter boosts the immune system and even forced laughter leads to a good feeling and relieves stress and anger (Cleese, 2001).

Physicians who express interest in patient opinions and who use humor more often are sued less often. Tasteful humor can reduce anxiety and create a bond of friendship, but humor used inappropriately can magnify the distance between patient and physician, especially if it belittles the patient.

13-1 Interviewing Effectively

The patient history is the most likely assessment activity to provide a diagnosis. The final diagnosis is evident in almost 80% of cases after the history alone and in an additional 12% of cases after the history and physical examination; laboratory testing is required to make the diagnosis in only 11% of cases (Schmitt et al., 1986).

The skilled family physician can spend 10 minutes with a patient, but the patient may think it was 20 minutes. This is much better than the physician who spends 20 minutes but leaves patients thinking that he was in a hurry and that they were encroaching on his time. Overly brief or abrupt conversations in the office or at the bedside can damage rapport severely. Physicians signal how much time they plan to spend by a variety of nonverbal cues, and patients rarely have the courage to counter this by asking for more time. The physician who hurriedly asks, “How are you?” while flipping through a chart with only a quick glance at the patient destroys communication. Even the busiest physicians can accomplish much quickly by giving full attention to the patient: Patients remember the outstanding physician who truly communicated with a relaxed posture and attentive manner in whatever time was available.

Analysis of taped physician-patient encounters in a pediatric clinic revealed that many of the mothers were dissatisfied because the physician paid too little attention to their concerns and apprehensions about their children. Their attitude had little relation to the amount of attention the physician actually paid to the infant, which was usually adequate (Korsch and Negrete, 1972).

Even in an established family practice where essentially none of the patients was dissatisfied with the physician, 54% of the patients either forgot to mention something of concern or misunderstood facts about diagnosis or treatment (Snyder et al., 1976). Of the 84 patients, 29 forgot to tell the physician something that was bothering them. This illustrates the wisdom of concluding every interview with the statement, “Is there anything else bothering you that we haven’t discussed?”

When meeting a new patient, the method used to address the patient during the introduction can help establish rapport by conveying an atmosphere of mutual respect. Greet the patient warmly with a handshake and a smile while maintaining eye contact. Giving the patient undivided attention for just 60 seconds conveys the impression that you are truly interested. Use the patient’s name during the introduction, during the interview, and on leaving. An appropriate introduction would be, “Good morning, Mrs. Brown, I’m Dr. —,” or, “Good morning, Mrs. Brown. I’m —, a second-year medical student, and I’ll be taking your medical history and examining you today.” It is also better to show concern for the patient with an opening statement such as, “How can I help you?” rather than, “What brings you here today?”

Facilitating Techniques

In addition to the nonverbal facilitating techniques of silence and body positioning, patients can be encouraged to talk further with simple comments such as, “And then?” or by repeating a portion of the statement just made:

Patient: *I have been very nervous lately.*

Doctor: *Nervous?*

Confrontation

Confrontation, wisely used, can help establish communication and rapport. Statements such as, “You look unhappy,” or “You appear very anxious,” are based on the physician’s observation of the patient. If the physician has been unable to establish rapport, it may help to approach the issue openly and frankly: “We don’t seem to be communicating very well. Can you tell me what is wrong?” This is also a useful maneuver when a previously good relationship suddenly turns sour.

Summarization or Paraphrasing

Summarization is a brief restatement of what the patient has said and gives the interviewer and the patient a chance to correct errors or misunderstanding. It demonstrates the physician’s interest in the patient’s history and his or her effort to collect the facts accurately. A summary gives the patient an opportunity to add more details but also lets him or her know that the physician was listening. The physician can restate what the patient has said and emphasize the important points to ensure clear understanding. Summarization ensures that both parties are using the same definitions and minimizes inappropriate assumptions. “Let me see if I have understood you correctly,” or, “Am I understanding this correctly?” are good ways to introduce a paraphrase.

Summarizing is also a subtle way of focusing on the important facts in the history without asking closed-ended questions that may inhibit the patient. A summary also can be used to change the subject when the physician wants to move on to another topic.

Concluding a History

In an effort to avoid leaving gaps in the history or allowing patients’ concerns to go unattended, it is wise to conclude every complete history with, “Is there anything else you would like to mention?” or “Is there anything that we have

not discussed?” This excellent practice is of little value, however, if at the same time the physician puts away pen and pad, closes the chart, and starts edging toward the door.

Open-Ended Questions

Probably the single most valuable rapport-promoting element of verbal communication is the use of open-ended questions at the onset of an interview. “Tell me more about it” is an interview technique and a state of mind. The physician who understands that no checklist of yes-or-no questions can possibly portray the patient as a unique human will create an atmosphere of sensitivity and interest that contributes greatly to the early establishment of rapport. Once the broad outlines of the patient’s unique situation are indicated, detailed questioning moves along quickly.

An open-ended question does not suggest what you would like the answer to be, and the patient may include additional information that was unexpected. Even if you need specific information, a good rapport builder is to start with a few open-ended questions and become more focused as you go (Dimitrius and Mazzearella, 1999).

Specific questions beget specific answers and rarely anything more. However, the physician may want to use this technique on occasion, as when dealing with the verbose, rambling patient who refuses to stick to the point, or when specific information is needed. When more general or hidden data are sought, however, the physician must choose questions and gestures that offer the maximal potential for obtaining information. To be effective, open-ended questioning requires that the physician appear relaxed and ready to listen regardless of the amount of pressure from waiting patients. After it becomes apparent that more time is necessary than is available, a new appointment is made to ensure adequate time.

Signals That Discourage Communication

While appearing to respond affirmatively and facilitate the conversation, people in fact can turn off the speaker if they frequently comment “yes” in a manner that conveys disinterest or impatience. Everyone has experienced the person who says “yes” before the sentence is finished or the point made. Patients can be subdued and reduced to silence in a similar manner, intentionally or unintentionally.

Confidentiality

Confidentiality is a cardinal principle of professionalism. Effective communication requires that the patient feel secure in the knowledge that all information will be kept strictly confidential. It is the ethical responsibility of each physician to maintain this bond of confidentiality. The family physician must appreciate this intimate and confidential bond and avoid any threat to its dissolution. Hippocrates said, “And whatever I shall see or hear in the

course of my profession, as well as outside my profession in my intercourse with men, if it be what should not be published abroad, I will never divulge, holding such things to be holy secrets” (Strauss, 1968, p. 325).

Assurance that all information and actions will be kept confidential is especially important when dealing with adolescents. They may not be aware of this basic ethical principle in the medical profession or realize that it applies to them. They may be reluctant to share information and trust completely for fear that parents or peers may find out.

Complex problems of confidentiality can arise for the physician who cares for several members of the same family. Family members often can provide important information that supplements what the clinician learns directly from the patient. Unfortunately, information sometimes may be offered only on the promise that it will not be disclosed to the patient. Secrets rarely can be kept for long; the patient sooner or later learns what has been confided, straining the bonds of trust. In general, it is best not to be a party to secrets but rather to find a way to discuss sensitive material. If rapport is to be maintained, the physician must diplomatically explore the possibility of dealing with such problems in a constructive manner as soon as the patient’s situation permits.

Rapport with Families

No patient exists in a social vacuum. Visible or invisible, family and friends provide a social environment that exerts an important influence on the clinical course of disease. Because the family usually has a stronger emotional influence on the patient than the physician, effective communication with the patient’s family is an important element in successful patient care. Their positive support is necessary if the physician’s plan of management is to be carried out. Family support of the physician’s treatment regimen can help ensure that a patient remains on a prescribed diet, takes medication as instructed, rests appropriately, or maintains a proper exercise program. An unsupportive family attitude can negate or severely jeopardize previous gains in treatment.

Family, friends, and colleagues can be valuable sources of important information regarding the patient’s illness beyond that given by the patient, including facts that were forgotten, repressed, or even unknown to the patient. Communication should be established through the most responsible family member (other than the patient). However, it is important that such discussion be known to patients, and that a summary of the discussion be shared with them by the physician to avoid a misunderstanding or conflict of ideas when patient and family interact. If the patient and the family have different sets of information, they may become suspicious of future communications with the physician.

Communication with concerned family and friends need not be time-consuming. If a serious or prolonged illness is involved, a family conference can outline what can be expected and what will be done. It is usually possible to identify one family member as the communication channel to whom future reports will be given, avoiding frequent and repetitious calls. Many clinicians find that optimal control

and satisfaction are achieved by initiating the calls themselves on a regular schedule.

Lack of understanding of the family's concerns and inadequate communication with family members are major factors leading to malpractice suits. Devaluing the patient or family views and failing to understand their concerns was a major reason mentioned by plaintiffs (Beckman et al., 1994). The most common complaint was the feeling of being deserted by the physician and feeling alone when the physician would not return calls or return to the bedside as promised, especially after an adverse event.

Rapport with Children

Working with children is one of the delights of practice. Children have a quality of freshness and directness that

adults often lack. There are no secret formulas for interacting with the young, although there are cautions to be observed. Most procedures are not uncomfortable if the physician exercises patience, but forced gaiety and false promises that "it won't hurt" immediately are perceived as dishonest, and once trust is destroyed, it may never be regained by any physician. Examining the ear of the mother or an older sibling, for example, before examining the child often allays anxiety. Let the child handle the stethoscope or otoscope. Simple rewards also can make the physician's office a place of interest for the child. Accompanying other members of the family on visits to the physician helps the child gain familiarity with the office and staff. The physician who spends a few extra minutes with children and family early in the professional relationship will reap enormous dividends in years to come.

13-2 *Care with Caring*

“One of the essential qualities of the clinician is interest in humanity, for the secret of the care of the patient is in caring for the patient.” This statement by Francis Peabody (1930, p. 57) could serve as the maxim for establishing patient rapport. While continuing to emphasize the curing aspects of medicine, family medicine places increased emphasis on its caring aspects. Caring is the opposite of apathy and implies the application of human tenderness and compassion to the curing of individuals. It involves respect for the individual and enables the physician to motivate patients to participate in their care. Physicians must convince patients that they care and are sincerely interested in providing help.

“Caring without science is well-intentioned kindness, but not medicine. Conversely, science without caring empties medicine of healing and negates the great potential of an ancient profession. The two complement and are essential to the art of doctoring” (Lown, 1996, p. 223). It has been said that more mistakes in medicine are made by those who do not care than by those who do not know. The caring implies an empathetic relationship between physician and patient. Empathy is the capacity of physicians to understand what the patient is experiencing, and it is best accomplished if physicians place themselves in the role of patients in an effort to understand their feelings. The capacity to understand another person’s feelings is the foundation of the physician-patient relationship.

Chekov, a physician himself, believed that medical students should spend one half of their time learning what it feels like to be ill. Although this may be an extreme method for developing empathy, it is important that the student, before becoming immersed in the technical and cognitive aspects of medicine, be able to identify with the patient’s feelings, fears, apprehensions, and expectations so that the knowledge acquired during medical school can be applied meaningfully in the context of these needs. Exposing

students to patients in the first year of medical school, before they have been preoccupied with the diagnosis and treatment of disease, offers them an opportunity to focus on the process of communication under the watchful gaze of an instructor. Barriers to effective communication then can be identified. For example, a student may have difficulty permitting a patient with terminal cancer to talk about impending death. More than one student has been known to convey discomfort nonverbally by conducting the interview standing at the foot of the hospital bed, adjacent to the door and ready to escape.

Although a physician may be able to cure a disease only occasionally, the physician always can console the patient. An unknown French author admonished the medical profession “to cure sometimes, to relieve often, to comfort always.” The family physician provides personalized patient care and attempts to minimize the often frightening and dehumanizing experience to which patients are subjected in our highly structured modern medical system. The physician must strive constantly to preserve personal dignity for the patient, especially when his or her identity is threatened by a strange and somewhat frightening hospital environment. *Care for* a patient is more personal than the *care of* a patient.

Most patients have some degree of stress related to their presenting complaint, and it is important that family physicians convey a sense of caring when attempting to resolve the problem. As Fuller (1993) stated, “On a daily basis, I assess the disease process and adjust the medical management as needed, but my joy comes from listening carefully, helping people to identify their stressors, providing my best advice when I think it is appropriate, but always offering my caring and understanding. ... I am both rewarded and fascinated to observe that people feel better just by recognizing that I care.” One of his patients said it best: “No one cares how much you know, until they know how much you care.”

Interpreting Laboratory Tests

ELIZABETH A. WARNER and ARTHUR H. HEROLD

CHAPTER OUTLINE

The Concept of “Normal” 157
Evaluating a Test’s Performance
Characteristics 157

Separating Diseased from Disease-Free
Persons 158

The use of the clinical laboratory to evaluate patients for the presence or absence of disease involves all medical and surgical specialties. Physicians in all areas of medical practice are dependent on laboratory testing to arrive at a correct diagnosis. Because many factors increase the uncertainty associated with a test result, physicians need to understand the limitations of interpreting test results.

Clinical decision making using diagnostic laboratory testing is based on the assumption that a given test is accurate and precise. Diagnostic test *accuracy* is the ability of a test to distinguish patients with a disease from those who are disease free (Leeflang et al., 2008). Test accuracy is not necessarily fixed; accuracy may vary among patient populations and with different clinical conditions. *Precision* is a measure of the reproducibility of a test measurement when the same specimen is rechecked under the same circumstances. Sources of imprecision include biologic variability and analytic variability. *Biologic variability* is the variation in a test result in the same person at different times because of physiologic processes, constitutional factors, and extrinsic factors (McClatchey, 2002) (Table 14-1). *Analytic variation* refers to the variation in repeated tests on the same specimen and relates to analytic technique and specimen processing. With current technology, biologic variation plays a larger role than analytic variation in most laboratory tests.

The Concept of “Normal”

The result of a laboratory test is compared with a reference standard, which traditionally has indicated values that are seen in healthy persons. Using the terms “normal results” or “normal range” implies that there is a clear distinction between healthy and diseased persons, when in reality there is considerable overlap.

The current standard of comparison for laboratory results is the *reference range*, which is frequently defined by results that are between chosen percentiles (typically the 2.5th to 97.5th percentiles) in a healthy reference population. Several problems are encountered when deriving a reference range. Often, the reference population is not representative of persons being tested. Differences in gender, age distribution, race, ethnicity, or the setting (hospitalized vs. ambulatory patients) between the reference population and the person receiving the test may be present. The person being tested should be tested under similar physiologic conditions (e.g., fasting, sitting, resting) as the reference

population. The size of the reference population may be too small to include a representative range of the population.

Two statistical methods, parametric and nonparametric, are generally used to define the reference intervals. The *parametric* method applies when the results of the sample population fit a normal gaussian distribution, with a bell-shaped curve around the mean. In this case, the 2.5th and 97.5th percentiles can be calculated using statistical formulas. When the reference values do not follow a normal distribution, *nonparametric* methods are used, arranging the results from the reference subjects in ascending order, and identifying values between the 2.5th and 97.5th percentiles as within the reference range.

Reference ranges for a particular test can be the manufacturer’s suggested reference range or may be modified because of differences in the population using the laboratory. The Clinical Laboratory Improvement Act (CLIA) of 1998 has defined three requirements for reference values: the normal or reference ranges must be made available to the ordering physician; the normal or reference ranges must be included in the laboratory procedure manual; and the laboratory must establish specifications for performance characteristics, including the reference range, for each test before reporting patient results. Using the manufacturer’s reference range is valid when the analytic processing of the test is the same as that done by the manufacturer and when the population being tested is similar to the reference population used to define the reference range. When selecting a reference range that includes 95% of the test results, 5% of the population will fall outside the reference range for a single test. When more than one test is ordered, the probability increases that at least one result will be outside the reference range. Table 14-2 compares the number of independent tests ordered with the probability of an abnormal result being present in healthy persons.

Evaluating a Test’s Performance Characteristics

Given that tests are not totally accurate or precise, one must have a way to quantify these shortcomings. A test’s ability to discriminate diseased from nondiseased persons is defined by its sensitivity, specificity, and positive and negative predictive values. Table 14-3 shows how each is calculated. Sensitivity and specificity are inherent technical aspects of a test and are independent of the prevalence of disease in

Table 14-1 Biologic Variables That Affect Test Results

Biologic rhythms	Circadian Ultradian Infradian
Constitutional factors	Age Gender Genotype
Extrinsic factors	Posture Exercise Diet Caffeine use Medication Alcohol use Pregnancy Intercurrent illness

Table 14-3 Diagnostic Test Performance Characteristics

Finding	Disease Present	Disease Absent
Test positive	True positive (TP)	False positive (FP)
Test negative	False negative (FN)	True negative (TN)

Sensitivity = $TP/(TP + FN)$; Specificity = $TN/(TN + FP)$
Positive predictive value = $TP/(TP + FP)$; Negative predictive value = $TN/(TN + FN)$.

the population tested. However, given that diseases have a spectrum of manifestations, sensitivity and specificity are improved if the population is heavily weighted with patients who have advanced (vs. early) illness.

Sensitivity is defined as the percentage of persons with the disease who are correctly identified by the test. *Specificity* is the percentage of persons who are disease-free and correctly excluded by the test. The *positive predictive value* is defined as the percentage of persons with a positive test who actually have the disease, whereas the *negative predictive value* is the percentage of persons with a negative test who do not have the disease. Predictive value is influenced by the sensitivity and specificity of the test and the *prevalence* (the percentage of people in a population who at a given time have the disease).

Separating Diseased from Disease-Free Persons

Under ideal circumstances, sensitivity and specificity approach 100%. In reality, they are lower. The best currently available test to decide who is diseased or disease-free could be imperfect and have sensitivities and specificities in the 80% range. Moreover, discrepancies between a test's efficacy and its effectiveness are common. *Efficacy* is a test's performance under ideal conditions, whereas *effectiveness* is its performance under usual circumstances. Tests under development are evaluated under highly rigorous criteria, but in clinical practice, inadvertent error can be introduced into the technical performance or interpretation of the test results. Also, test values for the diseased and disease-free populations overlap.

A cutoff value may be chosen to separate "normal" from abnormal (Figure 14-1). This decision is arbitrary and involves selecting a balance between sensitivity and specificity. The receiver operating characteristic (ROC) curve is a graphic analysis used to identify a cutoff that minimizes false-positive and false-negative results (Figure 14-2). The sensitivity and specificity are calculated for a number of cutoff values, with the variables *1-Specificity* plotted on the *x* axis and *Sensitivity* plotted on the *y* axis. Each point on the curve represents a cutoff for the test. A perfect test would have a cutoff that allowed both 100% sensitivity and 100% specificity. This would be a point at the upper-left corner of the graph. The most efficient cutoff for a single test is the one that gives the most correct results, represented by the value that plots nearest to the upper-left corner of the graph.

The optimal cutoff depends on the purpose of the test and essentially is a risk/benefit analysis. In situations where disease detection is most important, the cutoff may be chosen that maximizes sensitivity at the expense of decreasing specificity. If disease exclusion is the goal, sensitivity and negative predictive value need to be maximized. It is important that negative results be *true* negatives as opposed to false negatives, so that a negative test has correctly excluded the individual as having disease. Similarly, if disease confirmation is the goal, specificity and positive predictive value are critical. It is important that positive results are *true* positives and not false positives, so that healthy persons are not misidentified, especially when treatments (e.g., surgery) have serious risks.

The predictive value of a test is directly related to the pretest probability of disease. When the prevalence of disease is high in the population, a positive test result is expected and a negative result is not expected, because the disease is common. Similarly, when the prevalence is low, a negative test result is anticipated because few people have the disease. These characteristics of predictive value become clinically useful when one compares the outcome of a positive or negative test result with the pretest probability of disease (Figure 14-3). Prevalence (pretest probability of disease) is plotted against predictive value for a positive and negative test. Note that a test result loses its ability to discriminate those who have disease from those who do not at the extremes of prevalence. If disease probability is low, a positive or negative result does not change the posttest

Figure 14-1 Effect of changing a test's cutoff value on disease classification. (Modified from Cebul RD, Beck LH. *Teaching clinical decision making*. Westport, CT: Praeger; 1985, p. 4.)

Figure 14-2 Receiver operating characteristic (ROC) curve showing the effect of changing the cutoff values for separating disease from no disease. (From Tetraault GA. *Laboratory statistics*. In Henry JB, ed. *Clinical diagnosis and management by laboratory methods*. 20th ed. Philadelphia: Saunders; 2001.)

probability much—it is still low. Conversely, if disease probability is high, the posttest results, whether positive or negative, do not substantially alter an already high probability of disease being present. The predictive value has the greatest power to discriminate those with disease from those who are disease free in the mid-pretest probability range, near 50%. A positive test result suggests a higher posttest probability of disease than a negative result.

MULTIPLE TEST ORDERING

For many diseases, more than one test is available for diagnostic or screening purposes. The dilemma then becomes whether a positive result on several tests must be present before the diagnosis is confirmed, or whether a single

- Posttest probability when the test result is positive (positive predictive value)
- Posttest probability when the test result is negative (1 - negative predictive value)
- Results for a test with sensitivity (TP rate) = 95%, specificity (1 - FP rate) = 95%
- Results for a test with sensitivity (TP rate) = 75%, specificity (1 - FP rate) = 85%

Figure 14-3 The relationship between pretest and posttest probability of disease based on a positive or negative test result. *FP*, False-positive; *TP*, true positive. (From Sackett DL, Haynes RB, Guynett GH, et al. *Clinical epidemiology*. 2nd ed. Boston: Little, Brown; 1991, p. 92.)

positive test is sufficient to label the person as diseased. The various possibilities will have an impact on sensitivity and specificity if the tests are viewed separately. Consider the example in which two tests are available for the diagnosis of a disease. Three combinations can lead to an affirmative diagnosis:

1. If one of the two tests is positive, the diagnosis is made.
2. A positive result for both tests is required before the diagnosis is confirmed.
3. The second test is performed only if the first is positive, and the person is labeled as diseased only if the second is also positive.

The first combination will increase sensitivity and decrease specificity in comparison with each test alone, and the second combination will decrease sensitivity and increase specificity. These effects on sensitivity and specificity for multiple test ordering are similar to shifting the cutoff point for a single test.

The value of performing a second test only when the first is positive generally comes into play when the first test is significantly less expensive and easier to administer than the second test but is less specific, although highly sensitive. The second test is highly sensitive and specific but more costly to perform on large populations, especially for screening purposes. An example is the enzyme-linked immunosorbent assay (ELISA) and Western blot test for human immunodeficiency virus (HIV) testing. The ELISA has a high sensitivity and is relatively inexpensive and easy to perform, but it is less specific. The Western blot test has high sensitivity and specificity, but it is more expensive and more difficult to perform. Using the ELISA first identifies almost everyone with the disease, whereas the Western blot excludes the fraction of persons incorrectly labeled as having disease (false positives) by the ELISA test. This testing sequence has improved sensitivity and specificity over each test alone and is more cost-effective than initially performing both tests.

CONSIDERATIONS FOR ORDERING TESTS

In addition to diagnostic accuracy, the other important consideration in test ordering is the ultimate effect on the patient. What actions will be taken, based on the test results? What are the expected benefits or harms that might occur, based on a positive or a negative result? Will ordering a particular test be more likely to help than harm the patient? Unfortunately, at present, randomized controlled trials (RCTs) that examine the outcomes of test-and-treatment strategies are not available for most clinical situations. Thoughtful systematic reviews of diagnostic test accuracy, linked with clinical evidence examining treatment options, may be the best available evidence to help guide decisions on diagnostic testing (Cornell et al., 2008).

The following section presents an overview of 40 commonly ordered tests. Each section discusses the physiologic significance of the test, a typical range of reference values, and a listing of some common disease states that might explain an abnormal result. The reference ranges for each test are intended as guides and may differ from the reference ranges used by different laboratories, depending on the reference population and the test methodology.

Table 14-4 Causes of Decreased Albumin Levels

Reduced Absorption	Decreased Synthesis
Malabsorption Malnutrition	Chronic liver disease
Protein Catabolism	Increased Losses
Infection Hypothyroidism Burns Malignancy Chronic inflammation	Nephrotic syndrome Cirrhosis Protein-losing enteropathies Hemorrhage
Dilutional	
Syndrome of inappropriate antidiuretic hormone secretion (SIADH) Intravenous hydration	

ALBUMIN

Albumin is a transport protein that is produced mainly in the liver and maintains osmotic pressure. Albumin has a long half-life (20 days) and a small (approximately 5%) daily turnover. In humans, albumin levels increase from birth up to age 1 year, thereafter remaining stable at approximately 3.5 to 5.5 grams per deciliter (g/dL) throughout adult life. Albumin levels are reduced with advancing liver disease, nephrotic syndrome, protein-losing enteropathy, malnutrition, and some inflammatory diseases (Table 14-4). Elevations of serum albumin are unusual except in dehydration.

In severe acute infection, reduced albumin production combined with increased catabolism causes a reduction in serum albumin levels beginning in 12 to 36 hours and reaching a maximum nadir in about 5 days. As a marker for malnutrition, however, albumin levels decline relatively late. Albumin levels are most helpful in the evaluation of edema, liver disease, and proteinuria.

The difference between the serum albumin level and the albumin in ascites fluid, the serum-ascites albumin gradient (SAAG), can help differentiate portal hypertension from other causes of ascites. SAAG greater than 1.1 g/dL is seen with portal hypertension; SAAG less than 1.1 g/dL suggests another cause of the ascites, such as peritoneal inflammation or malignancy.

Most of the albumin filtered through the kidneys is reabsorbed, so significant urinary albumin is a sign of abnormal renal function. Large amounts (>300 mg/dL) of albumin can be detected on standard urine dipsticks. *Microalbuminuria* is defined as a persistent increase of urinary albumin that is below the detectable range of the standard dipstick test. Microalbuminuria is a marker for early diabetic nephropathy and also predicts macrovascular disease. Urinary albumin can be assayed from a spot urine specimen, which is corrected by the urine creatinine, or a 24-hour urine collection. A 24-hour urinary albumin excretion in mg/day equates to the same numeric value for the spot urine albumin (mg)/creatinine (g) ratio. Therefore the reference ranges for each test are normal less than 30, microalbuminuria 30 to 300, and clinical albuminuria greater than 300. Factors that may interfere with the test accuracy include strenuous or prolonged exercise, upright posture, hematuria, menses, genital or urinary infections, congestive heart

Table 14-5 Causes of Increased Alkaline Phosphatase Levels

Bone origin	Paget disease Osteomalacia Rickets Hyperparathyroidism Metastatic disease
Liver origin	Extrahepatic biliary obstruction <i>Pancreatic cancer</i> <i>Biliary cancer</i> <i>Common bile duct stone</i> Intrahepatic obstruction <i>Metastatic liver disease</i> <i>Infiltrative diseases</i> <i>Hepatitis</i> <i>Primary biliary cirrhosis</i> <i>Sclerosing cholangitis</i> <i>Cirrhosis</i> <i>Passive hepatic congestion</i>
Other causes	Drugs <i>Phenobarbital</i> <i>Phenytoin</i> <i>Chlorpropamide</i> Hyperthyroidism Temporal arteritis

failure, uncontrolled hypertension or uncontrolled hyperglycemia, and high protein or high salt intake.

ALKALINE PHOSPHATASE

Alkaline phosphatase (ALP) is found in a wide variety of tissues, including the liver, bone, intestine, and placenta. The reference value for ALP depends on age and gender, with higher levels in childhood, adolescence, and pregnancy. A typical reference range in an adult is 25 to 100 U/L. In adults, the source of an elevated ALP is the liver, bone, or medication (Table 14-5). Mild ALP elevations (one to two times above reference range) can occur with parenchymal liver disease, such as hepatitis or cirrhosis. Marked ALP elevations occur with infiltrative liver disease or intrahepatic or extrahepatic biliary obstruction. A persistently elevated ALP level can be an early sign of primary biliary cirrhosis. In cholestatic liver disease, bilirubin and γ -glutamyltransferase (GGT) levels are increased as well, with less prominent elevations in aminotransferase levels. To confirm a hepatic source of an elevated ALP level, one can simultaneously measure GGT, which is elevated in obstructive liver disease but not with bone disease. Imaging studies of the liver, by sonography or computed tomography (CT), can define an anatomic basis for obstruction in the setting of an elevated ALP level of hepatic origin.

AMINOTRANSFERASES

Liver chemistry tests are widely used to assess for liver disease. Common markers of hepatocellular damage are the aminotransferases, *aspartate aminotransferase* (AST) and *alanine aminotransferase* (ALT). While AST is also found in other tissues, such as the heart, skeletal muscle, and blood, ALT is more specific for liver. The aminotransferases are released by hepatocytes with cell injury or death. While the current reference range is approximately 10 to 40 U/L for AST and 15 to 40 U/L for ALT, some advocate that the

current upper limit of normal for ALT should be lowered (Pacífico et al., 2013). Studies examining healthy people with normal body mass index (BMI), normal glucose and lipid values, and no hepatotoxic medication find that the 95th percentile for ALT is 30 IU/L in men and 19 IU/L in women. The magnitude of the elevation of aminotransferases and the ratio of AST to ALT can help suggest the cause of liver disease but does not necessarily correlate with the severity of underlying liver disease or the prognosis. In fact, normal or minimally elevated aminotransferases may be seen in patients with end-stage liver disease. Mild elevation (more than five times the upper limit of normal) of the ALT or AST, with ALT greater than AST, is frequently found with chronic liver disease, including chronic viral hepatitis, fatty liver, and medications. Probably the most common cause of persistently elevated unexplained aminotransferases is fatty infiltration of the liver. Less common causes of mildly elevated aminotransferases with ALT greater than AST include autoimmune hepatitis, hemochromatosis, α -1-antitrypsin disease, Wilson disease, metastatic disease, and cholestatic liver disease. Mild aminotransferase elevations with AST greater than ALT are more suggestive of alcohol-related liver disease but can also occur with cirrhosis and fatty liver. With alcoholic hepatitis, AST levels typically are approximately twice ALT levels, but the AST levels rarely are greater than 300 U/L. Marked elevations (greater than 15 times upper limit of normal) of AST and ALT suggest significant necrosis, such as seen in acute viral or drug-induced hepatitis, in ischemic hepatitis, or as can occur with acute biliary obstruction (Green and Flamm, 2002). When AST is elevated without elevation of ALT, one should consider extrahepatic causes, particularly myocardial or skeletal muscle sources. When AST and ALT are elevated approximately the same, a hepatic origin is most likely. eTable 14-1 compares the differences in liver function tests between hepatocellular and obstructive disorders.

Lactate dehydrogenase (LDH) is elevated in liver disease but is nonspecific; it is also found in skeletal muscle, cardiac muscle, blood, and some pulmonary disorders. Measurement of LDH rarely adds useful information to the evaluation of liver disease. GGT is a microsomal enzyme that is inducible by alcohol and certain drugs, including warfarin and some anticonvulsants. Although not specific for alcohol abuse, GGT is the most sensitive liver enzyme for alcohol abuse.

AMYLASE AND LIPASE

Pancreatic disease, particularly *acute pancreatitis*, is often associated with elevations in amylase and lipase. Table 14-6 lists common causes of elevated amylase and lipase. Lipase measurements are recommended over amylase measurements to diagnose acute pancreatitis because of their greater sensitivity and specificity. Reference ranges vary among assays. Amylase and lipase values increase 3 to 6 hours after the onset of acute pancreatitis, both peaking at approximately 24 hours. Amylase levels fall to normal in 3 to 5 days; lipase levels return to normal in 8 to 14 days. Because of exocrine insufficiency caused by recurrent pancreatitis, amylase levels tend to be lower when alcohol is the cause of pancreatitis, as opposed to gallstone or drug-induced pancreatitis. Pancreatitis is likely when the amylase

eTable 14-1 Pattern of Liver Function Elevation

Test	Hepatocellular Disorders	Obstructive Disorders
Bilirubin	+	++
Aminotransferases	+++	+
Alkaline phosphatase	+	++

Perforated peptic ulcer	Renal failure
Ruptured ectopic pregnancy	
Renal failure	
Macroamylasemia	
Pregnancy	

is elevated to three times the upper limit of normal. When lipase levels are more than five times normal, pancreatitis is virtually always present. A normal amylase value, however, does not exclude pancreatitis, especially when induced by hypertriglyceridemia.

ANTINUCLEAR ANTIBODIES

Antinuclear antibodies (ANAs) are autoantibodies against parts of the cell's nucleus. When associated with symptoms of connective disease, such as arthritis, Raynaud phenomenon, or fever, ANA testing can help diagnose certain collagen vascular disorders (eTable 14-2). The likelihood that an ANA test will help with diagnosis depends on the pretest probability of disease. ANA tests are reported as negative (no staining) or positive at the highest cutoff of dilution of the serum that shows immunofluorescent nuclear staining. If positive, the description of the pattern is noted. When the ANA test is positive, testing for specific nuclear antigens should be guided by the clinical findings.

Although the ANA is 95% sensitive for *systemic lupus erythematosus* (SLE), it is not specific and is seen in other diseases. Higher titers are more specific for SLE but may be seen in the other autoimmune diseases. About 20% of normal people have an ANA titer of 1:40 or higher, and 5% have a titer of 1:160 or higher. In a series of referrals to a rheumatology clinic for a positive ANA, no patients with an ANA of less than 1:160 were diagnosed with ANA-associated rheumatic diseases. (Abeles and Abeles, 2013). Less than 5% of patients with definite SLE have a negative ANA titer. Because of the high prevalence of positive ANAs in normal people, physicians need to reserve the diagnosis of SLE for patients who have clinical findings compatible with SLE. ANA titers correlate poorly with relapses, remission, and severity of disease and are not helpful in monitoring the course or response to therapy. ANA testing should be ordered when a connective tissue disease is considered, but it is not generally helpful in the

evaluation of nonspecific complaints, such as fatigue, widespread pain, or low back pain (Solomon et al., 2002).

For patients with a positive ANA titer, further testing for specific nuclear antibodies can be obtained, guided by the pattern and titer of ANA staining and the clinical findings. Patients with low titer ANA who do have additional clinical findings that suggest an ANA-associated disease should have no further testing. The interpretation of testing for specific nuclear antigens can also be difficult; most of the "specific" antigens are not 100% specific for a particular disease and need to be interpreted in the clinical context. The anti-DNA test is highly specific for SLE, with about 95% specificity but only 50% to 60% sensitivity.

BILIRUBIN

Bilirubin is produced by catabolism of heme in extrahepatic tissues. Hepatocytes conjugate the bilirubin, and it is then excreted into bile. Blood bilirubin levels are a function of production rate and biliary excretion. Total bilirubin is a combination of lipid-soluble *unconjugated* bilirubin and water-soluble *conjugated* bilirubin. Total bilirubin is less than 1.5 mg/dL and is normally primarily unconjugated bilirubin. The initial step in the evaluation of an elevated bilirubin level is to distinguish conjugated (direct) from unconjugated (indirect) hyperbilirubinemia.

Probably the most common cause of unconjugated hyperbilirubinemia is *Gilbert syndrome*, a benign condition that affects up to 5% of the population. In Gilbert syndrome, only the unconjugated bilirubin is elevated; the rest of the liver enzymes are normal. Other causes of unconjugated hyperbilirubinemia include hemolysis, ineffective erythropoiesis (as in megaloblastic anemias), or a recent hematoma. With normal hepatic function, hemolysis is not associated with bilirubin levels greater than 5 mg/dL. In an asymptomatic person with mildly elevated unconjugated hyperbilirubinemia (<4 mg/dL), a presumptive diagnosis of Gilbert syndrome can be made if there are no medications that cause elevated bilirubin, there is no evidence of hemolysis, and the liver enzymes are normal (Green and Flamm, 2002). Conjugated hyperbilirubinemia generally occurs with defects of hepatic excretion, including extrahepatic biliary obstruction, intrahepatic cholestasis, cirrhosis, hepatitis, and toxins.

BLOOD UREA NITROGEN AND CREATININE

Measurements of blood urea nitrogen (BUN) and creatinine have been used to estimate renal function. The reference range for BUN level is 7 to 18 mg/dL. Elevations in BUN, however, are not specific for intrinsic renal disease and can be seen with hypovolemia, increased protein intake, corticosteroid use, hypercatabolism, and gastrointestinal bleeding. With volume depletion, urea is reabsorbed by the tubules, and the BUN is elevated proportionately more than creatinine. The BUN-to-creatinine ratio can help differentiate prerenal and postrenal causes of renal insufficiency from intrinsic renal disease. Ratios of 10:1 suggest intrinsic renal pathology; ratios greater than 20:1 suggest prerenal or postrenal causes. BUN can also be reduced in severe liver disease, malnutrition, and with the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

Currently creatinine is the most widely used laboratory test to estimate glomerular filtration rate (GFR). A product of muscle metabolism, serum levels of creatinine are related to muscle mass, age, gender, race, and dietary meat intake. At normal renal function, most of the urinary creatinine excretion is from glomerular filtration, with about 5% to 10% from tubular secretion. As GFR declines, a larger proportion of creatinine excretion is from tubular secretion. Some drugs, including cimetidine, trimethoprim, fenofibrate, and salicylates, can block the secretion of creatinine and falsely elevate creatinine levels, particularly in the setting of a low GFR. Creatinine levels increase as renal function is reduced in a parabolic fashion: At higher levels of renal function, large drops in GFR are reflected with small changes in creatinine; at lower levels of renal function, small changes in GFR are reflected in larger changes in creatinine. Although serum creatinine has long been used to estimate renal function, current guidelines from the National Kidney Foundation recommend using *estimated* GFR (eGFR) from serum creatinine to report kidney function. Many clinical laboratories now automatically report the eGFR using the Modification of Diet in Renal Disease (MDRD) equation. This equation uses age, serum creatinine, and gender to estimate the GFR, expressing GFR in mL/min/1.73 m². The MDRD eGFR is reasonably accurate when estimating eGFRs less than 60 mL/min; however, it may underestimate eGFR at higher GFRs (Ferguson and Waikar, 2012). In addition, the equations were developed in persons with chronic kidney disease and may not accurately calculate GFR in elderly, nonwhite, or healthy persons.

CALCIUM

The total calcium level is a measurement of free (also called *ionized*) calcium, protein-bound calcium, and a chelated fraction. Approximately 50% of total calcium is ionized, 40% to 50% is bound to albumin, and 5% to 20% is bound to other ions. Only the free or ionized portion of calcium is physiologically active. Because of the binding of calcium with albumin, simultaneous measurements of calcium and albumin need to be performed to interpret calcium abnormalities. For every 1 g/dL that serum albumin is decreased below 4 g/dL, the estimated serum calcium is corrected by adding 0.8 mg/dL to the measured calcium level. An alternative is to measure ionized calcium levels in patients with abnormalities of serum albumin. The reference range for serum calcium is 8.5 to 10.5 mg/dL and for ionized calcium, 4.65 to 5.28 mg/dL. A single serum calcium measurement is not precise enough to reliably diagnose hypercalcemia; an initial abnormality of calcium should be repeated. Both dehydration and prolonged tourniquet use can cause elevated calcium levels.

The etiology of *hypercalcemia* is either hyperparathyroidism or malignancy in more than 90% of hypercalcemic patients. In the ambulatory setting, most patients with hypercalcemia have hyperparathyroidism. Thiazides can also cause mild hypercalcemia; the typical patient is an older woman. The intact *parathyroid hormone* (PTH, parathormone) levels can differentiate hyperparathyroidism from other causes of hypercalcemia. Nonhyperparathyroid causes of hypercalcemia will give low or “normal” intact PTH levels in a setting of hypercalcemia, whereas the PTH

Table 14-7 Causes of Calcium Abnormalities

Hypercalcemia	
Hyperparathyroidism (primary and secondary)	Granulomatous diseases
Malignancies <i>Breast, lung, prostate, renal, myeloma, T-cell leukemia, lymphoma</i>	Sarcoidosis
Drugs <i>Thiazide diuretics</i>	Tuberculosis
<i>Milk-alkali syndrome</i>	Chronic renal failure
<i>Vitamin D intoxication</i>	Immobilization
	Hyperthyroidism
Hypocalcemia	
Hypomagnesemia	Drugs
Hypoparathyroidism	<i>Loop diuretics</i>
Malabsorption of calcium or vitamin D	<i>Phenytoin</i>
Acute pancreatitis	<i>Phenobarbital</i>
Rhabdomyolysis	<i>Cisplatin</i>
Hyperphosphatemia	<i>Gentamicin</i>
Chronic renal failure	<i>Pentamidine</i>
Transfusion of multiple units of citrated blood	<i>Ketoconazole</i>
	<i>Calcitonin</i>
	<i>Bisphosphonates</i>

level will be increased in hyperparathyroidism. Typically the hypercalcemia of hyperparathyroidism is modest, with calcium levels less than 11 mg/dL and minimal symptoms. Hospitalized patients are more likely to have malignancy as a cause of hypercalcemia. Calcium levels greater than 13 mg/dL are usually associated with malignancy. Occasionally, patients with a family history of hypercalcemia show a reduction in calcium excretion and have familial hypocalciuric hypercalcemia. Other causes of hypercalcemia are related to increased gastrointestinal (GI) absorption, increased bone resorption, and decreased renal excretion (Table 14-7).

Perhaps the most common cause of a low total calcium level is a *low albumin level*. When hypocalcemia is found, one should establish that the serum albumin is normal. If serum albumin is also reduced, one should perform the above correction or obtain an ionized calcium level. Another important cause of hypocalcemia is *hypomagnesemia*, which can lead to PTH resistance or reduced PTH secretion. Correction of the magnesium deficiency usually results in correction of the hypocalcemia. Other causes of hypocalcemia are listed in Table 14-7.

CARCINOEMBRYONIC ANTIGEN

Carcinoembryonic antigen (CEA), an oncofetal glycoprotein antigen, is used in the evaluation of patients with adenocarcinomas of the GI tract, especially colorectal cancer. CEA may be elevated in benign as well as malignant diseases (eTable 14-3). CEA is not recommended as a screening test for occult cancer (including colorectal) because of its low sensitivity and specificity. Its main value is in monitoring for persistent, metastatic, or recurrent colon cancer after surgery. A preoperative elevation should return to normal in 6 to 12 weeks (CEA half-life, 2 weeks) if all disease has been resected (Duffy et al., 2013). CEA has an approximate 60% sensitivity for detecting recurrence in the patient whose postoperative CEA value has returned to normal. The adult reference range for CEA is 2.5 ng/mL or less for

nonsmokers and 5.0 ng/mL or less for smokers. The degree of CEA elevation correlates with tumor bulk at diagnosis and therefore with prognosis. Values less than 5 ng/mL before therapy suggest localized disease and favorable prognosis, whereas levels greater than 10 ng/mL suggest extensive disease and a worse prognosis. About 30% of patients with metastatic colon cancer have normal CEA levels. Benign diseases do not usually produce CEA levels greater than 5 to 10 ng/mL. For an individual patient, repeat testing or longitudinal monitoring should be conducted at the same laboratory with the same methods because of variability among assays. A 20% to 25% increase in plasma concentration is considered a significant change. A rising CEA level may detect recurrent disease 2 to 6 months before it is clinically apparent.

COAGULATION STUDIES

The most common coagulation studies, *prothrombin time* (PT) and *partial thromboplastin time* (PTT), are used to evaluate patients with clotting disorders or to monitor patients taking heparin or oral anticoagulants. PT, a simple and inexpensive test for evaluating the extrinsic coagulation pathway, is the time in seconds for citrated plasma to clot after the addition of calcium and thromboplastin. Test accuracy depends on proper collection and instrument technique. Common uses include monitoring anticoagulant therapy with warfarin, evaluating liver function (because the liver synthesizes most of the clotting factors), and screening for coagulation disorders of the extrinsic system. PT is prolonged by defects in factors I (fibrinogen), II (prothrombin), V, VII, and X. Previously, PT measurements exhibited variability across laboratories because of differences in thromboplastin sensitivity. To correct for the type of thromboplastin used, the *international normalized ratio* (INR) is used to report PT results for patients taking oral anticoagulants. The INR is calculated as follows:

$$\text{INR} = (\text{Patient PT}/\text{Control PT})^{\text{ISI}}$$

The ISI is the international sensitivity index of the thromboplastin used at the local laboratory. Provided by the test's manufacturer, ISI reflects the responsiveness of the thromboplastin used in the PT test. The reference range for the PT and the INR in a non-anticoagulated patient is approximately 11 to 13 seconds and 0.9 to 1.1, respectively. The PT is prolonged with vitamin K deficiency, including those with fat malabsorption syndromes, recent broad-spectrum antibiotic use, and premature infants. In addition, severe liver disease, alcoholism, deficiencies of clotting factors, and circulating anticoagulants can prolong the PT. The PT is not affected by platelet disorders or platelet count. The target INR varies with specific indications. In general, an INR goal of 2.5 (range, 2.0-3.0) is generally accepted for the treatment of venous thromboembolic disease and atrial fibrillation, and 3.0 (range, 2.5-3.5) for patients at risk for arterial thromboembolism, including those with mechanical heart valves.

The *activated* PTT (aPTT, or simply PTT) is used to evaluate the intrinsic coagulation pathway, monitoring heparin therapy, screening for hemophilia A and B, and detecting clotting inhibitors. PTT is the time in seconds for citrated plasma to clot after a contact activator is added to plasma

and incubated at 37° C for 5 minutes. Thromboplastin and calcium are added and the time to clot formation is recorded, which should be within 10 seconds of the control. PTT is abnormally prolonged in most patients with coagulation disorders (approximately 90%) and is therefore the best screening test in persons suspected of having a clotting disorder. PTT screens for all coagulation factors that lead to thrombin formation except VII and XIII. These factors include factors I, II, V, VIII (antihemophilic), IX (Christmas), X, and XII (Hageman). PTT is useful to evaluate patients with a known, suspected, or active bleeding disorder; consumptive coagulopathy (e.g., disseminated intravascular coagulation); disorder of fibrin clot formation; or fibrinogen deficiency. In addition, PTT is prolonged with deficiency of the Fletcher (prekallikrein) and Fitzgerald factors, warfarin or heparin therapy, lupus anticoagulant, and vitamin K deficiency. PTT is significantly shortened by hemolysis, is affected by high or low hematocrit, but is not affected by platelet dysfunction or count. A prolonged PT or PTT can be caused by either a factor inhibitor or a deficiency of a clotting factor. To differentiate the two, a mixing study can be performed. When the abnormality is corrected after mixing with normal blood, a factor deficiency is likely. Failure to correct after mixing suggests the presence of a factor inhibitor.

When monitoring heparin therapy, the most widely used target for anticoagulation is a PTT 1.5 to 2.5 times the upper limit of normal. However, because of the great variation in thromboplastins used in different PTT assays, PTT results vary widely among laboratories. At present, there is no standardization similar to the INR for PTT results. Therapeutic heparin levels, as measured by antifactor Xa units, are approximately 0.3 to 0.7 antifactor Xa IU/mL. With plasma concentrations of heparin at 0.3 antifactor Xa IU/mL, investigators have found that mean PTT values ranged from 48 to 108 seconds, depending on the laboratory methods used. The American College of Chest Physicians recommends that each laboratory determine the PTT range that corresponds to a therapeutic heparin level (Garcia et al., 2012).

COBALAMIN (VITAMIN B₁₂) AND FOLATE ACID DEFICIENCY

Vitamin B₁₂ or folate deficiency may be suspected when a macrocytic anemia (mean corpuscular volume [MCV] >100 fL) or pancytopenia is present. Vitamin B₁₂ deficiency, but not folate deficiency, is also associated with neurologic symptoms, including paresthesias, numbness, ataxia, and cognitive decline. The megaloblastic anemia is identical for both folate and vitamin B₁₂ deficiency. *Megaloblasts* are enlarged blastic cells (precursors to the erythroid and myeloid cell lines) found in the bone marrow and caused by aberrant DNA synthesis. The peripheral blood smear typically shows the presence of oval macrocytes, hypersegmented neutrophils (>5% neutrophils with five lobes or any neutrophil with six lobes). The reticulocyte count is usually decreased.

The clinician must distinguish folate from vitamin B₁₂ deficiency, because supplementing one will not correct the symptoms from deficiency of the other—that is, folate replacement will not improve the neuropsychiatric

eTable 14-3 Conditions Associated with Elevated Carcinoembryonic Antigen Level

Disease	Patients with Elevated CEA (%)
Carcinoma of entodermal origin (colon, stomach, pancreas, lung)	60-75
Colon cancer

Table 14-8 Cobalamin (Vitamin B₁₂) and Folate Deficiency

Most Common Cause	Vitamin B ₁₂ Deficiency	Folate Deficiency
Inadequate intake	Strict vegetarian diet (rare) Alcoholism, elderly patients	Malnutrition Alcoholism
Increased need	Pregnancy, lactation	Pregnancy, lactation, infancy Neoplasia, hyperthyroidism, hemolysis
Defective absorption or storage	Decreased intrinsic factor (e.g., pernicious anemia, congenital deficiency of intrinsic factor, gastrectomy) Zollinger-Ellison syndrome Pancreatitis Ileal mucosal disease (e.g., sprue, regional enteritis, surgery, lymphoma) Tapeworm infestation, other parasites Bacterial overgrowth in blind-loop syndrome Drugs (e.g., colchicine, aspirin, metformin)	Malabsorption caused by: Drugs (e.g., anticonvulsants, antituberculosis agents, oral contraceptives, folate antagonist) Jejunal mucosal disease (e.g., amyloidosis, sprue, lymphoma, surgery) Liver disease (cirrhosis, hepatoma)

abnormalities caused by vitamin B₁₂ deficiency. The neurologic signs and symptoms of vitamin B₁₂ deficiency may precede hematologic abnormalities. Vitamin B₁₂ and folate deficiency often coexist because some causes overlap (Table 14-8).

The reference range for vitamin B₁₂ is often listed as 200 to 900 pg/mL; however, it is now recognized that a significant portion of patients with vitamin B₁₂ levels of 200 to 400 pg/mL have symptoms of vitamin B₁₂ deficiency. Vitamin B₁₂ levels may be falsely elevated in patients with anti-intrinsic factor antibodies, folate deficiency, and pregnancy. Because vitamin B₁₂ is a cofactor in the conversion of methylmalonic acid to succinyl coenzyme A (CoA) and homocysteine to methionine, deficiencies of vitamin B₁₂ will lead to increased levels of methylmalonic acid and homocysteine. Folate is required in the conversion of homocysteine to methionine, but not in the conversion of methylmalonic acid to succinyl CoA. Folate deficiency is associated with elevated homocysteine, but not methylmalonic acid. Testing for methylmalonic acid and homocysteine is often recommended to confirm if patients with levels in the low-normal range actually have vitamin B₁₂ or folate deficiency. However, one study examining patients in the ambulatory care setting with symptoms compatible with vitamin B₁₂ deficiency found significant intraindividual variability in vitamin B₁₂, methylmalonic acid, and homocysteine levels. More importantly, they found that many patients with symptoms compatible with vitamin B₁₂ deficiency and normal vitamin B₁₂, methylmalonic acid, and homocysteine had a clinical response to pharmacologic doses of vitamin B₁₂ (Solomon, 2005). Because of the limitations of vitamin B₁₂ assays in diagnosing vitamin B₁₂ deficiency, some recommend a clinical trial of vitamin B₁₂ with predetermined clinical endpoints in patients with compatible clinical findings (Stabler, 2013).

Folate levels greater than 4 ng/mL are considered normal; levels of 2 to 4 ng/mL are indeterminate, and levels less than 2 ng/mL are diagnostic of folate deficiency in the absence of recent fasting. A person in negative folate balance will become serum deficient before tissue folate stores decrease; therefore, a low serum folate level indicates a negative folate balance, but not necessarily tissue folate deficiency. Intake of folate may normalize serum levels initially, so serum folate levels should be determined before a hospitalized or potentially deficient patient is fed, takes vitamins, or is given a transfusion. In a person with borderline

folate levels, either measurement of homocysteine or red blood cell (RBC) folate levels may be helpful to confirm the diagnosis.

COMPLETE BLOOD COUNT

The complete blood count (CBC) measures circulating blood cells, including RBCs, white blood cells (WBCs), and platelets (eTable 14-4). Current technology uses electronic cell counters that can count and size the cells, providing an estimate of cell volume (MCV) and variation in cell size (red cell distribution width [RDW]), and give a five-part WBC differential, including neutrophils, lymphocytes, monocytes, eosinophils, and basophils (Tefferi et al., 2005). Typically, peripheral blood smears are prepared for manual review only when requested or when automated hematology analyzers flag abnormal results. By analyzing large numbers of cells, current instruments can generate more accurate data than by manual review for most parameters. Indications for manual review of a blood smear include the evaluation of hemolysis, RBC inclusions, myelodysplasia, megaloblastic changes, thrombocytosis, thrombocytopenia, leukocytosis, and immature or abnormal cells (Bain, 2005).

Red Blood Cells

A mild *anemia* is the most common abnormality found on a CBC. Factors that help determine whether further testing should be performed include the degree of anemia and the presence of other abnormalities in the CBC. The first step is to classify the anemia, based on MCV, as microcytic (<80 fL), normocytic (80-100 fL), or macrocytic (>100 fL). With a *microcytic* anemia, the most important test is the ferritin level, which suggests iron deficiency anemia when less than 30 ng/mL. With a *normocytic* anemia, potentially treatable causes should be excluded (e.g., recent bleeding, hemolysis, renal insufficiency, vitamin deficiency). Other causes of a normocytic anemia (e.g., anemia of chronic disease, primary bone marrow disorders) may need a bone marrow biopsy for definitive diagnosis. For a *macrocytic* anemia, important determinations are the medication history, alcohol use, and vitamin B₁₂ or folate deficiency.

Erythrocytosis refers to a hematocrit above the reference range. In *true* erythrocytosis, the total circulatory RBC mass is increased, whereas in *relative* erythrocytosis, the RBC mass is normal but the plasma volume is decreased, so the

eTable 14-4 Complete Blood Count Components

Test	Description	95% Reference Range Conventional	Reference Range International
Hemoglobin (Hb)	Measure of oxygen-carrying capacity of blood expressed as grams per unit volume (usually deciliters; g/dL).	M: 13.5-17.5 g/dL F: 12.0-16.0 g/dL	135-175 g/L 120-160 g/L
Hematocrit (Hct)	Measure of solid elements of blood (mostly RBCs), as percentage of whole blood (remainder is plasma). $Hct = MCV \times RBC$. Expressed in %, usually about three times Hb. Both Hct and Hb usually are low in anemia but may not be apparent early in acute blood loss, because plasma volume needs about 12-24 hours to equilibrate.	M: 39-49% F: 35-45%	0.39-0.49 0.35-0.45
Red blood cell (RBC) mass	Erythrocyte count; true measure of cells/L.	M: $4.3-5.7 \times 10^6$ cells/ μ L F: $3.8-5.1 \times 10^6$ cells/ μ L	$4.3-5.7 \times 10^{12}$ /L $3.8-5.7 \times 10^{12}$ /L
Red cell indices	MCH, MCHC, MCV. <i>Note:</i> In early anemia, MCV may change before Hb and Hct.		
Mean corpuscular hemoglobin (MCH)	Hb divided by RBC; represents the content (weight) of Hb in average RBC; not as useful as MCHC.	26-34 pg/cell	0.40-0.53 fmol/cell
Mean corpuscular hemoglobin concentration (MCHC)	Hb divided by Hct, concentration of Hb per unit volume of packed RBCs. Appearance of erythrocytes on peripheral smear is affected by Hb concentration in cell; low, hypochromic; normal, normochromic; high, hyperchromic.	31.37% Hb/cell or g Hb/dL RBCs	4.81-574 mmol Hb/L RBCs
Mean corpuscular volume (MCV)	$Hct \times 1000$ divided by the RBC count; reflects RBC size; small, microcytic; normal, normocytic; large, macrocytic. <i>Note:</i> Presence of microcytosis and macrocytosis in same sample may result in normal MCV.	80-100 fL 1fL (femtoliter) = 10^{-15} L = 1 cubic micrometer (μ m ³)	80-100 fL
Red cell distribution width (RDW)	Estimate of RBC size variability (anisocytosis); standard deviation (SD) of RBC size divided by MCV.	11.5-14.5	11.5-14.5
Reticulocyte count (%)	Expressed as percent of reticulocytes per 1000 RBCs counted.	0.5-1.5%	0.005-0.015 (number fraction)
Reticulocyte count (absolute)	Reticulocyte (%) \times RBC count; more meaningful expression of erythropoiesis.	$50 \times 10^3/\mu$ L	50×10^9 /L
Platelet count		$150-450 \times 10^3/\mu$ L	$150-450 \times 10^9$ /L

Exogenous erythropoietin

hematocrit is elevated. With true erythrocytosis, elevated erythropoietin levels suggest a secondary cause and can help distinguish secondary erythrocytosis from polycythemia vera (Table 14-9).

White Blood Cells

The WBC count is often requested to support a diagnosis of infection or an inflammatory process, or to monitor the course of a disease or response to treatment. The cell types that make up the WBC count include neutrophils (segmented and band forms), lymphocytes, monocytes, eosinophils, and basophils. *Bands* are immature neutrophils, and *segmented* forms are mature neutrophils. To diagnose neutropenia, the *absolute neutrophil count* (ANC) should be determined by multiplying the total WBC count by the percentage of bands plus mature neutrophils (segmented forms). With severe neutropenia, the ANC drops below 500 cells/mm³, and the patient is at increased risk for infections. Causes of neutropenia include drug reactions, bacterial and viral infections, hematopoietic diseases, cachexia, hypersplenism, and autoimmune diseases. Lymphopenia is present when the lymphocyte count is less than 1500 cells/mm³ in the adult or 3000 cells/mm³ in children. Causes of lymphopenia include immunosuppressant drugs, corticosteroid therapy, viral infections (including HIV), and genetic immunodeficiencies.

Leukocytosis, or an elevated WBC count, occurs when the total WBC count is greater than 10,000 cells/mm³. An elevated WBC count may be the result of a reactive process (leukemoid reaction) or leukemia. Leukemoid reactions can result from infections, toxic conditions, neoplasms, myeloproliferative diseases, and other hematologic disorders. The first step in the evaluation of leukocytosis is to determine what type of WBC is elevated. Leukocytosis may be caused by neutrophilia, eosinophilia, basophilia, monocytosis, or lymphocytosis (Table 14-10).

Table 14-10 Common Causes of Leukocytosis or Leukopenia Stratified by White Blood Cell Type**Leukocytosis**

Neutrophilia	Infections, leukemia, rheumatic and autoimmune disorders, neoplastic disorders, chemicals, trauma, endocrine and metabolic disorders, hematologic disorders, drugs
Eosinophilia	Infectious diseases, parasitic infections, allergic diseases, myeloproliferative and neoplastic diseases, cutaneous diseases, gastrointestinal diseases
Basophilia	Allergic reactions, chronic myeloid leukemia, myeloid metaplasia, polycythemia vera, ionizing radiation, hypothyroidism, chronic hemolytic anemia, splenectomy
Monocytosis	Infections, neoplastic disorders, gastrointestinal disorders, sarcoidosis, drug reactions, recovering from marrow suppression
Lymphocytosis	Viral infections, lymphocytic leukemia, other infectious diseases, neoplastic disorders

Leukopenia

Neutropenia	Overwhelming bacterial infection, viral infection, drug reaction, ionizing radiation, hematopoietic diseases, hypersplenism, anaphylactic shock, cachexia, autoimmune disease
Eosinopenia	Acute stress (usually physical), acute inflammatory states, Cushing's syndrome, corticosteroids
Basopenia	Sustained treatment with glucocorticoids, acute infection or stress, hyperthyroidism
Monocytopenia	Onset of steroid therapy; hairy cell leukemia
Lymphopenia	Immunodeficiency disorders, adrenocortical hormone excess, chemotherapeutic drugs, irradiation, impaired drainage of intestinal lymphatics, advanced lymphomas and carcinomas, anorexia

From Speicher CE. *The right test*. 3rd ed. Philadelphia: Saunders; 1998, pp. 281-283.

Platelets

Platelets, cellular fragments of the bone marrow precursor-cell megakaryocytes, are essential to clot formation and have a life span of about 10 days. Clinically, a disorder in platelets is usually suspected in a patient with excessive bleeding, typically from a mucocutaneous source or after trauma. Clinical evidence of bleeding does not occur until the platelet count drops below 50 to 70 × 10³/μL. Platelet counts of less than 10 to 20 × 10³/μL are associated with major spontaneous bleeding. *Thrombocytopenia* may be caused by disorders of production, distribution, or destruction (Table 14-11). In evaluating thrombocytopenia, one should first examine the peripheral smear for platelet clumping, or repeat the test using sodium citrate as the anticoagulant. *Thrombocytosis*, or an increased platelet count, may be caused by a reactive process or a myeloproliferative disorder. Reactive processes do not usually produce platelet counts greater than 1000 × 10³/μL. Common causes of thrombocytosis include iron deficiency, acute blood loss, inflammatory disorders, malignancies, splenectomy, and myeloproliferative disorders.

Table 14-11 Causes of Thrombocytopenia

Decreased Production	Increased Destruction
Congenital disorders	Immune thrombocytopenia
Radiation or chemotherapy	Drugs
Vitamin B ₁₂ or folate deficiency	Quinine
Drugs	Quinidine
Systemic lupus erythematosus	Heparin
Aplastic anemia	Sulfa drugs
Acute leukemia	Valproic acid
Lymphomas	Disseminated intravascular coagulation (DIC)
Alcohol abuse	Hemolytic-uremic syndrome
Viral infections, including human immunodeficiency virus (HIV)	HELLP (hemolysis, liver dysfunction, and low platelets) syndrome
Splenic sequestration	Sepsis
	Cardiopulmonary bypass
	Toxemia of pregnancy, eclampsia

CARBON DIOXIDE OR BICARBONATE

Acid-base disturbances are often recognized by abnormalities in the carbon dioxide (CO₂) content of blood, which is composed primarily of bicarbonate (HCO₃⁻), with small amounts of carbonic acid and dissolved carbon dioxide. The reference range for CO₂ is 22 to 29 mmol/L. A reduced serum bicarbonate concentration frequently suggests *metabolic acidosis*, particularly when combined with a low pH. An elevated serum bicarbonate level frequently occurs with *metabolic alkalosis*. Bicarbonate is often used as a buffer for excess acid production, and levels are reduced in metabolic acidosis. In the evaluation of acidosis, calculation of the serum *anion gap* is helpful in determining the cause of the acidosis, as follows:

The normal anion gap is 10 to 12 mmol/L. An increased anion gap generally indicates the presence of metabolic acidosis with elevation of unmeasured ions, such as lactic acid, phosphates, sulfates, and ketoacids. A normal anion gap acidosis is seen with bicarbonate losses and increased chloride reabsorption and most frequently occurs with chronic diarrhea, but also with certain types of renal tubular acidosis. Low anion gaps can occur with hypoalbuminuria, congestive heart failure, and occasionally, multiple myeloma.

An elevated serum bicarbonate level frequently occurs in the setting of metabolic alkalosis. Metabolic alkalosis can be generated by loss of acid, such as in vomiting, but normally the kidney corrects the abnormality promptly by excreting excess bicarbonate. To maintain a metabolic alkalosis, the kidney must not be able to excrete excess bicarbonate. This abnormality usually occurs in the setting of volume depletion, when sodium reabsorption is enhanced and the sodium must be accompanied by an anion to maintain electroneutrality. In the absence of available chloride in the urine, bicarbonate is reabsorbed with sodium, thereby maintaining the alkalosis. Urine chloride levels less than 10 mmol/L are present with chloride-responsive metabolic alkalosis, such as vomiting with volume depletion. Elevated urine chloride (>20 mmol/L) are associated with mineralocorticoid excess, such as hyperaldosteronism and hypercortisolism.

C-REACTIVE PROTEIN

An acute-phase reactant glycoprotein, C-reactive protein (CRP), is associated with inflammation. CRP is one of the first proteins to become elevated after an inflammatory process has begun and disappears rapidly when inflammation subsides. In healthy persons, CRP levels are usually less than 0.8 mg/L and are often below the detection limit for standard assays. Serum levels may increase dramatically to exceed 100 mg/L in the presence of bacterial and viral infections, inflammation, severe trauma, surgery, neoplastic proliferation, tissue injury, necrosis, and transplant rejection. Moderate elevations may be seen with myocardial infarction, autoimmune diseases, rheumatic fever, pregnancy, obesity, and postoperatively. CRP is not affected by age, race, or food intake and does not have significant circadian variation. Drugs that may reduce or suppress CRP levels by controlling inflammation include statins, fibrates, niacin, nonsteroidal antiinflammatory drugs (NSAIDs), steroids, salicylates, angiotensin-converting enzyme (ACE) inhibitors, and β -adrenergic blockers. Compared with the ESR, the CRP rises earlier, returns to baseline sooner, and is less influenced by altered physiologic states.

The levels of CRP used to assess atherosclerotic risk are much lower than those associated with inflammation, and highly sensitive immunoassays CRP tests (hsCRP; cardiac-CRP) can accurately measure to a lower limit of 0.3 mg/L. Many studies have found that hsCRP levels predict the long-term risk of myocardial infarction, ischemic stroke, peripheral vascular disease, and all-cause mortality in healthy subjects (Greenland, 2010). The hsCRP can be used to further evaluate patients judged to be at intermediate risk for the development of coronary heart disease (those with 10-year coronary heart disease [CHD] risk of 10% to 20%). CRP levels are divided into tertiles: low risk (<1.0 mg/L), average risk (1.0-3.0 mg/L), and high risk (>3.0 mg/L). A CRP in the highest tertile is associated with a twofold risk of major coronary events compared with a CRP in the lowest tertile. Unexplained levels of hsCRP levels higher than 10 mg/L should be repeated and evaluated for noncardiovascular causes, such as infection or inflammation (Smith et al., 2004).

ERYTHROCYTE SEDIMENTATION RATE

The erythrocyte sedimentation rate (ESR) is one of the oldest laboratory tests still in clinical use. The test measures the distance that erythrocytes (RBCs) fall in a column of anticoagulated blood in 1 hour. Plasma proteins known as *acute-phase reactants* facilitate erythrocyte aggregation, which in turn affects the rate at which the solid component of blood will settle in a capillary tube. The plasma proteins most responsible for this aggregation (rouleaux formation), in decreasing order, are fibrinogen, beta (β -) globulins, alpha (α -) globulins, gamma (γ -) globulins, and albumin. Inflammatory, infectious, neoplastic, and collagen vascular diseases increase the ESR. The ESR is helpful in the diagnosis of *polymyalgia rheumatica* and *temporal arteritis*; otherwise, it is both nonsensitive and nonspecific. In studies of patients with biopsy-proven temporal arteritis, 90% of patients had an ESR greater than 30 mm/h with mean ESR of 90 mm/h. About 4% of patients with biopsy-proven

Table 14-12 Factors Affecting the Erythrocyte Sedimentation Rate

Increase	Decrease	No Effect
Anemia	Polycythemia	Body temperature
Macrocytosis	Microcytosis	Recent meal
Female gender	Spherocytosis	Aspirin
Advanced age	Extreme leukocytosis	NSAIDs
Second- and third-trimester pregnancy	Sickle cell disease	First-trimester pregnancy
Hypoalbuminemia	Excessive anticoagulant	
Tilted ESR tube	Short ESR tube	
High room temperature	Low room temperature	
	Clotted blood sample	

ESR, Erythrocyte sedimentation rate; NSAID, nonsteroidal antiinflammatory drug.

temporal arteritis have a normal ESR (Smetana and Shmerling, 2002). When there is strong clinical evidence for temporal arteritis and a normal ESR, however, a temporal artery biopsy or a trial of corticosteroids should be considered. Although used to follow the response to corticosteroid therapy in polymyalgia rheumatica and temporal arteritis, ESR should be used in conjunction with clinical findings. Typically, ESR drops within a few days of corticosteroid therapy, falling to a level that is higher than normal. In addition, relapse can occur without ESR elevation.

Table 14-12 lists physiologic, pathologic, and technical factors that alter ESR, which is higher in women than men and higher in older persons. To determine ESR for healthy adult men, age in years is divided by 2, and for women, age in years plus 10 is divided by 2. Clinical considerations for using ESR have been defined (Brigden, 1998; Sox and Liang, 1986). It should not be used as a screening test for disease in asymptomatic persons. As a single test after a normal history and physical examination in asymptomatic persons, ESR contributes to disease detection of a serious illness in less than 6 of 10,000 persons. The underlying cause of an elevated ESR is usually apparent by the history and physical examination, especially for extreme elevations of about 100 mm/h. Many cases of unexplained elevated ESR are transient and not associated with serious disease. If no obvious cause is seen for elevated ESR, repeating the test in several months is recommended, rather than searching for occult disease.

FECAL OCCULT BLOOD TEST

The fecal occult blood test (FOBT) is used to detect blood loss in the stool that is not clinically apparent. Patients who report rectal bleeding or those with frank blood by rectal examination should undergo further diagnostic evaluation and do not need an FOBT. The two main FOBTs commercially available are the *guaiac-based tests*, which detect pseudoperoxidase in the heme portion of hemoglobin, and *immunochemical tests*, which detect the globulin portion of human hemoglobin.

The basis of the guaiac test is that the pseudoperoxidase of hemoglobin oxidizes guaiac to form a blue-colored quinone compound, after the addition of a hydrogen

peroxide developer. The likelihood of a positive guaiac test is related to the amount of blood present in the stool. Several factors have an impact on FOBT performance characteristics. Bleeding from proximal GI lesions, including the right colon, may allow for degradation of the heme, which will then not catalyze the guaiac reaction. The myoglobin or hemoglobin in red meat can give a false-positive reaction, although ingesting 8 oz of cooked red meat daily has only a 5% probability of giving a positive test result. Peroxidase-rich raw vegetables and fruits (turnips, parsnips, horseradish, artichokes, mushrooms, radishes, broccoli, cauliflower, beets, apples, oranges, bananas, melons, grapes, pears, plums, cantaloupe) may give a false-positive result if fecal specimens are tested immediately after collection. However, plant peroxidases are unstable with time; therefore, if a specimen is developed several days after collection, the likelihood of a false-positive test result because of plant peroxidases is reduced.

Gastric irritants such as aspirin, NSAIDs, and excessive alcohol consumption may also produce positive results. Oral iron supplements and acetaminophen do not affect the guaiac test. Ascorbic acid (vitamin C) in excess of 250 mg/day or multivitamins with vitamin C may cause a false-negative result because ascorbic acid is a reducing agent and interferes with the oxidation of guaiac. Other antioxidants should also be avoided.

The processes of collecting and processing FOBTs are important in the evaluation of the results. Delaying the processing of the slides allows for dehydration of the specimen, which allows degradation of peroxidase activity and will decrease the sensitivity of testing. The delay between preparation and laboratory testing should not exceed 6 days. The issue of rehydration of dried slides with water is controversial. Rehydration of slides increases sensitivity and decreases specificity (false-positive rate increases) (Bresalier, 2010). Patients should not collect specimens until 3 days after menses have stopped or if obvious rectal bleeding or hematuria is noted. For 3 days before testing, patients should avoid ingesting red meat, vegetables with high amounts of peroxidase (broccoli, turnip, cantaloupe, cauliflower, radishes), aspirin, NSAIDs, and vitamin C. The detection of the blue color of a positive test may be affected by other factors, including a thick stool smear, exposure to high ambient temperatures, and black stools from iron ingestion.

About 2% to 6% of asymptomatic adults have a positive FOBT test, 10% of whom have cancer and 20% to 30%, adenomas. The rest have upper GI sources of bleeding, non-neoplastic lower GI sources of bleeding (e.g., hemorrhoids), or no identified source of bleeding. With home-based testing, FOBT has best been studied using a regimen of three stools. Because only one specimen is obtained during a digital rectal examination (DRE), a single digital FOBT has poor sensitivity and therefore cannot be recommended as the sole test for screening for colon cancer.

Newer fecal immunochemical tests (FITs) are based on an antigen-antibody reaction that is specific for human hemoglobin. They do not react with animal hemoglobin or peroxide-containing foods. Moreover, the FIT is not affected by ingestion of vitamin C, iron, or rehydration, so no dietary restrictions are required. However, globulin levels are reduced in high temperatures and with a delay in testing,

which might reduce the sensitivity. Because globulin is broken down in the upper GI tract, the globulin tests do not detect bleeding from the upper GI tract as readily as guaiac-based tests. Current immunochemical tests use either one or two stool samples. The sensitive guaiac based tests (Hemoccult Sensa) and the FITs are more sensitive than Hemoccult II for colorectal cancer and advanced adenoma detection. Specificity for FIT testing is variable compared with sensitive guaiac-based tests, but probably similar. Several studies have shown participation rates are higher with the immunochemical tests than with guaiac-testing, likely because of the lower number of stool samples in the testing and the lack of dietary restrictions.

GLUCOSE

The reference range for a fasting plasma glucose level is between 70 and 99 mg/dL. *Hypoglycemia* is best documented by a plasma venous glucose level less than 50 mg/dL, although there is considerable variability in the level of hypoglycemia that causes symptoms. Asymptomatic hypoglycemia in a patient not taking insulin or oral hypoglycemic agents may be a laboratory artifact caused by ongoing metabolism of glucose in the specimen, especially if a delay has occurred in processing the specimen. The diagnosis of hypoglycemia is best made with typical symptoms associated with a laboratory confirmation of venous hypoglycemia, followed by relief of symptoms after ingesting glucose. The glucose tolerance test (GTT) can produce hypoglycemia in normal persons and should not be routinely ordered in the evaluation of hypoglycemia.

Hypoglycemia can be defined as iatrogenic, postprandial, or fasting. *Postprandial* hypoglycemia occurs after meals and is usually mild and self-limiting. *Alimentary* hypoglycemia occurs when patients have rapid gastric emptying. Insulin levels rise rapidly after a meal and fall more slowly than glucose levels, which results in hypoglycemia. *Fasting* hypoglycemia is seen much less often than reactive hypoglycemia and may be a harbinger of more severe disease, including insulin-producing pancreatic tumors and hepatic, adrenal, or renal insufficiency, or it may be the result of excess insulin or sulfonylurea administration. True fasting hypoglycemia needs to be confirmed by a prolonged fast, with simultaneous measurement of glucose and insulin. This technique can help determine whether the hypoglycemia is associated with excess insulin.

Diabetes mellitus is characterized by *hyperglycemia*. The American Diabetes Association has defined *normal* fasting plasma glucose as less than 100 mg/dL (5.6 mmol/L), *pre-diabetes* as 100 to 125 mg/dL (5.6-6.9 mmol/L), and diabetes mellitus as 126 mg/dL (7.0 mmol/L) or greater.

GLYCOSYLATED HEMOGLOBIN (HEMOGLOBIN A_{1c})

The glycosylated hemoglobin (hemoglobin A_{1c} [HbA_{1c}]) fraction measures nonenzymatic glycosylation of hemoglobin, which is related to level of glucose concentration over the life span of the erythrocyte. The HbA_{1c} fraction can be used to estimate glucose control in the previous 2 to 3 months. In persons with normal erythrocyte survival, the glucose levels in the last 30 days contribute to 50% of the

HbA_{1c}, whereas the glucose levels in the preceding 90 to 120 days contribute only 10% to the HbA_{1c} measurement. HbA_{1c} can be reported in the familiar percentage combined with the HbA_{1c}-derived average glucose (ADAG) (Saudek et al., 2008). Using the National Health and Nutrition Examination Survey (NHANES) III data that the population average for HbA_{1c} was 5.17 with standard deviation (SD) of 0.45, the International Expert Committee (2009) selected an HbA_{1c} of 6.5% (approximately 3 SD above average) as the cutoff point to diagnose diabetes mellitus, with confirmation by a fasting glucose greater than 126 mg/dL or oral GTT greater than 200 mg/dL, or a repeat HbA_{1c} greater than 6.5%. Screening with HbA_{1c} identifies fewer individuals with diabetes than either plasma glucose or GTT. Goals for achieving optimal control of diabetes are controversial, but a reasonable goal in most persons is an HbA_{1c} less than 7%. Conditions that shorten erythrocyte survival, such as hemolysis or recent bleeding, give a lower HbA_{1c} level. Black patients tend to have a slightly higher HbA_{1c} levels (by 0.2-0.3) than white patients (Inzucchi, 2012).

HELICOBACTER PYLORI

A spiral, urease-producing bacterium, *Helicobacter pylori*, is associated with almost 90% of duodenal ulcers. Testing is indicated in patients with either active or previously documented peptic ulcer disease, in the evaluation of dyspepsia who have no “alarm features,” and for patients with a history of gastric mucosa-associated lymphoid tissue (MALT) lymphoma (MALToma) (Chey and Wong, 2007). Several tests can be performed during endoscopy. Rapid urease testing of a biopsy specimen has sensitivity over 90% and specificity over 95%, with results available within 1 to 24 hours. The sensitivity of rapid urease tests is reduced by drugs that treat *H. pylori*, including bismuth, antibiotics, and proton pump inhibitors (PPIs). Histologic examination of gastric biopsies can also detect *H. pylori*. Culturing *H. pylori* has a lower yield, is more expensive, and is not widely done.

There are three nonendoscopic methods to detect *H. pylori* infection. Serologic tests for immunoglobulin G (IgG) antibody to *H. pylori* can identify previous infection and have sensitivity of approximately 88% but specificity of only 70% to 80%. Serologic tests are inexpensive and have a good negative predictive value. The positive predictive value depends on the prevalence of *H. pylori*. Even though titers may decline slowly after eradication of the organism with antibiotics, these tests have limited use in evaluation of the effectiveness of antibiotic therapy and cannot reliably distinguish current from past infection.

The value of *H. pylori* antibody testing in the evaluation of uninvestigated dyspepsia depends on the prevalence of *H. pylori* infection. In areas of high prevalence (>20%), serologic testing may be cost-effective for a test-and-treat strategy. In areas of lower prevalence, the low positive predictive value of serology limits its usefulness; either stool antigen testing or urea-breath is more accurate. Antibody testing is inexpensive and has a very good negative predictive value.

Urea breath tests using carbon 13 (¹³C)-urea or ¹⁴C-urea can detect ongoing replication of *H. pylori*. These tests are most helpful in determining whether *H. pylori* has been

successfully eradicated after a course of treatment, but they can also confirm active infection. After the ingestion of labeled urea, urease-producing *H. pylori* organisms break down the urea and produce labeled CO₂, which is absorbed into the circulation and exhaled, and can be measured by collecting an exhaled breath sample in a bag. False-negative breath tests may occur with the recent use of antibiotics, bismuth, or PPIs. Most studies find the sensitivity and specificity of the urease breath test to be greater than 95%.

Testing for *H. pylori* antigen in the stool by immunoassay has been found to have sensitivity over 90% and specificity approaching 100%, thereby making it an accurate noninvasive method to diagnose active *H. pylori* infection in untreated patients. As in urea breath testing, recent antibiotics, PPIs, and bismuth can cause false-negative results. Stool tests can also be used to confirm eradication, but no sooner than 4 weeks after completion of therapy. A rapid stool *H. pylori* antigen test is now available for on-site testing.

HEPATITIS SEROLOGY

Hepatitis A virus (HAV), hepatitis B virus (HBV), and less often hepatitis C virus (HCV) are the usual causes of acute viral hepatitis. A person with symptoms of acute hepatitis should have these four hepatitis serologies performed: immunoglobulin M (IgM) anti-HAV, hepatitis B surface antigen (HBsAg), IgM hepatitis core antigen (anti-HBc), and anti-HCV. At present, stool and blood assays for HAV antigen are not available. The diagnosis of hepatitis A is made by the detection of IgM anti-HAV during acute illness. A positive anti-HAV with only IgG anti-HAV indicates previous infection.

In hepatitis B, HBsAg is the earliest serologic marker of infection and is present before elevation of the aminotransferases. If HBsAg is present for more than 6 months, the patient should be considered chronically infected (carrier). Previous hepatitis B vaccination is indicated by the presence of anti-HBs only. After infection, antibodies to HBsAg (anti-HBs) typically indicate immunity to hepatitis B and appear several weeks to months after HBsAg disappears. The gap between the presence of HBsAg and anti-HBs is the “window period”; during this time anti-HBc can be detected in the blood. Anti-HBc can be differentiated into an IgM anti-HBc, which indicates recent infection, and an IgG anti-HBc, which indicates previous infection. HBeAg, a subparticle of core antigen, is present only when HBsAg is present and is a marker for infectiousness. Anti-HBe appears after HBeAg disappears, indicates decreasing infectivity and a good prognosis, and remains detectable for years. HBV DNA testing can be used to determine if the patient is a candidate for antiviral therapy. *Hepatitis delta virus* (HDV) infection coexists with hepatitis B in about 4% of hepatitis B infections and carries an increased mortality rate. HDV depends on the presence of HBV for expression and replication and can cause acute or chronic infection.

Hepatitis C occasionally presents as acute hepatitis, but more frequently is detected in the evaluation of patients with elevated aminotransferases or chronic liver disease. In 2012, the Centers for Disease Control and Prevention (CDC) recommended one-time screening for hepatitis C in persons in the United States born between 1945 and 1965,

regardless of risk factors. The commonly available screening test is an enzyme immunoassay that detects antibodies to hepatitis C. The antibody test is usually detectable about 8 to 12 weeks after exposure. In a patient with a positive anti-HCV test, further testing for HCV RNA is recommended to confirm active HCV infection. A positive anti-HCV antibody and a negative HCV RNA suggest either a false-positive screening test or previous hepatitis C exposure with resolution of the infection. Quantitative HCV-RNA (viral load) and genotype testing should be performed prior to treatment.

HUMAN IMMUNODEFICIENCY VIRUS

The diagnosis of HIV infection usually depends on the detection of antibodies to the virus. The recommended screening test for HIV infection is an initial enzyme immunoassay, the ELISA test, which can detect the presence of antibody to HIV 2 to 8 weeks after infection. An initially positive ELISA should be repeated, and repeatedly positive ELISAs need to be confirmed by a more specific test, most often the Western blot. Sensitivity and specificity of this testing pattern are both greater than 99.5%. A positive ELISA combined with a negative Western blot should be considered a false-positive HIV test and indicates that HIV infection is not present. A positive ELISA and an indeterminate Western blot result can be a marker for early HIV infection or advanced acquired immunodeficiency syndrome (AIDS), or it can be a false-positive test result. The predictive value of a positive HIV test depends on the prevalence in the population being tested.

Rapid HIV tests are currently available that check saliva, whole blood, and plasma. The whole-blood tests measure capillary blood with a finger stick and do not require centrifugation. These tests are interpreted visually, do not require instrumentation, and provide test results in minutes. Rapid tests may be preferred for testing in patients who are not likely to return for results of standard testing, for pregnant women at delivery with no HIV testing during their pregnancy, and for testing during occupational exposure. Rapid tests for HIV have both similar sensitivity and specificity greater than 99.5%, and also require confirmation.

Tests to measure HIV directly include quantitative HIV RNA testing by polymerase chain reaction (PCR), which measures viral load or actual viral replication. Quantitative HIV RNA measurements are useful in evaluating indeterminate Western blot results and acute HIV infection, when the patient presents before seroconversion. Because neonates born to HIV-infected mothers often have maternal antibodies for months, early testing with HIV DNA PCR can identify infants with HIV infection. Newer combination fourth-generation p24 antigen-HIV antibody tests may shorten the window period between acute HIV infection and detection, and can be used in postexposure testing for health care professionals (Kuhar et al., 2013). In 2006, the CDC recommended routine, voluntary HIV screening for all patients age 13 to 64 in any health care setting.

IRON STUDIES

Iron deficiency is the most common type of anemia worldwide and therefore a significant cause of human morbidity. Other than menstrual blood losses, negligible iron is lost in

a healthy person. Normally, regulation of iron absorption in the proximal small intestine controls iron balance. Iron deficiency results from increased need (growth of infancy or childhood, pregnancy), excessive loss (menstruation, hemorrhage, GI loss), inadequate intake (iron-deficient diet), or defective absorption (gastrectomy or sprue). In adult men or postmenopausal women with adequate iron stores, it takes 3 to 4 years for these stores to be depleted once negative iron balance starts.

During early *iron deficiency anemia*, the erythrocytes may be normochromic normocytic, and later the peripheral blood smear may show microcytosis, anisocytosis, poikilocytosis, and hypochromia. The reticulocyte count is low, and RDW is high (>16). Bone marrow stores of iron are decreased or absent. Serum iron has marked diurnal variation (higher in morning, lower later in day) and is increased transiently after meals. Because morning levels determine the reference range, iron levels should be performed on a fasting morning specimen. Obtaining a serum iron level without determining the level of transferrin (*total iron-binding capacity* [TIBC]) is of limited value. Serum iron is decreased with inflammation, infection, and ascorbate deficiency and increased with iron ingestion, transfusions, liver disease, aplastic anemia, and ineffective erythropoiesis. The total iron-binding capacity or transferrin is not subject to diurnal fluctuation, but it is reduced in chronic inflammation and malnutrition. The serum ferritin is the best indirect marker for the assessment of iron stores. The conventional cut off of a ferritin under 10 to 15 ng/mL is virtually diagnostic of iron deficiency anemia. However, using cutoffs of 30 ng/mL still results in a 92% sensitivity and 98% specificity for the deficiency of iron deficiency (Mast et al., 1998). Serum ferritin is an acute-phase reactant and can be elevated in some patients with liver disease, malignancy, or inflammatory or infectious diseases. In a patient with chronic inflammation, a rule of thumb is to divide the ferritin level by 3, and if lower than 20 ng/mL, suspect coexisting iron deficiency. Less than 10% of people with ferritin levels higher than 100 ng/mL have iron deficiency. Hemolysis may cause falsely high levels of serum iron (eTable 14-5).

Iron overload, typically related to hemochromatosis or to repeated transfusions, is associated with elevated iron, transferrin saturation, and ferritin levels. While a transferrin saturation more than 60% in men and more than 50% in woman has a 90% sensitivity in detecting symptomatic homozygous hemochromatosis, several guidelines recommend a cutoff of more than 45% in both men and women to allow greater detection of individuals at earlier stages of the disease. Ferritin levels of more than 300 ng/mL in men and 200 ng/mL in women are suggestive of iron overload, in the absence of chronic inflammation or liver disease.

LIPID PROFILE

Lipid levels are often obtained to evaluate cardiovascular risk. There are four major classes of lipoproteins: chylomicrons, very-low-density lipoprotein (VLDL) cholesterol (VLDL-C), low-density lipoprotein (LDL) cholesterol (LDL-C), and high-density lipoprotein (HDL) cholesterol (HDL-C). Approximately 60% to 70% of plasma cholesterol is carried as LDL-C. A direct association is seen between increased

LDL-C and the risk of CHD. HDL-C functions in the reverse transport of cholesterol to the liver and carries apolipoprotein A-1. HDL-C accounts for about 20% to 30% of total cholesterol. HDL-C and CHD have a strong independent inverse relationship; for every 1-mg/dL decrease in HDL, the risk of coronary artery disease (CAD) increases 2% to 3%. The Adult Treatment Panel (ATP) III of the National Cholesterol Education Program (NCEP Expert Panel, 2001) recommended lipid screening as a tool to promote cardiovascular disease risk reduction. The standard lipid profile, as recommended by the ATP III, consists of direct measurement of total cholesterol, HDL-C, and triglycerides, with a calculated LDL-C, obtained after a 9-hour fast. The Friedewald formula for calculating LDL is $LDL = \text{total cholesterol} - HDL - \text{triglycerides}/5$.

The Friedewald formula for estimating LDL is not valid in the following three conditions: when there are chylomicrons present, when the triglycerides are higher than 400 mg/dL, and when there is dysbetalipoproteinemia (type III hyperlipidemia). Hypertriglyceridemia and dysbetalipoproteinemia lead to underestimations of the LDL. Using the Friedewald formula, some non-LDL lipoproteins—intermediate-density lipoprotein (IDL) and lipoprotein (a)—are included in the LDL calculation. Measurements of direct LDL, although more costly, give more accurate values than calculations using this formula in patients with hypertriglyceridemia. Nonfasting total cholesterol and HDL measurements give reliable assessment of CHD risk without the need to measure triglycerides (Di Angelantonio et al., 2009). The American Heart Association (AHA) 2010 guidelines recommend against the use of measurements of lipoprotein subfraction, particle size, and density in asymptomatic adults for cardiovascular risk assessment, because there is no evidence that these measures improved predictive capacity over standard lipid panel (Ip et al., 2009). While an analysis showed a higher CHD risk in individuals with higher LDL particle numbers, the risk was similar to that of non-HDL cholesterol as a risk (El Harchaoui et al., 2007). Lipoprotein(a) levels have shown modest correlations with stroke and CHD risk, but because of concerns with standardization of measurement and lack of strong evidence of benefit of additional risk prediction beyond transitional risk factor assessment, the AHA recommended against testing in asymptomatic individuals.

There are a number of sources of physiologic and analytic variation in lipid measurements. Failure to fast before the test elevates the triglycerides and leads to an underestimation of the LDL. The total cholesterol and HDL are not significantly different in the fasting or postprandial state. Dietary changes begin to become apparent in lipid measurements in approximately 1 to 2 weeks; therefore, patients should have a stable diet for 3 weeks before testing. Morning specimens are preferred because triglycerides have diurnal variation—lowest in the morning, highest in the afternoon. Recent illness or surgery, including myocardial infarction, stroke, or cardiac catheterization, can lower lipid measurements for several weeks. For major illness or injury, it may be necessary to wait 2 to 3 months before measurement. Cholesterol levels decrease 24 hours after myocardial infarction and remain depressed for up to 12 weeks. Table 14-13 lists some drugs that can affect the lipid components. Major causes of secondary dyslipidemia also include

eTable 14-5 Iron-Related Laboratory Measurements in Common Anemias

Type of Anemia	Serum Iron	Total Iron-Binding Capacity	Transferrin Saturation	Serum Ferritin	Serum Transferrin Receptor
Iron deficiency anemia	Low	High	Low	Low	High
Anemia of chronic disease	Low	Low	Low	High*	Low
Thalassemia	High	Low	High	High	High
Megaloblastic anemia	High	Low	High	High	High
Hemolytic anemia	High*	Low*	High*	High*	High

*May fall within normal range.

Table 14-14 Causes of Magnesium Abnormalities

Hypermagnesemia	
Overingestion (usually in setting of renal insufficiency)	Renal insufficiency
Antacids	Addison disease
Cathartics	Hypothyroidism
Laxatives	Lithium intoxication
Hypomagnesemia	
Gastrointestinal causes	Drugs
Low-magnesium diet	Diuretics (thiazide and loop)
Malabsorption	Digitalis
Diarrhea	Cyclosporine
Renal tubular disorders	Cisplatin
Ketoacidosis	Aminoglycosides
Alcohol abuse	Proton pump inhibitors
	Amphotericin B

diabetes mellitus, hypothyroidism, nephrotic syndrome, and obstructive liver disease.

MAGNESIUM

Magnesium levels are not routinely included in standard chemistry panels, so abnormalities of magnesium frequently go unrecognized. The reference range of serum magnesium concentration is 1.7 to 2.2 mg/dL (1.5-1.7 mEq/L, or 0.75-0.95 mmol/L). The most common cause of *hypermagnesemia* is excess magnesium intake in a patient with chronic kidney disease (Table 14-14). Symptoms of hypermagnesemia are seen with levels greater than 4 to 6 mg/dL.

Hypomagnesemia is more common than hypermagnesemia. The three mechanisms causing hypomagnesemia are reduced intestinal absorption from malnutrition or malabsorption, increased urinary losses, and intracellular shifts. Hypomagnesemia is typically associated with alcohol abuse, hypokalemia, hypocalcemia, chronic diarrhea, and ventricular arrhythmias. Symptoms occur with serum concentrations less than 1 mEq/L. Clinically, hypomagnesemia is associated with neuromuscular hyperirritability, including tremors, tetany, and rarely, seizures. In distinguishing renal

wasting from extrarenal losses as the cause of hypomagnesemia, a 24-hour urine excretion of greater than 24 mg or a spot urine fractional excretion of magnesium greater than 2% suggests that the cause of hypomagnesemia is excessive renal losses.

MONONUCLEOSIS (EPSTEIN-BARR VIRUS INFECTION)

Mononucleosis is a common viral infection, particularly in adolescents and young adults. Typical symptoms include fever, pharyngitis, cervical lymphadenopathy, and fatigue. Typically, mononucleosis is associated with an infection by the Epstein-Barr virus (EBV). Laboratory findings include leukocytosis, with greater than 50% lymphocytes and more than 10% atypical lymphocytes. Almost 90% of patients with mononucleosis have abnormal liver enzymes. Mononucleosis is typically diagnosed by detecting a *heterophile antibody*, which is a nonspecific response to EBV infection. The heterophile antibody response is an IgM antibody that will agglutinate with the surface antigen of sheep and horse RBCs, but not with guinea pig kidney cells. Monospot tests are done with rapid slide agglutination procedures and horse RBCs to detect the heterophile antibody. Heterophile antibodies are negative in about 25% of patients in the first week of infection, and in 5% to 10% of patients in the second week or later (Luzuriaga and Sullivan, 2010). The heterophile antibody usually persists for 3 to 6 months after an acute infection, less frequently up to 1 year. The heterophile antibody has an overall false-negative rate of 10% to 15%, except in children younger than the age of 12, where the false-negative rate is higher. False-positive heterophile antibodies can occur with rubella, hepatitis, other viral infections, and lymphoma.

When the heterophile antibody is negative or the features of infectious mononucleosis are atypical, the disease can be confirmed with specific Epstein-Barr antibodies. Acute or recent infection is thought to be present if four serologic criteria are found: positive IgM to viral capsid antigen (VCA); high titers (>1:320) of IgG to VCA; positive early antigen antibody (anti-EA); and initial absence of antibody to Epstein-Barr nuclear antigens (EBNAs). The most useful

EBV-specific antibody to diagnose acute mononucleosis is the IgM VCA, which appears soon after the onset of symptoms and has sensitivity of 91% to 98% and specificity of 99%. Convalescent testing should document the appearance of IgG EBNA and disappearance of IgM VCA and anti-EA.

Syndromes mimicking infectious mononucleosis, but with negative heterophile antibodies, are considered *heterophile-negative* infectious mononucleosis. The most common syndromes are related to cytomegalovirus infection and toxoplasmosis. Occasionally, viral hepatitis, rubella, lymphoma, leukemia, and the drugs isoniazid and phenytoin can cause a mononucleosis-like syndrome. As acute HIV infection can present with similar symptoms, consideration should be given to testing for HIV nucleic acid in patients with risk factors for HIV infection. Because heterophile antibodies are not uniformly positive early in the disease, serial tests may often be needed weekly to confirm mononucleosis. Specific serologic tests for EBV and now PCR are relatively expensive and take longer to obtain results, so they are generally reserved for unclear cases and are not necessary in most patients with infectious mononucleosis. In an adolescent or young adult with appropriate clinical symptoms, heterophile antibodies are 95% sensitive and specific.

NATRIURETIC PEPTIDES (B-TYPE NATRIURETIC PEPTIDE AND N-TERMINAL PRO-B-TYPE NATRIURETIC PEPTIDE)

Blood levels of natriuretic peptides are used in the evaluation of *heart failure*. Cardiac cells release natriuretic peptides in response to stretch and wall tension. Ventricular myocytes release a pro-B-type natriuretic peptide (pro-BNP), which is cleaved into the active B-type natriuretic peptide (BNP) and the inactive N-terminal pro-BNP (NT-pro-BNP). Levels of both BNP and NT-pro-BNP increase with age, in renal insufficiency, and are higher in women; obesity is associated with lower BNP levels. Some medications, including spironolactone, ACE inhibitors, and angiotensin receptor blockers, lower BNP/NT-pro-BNP levels. Other conditions that increase natriuretic peptides include myocardial ischemia, atrial fibrillation, pulmonary embolus, pulmonary hypertension, chronic kidney disease, and sepsis.

The major established use of BNP testing is evaluating *acute dyspnea*, when the cause is uncertain, to differentiate whether the etiology is from heart failure versus another cause. In the setting of acute dyspnea, natriuretic levels are more accurate than clinical judgment in excluding or diagnosing acute decompensated heart failure. A normal level in a patient with acute dyspnea has a high negative predictive value and suggests that heart failure is unlikely the etiology. The optimal cutoffs for BNP/NT-pro-BNP vary with age. BNP less than 100 pg/mL or NT-pro-BNP less than 400 pg/mL makes the diagnosis of heart failure unlikely. Levels of BNP greater than 400 pg/mL or NT-pro-BNP greater than 2000 suggest heart failure (Dickstein et al., 2008). Elevated levels of BNP and NT-pro-BNP also are predictive of death or increased cardiovascular events. There is some evidence that the use of natriuretic peptide testing to guide heart failure therapy may improve clinical

outcomes, and clinical trials are ongoing to help determine optimal approaches (Januzzi, 2012).

PHOSPHORUS

Disorders of phosphorus metabolism are caused by variations in dietary intake, phosphorus excretion, and transcellular shifts. The reference range for serum phosphorus level is approximately 2.5 to 4.8 mg/dL in adults and 4.0 to 6.0 mg/dL in children. Because postprandial phosphorylation of glucose can decrease serum phosphorus levels, fasting specimens are more accurate. *Hyperphosphatemia* most often occurs in the setting of reduced renal excretion from renal insufficiency. Other causes of hyperphosphatemia include excess phosphate ingestion, either orally or with phosphate-containing enemas, hypoparathyroidism, and spurious causes such as thrombocytosis. Less common causes include acromegaly, hyperthyroidism, acidosis, and massive cell lysis from hemolysis, rhabdomyolysis, and tumor lysis after chemotherapy.

Hypophosphatemia is defined as a serum phosphorus level below 2.5 mg/dL. Clinically significant hypophosphatemia occurs at levels less than 1.5 mg/dL. The three major mechanisms associated with hypophosphatemia are decreased intestinal absorption, increased phosphate loss from the kidney, and increased phosphorus shift into the bones. Decreased absorption occurs most often with antacid use. Persistent hypophosphatemia most frequently results from disorders causing increased phosphate loss in the kidney, including hyperparathyroidism, vitamin D deficiency, renal tubular disease, chronic acidosis, and rickets. Intracellular shifts into cells and bones during acute respiratory alkalosis, refeeding after starvation, hyperalimentation, intravenous carbohydrate administration, rapid tumor growth, treatment of respiratory failure, or diabetic ketoacidosis can cause hypophosphatemia (Bacchetta and Salusky, 2012). If the cause of hypophosphatemia cannot be determined based on the history, a fractional excretion of phosphorus less than 5% suggests that the etiology is not from inappropriate renal loss; if the fractional excretion is more than 5%, it implies that the problem is renal; renal wasting of phosphorus. $(FE_{P_i}(\%)) = [(P_{urine}/P_{plasma}) \times 100 \times (Cr_{plasma}/Cr_{urine})]$ where P_{urine} and P_{plasma} are urine and plasma concentrations of phosphorus and Cr_{plasma} and Cr_{urine} are plasma and urine concentrations of creatinine, respectively.)

POTASSIUM

Potassium is the most abundant cation in the body and has a much higher concentration in the intracellular space than in extracellular fluids. Normal potassium levels are maintained despite fluctuating potassium intake by adjustments in renal secretion of potassium. *Hyperkalemia* is defined as a serum potassium level greater than 5.1 mmol/L. Occasionally, hyperkalemia can be an artifact (pseudohyperkalemia) of phlebotomy, associated with thrombocytosis, leukocytosis, or hemolysis during phlebotomy. In a patient with hyperkalemia of no apparent cause, a plasma potassium level can eliminate these effects on the potassium measurement. Because the normal response to increased potassium intake is to increase excretion, hyperkalemia is not likely to be attributed to increased intake unless there is

Table 14-15 Causes of Abnormal Potassium Levels

Hyperkalemia	Hypokalemia
PSEUDOHYPERKALEMIA	INADEQUATE DIET
Thrombocytosis Leukocytosis Prolonged tourniquet use during venipuncture Hemolysis	Malnutrition Alcoholism
REDUCED EXCRETION	RENAL LOSSES

NSAID, Nonsteroidal antiinflammatory drug.

a deficiency in potassium excretion. Shifts of potassium from intracellular to extracellular fluids, such as with acute metabolic acidosis, crush injury, burns, insulin deficiency, β -adrenergic blockade, and hemolysis, can be associated with a transient hyperkalemia. Persistent hyperkalemia is usually caused by decreased potassium excretion. Potassium excretion by the kidney is flow dependent; therefore, oliguria and anuria are important causes of hyperkalemia. Because aldosterone deficiency is an important cause of decreased potassium excretion, hyperkalemia is seen with hyperreninism, hypoaldosteronism, type 4 renal tubular acidosis, and drugs that inhibit aldosterone (Table 14-15).

Hypokalemia is associated with a serum potassium level of less than 3.5 mmol/L. Symptoms are nonspecific and include muscular weakness. Occasionally, hypokalemia is associated with sustained inadequate potassium intake, particularly in patients with alcohol abuse. Transient episodes of hypokalemia are associated with increased extracellular to intracellular potassium shifts and occur with catecholamine increase, hyperinsulinemia, and adrenergic drugs such as bronchodilators. More frequently, hypokalemia is a result of loop or thiazide diuretic therapy or GI losses of potassium, such as with protracted vomiting, diarrhea, and laxative abuse. Other causes of hypokalemia include hypomagnesemia, drugs, metabolic alkalosis, skin losses, and increased urinary losses. In cases when the cause of hypokalemia is not apparent, measuring urinary potassium is helpful. A random urine potassium-to-creatinine ratio greater than 15 mEq/gm creatinine suggests renal wasting (Groeneveld et al., 2005).

PREGNANCY TESTS

Current pregnancy tests use immunoassays to measure the beta subunit of human chorionic gonadotropin (hCG). Serum assays and sensitive urine assays can now detect pregnancy approximately 1 week after conception. Home pregnancy tests have variable sensitivity, ranging from about 50% to 97% sensitive when done on the first day of the missed period, and nearly 100% sensitive at 11 days after the missed period. The most common reason for a false-negative home pregnancy test is incorrect timing, such as performing the test too soon, so it is recommended to repeat a home test if the initial test is negative (Cole, 2012).

In the first 4 to 8 weeks of pregnancy, serum hCG levels double approximately every 2 days. Failure to double in 48 to 72 hours suggests an ectopic pregnancy or abnormal intrauterine pregnancy. For the first 2 weeks after conception, serum levels of hCG are higher than those in urine. However, beginning at approximately 3 weeks and for the remainder of the pregnancy, urine levels are higher than serum levels. Levels of hCG return to normal approximately 2 weeks after delivery. After an abortion, levels return to normal in approximately 3 to 8 weeks. Other conditions that can raise hCG levels include gestational trophoblastic neoplasms, such as hydatidiform mole and choriocarcinoma. False positive pregnancy tests are uncommon but may be seen in women who have heterophile antibodies and in perimenopausal women who produce pituitary hCG.

PROSTATE-SPECIFIC ANTIGEN

Prostate-specific antigen (PSA) is a glycoprotein produced by the epithelial cells of the prostate. This protein circulates in the serum and can become elevated because of benign and malignant conditions of the prostate. Fifty percent to ninety percent of PSA is protein bound and the remainder is free. PSA is used as a tumor marker for the screening, diagnosis, and management of prostate cancer. PSA lacks specificity for cancer, however, because it can be elevated in benign conditions such as benign prostatic hypertrophy (BPH) and prostatitis. Estimates suggest that a PSA higher than 4 ng/mL has sensitivity of 70% to 80% and specificity of 60% to 70% for prostate cancer. Factors other than prostate cancer can affect the PSA level (Table 14-16). Both prostate biopsy and transurethral resection of the prostate (TURP) can elevate the PSA, but DRE does not cause significant elevations in PSA.

Although elevations of the PSA are associated with increased risk of prostate cancer, the upper limit of normal of 4 ng/mL is arbitrary. PSA levels increase with age and recent sexual activity and are reduced with the use of 5- α -reductase inhibitors. During an initial screening examination, prostate cancer was found in 27% of men with PSA levels of 4.1 to 9.9 ng/mL and 59% with PSA higher than 10 ng/mL (Hernandez and Thompson, 2004) (eTable 14-6). However, prostate cancer is found in 23.9% of men with PSA of 2.1 to 3.0 ng/mL and 26.9% with PSA of 3.1 to 4.0 ng/mL (Thompson et al., 2004). The positive predictive value (PPV) of the PSA is doubled if the patient also has an abnormal DRE. A normal PSA does not exclude cancer; 20% to 40% of men with organ-confined prostate cancer

Table 14-16 Noncancer Factors That May Influence Prostate Specific Antigen

Factor	Change
Acute urinary retention	Increase
Androgens	Increase
Antiandrogens	Decrease
Bed rest	Decrease
Benign prostatic hypertrophy	Increase
Cirrhosis	Increase
Cystoscopy	Increase
Digital rectal examination	Not significant
Diurnal variation	No change
Ejaculation	Increase
Extensive exercise	Increase
Finasteride	Decrease
Physiologic variation	May fluctuate by 30%
Prostatic massage	Increase
Prostate needle biopsy	Increase
Prostatitis	Increase
Radial prostatectomy	Decrease
Radiation therapy	Increase initially then decrease
Transurethral resection of the prostate	Increase
Transurethral ultrasound of the prostate	No change
Urethral instrumentation	Increase

will have PSA within the reference range. The use of PSA velocity, free PSA/total PSA, and urinary prostate cancer antigen 3 (PCA3) for screening is unproven.

The use of PSA for screening for prostate cancer remains controversial. Although it is clear that PSA testing can lead to earlier detection of prostate cancer, it is not clear that early diagnosis and treatment offer significant reduction in overall mortality. Estimates suggest that 1 prostate cancer death is prevented in 1000 men aged 55 to 69 screened every 1 to 4 years over a decade, although 110 cases will be diagnosed (Carter et al., 2013). A significant number of men diagnosed with prostate cancer by PSA screening have a tumor that would never have become symptomatic. In addition to screening, PSA is used to monitor the response to treatment for localized prostate cancer. After radical prostatectomy, PSA levels should become undetectable. Any detectable levels suggest residual or recurrent tumor and may occur months or years before becoming clinically apparent. PSA levels fall after radiation therapy, although they usually do not become undetectable. A PSA recurrence has been defined as three successive increases in the PSA level after radiation therapy.

TOTAL PROTEIN

Total protein includes albumin and globulin. The factors that affect the total protein level include changes in fluid status, the balance of protein synthesis and catabolism, and protein losses. While dehydration can cause a relative increase in serum protein concentration, volume expansion causes a relative decrease in protein concentration. Elevated protein levels in the absence of dehydration are usually related to increased globulin levels. As previously discussed,

acute-phase reactants are proteins that are increased in inflammatory conditions and include CRP, haptoglobin, fibrinogen, ceruloplasmin, and α_1 -antitrypsin.

Serum protein *electrophoresis* separates proteins based on their mobility in an electric field and can provide a visual estimate of albumin and globulin levels. The five bands on the electrophoresis column include albumin, α_1 -globulin, α_2 -globulin, β -globulin, and γ -globulin. The immunoglobulins are found primarily in the γ region. Diffuse elevations in the γ region can occur with chronic infections, liver disease, autoimmune disorders, and granulomatous diseases. A monoclonal spike in the γ region indicates proliferation of a single immunoglobulin, as seen in myeloma or a monoclonal gammopathy of uncertain significance. Immunoglobulin abnormalities noted on protein electrophoresis can be further characterized by *immunofixation*, which can confirm a monoclonal immunoglobulin and can determine the heavy or light chain type of the immunoglobulin.

RHEUMATOID FACTOR AND ANTI-CYCLIC CITRULLINATED PEPTIDE ANTIBODIES

The diagnosis of rheumatoid arthritis (RA) is usually made based on clinical findings, supported by laboratory testing. In 2010, the American College of Rheumatology/European League against Rheumatism classification criteria included the laboratory tests of rheumatoid factor (RF) and anti-cyclic citrullinated peptide antibodies (ACPAs) in the criteria for the diagnosis of RA. The mainstay of testing has been the RF, which is an autoantibody directed against the Fc portion of the IgG molecule. The sensitivity of RF is approximately 54% to 88% and the specificity 48% to 92%, depending on the method used (Lee and Schur, 2003). RF is not specific for RA and may be detected in the serum of persons with other rheumatoid conditions, chronic infections, or inflammatory conditions, as well as in healthy older adults.

Results are usually reported as a titer determined by using a tube dilution method. A significant titer is 1:80 or greater. In RA, titers are often 1:640 to 1:520 but can even be found up to 1:320,000. Very high titers more likely indicate severe disease or systemic involvement. Increasing serial titer elevations can be used to monitor RA disease progression but not response to therapy. RF titers may decrease during remission, but only rarely do they become undetectable. The ESR is a better index of disease activity.

The ACPA test complements RF in the diagnosis of RA. ACPAs have been found to be present in RA early in the disease course and have a high predictive value for developing RA. The sensitivity and specificity of the ACPA is 60% to 80% and 85% to 98%, respectively. The advantage of ACPA over RF is that it is much more specific for RA. In patients with a moderate pretest probability of RA, positive ACPA significantly increases the likelihood of RA (Shmerling, 2009).

SODIUM

Disorders of body fluid balance are categorized as hypo-osmolar, when there is excess water to solute balance, or hyperosmolar, when there is reduced water to solute

eTable 14-6 Positive Predictive Value of Total Prostate-Specific Antigen for Prostate Cancer

Digital Rectal Examination	PSA Value		
	0.0-4.0 ng/mL	4.1-10 ng/mL	>10 ng/mL
Negative	9%	20%	31%
Positive	17%	45%	77%

PPV, Positive predictive value; PSA, prostate-specific antigen.

Data from Oesterling JE. Prostate-specific antigen: a valuable clinical tool.

Oncology. 1991;5:107-122.

balance. Given that sodium is the primary solute in the body, these disorders are manifested as either hyponatremia or hypernatremia. The reference range for serum sodium concentration is 135 to 145 mmol/L. In the evaluation of abnormal sodium levels, it is helpful to measure or calculate the plasma osmolality, which typically has a range of 280 to 295 mOsm/kg H₂O. The osmolality can also be calculated using the following formula:

$$\text{Calculated osmolality} = (2 \times \text{Na}) + (\text{BUN}/2.8) + \text{glucose}/18$$

This formula gives comparable results to measured osmolality, except in the presence of significant unmeasured solutes, such as mannitol or radiologic contrast dyes.

In most cases, *hyponatremia* is associated with hypoosmolality (eTable 14-7). Pseudohyponatremia can be seen with very elevated glucose or protein levels, causing artifactually low serum sodium levels; in these cases measured plasma osmolality is normal. Hyponatremia can be associated with normal or increased measured osmolality in the presence of other osmotically active substances, such as glucose and mannitol. In the setting of hyperglycemia, every 100 mg/dL rise in glucose lowers serum sodium by 1.6 mmol/L.

The diagnostic evaluation of hypoosmolar hyponatremia should begin with an assessment of the patient's volume status and urine electrolytes (Verbalis et al., 2013). Hyponatremia can occur in states of volume deficiency, euvolemic states, or hypervolemic conditions (Table 14-17). *Hypovolemic hyponatremia* can occur with GI, renal or third space losses, and patients typically demonstrate clinical findings of hypovolemia. With nonrenal causes, the urine Na⁺ should be less than 30 mmol/L and the urine osmolality higher than 100 mOsm/kg H₂O. Hypovolemic hyponatremia responds readily to isotonic fluid replacement.

Hypervolemic hyponatremia can occur with advanced congestive heart failure, cirrhosis, nephrotic syndrome, and renal failure in the presence of total-body sodium overload and edema. In these disorders, effective renal blood flow is

reduced, thus stimulating the release of arginine vasopressin (AVP), also known as antidiuretic hormone (ADH), which reduces renal excretion of water. Both sodium and water are increased, but water is increased proportionally more than sodium. In the absence of diuretic therapy, urine sodium is generally less than 30 mmol/L, and urine osmolality is over mOsm/kg H₂O.

Euvolemic hyponatremia is caused by an excess in body water. The most common cause of *euvolemic hyponatremia* is the syndrome of inappropriate ADH secretion (SIADH), which occurs when the stimulus for ADH secretion is not related to osmolality or reduced renal blood flow. No edema is present, although mild volume expansion and a modest increase in weight are seen. Continued release of ADH occurs despite low plasma osmolality. Criteria for diagnosis of SIADH include (1) the presence of hypoosmolality ($P_{\text{osm}} < 275$ mOsm/kg H₂O); (2) urine sodium level greater than 30 mmol/L, assuming adequate sodium intake; (3) urine osmolality greater than 100 mOsm/kg H₂O; (4) clinical euvolemia; and (5) absence of diuretic therapy, hypothyroidism, and glucocorticoid deficiency. Other clinical findings that suggest SIADH includes a uric acid level less than 3 mEq/dL and BUN less than 10 mg/dL. Serum ADH (AVP) levels are not helpful because most causes of hyponatremia are associated with elevated AVP (ADH) levels. The major causes of SIADH are drugs and pulmonary and central nervous system diseases. SIADH can respond to fluid restriction or correction of the underlying disorder. Another cause of euvolemic hyponatremia is called *primary polydipsia*, which occurs in people who consume massive amounts of water and have very large volumes of urine. In general, plasma osmolality is mildly decreased. These individuals have low urine sodium and dilute urine. The hyponatremia readily responds to a reduction in fluid intake.

Hypertonic disorders are associated with excess water losses compared with solute losses. Clinically manifested as hypernatremia, this serious electrolyte abnormality generally occurs in the setting of a significant underlying medical illness. The primary causes are deficient water intake or excessive water excretion. For example, when a patient has significant diarrhea, hypernatremia can develop when the patient cannot ingest enough water to compensate for the loss. When the clinical evaluation is not clear, measurement of urine osmolality is helpful. In the setting of hypernatremia and insufficient water intake, the urine should be maximally concentrated, higher than 800 mOsm/kg H₂O. In the setting of hypernatremia, if the urine osmolality is less than 800 mOsm/kg H₂O, a renal concentrating defect is present. This can be seen with hyperglycemia, an osmotic diuresis, or diabetes insipidus. A rise in urine osmolality after administering desmopressin (DDAVP) will distinguish central diabetes insipidus from nephrogenic diabetes insipidus.

Less frequently, hypernatremia can occur in a setting of increased total-body sodium from an excessive exogenous sodium load. Hypertonic intravenous fluids, salt-water near-drowning, and hypertonic dialysis can cause hypernatremia.

Table 14-17 Classification of Hyponatremia

Clinical Findings	Causes
VOLUME DEPLETION Tachycardia Hypotension Urine sodium <30 mmol/L (if nonrenal losses) Urine osmolality >100 mOsm/kg H ₂ O Increased urine osmolality	Gastrointestinal losses: vomiting, diarrhea Renal losses: diuretics, chronic renal failure, salt-wasting nephropathies Skin losses: burns Third-space losses: pancreatitis
VOLUME OVERLOAD Edema Urine sodium <10 mEq/L Urine osmolality high	Congestive heart failure, nephrotic syndrome, cirrhosis
Euvolemic	SIADH
No edema or evidence of dehydration Urine sodium >30mmol/L (unless sodium-restricted diet) Urine osmolality >100 mOsm/kg H ₂ O Normal thyroid and adrenal function Psychogenic polydipsia	CNS disorders: infection, mass lesion, head trauma Pulmonary: lung cancer, infection Drugs: chlorpropamide, opiates, nicotine, phenothiazines, vincristine, SSRIs

CNS, Central nervous system; SIADH, syndrome of inappropriate diuretic hormone; SSRI, selective serotonin reuptake inhibitor.

STREPTOCOCCAL TESTING

Acute pharyngitis is a frequent office diagnosis, but the only common form of pharyngitis that requires antibiotic

eTable 14-7 Classification of Hypernatremia

Total Body Sodium (Na)	Causes	Urine Measurements
Reduced total body sodium (both Na and water losses, but relatively more loss of water)	Gastrointestinal losses: diarrhea, lactulose Skin losses: excess sweating Renal losses: loop diuretics, osmotic diuretics	Urine Na <10 mEq/L Hypertonic urine Urine Na ≥20 mEq/L Hypotonic or isotonic urine
Normal total body Na (loss of water)	Renal losses: central or nephrogenic diabetes insipidus, lithium, demeclocycline, hypercalcemia, hypokalemia Nonrenal losses: insensible losses from skin or respiratory tract	Variable urine Na Variable urine tonicity Urine Na variable Hypertonic urine
Increased total body Na (addition of sodium)	Hypertonic intravenous fluids Hypertonic dialysate Saltwater drownings	Urine Na >20 mEq/L Hypertonic or isotonic urine

Modified from Schrier RW. *Renal and Electrolyte Disorders*. 4th ed. Boston: Little, Brown; 1992, p. 43.

treatment is that caused by *group A β-hemolytic streptococci* (GABHS). Approximately 20% to 30% of children and adolescents and 5% to 15% of adults with sore throat have streptococcal pharyngitis. Suggestive clinical features include fever, no cough or rhinorrhea, tonsillar exudates or beefy-red pharynx, and tender anterior cervical lymphadenopathy. Because of the overlap in symptoms between viral and strep pharyngitis, the 2012 American Society of Infectious Disease guidelines recommend testing, unless the patient has symptoms clearly suggestive of a viral etiology. For an acutely ill patient, the *rapid antigen detection test* (RADT) and traditional bacterial throat culture are available to identify GABHS. In the setting of pharyngitis and a typical syndrome, a positive culture or RADT is sufficient to begin treatment. The sensitivity of both is affected by throat swab technique. Testing should be done of both tonsils or tonsillar pillars and the posterior pharynx. Antigen or bacterial recovery from the throat is increased by rigorous swabbing. The RADT has the advantage of giving immediate results, which allows for early antibiotic therapy and thus decreases the duration of illness, complications, and contagiousness. Recent antibiotic use may give a false-negative result. The major limitation of rapid streptococcal tests is low sensitivity (70% to 90% on average), but specificity is approximately 95%. Therefore, a positive test can be accepted as evidence of disease and therapy begun without further testing. However, a negative result does not exclude the possibility of GABHS as the source of the pharyngitis. Children and adolescents with a negative RADT should have a throat culture for confirmation. Because of the low incidence of streptococcal pharyngitis and the extremely low risk of rheumatic fever in adults, the American Society of Infectious Diseases supports the use of RADT alone in adults, without confirmation by cultures (Shulman et al., 2012).

The throat culture is performed on sheep blood agar plate under aerobic conditions. If proper collection and plating technique are used, throat culture sensitivity is 95% and specificity 99.5%. With poor technique, sensitivity can be as low as 30%. Previous antibiotic use may diminish the colony count. If clinical conditions suggest the presence of other pharyngeal pathogens, such as *Neisseria gonorrhoeae*, the laboratory test should be altered because different collection and plating techniques are required. Throat culture results are generally reported 24 to 28 hours after plating. Antibiotic sensitivities are not routinely reported because GABHS is uniformly sensitive to penicillin.

SYPHILIS TESTING

The sexually transmitted disease (STD) syphilis is usually diagnosed with serologic testing. Although darkfield microscopy can identify spirochetes in fluid obtained from lesions of primary syphilis, the test has many false-negative readings, and most physicians are not trained to perform these tests. PCR for *Treponema pallidum* DNA is now commercially available for diagnosing primary syphilis using a swab from an ulcer, with early reports showing good sensitivity and specificity.

The major serologic tests for syphilis are the nonspecific nontreponemal Venereal Disease Research Laboratories (VDRL) and rapid plasma reagin (RPR) tests, which measure

antibody production to a cardiolipin-cholesterol-lecithin antigen, and the specific treponemal antibody tests, which measure antibodies against the spirochete *T. pallidum*. Because of false-positive results in each of these tests, the use of both types of tests are required for a diagnosis. The usual screening for syphilis is a two-step process, beginning with the RPR or VDRL test, followed by specific treponemal antibody testing for confirmation. However, some laboratories are now performing treponemal enzyme immunoassay (EIA) tests first, followed by nontreponemal tests for confirmation of current infection.

The RPR or VDRL is reported as a titer of the highest dilution giving a positive test. The VDRL usually becomes positive approximately 1 to 4 weeks after the development of a chancre. The highest titers of nontreponemal tests are seen in secondary syphilis. The sensitivity of the RPR or VDRL is 78% to 86% in primary syphilis, 100% in secondary syphilis, and 95% to 98% in latent syphilis. Titers of VDRL or RPR parallel disease activity. After appropriate treatment of primary or secondary syphilis, titers decline and usually become negative within 1 year. A fourfold decline in titers 6 months after treatment suggests an adequate response to treatment of primary or secondary syphilis. A fourfold rise in titers after treatment suggests reinfection. Low titers may persist after treatment of late and latent syphilis. Approximately 20% of nontreponemal screening tests are false positive; false-positive tests usually have titers less than 1:8. Causes of false-positive nontreponemal tests include autoimmune disorders, HIV infection, infectious mononucleosis, endocarditis, and lymphoma.

The treponemal tests, such as the fluorescent treponemal antibody absorption (FTA-ABS) test or *T. pallidum* enzyme immunoassay (EIA), are used to confirm infection in a patient with a positive nontreponemal test. The treponemal tests are reported as positive or negative. The FTA has a sensitivity of 84% in primary syphilis and almost 100% in other stages of syphilis. The specificity is 96%; approximately 1% of the population has a false-positive treponemal antibody. Treponemal tests remain positive in 95% of patients, even after treatment, and are not used to monitor treatment response and cannot distinguish active from treated syphilis. If using treponemal EIA for screening, the CDC recommends performing a standard nontreponemal test after a positive treponemal EIA to guide treatment decisions. If the nontreponemal test is negative, then a different treponemal test should be performed to confirm infection. If the second treponemal test is positive, those without a history of treatment should be treated and those with a prior history of treatment should be offered treatment if there is a likelihood of reexposure (Workowski and Berman, 2010). Rapid testing using point-of-care testing for immunoassays against treponemal antigens is now available. The sensitivities appear to be from 84% to 97%, and the specificity is 92% to 98%.

In neurosyphilis, cerebrospinal fluid (CSF) abnormalities include elevated protein, a lymphocytic pleocytosis, and a positive VDRL. The CSF VDRL is the preferred test because it is more specific than the CSF FTA. However, the sensitivity is low enough that a negative CSF VDRL does not rule out neurosyphilis. In congenital syphilis, the diagnosis can be difficult because both FTA and VDRL

antibodies can be transferred passively to newborns, and their identification at birth in the baby does not necessarily indicate infection. Passively transmitted antibodies generally decline in the first 2 months of life. If titers rise after birth, congenital syphilis is likely. Testing using specific *T. pallidum* EIA IgM may allow earlier diagnosis of congenital syphilis.

TESTOSTERONE

Evaluating men for low testosterone should be done only when there are clear signs and symptoms of androgen deficiency. Serum testosterone levels are highest in the morning, fluctuate by season, and are subject to episodic secretion and measurement variations. Therefore, the standard is to obtain more than one sample between 8:00 and 10:00 a.m. Other factors that affect testosterone levels include acute and chronic systemic illnesses, some medications including opioids and glucocorticoids, eating disorders, excessive exercise, and changes in the sex hormone-binding globulin (SHBG). The SHBG is affected by weight; diabetes mellitus; aging; thyroid, renal, and liver disease; acromegaly; HIV infection; and medications.

Most of the circulating testosterone is tightly bound to SHBG or loosely bound to albumin, while only about 0.5% to 3% is unbound, free testosterone. Bioavailable testosterone refers to the free plus albumin-bound fraction. Measuring the total serum testosterone is generally adequate. Checking the free or bioavailable testosterone concentration is usually necessary only when the total is low or conditions that affect the SHBG are present. The free and bioavailable testosterone tests cost significantly more than the total testosterone. The reference range for total, bioavailable, and free testosterone varies by laboratory and assay. In individuals with repeatedly low testosterone levels, measuring the luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels can help distinguish primary from secondary hypogonadism. These gonadotropins are high in primary (testicular) and low in secondary (pituitary) hypogonadism.

The serum testosterone level at which therapy should begin is unknown. Generally older men with low testosterone levels and men with borderline levels who are asymptomatic or have nonspecific symptoms should not be treated. The treatment goal is the minimal testosterone level that improves symptoms but no more than the mid normal reference range (Bhasin et al., 2010).

THYROID TESTING

Currently available tests for assessing thyroid function measure functional activity of the thyroid, the hypothalamic-pituitary-thyroid axis, or thyroid hormone levels. The third-generation thyroid-stimulating hormone (TSH) test is the best method to confirm or exclude primary thyroid disease in an ambulatory population. TSH is produced by the pituitary and is inhibited by circulating thyroxine (T_4) and triiodothyronine (T_3). In general, a normal TSH level is approximately 0.5 to 5 mIU/L and excludes hyperthyroidism or primary hypothyroidism. Supersensitive tests measure TSH at levels at least as low as 0.01 mIU/L. TSH levels less than 0.1 mIU/L suggest hyperthyroidism. Levels

of 0.1 to 0.5 mIU/L may represent subclinical hyperthyroidism or excess thyroid hormone administration. Levels of 6 to 10 mIU/L are often considered subclinical hypothyroidism, are usually associated with normal free T_4 levels, and are not usually associated with symptoms. In patients with subclinical hypothyroidism, the presence of thyroid antibodies suggests a risk of conversion to frank hypothyroidism of about 5% per year. Symptomatic hypothyroidism occurs with TSH levels greater than 10 mIU/L. The TSH test is also the best way to monitor the results of replacement or suppressive therapy. Although the TSH level is an excellent screen for thyroid function in ambulatory patients, it must be interpreted with caution in acutely ill patients. TSH levels should be used to diagnose thyroid disorders in acutely ill hospitalized patients only when less than 0.1 mIU/L or greater than 20 mIU/L. TSH levels can be decreased by glucocorticoids, dopamine, and octreotide.

Measurements of circulating thyroid hormone should be obtained to confirm abnormal TSH levels. Measurement of free T_4 levels measure the total amount of hormone in blood, free and protein bound. Total T_4 or T_3 levels can be misleading in the setting of protein-binding abnormalities, such as estrogen therapy and liver disease. An approximate reference range in the adult for free T_4 is 0.7 to 2.5 ng/dL and for free T_3 0.2 to 0.5 ng/dL. Free T_3 testing is usually not necessary. One exception is in early hyperthyroidism, when the TSH is suppressed, free T_4 is normal, and free T_3 is elevated.

Primary hypothyroidism accounts for more than 95% of cases of hypothyroidism and is associated with an elevated TSH and reduced free T_4 . Central hypothyroidism (secondary or tertiary) is associated with low free T_4 and normal to low TSH. Primary hyperthyroidism is associated with a suppressed TSH and elevated free T_4 . Subclinical hyperthyroidism is associated with a reduced TSH but normal free T_4 and T_3 levels.

The radioactive iodine uptake scan measures 24-hour thyroid uptake of a labeled quantity of radioactive iodine. In normal persons, uptake is 8% to 30%. Lower limits of normal cannot be reliably differentiated from hypothyroidism in the radioactive iodine uptake scan. Its major value is to help identify causes of thyrotoxicosis associated with low levels of iodine uptake, such as thyroiditis and fictitious hyperthyroidism from overingestion of thyroid hormones. Other causes of reduced thyroid hormone uptake include recent iodine contrast administration and amiodarone.

URIC ACID

Uric acid is produced in the liver as a byproduct of purine metabolism. Measurement of uric acid is useful in the evaluation of *gout* and monitoring of certain types of chemotherapy. Uric acid levels are increased in situations with increased dietary purine intake, reduced excretion, or increased production. In addition, volume status affects uric acid secretion. With a decrease in extracellular volume, uric acid excretion declines, and serum uric acid levels increase. Conversely, volume expansion increases uric acid excretion and leads to *hypouricemia*. Several drugs inhibit the reabsorption of uric acid in the kidney and therefore lead to *uricosuria* (Table 14-18).

Table 14-18 Causes of Hyperuricemia

Overproduction	
Myeloproliferative disorders	Psoriasis
Polycythemia vera	Toxemia of pregnancy
Hemolytic anemia	Ethanol
Malignancies	
Decreased Excretion	
Renal failure	Hyperparathyroidism
Volume depletion	Diabetic ketoacidosis
Hypothyroidism	
Drugs	
Thiazides	Pyrazinamide
Furosemide	Cyclosporine
Aspirin (low dose)	Niacin
Ethambutol	Vitamin B ₁₂ therapy

Progressively higher levels of *hyperuricemia* predict the likelihood of gout; however, most authorities believe that asymptomatic hyperuricemia should not be treated. At 37°C, saturation in plasma occurs when uric acid levels are greater than 6.8 mg/dL. Most patients with gout have uric acid levels greater than 7 mg/dL at some time, but they can have normal serum uric acid levels at the time of an acute gouty attack. Although a biologically significant uric acid level is greater than 6.8 mg/dL, the upper limits of “normal” based on population studies are 7.7 mg/dL for men and 6.8 mg/dL for women. The incidence of gout is approximately 5% per year in men with uric acid levels greater than 9 mg/dL, but only 0.5% per year in men with uric acid levels of 7.0 to 8.9 mg/dL.

A distinction between production of uric acid and reduced uric acid excretion as a cause of hyperuricemia may be helpful in evaluating patients with gout. Underexcretion is identified when the *fractional excretion* (excretion of uric acid/excretion of creatinine) is less than 6%. When a person is consuming a standard diet, excretion of uric acid greater than 800 mg/day is considered *hyperuricosuria*. Follow-up testing for patients with hyperuricosuria can be repeated on a low-purine diet, with 24-hour excretion of uric acid greater than 600 mg indicating uric acid overproduction. Of patients with gout, an estimated 90% have reduced uric acid excretion, and less than 10% have overproduction of uric acid as the cause. Drugs that lower serum uric acid include losartan, amlodipine, fenofibrate, and atorvastatin.

URINE DRUG SCREENS

The standard urine drug screen in a clinical setting is a panel of immunoassays designed to detect common drugs of abuse. The panel can include the five drugs required by federal workplace testing: amphetamines, cocaine, opiates, marijuana, and PCP. Panels can also include other classes of drugs, such as benzodiazepines, and more specific assays for synthetic opioids, such as oxycodone, methadone, and fentanyl. Point-of-care testing kits can be ordered for office use that are individualized to the need of the practice. These point-of-care tests provide results in minutes and have generally good sensitivity.

Table 14-19 Expected Results on Urine Opiate Screen and Gas Chromatography/Mass Spectrometry

Prescribed Opioid	Opiate Immunoassay	GC/MS
Morphine	Positive	Morphine Codeine
Codeine	Positive	Codeine Morphine Hydrocodone
Hydrocodone	Positive/negative*	Hydrocodone hydromorphone
Hydromorphone	Positive/negative*	Hydromorphone
Oxycodone	Positive/negative*	Oxycodone Oxymorphone
Oxymorphone	Negative	Oxymorphone
Methadone	Negative	Methadone
Fentanyl	Negative	Fentanyl

GC/MS, gas chromatography/mass spectrometry.

*Depends on the cross-reactivity of the opiate assay with the prescribed drug; varies among assays.

Urine drug screens use cutoff points to define a positive and negative test. These cutoffs are somewhat arbitrary, are chosen mainly to maximize sensitivity and specificity, and do not correlate with the degree of impairment or toxicity. Urine that contains a drug concentration below the cutoff will be reported as negative, even though the drug is present. With standard drug screens, the immunoassays can produce false-positive results. In clinical settings, confirmatory testing using more specific tests, such as gas chromatography/mass spectrometry (GC/MS) or liquid chromatography/mass spectrometry (LC/MS), may be ordered to confirm either the presence or absence of a drug.

Generally, drugs and their metabolites are detectable in urine tests for about 3 days after use. A notable exception is marijuana, which can be present in the urine for weeks after heavy use. Urine drug screens have significant limitations, which are not always recognized. For example, most immunoassays for “opiates” are designed to detect heroin and measure codeine, which is a byproduct of heroin and morphine metabolism. However, synthetic opioids such as fentanyl or methadone do not cross-react with “opiate” immunoassays and will produce a negative result. Oxycodone has variable cross-reactivity with standard opiate assays. See Table 14-19 for a chart listing “expected” results on urine opiate screens and GC/MS. Urine drug panels with specific assays for oxycodone, hydrocodone, methadone, and fentanyl are available for monitoring chronic opioid therapy.

VITAMIN D

Vitamin D is now recognized not only for its importance in preventing rickets, but also in preventing osteopenia, osteoporosis, muscle weakness, and falls. Testing levels of vitamin D can be considered in patients at increased risk of vitamin D deficiency, including elderly patients and those with osteoporosis, osteopenia, fat malabsorption, chronic kidney disease, and increased skin pigmentation. The term “vitamin D” includes vitamin D₂ and vitamin D₃. Vitamin

D₂ (calciferol) is manufactured from the plant sterols in yeast, and vitamin D₃ (cholecalciferol) is manufactured from lanolin. Vitamin D is hydroxylated by the liver into 25-hydroxyvitamin D [25(OH)D], the major circulating form of vitamin D in the body. The kidney converts 25(OH)D into 1,25-dihydroxyvitamin D [1,25(OH)₂D], which is the active form of vitamin D (Rosen, 2011).

The laboratory diagnosis of vitamin D deficiency relies on measuring the levels of 25(OH)D. Measuring 1,25(OH)₂D is not recommended in clinical practice because it is not a reliable indicator of vitamin D status. 1,25(OH)₂D has a half-life of only 4 hours, whereas 25(OH)D has a half-life of about 3 weeks. In addition, vitamin 1,25(OH)₂D levels can actually increase with vitamin D deficiency because increasing PTH levels stimulate the conversion of 25(OH)D to 1,25(OH)₂D.

The serum 25(OH)D is a measurement of vitamin D intake and that made in the body after sun exposure. Although some laboratories may report 25(OH)D₂ and 25(OH)D₃ levels, it is the total level that is used clinically to monitor vitamin D status. PTH rises when the 25(OH)D levels are less than 30 ng/mL. Although laboratories may list 20 to 100 ng/mL as the reference range for 25(OH)D, most experts define a preferred level of 25(OH)D as 30 to 60 ng/mL, with deficiency defined as less than 20 ng/mL and insufficiency as 20 to 30 ng/mL.

CHAPTER OUTLINE

Principles 183

Syndromes 191

Pathogens 226

As a boon to humankind, the taming of yesteryear's infectious diseases ranks alongside anesthesia, aseptic surgery, and improved public health. Still, infections cause about one third of deaths worldwide, are a leading cause or contributor to deaths in developed nations, and present an array of challenges as new pathogens emerge and old pathogens become drug resistant. Factors contributing to the burden of infectious diseases in the United States include an aging population, medical progress (as in the treatment of cancer, cardiovascular diseases, and degenerative joint disease), immigration, HIV/AIDS, the emergence of new pathogens and of drug resistance in old pathogens, suburbanization, homelessness, incarceration, outdoor activities, and international travel.

Most family physicians will find that infectious diseases account for much of the joy and some of the sorrow of their careers. Self-limited infections comprise much of the throughput of daily office practice, but avoiding tragedy when nonspecific symptoms and signs portend life-threatening illness requires constant vigilance. This chapter focuses mainly on principles and diagnosis. Drug dosages are omitted; these are now universally available through electronically based resources, and no drug should be prescribed without thorough knowledge of routes of elimination; side effects; drug-drug interactions; status for use during pregnancy; and dose adjustments necessary for impaired kidney or liver function, unusually large body mass, and extremes of age.

Principles

This section reviews some principles fundamental to preventing, diagnosing, and managing infectious diseases in family medicine.

THE PATHOGENESIS OF INFECTIOUS DISEASES

The germ theory of disease as developed by Robert Koch, Louis Pasteur, and others during the 19th century held that a single virulent pathogen caused a specific disease. The germ theory has since become more nuanced, and Koch's postulates for establishing pathogenicity continue to evolve.

Several concepts are useful for understanding the pathogenesis of infection:

1. A *formula for infection* holds that the likelihood of clinical infection is proportionate to the product of the virulence (V) of an invading microorganism multiplied by the number (N) of microorganisms, divided by the resistance (R) of the host—that is, likelihood of infection = $(V \times N)/R$. Only highly virulent organisms, such as the agents of tuberculosis (TB), tularemia, and plague, require just a few microorganisms to make a healthy person sick. Less virulent organisms require large numbers or impaired host resistance.
2. The *epidemiologic triad* consists of a *reservoir* for a potential pathogen in the animate or inanimate environment; a *means of transmission* such as physical contact, droplets, contaminated food or water, or an insect vector; and a *susceptible host*, whose resistance to disease (as expressed in the “formula for infection”) may have been reduced by disease, trauma, or drugs.
3. *Colonization*—the multiplication of a potential pathogen on an epithelial surface—is a common event that is occasionally (but not usually) followed by *invasion* of subepithelial tissues resulting in disease.
4. *Exogenous* microorganisms are those acquired from the animate or inanimate flora; *endogenous* microorganisms belong to the patient's microbial flora. *Endogenous* microorganisms can be permanent (e.g., *Escherichia coli*, enterococci, and anaerobic bacteria in the colon) or *transient colonizers* (e.g., *Streptococcus pneumoniae* and *Neisseria meningitidis* in the upper respiratory tract).
5. A *locus minoris resistentiae* (place of least resistance) occurs whenever the integrity of tissue is disrupted by trauma, a foreign body, or an implanted device. Such a locus creates a safe haven for microorganisms by depriving access by host defenses.

Let us illustrate these concepts with the case of a 17-year-old high school football player who, during a Friday night game, bruised his hip while going through the line. The next evening, as he prepared for a date, he squeezed a pimple. A week later he presented the emergency department with fever, chills, and pain, redness, and swelling over

Key Points

- Concepts useful for understanding the pathogenesis of infection include the formula for infection, the epidemiologic triad, endogenous versus exogenous flora, colonizing flora, and the *locus minoris resistentiae*.
- Protocols for managing common and usually self-limited infections such as upper respiratory infections (URIs) and urinary tract infections (UTIs) should include checklists for symptoms and signs that might portend more serious illness.
- A thorough history and physical examination, combined with simple laboratory tests such as the complete blood count and urinalysis, should precede request for expensive “send-out” studies.
- A system should be in place for reviewing laboratory results, especially critical results such as positive blood cultures and acid-fast bacillus (AFB) cultures. Failure to notice and act upon positive results can lead to tragedy.
- Evaluation for immunodeficiency in patients with frequent URIs or recurrent boils (furunculosis) is seldom worthwhile.
- Common misconceptions about contraindications for vaccines include mild illness, present antibiotic therapy, disease exposure or convalescence from an acute illness, pregnancy in the household, breastfeeding, premature birth, allergies to products that are not contained in the vaccine, the need for tuberculin skin testing, and the need for multiple vaccines.
- Before prescribing presumptive (empiric) antibiotics, one should clarify the syndrome, estimate its severity, ask whether it is treatable, consider the most likely pathogen(s), and assess the patient’s comorbidities.
- For a returning traveler who presents with new medical complaints, the clinician should make two lists of diagnostic possibilities: one for destination-related illnesses and the other for diseases that might have occurred had the patient stayed home.
- An office practice should have in place an infection control plan and promote a “culture of cleanliness.”

the hip. Blood cultures revealed *Staphylococcus aureus*, and further studies confirmed *S. aureus* osteomyelitis of the upper femur.

This case illustrates the dynamics of colonization and invasive infection by *S. aureus* (Figure 15-1), an organism of intermediate virulence that requires large numbers of bacterial cells to cause disease unless host defenses are compromised. A locker room full of colonized teammates promoted the patient’s *S. aureus* nasal colonization, which led to a tiny abscess in a hair follicle, which led to small numbers of *S. aureus* in his bloodstream after he squeezed the pimple. Disruption of capillaries in the metaphyseal end of his femur produced a small hematoma (a *locus minoris resistentiae*) in which a few *S. aureus* bacteria escaped host defenses; otherwise, he would never have known of their presence. Thinking in epidemiologic and pathophysiologic terms usually allows the inquisitive clinician to formulate a plausible story about why an infection occurred in a particular person at a particular time. Serious infection is usually an accidental event in a world in which each of us lives intimately with billions of microorganisms.

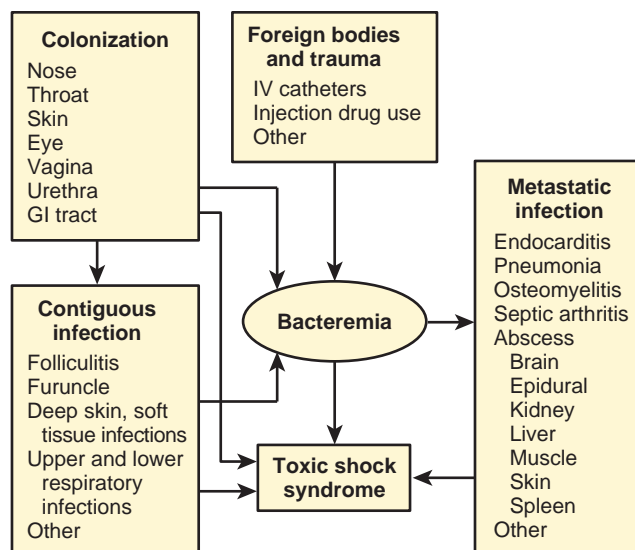

Figure 15-1. Dynamics of colonization and infection by *Staphylococcus aureus*. Nasal colonization often precedes contiguous infection, which can lead to bacteremia. Bacteremia carries the potential for serious infection in deep organs and tissues, especially when a *locus minoris resistentiae* is present. Toxin-producing strains can cause the staphylococcus toxic shock syndrome. GI, Gastrointestinal; IV, intravenous.

THE HISTORY AND PHYSICAL EXAMINATION

Symptoms suggestive of infectious disease prompt the clinician to search for a *syndrome*. Usually, the likely diagnosis is quickly apparent. For the more common syndromes seen in family medicine—for example, the common cold, otitis media, acute pharyngitis, and acute uncomplicated cystitis—it is helpful to design, maintain, and regularly update office protocols that can be implemented by physician extenders. Such protocols should ideally contain checklists to catch unusual symptoms and signs that might indicate something more serious.

The chief complaint should be recorded verbatim along with a statement as to its *duration*. Was the onset gradual or sudden? Was there an identifiable *prodrome*? It is useful to ask: “When was the *last time* you were in your usual state of health?” This question, which may have to be asked repeatedly, sometimes yields the first hint of a serious underlying problem.

The physical examination should include accurate vital signs, including a measurement (not an estimate) of the respiratory rate. Experienced clinicians often begin the physical examination by looking at the patient’s hands. Splinter hemorrhages in the nail beds, Osler nodes, small pustules (Figure 15-2), or Janeway lesions (painless small red spots on the palms) suggest endocarditis, as do petechial lesions on the palpebral conjunctiva. A careful history and physical examination should always precede and can often eliminate the need for expensive laboratory tests.

USE OF LABORATORIES

The Clinical Laboratory Improvement Act (CLIA) and its amendments now preclude many and perhaps most primary care clinicians from performing in-office tests such as the complete blood count (CBC), differential blood count, and

Figure 15-2. A small pustule (“purulent purpura”) on the finger of a patient with *Staphylococcus aureus* endocarditis.

examination of specimens stained with Gram’s method. These are considered to be of moderate complexity and require expense and inconvenience to assure compliance with CLIA regulations. Family physicians commonly rely on three types of laboratories:

1. An in-house laboratory, typically for CLIA-waived tests, provider-performed microscopy, and phlebotomy service for send-out specimens
2. A laboratory at a local hospital or other facility for most types of routine cultures, fungal cultures, mycobacterial (AFB) cultures and stains, and various serologic tests
3. One or more reference laboratories

Communication with laboratories can be time consuming but is of crucial importance, especially when results do not support a strong clinical impression. Here are some suggestions for effective use of laboratories:

1. Do not overlook the value of the total white blood cell (WBC) count, differential count, and platelet count and examination of the urine sediment. These often provide subtle clues to serious illness.
2. *C-reactive protein* (CRP), which is superseding erythrocyte sedimentation rate (ESR) as a marker of inflammation (because it is less influenced by noninflammatory factors), is useful for diagnosing infection and monitoring the efficacy of therapy (Ansar and Ghosh, 2013).
3. The *procalcitonin level* is increasingly used as a biomarker of sepsis but must be interpreted in the context of other findings (Wacker et al., 2013).
4. *Blood cultures* should be obtained before antibiotics are given to patients with predispositions to endocarditis.
5. A system should be in place for reviewing laboratory results, especially critical results such as positive blood cultures and AFB cultures. Failure to notice and act on positive results can lead to tragedy.
6. It is often useful to ask the laboratory to hold a serum specimen for the possibility that further testing may be needed, especially for situations requiring paired acute and convalescent samples.
7. It is usually inappropriate to obtain specimens for culture from predictably colonized drainage, body surfaces, or

fluids. Examples include swabs from ulcers or open wounds, sinus tract drainage, nasal swabs (except to look for *S. aureus* colonization), and nasopharyngeal swabs for patients with otitis media.

8. Do not send a swab specimen when a generous amount of purulent material is available, as from an incision and drainage procedure.

An array of new procedures, most of them nucleic acid based, are available in special situations, and exciting new tests loom on the horizon (Mitsuma et al., 2013).

IMPAIRMENTS OF HOST DEFENSES

Careful clinicians keep in mind their patients’ predispositions to specific diseases (Table 15-1). Such host factors include age and common acquired diseases; immunosuppressive drugs; and, less often, primary (congenital) immunodeficiency disorders.

Common Acquired Conditions Predisposing to Infection

Poorly controlled diabetes mellitus impairs neutrophil function, predisposing to several unique syndromes (malignant otitis externa, rhinocerebral mucormycosis, and polymicrobial osteomyelitis of the small bones of the feet) and to gas-forming infections; soft tissue infections, including necrotizing fasciitis; and UTIs. Patients with diabetic sensory polyneuropathy should take scrupulous care of their feet, including daily inspection.

Acute alcohol intoxication predisposes to pneumonia. Habitual alcohol use impairs maturation of neutrophils in the bone marrow and depresses cell-mediated immunity. Patients with alcohol-related liver disease are vulnerable to overwhelming sepsis (the “ALPS syndrome” denotes alcoholic liver disease, leukopenia, and pneumococcal sepsis, but gram-negative bacilli can also be responsible) and spontaneous bacterial peritonitis. Spontaneous bacteremia—most often caused by infection with *E. coli*—also occurs. *Vibrio vulnificus* septicemia associated with severe cellulitis with formation of bullae is associated with alcoholism, cirrhosis, and the ingestion of raw oysters.

Anatomic or functional asplenia carries a lifetime risk—estimated to be as high as 5%—of overwhelming sepsis with high mortality rates. *S. pneumoniae* causes about 60% of cases; other causes include *Haemophilus influenzae*, *N. meningitidis*, various aerobic gram-positive and gram-negative bacteria, *Capnocytophaga canimorsus* (after dog bites), and babesiosis (in areas endemic for this tickborne parasite). The risk of overwhelming sepsis after splenectomy is greatest during the first 2 years. All patients with anatomic or functional asplenia should receive the pneumococcal, meningococcal, and *H. influenzae* vaccines.

Immunosuppressive Drugs

Corticosteroids promote infections mainly by impairing neutrophil, lymphocyte function, and wound healing. A general consensus holds that doses of 10 to 15 mg of prednisone equivalent, given for at least 2 months, impairs lymphocyte function. Common opportunistic pathogens

Table 15-1 Some Host Factors Predisposing to Infectious Diseases

Host Factor	Selected Infections
POPULATION-RELATED HOST FACTORS	
Refugees and international adoptees	Hepatitis B, hepatitis C, hepatitis D (delta agent), CMV, HIV, measles, TB, syphilis, intestinal pathogens, cysticercosis, malaria
Homeless persons	Pneumococcal pneumonia; meningococcal disease; TB; parasitic diseases; periodontal diseases; common skin infections, including cellulitis, arboviral encephalitis, and trench fever (<i>Bartonella henselae</i> and <i>Bartonella quintana</i>)
Incarcerated persons	Sexually transmitted diseases, HIV, TB, hepatitis B and C
UNDERLYING DISEASES OR CONDITIONS	
Diabetes mellitus	See text
Alcoholism and liver disease	Pneumonia, lung abscess, anaerobic pleuropulmonary infection, lung abscess, spontaneous bacterial peritonitis, TB
Injection drug use	Hepatitis A, B, C, and D (delta agent); skin and soft tissue infections, including <i>S. aureus</i> infections and necrotizing fasciitis; intravascular infections, including endocarditis and septic arthritis
Splenectomy	Overwhelming sepsis caused by <i>Streptococcus pneumoniae</i> or other pathogens (see text)
Spinal cord injury	UTIs, decubitus ulcers, pneumonia (the leading cause of death)
Organ transplant recipients	CMV infection (usually after the first month), EBV infection (which may cause posttransplantation lymphoproliferative disease), polyomavirus BK virus infection (which in kidney transplant recipients may cause nephropathy and organ rejection), <i>Pneumocystis jiroveci</i> pneumonia, invasive aspergillosis, strongyloidiasis
Granulocytopenia (absolute granulocyte count <1000/mL of blood)	Bacterial sepsis; fungal sepsis; invasive mold infections including aspergillosis, bowel ulcers (neutropenic enterocolitis or "typhlitis")

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; TB, tuberculosis; UTI, urinary tract infection.

associated with impaired lymphocyte function include viruses (notably DNA viruses such as the herpesviruses but also RNA viruses, including human papillomavirus [HPV] and measles virus), intracellular bacteria (notably *Mycobacterium tuberculosis*; *Listeria monocytogenes*; and *Nocardia*, *Salmonella*, *Brucella*, and *Legionella* spp.), fungi (notably *Cryptococcus neoformans*, the regional mycoses, and *Pneumocystis jiroveci*), and parasites (e.g., *Toxoplasma gondii* and *Strongyloides stercoralis*). Patients receiving corticosteroids should know to watch for infection because signs and symptoms are rendered subtle by the blunted immune response.

Biologic agents commonly used for diseases such as rheumatoid arthritis, notably monoclonal antibodies directed against tumor necrosis factor, and other inflammation-inducing cytokines also predispose to opportunistic pathogens associated with impaired lymphocyte function. The infectious risk varies among the available biologic agents. Rituximab, a monoclonal antibody directed against CD20 B cells, has been associated with bacterial infections and, rarely, with progressive multifocal leukoencephalopathy (PML).

Primary Immunodeficiency Disorders

Rare primary immunodeficiency disorders presenting in childhood—for example, X-linked agammaglobulinemia, DiGeorge syndrome, severe combined immunodeficiency syndromes, chronic granulomatous disease, reticular dysgenesis, Chédiak-Higashi syndrome, and ataxia-telangiectasia—are beyond the scope of this chapter. Here, we review several immunodeficiency disorders that may present during adolescence or early adulthood:

1. *Selective IgA deficiency* occurs worldwide in one in every 300 to 700 persons but seldom predisposes to

infection. A few patients have recurrent infections, especially URIs, atopic disorders, or autoimmune disorders. Anaphylaxis can result from the administration of blood products or intravenous immune globulin.

2. *Common variable immunodeficiency* occurs worldwide in about one in 25,000 persons and predisposes to frequent sinopulmonary infections, ear infections, conjunctivitis, chronic lung diseases, autoimmune disorders ($\approx 25\%$ of patients), gastrointestinal disorders (including inflammatory bowel disease, malabsorption, and pernicious anemia), and lymphoma. Diagnosis is usually made by measuring serum levels of IgG, IgA, and IgM. If the levels are low but not extremely low (i.e., below 200 mg/dL), one can confirm the diagnosis by testing the antibody response to vaccines (e.g., the pneumococcal and tetanus vaccines). Immune globulin replacement therapy reduces the incidence of infections.
3. *Inherited deficiencies in the complement system*, which consist of about 30 known proteins, occur in about 0.03% of all persons and are usually inherited as autosomal recessive traits. Predisposition to disease varies according to which protein is deficient. Affected patients are predisposed to recurrent mild or serious bacterial infections. Deficiency of certain components (properdin, C3, factor H, and factor I) predisposes to infection by encapsulated organisms such as *S. pneumoniae*. Deficiency of late-acting components (C5, C6, C7, and C8) predisposes to disseminated meningococcal and, less commonly, gonococcal infection. Screening for complement deficiencies is accomplished by testing for total hemolytic complement (CH₅₀).
4. The recurrent infection hyperimmunoglobulin E syndrome (known as Job syndrome, after the biblical personage) usually becomes apparent during childhood but may present later in life. Features include recurrent skin

and soft tissue infections, especially staphylococcal; recurrent sinopulmonary infections; dry eyes; and phenotypic abnormalities in bone structure. Immunoglobulin E levels are dramatically elevated.

5. Immunoglobulin G subclass deficiency, diagnosed by low levels of one or more subclasses (IgG₁, IgG₂, IgG₃, and IgG₄), is controversial. Patients suspected of this and other subtle abnormalities of humoral immunity (e.g., “specific antibody deficiencies” in which immunoglobulin levels are normal but patients fail to respond to a specific antigen) should probably be referred to an immunologist.

Extensive immunologic evaluation for “frequent colds” or frequent “boils” (furunculosis) is seldom worthwhile unless there are other reasons to suspect immunodeficiency.

IMMUNIZATION

Active immunization consists of the administration of vaccines or toxoids, which induces an immune response. Passive immunization, which will not be considered further here, consists of the administration of an exogenously produced immunoglobulin. All family physicians should stay abreast of nationally recommended vaccines for the general population ([Advisory Committee on Immunization Practices, 2014](#); also available at <http://www.cdc.gov/vaccines>) and should be aware of special recommendations for immunocompromised persons ([Rubin et al., 2014](#)). (See [Figures 7-6 and 7-7](#) for current immunization recommendations.)

Vaccines are of two broad types. *Live attenuated vaccines* are produced by modifying the disease-causing “wild form” of a virus or bacterium into an innocuous form, which induces an immune response after multiplying in the recipient. With rare exception (mainly orally administered agents such as the live polio vaccine), such vaccines usually confer immunity with a single dose. Commonly used live attenuated vaccines include those for measles, mumps, rubella, polio, yellow fever, varicella, influenza (the live, intranasally administered vaccine), zoster, and (formerly) vaccinia for smallpox. Because they replicate in the recipient, live attenuated vaccines must be given cautiously if at all to immunocompromised persons.

Inactivated vaccines are derived from killed viruses or bacteria and, in the case of bacteria, may consist of either the whole organism or fractional components such as toxoids, subunits, or polysaccharide surface antigens. An effective immune response often requires multiple doses spaced over time. Periodic booster inoculations may be necessary to sustain protective antibody levels. Inactivated bacterial vaccines may consist of the entire organism or fractional components such as toxoids, subunits, and polysaccharide surface antigens. Inactivated vaccines include those for polio, influenza (the intramuscularly administered vaccine), hepatitis A, hepatitis B, acellular pertussis, diphtheria, tetanus, botulism, *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*. Because they do not replicate in the recipient, inactivated vaccines can be given safely to immunocompromised persons.

A practice should have in place two reminder systems: one for its staff members and the other for its patient population. Many vaccines should be mandatory for staff

members. All patients except children younger than 6 months of age should be urged to receive the annual vaccine against influenza. Teenage girls should be encouraged to receive the HPV vaccine to reduce the incidence of condyloma and risk of cervical cancer ([Herweijer et al., 2014](#)); persons older than 60 years of age should receive the varicella-zoster (shingles) vaccine to reduce the risk and severity of shingles and postherpetic neuralgia. Physicians and staff should hone arguments for those who refuse vaccines or, worse, refuse them for their children. Herd immunity is everyone’s responsibility.

Contraindications to vaccines are relatively few. Valid contraindications include allergy, mainly type I allergy (anaphylaxis, angioedema, urticaria, and bronchospasm), and severe illness. As stated earlier, inactivated vaccines (but not live vaccines) may be given if indicated to immunosuppressed persons; the same holds for pregnant women. Anyone with a history of Guillain-Barré syndrome developing within 6 weeks of receiving the influenza vaccine should not receive the influenza vaccine. Recent administration of a blood product is a relative contraindication to a live attenuated vaccine because the blood product may have contained antibodies that will render the vaccine ineffective. Care should be taken administering the MMR (measles, mumps, and rubella) and MMRV (measles, mumps, rubella, and varicella) vaccine when there is a history of seizures because these vaccines carry a small risk of febrile seizures in children. The acellular pertussis, DTaP (diphtheria, tetanus, and acellular pertussis), and varicella vaccines do not carry a similar risk.

Many people erroneously think that vaccines are contraindicated during mild illness, present antibiotic therapy, disease exposure or convalescence from an acute illness, pregnancy in the household, breastfeeding, premature birth, allergies to products that are not contained in the vaccine, the need for tuberculin skin testing, and the need for multiple vaccines. Screening questionnaires for vaccine administration can be found at sources such as the Immunization Action Coalition (<http://www.immunize.org>).

Adverse reactions to vaccines most commonly consist of pain and erythema at an injection site or fever. Syncope sometimes occurs, especially among adolescents and young adults. Anaphylactic reactions—the symptoms of which include flushing, facial edema, swelling of the mouth or throat, dyspnea, and wheezing—are life threatening. Facilities administering vaccines should therefore have available supplies and procedures for managing anaphylaxis.

ANTIMICROBIAL AGENTS

Antimicrobial therapy is of three types: presumptive (empiric) therapy when the microbial etiology is unproven, precise (targeted) therapy after isolation of the infecting microorganism(s), and preventive (prophylactic) therapy in certain well-defined situations.

Presumptive (Empiric) Antimicrobial Therapy

The decisions about whether to prescribe presumptive therapy and what agents to describe depend on answers to structured questions ([Figure 15-3](#)). The *presumed infectious*

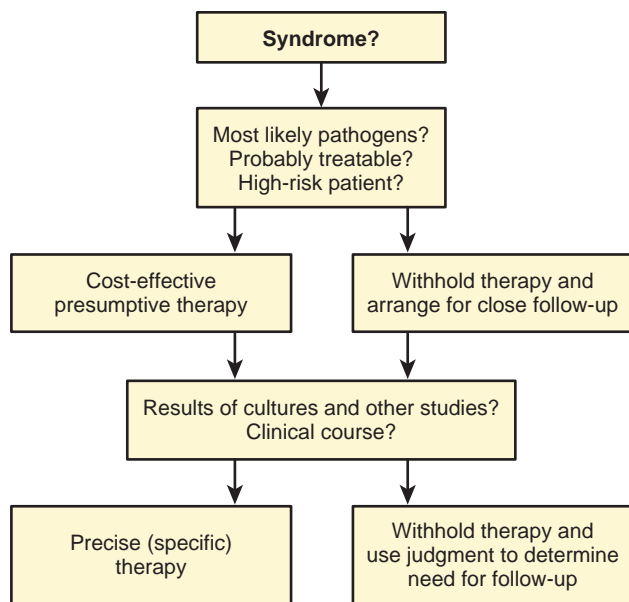

Figure 15-3. Decision making about antimicrobial therapy for infectious disease begins with accurate definition of the patient's syndrome.

syndrome should be defined as accurately as possible. The *severity* of the syndrome and the presence of *underlying conditions* such as serious diseases, use of immunosuppressive drugs, and advanced age affect (1) the decision to give antibiotics or “watch and wait” and (2) if presumptive therapy is given, the decision whether to cover most of the potential pathogens or just the more likely ones. What is the margin for error? One must also decide whether to admit the patient to the hospital and, if not, the frequency of follow-up.

Precise (Targeted) Antimicrobial Therapy

All aspects of a serious or potentially serious illness should be reviewed within 48 to 72 hours after the initial encounter. Within this time frame, (1) the causative pathogen will usually have been isolated if it is ever to be isolated (rare exceptions include mycobacteria, fungi, and certain fastidious bacteria) and (2) the patient will have shown improvement if the drug regimen covers the pathogen(s) and no complicating factor such as an undrained abscess is present. The choice of drugs should be revisited. *De-escalation* consists of narrowing the spectrum of antimicrobial coverage based on the specific microorganism(s) isolated and the clinical response. Overcoming the reluctance to “leave things as they are because the patient is getting better” usually works to the patient's advantage because unnecessarily broad coverage predisposes to colonization by drug-resistant organisms and risks collateral damage such as drug reactions and colitis caused by infection with *Clostridium difficile*.

Preventive (Prophylactic or Preemptive) Antimicrobial Therapy

Preventive antimicrobial therapy works best when given within 1 hour of a planned invasive procedure in which infection would be disastrous. Preventive therapy works

less well when drugs are given over extended period or indefinitely, but there are nevertheless well-defined indications for such therapy. Examples include prophylaxis against *P. jiroveci* and *Mycobacterium avium* complex infections in patients with advanced HIV disease, prophylaxis against recurrent bacterial cystitis in sexually active women, and use of antiviral agents to protect solid organ transplant recipients from serious cytomegalovirus (CMV) infection.

Specific Antimicrobial Agents

Knowledge of antimicrobial spectrum of activity, pharmacokinetics, pharmacodynamics, and drug–drug interactions aids antibiotic selection, as does knowledge of local antibiotic susceptibility patterns. Table 15-2 lists commonly used antibiotics by class and mechanism of action, with selected comments on precautions. A general knowledge of the efficacy, safety, and cost of commonly used antibiotics is essential. The practice of “thinking generically” even if one prescribes by trade names promotes awareness of new developments (including adverse drug reactions) as these appear in the literature.

Outpatient Parenteral Antimicrobial Therapy

A few family physicians may become involved with programs for outpatient parenteral antimicrobial therapy; more commonly, clinicians will find themselves monitoring such therapy, often in patients who have been released from the hospital. Clinicians should be aware of various temptations (including financial incentives) to prescribe parenteral therapy when orally administered drugs would suffice. Examples of drugs that when given orally provide nearly 100% bioavailability include trimethoprim–sulfamethoxazole (TMP-SMX), the fluoroquinolones (e.g., levofloxacin), metronidazole, and chloramphenicol (seldom used today because of rare cases of aplastic anemia). Patients on outpatient parenteral antimicrobial therapy should be monitored not only for serum drug levels (as for vancomycin and the aminoglycosides) and renal function but also for the potential for sepsis related to vascular access lines.

TRAVEL AND GEOGRAPHIC MEDICINE

Travelers are well advised to review destination-specific recommendations, now widely available on the Internet. Perhaps the most useful website is that of the travel health section of the Centers for Disease Control and Prevention (CDC) (<http://www.cdc.gov/travel>). Other federally sponsored websites include the CDC's Health Information for International Travel (<http://www.cdc.gov/mmwr>) and the U.S. State Department's travel warnings (<http://www.state.gov/travel>).

Travelers to developing countries should know precautions against traveler's diarrhea. Most travelers are advised to use bismuth subsalicylate (Pepto-Bismol) for prevention; loperamide (Imodium) for symptomatic treatment; and a fluoroquinolone for severe (*not* mild or moderately severe) diarrhea, which is usually of bacterial etiology (notably, *E. coli* and *Campylobacter*, *Salmonella*, and *Shigella* spp.). Traveler's diarrhea can also be caused by viruses (especially rotaviruses and, on cruise ships, noroviruses) and protozoa (notably *Cryptosporidium* spp., microsporidia, and *Giardia*

Table 15-2 Common Antibiotics by Class

Antimicrobial Class (Action)	Selected Agents	Selected Comments
β -lactams (disrupt cell wall synthesis by inhibiting formation of peptidoglycan cross-links)	<p><i>Penicillins</i>: penicillin V, penicillin G</p> <p><i>Aminopenicillins</i>: ampicillin, amoxicillin, bacampicillin</p> <p><i>Antistaphylococcal penicillins</i>: methicillin, nafcillin, oxacillin, dicloxacillin</p> <p><i>Extended-spectrum penicillins</i>: ticarcillin, piperacillin</p> <p><i>β-lactam-β-lactamase inhibitor combinations</i>: ampicillin-sulbactam; amoxicillin-clavulanate; ticarcillin-clavulanate; piperacillin-tazobactam</p> <p><i>Carbapenems</i>: imipenem, ertapenem, meropenem, doripenem</p> <p><i>Monobactam</i>: aztreonam</p> <p><i>First-generation cephalosporins</i>: cefazolin, cephalexin</p> <p><i>Second-generation cephalosporin</i>: cefuroxime</p> <p><i>Third-generation cephalosporins</i>: ceftriaxone, cefotaxime, ceftazidime, cefdinir</p> <p><i>Fourth-generation cephalosporin</i>: cefepime</p> <p><i>Fifth-generation cephalosporin</i>: ceftaroline</p> <p><i>Cepharmycins</i>: cefoxitin, cefotetan</p>	<p>When patients give a history of allergy to penicillin or other β-lactam antibiotics, the adverse reaction and the year of its occurrence should be recorded.</p> <p>Type 1 (IgE-mediated allergy) is defined by anaphylaxis, urticaria, angioedema, or bronchospasm.</p> <p>Type 1 cross-reactivity occurs among all β-lactam antibiotics with the singular exception of aztreonam. However, the risk of type 1 cross-reactivity between penicillins, carbapenems, and cephalosporins is low (< 3% to 5%).</p> <p>Neurotoxicity, manifested by somnolence, coma, and seizures, is potentially fatal and is dose related; carbapenems confer the highest risk.</p> <p>Carbapenems are active against most aerobic and anaerobic bacteria; holes in coverage include MRSA, <i>Stenotrophomonas maltophilia</i>, <i>Burkholderia cepacia</i>, <i>Legionella</i> spp., and <i>Corynebacterium jeikeium</i>.</p> <p>Aztreonam is active only against aerobic gram-negative bacilli; it can be used safely in patients with a history of type 1 allergy to other β-lactams.</p> <p>Cephalosporins lack coverage against enterococci, thus predisposing to enterococcal superinfection.</p> <p>All broad-spectrum antibiotics predispose to <i>C. difficile</i> colitis.</p>
Glycopeptides (disrupt cell wall synthesis, apparently by steric hindrance of the formation of backbone glycan chains)	Vancomycin, telavancin	<p>Penetrate poorly into CSF</p> <p>Complications include infusion-related “red man’s syndrome,” nephrotoxicity, and thrombocytopenia.</p> <p>Monitoring of trough serum levels is recommended for safety.</p> <p>Telavancin, compared with vancomycin, is more active on a weight basis against gram-positive bacteria, including MRSA (i.e., the minimum inhibitory levels are lower) and has a longer serum half-life but has greater nephrotoxicity.</p>
Lipopeptide (disrupts cell membrane, creating holes that allow potassium efflux)	Daptomycin	<p>Daptomycin is inactivated by pulmonary surfactant and is therefore not effective for pneumonia.</p> <p>Rhabdomyolysis can occur; the serum CPK level should be monitored weekly.</p> <p>Severe eosinophilic pneumonia can occur.</p>
Oxazolidinones (disrupt protein synthesis at the 50S ribosomal subunit)	Linezolid, tedizolid	<p>Prolonged courses can cause myelosuppression ($\leq 10\%$ of patients) and potentially irreversible peripheral and optic neuropathy.</p> <p>When used in combination with serotonergic agents (e.g., SSRIs), can cause a serotonin release syndrome.</p> <p>Useful for pneumonia caused by MRSA because of excellent penetration into lungs</p>
Glycylglycine (disrupts protein synthesis at the 30S ribosomal subunit)	Tigecycline	<p>Nausea and vomiting are prominent after initial doses.</p> <p>Approved for complicated skin and skin structure infections, intraabdominal infections, and community-acquired pneumonia.</p> <p>Use for nonapproved indications has been associated with increased mortality; hence, a “black box” warning.</p>
Folate antagonist (inhibit nucleic acid synthesis)	Trimethoprim-sulfamethoxazole (TMP-SMX)	<p>Active against numerous bacteria</p> <p>Near 100% bioavailability</p> <p>Trimethoprim component causes benign increases in serum creatinine.</p> <p>Sulfa component confers risks of serious allergic reactions, including Stevens-Johnson syndrome.</p> <p>Side effects include nephrotoxicity, hyperkalemia, bone marrow suppression, and photosensitivity.</p>
Fluoroquinolones (inhibit various topoisomerase enzymes and DNA gyrase)	Ciprofloxacin, levofloxacin, gemifloxacin, moxifloxacin, norfloxacin, ofloxacin	<p>Can cause QTc prolongation with risk of torsades de pointes</p> <p>Risk of tendonitis and tendon rupture is increased by concomitant corticosteroid use</p> <p>Avoid in pregnancy and in children because of cartilage malformation.</p> <p>Other side effects include photosensitivity and dysglycemia.</p>
Nitroimidazole (appears to disrupt DNA and inhibit nucleic acid synthesis by poorly understood mechanisms)	Metronidazole	<p>Active against most anaerobic bacteria and some parasites</p> <p>Near 100% oral bioavailability</p> <p>Causes disulfiram reactions; avoid concurrent alcohol use (even with the vaginal preparation).</p> <p>High doses cause nausea and vomiting.</p> <p>Prolonged use can cause neurotoxicity, including encephalopathy and sensory or motor peripheral neuropathy.</p>

Continued on following page

Table 15-2 Common Antibiotics by Class (Continued)

Antimicrobial Class (Action)	Selected Agents	Selected Comments
Tetracyclines (inhibit protein synthesis at the 30S ribosomal subunit)	Tetracycline, doxycycline, minocycline	Avoid during pregnancy and in children younger than 8 years of age because of teeth discoloration* (see RMSF). Photosensitivity, skin discoloration (minocycline), esophagitis (doxycycline) Avoid coadministration of oral tetracyclines and multivalent cations (e.g., calcium and magnesium).
Macrolides (inhibit protein synthesis at the 50S ribosomal subunit)	Azithromycin, clarithromycin, erythromycin, fidaxomicin	Can cause QTc prolongation with risk of torsades de pointes Drug–drug interactions secondary to 3A4 inhibition (clarithromycin, erythromycin) Side effects include nausea, vomiting, diarrhea; dysgeusia (clarithromycin). Fidaxomicin, a “nonabsorbable” agent marketed to treat refractory <i>Clostridium difficile</i> infection, can cause hypersensitivity reactions.
Lincosamide (inhibits protein synthesis at the 50S ribosomal subunit)	Clindamycin	Classically associated with <i>Clostridium difficile</i> colitis Active against most anaerobic bacteria other than <i>C. difficile</i> and against many gram-positive aerobic bacteria Susceptibility testing against gram-positive bacteria includes a “D-test” to screen for drug-resistant subpopulations of bacteria. Side effects include nausea, vomiting, diarrhea, and abdominal cramping.
Rifamycins (inhibit DNA-dependent RNA synthesis)	Rifampin, rifapentine, rifabutin, rifamixin	These drugs should never be used alone because of the potential for emergence of resistance. Risk of hepatitis increases with concurrent use of isoniazid or pyrazinamide. Allergic reactions include interstitial nephritis.
Aminoglycosides	Streptomycin, gentamicin, tobramycin, amikacin	Nephrotoxicity, although usually reversible, is associated with increased mortality rates among hospitalized patients. Auditory and vestibular toxicity are irreversible. Can also cause neuromuscular blockade
Polymyxins	Polymyxin B, colistimethate	Use may possibly expand because of continued emergence of resistant gram-negative bacilli. Risk of nephrotoxicity and neuromuscular blockade may be less than previously reported. Nevertheless, consultation should probably be sought before use.
Nitrofurantoin (inhibits protein, DNA, RNA, and cell wall synthesis by unclear mechanisms)	Nitrofurantoin	Acute pulmonary reactions result from hypersensitivity. Chronic pulmonary toxicity, usually after >6 months of use, includes pulmonary fibrosis that can be misdiagnosed as heart failure. Nausea, vomiting, and headache are the most common side effects.
Streptogramins (inhibit protein synthesis at the 50S ribosomal subunit)	Quinupristin–dalfopristin	Separately, quinupristin and dalfopristin are bacteriostatic. In combination, these agents are synergistic against gram-positive bacteria. Indications are vancomycin-resistant <i>Enterococcus faecium</i> and MRSA. Toxicity includes phlebitis. Side effects include arthralgia, myalgia, nausea, vomiting, and diarrhea.
Phosphonic acid derivative (blocks cell wall synthesis by inactivating enolpyruvyl transferase)	Fosfomycin	Broadly active against many gram-negative and gram-positive bacteria Used to treat UTIs, usually as a single megadose

CSF, Cerebrospinal fluid; CPK, creatine phosphokinase; MRSA, methicillin-resistant *Staphylococcus aureus*; SSRI, selective serotonin reuptake inhibitor; UTI, urinary tract infection.

*See text regarding use of tetracyclines in children with suspected Rocky Mountain spotted fever (RMSF).

and *Isospora* spp.). Travelers should take full supplies of their maintenance medications (indeed, a slight excess to allow for delays). Parting advice might include reminders that accidents (notably, road accidents) are the most common cause of travel-related death and that risk of sexually transmitted disease, including HIV, runs high in some destinations.

For a returning traveler who presents with new medical complaints, the clinician should make two lists of

diagnostic possibilities. One list contains destination-related illnesses; the other list contains diseases that might have occurred had the patient stayed home. It is important to include a travel history whenever one evaluates a patient for a possible infection of unclear etiology because some travel-related illnesses have long incubation periods; examples include TB, HIV/AIDS, brucellosis, and leishmaniasis.

Malaria is now the major infectious cause of death among returning U.S. travelers and is discussed below in the

section on parasites. Other potentially fatal diseases include typhoid fever. Febrile illnesses in travelers returning from the Caribbean can be caused by dengue (“break bone fever”) and, since 2013, chikungunya (“chik fever”), both caused by viruses transmitted by *Aedes* mosquitoes. Febrile illnesses in travelers can also be caused by rickettsial infection and, rarely, yellow fever.

INFECTION CONTROL

Everything should be done to minimize the risk that people entering a facility to improve their health will leave with newly acquired pathogens. An office infection control plan should include written procedures for cleaning and disinfection of instruments, management of infectious waste, proper storage of sterilized supplies, wiping down of examination tables and horizontal surfaces at the end of

each day, and an employee health policy that extends to all physicians and staff. The plan should be supervised by a designated person (often a nurse) empowered to implement corrective measures. The practice should promote a “culture of cleanliness” that starts with strong emphasis on hand hygiene.

Syndromes

INFECTIOUS DISEASE EMERGENCIES

The clinician should memorize the essential features of various life-threatening infections that may present with nonspecific symptoms and signs. [Table 15-3](#) discusses some of these syndromes; others are discussed elsewhere in this chapter.

Key Points

- Patients with suspected infection should be evaluated for severity: sepsis, sepsis syndrome, severe sepsis, and septic shock.
- Differential diagnosis of the “flulike illness” includes sepsis caused by *S. aureus* or gram-negative bacilli, Rocky Mountain spotted fever (RMSF), septic abortion, and malaria.
- Infectious causes of the “worst headache ever” include meningitis, brain abscess, RMSF, sphenoid sinusitis, and falciparum malaria.
- Necrotizing infections of skin, fascia, and muscle constitute a diverse group of syndromes of which *necrotizing fasciitis* is the most common. Necrotizing fasciitis should be considered whenever tissue injury to the skin or subcutaneous tissue is accompanied by *and muscle* constitute a diverse group of syndromes that should be considered whenever tissue injury to the skin or subcutaneous tissue is accompanied by systemic toxicity, pain disproportionate to physical findings; marked swelling; or blebs, bullae, or crepitance.
- Fever with localized pain or tenderness over the spine suggests vertebral osteomyelitis or spinal epidural abscess.
- Blood cultures should be obtained before antibiotics are prescribed to patients with conditions predisposing to endocarditis, such as regurgitant murmurs, congenital heart disease, or prosthetic heart valves.
- Acute bacterial meningitis can be misdiagnosed as “gastroenteritis” at the first clinical encounter because of prominent nausea.
- When an adolescent or young adult presents with a flulike illness and does not seem acutely ill but *might* have meningococcal disease, prescribe a “buddy check” whereby someone checks on the patient several hours after bedtime.
- Patients with fever with lethargy, impaired speech, bizarre behavior, or hallucinations should be evaluated for herpes simplex virus (HSV) encephalitis.
- Unusual causes of cellulitis include infection with *Aeromonas hydrophila*, *H. influenzae*, *S. pneumoniae*, *Cryptococcus neoformans*, *Erysipelothrix rhusiopathiae*, and *Streptococcus iniae*.
- Malignant otitis externa usually occurs in patients with diabetes mellitus, is caused by *Pseudomonas aeruginosa*, involves the temporal bone, and can extend into the brain.
- When patients present with suspected pneumonia, one should ask whether the problem could be something else (e.g., pulmonary embolism), whether the severity warrants hospitalization, and whether an unusual microorganism could be responsible.
- Clinical judgment takes precedent over a negative “rapid flu test” result whenever someone presents with typical symptoms of influenza at a time when influenza is prevalent in a community.
- Routine stool cultures have a low yield except in patients with severe disease or patients with the dysentery syndrome (small, frequent stools with blood and mucus).
- Patients older than 50 years of age with *Salmonella* gastroenteritis should receive antibiotics because of the risk of mycotic aneurysm of the aorta.
- Amebiasis should be excluded before steroids are prescribed for presumed first-episode ulcerative colitis.
- About 2% to 3% of patients with *C. difficile* colitis develop severe complications such as toxic megacolon or perforation of the colon; marked leukocytosis (WBC count >30,000/mm³) strongly suggests severe disease.
- Treatment of asymptomatic bacteriuria, even when accompanied by pyuria, should be discouraged in elderly patients and in patients with obstructive uropathy because such treatment encourages colonization by difficult-to-treat microorganisms.
- Gonococcal infection is underdiagnosed in women, who are prone to develop pelvic inflammatory disease (PID), infertility, and disseminated infection with the gonococcal arthritis–dermatitis syndrome.
- Up to half of patients with RMSF do not have rash during the first week of illness; diagnostic clues include thrombocytopenia, hyponatremia, and mild elevation of aminotransferases.
- Serologic testing for Lyme disease should be discouraged for patients with nonspecific symptoms, who have not had documented erythema chronicum, and who have not spent much time in a highly endemic geographic area.
- Primary care clinicians play essential roles in the diagnosis, management, and prevention of HIV disease, which is highly treatable for patients who are able to comply with all recommendations.

Table 15-3 Classic Presentations of Some Infectious Diseases

Presentation	Cause(s)
Acute flulike illness with fever, malaise, myalgias, or arthritis	Septicemia caused by <i>Staphylococcus aureus</i> or gram-negative bacilli, endocarditis, RMSF, septic abortion, malaria, primary HIV infection
“Worst headache ever”	Meningitis, brain abscess, encephalitis, RMSF, sphenoid sinusitis, falciparum malaria
Severe, progressive, unilateral retroorbital or frontal headache	Septic cavernous sinus thrombosis
Fever, headache, stiff neck, nausea, and vomiting in previously healthy college student (especially a freshman)	Meningitis caused by <i>Neisseria meningitidis</i> , meningococemia
Fever, headache, and altered mental status in an older adult with paranasal sinus tenderness, an abnormal chest examination, or a red tympanic membrane	Meningitis caused by <i>Streptococcus pneumoniae</i>
Low-grade fever and altered mental status in a frail elderly nursing home resident	Meningitis caused by <i>S. pneumoniae</i> , <i>Listeria monocytogenes</i> , or an aerobic gram-negative bacillus
Fever, headache, and focal neurologic signs	Brain abscess, subdural empyema, intracranial epidural abscess
Fever and localized back pain progressing to weakness of the lower extremities, with impaired bowel or bladder function	Spinal epidural abscess (usually caused by <i>S. aureus</i>)
Fever with flulike illness in an older person with a history or physical findings of valvular heart disease and evidence of heart failure	Endocarditis caused by <i>S. aureus</i> on the aortic or mitral valve
Fever with flulike illness in an injecting drug user with patchy pulmonary infiltrates on chest radiographic examination	Endocarditis caused by <i>S. aureus</i> on the tricuspid or pulmonic valve
Fever with flulike illness in a patient with known cirrhosis and who has recently ingested raw oysters who may have skin lesions suggesting cellulitis with bullae	Sepsis caused by <i>Vibrio vulnificus</i>
Fever, sore throat, tenderness over the anterior aspect of the neck or along the sternocleidomastoid muscle	Lateral or retropharyngeal space infection, septic thrombosis of the internal jugular vein (Lemierre syndrome)
Sore throat with difficulty breathing; pharynx relatively normal on physical examination	Acute epiglottitis
Severe localized pain over a seemingly trivial skin or soft tissue lesion, with or without a systemic toxicity	Necrotizing fasciitis
Severe localized pain over a skin lesion that contains bullae, watery discharge, or crepitation	Clostridial myonecrosis (gas gangrene) or necrotizing fasciitis
Fever with toxicity and a painful lymph node, with history of outdoors activity in the southwestern United States	Bubonic plague
Flulike illness progressing to hypotension and pulmonary edema in a patient with history of outdoors activity in the southwestern United States	Hantavirus pulmonary syndrome
Rapid onset of dyspnea, fever, diaphoresis, and cyanosis in a patient recently treated for “viral upper respiratory infection”	Inhalational anthrax due to bioterrorism
Fever with lethargy and confusion, personality change, or impaired speech	Herpes simplex encephalitis
Severe sepsis syndrome (sepsis with evidence of impaired organ perfusion) in a patient with a scar over the left upper quadrant of the abdomen	Fulminant postsplenectomy infection syndrome, most commonly caused by <i>S. pneumoniae</i> or <i>Haemophilus influenzae</i>
Returning traveler with fever, headache, and systemic toxicity	Malaria caused by <i>Plasmodium falciparum</i>
Shock, multiorgan failure, and diffuse erythroderma suggesting a sunburn, usually in a younger person	Toxic shock syndrome caused by <i>S. aureus</i>
Shock, multiorgan failure, and localized skin lesion with severe pain in a middle-aged or older person	Toxic shock syndrome caused by <i>Streptococcus pyogenes</i> (group A streptococcus)
Fever with abdominal pain and back pain in an older person with atherosclerosis and a recent diarrheal illness	Mycotic aneurysm of the abdominal aorta caused by <i>Salmonella</i> spp.
Ascending flaccid paralysis in a young person who has been in a tick habitat	Tick paralysis
Descending paralysis, symmetric cranial nerve palsies, dilated pupils, dry mouth, and furrowed tongue	Botulism
Fever with relative bradycardia, bilateral patchy pulmonary infiltrates, mild elevation of the aminotransferases, and history of exposure to wild rabbits or other animals	Tularemia

RMSF, Rocky Mountain spotted fever.

The Sepsis Syndrome: Differential Diagnosis of the Flulike Illness

Primary care clinicians frequently see patients with fever, malaise, myalgia, and other constitutional symptoms. When localizing symptoms are few, when the patient does

not appear ill or “toxic,” and when physical examination is unrevealing, such patients are often presumed to have a “flulike illness” or “viral syndrome.” Some of these patients, however, have life-threatening disease. Examples include septicemia caused by *S. aureus* or aerobic gram-negative

bacilli, septic abortion, endocarditis, and RMSE. The clinician's task is to determine which patients require close observation, special laboratory studies, and empiric antimicrobial therapy.

The following definitions express the stages of sepsis in ascending order of severity:

1. *Sepsis* denotes clinical evidence of infection plus a host response: fever (temperature >38.0 °C [100.4 °F]) or hypothermia (temperature <96.8 °F [36.0 °C]), tachycardia (heart rate >90 beats/min), tachypnea (respiratory rate >20 breaths/min or PaCO₂ <32 mm Hg), and both quantitative and qualitative changes in circulating WBCs (total WBC count $>12,000$ cells/mm³ or $<4,000$ cells/mm³ or $>10\%$ band neutrophils in the differential count).
2. *Sepsis syndrome* denotes sepsis plus evidence of impaired organ perfusion. Evidence of impaired organ perfusion includes altered mental status, decreased urine output, and low oxygen saturation by pulse oximetry. Lactic acidosis may also be present.
3. *Severe sepsis* denotes sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion abnormalities include oliguria and altered mental status. Hypotension is defined as systolic blood pressure less than 90 mm Hg or a decrease of greater than 40 mm Hg from the patient's baseline in the absence of hypotension.
4. *Septic shock* is defined as sepsis with hypotension despite adequate fluid resuscitation along with perfusion abnormalities such as lactic acidosis, oliguria, or alteration in mental status.

The concept of a *systemic inflammatory response syndrome* expresses the idea that the body responds in a fixed number of ways to a wide variety of insults. Thus, shock with acute respiratory syndrome and renal failure can result not only from infectious disease but also, for example, from acute hemorrhagic pancreatitis.

It cannot be stressed too strongly that *S. aureus* sepsis often presents as an undifferentiated flulike illness. Patients with *S. aureus* sepsis can progress rapidly to sepsis syndrome, severe sepsis, septic shock, and refractory septic shock.

Faced with a patient with possible sepsis syndrome, the clinician has three tasks:

1. Look for clues of infection and its severity by careful history and physical examination (including pulse oximetry if available).
2. Determine whether the patient's general appearance, underlying condition, or findings on CBC (notably, leukocytosis, leukopenia, bandemia, or thrombocytopenia) warrant admission to the hospital.
3. Assure close follow-up if it is deemed that admission to the hospital is not warranted.

Necrotizing Fasciitis and Other Necrotizing Infections of Skin, Fascia, and Muscle

A survey of members of the Infectious Diseases Society of America (IDSA) conducted by the present author indicated that *necrotizing fasciitis* more than any other infectious disease emergency is likely to result in misdiagnosis with

disastrous consequences. *Necrotizing infections of skin, fascia, and muscle* constitute a diverse group of syndromes that should be considered whenever tissue injury to the skin or subcutaneous tissue is accompanied by any combination of (1) blebs, bullae, or crepitation (all of which suggest gas formation); (2) marked swelling; (3) pain disproportionate to the physical findings; (4) bluish-gray skin discoloration; and (5) systemic toxicity.

Necrotizing fasciitis caused by group A streptococci has received lay attention as the "flesh-eating bacteria syndrome." Many affected patients have features of the streptococcal toxic shock syndrome. A second type of necrotizing fasciitis is caused by various aerobic and anaerobic bacteria, often in combination. The resulting syndromes include *non-clostridial anaerobic cellulitis*, *synergistic necrotizing cellulitis*, and *Fournier's gangrene* (which involves the perineum; lower abdominal wall; and, in males, the scrotum and penis; many patients have underlying diabetes mellitus). *Clostridial myonecrosis (gas gangrene)* is a fulminant, necrotizing infection of muscle with marked toxicity caused by toxin-producing clostridial strains, notably *C. perfringens*. Up to 3000 cases occur in the United States each year, most of which are related to trauma or penetrating injury. A spontaneous form occurs in patients with cancer and is frequently caused by *Clostridium septicum*. Pain is often the initial complaint. When the infection affects an extremity, patients often note that the limb feels "heavy." The skin becomes dark and often mottled, with edema and multiple bullae. Crepitus is usually less marked than in clostridial cellulitis.

Necrotizing skin and soft tissue infections require a high index of diagnostic suspicion. Leukocytosis (total WBC count $>15,400$ /mm³) and hyponatremia (serum sodium level <135 mmol/L) were shown in one study to help distinguish necrotizing fasciitis from less severe soft tissue infections. Imaging studies, especially magnetic resonance imaging (MRI), help clarify the diagnosis but surgical exploration is usually necessary to define the type and extent of the infection. Appropriate initial antimicrobial therapy should cover both aerobic and anaerobic pathogens. Removal of all involved tissue by wide debridement (and sometimes amputation) is necessary to prevent death.

KEY TREATMENT

- Non-penicillin-allergic patients with necrotizing fasciitis caused by *Streptococcus pyogenes* (group A streptococci) should be treated with penicillin G combined with clindamycin (to inhibit toxin production) (SOR: A).
- Non-penicillin-allergic patients with community-acquired necrotizing fasciitis of mixed microbial etiology should be treated with three drugs, such as ampicillin-sulbactam plus clindamycin plus ciprofloxacin (SOR: A).
- Penicillin G is the drug of choice for gas gangrene (anaerobic myonecrosis) caused by infection with *Clostridium perfringens* (SOR: A).

Spinal Epidural Abscess

Spinal epidural abscess was, in the author's survey of IDSA members, the second most likely serious infection to be

misdiagnosed with unfortunate results. The full-blown triad consists of fever, localized pain, and tenderness over the spine and symptoms and signs of spinal cord compression (impaired bowel or bladder function and then weakness or paralysis of the lower extremities). A flulike prodrome often signifies bacteremia caused by *S. aureus*, the most common causative organism. Patients suspected of this diagnosis should have a prompt MRI and be hospitalized because prompt surgical drainage, combined with antimicrobial therapy, is nearly always necessary for successful outcome.

Staphylococcal and Streptococcal Toxic Shock Syndromes

The toxic shock syndromes are caused by strains of *S. pyogenes* (group A streptococci) and *S. aureus* that produce unique toxins that function as superantigens, causing lymphocytes to produce massive quantities of inflammatory cytokines. These syndromes present as acute illnesses with fever, hypotension, tachycardia, and tachypnea. Staphylococcal toxic shock syndrome is usually preceded by a short flulike prodrome with chills, malaise, and generalized aching. A flulike prodrome is less common in streptococcal toxic shock syndrome, in which patients typically have symptoms and signs of localized infection, most commonly on an extremity and with severe pain. Suspicion of either syndrome should prompt hospitalization.

KEY TREATMENT

- Empiric therapy of staphylococcal toxic shock syndrome in non-penicillin-allergic patients consists of high-dose antistaphylococcal antibiotics (SOR: A).
- Treatment of streptococcal toxic shock syndrome consists of high-dose penicillin G combined with clindamycin to suppress toxin synthesis (SOR: A).

Endocarditis

The term “infective endocarditis” usually refers to infection of the heart valves, but other surfaces can be affected, such as the endocardium adjacent to a ventricular septal defect. “Endarteritis” refers to an identical process affecting a large blood vessel, such as a patent ductus arteriosus. Endocarditis is uniformly fatal without treatment. The diagnosis can be masked by prior antibiotic therapy. The primary care clinician’s task is to know when to suspect endocarditis, when to request blood cultures, when to obtain special studies such as echocardiography, and when to refer patients for hospitalization.

The manifestations of endocarditis are caused by (1) continuous presence of microorganisms in the bloodstream; (2) embolism from the vegetations; (3) circulating immune complexes; and (4) destruction of cardiac tissue, causing heart failure and arrhythmias. “Viridans” streptococci are historically the most common causes of endocarditis, but staphylococci were more common in some recent series. Enterococci cause up to 18% of cases. Coagulase-

negative staphylococci and fungi are important causes in patients with prosthetic valves. The many uncommon microorganisms causing endocarditis sometimes have specific associations, such as the well-known association of *Streptococcus gallolyticus* (formerly known as *Streptococcus bovis*) endocarditis or bacteremia with colorectal neoplasia.

Blood cultures are the keys to diagnosis. The modified Duke criteria for “definite” or “possible” endocarditis also take into account findings on echocardiography, predisposing heart conditions or injection drug use, documented vascular phenomena (evidence of embolism, telltale skin lesions, and other events), and immunologic phenomena. Classic “subacute” endocarditis caused by viridians streptococci typically unfolds over weeks to even months, and patients often seek medical assistance for complaints that seem unrelated to the heart. Therefore, when patients with predisposing conditions (e.g., regurgitant murmurs, new murmurs, prosthetic valves, or congenital heart disease) have indications for antibiotics, it is prudent to obtain blood cultures even when an alternative diagnosis seems clear-cut.

Blood cultures are positive in most patients with endocarditis. When endocarditis is strongly suspected and blood cultures are sterile, one should discuss alternative culture methods with the microbiology laboratory. The most common cause of “culture-negative” endocarditis is prior antibiotic therapy. Exposures that suggest unusual causes include cats (*Bartonella* spp.), cattle (*Coxiella burnetii*), goats or wild pigs (*Brucella* species), and psittacine birds (*Chlamydia psittaci*). Serology (IgM and IgG) is useful for all of these possibilities and also for *Mycoplasma* spp.; urinary antigen may be helpful for endocarditis caused by *Legionella* spp. Fungal endocarditis can be caused by *Candida* spp., *Histoplasma capsulatum*, and *Aspergillus* spp.

Patients with strongly suspected endocarditis should be hospitalized.

Meningococcal Disease

Meningococemia with or without meningitis is one of the few infectious diseases capable of killing a previously healthy person within hours. It mainly affects children, adolescents, and young adults (notably, college freshmen) but can occur at any age. Initial symptoms are often nonspecific. A prodromal URI may be followed by a flulike illness with fever, chills, malaise, generalized aching, headache, nausea, and vomiting. A petechial rash, found in up to 60% of patients, appears first on the ankles, wrists, axillary folds, and points of pressure (as from elastic) (Figure 15-4). The rash later becomes purpuric. When a patient is seen in the ambulatory setting, the patient does not seem especially sick, and yet *might* have meningococemia—for example, a patient with low-grade fever, mild headache, and nausea—a “buddy check” is recommended: (1) ascertain that the patient has someone who can check on him or her during the night, (2) have the designated “buddy” awaken the patient about 4 hours after bedtime, check the patient’s level of consciousness, and look for “little red spots” on the aforementioned sites, and (3) report to the emergency department if there is any deterioration.

Figure 15-4. Petechial rash over the foot, ankle, and lower extremity in a college freshman with meningococemia.

KEY TREATMENT

- Patients in whom meningococemia is strongly suspected should be given ceftriaxone as soon as possible (ideally, after obtaining blood cultures) and then hospitalized (SOR: A).

Acute Bacterial Meningitis and Aseptic Meningitis

Acute bacterial meningitis is a medical emergency variably characterized by fever, headache, meningismus (stiff neck), nausea, vomiting, and altered mental status. None of these symptoms is sufficiently sensitive to exclude meningitis by its absence. The presentation is subtle in about 15% of patients, especially in young children and elderly adults. Nausea and vomiting may predominate during the early stages, leading to a misdiagnosis of gastroenteritis.

Meningitis caused by *H. influenzae* type b now affects only about two in every 100,000 children because of wide vaccination against this microorganism. *N. meningitidis* is the most common cause of meningitis in children, adolescents, and young adults. The quadrivalent meningococcal conjugate vaccine covers four of the five major meningococcal serotypes; the exception is serogroup B, which causes about one third of cases of invasive meningococcal disease in the United States.

S. pneumoniae causes meningitis in all age groups and is the most common cause in older adults. The majority of patients with pneumococcal meningitis, unlike most patients with meningococcal meningitis, have a predisposing condition such as otitis media, sinusitis, pneumonia, or basilar skull fracture. The diagnosis of pneumococcal meningitis is often delayed because another condition—for example, acute alcoholism, severe pneumonia, or

neurologic disease—might account for the patient's sluggishness. Less common causes of bacterial meningitis include *Streptococcus agalactiae* (the group B streptococcus), especially in children; *Listeria monocytogenes* in elderly adults and debilitated or immunosuppressed individuals; and aerobic gram-negative bacilli in neonates, elderly persons, and patients who have undergone neurosurgical procedures. A subacute or chronic onset of symptoms of meningitis raises the possibility of tuberculous or fungal meningitis.

When acute bacterial meningitis is suspected, lumbar puncture (LP) should be performed as soon as possible unless symptoms and signs (e.g., localizing neurologic findings) suggest an intracranial mass lesion. The cerebrospinal fluid (CSF) formula—that is, the combination of the WBC count and differential, glucose, and protein—often confirms the diagnosis or steers the clinician in the right direction. A high WBC count ($>1000/\text{mm}^3$) with a predominance of polymorphonuclear neutrophils, a low glucose level (<40 mg/dL or $<40\%$ of the simultaneous blood glucose), and a high protein content (>160 mg/dL) are nearly diagnostic of acute bacterial meningitis. Gram stain sometimes indicates the causative microorganism. In patients with aseptic meningitis (discussed later), the CSF WBC count is usually lower, the glucose level usually normal, and the protein content either normal or slightly elevated. When immediate LP is not feasible or when it is deemed best to exclude central nervous system (CNS) mass lesion by computed tomography (CT), it may be prudent to give an initial dose of an antibiotic (usually ceftriaxone) before the LP.

KEY TREATMENT

- Recommended empiric antimicrobial therapy for acute bacterial meningitis is age related (SOR: A).
- Vancomycin plus a third-generation cephalosporin are recommended between the ages of 1 month and 50 years (SOR: A).
- Adjunctive dexamethasone is recommended for infants and children with *H. influenzae* type b meningitis but not if they have already received antibiotics (SOR: A).
- Ampicillin is often added in older adults to cover *Listeria monocytogenes*, and when aerobic gram-negative bacilli are a possibility, patients should receive a drug active against *P. aeruginosa* until the diagnosis is clarified (SOR: B).
- Most adult patients—especially those with proven or suspected pneumococcal meningitis—should receive adjunctive dexamethasone therapy to blunt the intense inflammatory response that causes much of the disability (SOR: B).

Aseptic Meningitis

Aseptic meningitis is discussed here only because it needs to be distinguished from acute bacterial meningitis because the correct diagnosis of aseptic meningitis spares the patient expense and inconvenience. The term “aseptic meningitis,” which in practice is basically synonymous with “viral meningitis,” was coined in the 1930s to denote a clinical syndrome characterized by fever, headache, photophobia,

unrevealing microbiologic studies on CSF, and a self-limited course without treatment. Enteroviruses are the most common proven cause and usually cause aseptic meningitis during the summer and fall months. Affected patients often complain of a severe headache—which is sometimes greatly relieved by LP—but mental status is normal, and they do not appear acutely ill. The CSF differential count may show a predominance of polymorphonuclear leukocytes when the patient is first seen. However, repeating the LP within the next 24 hours, even within 4 to 6 hours, reveals a predominantly lymphocytic pleocytosis despite withholding antibiotics. The prognosis for aseptic meningitis is, by definition, excellent, although occasional patients experience one or more recurrences.

Not infrequently, a patient who has received antibiotics presents with symptoms and signs suggesting aseptic meningitis. The differential diagnosis then includes aseptic meningitis versus *partially treated bacterial meningitis*. Partial treatment of bacterial meningitis may cause the CSF pleocytosis to become predominantly lymphocytic and the CSF glucose level to return toward normal. However, the CSF protein level usually remains elevated. Testing the CSF for bacterial antigens or bacterial DNA may be useful in this situation.

Encephalitis

Encephalitis is a life-threatening process characterized pathologically by inflammation of the brain parenchyma and clinically by neurologic abnormalities, including altered consciousness, localizing (focal) symptoms and signs, and seizures. Of the more than 100 microbial causes, HSV ranks first in importance for U.S. clinicians because of its potential severity and the availability of effective drug therapy.

Herpes simplex virus encephalitis usually begins with fever and lethargy and progresses rapidly to stupor and torpor. Impaired speech, bizarre behavior, or hallucinations suggest involvement of the temporal and frontal lobes, which can be confirmed by neuroimaging (for which MRI is more sensitive than CT). The CSF usually shows a lymphocytic pleocytosis, although the leukocyte count is normal in about 5% of patients. Red blood cells are usually present in the CSF, reflecting the necrotizing nature of the inflammatory process. Polymerase chain reaction (PCR) testing of CSF for herpes simplex viruses (HSV-1 and HSV-2) has a sensitivity of greater than 95% and a specificity of nearly 100%. Occasionally, the PCR test has a false-negative result early in the infection. Death and residual disability are common even with treatment.

Arboviruses causing encephalitis in the United States include the *St. Louis encephalitis virus* (which often strikes elderly adults and homeless individuals), the *Eastern equine encephalitis virus* (with a mortality rate in humans as high as 33%), the *California encephalitis virus* (which, similar to HSV, can cause a severe encephalitis with long-term sequelae and behavioral disorders in survivors), and *West Nile encephalitis virus*. West Nile virus, carried by migrating birds and transmitted to humans mainly by *Culex* mosquitoes; has since 1999 been recognized in most U.S. states; causes symptomatic disease (typically fever, often with rash and lymphadenopathy) in about 20% of infected persons; and results in serious CNS disease in fewer than 1% of

persons, many of whom are elderly. The spectrum of CNS disease caused by West Nile virus includes encephalitis, meningoencephalitis, meningitis, and myelitis with flaccid paralysis. Diagnosis of arboviral encephalitis is usually made by serologic testing; virus-specific IgM antibodies can be detected in CSF and serum in nearly all cases by the 10th day of illness. There is no specific treatment. Uncommon and rare causes of encephalitis in the United States include rabies; dengue; yellow fever; and, in immunocompromised persons, HHV-6 and JC virus (the cause of progressive multifocal leukoencephalopathy [PML]).

Suppurative Intracranial Infections (Parameningeal Infections)

The term *parameningeal infection* encompasses syndromes that require prompt diagnosis and usually surgical drainage: brain abscess, subdural empyema, septic thrombosis of the dural veins, and epidural abscess. Neuroimaging (with MRI being superior to CT) simplifies the diagnosis.

Brain abscess often evolves slowly. The classic triad—headache (present in ≈70% of patients), fever, and focal neurologic signs—is present in fewer than half of adults. Streptococci, especially anaerobic streptococci (peptostreptococci) and *Streptococcus anginosus*, are the most common bacterial causes, but *S. aureus* and aerobic gram-negative bacilli can also be involved.

Subdural empyema usually results from sinusitis, especially frontal sinusitis, and should be suspected when a patient with sinusitis gradually develops severe headache with nausea or vomiting.

Cavernous sinus thrombosis usually results from contiguous spread of infection from a nasal furuncle (hence, the admonition not to “squeeze a pimple” in the so-called dangerous area of the face), ethmoid or sphenoid sinusitis (Figure 15-5), or dental infections. *S. aureus* is the most common pathogen (≈70% of cases) followed by streptococci, gram-negative bacilli, and anaerobic bacteria. The

Figure 15-5. Complete opacification of the sphenoid sinusitis, presenting as the “worst headache ever” and leading to a fatal outcome because of misdiagnosis. Arrows indicate sphenoid sinuses.

classic presentation consists of headache, photophobia, unilateral periorbital edema, and bulging of the eye (proptosis). Examination of the eye may reveal ptosis; chemosis; and palsies involving the third, fourth, fifth, and sixth cranial nerves, with disturbance of lateral gaze (sixth nerve palsy) being the most common. The pupil may be dilated and sluggishly reactive. Suspicion of cavernous sinus thrombosis should prompt immediate hospitalization, imaging studies, and institution of antimicrobial therapy directed broadly against the aforementioned pathogens.

Botulism

Botulism, caused by an extremely potent neurotoxin produced by *Clostridium botulinum*, is uncommon in the United States but occasionally causes outbreaks and is a potential agent of bioterrorism. The disease typically presents with symmetric cranial nerve palsies and descending motor paralysis; other features include blurred vision, diplopia, dilated pupils, dry mouth, normal blood pressure, mental alertness despite the striking neurologic deficits, and intact sensation. Conditions that mimic botulism include stroke, Guillain-Barré syndrome, myasthenia gravis, diphtheria, and organophosphate poisoning. Infant botulism, now the most common form in the United States, often begins with weakness, including a weak cry, feeding problems, irritability, and hypotonia. Aggressive intensive care with mechanical ventilation enables patients to survive. An antitoxin is available from the CDC.

Tetanus

Tetanus (called “lockjaw” because of the characteristic rigidity of the masseter muscles) affects more than 100 persons in the United States each year, mainly older persons and especially older women. All of its manifestations are attributed to a toxin. The portal of entry is often trivial and overlooked. Dystonic reactions to neuroleptic drugs and other central dopamine antagonists can resemble tetanus; however, patients with dystonic reactions tend to show lateral neck turning and respond to diphenhydramine or benzotropine. Strychnine poisoning resembles tetanus. Patients with suspected tetanus should be hospitalized.

Bioterrorism

Family physicians are crucial to the early recognition of bioterrorism because—unlike terrorism with chemical or physical agents—affected persons may be widely dispersed before disease manifestations appear. Potential agents of bioterrorism have been grouped into three categories designated A, B, and C. *Category A* organisms are easily disseminated from a central source or readily transmitted from person to person, cause high mortality, and may disrupt society. These include the agents of smallpox, anthrax, plague, tularemia, botulism, and certain viral hemorrhagic fevers. *Category B* organisms are moderately easy to disseminate, cause low mortality but considerable morbidity, and pose problems in recognition. These include the agents of salmonellosis, shigellosis, cryptosporidiosis, hemorrhagic colitis (*E. coli* O157:H7), Q fever (*Coxiella burnetii*), and viral encephalitis. *Category C* includes organisms that could be bioengineered in the future with the potential to cause high morbidity and mortality with a major impact on public health. These include multi-drug-resistant *M.*

tuberculosis (TB), tickborne hemorrhagic fever viruses, tickborne encephalitis virus, Nipah virus, and various respiratory viruses. Bioterrorism should be suspected whenever clinicians encounter either a large number of cases of severe illness in previously healthy persons or a single case of a rare infectious disease. Other clues are higher morbidity and mortality than would be expected from a common disease; failure of a common disease to respond to the usual therapy; disease with an unusual geographic or seasonal distribution; outbreaks of unexplained disease in animals that precede or accompany severe illness in humans; and outbreaks associated with common exposures, including water sources and ventilation systems.

SKIN AND SOFT TISSUE INFECTIONS

Infections of skin and soft tissue are common in family medicine and must sometimes be distinguished from life-threatening conditions such as necrotizing fasciitis, discussed earlier. A rapid increase in ambulatory care visits for skin infections in the United States, estimated to now exceed 14 million visits per year, is attributed in part to the spread of methicillin-resistant *S. aureus* (MRSA). Issues for primary care clinicians include (1) when to suspect that skin lesions reflect a systemic illness, such as endocarditis; (2) when to treat empirically without special studies; (3) when to obtain Gram stains, cultures, or—if necrotizing soft tissue infection is a possibility—imaging studies such as MRI; (4) when to supplement incision and drainage of abscesses with antibiotics; and (5) when to hospitalize.

Impetigo and Ecthyma

Nonbullous impetigo is a superficial vesiculopustular infection of the stratum corneum, usually seen in children during the summer months. The vesicles quickly rupture to form thick, “stuck-on” golden-yellow to honey-colored crusts. *S. pyogenes* (group A streptococci) is the classic cause, but in some localities, *S. aureus* is now more common. Most cases are self-limited, although poststreptococcal glomerulonephritis can develop.

Ecthyma resembles nonbullous impetigo in that it usually caused by group A streptococci or staphylococci and begins with vesicles that become pustules and then rupture. Ecthyma differs from nonbullous impetigo in that (1) it occurs most commonly on the lower extremities; (2) occurs in other age groups besides young children, especially in elderly adults; (3) extends through the epidermis, leaving a “punched out” ulcer with raised violaceous margins; and (4) usually calls for systemic antibiotics. “Uncomplicated ecthyma” must be distinguished from *ecthyma gangrenosum* caused by systemic infection (notably, *P. aeruginosa*) and usually featuring a necrotic eschar in the center of the lesion.

Bullous impetigo usually occurs in infants and young children, is caused by *S. aureus* strains that produce an exfoliative toxin, and is characterized by vesicles that evolve into large flaccid bullae. Rupture of the bullae leaves exposed, moist, red skin before the formation of a thin, light brown, “varnish-like” crust. The mild form is self-limited, but a generalized form (the *staphylococcal scalded skin syndrome*, also called *pemphigus neonatorum* when it affects neonates) is life threatening.

KEY TREATMENT

- Topical mupirocin is recommended for localized nonbulbous impetigo, although resistant bacterial strains occur (SOR: A).
- Oral antibiotic therapy with agents active against *S. pyogenes* and *S. aureus* may be required for nonbullous impetigo presenting with multiple lesions and for patients who fail topical therapy (SOR: A).

Folliculitis, Furuncles, Carbuncles, and Skin Abscesses

Folliculitis (pyoderma involving the hair follicles and apocrine glands) affects nearly everyone at one time or another and is usually self-limited. Occasionally, it progresses to larger lesions (furuncles and carbuncles). The characteristic “unit lesion” is a 2- to 5-mm erythematous papule that often contains a small pustule at its apex. The lesions are typically multiple and often pruritic. When over the bearded area of the face, the condition is known as *syccosis barbae*. Most cases in outpatients are caused by *S. aureus*. *P. aeruginosa* causes widespread folliculitis in patients exposed to contaminated hot tubs, whirlpools, swimming pools, or wet suits. Other gram-negative bacilli sometimes cause folliculitis in patients who have received prolonged courses of antibiotics for acne or rosacea. *Candida albicans* and *Malassezia furfur* cause folliculitis in patients who are immunocompromised, who have diabetes mellitus, or who have received antibiotic or steroid therapy.

Variants of folliculitis include (1) *eosinophilic folliculitis* (“itchy folliculitis”), which occurs mainly in HIV-infected patients, especially over the trunk but also over the face; (2) *pseudofolliculitis barbae* (“razor bumps” or “ingrown hairs”), a papular or pustular inflammatory reaction affecting persons with curly hair (especially African American men) who shave; (3) “steroid acne,” a folliculitis resulting from systemic or topical corticosteroid therapy, sometimes caused by *Pityrosporum ovale*; (4) *viral folliculitis*, most commonly associated with herpesvirus infection in immunocompromised persons; and (5) *papular drug eruptions* (“acneiform dermatoses”).

Furuncles (“boils”) are thought to arise from folliculitis. “Furunculosis” refers to multiple or recurrent furuncles. These lesions are 1 to 2 cm in diameter (or about the size of a marble) and are nearly always caused by *S. aureus*. The time-honored treatment consists of warm, wet compresses to promote “coming to a head” with spontaneous drainage. Patients should be advised not to apply pressure or squeeze lesions because of the risk of bacteremia. Frequent recurrences (furunculosis) are usually frustrating to manage; many methods have been tried, but none is uniformly effective. Scrupulous hygiene and frequent bathing are often combined with an attempt to suppress *S. aureus* nasal carriage because many (perhaps most) patients are carriers. Limited experience suggests that a strategy of repeating a 5-day course of 2% mupirocin nasal ointment every month may be cost effective. Individualized treatment is recommended; a flowchart for patients might include separate columns for date; results of cultures, including nasal cultures; topical and systemic antibiotic therapy

administered; and new furuncles with their locations and treatment.

Carbuncles are deeper, complex lesions, typically located over the nape of the neck, the back, or the thighs. Some patients with carbuncles meet the criteria for the sepsis syndrome.

Skin abscesses differ from furuncles and carbuncles in that they are deeper and do not necessarily arise in hair follicles. They are usually caused by *S. aureus*, and in recent years community-acquired MRSA (CA-MRSA) has become an extremely important etiology. Patients often give a spurious history of “spider bite” that evolved into an angry-looking furuncle or skin abscess with surrounding erythema. Incision and drainage may be necessary for large fluctuant lesions, and primary care physicians are well advised to learn newer approaches to drainage (Singer and Talan, 2014). IDSA guidelines published in 2011 suggest that adjunctive antibiotic therapy is unnecessary for patients without complicating factors (see later discussion). There is now broad consensus that antibiotics are overused for uncomplicated skin infections, including abscesses. Randomized placebo-controlled trials of TMP-SMX for skin abscesses in children and adults showed no significant benefit over drainage alone, although patients receiving antibiotic were slightly less likely to develop new lesions (Singer and Talan, 2014). However, many clinicians prefer to prescribe an adjunctive antibiotic, most commonly TMP-SMX, because alternatives such as linezolid are usually prohibitively expensive. Results of a recent study suggested that about half of antibiotic prescriptions for uncomplicated skin infections were avoidable—that is, complicating factors as listed were absent (Hurley et al., 2013).

KEY TREATMENT

- Most patients (≈90%) with fluctuant skin abscesses respond to drainage, and antibiotic therapy does not significantly improve the outcome (SOR: A).
- Indications for antibiotic therapy in patients with skin abscesses include involvement of an area that is difficult to drain (e.g., the face, the hands, or the genitalia), multiple foci of infection, rapid progression with associated cellulitis, diabetes mellitus, HIV infection, serious coexisting diseases or immunosuppressive therapy, temperature above 38.0 °C (100.4 °F), and extremes of age (younger than 3 years or older than 75 years).
- When antibiotics are indicated for patients with skin abscesses, drugs of choice include TMP-SMX, tetracycline, and clindamycin—with the caveat that up to 50% of CA-MRSA strains are resistant to clindamycin, and inducible resistance occurs.

Erysipelas and Cellulitis

“Cellulitis,” a clinical diagnosis, denotes a spreading infection in the subcutaneous tissue. *Erysipelas* is a rapidly progressive superficial form of cellulitis usually caused by *S. pyogenes* (group A streptococci). The involved skin is usually a bright, fiery red and sharply demarcated from uninvolved skin (Figure 15-6). Erysipelas most commonly occurs on the lower extremities, often with bright red “lymphangitic

Figure 15-6. Erysipelas (superficial cellulitis) of the chest and abdominal walls caused by *Streptococcus pyogenes*. Note the primary lesion below the axilla and the sharp demarcation between normal and inflamed skin.

streaks” leading toward tender regional lymph nodes. Cellulitis other than erysipelas is commonly caused by *S. pyogenes*, *S. aureus*, or both. The line of demarcation between involved and uninvolved skin is blurred, in contrast to erysipelas, and lymphangitic streaks are seldom present. Abscess formation or extension into fat or fascial layers may occur. The history and the patient’s demographics may suggest an alternative etiology, such as *Aeromonas hydrophila* when wounds have been exposed to fresh water; *V. vulnificus* when wounds have been exposed to saltwater or brackish water; *H. influenzae* in children; miscellaneous aerobic gram-negative bacilli in immunocompromised patients and patients with diabetes mellitus; non-group A β -hemolytic streptococci in frail elderly persons; *S. pneumoniae* in immunocompromised patients and persons with alcoholism; *Cryptococcus neoformans* in patients taking immunosuppressive medication; *Erysipelothrix rhusiopathiae* when abrasions have been exposed to freshwater fish, shellfish, meat, hides, or poultry; and *S. iniae* from similar exposure to raw fish, notably tilapia.

Imaging studies such as MRI may be advisable when clinical findings raise the possibility of necrotizing fasciitis, as discussed earlier. Blood cultures should be obtained when severe systemic toxicity is present; however, the yield is low. Aspiration of the lesion for culture may be helpful (up to 30% yield) in immunocompromised persons; the technique is to inject a small amount of sterile saline *without preservative* into unbroken skin and then pull back on the syringe and inoculate a blood culture bottle.

Recurrent Cellulitis

Approximately 17% of patients with lower extremity cellulitis develop recurrence within 2 years. Risk factors for recurrence include tibial lesions, dermatitis, large body size, chronic peripheral edema, malignancy, and dermatitis. Treatment of predisposing conditions such as dermatitis, support stockings, skin hygiene, and decolonization in patients with MRSA may be beneficial.

KEY TREATMENT

- Penicillin G is the drug of choice for erysipelas (a rapidly spreading superficial form of cellulitis) in non-penicillin-allergic patients (SOR: A).
- Patients presenting with cellulitis that does not have the classic features of erysipelas should be asked about risk factors for cellulitis caused by unusual organisms (see earlier discussion) (SOR: A).
- When unusual etiologies of cellulitis seem unlikely, non-penicillin-allergic patients with cellulitis other than erysipelas should be treated with an antistaphylococcal penicillin or a first-generation cephalosporin unless MRSA is suspected, in which case vancomycin should be prescribed (SOR: A).
- Patients with frequent recurrences (>three episodes/year) may benefit from prophylactic antibiotics. Low-dose oral penicillin (250 mg twice daily) was recently shown effective in preventing recurrences (SOR: B) (Thomas et al., 2013). Other regimens include monthly injections of intramuscular penicillin and oral erythromycin (SOR: C).

Diabetic Foot Ulcer Infections

Diabetic foot infections are distressingly common and often lead to amputation. Evaluation should be at three levels: the patient as a whole (including glucose control), the affected limb (whether sensory polyneuropathy and peripheral vascular disease are present), and the wound itself. Evaluation of the wound includes (1) determining whether the wound is infected, defined by purulence or by at least two of the classic signs of inflammation (erythema, warmth, tenderness, pain, and swelling or induration); (2) whether infection, if present, is superficial or deep; and (3) whether osteomyelitis is present. Recurrent or deepening foot ulcers suggest bone involvement, as does a positive “probe-to-bone test” (i.e., passing a sterile stainless-steel instrument to the depth of the wound produces a “click” on striking bone), but MRI is the most sensitive way to establish or exclude osteomyelitis short of bone biopsy. Patients with severe infections should be hospitalized, as should patients with moderately severe infections with complicating factors such as poor home support.

KEY TREATMENT

- Patients with mild to moderately severe diabetic foot ulcers can be treated with an antibiotic active against gram-positive cocci—notably, *S. aureus*, including MRSA and streptococci (SOR: A).
- Patients with severe diabetic foot infections should be managed with attention to various guidelines (IDSA and others) in consultation with a surgeon (SOR: A).
- Antibiotic therapy for patients with severe diabetic foot infections is optimally guided by deep cultures obtained through unbroken skin or by bone biopsy (SOR: A).
- Surface (swab) cultures and cultures of material from draining sinus tracts have little if any role in the management of diabetic foot infections and should be discouraged (SOR: B).

Bite Wound Infections

Animal bites prompt about 1% of emergency department visits in the United States, are most commonly inflicted by dogs (80%), and occur most often on the distal extremities, but may also be on the head or neck of children. *Pasteurella multocida* is the most frequent isolate, but cultures reveal on average about five species of aerobic and anaerobic bacteria. Dog bites necessitate evaluation for rabies transmission. Human bites, which include clenched-fist injuries (“fight bites”), are likely to involve not only anaerobic bacteria and streptococci but also *Eikenella corrodens*, a gram-negative bacillus usually resistant to first-generation cephalosporins and macrolides.

KEY TREATMENT

- For non-penicillin-allergic patients with animal bite wounds, treatment should consist of orally administered ampicillin-clavulanate or intravenously administered ampicillin-sulbactam, depending on the severity (SOR: B).
- Human bite wounds should be treated with intravenous ampicillin-sulbactam or cefoxitin (SOR: B).
- Prophylactic antibiotic therapy after human bites reduces the incidence of infection (SOR: C).
- Prophylactic antibiotic therapy after bites (of any kind) of the hand reduces the incidence of infection (SOR: B), and a hand surgeon should be consulted if the tendons or bones of the hands are likely to be involved (SOR: A).
- Patients should be given tetanus immunization if necessary (SOR: A) and postexposure prophylaxis against HIV if indicated (SOR: B).

UPPER RESPIRATORY INFECTIONS

Upper respiratory infections (URIs) comprise at least half of all symptomatic illness in a community and exact tolls measurable as morbidity, absenteeism from school and work, direct health care costs, and overuse of antibiotics. Most URIs are self-limited, but progression to life-threatening illness occurs, and progression to chronic disease is common.

The Common Cold (Acute Viral Rhinosinusitis)

The common cold is an acute-self-limited catarrhal syndrome limited to the mucosal membranes of the upper respiratory tract and responsible for about three fourths of all illnesses in young infants and up to half of illnesses in adults. About half of cases are caused by rhinoviruses; about 10% by coronaviruses; and the rest by other viruses, including respiratory syncytial virus (RSV), adenoviruses, and influenza and parainfluenza viruses. Rhinoviruses remain viable on skin or objects for at least 2 hours and are transmitted most efficiently by direct contact.

The common cold is a clinical diagnosis based largely on symptoms: a sore or scratchy throat at onset, nasal congestion or obstruction (CT scan shows abnormalities of the paranasal sinuses in up to 87% of cases, hence the alternative term “viral rhinosinusitis”), and cough (“chest cold”) in about 30% of cases beginning the fourth and fifth days. In young children, alternative diagnoses include foreign

body and *streptococcal nasopharyngitis*. *Allergic rhinitis* differs from the common cold by seasonal occurrence, itchy eyes, and more than 20% eosinophilia in nasal secretions. *Persistent, low-grade bacterial sinusitis* is recognized by long duration of symptoms. High fever, chills, myalgias, signs of meningeal irritation, or proptosis should prompt consideration of another diagnosis.

Well-controlled trials are lacking for most agents purported to help. The published literature provides mild support for ipratropium bromide and zinc lozenges but little support for antihistamines, decongestants, antiinflammatory drugs, and herbal regimens, including *Echinacea*. Nearly all authorities agree that antibiotics should be discouraged. Preventive measures include hand hygiene, use of disposable tissues by persons with colds, avoidance of hand contact with patients or fomites, and the vitamins supplied in a normal diet. Decontamination of surfaces with phenol-alcohol (Lysol) reduces transmission.

The *severe acute respiratory syndrome* (SARS), which begins with symptoms suggesting the common cold but progresses to full-blown acute respiratory distress syndrome (ARDS) and is therefore life threatening, appeared in Southeast Asia in 2002 and was shown to be caused by a newly recognized coronavirus designated SARS-CoV. More recently, in 2012, a similar illness appeared on the Arabian Peninsula, has been designated the *Middle East respiratory syndrome* (MERS), and has been shown to be caused by a coronavirus designated MERS-CoV. These syndromes raise the disturbing possibility that coronaviruses could become major causes of mortality or even an agent of bioterrorism.

Sinusitis

See [Chapter 18](#), Otorhinolaryngology.

Otitis Externa

Otitis externa, a spectrum of conditions caused by infection, allergy, or primary skin disease, affects up to 10% of all persons during their lifetimes. The spectrum includes:

1. *Acute localized otitis externa* beginning as one or more pustules or furuncles in the ear, usually caused by *S. aureus*, presenting as itching, pain, swelling, redness, and sometimes decreased hearing and with one or more small pustules or furuncles in the ear canal on physical examination.
2. *Acute diffuse otitis externa* (*swimmer's ear*) presenting as severe and even intolerable earache (otalgia), itching, discharge, and hearing loss, most commonly caused by *P. aeruginosa*, and with diffuse erythema and edema in the ear canal on examination.
3. *Erysipelas* involving the concha and ear canal, caused by group A streptococci (*S. pyogenes*), presenting with a diffusely red and painful ear and with hemorrhagic bullae sometimes seen on the walls of the ear canal.
4. *Chronic otitis externa*, presenting with mild discomfort and flaking of the skin of long duration, often with a history of frequent use of antibiotic-containing otic preparations.
5. *Eczematous otitis externa*, presenting with severe itching and with physical findings of scaling of the skin surface with crusting, oozing, and erythema, reflects involvement of the ear by skin disease such as

contact dermatitis, seborrheic dermatitis, and atopic dermatitis.

6. *Malignant otitis externa*, also called *invasive otitis externa*, usually affecting patients with diabetes mellitus and caused by *P. aeruginosa*. The clinical course is often deceptively subacute or chronic: (1) initial symptoms and signs suggest uncomplicated otitis externa; (2) multiple courses of ear drops prove unhelpful; (3) the epithelium of the ear canal becomes macerated with cellulitis, formation of polypoid granulation tissue, persistent pain, continued drainage from the ear (otorrhea), and hearing loss; and (4) brain involvement becomes manifest by meningitis or cranial nerve palsies (VII, IX, X, and XII). It is thought that the causative bacteria, having burrowed below the epithelium of the ear canal, slip through gaps between the ear cartilages (fissures of Santorini), gain access to the temporal bone (causing osteomyelitis), and then extend into the base of the brain. Appropriate management includes imaging (MRI with gadolinium enhancement), aggressive debridement of the ear canal by an otolaryngologist, and systemic antimicrobial therapy directed against *P. aeruginosa*.

Except for the latter syndrome, patients with otitis externa can usually be managed conservatively with local care and topical otic preparations (containing appropriate antimicrobial agents when indicated), but patients with severe disease or complete occlusion of the ear canal should be referred to an otolaryngologist.

Otitis Media and Mastoiditis

Acute otitis media is mainly but not exclusively a disease of childhood, is caused by various virulent bacteria, and is optimally diagnosed by demonstrating reduced mobility of the tympanic membrane by pneumatic otoscopy. Tympanocentesis is required for accurate microbiologic diagnosis and should be considered in newborn infants, when the illness is unusually severe, when the patient fails to respond to antibiotics, or when a suppurative complication is confirmed or suspected. Acute otitis media must be distinguished from *otitis media with effusion* (*serous otitis media*), which consists of an asymptomatic or hyposymptomatic middle ear effusion without fever or otalgia.

Chronic suppurative otitis media is a complication of acute otitis media, usually occurring when a defect is present in the tympanic membrane, such as a perforation or the presence of a tympanostomy tube. It is accompanied by purulent drainage (otorrhea). Mastoiditis is invariably present. The associated bacteria vary depending on whether an infected *cholesteatoma* is present; cholesteatomas typically contain anaerobic bacteria and may therefore impart a foul odor. When cholesteatoma is not present, gram-negative bacilli, including *P. aeruginosa* and *E. coli*, are often found.

Mastoiditis, which before the advent of antibiotics was often a dramatic illness with a high incidence of intracranial complications, usually presents today as an indolent, low-grade, and often painless infection of the temporal bone. Spontaneous resolution is rare if it occurs at all.

Complications of chronic suppurative otitis media and mastoiditis include bone destruction, subperiosteal

abscess, facial paralysis, labyrinthitis, petrositis, and—more dangerously—brain abscess, subdural abscess, epidural abscess, and septic thrombosis of one or more venous sinuses.

Acute Pharyngitis: Group A Streptococcal Pharyngitis versus Viral Pharyngitis

Acute pharyngitis (sore throat) is one of the most common problems in clinical practice and, more often than not, of viral etiology. The usual clinical problem consists of recognizing and treating pharyngitis caused by group A streptococci (*S. pyogenes*), which accounts for about 15% to 30% of cases in children between the ages of 5 and 15 years and about 5% to 15% of cases in adults. Accurate diagnosis of streptococcal pharyngitis is desirable to prevent overuse of antibiotics; reduce the duration and severity of symptoms; reduce disease transmission; and, in children, prevent suppurative complications and acute rheumatic fever (a non-suppurative complication). Through the years, numerous clinical criteria have been proposed for identifying patients likely to have group A streptococcal pharyngitis rather than viral pharyngitis, which is more common in all populations. In general:

1. In children younger than 3 years of age, symptoms are atypical and may be protracted. The term “streptococcosis” has been applied to the triad of prolonged nasal congestion and discharge, low-grade fever, and tender cervical lymphadenopathy. Children younger than 1 year of age may present with fussiness, decreased appetite, and low-grade fever.
2. In children older than 5 years of age, the following clinical features increase the likelihood of streptococcal pharyngitis to greater than 50% but do not suffice for accurate diagnosis: the presence of pharyngeal exudates, palatal petechiae, or a scarlatiniform rash; vomiting; and tender cervical lymphadenopathy. Various scoring systems have been devised, but none obviates the need for diagnostic testing.
3. In adults, a checklist known as the Centor system uses four criteria: fever, tonsillar exudates, tender cervical lymphadenopathy, and absence of a cough. It has been suggested that patients with two or fewer of these four criteria do not need diagnostic testing or antibiotics unless they are at high risk for severe infections (e.g., patients with poorly controlled diabetes mellitus, immunocompromised persons, and those receiving long-term steroid therapy).

Protocols for managing acute pharyngitis in family medicine should take into account the numerous potential etiologies beyond streptococcal pharyngitis and viral pharyngitis.

KEY TREATMENT

- Rapid antigen detection tests or throat cultures should be obtained in patients with suspected streptococcal pharyngitis (SOR: A).
- Patients with proven streptococcal pharyngitis should be treated with penicillin or ampicillin or, in the case of penicillin allergy, a first-generation cephalosporin (if not allergic) or macrolide antibiotic (SOR: A).

- Postponing therapy for 24 to 48 hours while awaiting the results of throat culture does not reduce the efficacy of treatment. Indeed, therapy has been shown to effectively prevent nonsuppurative sequelae, such as acute rheumatic fever, even if begun 9 days after the onset of symptoms (SOR: A).

Acute Pharyngitis: Exclusion of Dangerous Syndromes

The differential diagnosis of acute pharyngitis includes at least five medical emergencies:

1. *Acute epiglottitis (supraglottitis)*: This is a life-threatening cellulitis of the epiglottis and adjacent structures occurring mainly in children and usually but not always caused by *H. influenzae* type b. Children usually present with a sudden onset of fever, dysphonia, dysphagia, and difficulty breathing. The child often leans forward and drools. Children with suspected acute epiglottitis should undergo emergency endotracheal intubation because airway obstruction carries an 80% mortality rate. Most authorities agree that no attempt should be made to confirm the diagnosis (by laryngoscopy or imaging) before securing an airway. Adults are more likely to present with severe sore throat, odynophagia, and sensation of airway obstruction.
2. *Peritonsillar abscess (quinsy)*: This diagnosis is suggested by medial displacement of a tonsil or bulging of the ipsilateral soft palate. Patients usually present with severe sore throat on the side of involvement, fever, and a “hot potato” or muffled voice. Trismus (spasm of the muscles of mastication on opening the mouth) occurs in about two thirds of patients. Swelling of the neck and ipsilateral ear pain are also common, as is pooling of saliva or drooling.
3. *Submandibular space infection (Ludwig’s angina)*: This diagnosis is suggested by a tender, symmetric, “woody” induration in the submandibular area in a patient whose symptoms may include fever, chills, malaise, stiff neck, mouth pain, drooling, and dysphagia, and who may—as in children with acute epiglottitis—lean forward in an effort to increase the diameter of their airway.
4. *Retropharyngeal space infection*: This diagnosis often presents with a bulge in the posterior wall of the pharynx or swelling of the lateral aspect of the neck and is usually caused by mixed aerobic and anaerobic bacteria.
5. *Septic thrombosis of the internal jugular vein (Lemierre syndrome)*: This diagnosis is usually caused by *Fusobacterium* spp. (an anaerobic bacterium in the normal flora) and accompanied by fever, septic pulmonary emboli, and pleural effusions.
2. *Anaerobic pharyngitis (Vincent’s angina)*: This uncommon infection is caused by a mixture of anaerobic bacteria and spirochetes, with group A streptococci and *S. aureus* sometimes having a role. Patients present with purulent exudates, and the breath often has a foul odor. Complications include peritonsillar abscess and septic thrombosis of the internal jugular vein.
3. *Kawasaki disease*: Sore throat in young child with conjunctivitis, erythema of the lips, strawberry tongue, edema of the hands and feet, and rash raises this diagnostic possibility, which can involve the coronary arteries.
4. *Yersinia enterocolitica*: Exudative pharyngitis and tender cervical lymphadenopathy can be part of a fulminant febrile illness with a high mortality rate; other features include abdominal pain with or without diarrhea. Outbreaks have resulted from contaminated food or beverages.
5. *Primary HIV infection (acute retroviral syndrome)*: The symptoms may include sore throat in addition to fever, weight loss, lymphadenopathy, rash, and splenomegaly.
6. *N. gonorrhoeae*: Although seen mainly in sexually active adolescents, gonococcal pharyngitis can occur at any age. The pharynx may appear erythematous with exudates or may appear normal despite positive cultures.
7. *Tularemia*: The typhoidal form of tularemia, which results from inhalation of the organism, typically begins with fever and sore throat suggesting streptococcal pharyngitis.

Less serious causes of sore throat include:

1. *Infectious mononucleosis*: Mononucleosis caused by Epstein-Barr virus (EBV) can present with sore throat and prominent pharyngeal exudates mimicking streptococcal pharyngitis. Pharyngitis is usually milder in mononucleosis caused by CMV.
2. *Arcanobacterium hemolyticum*: Pharyngitis caused by this bacterium occurs mainly in adolescents. A scarlatiniform rash on the extensor surfaces of the upper extremities—which does not peel, unlike the rash of scarlet fever—occurs in about half of patients and is highly suggestive. The organism grows slowly on sheep agar blood plates and is resistant to penicillin; erythromycin is the drug of choice.
3. *HSV*: Pharyngitis occurs mainly in adolescents and is usually caused by HSV-1. Nearly half of patients have exudates. Vesicles and shallow ulcers on the palate, sometimes confluent, are suggestive, but only a minority of patients have “fever blisters” on their lips.
4. *Influenza*: Sore throat is sometimes the chief complaint, but other symptoms such as myalgia, headache, cough, and severe fatigue soon predominate.
5. *Non-group-A β-hemolytic streptococci*: Groups C and G streptococci can cause pharyngitis clinically indistinguishable from that caused by *S. pyogenes*, sometimes in outbreaks from a common food source. Some researchers report frequent pharyngitis caused by group C streptococci among college-aged students.
6. *Miscellaneous causes*: These include *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae* (previously known as *Chlamydia pneumoniae*), *Treponema pallidum* (syphilis), and numerous viruses.

Acute Pharyngitis: Other Microbial Etiologies

Uncommon but serious causes of sore throat include the following:

1. *Diphtheria*: Diphtheria, which is now rare in the United States, classically presents as a sore throat with a gray, adherent pseudomembrane that is easily mistaken for an exudate. Classically, diphtheria has a slow onset and marked systemic toxicity.

LOWER RESPIRATORY INFECTIONS

Lower respiratory tract infections are common in family medicine; are responsible for much of the overuse of antibiotics; and remain common causes of death, especially among elderly individuals.

Acute Bronchitis (“Chest Cold”) and Tracheobronchial Infections without Pneumonia

Acute bronchitis (“chest cold”) is extremely common, usually of viral etiology, and results in overuse of antibiotics. The term “acute infectious bronchitis” is sometimes used to distinguish this entity from other causes of cough, and the term “tracheobronchitis” is sometimes used for accuracy because the trachea is also inflamed. The incidence of acute bronchitis is highest in children younger than 5 years of age, with another peak among elderly adults. The disease is seasonal and most common in midwinter.

Most cases (95% by some estimates) are caused by viruses. All of the common viruses affecting the upper respiratory tract have been implicated. *M. pneumoniae* and *C. pneumoniae* may cause protracted cases of bronchitis. *Bordetella pertussis*, the agent of whooping cough, has become an important cause of acute bronchitis in adults with cough lasting more than 3 weeks.

The onset is typically preceded by a prodrome of at least 24 hours with symptoms of common cold and pharyngitis. A dry cough signifying inflammation of the early airway evolves into a cough productive of moderate amounts of mucopurulent sputum. Fever, headache, myalgias, and retrosternal chest pain or discomfort may be present. Physical examination often reveals tracheal tenderness, and auscultation of the lung may reveal a few coarse crackles and occasional wheezes. The patient rarely appears toxic.

More than 90% of patients with cough lasting longer than 3 weeks have the postnasal drip syndrome, asthma, gastroesophageal reflux, or drug-induced cough (of which angiotensin-converting enzyme [ACE] inhibitors are now the most common cause). Isolation of *B. pertussis* requires special media and 5 to 7 days of incubation. The organism can be identified more rapidly by a direct fluorescein-labeled antibody method.

Acute bronchitis provides an excellent opportunity to counsel patients about smoking.

KEY TREATMENT

- Numerous trials indicate that antibiotics confer only modest benefit for acute bronchitis and should be reserved for patients at high risk of complications, including elderly adults, those with chronic lung disease, and those with compromised host defenses (SOR: A).
- Patients with prolonged bronchitis caused by *M. pneumoniae* and *C. pneumoniae* may respond to therapy with a tetracycline or macrolide antibiotic (SOR: B). More than one course of antimicrobial therapy may be required for bronchitis caused by *C. pneumoniae*, which can cause a stubborn respiratory illness (SOR: B).

- Pertussis should be treated with macrolide antibiotics (erythromycin, azithromycin, or clarithromycin) (SOR: A).
- Adults should strongly consider making the acellular pertussis vaccine (contained in the Tdap vaccine) part of their routine immunizations.

Acute Exacerbations of Chronic Bronchitis

The American Thoracic Society (ATS) defines chronic bronchitis—which is caused mainly by cigarette smoking—as excessive sputum production with cough, present on most days for at least 3 months a year and for at least 2 successive years and without an underlying disorder such as TB or bronchiectasis. This common disorder affects up to 25% of the adult population and can progress to full-blown chronic obstructive pulmonary disease. The extent to which acute exacerbations of chronic bronchitis are caused by treatable infections remains controversial. Current opinion holds that most exacerbations of chronic bronchitis are caused by viruses or noninfectious agents, even though cultures of sputum often show nontypeable strains of *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, or other bacteria. Still, evidence suggests that recurrent bacterial infections in patients with chronic bronchitis contribute to deterioration of pulmonary function. Short (5 to 7 days) courses of antibiotics, although controversial and usually effecting only modest improvement in airflow, are usually given to patients with markedly impaired baseline pulmonary function because of the serious consequences of respiratory failure.

KEY TREATMENT

- Patients with acute exacerbations of chronic obstructive lung disease and who present with increasing shortness of breath and purulent sputum should be treated with antibiotics (SOR: A).
- Amoxicillin–clavulanate or fluoroquinolones (other than ciprofloxacin) are now preferred by some authorities over older drugs such as doxycycline, TMP-SMX, and amoxicillin for acute exacerbations of chronic obstructive lung disease (SOR: B).
- The practice of giving prophylactic antibiotics through the winter months is not supported by solid evidence and should be discouraged (SOR: B).
- Patients with chronic obstructive lung disease should receive the pneumococcal vaccine and yearly immunization against influenza (SOR: A).

Bronchiectasis

Bronchiectasis is an acquired disorder characterized anatomically by abnormal dilatation of bronchi and bronchioles and clinically by chronic productive cough and frequent lower respiratory infections. Its prevalence fell dramatically after the introduction of broad-spectrum antibiotics and vaccines against measles and pertussis. Specific causes include (1) *necrotizing pneumonia* in which treatment has been delayed; (2) *cystic fibrosis*, often as the presenting manifestation; (3) *allergic bronchopulmonary aspergillosis* in which the diagnosis has been delayed; (4) *immunodeficiency syndromes*; (5) the *dyskinetic cilia syndromes*; and (6) possibly

Helicobacter pylori infection. *M. avium*–*intracellulare* complex (MAC) infection is not infrequently associated with bronchiectasis in women (see later discussion under Mycobacterial Infections).

Patients with advanced bronchiectasis have daily cough productive of large amounts of thick, mucopurulent, tenacious sputum. However, most patients produce lesser amounts of sputum, at least during the early stages, and cough may be nonproductive (“dry bronchiectasis”) or even absent. Dyspnea and hemoptysis are common.

Ultrasensitive, high-resolution CT scanning, now the imaging procedure of choice, demonstrates bronchial wall thickening and luminal dilatation. Workup includes a CBC and differential, quantitative immunoglobulin levels (IgA, IgG, and IgM), sputum Gram stain and culture for routine pathogens, and sputum culture for mycobacteria (AFB culture) and fungi. Screening tests for allergic bronchopulmonary aspergillosis include differential blood count (looking for eosinophilia), IgE level, and testing for precipitating antibodies to *Aspergillus* spp. Cystic fibrosis should be suspected when bronchiectasis begins in childhood, adolescence, or young adulthood.

There is no curative treatment other than resection of the involved portion of the lung. High-dose antibiotic therapy should be prescribed for episodes of fever associated with increased sputum production.

Bronchiolitis (“Wheezy Bronchitis” or “Asthmatic Bronchitis”)

Bronchiolitis is a common disease of early childhood characterized by wheezing and nearly always caused by a virus, most typically RSV. The diagnosis is based on clinical findings and a self-limited course, with improvement beginning between the third and seventh days of the illness. Antibiotics are not indicated except for the rare patient with bacterial superinfection, but patients should be observed closely until improvement occurs. Some evidence suggests that the combined use of glucocorticoids and nebulized epinephrine may reduce the need for hospitalization, but the data should be interpreted cautiously (Fernandes and Hartling, 2014).

Acute Community-Acquired Pneumonia

Pneumonia remains a leading cause of death and the most common infectious cause of death in developed countries. Data suggesting a 28-fold increased cost for managing the disease on an inpatient basis prompted a renewed effort to identify patients who can be safely managed on an outpatient basis (Wunderink and Waterer, 2014). Unfortunately, it is difficult to make a precise etiologic diagnosis of pneumonia, especially at the first clinical encounter. In the past, many physicians placed much emphasis on examination of a carefully obtained Gram stain of sputum. In recent decades, more emphasis has been placed on grading the severity of the disease and treating accordingly.

Attack rates are highest at the extremes of life: younger than 4 years and older than 65 years of age. The incidence peaks during the winter months.

The distinction between “classical bacterial pneumonia” (lobar pneumonia typically caused by *S. pneumoniae*) and “atypical pneumonia” (classically caused by *M. pneumoniae*) has become blurred but remains conceptually useful. Classic bacterial pneumonia primarily involves inflammation of the alveoli, resulting in purulent sputum, elevated

WBC count (or, in some patients, low or normal WBC count with excess band neutrophils on differential count), and peripherally located pleuritic chest pain. Atypical pneumonia primarily involves inflammation of the tracheobronchial mucosa and the interstitium of the lungs, resulting in nonpurulent (and scanty) sputum, normal WBC count, and centrally located, substernal chest pain. Classic pneumococcal pneumonia usually begins abruptly, but the onset is more likely to be gradual in atypical pneumonia (Table 15-4).

The diagnosis of acute pneumonia is usually based on the history, physical findings, and chest radiographic examination. Acute pneumonia is distinguished from chronic pneumonia (see later discussion) on the basis of the history. Three essential questions are:

1. Is the problem pneumonia or something else? The following should be considered: pulmonary thromboembolism (arguably the most common cause of “atypical pneumonia”), congestive heart failure with an associated viral URI or “viral syndrome,” hypersensitivity pneumonitis caused by drugs or thermophilic actinomycetes, bronchiolitis obliterans organizing pneumonia (also known as cryptogenic organizing pneumonia), idiopathic acute eosinophilic pneumonia (characterized by a high fever, bilateral pulmonary infiltrates, and respiratory failure. Peripheral blood eosinophilia is usually absent, in contrast to chronic eosinophilic pneumonia [Carrington’s syndrome]), foreign body aspiration, connective tissue diseases, pulmonary alveolar proteinosis, allergic bronchopulmonary aspergillosis, tumors (especially choriocarcinoma), pulmonary hemorrhage (as in Goodpasture’s syndrome and mitral stenosis), and inhalation of freebase cocaine (“crack lung syndrome” characterized by fever, hypoxemia, hemoptysis, respiratory failure, and diffuse alveolar infiltrates).
2. How severe is the pneumonia and is hospitalization required? Guidelines for making these determinations continue to evolve. A Pneumonia Severity Index (PSI), which includes 20 variables and requires the use of a decision support tool, stratifies patients into five groups. The CURB-65 system offers a more practical way to grade severity of pneumonia, using five prognostic variables: confusion (based on a specific mental status test or disorientation to time, place, and person), urea (blood urea nitrogen >20 mg/dL), respiratory rate (>30 breaths/min), blood pressure (systolic pressure <90 mm Hg or diastolic pressure <60 mm Hg), and age >65 years. One point is given for each variable; patients with a score of 2 should be admitted to the hospital, and patients with a score of 3 or greater should be considered for admission to the intensive care unit. These criteria should not replace clinical judgment, which should take into account the patient’s ability to maintain oral intake, knowledge of the patient’s comorbidities, living situation, proclivity toward substance abuse, ability to comply with a drug regimen, and cognitive impairment. Pulse oximetry to assess the adequacy of oxygenation should ideally be performed in patients selected for outpatient management.
3. What is the most likely causative organism? Although the current style of practice in the United States places less emphasis on predicting the causative organism

than was formerly the case—with the admonition that blood cultures should be obtained before treatment for patients who require hospitalization (SOR: A) and a hospital quality indicator—clinicians should be familiar with the spectrum of etiologies (Tables 15-4 to 15-6).

Pneumococcal pneumonia continues to be the most common proven cause of severe community-acquired pneumonia, accounting for about two thirds of cases of pneumonia with positive blood cultures. Viral URI predisposes. Risk factors for invasive pneumococcal disease

Table 15-4 Clues to the Etiology of Pneumonia from the History

History	Suggested Etiologies
Sudden onset	Acute bacterial pneumonia, most often caused by <i>Streptococcus pneumoniae</i>
Gradual onset	“Atypical” pneumonia, often caused by <i>Mycoplasma pneumoniae</i> or <i>Chlamydia pneumoniae</i>
Respiratory illness in the family	<i>Mycoplasma pneumoniae</i> , RSV, influenza
Recent exposure to small children	<i>Mycoplasma pneumoniae</i> , RSV
Chronic bronchitis or chronic obstructive lung disease	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> , <i>Chlamydia pneumoniae</i> , <i>Pseudomonas aeruginosa</i>
Nursing home resident or recent hospitalization	<i>S. pneumoniae</i> , <i>H. influenzae</i> , aerobic gram-negative bacilli, RSV
Alcoholism	<i>S. pneumoniae</i> , aerobic gram-negative bacilli (notably <i>Klebsiella pneumoniae</i>), mixed anaerobic and aerobic bacteria (“mouth flora”), <i>Mycobacterium tuberculosis</i>
Altered mental status, seizures, alcoholism, recent dental manipulation	“Mouth flora aspiration pneumonia” (mixed anaerobic and aerobic bacteria), <i>S. pneumoniae</i>
Homelessness or incarceration	<i>S. pneumoniae</i> ; <i>M. tuberculosis</i>
Injection drug use	<i>Staphylococcus aureus</i> (consider septic pulmonary emboli from right-sided endocarditis), <i>S. pneumoniae</i>
Home use of small-volume nebulizers	<i>Pseudomonas aeruginosa</i> ; other aerobic gram-negative bacilli
Recent influenza A or B	<i>S. pneumoniae</i> , <i>S. aureus</i> , group A streptococci (<i>S. pyogenes</i>)
Diabetic ketoacidosis	<i>S. pneumoniae</i> , <i>S. aureus</i>
Exposure to contaminated aerosols (showers, air coolers, water supplies), hotel or cruise ship stay in previous 2 weeks	<i>Legionella pneumophila</i> (legionnaire’s disease)
Cystic fibrosis	<i>P. aeruginosa</i> , <i>S. aureus</i> , <i>Burkholderia cepacia</i>
B-lymphocyte disorder (agammaglobulinemia, multiple myeloma, chronic lymphocytic leukemia)	<i>S. pneumoniae</i>
Sickle cell anemia	<i>S. pneumoniae</i>
Exposure to birds (parakeets, cockatoos, budgerigars)	<i>Chlamydia psittaci</i> (psittacosis)
Exposure to cows, sheep, goats, or parturient cats	<i>Coxiella burnetii</i> (Q fever)
Exposure to tissues or body fluids of rabbits, foxes, or squirrels	<i>Francisella tularensis</i> (tularemia)
Exposure to raw wool, goat hair, animal hides, cattle, pigs, or horses	<i>Bacillus anthracis</i> (anthrax)
Exposure to ground squirrels, rats, chipmunks, or prairie dogs	<i>Yersinia pestis</i> (plague)
Exposure to rodent droppings, urine, or saliva; exploration in the “four corners” area of the southwestern United States	Hantavirus pulmonary syndrome
Exposure to water contaminated with animal urine or to wild rodents, dogs, cattle, pigs, or horses	<i>Leptospira</i> spp. (leptospirosis)
Military recruit	<i>Neisseria meningitidis</i> , adenovirus type 4 or 7
Travel to the southwestern United States or southern California, especially if exposed to a windstorm	<i>Coccidioides immitis</i> (coccidioidomycosis)
Travel to Ohio or Mississippi river valleys; exposure to bat droppings or to dust from soil enriched by bird droppings; exploration of a cave	<i>Histoplasma capsulatum</i> (histoplasmosis)
Travel to Southwest Asia, West Indies, Australia, Guam, or South or Central America	<i>Burkholderia pseudomallei</i> (melioidosis)
Weight loss	<i>M. tuberculosis</i> , postobstruction pneumonia behind endobronchial carcinoma
Pulmonary alveolar proteinosis	<i>Nocardia</i> spp. (nocardiosis)
HIV disease (early)	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>M. tuberculosis</i>
HIV disease (late, with CD4 lymphocyte count <200/mm ³)	As above plus <i>Pneumocystis jiroveci</i> , <i>Cryptococcus neoformans</i> , <i>Histoplasma capsulatum</i> , <i>Aspergillus</i> spp., <i>Pseudomonas aeruginosa</i> , and nontuberculous mycobacteria (especially <i>Mycobacterium kansasii</i>)
Associated acute arthritis	Drug reaction or connective tissue disease
Suspicion of bioterrorism	<i>Bacillus anthracis</i> (anthrax), <i>Yersinia pestis</i> (plague), <i>Francisella tularensis</i> (tularemia)

RSV, Respiratory syncytial virus.

Table 15-5 Clues to the Etiology of Pneumonia from the Physical Examination

Finding	Suggested Etiologies
Relative bradycardia	Viral infection, tularemia, <i>Mycoplasma pneumoniae</i> , legionnaire's disease, psittacosis
Altered mental status	Associated meningitis, TB, fungal disease, legionnaire's disease, endocarditis
Prominence of symptoms "outside the chest," such as headache and diarrhea	Legionnaire's disease
Poor oral hygiene with foul odor to the breath	"Mouth flora" aspiration pneumonia (mixed aerobic and anaerobic bacteria)
Bullous myringitis	<i>M. pneumoniae</i>
Skin lesions	Atypical measles, varicella-zoster, fungal pneumonia, nocardiosis, staphylococcal pneumonia with bacteremia
Erythema multiforme	<i>M. pneumoniae</i>
Erythema nodosum	Histoplasmosis, coccidioidomycosis, TB
Ecthyma gangrenosum	<i>Pseudomonas aeruginosa</i> , <i>S. aureus</i>
Relatively clear lung fields to auscultation despite impressive infiltrates by imaging	<i>M. pneumoniae</i> , <i>Chlamydomydia pneumoniae</i>
Splenomegaly	Psittacosis, typhoid fever, brucellosis, endocarditis

TB, Tuberculosis.

Table 15-6 Clues to the Etiology of Pneumonia and Their Implications from Chest Radiography or Computed Tomography

Finding	Suggested Causes and Implications
Lobar consolidation	<i>Streptococcus pneumoniae</i> ; less commonly, gram-negative bacilli
Multilobar consolidation	Hospitalization should be strongly considered
Bilateral lower lobe involvement	Consider thromboembolism, including septic embolism, chronic aspiration pneumonia, <i>Mycoplasma pneumoniae</i> pneumonia
Patchy bilateral infiltrates	Right-sided endocarditis, septic embolism, "atypical pneumonia" (especially tularemia)
Radiography or CT scan much more impressive than physical examination would suggest	Atypical pneumonia (especially <i>M. pneumoniae</i> pneumonia); pulmonary embolism
Volume loss	TB, carcinoma
Miliary pattern	TB, histoplasmosis, coccidioidomycosis, bacterial sepsis
Pulmonary nodules	Fungal infection (especially cryptococcosis), septic pulmonary embolism, <i>Legionella micdadei</i> pneumonia
Cavitary lesions	Aspiration pneumonia, gram-negative bacillary pneumonia, TB, cavitary carcinoma
Massive pleural effusion	<i>Streptococcus pyogenes</i> (group A streptococcus)
Hilar lymphadenopathy	TB, pertussis, tularemia, pneumonic plague, carcinoma
Clear chest radiograph despite strong suspicion of pneumonia	Experimental studies and anecdotal reports support the idea that occasional patients with pneumonia have normal chest radiographs because of dehydration; infiltrates "blossom" after administration of IV fluids

CT, Computed tomography; IV, intravenous; TB, tuberculosis.

include extremes of age, alcoholism, HIV disease, end-stage renal disease, sickle cell disease, diabetes mellitus, dementia, malnutrition, malignancy, diseases affecting B lymphocyte function, and immunosuppressive disorders. Risk factors for pneumococci with reduced susceptibility to penicillin G (defined by minimum inhibitory concentration $>2 \mu\text{g/mL}$ for nonmeningeal isolates) include extremes of age (2 years or younger or 70 years or older), prolonged hospitalization, recent β -lactam antibiotic therapy, attendance at a day care center (either as a child or staff person), residence in a nursing home, or chronic disease (e.g., cirrhosis or chronic lung disease).

H. influenzae is a frequent cause of pneumonia in elderly patients and in patients with serious underlying diseases, including chronic obstructive lung disease. The pneumonia usually has a patchy or segmental distribution, which is characteristic of bronchopneumonia rather than lobar pneumonia.

S. aureus pneumonia, when community acquired, tends to be an acute, fulminant pneumonia. *S. aureus* is an uncommon cause of community-acquired pneumonia, explaining only about 1% of cases, except during influenza epidemics. Influenza virus markedly predisposes to staphylococcal colonization of the respiratory mucosa. Staphylococcal pneumonia tends to be a necrotizing process with abscess formation. In children, chest radiography may show air pockets known as pneumatoceles.

Group A streptococcal (*S. pyogenes*) pneumonia, which is rare except during influenza epidemics, often features the rapid development of a large empyema requiring chest tube drainage.

Klebsiella pneumoniae pneumonia is a relatively common cause of pneumonia in patients with alcoholism and often assumes a lobar pattern especially of the upper lobes. *E. coli* and other aerobic gram-negative bacilli are relatively common causes of pneumonia in the frail elderly.

P. aeruginosa, although a common cause of nosocomial pneumonia, is rarely associated with community-acquired pneumonia in patients without underlying lung disease or severe debility.

Pneumonia caused by “mouth flora” bacteria (mixtures of aerobic and anaerobic bacteria with anaerobes usually predominating) occurs most frequently in patients with alcoholism or poor oral hygiene. “Mouth flora” pneumonia in an edentulous patient should prompt suspicion of endobronchial obstruction caused by lung cancer. A foul odor of the breath is present in many but not all affected patients. Lung abscess or empyema is common.

M. pneumoniae is a cell wall–deficient organism with particular affinity for respiratory epithelium. Patients with *M. pneumoniae* pneumonia may have a second pulmonary pathogen. This disease mainly affects adolescents and younger adults and most commonly involves the lower lobes, sometimes with pleural effusions. Bullous myringitis (erythema of the tympanic membrane with a “bleb”) occurs in fewer than 5% of patients but has a high positive predictive value for *M. pneumoniae* pneumonia. The chest radiography commonly shows infiltrates that are more extensive than physical examination would suggest. Extrapulmonary manifestations, which can dominate the clinical course, include hemolytic anemia, rashes (including the Stevens-Johnson syndrome), CNS complications (ranging in severity from aseptic meningitis to transverse myelitis), cardiac complications (including myocarditis), and polyarthralgia. Diagnosis is most commonly made by measuring IgM and IgG antibodies to *M. pneumoniae*.

Pneumonia caused by *C. pneumoniae*, in contrast to *M. pneumoniae* pneumonia, predominantly affects older persons. Younger persons infected with *C. pneumoniae* are more likely to manifest pharyngitis than pneumonia. Symptomatic *C. pneumoniae* pneumonia is usually, but not always, a relatively mild illness, but recovery is typically slow.

Legionnaire’s disease is a relatively common cause of pneumonia in some geographic areas. Clinically severe cases tend to occur in persons with compromised host defenses, often in the setting of chronic obstructive lung diseases, immunosuppression, or advanced age. The urine antigen test for *L. pneumophila* serogroup 1 has a sensitivity of about 80% and a specificity approaching 100%; this serogroup accounts for about 80% of cases of legionnaire’s disease.

Psittacosis (ornithosis) caused by *Chlamydia psittaci* is a rare cause of pneumonia (most commonly, with consolidation of a lower lobe) in the United States; other presentations of psittacosis include a typhoidal illness with fever, malaise, relative bradycardia, and hepatosplenomegaly; a mononucleosis-like syndrome with fever, sore throat, lymphadenopathy, and hepatosplenomegaly; fever of unknown origin (FUO); and a nonspecific flulike illness. Diagnosis is based on serology. Doxycycline is the drug of choice.

Macrolides are now recommended for previously healthy persons with community-acquired pneumonia who do not have risk factors for penicillin-resistant pneumococci and do not have indications for hospitalization except in regions with high rates (>25%) of macrolide-resistant *S. pneumoniae* (SOR: A). When patients have comorbidities or have received antimicrobials within the previous 3 months, alternatives

include fluoroquinolones *other than ciprofloxacin* (SOR: A) or third-generation cephalosporins combined with either a macrolide or doxycycline (SOR: B).

For patients with comorbidities and who require hospitalization, reference should be made to protocols for antibiotic selection now in place at most, if not all, U.S. hospitals. For patients not requiring admission to an intensive care unit, combined therapy with a β -lactam agent (e.g., ceftriaxone) plus either a macrolide or doxycycline is often prescribed (SOR: A), with fluoroquinolones being recommended for penicillin-allergic patients.

Health Care–Associated Pneumonia

In 2005, the ATS and IDSA designated “health care–associated pneumonia” as a third category of pneumonia based on patient population—that is, a category in addition to the previous categories of “community-acquired pneumonia” and “hospital-acquired pneumonia.” The definition of health care–associated pneumonia includes residing in an extended-care facility for 2 days or more during the preceding 90 days, receiving home infusion therapy or wound care as an outpatient, and attending a hemodialysis center during the preceding 30 days. This entity has become somewhat controversial. A recent analysis of 24 studies confirmed that patients with health care–associated pneumonia, compared with patients with “community-acquired pneumonia” without the listed risk factors, were more likely to have pneumonia caused by MRSA or aerobic gram-negative bacilli, including *P. aeruginosa* (Chalmers et al., 2014).

INFLUENZA

Influenza causes about 36,000 deaths in the United States each year, or about the same number as caused by traffic accidents. Influenza viruses infecting humans are classified as A, B, and C (rare), with influenza A viruses being classified further on the basis of changes in the antigenic characteristics of envelope glycoproteins known as hemagglutinin (H) and neuraminidase (N) antigens. The RNA genome of influenza A viruses is constantly undergoing rearrangement. *Antigenic shifts* denote major changes in the viral genome and often precede epidemics and pandemics. *Antigenic drift* reflects minor changes associated with more localized outbreaks. The influenza B virus is less inclined to mutate; antigenic drifts in its H antigen occur, but antigenic shifts have not been reported.

The names assigned to influenza viruses disclose their identities. Consider, for example, the viruses represented in the 2013 to 2014 quadrivalent vaccine. The virus designated “A (H1N1)/California/7/2009” identifies an influenza A virus with hemagglutinin type 1 and neuraminidase type 1 (thus, H1N1) first isolated in California in 2009 as the seventh strain in a sequence. Antigenic shifts in the influenza virus—such as the recently recognized H5N1 and H3N7 influenza A viruses in birds—carry the potential for global pandemic influenza because few humans have naturally occurring protective antibodies. Influenza B vaccines have only one recognized type of the H antigen and one of the N antigen, and hence their designations are shorter. Thus, “B/Massachusetts/2/2012” identifies an influenza B virus isolated in Massachusetts during 2012 as the second strain in a sequence. Outbreaks of influenza A attack 10%

to 20% of the general population, with high rates especially in children attending day care centers and in institutions such as nursing homes. Pandemics of influenza A can attack more than 50% of the general population.

The clinical spectrum of influenza ranges from a self-limited illness resembling the common cold to death from overwhelming viral pneumonia within a few hours. Adults can often date to the hour the onset of symptoms, such as throbbing headache, photophobia, myalgia, sore throat, substernal soreness, nonproductive cough, and disabling fatigue. Preschool children tend to have fever, rhinitis, pharyngitis, vomiting, and diarrhea. In elderly patients, the course is often dominated by high fever, nasal obstruction, lassitude, and diarrhea. In all age groups, the constitutional symptoms may be more impressive than the respiratory symptoms (Memoli et al., 2014).

More than 10 “rapid flu tests,” which provide results within 15 minutes, have been approved by the U.S. Food and Drug Administration (FDA). In general, their sensitivity is about 50% to 70% and their specificity about 90% to 95%. These tests are especially useful for making treatment decisions about patients with flulike symptoms in the absence of reported influenza in a community. However, a negative rapid flu test result should never be the basis for excluding influenza when a patient presents with compatible symptoms and signs of influenza and the disease is prevalent in a community. The symptoms of influenza overlap with other viral respiratory infections; recent data suggest that RSV commonly causes acute respiratory illness in older adults, although the onset is usually more gradual compared with influenza (Sundaram et al., 2014). And even when influenza seems obvious, the possibility of other life-threatening diseases should be kept in mind (Figure 15-7).

Pneumonia is the major life-threatening complication. *Primary influenza pneumonia*, which should be suspected when high fever and dyspnea persist for more than several days, is more common among elderly and immunocompromised individuals but can also affect previously healthy young adults. *Secondary bacterial pneumonia* should be

Figure 15-7. Keys to the diagnosis of *Staphylococcus aureus* endocarditis in a patient presenting with fever and heart failure at the peak of an influenza A epidemic included small embolic lesions in the skin and a large splinter hemorrhage beneath a nailbed.

suspected whenever a patient who seemed to be improving takes a dramatic turn for the worse. It is most often caused by *S. pneumoniae* (up to half of all cases), but *S. aureus* is also common in this setting.

We now know that influenza is mainly a disease of children, who spread the virus to their parents, grandparents, and others. Again, everyone older than 6 months of age should receive the annual flu vaccine barring a strict contraindication.

KEY TREATMENT

- Patients with severe, complicated, or progressive influenza if diagnosed within the first 2 days of illness should be treated with an antiviral agent, which may reduce the duration of illness and the risk of serious complications. Oseltamivir and zanamivir are currently recommended for this purpose (SOR: A).
- Oseltamivir (Tamiflu) is given in a dose of 75 mg twice daily. Higher doses do not seem to improve efficacy (SOR: B).
- Antiviral drug therapy is not recommended for patients with uncomplicated influenza with symptoms of more than 48 hours' duration (SOR-A).

GASTROINTESTINAL AND INTRAABDOMINAL INFECTIONS

Acute intraabdominal infection, mainly infectious diarrhea, is second only to cardiovascular disease as a cause of death worldwide. In the United States, acute gastroenteritis is second only to viral respiratory disease as a cause of acute illness. Most episodes are self-limited, but infectious diarrhea and various foodborne diseases annually account for more than 500 deaths. Other intraabdominal infections are relatively common and present dilemmas in diagnosis and management. Family medicine clinicians should know the following diagnostic pitfalls:

1. Acute bacterial meningitis is (to reiterate) sometimes misdiagnosed as “gastroenteritis” because of prominent nausea and vomiting.
2. Intrathoracic disorders such as pneumonia, pulmonary thromboembolism, and acute myocardial infarction sometimes present as pain in the upper abdomen. Conversely, pain in the lower chest can reflect intraabdominal pathology.
3. Unrecognized esophageal disease with reflux can cause asthma, persistent sore throat, and chronic aspiration pneumonia. The latter can lead to bronchiectasis and nontuberculous mycobacterial infection.
4. Fever with right lower abdominal pain suggesting acute appendicitis (pseudoappendicitis syndrome) can be caused by *Yersinia enterocolitica* (the usual cause), *Salmonella enteritidis* or *S. typhi*, or *Campylobacter jejuni*.
5. Abdominal pain in a person with diabetes mellitus can indicate a life-threatening syndrome such as emphysematous pyelonephritis or emphysematous cholecystitis.
6. Abdominal pain, fever, or evidence of sepsis in a person with cirrhosis and ascites should suggest the possibilities of spontaneous bacterial peritonitis or spontaneous bacteremia.

7. Abdominal pain and evidence of sepsis in an elderly person should raise the possibility of an “acute abdomen” caused by such disorders as acute cholecystitis, diverticulitis, perforation of the colon, acute appendicitis, or ruptured aortic aneurysm.
8. Abdominal pain and fever in a patient who has recently had diverticulitis, cholecystitis, or pancreatitis should raise the possibility of intraabdominal abscess.

Food Poisoning

Central food processing and distribution and the trend toward meals away from home make food poisoning an increasingly important problem in the United States, with about 5000 outbreaks being reported each year. A cause is determined in about two thirds of outbreaks, usually bacteria (75%) but also chemical agents (17%), viruses (6%), and parasites (2%). Symptoms range from mild facial flushing (“Chinese restaurant syndrome”) or gastroenteritis to life-threatening paralysis or colitis. Onset of symptoms within an hour suggests a chemical agent. Onset between 1 and 6 hours suggests ingestion of a preformed toxin, usually in food contaminated with *S. aureus* or *Bacillus cereus*; vomiting and crampy abdominal pain are the usual symptoms, but diarrhea occurs in about one third of cases. Onset between 8 and 16 hours raises a number of possibilities, especially bacteria such as *C. perfringens* and enterotoxin-producing strains of *B. cereus*; characteristic symptoms are crampy abdominal pain and diarrhea—symptoms that can be caused by many enteric pathogens. Investigation is seldom indicated for an individual case, but the simultaneous occurrence of two or more cases should prompt notification of local health authorities.

Infectious Diarrhea

Acute diarrhea is extremely common in family medicine. The clinician’s first task is to decide whether the problem is infectious or noninfectious (Figure 15-8). The focus here will be mainly on diarrhea as it presents in adolescent or adult patients. Noninfectious causes of diarrhea include food allergies, endocrine disorders, inflammatory bowel disease, and drugs (including cocaine), which should be considered in the differential diagnosis of ischemic colitis with abdominal pain and bloody diarrhea in a young or middle-aged adult. Findings suggesting medically important diarrhea warranting further investigation include high fever (≥ 38.5 °C [101.3 °F]), profuse watery diarrhea with severe volume depletion, severe abdominal pain (especially in a person older than 50 years of age), bloody diarrhea, diarrhea in a patient with hemolytic anemia or renal failure, the dysentery syndrome (small-volume stools with blood and mucus), duration longer than 3 days, advanced age (79 years or older), an immunocompromised state, or the occurrence of many similar cases suggesting a community outbreak. Acute bloody diarrhea is an urgent medical problem.

The distinction between “small bowel diarrhea” and “large bowel diarrhea” (Table 15-7) is conceptually useful and clinically relevant despite considerable overlap. About 90% of cases of acute, community-acquired infectious diarrhea in the United States represent “small bowel” diarrhea characterized by infrequent watery stools. About 5% to 10% of cases represent “large bowel” diarrhea or the *dysentery syndrome*, characterized by frequent small-volume

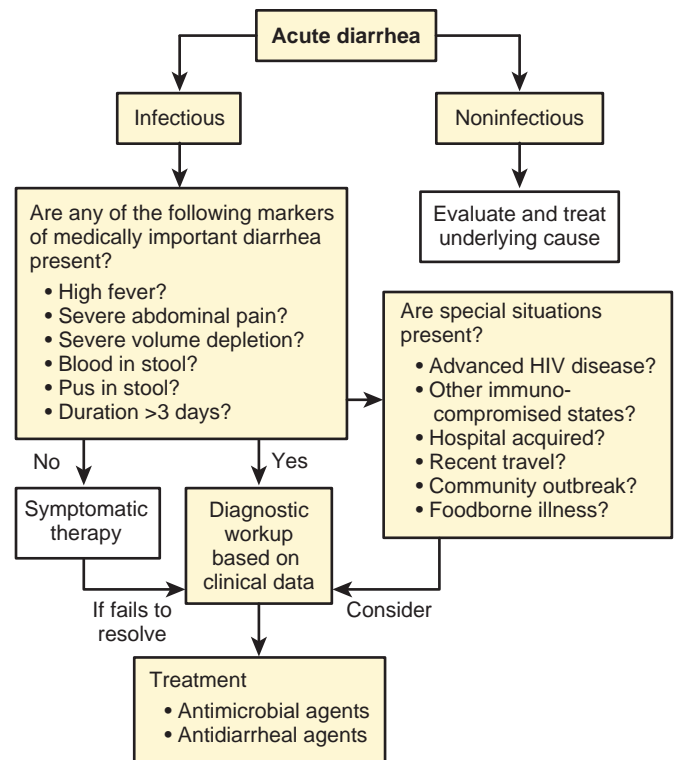

Figure 15-8. Evaluation of an adolescent or adult patient with acute diarrhea is based on the answers to a series of structured questions.

stools that often contain blood and mucus. Diagnostic workup has a higher yield in the dysentery syndrome than in “small bowel diarrhea,” a situation in which routine stool cultures are discouraged.

Gross inspection of stool facilitates the distinction between noninflammatory and inflammatory diarrhea (see Table 15-7). Patients should bring a specimen to the office in a convenient container, such as a large, sealed glass jar. When the presence of blood and mucus suggests inflammatory diarrhea, the stool should be examined for WBCs. The traditional method is rapid and inexpensive: a drop of stool is placed on a glass slide, a drop of methylene blue is added, a coverslip is applied, and the preparation is examined using the high-dry or oil-immersion lens of the microscope. The commercially available Lactoferrin stool WBC test (Leuko-Test) may be more sensitive. Stool cultures, toxin assays, and microscopic examination for ova and parasites should be obtained on a selected basis based on the overall clinical picture, often taking into account the appearance of the stool and the presence or absence of fecal WBCs. Surveys indicate that only 0.6% to 6% of routine stool cultures yield pathogens, suggesting the need for greater selectivity.

KEY TREATMENT

- Most patients with diarrhea should be treated symptomatically, with attention to fluid and electrolyte replacement and judicious use of antimotility drugs (SOR: A).
- Antimotility agents should be avoided in patients with bloody diarrhea, who might have colitis caused by *C. difficile* or Shiga toxin-producing *E. coli* (SOR: A).

Table 15-7 Comparison of Small Bowel Diarrhea and Large Bowel Diarrhea

Parameter	Small Bowel Diarrhea	Large Bowel Diarrhea
Medical synonym	Noninflammatory diarrhea	Inflammatory diarrhea (dysentery)
Vernacular term	"The runs"	"The squirts"
Character of stools	Watery	Semiformed, typically with mucus and blood
Frequency of stools	Infrequent	Frequent
Pain on defecation	Usually absent	Often present
Pathophysiology	The small bowel secretes excessive fluid or fails to absorb fluids; the large bowel functions normally as a reservoir and therefore stores a large volume of fluid until overdistention prompts a bowel movement, typically on an urgent basis.	The colon is inflamed and therefore fails in its normal function as a reservoir, prompting frequent, small-volume bowel movements, which are often painful because of inflammation involving the rectum.
Polymorphonuclear leukocytes in the stool	Seldom present	Usually present
Fever	Usually absent	Often present
Associated symptoms	Abdominal cramping, bloating, and gas; symptoms of volume depletion (dehydration) if severe	Systemic toxicity; pain and tenderness in the lower quadrant of the abdomen
Classic prototype	Cholera	Shigellosis
Some important considerations	Viruses; enterotoxigenic <i>Escherichia coli</i> (traveler's diarrhea), protozoa (including giardiasis and cryptosporidiosis)	<i>Campylobacter jejuni</i> , Shiga toxin-producing strains of <i>E. coli</i> (especially <i>E. coli</i> 0157:H7); amebiasis; also consider noninfectious causes such as ulcerative colitis and ischemic colitis

- Specific antimicrobial therapy for infectious diarrhea is recommended for at least six situations encountered in primary care in the United States: traveler's diarrhea, shigellosis, *C. difficile* colitis, *C. jejuni* infection, *Salmonella* gastroenteritis in persons older than 50 years of age, and proven infection by certain parasites.

Shiga-Toxin-Producing *Escherichia Coli* (*E. coli* 0157:H7 and Other Serotypes). Strains of *E. coli* that produce Shiga toxin account for fewer than 1% of all cases of infectious diarrhea in primary care, but stool cultures are positive for these strains in up to 8% of patients with infectious diarrhea whose stools are visibly bloody. Most of these infections result from beef, notably undercooked hamburgers. Patients with hemorrhagic colitis caused by *E. coli* 0157:H7 and other serotypes should be hospitalized because of the risk of severe complications, including *hemolytic-uremic syndrome*.

KEY TREATMENT

- Antimotility drugs should be avoided, especially in children, because they increase the duration and extent of exposure to the toxin (SOR: A).
- Antibiotics convey a 17-fold increased risk of hemolytic-uremic syndrome and should therefore not be used (SOR: A).

***Salmonella* Species.** Typhoid fever has been eliminated as a major public health problem in the United States and other developed countries, although occasional cases still occur, mainly in returning travelers. Enteric infections from nontyphoidal *Salmonella* spp. are extremely common in the United States as elsewhere because of the wide presence of *Salmonella* in foodstuffs, especially poultry and eggs. *Salmonella* infections encompass at least five syndromes:

1. *Gastroenteritis caused by nontyphoidal species* is usually manifested as nausea, vomiting, and diarrhea 6 to 48 hours after ingestion of contaminated food or water. Stools are usually loose, of moderate volume, and without blood, and cultures are usually positive.
2. *Bacteremia with endovascular infection* can manifest as mycotic aneurysm (especially of the aorta, [Figure 15-9](#)); infection of vascular grafts; or, rarely, endocarditis. Blood cultures, if obtained, are positive in up to 4% of patients with *Salmonella* gastroenteritis, but the bacteremia is usually transient unless host factors present a *locus minoris resistentiae*. Advanced atherosclerosis of the aorta predisposes to colonization and then infection.
3. *Localized metastatic infections* can present as CNS infections; osteomyelitis or septic arthritis (especially in the context of sickle cell disease or immunosuppression); soft tissue infections; UTI (notably in the presence of stones; malignancy; renal transplant; or, in some parts of the world, schistosomiasis); and, rarely, other syndromes.
4. An *asymptomatic carrier state* occurs in 0.2% to 0.6% of persons with nontyphoidal salmonellosis, is more common in women and in persons with abnormalities of the biliary tract, and assumes importance in the food industry.
5. *Enteric fever* (typhoid fever caused by *S. typhi* and *paratyphoid* fever caused by other species) classically begins as a stepwise fever that becomes sustained (i.e., the temperature does not return to the baseline). Diarrhea is seldom the presenting complaint, and about 30% of patients, mainly adults, have constipation rather than diarrhea. Abdominal pain, sometimes with small "rose spots" on the trunk and abdomen, develops during the second week, and serious complications—including perforation of the bowel or hemorrhage—occur during the third week. Blood cultures are positive in 40% to 80% of

Figure 15-9. Mycotic aneurysm of the abdominal aorta demonstrated by aortography in a patient who had recently had *Salmonella* gastroenteritis.

cases, stool cultures in 30% to 40%, and bone marrow cultures in up to 98%.

KEY TREATMENT

- Antimicrobial therapy for gastroenteritis caused by nontyphoidal strains of *Salmonella* spp. is recommended for patients with more severe disease and for those predisposed to complications (namely, persons younger than 2 years of age or older than 50 years of age, those with malignancy or impaired T-lymphocyte function, those with disorders that cause “phagocyte blockade,” and those with vascular grafts) (SOR: B).
- When antimicrobial therapy is indicated, current drugs of choice are TMP-SMX or a fluoroquinolone (SOR: B).

Shigella Species. *Shigella* spp., the classic cause of dysentery (see Table 15-7) are highly communicable. *S. dysenteriae* serogroup 1 (the Shiga bacillus) is the most virulent *Shigella* species and an important cause of morbidity and mortality in young children worldwide. *S. sonnei*, which causes a relatively mild disease, accounts for 60% to 80% of shigellosis in the United States. The highest attack rates occur in children between 1 and 4 years of age. Although the inflammatory response is severe, it is relatively superficial, and bacteremia is therefore uncommon.

KEY TREATMENT

- Antimicrobial therapy for dysentery caused by *Shigella* spp. consists of TMP-SMX or a fluoroquinolone (SOR: A).

Campylobacter Species. *C. jejuni*, now the most common bacterial pathogen isolated from stool cultures in the United States, mainly affects small children, adolescents, and young adults. Fever and abdominal pain are the usual presenting complaints. Atypical features include a severe flulike illness, a pseudoappendicitis syndrome (*C. jejuni* has been isolated in up to 3% of persons undergoing surgery for acute appendicitis), and acute colitis suggesting inflammatory bowel disease (ulcerative colitis or Crohn’s disease). Other complications include cholecystitis, pancreatitis, hepatitis, peritonitis, the hemolytic-uremic syndrome, exacerbation of preexisting inflammatory bowel, and a Guillain-Barré variant known as the Miller-Fisher syndrome (in which cranial nerves are affected in addition to the ascending polyneuritis). *Campylobacter fetus* less commonly causes diarrhea, but, having a marked predilection for vascular sites, can also cause endocarditis, pericarditis, and thrombophlebitis.

KEY TREATMENT

- *C. jejuni* enteritis is usually treated with erythromycin (SOR: B).
- Most patients with severe gastroenteritis caused by *C. jejuni* and nearly all patients with *C. fetus* gastroenteritis should be hospitalized (SOR: A).

Yersinia Infection. Two *Yersinia* species, *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*, cause gastroenteritis indistinguishable from other types of inflammatory diarrhea and most commonly affect young children. Localization of the bacteria to the lymphoid tissue in the ileum (Peyer patches) and mesenteric lymph nodes causes a clinical syndrome closely mimicking acute appendicitis (the *pseudo-appendicitis syndrome*). *Yersinia* spp. can also cause liver abscesses in patients with iron overload syndromes or diabetes mellitus. When yersiniosis is suspected, the laboratory should be notified to use special media for processing stool cultures.

KEY TREATMENT

- Antibiotics are not recommended for most enteric *Yersinia* infections (SOR: C).
- Regimens for severe infections or infections in immunocompromised persons caused by *Yersinia* spp. include TMP-SMX, fluoroquinolones, or combination therapy with doxycycline and an aminoglycoside (SOR: B).

Vibrio Infection. Cholera, caused by *Vibrio cholerae*, is the classic cause of noninflammatory but life-threatening diarrhea. Stimulation of the adenyl cyclase system by the organism’s toxin results in massive secretory diarrhea from a histologically normal small intestine, risking death from dehydration unless treated aggressively. *Vibrio parahaemolyticus* is an important cause of gastroenteritis associated with ingestion of inadequately cooked or uncooked seafood

(notably, raw oysters). Explosive watery diarrhea is usually the first symptom. Although usually mild, *V. parahemolyticus* infection can be fatal in young children, elderly adults, and severely debilitated individuals. *V. vulnificus*, previously discussed in this chapter, causes bloodstream and soft tissue infections but seldom causes diarrhea.

Viral Gastroenteritis. Viruses—notably rotaviruses and noroviruses—are the most common causes of diarrhea in the United States, but the disease is usually mild. *Rotaviruses* cause diarrhea mainly in children younger than 5 years of age but can also cause serious diarrhea in elderly adults, especially in long-term care facilities. Noroviruses are transmitted person to person; result in extensive fecal shedding; and cause large outbreaks of diarrhea in contained environments such as cruise ships, health care institutions, and schools. Diarrhea begins abruptly, often with nausea and vomiting (*winter vomiting disease*); stools are watery; and symptoms usually resolve after 3 days.

Parasitic Diarrheas. Parasitic causes should be considered in patients with diarrhea lasting more than 7 days. Of the numerous causes of parasitic diarrhea throughout the world (see later section on Parasites), the most important in the United States are three protozoa: *Giardia lamblia*, *Cryptosporidium parvum*, and *Entamoeba histolytica*. Molecular-based technologies are replacing traditional microscopy (“stool for ova and parasites”) for diagnosis because the latter has low sensitivity. In a recent study, real-time PCR was 100% sensitive and specific for detecting these three protozoa, but traditional microscopy was only 38% sensitive (although nearly 100% specific) (Van Lint et al., 2013).

Giardiasis can be acquired from lake or stream water; contaminated food; or personal contact, especially in day care centers. *Giardia lamblia*, a flagellated protozoan, is found in many mammals, including beavers, dogs, and cats. *Giardia* cysts resist chlorination of water but are killed by boiling. Campers, who are at high risk, should therefore boil water obtained from streams or lakes. Diarrhea, when it is established, is usually protracted. Cysts can be hard to find in stools; a commercially available immunoassay is now recommended.

Cryptosporidiosis in immunocompetent persons is often asymptomatic or the cause of a mild and self-limited diarrhea. Treatment is not recommended. Large outbreaks of diarrhea caused by *Cryptosporidium parvum* have resulted from contamination of municipal water supplies. In persons with advanced HIV disease, cryptosporidiosis is a major cause of severe, intractable diarrhea. Diagnosis is usually made by partial acid-fast staining of stools or by newer antigen detection methods.

Amebiasis, caused by *E. histolytica*, is highly prevalent in many developing countries, in certain institutional settings in the United States, and among recent immigrants from Mexico. Up to 90% of persons with *E. histolytica* are asymptomatic cyst passers. Some infected persons have acute nonspecific diarrhea with bloody stools. The disease can present as fulminant colitis, mainly in children; this presentation can be misdiagnosed as ulcerative colitis; hence, amebic disease should be excluded if steroids are to be used for presumed first-episode ulcerative colitis.

Nonpathogenic amebae, notably *E. dispar*, can be confused with *E. histolytica* on microscopic examination. Antigen-detection methods are available for testing stool samples for *E. histolytica*, and serologic tests are usually positive in patients with liver abscess, the major systemic complication.

KEY TREATMENT

- Metronidazole is the drug of choice for giardiasis (SOR: A).
- Paromomycin and nitazoxanide have been used for treatment for cryptosporidiosis, but results are often unsatisfactory (SOR: B).
- Metronidazole, combined with either diiodohydroxyquin or paromomycin, is the drug of choice for amebiasis (SOR: A).

***Clostridium difficile* Infection.** Diarrhea is a relatively common complication of antimicrobial therapy and is associated with *C. difficile* in about 10% to 30% of cases. Pseudomembranous colitis caused by *C. difficile* occurs in about one in 10,000 courses of antibiotic therapy in ambulatory patients. Primary care clinicians are likely to encounter *C. difficile* in three groups of patients: (1) patients given broad-spectrum antibiotics—most commonly ampicillin, amoxicillin, newer cephalosporins, and clindamycin; (2) patients recently released from the hospital; and (3) patients in long-term care facilities. Asymptomatic *C. difficile* colonization is common, and the spores (which resist common disinfectants, including alcohol-based hand sanitizers) often contaminate the environment. The occurrence of person-to-person transmission mandates scrupulous hand hygiene with soap and water after direct contact with patients known or suspected to be colonized by this organism. *C. difficile* colitis typically presents as watery diarrhea with a low-grade fever and abdominal pain. About 2% to 3% of patients have serious complications, including ileus, toxic megacolon (maximum colonic diameter ≥ 7 cm), intestinal perforation, and protein-losing enteropathy. Marked leukocytosis (WBC count $>30,000$ mm³) indicates severe disease, in which fecal polymorphonuclear leukocytes (PMNs) can usually be demonstrated.

The recent introduction of PCR-based molecular testing for *C. difficile* toxin A and B genes has simplified the diagnosis because the newer assays have near 100% sensitivity. However, these assays cannot distinguish infection from asymptomatic colonization. Endoscopic evaluation of the colon is generally reserved for cases in which the diagnosis is in doubt. Although optimum therapy of *C. difficile* remains controversial, all authorities agree on one point: broad-spectrum antimicrobial therapy should be stopped if at all possible.

KEY TREATMENT

- Drugs that alter normal intestinal motility should be avoided in patients with colitis caused by *C. difficile* (SOR: A).
- Orally administered metronidazole is recommended for mild to moderately severe cases of colitis caused by *C. difficile* (SOR: A).

- Orally administered vancomycin is recommended for severe cases of *C. difficile* colitis (SOR: B).
- The array of alternative agents now includes fidaxomicin, but no treatment is entirely satisfactory for patients with severe disease or frequent relapses (SOR: B).
- *C. difficile* colitis recurs in about 20% of patients, and numerous measures, including fecal transplantation, continue to be studied (SOR: C).

URINARY TRACT INFECTIONS

Urinary tract infections are the most common bacterial infections encountered in family medicine, affect perhaps half of all persons during their lifetimes, and are becoming increasingly problematic because of the emergence of drug-resistant strains of uropathogenic *E. coli*. UTI is mainly a disease of women except during early infancy and late adulthood (Barber et al., 2013).

The term “UTI” denotes a diverse group of conditions having in common the presence of microorganisms in bladder urine with or without symptoms and signs of disease. The term *asymptomatic bacteriuria* denotes the presence of greater than 10^5 colony-forming units (CFUs) of bacteria per milliliter of urine. Current opinion holds that lower counts (as little as 10^3 CFU/mL of urine) should be given credence in symptomatic patients (those suspected of having cystitis or pyelonephritis) and in patients whose specimens are obtained directly from an indwelling catheter. *Uncomplicated UTI*, in which infection is confined to the urinary bladders, is mainly a disease of women. About one in three women develop UTI requiring treatment by early adulthood. *Complicated UTI* implies the presence of predisposing anatomic, functional abnormalities; is more difficult to treat; and requires aggressive evaluation and patient follow-up. Some authorities maintain that *all* UTIs in patients other than young, healthy, nonpregnant women should be considered complicated.

Many authorities suggest abandoning the terms “lower” and “upper” UTI, but these terms are conceptually useful for indicating which patients need urologic intervention. The term “lower UTI” refers to infection at or below the level of the bladder and in clinical practice is synonymous with “cystitis,” a syndrome characterized by dysuria (pain on voiding), frequency, urgency, and variable suprapubic tenderness. “Lower UTI” also encompasses prostatitis, urethritis, and infection of the periurethral glands. The term “upper UTI” refers to infection above the level of the bladder—that is, of the ureters, kidneys, and perirenal tissues. This term usually implies pyelonephritis but can also denote intrarenal abscess (“renal carbuncle,” usually caused by *S. aureus*) and perinephric abscess. *Obstructive uropathy* refers to obstruction of urine flow at any level.

Urine culture remains the gold standard for diagnosis but is unnecessary in most cases of uncomplicated UTI. Grossly clear urine has a negative predictive value of 91% or greater for significant bacteriuria. Combined use of the leukocyte esterase-nitrite test (by dipstick analysis of urine) has a sensitivity of 70% to 90% for UTI. Most patients with symptomatic UTI have pyuria. Urine culture should be obtained for patients with complicated UTI and for patients with recurrent uncomplicated UTI if the recurrences are not

clearly related to sexual activity. Because the bacteria that usually cause UTI multiply rapidly at room temperature, false-positive cultures can result when specimens are not plated out or refrigerated promptly. The pretest probability of a positive urine culture is increased by a history of UTI symptoms, back pain, hematuria, or bacteriuria by dipstick analysis.

Asymptomatic Bacteriuria

Asymptomatic bacteriuria as defined above is relatively common in certain patient groups. Screening for asymptomatic bacteriuria is strongly recommended in the first trimester of pregnancy because pregnant women are at increased risk of acute pyelonephritis. Screening is discouraged in most patient populations. Eradication of the infecting microorganism commonly results in bladder colonization by a more difficult-to-treat pathogen.

KEY TREATMENT

- Antibiotic therapy for asymptomatic bacteriuria is indicated (1) during pregnancy, (2) in young children with vesicoureteral reflux, (3) in selected patients with urologic problems or ureteral obstruction (especially when such patients are scheduled for implant surgery of any kind, in which transient bacteremia might have disastrous consequences), (4) in renal transplant recipients during the early postoperative period, and (5) for patients with severe granulocytopenia (SOR: A).
- In other patient groups, notably elderly patients and especially elderly women, treatment of asymptomatic bacteriuria can be distinctly harmful and is therefore not recommended (Mody and Juthani-Mehta, 2014) (SOR: A).
- When a patient has asymptomatic bacteriuria caused by a microorganism resistant to the usual antibiotics or treatable only with a relatively toxic agent (e.g., an aminoglycoside antibiotic), it is often best to (1) record the presence of the microorganism in the patient’s medical record and (2) prescribe antibiotics when and if the patient develops any combination of fever, flank tenderness, or documented bacteremia (SOR: B).
- The presence of pyuria in a patient with asymptomatic bacteriuria does not constitute an indication for antibiotic therapy (SOR: C).

Uncomplicated Cystitis in Nonpregnant Adolescent and Adult Women

Uncomplicated acute cystitis in nonpregnant adolescent and adult women is typically caused by *E. coli* or, during the spring and summer months, *Staphylococcus saprophyticus* (Table 15-8). Diagnosis is usually based on symptoms: urinary urgency and frequency, dysuria, suprapubic discomfort, and cloudy urine. Vaginitis and genital herpes simplex infection should be excluded. The presence of fever or flank pain (i.e., pain experienced at the costovertebral angle, or “over the kidney”) strongly suggests acute pyelonephritis. Patients with acute pyelonephritis often have “lower urinary tract” symptoms, but patients with infection confined to the lower urinary tract seldom, if ever, experience fever and chills. A wealth of experience supports the

Table 15-8 Some Microorganisms Causing Urinary Infection and their Clinical Correlates

Microorganism	Clinical Correlates
<i>Escherichia coli</i>	Causes >70% of uncomplicated UTIs and many complicated UTIs. Uropathogenic strains possess <i>P. fimbriae</i> (pyelonephritis-associated pili) to bind to urinary tract epithelial cells and thereby colonize the bladder. Certain strains known as ST131 strains exhibit high levels of resistance to antibiotics.
<i>Staphylococcus saprophyticus</i>	A coagulase-negative staphylococcus species causing up to 15% of uncomplicated UTIs in women and more common during the spring and summer months. It can be distinguished from other coagulase-negative staphylococci by its resistance to novobiocin.
<i>Proteus mirabilis</i>	A urea-splitting gram-negative bacillus that causes the urine to be alkaline (pH ≥7), thereby promoting the formation of struvite calculi capable of becoming large “staghorn” calculi that can completely obstruct the renal pelvis.
Aerobic gram-negative bacilli other than <i>E. coli</i> and <i>P. mirabilis</i>	<i>Klebsiella</i> spp. occasionally cause uncomplicated community-acquired UTI, but the presence of species of aerobic gram-negative bacilli usually signifies complicated UTI, typically in patients who have received multiple courses of antibiotics, have indwelling bladder catheters, or who have undergone urologic intervention.
Enterococci	The presence of enterococci in the urine usually correlates with some combination of prior antimicrobial therapy, urologic instrumentation, or obstructive uropathy. Enterococci seldom cause acute symptomatic UTI (Hooton et al., 2013). However, enterococcal UTI is a risk factor for enterococcal endocarditis.
<i>Staphylococcus aureus</i>	The presence of <i>S. aureus</i> in the urine can represent a “spillover” from bacteremia rather than infection of the urinary tract per se, although exceptions may occur, especially in older men with obstructive uropathy. <i>S. aureus</i> bacteriuria can also signify the presence of an intrarenal abscess (renal carbuncle).
Group B streptococci (<i>Streptococcus agalactiae</i>)	Group B streptococci rarely cause acute cystitis in healthy young women (Hooton et al., 2013). However, group B streptococci can cause symptomatic UTI in older patients with risk factors for complicated UTI.
<i>Staphylococcus epidermidis</i>	<i>S. epidermidis</i> is a frequent contaminant of urine cultures because of its heavy presence in normal skin flora. Symptomatic UTI occurs mainly in persons with indwelling urinary catheters.
<i>Candida albicans</i> and other yeasts	The tendency of yeast cells to clump together makes the “10 ⁵ CFU/mL of urine” less accurate for defining “significant” growth of yeasts in urine culture compared with bacteria. Yeasts are usually encountered in catheterized patients who have received multiple courses of antibiotics. Patients are often asymptomatic, and treatment is often not required. However, yeasts can infect the kidneys and can give rise to “fungus balls” that obstruct the ureters.
<i>Lactobacillus</i> spp., <i>Gardnerella vaginalis</i> , and <i>Mycoplasma</i> spp.	These microorganisms have been implicated as causes of UTI, but their relative importance is unclear.
Adenoviruses	Adenoviruses occasionally cause acute hemorrhagic cystitis, mainly in children and young adults.

UTI, Urinary tract infection.

practice of managing first episodes of uncomplicated cystitis, and recurrent episodes clearly related to sexual activity, with short (3-day) courses of antimicrobial agents without a urine culture.

Of great current concern is the emergence throughout the world of uropathogenic *E. coli* strains of sequence type 131 (ST131 strains) (see Table 15-8), which often exhibit high-level resistance to multiple antibiotics.

KEY TREATMENT

- Fluoroquinolones and β-lactam antibiotics should no longer be used as empiric therapy for acute cystitis because of the emergence of resistance among uropathogenic *E. coli* (SOR: A).
- Common treatment options for uncomplicated cystitis include TMP-SMX, nitrofurantoin, and fosfomycin (SOR: A). Most patients improve rapidly; failure to improve should raise the possibility of a complicating factor (SOR: A).
- Forcing fluids has not been proven to be beneficial for acute cystitis (SOR: B).
- Cranberry juice is probably unhelpful unless taken in large quantities (SOR: B).
- Strategies for prevention and treatment of recurrent UTI in young, nonpregnant women include patient-initiated

self-treatment of symptomatic episodes, continuous low-dose prophylaxis, and postcoital prophylaxis. A recent analysis of the literature indicated daily low-dose nitrofurantoin to be the most effective of five alternatives for this purpose (Eells et al., 2014) (SOR: B).

Acute Pyelonephritis

Acute pyelonephritis usually arises from ascent of bacteria from the bladder to the renal medulla. Pyelonephritis in patients with structurally normal urinary tracts is usually caused by uropathogenic *E. coli* strains. Other aerobic gram-negative bacilli come into play in patients with complicated urologic histories. Fever, flank pain, nausea, and vomiting—with or without symptoms of lower UTI (dysuria, frequency, urgency)—suggest the diagnosis. PID is often misdiagnosed as acute pyelonephritis. Pelvic examination should therefore be undertaken when risk factors for sexually transmitted disease (STD) are present. Pyuria is nearly always present, and microscopic examination of the urine may reveal WBC casts (Figure 15-10). Urine culture should be performed because the nitrite test lacks sensitivity and will not provide the information about the causative organism that will be needed if initial therapy fails. Blood cultures should be performed in patients who require hospitalization. A pregnancy test should be obtained if the

Figure 15-10. A white blood cell cast, in the setting of pyuria, fever, and flank pain, is essentially pathognomonic of acute pyelonephritis.

reliability of contraception is in doubt or menses are irregular.

KEY TREATMENT

- Patients with acute pyelonephritis and severe symptoms including nausea and vomiting should be started on parenteral antibiotic therapy, such as ceftriaxone (SOR: A).
- Indications for hospitalization include severe sepsis, uncertainty about the diagnosis, and inability to maintain hydration (SOR: A).
- Outpatient therapy often suffices for nonpregnant women with mild to moderately severe disease and who can be expected to be compliant with treatment (SOR: A).
- When the infecting microorganism is susceptible to the chosen drug, marked improvement usually occurs within 72 hours unless ureteral obstruction, renal or perinephric abscess, or other serious complication is present. Failure to respond within 72 hours should prompt evaluation of the urinary tract by CT scan or ultrasound examination. Imaging studies are also indicated in patients who have had two or more recurrences of acute pyelonephritis (SOR: A).

Complicated Urinary Tract Infection in Adults

Complicated UTI (as defined earlier) often begins more insidiously. Gradually worsening symptoms sometimes antedate the diagnosis by weeks or months, as opposed to less than 3 days in most cases of acute uncomplicated pyelonephritis. Complicated UTI should also be suspected when standard therapy of upper UTI fails to effect clinical

improvement (return of temperature and WBC to normal) within 5 days.

Perinephric abscess is typically associated with urinary calculi, diabetes mellitus, or both. *Renal cortical abscess* (renal carbuncle, often a result of *S. aureus* bacteremia) may present with symptoms suggesting acute pyelonephritis but responds poorly to therapy. Imaging studies (CT scan or ultrasonography) facilitate these diagnoses. *Xanthogranulomatous pyelonephritis* is an unusual variant of chronic pyelonephritis usually seen in middle-aged women with history of recurrent UTI. The lesion is usually unilateral, and imaging studies typically show a large, nonfunctioning kidney with several stones or a staghorn calculus. This entity can be confused with malignancy. *Emphysematous pyelonephritis* is a rare gas-forming infection of the renal parenchyma, usually seen in patients with diabetes mellitus, with a high risk of multiorgan failure and death. Diagnosis is now made by CT scan. Aggressive urologic intervention sometimes obviates the need for nephrectomy to save the patient's life.

Urinary Tract Infections in Adult Men

About half of adult men, and perhaps most men who survive well into their eighties, seek medical attention for UTI during their lifetimes. Men with UTI usually undergo imaging procedures to exclude obstructive uropathy. *Acute bacterial prostatitis* presents with some combination of fever, dysuria, pelvic or perineal pain, and pyuria. Rectal examination, which is painful and can cause bacteremia, should be avoided when the diagnosis seems straightforward. Initial antibiotic coverage, unless guided by Gram stain or spun urine sediment, should include drugs with broad-spectrum activity against aerobic gram-negative bacilli and gram-positive cocci. The diagnosis of *chronic bacterial prostatitis* is usually made in the course of investigating the cause of recurrent UTI or asymptomatic bacteriuria. Rectal examination often shows a tender and boggy prostate, but findings may be normal. Urinalyses and urine cultures taken before and after prostate massage (the four-cup test) can be useful but cannot exclude this diagnosis. Antimicrobial therapy must be prolonged, typically for 4 to 12 weeks, and is made difficult by the poor penetration of many antibiotics into the prostate. Occasional patients have granulomatous prostatitis caused by TB or fungi (notably, blastomycosis, coccidioidomycosis, and cryptococcosis; rarely histoplasmosis), which is suggested by failure to respond to antibiotics and by the finding of an indurated, firm, or nodular prostate. *Epididymitis* in young adults is most often the result of STD; epididymitis in older adults is usually caused by gram-negative or gram-positive bacteria and is associated with prostatic disease.

SEXUALLY TRANSMITTED DISEASES

The serious health consequences of STDs disproportionately affect women, children, and adolescents, especially among racial and ethnic minority groups. Barriers to effective STD prevention include lack of public awareness, inadequate training of health care professionals, and socio-cultural misconceptions of the risks and consequences. Some studies suggest that fewer than 50% of family

physicians obtain adequate histories of sexual practices in their new patients despite the obvious role of primary care in prevention. The focus here is mainly on recognition; family medicine physicians can stay current with evolving treatment recommendations through the CDC's website (<http://www.cdc.gov/std/treatment>).

KEY TREATMENT

- The practice of treating partners of patients with most STDs (syphilis is the major exception) has been shown to be effective for preventing reinfection and for reducing the further spread of infection (SOR: B).

Urethritis, Vaginitis, Cervicitis, and Pelvic Inflammatory Disease in Women

Consequences of STDs in women include infertility, fetal complications including death, and the end results of unrecognized syphilis and gonorrhea.

Urethritis (inflammation of the urethra, characterized by a burning sensation during urination or itching or discharge at the urethral meatus) in women, usually caused by *N. gonorrhoeae*, *Chlamydia trachomatis*, or HSV, presents with some combination of dysuria, urinary frequency, and lower abdominal pain. It must be differentiated from acute cystitis, which, similar to urethritis, is often preceded by sexual activity. When in doubt, patients should be tested for gonorrhea and *C. trachomatis* infection; nucleic-acid based tests on urine or on urethral specimens are highly sensitive and specific.

Vaginitis is discussed in the chapter on gynecology.

Cervicitis (inflammation of the cervix) is a common but poorly understood condition that has been found in 32% to 45% of women attending STD clinics and is often asymptomatic. Cervicitis can present with vaginal discharge, post-coital bleeding, or deep dyspareunia. *Mucopurulent cervicitis* is defined by the presence of a mucopurulent discharge from the endocervical os or by friability or easily induced bleeding when the endocervix is first touched by a swab. *Trichomonas vaginalis* is the most common cause, but other important causes include *N. gonorrhoeae* and *C. trachomatis*. In about 40% of cases, no pathogen is identified, and some cases are presumed to be of noninfectious etiology. Management of sexual partners should be based on the suspected or detected infection in the index patient if contact occurred within the preceding 60 days.

Pelvic inflammatory disease—inflammation of the upper female genital tract and related structures—can manifest as endometritis, salpingitis, adnexitis, tuboovarian abscess, pelvic peritonitis, perihepatitis, or chronic pelvic pain. Salpingitis predisposes to tubal pregnancy, tuboovarian abscess, and infertility. The risk for tubal-factor infertility is 7% after one episode of PID and increases to 28% after 3 or more episodes. Women with PID have a 7- to 10-fold increased risk of ectopic pregnancy, which accounts for 9% of all pregnancy-related deaths. Most cases of PID begin with *C. trachomatis* and/or *N. gonorrhoeae* infection. Damage to the fallopian tube mucosa allows invasion by opportunistic bacteria from the vaginal flora: gram-negative bacilli, various anaerobic bacteria, group B streptococci, and genital mycoplasmas. The clinical spectrum of PID ranges

from asymptomatic infection to mild endometritis or salpingitis to generalized peritonitis. Women with gonococcal PID may present with abdominal pain of less than 3 days' duration; women with chlamydial PID tend to present with abdominal pain of longer than 1 weeks' duration. The minimum criterion for a clinical diagnosis of PID consists of one or more of the following: lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Empiric therapy should be given when all three of these are present. Additional criteria that support the diagnosis are temperature of 38.3 °C (101 °F) or above, an abnormal cervical or vaginal discharge, an elevated ESR or CRP level, or documentation of cervicitis caused by *N. gonorrhoeae* or *C. trachomatis* by culture or nucleic acid-based tests.

The approach to treatment of PID includes the decision whether to hospitalize, patient education, follow-up, and treatment of sex partners. Antimicrobial therapy should include coverage against *N. gonorrhoeae*, *C. trachomatis*, anaerobic bacteria, streptococci, and gram-negative bacilli.

KEY TREATMENT

- Patients with cervicitis should be considered for presumptive treatment of *C. trachomatis* and *N. gonorrhoeae* if precise diagnosis and assured follow-up cannot be obtained (SOR: A).
- Empiric therapy for PID should be given when all three of the following are present: lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness (SOR: A).

Urethritis in Men

Causes of urethritis in men include *N. gonorrhoeae*, *C. trachomatis*, *Ureaplasma urealyticum*, *Mycoplasma genitalium*, and occasionally *Trichomonas vaginalis*, HSV, syphilis, and various bacterial pathogens. Whereas gonococcal urethritis usually causes purulent discharge and dysuria, nongonococcal urethritis usually causes a scant, mucoid discharge and may be asymptomatic. Up to 30% of men with gonococcal urethritis, discussed in more detail later, have concomitant chlamydial infection. Some studies suggest that up to two thirds of cases of nongonococcal urethritis in men are undiagnosed. Treatment depends on the etiology.

Chlamydia trachomatis Infection

Chlamydia trachomatis is one of the most common sexually transmitted pathogens, especially between the ages of 15 and 24 years. In men, the spectrum includes urethritis, proctitis, epididymitis, and reactive arthritis. In women, the spectrum includes urethritis, Bartholin's cystitis, endometritis, salpingitis, tuboovarian abscess, ectopic pregnancy, pelvic peritonitis, and perihepatitis. Among women with gonorrhea, 30% to 50% have concomitant *Chlamydia* infection. Multiple exposures to different chlamydial serotypes may be a risk factor for carcinoma of the cervix. About 75% to 90% of cases of chlamydial cervicitis are asymptomatic. Infected men commonly have urethritis. Nucleic acid amplification tests are now widely used for diagnosis. Appropriate specimens in women include vaginal swabs, endocervical swab, self-collected vulvovaginal

swabs, and urine; appropriate specimens in men include urethral swabs and urine.

KEY TREATMENT

- All patients with gonorrhea—both men and women—should be treated empirically for concomitant chlamydial infection. Azithromycin and doxycycline are the preferred antibiotics.

Gonorrhea

N. gonorrhoeae, similar to many sexually transmitted pathogens, is usually (95%) symptomatic and easily diagnosed in men but is a more subtle and dangerous pathogen in women. About 10% to 20% of women develop acute salpingitis or PID. Underdiagnosis in women can lead to disseminated gonococcal infection, which most commonly presents as septic arthritis or tenosynovitis, sometimes with tender, necrotic skin nodules with an erythematous base on the distal extremities (the *gonococcal arthritis-dermatitis syndrome*). Rare complications include endocarditis and meningitis.

Gram stain of urethral exudates has a high sensitivity (90% to 95%) for men with symptomatic gonococcal urethritis but is much less reliable in women. Nucleic acid amplification tests (notably, PCR) have largely replaced Gram stain and culture for diagnosis of gonorrhea in the United States but do not provide information about drug susceptibility. Fluoroquinolones are no longer used for treatment of gonorrhea because of the high prevalence of resistance. Gonococci increasingly show resistance to other agents, and few new drugs are in the pipeline (Hook and Van der Pol, 2013).

KEY TREATMENT

- Current therapy for uncomplicated gonorrhea consists of ceftriaxone plus either azithromycin or doxycycline, but the literature should be followed (SOR: A).

Syphilis

Syphilis, caused by the spirochete *Treponema pallidum*, remains a public health concern in the United States with disproportionately high rates in various racial and ethnic groups and in HIV-infected persons, in whom the disease can be difficult to treat. *Primary syphilis* typically presents 2 to 6 weeks after exposure as a painless, indurated ulcer (*chancre*) with well-defined borders and a clean base, usually on the genital mucosa but sometimes on the oral or anorectal mucosa. *Secondary syphilis*, which develops in 60% to 90% of persons with untreated primary syphilis, is a systemic disease caused by dissemination of treponemes and is characterized by combinations of fever; generalized lymphadenopathy; headache; sore throat; arthralgias; rash; and, less often, involvement of the CNS, eyes, liver, and kidneys (as immune-complex glomerulonephritis). *Latent syphilis* is defined by reactive serologic tests without evidence of disease. *Tertiary (late) syphilis* presents as cardiovascular disease (aortic aneurysms, aortic regurgitation, and

coronary stenosis), neurologic disease (as general paresis, tabes dorsalis, CNS gumma [inflammatory mass with necrotic center]), and other syndromes that earned syphilis the reputation of “great masquerader.”

Definitive diagnosis of primary syphilis is based on demonstrating spirochetes by dark-field microscopy or direct immunofluorescence. Diagnosis of other states of the disease is based largely on serologic tests, which include both nontreponemal tests (notably, rapid plasma reagin [RPR] test and, for CSF, the Venereal Disease Research Laboratory [VDRL] test) and specific treponemal tests, notably the microhemagglutination–*Treponema pallidum* (MHA-TP) test. Secondary syphilis is the only stage of the disease in which serologic testing is reliable, the RPR being 99% sensitive and the MHA-TP 100% sensitive. Tertiary (late) syphilis is usually diagnosed by the combination of a reactive RPR and a confirmatory test (e.g., the MHA-TP) combined with clinical symptoms and signs consistent with the disease.

Benzathine penicillin G is used for non-penicillin-allergic patients with early syphilis and their recent (within 90 days) sex partners. Indications for CSF evaluation include neurologic, auditory, ophthalmic, or cardiovascular signs (e.g., aortic regurgitation); treatment failure (defined by failure of the nontreponemal titers to decrease fourfold, e.g. from 1 : 32 to 1 : 8, within 6 months of therapy for primary or secondary syphilis); and latent syphilis in the setting of HIV disease. High-dose penicillin G given intravenously remains the treatment of choice for non-penicillin-allergic patients with late syphilis. Latent syphilis (detected by nontreponemal serology, confirmed by specific treponemal serology, and—by definition—with exclusion of late syphilis by LP) is treated with several courses of benzathine penicillin G.

KEY TREATMENT

- Penicillin G is the treatment of choice for all stages of syphilis in non-penicillin-allergic patients, but the preparation and dosage depend on the stage of the disease (SOR: A).

Other Causes of Genital Ulcers

Most genital, anal, and perianal ulcers in the United States are caused by HSVs (discussed later in the section on herpesviruses) or syphilis. *Chancroid*, caused by *Haemophilus ducreyi*, is endemic in some parts of the United States and causes a soft, painful ulcer (“soft chancre”) in contrast to the hard, painful ulcer of syphilis. The diagnosis is usually clinical because media for isolating *H. ducreyi* are not widely available. A painful ulcer combined with tender lymphadenopathy is highly suggestive, but syphilis and HSV infection must be excluded in every case. Various treatments are usually curative. The painless genital ulcer of *lymphogranuloma venereum* is typically inconspicuous; the early course is dominated by massive suppurative inguinal lymphadenopathy (*buboes*) and the late course by abscesses, fistulas, strictures, and sinus tracts. The diagnosis is usually confirmed by serology, and treatment consists of doxycycline combined with drainage of buboes and abscesses.

Human Papillomavirus Infection

Human papillomavirus infection is the most common viral STD worldwide. In the United States, the incidence of HPV has been especially high among college students (35% to 43%), minorities, and persons with multiple sex partners. Most genital HPV infections are subclinical and transmitted by sexual contact. Approximately 100 types of HPV have been identified. About 30 types have been shown to infect the anogenital area; these have been divided into “low-risk” and “high-risk” groups based on their associations with anogenital cancer. HPV types 6 and 11 are found in about 90% of cases of condylomata acuminata (genital warts) but are rarely associated with cancer. On the other hand, HPV types 16, 18, 31, and 35 have been associated with squamous cell cancer of the vulva, vagina, cervix (with about 95% of squamous cell carcinomas of the cervix being positive for HPV DNA), penis, and anus. None of the several treatment measures assure a cure.

MUSCLE, BONE, JOINT, AND ORTHOPEDIC HARDWARE INFECTIONS

These infections are nearly always serious, requiring hospitalization or consultation.

Pyomyositis

Pyomyositis, an acute infection most commonly affecting the large muscles of the lower extremities or trunk, is fairly common in parts of the tropics but uncommon in the United States; about 95% of cases in the tropics and about two thirds of cases in the United States are caused by *S. aureus*. There is often a history of blunt trauma, causing a *locus minoris resistentiae*. Pyomyositis is also associated with HIV disease, injection drug use, and defects in host defenses. Imaging studies, notably MRI, enable the diagnosis. Patients should be hospitalized and receive both intravenous antibiotics and surgical drainage because untreated pyomyositis often progresses to severe sepsis and death.

Osteomyelitis

Osteomyelitis—infection of bone—is of diverse etiologies and commonly presents diagnostic and therapeutic dilemmas. According to one of several classifications, osteomyelitis is of three broad types: (1) hematogenous, (2) related to trauma or contiguous infection, and (3) polymicrobial osteomyelitis of the small bones of the feet in patients with diabetes mellitus. Osteomyelitis commonly complicates compound fractures and contributes to nonunion.

Acute hematogenous osteomyelitis most often involves the metaphyses of long bones (notably, of the tibia and fibula) in children and adolescents and the spine in adults (Petola and Pääkkönen, 2014). *S. aureus* is the most common cause, but numerous bacteria and other organisms (notably, *M. tuberculosis* and fungi) sometimes cause acute hematogenous osteomyelitis. Some patients present with few, if any, symptoms of local infection, the illness being dominated by fever and systemic toxicity. However, careful palpation often reveals localized areas of tenderness. Vertebral osteomyelitis should be considered in all adults with unexplained fever; palpation or percussion of

the entire spine may yield the first diagnostic clue. The WBC count is usually elevated, as are ESR and CRP, and blood culture results are often positive. MRI is more sensitive than plain radiographs for early diagnosis. Because therapy must be prolonged—at least 6 weeks—it is extremely important to secure a microbiologic diagnosis even if this requires bone biopsy for culture. Aggressive treatment of acute osteomyelitis reduces the risk of chronic osteomyelitis, which carries a lifelong risk of relapse.

SEPTIC ARTHRITIS

Acute septic arthritis in previously healthy persons is mainly caused by *S. aureus* and usually involves the large joints of the extremities. The affected joint is hot and swollen, and synovial fluid usually shows greater than 50,000 WBCs, predominantly neutrophils. *N. gonorrhoeae* should be considered in sexually active individuals; *P. aeruginosa* should be considered in injection drug users (in whom septic arthritis commonly affects unusual joints such as the sternoclavicular and sacroiliac joints), and gram-negative bacteria should be considered in patients with such risk factors as advanced age, rheumatoid arthritis, prosthetic joints, other joint surgeries, diabetes mellitus, skin infections, and immune suppression. TB and fungal infection should always be considered in subacute and chronic cases. Diagnosis depends largely on synovial fluid analysis and culture; when gonococcal septic arthritis is suspected, it is useful to inoculate culture media at the bedside after arthrocentesis. Treatment of septic arthritis consists of high-dose antimicrobial therapy; an orthopedic surgeon should be consulted for complicated cases requiring drainage.

Reactive Arthritis

Reactive arthritis, formerly known as “Reiter’s syndrome” and now classified as a spondyloarthropathy, affects joints of the lower back, hand, feet, knees, and ankles. It occurs most often in men, has a strong association with the *HLA-B27* gene, and often follows (as a presumed immunologic reaction) urethritis caused by *C. trachomatis* or enteritis caused by *Campylobacter*, *Salmonella*, *Shigella*, or *Yersinia* spp. The onset can be acute, subacute, or chronic, and the diagnosis is made on clinical grounds.

Orthopedic Hardware Infections

Infections of prosthetic joints or of hardware used for stabilization of fractures can present with acute symptoms and signs or as pain, loosening of components, and subtle signs of inflammation months to years after implantation. Most infections result from wound contamination during surgery; clinical presentation is acute or subacute if caused by *S. aureus* but usually chronic if caused by coagulase-negative staphylococci. Rarely, infection is caused by wound dehiscence. Recent studies suggest that *S. aureus* bacteremia carries a substantial risk (18% to 60%) of infecting a preexisting prosthetic joint, which acts as a *locus minoris resistentiae*. Management of these infections is difficult and usually involves an orthopedic surgeon and an infectious diseases specialist working in concert with the primary care clinician.

Table 15-9 Some Ticks and Their Diseases in the United States

Tick	Appearance	Geographic Distribution	Characteristics	Diseases
American dog tick (<i>Dermacentor variabilis</i>)	Dark brown; rounded mouth parts	Widely distributed east of the Rocky Mountains and in limited areas on Pacific Coast	Favors trails and roadsides near clearings; commonly found on dogs	RMSF; human granulocytotropic ehrlichiosis; tularemia
Blacklegged tick (deer tick) (<i>Ixodes scapularis</i>)	Dark brown; long mouth parts	Northern form: eastern and central United States to Virginia; southern form: southern United States to Mexico	Favors edges of paths and roads; adults active in fall, winter, and spring; immature forms (nymphs) active in spring and summer	Northern form: Lyme disease, human granulocytotropic anaplasmosis; babesiosis (the feeding habits of the southern form make it an unlikely vector of human disease)
Lone star tick (<i>Amblyomma americanum</i>)	Red-brown; long mouth parts; white spot on the back of females	Southeastern and eastern United States	Bites aggressively in southern areas	Human monocytotropic ehrlichiosis; tularemia; STARI syndrome
Gulf Coast tick (<i>Amblyomma maculatum</i>)	Brown females with mouth parts and metallic markings on scutum*	Coastal areas along the Atlantic Coast and Gulf of Mexico	Bites aggressively	<i>Rickettsia parkeri</i> rickettsiosis (a form of spotted fever)
Rocky Mountain wood tick (<i>Dermacentor andersoni</i>)	Dark brown; white markings on scutum*	Rocky Mountains and adjacent areas	Favors bushy vegetation	RMSF; tularemia; tick paralysis
Western blacklegged tick (<i>Ixodes pacificus</i>)	Similar to <i>I. scapularis</i>	Canadian Pacific coast through California	Favors wild grasses and low vegetation in both urban and rural settings	Lyme disease; human granulocytotropic anaplasmosis; can also cause type I hypersensitivity reactions [†]
Relapsing fever ticks (<i>Ornithodoros turicata</i> and other species)	A gray soft tick up to 1 cm in diameter	Southwestern and south-central United States to northern Florida; Rocky Mountains	Found especially in rodent-infested rustic mountain cabins	Relapsing fever
Brown dog tick (<i>Rhipicephalus sanguineus</i>)	Red-brown; slightly longer than most other tick species	Probably the most widely distributed tick in the world	Dogs; prefers warm, dry, indoor conditions	RMSF
<i>Amblyomma cajennense</i> (Cayenne tick)	Mottled brown body; large black region on the abdomen of adult females	Southern United States, extending into Latin America and South America	Likes grassy areas with horses (a preferred host)	RMSF

*Scutum: a dorsal plate found on hard ticks.

[†]Type I hypersensitivity reactions: anaphylaxis, angioedema, urticaria, and bronchospasm.

RMSF, Rocky Mountain spotted fever; STARI, Southern tick-associated rash illness.

TICKBORNE DISEASES

As insect vectors for human disease, ticks rank first in North America and second to mosquitoes worldwide. A small number of the nearly 900 known species of ticks account for most tick-transmitted diseases of humans in North America (Table 15-9). Tick-related diseases occur mainly during the warmer parts of the year, peaking during the summer. Preventive measures include avoiding tick habitats during peak seasons; wearing light-colored clothing; covering most of the body (e.g., long-sleeved shirts, trousers, socks, and shoes); covering exposed areas with DEET-containing repellent; and checking the body (including the hair, neck, axilla, and genital areas) for ticks on a regular basis. The best way to remove a tick is to grasp the mouthparts (attachment point) with forceps and then pull gently until the tick releases. The use of chemicals or flames may cause the tick to break, potentially increasing the risk of transmission. The area should be cleaned thoroughly after ensuring removal of the entire tick, including the embedded mouth.

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever, the most important life-threatening tickborne illness in the United States, is transmitted by several tick species (see Table 15-9). Five states (Arkansas, the Carolinas, Oklahoma, and Tennessee) account for 56% of cases. *Rickettsia rickettsii*, the causative organism, has a tropism for vascular endothelium, which explains at least in part the severe, generalized nature of the disease. After an incubation period of 2 days to 2 weeks, patients present with fever, chills, headache, malaise, myalgia, and other symptoms, often followed by multiorgan failure with seizures and coma. A maculopapular rash begins within 2 to 5 days on the extremities, classically involves the palms and soles, and evolves into a petechial rash. However, the rash may be absent in more than half of patients during the first week and never develops in up to 10% of patients (so-called “Rocky Mountain spotless fever”). The nonspecific presenting symptoms and signs present a diagnostic challenge. Common laboratory findings include thrombocytopenia, mild elevations in liver enzymes, and hyponatremia.

KEY TREATMENT

- Suspicion of RMSF should prompt strong consideration for empiric therapy with doxycycline because serum antibodies may not be detectable until 7 to 10 days after onset, and therapeutic delays increase the mortality rate. The remote risk of staining the teeth with a short course of doxycycline should not preclude its use in children (SOR: A).
- Chloramphenicol may be an alternative in severe disease but should be avoided in pregnancy (specifically the third trimester) given the risk of gray baby syndrome (SOR: A).

Ehrlichiosis and Anaplasmosis

Ehrlichiosis and anaplasmosis are caused by at least five species of obligate intracellular bacteria that infect and destroy WBCs (monocytes or neutrophils, depending on the species). The resulting tick-transmitted diseases in the United States include (1) *human monocytotropic ehrlichiosis* caused by *Ehrlichia chaffeensis*, (2) *human granulocytotropic ehrlichiosis* caused by *Ehrlichia ewingii*, and (3) *human granulocytotropic anaplasmosis* caused by *Anaplasma phagocytophilum* (see Table 15-9). After an incubation period of 1 to 2 weeks, patients present with some combination of fever, chills, headache, malaise, myalgia, gastrointestinal symptoms, cough, rash, and confusion. Common laboratory abnormalities are mild anemia, thrombocytopenia, leukopenia, and mild to moderate elevation of the aminotransferases. Characteristic morulae (clusters of bacteria) are sometimes seen in peripheral blood smears. Nucleic acid-based tests offer promise, but a retrospective diagnosis is usually based on serology, ideally on paired acute and chronic serum samples.

KEY TREATMENT

- Doxycycline is the drug of choice for both adults and children with ehrlichiosis or anaplasmosis.

Babesiosis

Babesiosis is a protozoan infection caused in the northeastern United States by *Babesia microti* and transmitted by two species of *Ixodes* tick or, rarely, by blood transfusion. Symptoms and signs of babesiosis include fever, chills, diaphoresis, malaise, fatigue, gastrointestinal symptoms, jaundice, mild splenomegaly, and rarely hepatomegaly. The disease is usually mild in immunocompetent persons but severe in asplenic or immunocompromised persons. Laboratory findings include hemolytic anemia, thrombocytopenia, mild elevations of the aminotransferases, and acute renal failure. The organisms can often be visualized within erythrocytes on peripheral smear, and *Babesia* DNA can be demonstrated in blood by PCR. Two-drug regimens are used for treatment; infectious diseases consultation should be considered.

Lyme Disease

Lyme disease is the most common tickborne infection in the United States, where it is caused by *Borrelia burgdorferi* and

transmitted by two species of ticks (see Table 15-9). Symptoms and signs of the initial infection include malaise, headache, fever, myalgia, arthralgia, lymphadenopathy, and a rash known as erythema migrans (a “target” or “bull’s eye” lesion with central clearing). Patients with disseminated disease may have cardiac conduction defects, myocarditis, transient oligoarthritis, seventh-nerve palsy (Bell palsy, which is sometimes bilateral), and meningitis or meningoencephalitis. Laboratory findings may include an elevated ESR and mild elevation of the aminotransferases. When meningitis is present, the CSF fluid typically shows a lymphocytic pleocytosis with mildly elevated protein and normal glucose. A single prophylactic dose of doxycycline (200 mg) may be given within 72 hours of confirmed tick exposure in highly endemic areas. Untreated patients are at risk of late complications, most commonly migratory arthritis commonly (85% of patients) involving the knee.

Most authorities agree that serologic testing for Lyme disease should be strongly discouraged for patients with nonspecific symptoms (e.g., fatigue and myalgia) who have not spent considerable time in a geographic area highly endemic for Lyme disease. Also, only the enzyme-linked immunosorbent assay (ELISA) test should be ordered. The result of the Western blot test (and, notably, the test for IgM antibodies by Western blot) is often false positive when the pretest probability of Lyme disease is low (as one would predict from Bayes’ theorem).

KEY TREATMENT

- Drugs of choice for Lyme disease without CNS involvement are doxycycline, amoxicillin, and cefuroxime, given for 14 to 21 days (SOR: A).
- Ceftriaxone is the drug of choice for Lyme disease with CNS involvement (SOR: A).
- Controlled trials indicate that antibiotics are not useful for so-called “chronic Lyme disease,” a controversial entity (SOR: A).

Tularemia

Tularemia can be transmitted by several tick species (see Table 15-9). The disease is classified on the basis of its portal of entry as ulceroglandular, glandular, oropharyngeal, oculoglandular, typhoidal, or pneumonic. Symptoms include fever, chills, headache, malaise, fatigue, anorexia, myalgia, chest discomfort, cough, sore throat, and gastrointestinal symptoms. Relative bradycardia is often present. Common laboratory findings are thrombocytopenia, hyponatremia, and elevations of the aminotransferases and creatine phosphokinase. The diagnosis is based on a fourfold change in antibody titer in paired sera or on the isolation of the organism, which, however, can be hazardous to laboratory personnel. A positive immunofluorescent antibody test result supports the diagnosis. Prophylaxis may be given with doxycycline after a confirmed exposure.

KEY TREATMENT

- Tularemia should be treated with streptomycin or gentamicin (SOR: A).

Emerging Tickborne Diseases

The *STARI* (Southern tick-associated rash illness) *syndrome* denotes a mild, flulike illness accompanied by a rash suggestive or typical of erythema migrans associated with a bite of the Lone Star tick and with negative serologic test results for Lyme disease. This syndrome was first described in Missouri and in the southeastern United States but now occurs in other regions such as the Midwest and the mid-Atlantic states. A spirochete, *Borrelia lonestari*, has been suspected but not proven to be the cause. Patients have been treated with doxycycline, but the efficacy of drug therapy is unknown because serious long-term consequences have not been established.

Powassan, so named after the town of Powassan, Ontario, where a young boy died from an apparently new disease, is caused by an RNA virus transmitted by various *Ixodes* ticks and by *Dermacentor* ticks. The disease presents as encephalitis, which is fatal in about 10% of cases and results in permanent neurologic deficits in about half of survivors. There have been about 50 known deaths in the United States at the time of this writing. Diagnostic tests have limited availability, and there is no known effective treatment.

American tick bite fever, also known as *Rickettsia parkeri* after the causative organism, features a maculopapular rash but can be differentiated from RMS by the presence of an eschar (a black wound) at the site of inoculation. The epidemiology and distribution of this disease in the United States remain to be elucidated. Doxycycline has been used for therapy.

364D rickettsiosis, a recently recognized disease, likewise features an eschar at the site of the tick bite. The distribution of the disease and the full spectrum of its manifestations remain to be determined.

FEVER OF UNCLEAR ORIGIN

Unexplained fevers are common in primary care, but most resolve within 1 or 2 weeks. The classic definition of FUO, known as the Petersdorf-Beeson criteria, consists of (1) an illness of at least 3 weeks' duration, (2) measured temperature greater than 38.3 °C (101 °F) on several occasions, and (3) no diagnosis after 1 week of intensive diagnostic efforts in the hospital. These criteria have been modified by today's emphasis on performing diagnostic procedures in ambulatory settings, and the spectrum of illnesses causing FUO continue to evolve as advances in imaging, microbiology, and serology enable earlier diagnosis. Various subsets of FUO (e.g., health care-associated FUO, immune-deficient FUO, and HIV-related FUO) are also recognized. There are more than 100 documented causes of "classic FUO," but even infectious diseases specialists see relatively few patients who fulfill the modified Petersdorf-Beeson criteria. Still, a general familiarity with the major causes of "true FUO" (Table 15-10) is useful because these disorders may be encountered in other ways. Patients whose FUO remains undiagnosed after intense evaluation often do well on long-term follow-up. Drugs should always be considered as causes of FUO in the ambulatory setting. The best approach is to discontinue all nonessential drugs; in most instances,

a definite downward trend in temperature occurs within 72 hours.

As a general rule, with the exception of elderly patients and patients receiving antiinflammatory drugs, it is useful to insist that "fever" be defined by a measured temperature of greater than 38.3 °C (101 °F). Extensive testing for lesser degrees of temperature elevation is usually unproductive unless patients have symptoms or signs strongly suggesting a disease of one or another category. A few patients present with prolonged (i.e., for more than several days) fever (temperature >38.3 °C [101 °F]) without localizing symptoms and signs, but a careful history and physical examination usually provide diagnostic clues.

Occasional patients exhibit *periodic fever*, defined by recurrent febrile illnesses usually lasting 1 to 3 days with fever-free intervals of at least 14 days. Some of these patients have hereditary periodic fever syndromes (e.g., familial Mediterranean fever, Muckle-Wells syndrome, hyperimmunoglobulin D syndrome, and TNF receptor-1-associated periodic syndrome); others are ultimately found to have a discernible cause, but in many cases, no cause is found, yet the patient remains well apart from the recurrent fevers.

Fever and Rash

Numerous diseases cause fever with rash or other lesions of the skin and mucous membranes (Table 15-11). *Adult Still disease* (see Table 15-10) and *acute rheumatic fever* (see Table 15-11) present with fever and arthritis or arthralgia, sometimes with a subtle rash. *Kawasaki disease*, a systemic vasculitis of unknown cause, mainly affects children but occasionally presents in adolescents and young adults. Patients should be hospitalized or referred to a consultant.

Leptospirosis, which in the United States occurs mainly in persons exposed to water or soil contaminated with animal urine, may cause a systemic disease with fever, chills, headache, nausea, vomiting, abdominal pain, and conjunctival suffusion. Patients who become jaundiced are at high risk of death from multiorgan failure. The diagnosis should be suspected in febrile patients potentially exposed to leptospirosis through such outdoor activities as farming, ranching, freshwater swimming, white-water rafting, or hunting.

Parvovirus B19 causes a characteristic "slapped cheek" rash in children (erythema infectiosum or fifth disease) but in adults is more likely to present with symmetric polyarthralgia or polyarthritis affecting mainly the small joints of the hands and feet and often accompanied by rashes that can be maculopapular, purpuric, or lacy and reticular. The diagnosis is made by demonstrating IgM antibodies. Parvovirus DNA can be demonstrated in blood by PCR, but positive results occur in otherwise healthy persons. The virus selectively infects red blood cell precursors, which can be disastrous in pregnant women, persons with high red blood cell turnover, and immunosuppressed persons.

Fever and Lymphadenopathy

Fever with lymphadenopathy has many potential causes, including malignancy (Table 15-12). Tender lymph nodes greater than 1.5 cm in diameter—especially if firm or fluctuant—usually signify a pathologic process. Lymph node biopsy is frequently appropriate when a diagnosis is not readily apparent by history; physical examination; and initial laboratory tests, including serologic tests. The more

Table 15-10 Some Causes of Classic Fever of Unknown Origin

Disease	Comments and Clues
INFECTIONS	
Tuberculosis	Mainly, disseminated (miliary) and extrapulmonary TB. Consider repeated physical examinations, bone marrow biopsy and culture, and liver biopsy and culture.
Intraabdominal abscess and other occult abscesses	Some cases remain elusive despite investigations with ultrasonography, CT, and MRI.
Hepatobiliary disease	Suggested by elevation of the serum alkaline phosphatase; consider recurrent bouts of ascending cholangitis (Charcot intermittent fever) caused by sepsis from gram-negative bacteria.
Endocarditis	Look for subtle clues in the skin and mucous membranes; apply protocols for evaluating suspected "culture-negative endocarditis" with various culture methods and serologic tests.
UTI	Atypical urinary tract infections include renal abscess (renal carbuncle) and perinephric abscess.
CMV infection	An important cause of FUO in younger persons who do not appear ill and have a paucity of physical findings; serology is helpful.
Miscellaneous infections	These include sinusitis, catheter-related infections, osteomyelitis, malaria, brucellosis, psittacosis, and disseminated fungal disease.
TUMORS	
Leukemias, lymphomas, and multiple myeloma	Look for the hectic "Pel-Ebstein" fever pattern of Hodgkin disease, although this is relatively uncommon; severe itching at night is a helpful clue.
Solid tumors	Carcinoma of the kidney may present as FUO without other manifestations. Many tumors cause fever when liver metastases are present.
CONNECTIVE TISSUE DISEASES	
Adult Still disease	Clues include a double-quotidian pattern (two fever spikes per day), sore throat, arthritis or arthralgia, lymphadenopathy, an evanescent salmon-pink rash, leukocytosis, and high serum ferritin level.
Temporal arteritis	A major cause of FUO, especially in older patients. Clues include diplopia or other visual symptoms, pain on chewing (intermittent masticatory claudication), and extremely high ESR (>100 mm/hr) or CRP.
Polyarteritis nodosa and other forms of vasculitis	Clues to polyarteritis include peripheral neuropathies (mononeuritis multiplex), renal involvement with active urine sediment, and occasionally eosinophilia. Other forms of vasculitis causing fever include hypersensitivity angiitis, Wegener granulomatosis, and vasculitis accompanying rheumatoid arthritis.
MISCELLANEOUS CAUSES	
Granulomatous diseases	Sarcoidosis, Crohn disease, and granulomatous hepatitis of unclear origin can cause FUO. Diagnosis requires biopsy and rigorous exclusion of infection.

CMV, Cytomegalovirus; CRP, C-reactive protein; CT, computed tomography; ESR, erythrocyte sedimentation rate; FUO, fever of unknown origin; MRI, magnetic resonance imaging; TB, tuberculosis; UTI, urinary tract infection.

Table 15-11 Some Diseases Associated with Fever and Rash

Disease	Morphology of Rash	Distribution of Rash
Acute rheumatic fever	Macules, erythema marginatum (erythematous, annular, or polycyclic macules that spread rapidly), subcutaneous nodules	Erythema marginatum on trunk or extremities; subcutaneous nodules on extensor surfaces near joints
Babesiosis	Petechiae, purpura, ecchymoses	Generalized
Coccidioidomycosis	Papules, nodules, plaques, ulcers, papulopustules	Head
Cryptococcosis	Papules, plaques, nodules, palpable purpura, cellulitis, pyoderma gangrenosum-like ulcers	Head and neck
Disseminated candidiasis	Erythematous papules and nodules	Trunk and extremities
Disseminated gonococcal infection	Macules, papules, vesicles, and petechiae initially, which may evolve into hemorrhagic vesiculopustules	Distal extremities, typically near an infected joint
Ecthyma gangrenosum and <i>Pseudomonas</i> sepsis	Erythematous to purpuric macules, hemorrhagic vesicles, bullae, nodules, or painless ulcers with a central necrotic, black eschar	Especially in axillary and anogenital regions
Ehrlichiosis	Usually, macules and papules; may be petechial; diffuse erythema is sometimes seen	Trunk
Epidemic typhus	Macules, papules, petechiae	Axillary folds, trunk, extremities (characteristically the face, palms, and soles are spared)
Herpes zoster and disseminated herpes zoster	Grouped vesicles on an erythematous base; hemorrhage bullae; in the disseminated form, large ulcers and plaques	Herpes zoster (shingles) has a dermatomal distribution; disseminated herpes zoster is generalized

Table 15-11 Some Diseases Associated with Fever and Rash (Continued)

Disease	Morphology of Rash	Distribution of Rash
Histoplasmosis	Ulcers, papules, plaques, purpura, abscesses, nodules, mucosal ulcerations	Generalized
Infective endocarditis	Petechiae, purpura, Osler nodes, Janeway lesions, splinter hemorrhages	Petechiae and purpura on heels, shoulders, legs, oral mucosa, conjunctivae; Osler nodes on digits (especially pulps of fingers and toes); Janeway lesions on palms and soles; splinter hemorrhages on nail plates
Kawasaki disease	Erythema (most often raised, deep red, plaquelike eruption); swelling of hands and feet; involvement of mucous membranes (dry, fissured lips, strawberry tongue; oropharyngeal erythema; conjunctival suffusion; later, desquamation)	Generalized, especially on trunk and extremities; accentuation in perineal area
Leptospirosis	Macules, papules, urticaria (wheals), purpura	Trunk
Lyme disease	Macules, papules, erythema chronicum (target or bulls-eye lesion)	Trunk, lower extremities; classically a single lesion but multiple lesions can be present
Meningococemia and purpura fulminans	Petechiae, macules, papules, purpura (may become ecchymotic)	Generalized, especially on the lower extremities; neck and face usually spared
Murine typhus	Macules, papules, morbilliform rash	Begins on inner surfaces of arms and axillae; quickly becomes generalized, involving especially the trunk (limited involvement of face, palms, and soles)
<i>Mycoplasma pneumoniae</i> infection	Maculopapular or morbilliform rash most common; a variety of rashes can be seen, including urticaria, erythema multiforme (including Stevens-Johnson syndrome), erythema nodosum, and papulovesicular lesions	Variable
North American blastomycosis	Inflammatory papules and nodules with crusts; hyperkeratotic plaques with central ulceration	Face and extremities
Parvovirus B19 infection in children	“Slapped cheeks” rash (erythema infectiosum)	Face
Parvovirus B19 infection in adults	Variable: maculopapular, purpuric, or lacy and reticular	Usually the extremities, especially distal (“gloves and socks”)
Primary HIV infection	Macules, papules, mucocutaneous ulcers, palatal papules	Face, trunk
Rat-bite fever caused by <i>Spirillum minus</i>	Maculopapular, later becoming petechial	Begins on abdomen; progresses to extremities; may involve palms and soles
Rat-bite fever caused by <i>Streptobacillus moniliformis</i>	Maculopapular or petechial	Most extensive on extremities; typically around joints; may become generalized
Rocky Mountain spotted fever	Macules, papules; later becomes petechial	Wrists and ankles initially, then palms and soles; finally, centripetal spread to face, trunk, and more proximal aspects of extremities
Scarlet fever (usually <i>Streptococcus pyogenes</i>)	Diffuse erythema with punctuate elevations (“sandpaper skin”); linear striations (Pastia lines) or confluent petechiae (which can be demonstrated on arms by applying a tourniquet)	Generalized, with sparing of area around mouth (“circumoral pallor”)
Secondary syphilis	Macules, papules, mucous patches, condylomata lata; rash is sometimes pustular	Usually generalized with involvement of palms and soles; sometimes confined to palms and soles or to face
Staphylococcal toxic shock syndrome	Scarlatiniform rash (diffuse erythema, which can resemble sunburn); strawberry tongue; desquamation late in the course	Generalized
Streptococcal toxic shock syndrome	Localized area of cellulitis or necrotizing fasciitis; sometimes general erythema as well	Localized or generalized
Stevens-Johnson syndrome and toxic epidermal necrolysis	Macules, plaques, target lesions (both typical and atypical), vesicles, bullae, erosions and blisters of mucous membranes	Generalized
Typhoid fever (<i>Salmonella typhi</i>)	Slightly raised pink macules that blanch on pressure (rose spots)	Trunk, anteriorly and posteriorly (typically in crops of about 10 to 20 lesions)
<i>Vibrio vulnificus</i> infection	Large, hemorrhagic bullae are characteristic; also, cellulitis, lymphangitis	Especially on lower extremities

Table 15-12 Localized and Generalized Lymphadenopathy of Infectious Etiology

Lymph Node Group	Some Principal Considerations
Cervical	Pharyngitis of diverse causes, mycobacterial lymphadenitis (both TB and nontuberculous mycobacteria), Kawasaki disease, localized infections of the scalp, rubella (occipital lymphadenopathy)
Supraclavicular	Granulomatous diseases, including TB (supraclavicular and scale lymph nodes often indicate malignancy)
Axillary	Localized infection of the upper extremities, cat scratch disease
Subpectoral	When cellulitis or subpectoral abscess develops presentation can suggest an intraabdominal infection
Epitrochlear	Localized infection of upper extremities, cat scratch disease, sporotrichosis, herpetic whitlow
Inguinal and femoral	STDs (notably, syphilis, lymphogranuloma venereum, herpes simplex, and chancroid), localized infection of lower extremities
Iliac	Suppurative lymphadenitis with abscess formation, usually caused by <i>Staphylococcus aureus</i> ; can be difficult to diagnose
All lymph nodes (generalized lymphadenopathy)	Heterophile-positive mononucleosis (EBV), heterophile-negative mononucleosis (CMV), HIV infection, secondary syphilis, TB, histoplasmosis, brucellosis, tularemia, measles, dengue

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; STD, sexually transmitted disease; TB, tuberculosis.

common diseases causing fever and lymphadenopathy tend to have a benign course.

Cat scratch disease is a relatively common, slowly progressive, usually self-limited regional lymphadenitis caused by *Bartonella henselae* and mainly affecting children who have had contact with a cat (typically a kitten or feral cat). Tender, occasionally suppurative lymphadenopathy occurs most often in the cervical or axillary regions. A single lymph node is involved in about half of cases. Complications include *Parinaud's ocular glandular syndrome* (granulomatous conjunctivitis with preauricular lymphadenitis), atypical pneumonia, granulomatous hepatitis, prolonged fever, encephalopathy, neuroretinitis (with star-shaped macular exudates), and osteomyelitis. Serologic testing for IgM and IgG antibodies has a 95% sensitivity and 98% specificity for diagnosis.

Toxoplasmosis in immunocompetent persons can present mainly as fever and lymphadenitis. Cats are the usual source of infection (mainly by cleaning litter boxes), but ingestion of undercooked meat (including lamb in many countries and venison in the United States) can also transmit the disease. Testing for IgM antibodies spares the patient the need for lymph node biopsy, which, if done, usually shows prominent clusters of epithelioid histiocytes surrounding the germinal centers.

HIV/AIDS

Since its recognition in 1981, HIV infection and its end-stage manifestation, AIDS, have become global concerns, affecting more than 34 million people worldwide and more than 1.1 million people in the United States, where about 50,000 new infections occur each year. About 50% of HIV-infected persons worldwide and about 15% of HIV-infected persons in the United States are unaware of their infection. HIV disease, which is spread mainly by sexual contact but also by blood exposure and mother-to-child transmission, disproportionately affects African Americans and Hispanics and Latinos.

Combination antiretroviral therapy (ART) has transformed HIV from a uniformly fatal disease to a chronic condition that is well tolerated provided the patient complies with therapy. Primary care clinicians are pivotal to early diagnosis, comprehensive care, and prevention.

Management in the primary care setting reduces the stigma of the disease and helps patients cope with attendant mood disorders, life adjustments, and social problems. Primary care clinicians who wish to assume responsibility for all aspects of the disease, including the selection of ART regimens, must invest time and effort to stay current with this rapidly evolving area of medicine. Most family medicine clinicians will find it advantageous to manage HIV-infected patients in partnership with a physician who makes this disease a substantial part of his or her practice (or, in many communities, an HIV treatment center).

HIV belongs to the viral group Retroviridae (retroviruses) and subgroup Lentiviridae (lentiviruses). Its RNA genome undergoes frequent mutations; although the average time for viral replication is about 2 days, about 10^7 mutations take place every minute leading to genetic variations. Such variations mandate strict adherence to a multidrug ART regimen to delay the emergence of drug-resistant strains. After initial infection, there is a burst of viral replication with a high level of viremia. Some, but not all, patients develop within 2 to 4 weeks (range, 1 to 6 weeks) the acute retroviral syndrome, which may present as a flulike illness, sometimes with a maculopapular rash; as a heterophile-negative mononucleosis syndrome (occasionally the Monospot test result is false positive); or as aseptic meningitis. The patient then remains asymptomatic for months to years but is fully capable of spreading the virus to others. The quantitative HIV RNA level (viral load) declines from its postinfectious peak and becomes relatively stable at a "set point" reflecting a balance between viral replication and the host response. The CD4 count gradually declines, and because CD4+ T lymphocytes are crucial to cell-mediated immunity, severe complications or death usually results after months to years (median, 2 to 3 years; range 1 to >15 years). AIDS is defined by a CD4 count less than $200/\text{mm}^3$ or by certain opportunistic infections or tumors that seldom occur in immunocompetent persons. Advances in therapy make the distinction between "HIV infection" and "AIDS" less relevant than was formerly the case.

Diagnosis of HIV Infection

HIV-infected persons come to medical attention either as a result of testing for infection or seeking help for symptoms and signs of illness. The United States Prevention Services

Task Force and the CDC now recommend voluntary testing in all health care settings after informing individuals and allowing them to opt out. Early diagnosis increases access to care and enables earlier treatment, delaying progression and reducing the risk of transmission. In the past, serologic diagnosis depended on an ELISA test followed by a confirmatory Western blot test. Newer fourth-generation HIV enzyme immunoassay (EIA) tests detect both HIV antibodies and the HIV p24 antigen, on average 6 to 7 days after infection. Rapid screening tests are inexpensive, quick, and easy to perform (<20 minutes' turnaround time), require no instrumentation, and are CLIA waived.

Testing for HIV is strongly recommended when patients between the ages of 13 and 64 years present with any of the following: (1) STDs; (2) constitutional symptoms such as fever, night sweats, anorexia, and weight loss; (3) thrush (oropharyngeal candidiasis); (4) herpes zoster in persons younger than 50 years of age; (5) asymptomatic generalized lymphadenopathy; and (5) oral hairy leukoplakia (white spike-like lesions on the lateral edges of the tongue, which represent crystals of EBV). HIV-infected persons are more likely to have severe or prolonged aphthous stomatitis and any of several skin conditions, including seborrheic dermatitis, psoriasis, molluscum contagiosum, recurrent herpes simplex, and folliculitis.

P. jiroveci pneumonia, the opportunistic infection that in June 1981 brought what is now called HIV/AIDS to world attention, remains a common presentation in persons who have not sought HIV testing or, if tested, were lost to follow-up. The onset is often insidious over weeks to even months with cough, shortness of breath, and low-grade fever. Chest radiography classically shows diffuse bilateral infiltrates, but findings may be normal in up to 30% of patients. The causative organism, now considered a fungus rather than a protozoan, can often be demonstrated in induced sputum or specimens obtained by bronchoalveolar lavage. Many, and perhaps most, patients are now treated empirically when the disease is suggested by symptoms, signs, hypoxemia, and elevation of the serum lactic dehydrogenase level. High-dose TMP-SMX is the treatment of choice in patients without a history of hypersensitivity to sulfa drugs and is supplemented with corticosteroids when hypoxemia is severe ($\text{PaO}_2 \leq 70$ mm Hg on room air). Other AIDS-defining infections include cryptococcosis, CNS toxoplasmosis (usually with multiple ring-enhancing mass lesions on CT or MRI), CMV retinitis, and disseminated *M. avium* complex disease, for which a single AFB blood culture has a 90% to 95% sensitivity. Other patients seek medical attention because of multiple firm, slightly raised or nodular, 0.5- to 2-cm violaceous or dark red skin lesions determined on biopsy to be Kaposi sarcoma.

Initial Management of HIV Disease

Diagnosis of HIV disease should prompt education about the nature of the disease, reassurance of the possibility of a near-normal life *contingent* on adherence to a drug regimen, and aggressive follow-up with peer and substance counselors and the local health department for contact investigation. All new patients should have the following tests: CD4 count, quantitative HIV RNA (viral load), HIV genotype test (to screen for drug resistance), CBC, serum creatinine (and calculated creatinine clearance), urinalysis,

tuberculin skin test (or interferon- γ release assay), anti-*Toxoplasma* IgG serology, hepatitis B screening (HBsAg, anti-HBsAg, anti-HBc, with vaccination against HBV for those who are susceptible to infection), hepatitis C virus antibody (with quantitative HCV RNA if positive), serology for syphilis (RPR), screening for gonorrhea and chlamydia infection, and chest radiography. Patients other than men who have sex with men (who can be assumed to be CMV seropositive) should have serology for CMV (anti-CMV IgG), and all women should have a cervical Pap test screening for trichomoniasis (SOR: A) (Aberg et al., 2014).

It is now recommended that ART be prescribed to *all* HIV-infected patients. At the time of this writing (February 2014), three one-pill, once-daily regimens are available, Atripla (efavirenz plus tenofovir plus emtricitabine), Complera (rilpivirine plus tenofovir plus emtricitabine), and Stribild (elvitegravir plus cobicistat plus tenofovir plus emtricitabine) (Johnson and Saravolatz, 2014). Optimally, the family physician, the consultant, and the patient should share (and maintain individually) a flow sheet with four columns: the date, the patient's CD4 count (CD4+ T lymphocyte count/mm³ of blood), the patient's viral load (copies of HIV viral RNA/mm³ of blood), and the patient's ART drug regimens. Monitoring therapy includes not only CD4 counts and viral loads but also watching for drug side effects such as dyslipidemia, glucose intolerance, and renal abnormalities. Patients should receive routine vaccines, including annual flu shots; should receive the pneumococcal vaccine; and should be vaccinated against hepatitis B if they lack anti-HBsAg antibodies.

Patients who are stable on ART with suppressed viral loads and CD4 counts greater than 200 per mm³ for more than 2 to 3 years can be seen as infrequently as every 6 months, with monitoring of their viral loads every 6 months (SOR: A) and CD4 counts every 6 to 12 months (SOR: B). Recently diagnosed patients, those with acute illnesses, and those who are failing ART or who have recently changed ART need to be seen more frequently. The viral load should be monitored more frequently after initiation or change in ART (preferably within 2 to 4 weeks and no longer than 8 weeks, with repeat testing every 4 to 8 weeks until the viral load becomes undetectable) (SOR: B). Because the CD4 count can fluctuate up to 30%, at least two CD4 counts 4 to 8 weeks apart are necessary to assess the immunologic stage of the patient's disease.

KEY TREATMENT

- All patients with confirmed HIV disease should be treated with highly active antiretroviral drugs (SOR: B).
- Patients with HIV disease must understand the extreme importance of compliance with their drug regimens (SOR: A).

Pregnancy and HIV

All HIV-infected women of childbearing age should be asked about their desires regarding pregnancy upon initiation of care and regularly thereafter. Pregnant women should receive ART, irrespective of their immunologic or virologic status, to prevent infection of the fetus (SOR: A). Infants exposed to HIV in utero should receive antiretroviral

postexposure prophylaxis and undergo HIV diagnostic testing at 10 to 21 days of life, 1 to 2 months of age, and 4 to 6 months of age (SOR: B).

Postexposure Prophylaxis

Postexposure prophylaxis (PEP) should be considered for health care workers and others who may have been exposed to HIV-infected blood during work or line of duty and also for those who may have been exposed by sexual assault, unprotected casual sex, or sex with a partner considered at high risk for infection. PEP should be given as soon as possible; logic suggests “the sooner the better,” and animal models suggest PEP is unlikely to work if initiated more than 72 hours after exposure. When persons seek PEP, two questions should be asked:

1. Was the exposure risky? All sexual exposures should be considered risky, but in other settings, risky exposures are defined as blood contact by percutaneous injury (especially if blood was present in hollow needle); blood contact by splash to mucous membranes (eyes, mouth, and nose); or contact of nonintact skin with blood, tissue, or potentially infected body fluids.
2. Was the source risky? The source patient should be identified and tested for HIV, preferably with a rapid test.

If the answer to both questions is yes, drugs should be given. Because anxiety runs high after potential exposure to HIV, it is often best to start PEP when the facts are unclear or the patient is in doubt, deferring for one to several days the decision whether to complete the 28-day course.

KEY TREATMENT

- Recommended PEP for HIV at the time of this writing is the combination of twice-daily raltegravir (Isentress) and once-daily tenofovir–emtricitabine (Truvada) (Kuhar et al., 2013) (SOR: B).

Preexposure Prophylaxis

In June 2012, based on studies in heterosexual and homosexual persons, the FDA approved the use of tenofovir plus emtricitabine (TDF–FTC) for the prevention of HIV transmission among sexually active individuals at high risk for HIV transmission.

Pathogens

The purpose of this section is to help family physicians round out their understanding of infectious diseases and to review briefly some pathogens not discussed elsewhere in this chapter.

DRUG-RESISTANT AND UNUSUAL BACTERIA

Drug-resistant bacteria are now commonplace (John and Steed, 2013). Some infections have become untreatable because of a lack of any effective antibiotic.

MRSA is perhaps the most problematic bacterial pathogen now seen in family medicine. The distinction between hospital-acquired and community-acquired MRSA strains

Key Points

- Problematic drug-resistant bacteria include MRSA, vancomycin-resistant *Enterococcus faecium*, uropathogenic T131 strains of *E. coli*, and gram-negative bacilli expressing extended-spectrum β -lactamases and carbapenemases.
- Eight human herpesviruses are now recognized; HHV-6 causes roseola infantum (sixth disease), a major cause of febrile seizures in young children, and HHV-8 causes Kaposi sarcoma in patients with advanced HIV disease.
- *Candida albicans* remains susceptible to fluconazole, but *Candida krusei* is intrinsically resistant to fluconazole, and up to 25% of *Candida glabrata* strains are now resistant.
- Cryptococcal meningitis and tuberculous meningitis should be considered in patients with chronic or persistent headache and neurologic signs, including slow deterioration of mental function.
- Primary care clinicians who live in regions endemic for histoplasmosis, blastomycosis, or coccidioidomycosis should be thoroughly familiar with these diseases and their protean manifestations.
- Although TB remains problematic in certain populations in the United States, a positive acid-fast bacillus stain or culture is now more likely to indicate a nontuberculous mycobacterium.
- Malaria caused by *Plasmodium falciparum* is the most common cause of infection-related death in returning U.S. travelers and constitutes a medical emergency.

is becoming blurred, but the latter are often susceptible to broad-spectrum antibiotics such as TMP-SMX, doxycycline, and clindamycin. MRSA strains are often less susceptible to vancomycin (minimum inhibitory concentration [MIC] ≥ 2 $\mu\text{g}/\text{mL}$) than was formerly the case. Serious infections caused by such strains are often treated with high-dose vancomycin (aiming for trough serum levels of 20 $\mu\text{g}/\text{mL}$ or higher), daptomycin (for nonpulmonary infections), or linezolid. Recent studies demonstrate that infectious diseases consultation and use of an evidence-based bundle reduce the mortality rate from *S. aureus* bacteremia (López-Cortés et al., 2013; Schmidt et al., 2014).

Coagulase-negative staphylococci are the most problematic bacteria for implant surgeons because of their ability to promote formation of biofilms (“slime”) around devices of all types, including prosthetic joints, prosthetic heart valves, cardiac pacemakers and defibrillators, vascular access catheters, CSF shunts, and others. Device removal is usually necessary. Coagulase-negative staphylococci are often multiresistant and, similar to MRSA, often show reduced susceptibility to vancomycin. Of more than 16 species of CNS, *S. epidermidis* is the most common and *S. lugdunensis* the most aggressive.

Enterococci have always posed therapeutic problems (especially when causing endocarditis), but the emergence of vancomycin-resistant enterococci (VRE, which are usually *E. faecium* rather than the more common *E. faecalis*) presents therapeutic dilemmas.

The α -hemolytic and nonhemolytic “viridians” streptococci, similar to enterococci, are commensal organisms that assume clinical importance mainly as causes of endocarditis or infections in patients with deficient host defenses. These organisms are often less susceptible to penicillin G

and ampicillin than was formerly the case. A subgroup of viridans streptococci variably known as the *Streptococcus anginosus* or *Streptococcus milleri* group is capable of causing severe infections, including brain abscess and pneumonia.

S. pneumoniae (the pneumococcus) often shows low-level (and occasionally high-level) resistance to penicillin and the third-generation cephalosporins, prompting the recommendation for combined therapy with ceftriaxone and vancomycin for life-threatening pneumococcal pneumonia and for pneumococcal meningitis.

Aerobic gram-negative bacilli now commonly resist many antibiotics, and occasionally all antibiotics. In many U.S. communities, *E. coli* resistance to ampicillin exceeds 50%, resistance to the fluoroquinolones exceeds 30%, and many isolates are resistant to TMP-SMX and other agents. Uropathogenic T131 strains (see Table 15-8) have previously been discussed. Gram-negative bacilli become resistant to the β -lactam antibiotics (see Table 15-2) by producing β -lactamase enzymes, of which there are several families: penicillinases, cephalosporinases, broad-spectrum β -lactamases, extended-spectrum β -lactamases, and carbapenemases. Carbapenemases are of concern because the carbapenems (see Table 15-2) are often the last resort for gram-negative bacillary infection. Isolates of *P. aeruginosa*, *Acinetobacter* spp., and other gram-negative bacilli are frequently resistant to aminoglycoside antibiotics.

Anaerobic bacteria are usually treated empirically because most hospital laboratories do not offer routine susceptibility testing. Historically, chloramphenicol, then clindamycin, and now metronidazole have been the drugs of choice especially for infections likely to involve the *Bacteroides fragilis* group of anaerobic bacteria. *B. fragilis* has now demonstrated its ability to be metronidazole resistant. Other anaerobes that may exhibit unique susceptibility patterns include *Prevotella*, *Fusobacterium*, and *Clostridium* spp., *Bilophila wadsworthia*, and *Sutterella wadsworthensis* (Brook et al., 2013).

Family physicians should have passing familiarity with certain infrequently isolated bacteria. Helpful acronyms include HACEK for certain fastidious gram-negative bacteria that sometimes cause endocarditis (*Haemophilus parainfluenzae*, *Haemophilus aphrophilus*, *Haemophilus paraphrophilus*, *Actinobacillus actinomycescomitans*, *Aggregatibacter aphrophilus*, *Corynebacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) and MYSFACE for aerobic gram-negative bacilli that often pose problems because of drug resistance (*Morganella morganii*, *Yersinia enterocolitica*, *Serratia marcescens*, *Providencia* species, *Proteus vulgaris*, *P. aeruginosa*, *Acinetobacter* spp., *Citrobacter* spp., and *Enterobacter* spp.).

Higher bacteria of clinical importance—called “higher” because they produce branching, filamentous forms resembling fungi—are the *Actinomyces* (anaerobic bacteria that cause actinomycosis) and *Nocardia* spp. (obligate aerobic bacteria that cause nocardiosis). *Actinomyces* species produce characteristic “sulfur granules,” and *Nocardia* spp. are often recognized microscopically by their weakly acid-fast branching filaments. The classical clinical presentations of actinomycosis are cervicofacial, pulmonary, and intraabdominal disease, typically with draining sinus tracts. Nocardiosis causes pneumonia and brain abscess and opportunistic infection in immunocompromised persons.

HERPESVIRUSES

The herpesviruses are large DNA viruses that establish life-long latent infection by poorly understood processes. Nearly 100 herpesviruses have been isolated from various animal species, eight of which are currently recognized as human pathogens (Table 15-13). Transmission usually involves person-to-person contact with transfer of an infected body fluid onto a susceptible tissue such as the eye, mouth, respiratory tract, or urogenital mucosa. Several classes of antiviral drugs are available, all of which should be used with

Table 15-13 Human Herpesviruses

Herpesvirus	Virus	Major Diseases	Route of Transmission
1	Herpes simplex type 1	Herpes labialis, herpes stomatitis, keratitis, skin lesions (herpes gladiatorum; herpes whitlow), genital ulcers, encephalitis, multiple congenital abnormalities	Close contact for both types; sexual contact especially for type 2; skin-to-skin contact in other forms, including herpes gladiatorum
2	Herpes simplex type 2		
3	Varicella-zoster virus	Varicella; herpes zoster (localized and disseminated); pneumonia, encephalitis, myelitis, cerebellar ataxia	Contact or respiratory
4	Epstein-Barr virus	Heterophile-positive mononucleosis, lymphomas, nasopharyngeal carcinoma, meningoencephalitis, lymphoproliferative syndrome (transplant recipients)	Saliva
5	Cytomegalovirus	Heterophile-negative mononucleosis; fever of unknown origin; in immunocompromised patients, retinitis, colitis, radiculopathy; multiple congenital abnormalities	Contact; bloodborne; transplantation; congenital
6	Herpes lymphotropic virus	Roseola infantum (exanthema subitum) in children (HHV-6B); numerous possible associations with various diseases including multiple sclerosis	Contact or respiratory
7	HHV-7	Fever, rash, and febrile seizures in children	Unknown
8	HHV-8	Kaposi sarcoma (common) and primary effusion lymphoma (uncommon) in persons with HIV disease; may also cause multicentric Castlemans disease	Possible exchange of body fluids

HHV, Human herpesvirus.

careful attention to routes of elimination, side effects, and drug–drug interactions.

In family medicine, antiviral drug therapy for herpesvirus infections consists almost entirely of nucleotide analogues: acyclovir, valacyclovir, famciclovir, ganciclovir, and valganciclovir. The oral bioavailability of acyclovir is only about 10% to 20% and decreases as the dose is increased. Valacyclovir is a prodrug of acyclovir that is almost completely converted to acyclovir after oral administration. Similarly, the oral bioavailability of ganciclovir is only about 5%; valganciclovir is a prodrug with superior oral bioavailability. Other drugs active against herpesviruses include cidofovir and foscarnet; these are used in special situations (Evans et al., 2013; Field and Vere Hodge, 2013).

Human Herpesviruses 1 and 2 (HSV-1 and HSV-2)

Human herpesviruses 1 and 2 are commonly known as HSV-1 and HSV-2. These viruses cause ulcers of the lips (herpes labialis) and buccal mucosa (herpes stomatitis), keratitis, skin lesions (e.g., herpetic whitlow involving the fingers, or herpes gladiatorum involving any part of the body), encephalitis (especially HSV-1), aseptic meningitis (especially HSV-2), congenital disease of the newborn, pneumonia (rare), and—of greatest concern to family physicians—lesions of the genital tract. The characteristic lesion is a vesicle on an erythematous base. Vesicular lesions are typically grouped and may be confluent. A survey of men and women age 14 to 49 years between 2005 and 2010 revealed a 54% seroprevalence of HSV-1 and a 16% seroprevalence of HSV-2.

Genital lesions are predominantly caused by HSV-2, but HSV-1 causes a significant percentage of cases. Genital herpes simplex affects about one in six persons in the United States between the ages of 14 and 49 years and is usually acquired by sexual contact, although oral-to-genital transmission occurs. Primary genital herpes often begins with fever, chills, headache, malaise, and localized pain or paresthesia before the appearance of the highly characteristic grouped vesicles. Involvement of the vulva can be especially painful. Extragenital manifestations include disturbances of bowel and bladder function; extensive ulcerations of the buttock, groin, and thighs; aseptic meningitis; transverse myelitis; and sacral radiculopathy.

Serologic testing is generally unhelpful. Viral culture is highly sensitive if done during the vesicle stage of the disease. However, PCR has become the diagnostic procedure of choice. Determining whether genital herpes is caused by HSV-1 or HSV-2 has prognostic implications because HSV-2 is associated with more frequent recurrences. All patients should receive counseling, as should asymptomatic sex partners.

KEY TREATMENT

- Antiviral drugs (acyclovir and valacyclovir) reduce the severity and duration of symptoms during the first episode of genital herpes but do not reduce the frequency of recurrence or the risk of transmission to others (SOR: A).
- Recurrent episodes of genital herpes, for which famciclovir is also approved, can be treated episodically or with continuous suppressive therapy (SOR: B).

- Strains of HSV-1 and HSV-2 resistant to the above agents are uncommon in primary care; foscarnet is usually effective but has significant nephrotoxicity (SOR: B).

Varicella-Zoster Virus

Varicella-zoster virus causes chickenpox (varicella) and shingles (herpes zoster), the latter usually resulting from reactivation of latent virus in a dorsal root ganglion. Varicella is highly contagious. Before the advent of routine vaccination in 1995, varicella typically occurred in preschool and school-aged children. A prodrome with fever, headache, and sore throat is followed by the widespread appearance of vesiculopustules on an erythematous base. The hallmark of varicella is the presence of lesions in all stages of development—in contrast to smallpox, in which the lesions are at the same stage of development at a given time. Patients are contagious 1 to 2 days before the onset of the rash and remain contagious until all of the lesions are crusted, typically 4 to 7 days after appearance. Most cases in immunocompetent persons are self-limited. Complications include secondary bacterial infections (including necrotizing fasciitis caused by group A streptococci), pneumonia, cerebellar ataxia, and encephalitis. The virus is dangerous during pregnancy; it can cause severe pneumonia in the mother, loss of the fetus, and—in cases of severe material varicella during the first half of pregnancy—a fetal varicella syndrome with irreversible abnormalities.

Herpes zoster (shingles) occurs mainly in older and immunocompromised persons, with an annual incidence in the United States of about four cases per 1000 persons. The dermatomal distribution of the vesiculopustular rash is virtually diagnostic. Complications include postherpetic neuralgia (the incidence of which sharply increases with age), ocular involvement (herpes zoster ophthalmicus, which should prompt urgent referral to an ophthalmologist), ear involvement with facial paralysis (the Ramsay Hunt syndrome), skin and soft tissue infections (including, again, necrotizing fasciitis), meningoencephalitis, pneumonia, hepatitis, acute retinal necrosis, and death—especially when the disease appears in disseminated form in immunocompromised persons.

KEY TREATMENT

- Acyclovir, if started within the first 24 hours, can reduce the severity and duration of varicella (SOR: A).
- Antiviral drug therapy reduces the incidence of postherpetic neuralgia (SOR: B).
- Administration of varicella vaccine to a susceptible child within 3 days of exposure may modify or prevent disease (SOR: A).
- Older (>60 years) immunocompetent persons should be urged to receive the varicella-zoster (shingles) vaccine even if they previously had herpes zoster (SOR: A).

Epstein-Barr Virus and Cytomegalovirus

These clinically important viruses, the respective causes of heterophile-positive and heterophile-negative mononucleosis, have been previously discussed in this chapter; some additional manifestations are shown in Table 15-13. Deep

Table 15-14 Selected Antifungal Drugs

Antimicrobial Class (Action)	Selected Agents	Selected Comments
Polyenes (bind to ergosterol in fungal cell membranes, disrupting the steric integrity of the membrane)	Amphotericin preparations: Amphotericin B deoxycholate, amphotericin B lipid complex, amphotericin B cholesteryl sulfate, amphotericin B liposomal Agents for oral or topical use: Nystatin, candicidin, others	Amphotericin B deoxycholate revolutionized the treatment of deep fungal infections but is nephrotoxic. Other toxicities include infusion-related fever, nausea, vomiting, and hypotension; hypokalemia and hypomagnesemia; metabolic acidosis; and nephrogenic diabetes insipidus. The newer “lipid formulations” are less toxic but much more expensive.
Antimetabolite pyrimidine analogue (disturbs binding of essential proteins; inhibits fungal DNA synthesis)	Flucytosine	Initially developed as an antimetabolite, flucytosine has significant myelotoxicity, including fatal bone marrow failure. Serum levels should ideally be monitored when therapy is prolonged, especially in patients with impaired renal function.
Azole compounds (inhibit lanosterol demethylase, a cytochrome enzyme of the P450 group, blocking synthesis of ergosterol)	Imidazoles: Ketoconazole, others Triazoles: Fluconazole, itraconazole, voriconazole, others	Toxicity in humans derives largely from effect on P450 enzymes. Use should take into account all drugs the patient is taking because of the potential for serious drug interactions.
Echinocandins (inhibit glucan synthesis in the cell wall by the enzyme 1,3- β glucan synthase)	Anidulafungin, caspofungin, micafungin	More reliable coverage against <i>all Candida</i> spp. than fluconazole. No clinically useful activity against <i>Cryptococcus</i> spp. Potential for drug–drug interactions. Generally well tolerated.
Allylamines (inhibit squalene epoxidase, an enzyme required for ergosterol synthesis)	Terbinafine, amorolfine, butenafine, naftifine	Mainly used for topical therapy for dermatologic conditions such as ringworm, athlete’s foot, and tinea cruris (jock itch). Rare indications for systemic use.
Griseofulvin (small molecule unrelated to other antifungals; binds to keratin precursor cells; on entering fungi, interferes with microtubules, thus inhibiting mitosis)	Griseofulvin	Mainly used for oral therapy of dermatophytosis with severe involvement of nails, hair, or large body surface areas. Contraindicated in pregnancy, severe liver disease, systemic lupus erythematosus, and porphyria. Antagonizes oral anticoagulants and contraceptives. Decreases absorption of phenobarbital.

infections caused by CMV, which occur mainly in immunocompromised patients, require referral; drugs include ganciclovir, valganciclovir, cidofovir, and foscarnet.

Other Human Herpesviruses

HHV-6 B, discovered in 1986, causes the childhood illness *roseola infantum* (also known as *exanthema subitum* or “sixth disease”), which is perhaps the most common cause of febrile seizures in children between the ages of 6 and 24 months. About 95% of adults are seropositive for HHV-7, but its role in disease is unclear. HHV-8 has emerged as the apparent cause of *Kaposi sarcoma* in HIV-infected persons, in whom it also causes *primary effusion lymphoma*. HHV-8 may also cause *multicentric Castlemann disease*.

FUNGI

Only about 150 of the nearly 250,000 identified species of fungi are known to cause disease. Noninvasive, superficial fungal infections of the skin and related structures (dermatophytosis) are discussed in the chapter on dermatology. Here we will mainly discuss candidiasis; sporotrichosis; and the “deep” mycoses, including the three major “regional” mycoses in the United States: histoplasmosis, coccidioidomycosis, and blastomycosis. The major antifungal drugs are shown in [Table 15-14](#).

Candidiasis

Candidiasis, commonly known among the laity as “yeast infection,” encompasses a wide range of mucosal, skin, and nail infections. Oral candidiasis (thrush) takes several forms: pseudomembranous, erythematous, and hyperplastic candidiasis; denture-related stomatitis (involving

Candida spp. in about 90% of cases), angular stomatitis (involving *Candida* spp., often as a mixed infection with *S. aureus*, in about 80% of cases), and median rhomboid glossitis. Candida vulvovaginitis is discussed in the chapter on gynecology; its male counterpart is candidal balanitis—infection of the glans penis, usually in persons who are uncircumcised. The multiple forms of cutaneous candidiasis and nail infection (onychomycosis) are covered in the chapter on dermatology. Esophageal candidiasis is a major problem in advanced HIV/AIDS infection and is usually treated with azole compounds (fluconazole or others, see [Table 15-14](#)).

Candida bloodstream infection (candidemia) is most likely to present in primary care practices as sepsis related to vascular access devices, especially in patients receiving hyperalimentation. Removal of the access device must be supplemented with antifungal drugs. *Candida albicans*, which is nearly always susceptible to fluconazole, is the most common isolate, but other *Candida* species may come into play. *Candida krusei* is intrinsically resistant to fluconazole and should be considered a distinct possibility whenever a patient who has recently taken fluconazole has a positive blood culture for *Candida* spp. Up to 25% of *Candida glabrata* isolates are now resistant to fluconazole. Complications of invasive candidiasis include endophthalmitis with the potential for permanent vision loss, osteomyelitis, and septic arthritis. *Candida* peritonitis results from infection of a peritoneal dialysis catheter but also occurs in patients with intraabdominal infection or necrotizing pancreatitis. *Candida* endocarditis usually occurs in patients with prosthetic heart valves; blood cultures may be sterile despite large vegetations with potential to cause embolism to major arteries.

KEY TREATMENT

- The isolation of *Candida* spp. from a blood culture should prompt a request to the laboratory for speciation, and empiric therapy either with fluconazole (if the patient is not severely ill and the likelihood of *C. krusei* or *C. glabrata* is low) or an echinocandin compound (SOR: A).
- Amphotericin B remains an alternative, with the caveat that 2 *Candida* spp.—*Candida lusitanae* and *Candida guilliermondii*—are often resistant to amphotericin B (or will develop resistance during therapy) (SOR: A).

Cryptococcosis

There are more than 30 known species of *Cryptococcus*, of which two, *Cryptococcus neoformans* and *Cryptococcus gattii*, are recognized human pathogens. The former has a worldwide distribution and is the usual cause of disease; the latter has a more local distribution, including the Pacific Northwest in the United States and British Columbia in Canada. Similar to most deep fungal infections, cryptococcosis is usually acquired by inhalation. Pulmonary disease, which can resemble pneumonia or even metastatic cancer, is sometimes discovered accidentally on a chest radiograph taken for another reason. Meningitis is the most common clinical manifestation of cryptococcosis in both immunocompetent and immunocompromised persons. Between 80% and 90% of recognized cases of cryptococcal meningitis now occur in persons with HIV/AIDS, and other cases are associated with corticosteroid therapy, lymphomas, or other conditions that suppress T-cell immunity. Immunologically intact persons with cryptococcal meningitis sometimes give a history of exposure to accumulations of aged bird droppings, such as roosting sites, attics, or vacant old buildings.

KEY TREATMENT

- Initial therapy for cryptococcal meningitis should be started in the hospital and usually consists of amphotericin B plus flucytosine whether for immunocompromised persons (SOR: A) or immunocompetent persons (SOR: B), for whom high-dose fluconazole is an alternative.

Sporotrichosis

Sporotrichosis, caused by *Sporothrix schenckii*, is encountered in primary care mainly as the syndrome of nodular lymphangitis—nodular swellings along the path of lymphatic vessels, often with recognizable linear streaks (Figure 15-11). Less commonly, this syndrome is caused by *Nocardia brasiliensis*, *Mycobacterium marinum*, *Leishmania* spp., *Francisella tularensis*, *Mycobacterium kansasii*, and various other fungi and pyogenic bacteria, including staphylococci and streptococci. Biopsy or aspiration of tissue for culture is usually required for determining the causative organism.

KEY TREATMENT

- Itraconazole is the drug of choice for sporotrichosis (SOR: A).

Figure 15-11. Hemorrhagic vesicular lesion on an erythematous base in a patient with the gonococcal arthritis–dermatitis syndrome. The lesion will rupture, leaving a tender, necrotic nodule.

Histoplasmosis

Histoplasma capsulatum is a dimorphic fungus (i.e., it assumes a yeast form in tissues but is a mold in the environment and in cultures) endemic to the soil of the Ohio and Mississippi river valleys but found occasionally throughout much of the world. Most persons residing in endemic areas become infected, but fewer than 10% come to medical attention. The disease assumes several forms. Acute pulmonary histoplasmosis is usually a mild disease but can cause high fever; chest radiographs show patchy infiltrates. Mediastinal lymphadenopathy often develops and usually remains asymptomatic; considering the possibility of histoplasmosis can spare the patient an unnecessary surgical exploration. Healed pulmonary histoplasmosis typically leaves pulmonary calcifications similar to those of healed TB. Inhalation of massive numbers of spores, especially if previous infection has conferred some degree of immunity, can cause miliary granulomatosis of the lungs that heals, leaving a “buckshot” pattern of calcification. Acute progressive disseminated histoplasmosis, which carries a mortality rate of 83% to 100% if untreated, should be considered in immunocompromised patients, especially those with HIV disease. The diagnosis can sometimes be made on peripheral blood smear. Subacute progressive disseminated histoplasmosis should be suspected in patients with combinations of fever, weight loss, localizing symptoms (especially of the gastrointestinal tract or CNS), hepatomegaly, punched-out mouth ulcers, and cytopenias. Other forms include isolated chronic cavitary lung disease, pulmonary nodules (which can enlarge over time, suggesting lung cancer), mediastinal fibrosis (which can obstruct major blood vessels and cause heart failure), broncholithiasis, and adrenal insufficiency. Urine and serum antigen tests are especially useful in persons with HIV disease, but definitive diagnosis of histoplasmosis is based on culture.

KEY TREATMENT

- Amphotericin B is the drug of choice for disseminated and severe pulmonary infection (SOR: A).
- Itraconazole is useful in other situations (SOR: A).

North American Blastomycosis

North American blastomycosis, caused by the dimorphic fungus *Blastomyces dermatitidis*, resembles histoplasmosis in many respects: endemicity in the Mississippi and Ohio river basins; acquisition by inhalation; pulmonary disease as the usual manifestation; disseminated disease, especially in severely immunocompromised persons; and use of amphotericin B for severe disease (SOR: A) but with a definite role for itraconazole. Blastomycosis differs from histoplasmosis in that it is more likely to be symptomatic (50%, vs. <10% for histoplasmosis) and more likely to secondarily involve the skin, bone, and genitourinary tract. As with histoplasmosis, serum and urine antigen tests are available, but diagnosis is optimally made by culture. However, the diagnosis is strongly suggested by a potassium hydroxide (KOH) preparation of pus, skin scrapings, or sputum, which reveals budding yeasts with a distinctive appearance: a highly refractile cell wall and a single, broad-based daughter yeast (in contrast to other budding yeasts).

Coccidioidomycosis

Coccidioidomycosis, caused by the dimorphic fungus *Coccidioides immitis*, is endemic in the southwestern United States (notably, southern Arizona, central California, southern New Mexico, and western Texas) and parts of Central and South America. The disease should be suspected in tourists and travelers returning from these areas. As with histoplasmosis and blastomycosis, the disease is acquired by inhalation, usually takes the form of pulmonary disease, but occasionally disseminates especially in persons with HIV/AIDS. Pulmonary manifestations include patchy pneumonia, pleural effusion, nodules, thin-walled cavities (~8% of patients), and chronic fibrocavitary pneumonia. Most acute pulmonary infections are self-limited and do not require treatment. Dissemination may involve the skin (with papules, nodules, plaques, or ulcers), bones, joints, and CNS. Coccidioidal meningitis carries the potential for CNS vasculitis with ischemic stroke or hemorrhage. IgM and IgG antibody tests are useful but culture is required for definitive diagnosis. Management of coccidioidomycosis involves many subtleties; the IDSA guidelines should be consulted.

Aspergillosis

Aspergillus spp. are saprophytic molds found worldwide, frequently colonizing mucosal surfaces, commonly contaminating laboratory culture specimens, and causing a spectrum of clinical syndromes:

1. *Allergic bronchopulmonary aspergillosis*, a hypersensitivity disease of the respiratory tract occurring especially in patients with asthma or cystic fibrosis, discussed earlier under the discussion of bronchiectasis
2. *Aspergilloma (fungus ball)*, developing within a preexisting lung cavity or in a paranasal sinus, is often asymptomatic but may cause life-threatening hemoptysis or, when involving a paranasal sinus, recurrent bacterial infection and locally invasive disease
3. *Superficial aspergillosis*, typically occurring as chronic otitis externa caused by *Aspergillus niger*
4. *Asymptomatic colonization of mucosal surfaces*
5. *Invasive aspergillosis*, usually in the lungs (80% to 90% of cases) of immunocompromised persons (most commonly in the setting of severe granulocytopenia) as a fulminant, rapidly progressive disease. Definitive diagnosis requires tissue biopsy because positive cultures, even if obtained by bronchoscopy, can reflect contamination. A characteristic CT appearance includes the “halo sign” and the “air-crescent sign.”

Mucormycosis

The term “mucormycosis” denotes invasive tissue infection by one or another of a diverse group of molds belonging to the order Mucorales. Most affected patients have a predisposing factor such as diabetes mellitus (poorly controlled or with a recent history of ketoacidosis), extensive trauma, burns, or an immunocompromised state. *Mucoraceae* species, such as *Aspergillus* spp., invade the walls of blood vessels, causing infarction and gangrene of tissues. Patients with rhinocerebral mucormycosis sometimes have on physical examination localized black (infarcted) areas on the nasal or palatal mucosa. Extension to the brain is life threatening. Pulmonary mucormycosis, similar to invasive pulmonary aspergillosis, occurs mainly in patients with severe prolonged granulocytopenia.

Less Common Deep Fungal Infections

Fungi belonging to the genus *Fusarium*, which cause infection in immunocompetent persons after traumatic inoculation, cause three major syndromes: fungal keratitis; onychomycosis; and chronic infections of skin, muscle, bone, or joints. The latter include *mycetoma (Madura foot)*, a slowly progressive and often painful destruction caused by various saprophytic soil fungi, including *Fusarium* spp.

Pseudallescheria boydii (the sexual or perfect stage of the organism) and *Scedosporium apiospermum* (the asexual or imperfect stage of the same organism) can cause a localized, recalcitrant infection in immunocompetent hosts. *P. boydii* occasionally causes invasive fungal sinusitis, meningitis, or disseminated infection.

The *dematiaceous fungi* are characterized by a melanin-like pigment in their cell walls that confers a dark-brown or black appearance to their hyphae or spores in tissue specimens and cultures. They cause a disease known as phaeo-hyphomycosis. The most severe form consists of invasive fungal sinusitis, which may spread to the brain.

MYCOBACTERIA

Tuberculosis remains the most important mycobacterial disease worldwide, but its incidence has been steadily declining in the United States, coincident with better control of HIV/AIDS. However, TB remains prevalent among disadvantaged populations, such as frail elderly adults, immigrants, injection drug users, homeless persons, the inner city poor, and persons infected with HIV. Today’s family medicine clinicians are more likely to encounter nontuberculous mycobacteria, especially *M. avium-intracellulare*.

Tuberculosis

Tuberculosis usually presents as a pulmonary disease but is extrapulmonary in 10% to 25% of patients worldwide. Extrapulmonary TB takes one of three forms: disseminated

(miliary) TB, which is more common in children and in immunosuppressed persons; “serosal” TB (tuberculous pleurisy, meningitis, pericarditis, peritonitis, and arthritis); and TB of solid organs (including tuberculous osteomyelitis and TB of the adrenal glands, formerly the usual cause of Addison disease).

Pulmonary TB typically manifests as some combination of fever, night sweats, productive cough, hemoptysis, anorexia, and weight loss. Imaging typically reveals upper lobe cavitory lesions (reactivation TB) but can also disclose consolidation in the apex of a lower lobe or base of an upper lobe (primary TB) or nodular lesions, with or without lymphadenopathy. In HIV-infected persons, TB may be more severe, the clinical findings atypical, and the chest radiographic findings are occasionally normal.

Latent TB is defined by a positive tuberculin skin test result or a positive interferon- γ release assay (the QuantiFERON-TB Gold test and the T-SPOT TB Test) without evidence of disease. The latter tests offer the convenience of a one-time blood sample, greater specificity for *M. tuberculosis*, and lack of an anamnestic response on repeat testing. A positive test result by either method should prompt consultation with guidelines for preventive therapy against TB with isoniazid.

Patients with AFB-positive sputum smears confirmed by molecular methods—and also those with positive AFB smears and a high index of suspicion for TB—should be started on a multidrug regimen. The standard therapy in the United States consists of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB). Patients at low risk of having a multidrug-resistant strain of *M. tuberculosis* are generally considered no longer contagious after 2 weeks of therapy even though it may take longer (≤ 8 weeks) for the sputum to become AFB smear negative. Pulmonary TB is treated for 6 months irrespective of host status, including HIV status, and should be supervised by the local or state health department.

Disseminated TB results from lymphohematogenous spread. The term “miliary” derives from the resemblance of the small granulomatous lesions to millet seeds, but granuloma formation may be absent in immunocompromised persons (notably, HIV-infected persons), children, pregnant women, or persons with alcoholism and liver disease. The presentation is often subtle. The diagnosis may require tissue biopsy.

Unexplained pleurisy, pericarditis, peritonitis, or chronic arthritis with effusion should prompt consideration of TB, but the most treacherous syndrome of “serosal TB” is TB meningitis because diagnosis is difficult, and permanent brain damage can result. Use of PCR on CSF represents a distinct advance; in a small series, a multiplex PCR had 94% sensitivity and 100% specificity for culture-confirmed TB meningitis.

See [Chapter 16](#) on pulmonary medicine for more information.

Nontuberculous Mycobacteria

Nontuberculous mycobacteria—also known as atypical mycobacteria or as mycobacteria other than tuberculosis (MOTT)—are typically environmental organisms, are not transmitted from one person to another, and are often of little or no significance when isolated from clinical

specimens. However, their clinical importance is increasing. Most hospital laboratories lack the supplies necessary to identify these organisms, and thus the clinician should know when to request referral of the isolate to a reference laboratory.

Pulmonary disease associated with NTM includes at least four syndromes:

1. Chronic cavitory pulmonary disease in patients with underlying chronic obstructive pulmonary disease, typically in white male cigarette smokers and resembling upper lobe cavitory TB but usually milder. The responsible microorganism is usually MAC or *M. kansasii*.
2. Nodular or reticulonodular pulmonary disease, often with bronchiectasis and typically in a thin white woman older than 50 years of age (the so-called Lady Windermere syndrome). These patients sometimes have a pectus excavatum deformity or mitral valve prolapse. MAC is the usual pathogen, but *M. kansasii* and *M. abscessus* also cause this syndrome.
3. Bronchiectasis in patients with cystic fibrosis. The usual isolates are MAC or *M. abscessus*, and it can be difficult to determine whether these isolates represent colonization or infection.

Chronic lower lobe pneumonia often presents as a hazy infiltrate in a patient predisposed to aspiration, usually as a result of disease of the lower esophagus. Opportunistic mycobacteria isolated in this setting include *M. fortuitum*, *M. abscessus*, *M. smegmatis*, and MAC. Because colonization by the ubiquitous organisms is commonplace, a single positive culture does not suffice for diagnosis of disease. Guidelines for diagnosis and treatment issued by the American Thoracic Society (the website is referenced in the following) should be consulted, but in general, diagnosis of nontuberculous mycobacterial disease requires (1) a compatible clinical syndrome; (2) appropriate exclusion of other diagnoses; and (3) multiple positive culture results. Transbronchial biopsy may also be required.

Distinctive syndromes of extrapulmonary disease caused by nontuberculous mycobacteria include:

1. *Cervical lymphadenitis* (scrofula), typically painless and unilateral and sometimes associated with fistula formation, occur most often in young children. MAC causes about 80% of cases in the United States; *M. scrofulaceum* also causes this syndrome, as does *M. tuberculosis* (TB). Surgical excision rather than drainage should be performed to avoid the formation of a sinus tract.
2. A lymphocutaneous syndrome resembling sporotrichosis, which constitutes an occupational hazard for those who keep aquariums and can also result from puncture wounds inflicted by fish or crabs, is caused by *M. marinum*. Outbreaks have been related to swimming pools.
3. Postoperative infections, typically occurring in incision sites or after cosmetic surgery (e.g., after breast augmentation), can result from rapidly growing mycobacteria: *M. fortuitum*, *M. chelonae*, and *M. abscessus*. When suspected, AFB cultures should be requested and the laboratory alerted to look for nontuberculous mycobacteria.

4. Unusual rheumatologic infections in tendon sheaths, bone, or bursa can be caused by MAC and *M. marinum*.
5. A painless, mobile, nodular swelling of the skin that evolves into extensive skin and soft tissue destruction with larger ulcers on an extremity occurs in tropical and subtropical climates, is known as “Buruli ulcer,” and is caused by *M. ulcerans*.
6. Positive blood cultures in patients with vascular access catheters occur occasionally in patients being treated for cancer and are associated with high fever that responds to catheter removal and antibiotic therapy. The most common isolate (86% of cases) in one series was *M. mucogenicum*.

Leprosy

Leprosy, caused by *M. leprae*, affects between 100 and 200 persons in the United States each year, occurs mainly (85% of cases) in immigrants, and is endemic in several southern states (Louisiana, Arkansas, Texas, and Mississippi). Lepromatous leprosy, manifested by symmetric skin nodules, plaques, and dermal thickening and causing facial disfiguration (“leonine” facies), occurs in persons with essentially no immunity to *M. leprae*. Tuberculoid leprosy, a less severe form, features asymmetrically distributed skin plaques and involves the peripheral nerves. The *anesthetic plaque*—a focally hypopigmented skin lesion with loss of touch and pain sensation—is the hallmark of tuberculoid leprosy. In lepromatous leprosy, but not in tuberculoid leprosy, dermal macrophages are stuffed with *M. leprae*, an organism that still defies culture in artificial media.

PARASITES

With a few exceptions, most physicians in the United States seldom encounter or even think about parasitic diseases. The epidemiologic history is crucially important to diagnosis and management. Recent and remote travel, occupation, socioeconomic status, recreation, animal exposures, and living arrangements provide valuable clues. Immuno-compromised persons, including those with HIV disease, are subject to reactivation of parasitic infections that would

otherwise lie dormant; these include toxoplasmosis, cryptosporidiosis, and disseminated strongyloidiasis.

Malaria

Malaria, the most important parasitic disease in terms of mortality, is caused by five species of *Plasmodium*: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. The clinical hallmark is fever manifested by a three-phase paroxysm: a “cold stage” with chills or shaking lasting 15 minutes to several hours, a “hot stage” of high fever lasting several hours, and drenching sweats. Fever occurring with clockwise regularity typifies malaria caused by *P. vivax*, *P. ovale*, and *P. malariae*. *P. falciparum* is life threatening, as is *P. knowlesi*, which since its recent description in macaque monkeys in Southeast Asia has been shown to infect humans. *P. falciparum* infects red blood cells of all ages, giving rise to massive parasitemia; it also adheres to endothelial cells, resulting in microvascular disease. Complications include obstruction of brain capillaries with delirium, seizures, and coma (cerebral malaria); renal failure with hemoglobinuria (“blackwater fever”); pulmonary edema; and hypoglycemia. Malaria must be considered in any returning traveler with fever. Diagnosis is made by examining thick and thin blood films. The CDC maintains a Malaria Hotline (855-856-4713), which is available to the public during normal working hours and can be contacted at all times at (770-488-7100).

Other Parasitic Diseases

Family physicians should be prepared to encounter a few parasitic diseases (e.g., lice, pinworms, scabies, and toxoplasmosis), should recognize several others that may occasionally present in their practices depending on the geographic region (e.g., cutaneous larva migrans, echinococcosis, swimmer’s itch, and—for practices with Hispanic immigrants—cysticercosis), should be aware that dirofilariasis can lead to an unnecessary thoracotomy, and should warn their young patients who enjoy warm freshwater ponds and lakes against activities such as diving that risk primary amebic meningoencephalitis (Table 15-15). Family physicians may occasionally encounter patients with

Table 15-15 Selected Parasites

Disease	Parasite (Usual Transmission)	Comments
Amebiasis*	<i>Entamoeba histolytica</i>	See text
Amebic meningoencephalitis*	<i>Naegleria fowleri</i> (enters CSF through cribriform plate; associated with warm freshwater lakes and ponds)	Rapidly progressive with mortality rate of about 95% Diagnosis can be made by demonstrating trophozoites on a wet mount of CSF
Angiostrongyliasis	<i>Angiostrongylus cantonensis</i> (ingestion of raw or undercooked snails or other vectors)	Eosinophilic meningitis or meningoencephalitis
Ascariasis*	<i>Ascaris lumbricoides</i> (food or beverages contaminated with <i>Ascaris</i> eggs)	Pulmonary symptoms with eosinophilia (PIE syndrome) Intestinal obstruction, mainly in children Pancreatic and biliary obstruction, mainly in adults
Babesiosis*	<i>Babesia microti</i> (in United States)	See text
Chagas disease (American trypanosomiasis) [†]	<i>Trypanosoma cruzi</i> Reduviid bugs (Triatominae)	Acute: febrile illness sometimes with lymphadenopathy, local swelling at site of bite (chagoma), and edema of eyelids Late: dilated cardiomyopathy, megaesophagus, megacolon, neuropathy

Continued on following page

Table 15-15 Selected Parasites (Continued)

Disease	Parasite (Usual Transmission)	Comments
Clonorchiasis	<i>Clonorchis sinensis</i> (ingestion of undercooked, smoked, or pickled freshwater fish)	Acute: fever and right upper quadrant pain caused by gallbladder obstruction Chronic: cholangiohepatitis; recurrent cholangitis; cholangiocarcinoma
Cryptosporidiosis*	<i>Cryptosporidium parvum</i> and others	See text
Cutaneous larva migrans ("creeping eruption," "ground itch," "sandworms")*	<i>Ancylostoma braziliense</i> (skin contact with contaminated soil, as by walking barefoot on beaches frequented by dogs)	Intensely pruritic, serpiginous, erythematous eruption often complicated by secondary bacterial infection induced by scratching
Cyclosporiasis*	<i>Cyclospora cayetanensis</i> (ingestion of contaminated fruits and vegetables)	Watery diarrhea, usually self-limited Outbreaks in United States traced to contaminated lettuce or raspberries
Cysticercosis†	<i>Taenia solium</i> (ingestion of undercooked pork or of raw vegetables grown in fields irrigated with untreated sewage water)	Cystic lesions in brain (neurocysticercosis) with seizures and hydrocephalus Subcutaneous nodules Eye involvement
Diphyllobothriasis*	<i>Diphyllobothriasis</i> (ingestion of raw or undercooked fish)	Nausea, vomiting, diarrhea, abdominal pain, weight loss Megaloblastic anemia (tapeworm competes for vitamin B ₁₂)
Dirofilariasis*	<i>Dirofilaria</i> spp. (mosquito bites; principle hosts are dogs, wolves, foxes, and raccoons)	Inflammatory nodules under skin or conjunctiva Pulmonary lesions that appear as coin lesions
Fasciolopsiasis	<i>Fasciolopsis buski</i> (ingestion of raw aquatic plants)	Diarrhea, abdominal pain, anemia Obstruction of biliary or pancreatic ducts Allergic reactions
Giardiasis*	<i>Giardia lamblia</i>	See text
Hookworm*	<i>Necator americanus</i> (United States); <i>Ancylostoma duodenale</i> (skin contact with egg-contaminated soil)	Pruritic lesions at site of penetration ("ground itch") Iron-deficiency anemia Intellectual impairment and growth retardation in children
Echinococcosis (hydatid disease)*	<i>Echinococcus granulosus</i> , <i>E. multilocularis</i> , <i>E. vogeli</i> , <i>E. oligarthrus</i> (ingestion of eggs)	Slow-growing masses in liver or other organs: "alveolar cysts" (<i>E. granulosus</i> , the most common form); "multilocular cysts" (<i>E. multilocularis</i>); "polycystic disease" (rare; <i>E. vogeli</i> and <i>E. oligarthrus</i>) Anaphylaxis from cyst rupture (whether spontaneous, traumatic, or during surgical extraction)
Hymenolepiasis	<i>Hymenolepis nana</i> ; <i>H. diminuta</i> (ingestion of eggs)	Usually asymptomatic May cause anorexia, abdominal pain, diarrhea, perirectal itching, and irritability
Lice*	<i>Pediculus humanus capitis</i> , <i>Pediculus humanus corporis</i> , <i>Phthirus pubis</i> (person-to-person contact [<i>Pediculus humanus capitis</i> and <i>Phthirus pubis</i>], also clothing or bed sheets [<i>Pediculus humanus corporis</i>])	Intense pruritus (from allergic reaction) often with excoriation and secondary bacterial infection from scratching in all forms Body lice (<i>P. humanus corporis</i>) can transmit epidemic typhus, trench fever, and epidemic relapsing fever Pubic lice (<i>Phthirus pubis</i>) should prompt investigation for other sexually transmitted diseases
<i>Loa loa</i> filariasis (subcutaneous filariasis)	<i>Loa loa</i> microfilaria (tabanid flies, mainly deerflies and mango [mangrove] flies)	Usually asymptomatic Local swellings (calabar swellings) in extremities caused by allergic reactions Subconjunctival involvement ("African eye worm")
Lymphatic filariasis (Bancroftian filariasis; elephantiasis)	<i>Wuchereria bancrofti</i> , <i>Brugia malayi</i> , <i>Brugia timori</i> (mosquitoes)	Elephantiasis: edema, often massive, secondary to lymphatic obstruction
Malaria†	<i>Plasmodium vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> , <i>P. falciparum</i> , <i>P. knowlesi</i>	See text
Ocular larva migrans*	<i>Toxocara canis</i> (ingestion of eggs)	Visual defects secondary to endophthalmitis, uveitis, or chorioretinitis Retinal lesion can mimic retinoblastoma, leading to enucleation
Onchocerciasis (river blindness)	<i>Onchocerca volvulus</i> (black flies)	Skin: itching and inflammation Eyes: visual defects caused by involvement of nearly any part of the eye (second only to trachoma as leading cause of blindness worldwide)
Paragonimiasis	<i>Paragonimus westermani</i> (ingestion of inadequately cooked or pickled crab ["drunken crabs"] or crayfish)	Acute: diarrhea, fever, urticaria, hepatosplenomegaly, eosinophilia Lungs: nodules or cavities with hemoptysis ("endemic hemoptysis") Can involve other organs, including the brain
Pinworm (enterobiasis)*	<i>Enterobius vermicularis</i> (usually, ingestion of eggs)	Perianal itching

Table 15-15 Selected Parasites (Continued)

Disease	Parasite (Usual Transmission)	Comments
Scabies* ("7-year itch")	<i>Sarcoptes scabiei</i> (usually, skin-to-skin contact)	Rash with intense itching and superficial borrows, often in a row Crusted scabies (formerly known as "Norwegian scabies"): severe form mainly in elderly and immunocompromised persons
Schistosomiasis	<i>Schistosoma mansoni</i> , <i>S. haematobium</i> , <i>S. japonicum</i> ; occasionally other schistosomes (contact with water inhabited by freshwater snails)	Numerous symptoms depending on the species—organ damage is mainly caused by an immune reaction to eggs Portal hypertension (with varices) and pulmonary hypertension (<i>S. mansoni</i> , <i>S. japonicum</i>) Cystitis with risk of bladder cancer (<i>S. haematobium</i>)
Sleeping sickness (African trypanosomiasis)	<i>Trypanosoma brucei gambiense</i> , <i>T. brucei rhodesiense</i> (tsetse flies)	Acute: fever, headache, pruritus, arthralgia Late: confusion, insomnia, loss of coordination, numbness
Strongyloidiasis*	<i>Strongyloides stercoralis</i> ; occasionally, <i>S. fülleborni</i>	Skin symptoms, including <i>larva currens</i> , a rapidly progressive migratory dermatitis with a wide band of urticaria and perianal involvement Diarrhea, abdominal pain, weight loss <i>Hyperinfection syndrome</i> occurs in immunosuppressed patients
Swimmer's itch (cercarial dermatitis)*	Various species of <i>Schistosoma</i> (skin penetration by larvae)	Itchy papules (inflammatory immune reaction)
Toxoplasmosis*	<i>Toxoplasma gondii</i>	See text
Trichinosis*	<i>Trichinella spiralis</i> , others (ingestion of undercooked pork or wild game)	Usually asymptomatic Acute: muscle pain, fever, weakness, periorbital edema, splinter hemorrhages in nails Rarely, myocarditis, encephalitis, pneumonia
Visceral larva migrans*	<i>Toxocara canis</i> , <i>T. cati</i> , other nematodes (ingestion of eggs in contaminated soil [often from pica in young children] or unwashed meat and vegetables)	Usually mild and self-limited. Abdominal pain, cough, fever, wheezing, irritability Rarely, cardiac or CNS involvement

CNS, Central nervous system; CSF, cerebrospinal fluid; PIE, pulmonary infiltrates with eosinophilia.

*Endemic in all or parts of the United States (in some instances, in restricted populations or geographic areas).

†Seldom acquired in the United States but may be encountered in returning travelers and in Hispanic immigrants.

delusions of parasitosis, a heterogeneous disorder that can be surprisingly difficult to manage.

PRIONS

Prions are transmissible proteins that, although lacking genetic material, cause disease in humans characterized by progressive neurologic deterioration, leading to death and pathologically by spongiform changes in the brain parenchyma. Of the five known syndromes in humans, the most important in the United States is Creutzfeldt-Jakob disease. Useful for diagnosis are MRI (which can be suggestive but diagnostic) and measurement of 14-3-3 protein in CSF (which has low sensitivity and specificity). Surgical procedures should be avoided because of the risk of contaminating instruments and exposing health care workers to this untreatable disease.

Lung Disease in Primary Care

Breathing and the heartbeat draw the line between life and death. Pulmonary disease, respiratory symptoms, and respiratory failure are common high-impact conditions. For example, asthma is the most common chronic disease of childhood. Lung cancer is now the leading cause of cancer death for both men and women in the United States. Lung cancer accounts for 28% of cancer deaths in men and 26% of cancer deaths in women ([American Cancer Society, 2013](#)). In part because of the global spread of tobacco, the World Health Organization (WHO) now lists chronic obstructive pulmonary disease (COPD) as the fifth leading cause of death, with an expected 30% increase over the coming decade ([World Health Organization, 2013](#)).

SMOKING AND OTHER RISK FACTORS FOR LUNG DISEASE

The Centers for Disease Control and Prevention (CDC) describe smoking as the single most preventable cause of premature death in the United States, contributing to more than 440,000 deaths per year, or one in every five deaths ([CDC, 2013a](#)). People who smoke have more than a 20-fold increase in risk of death from lung cancer and a 10-fold increase in risk of death resulting from bronchitis or emphysema. For women in the United States, almost twice as many deaths are caused by lung cancer than by breast cancer. Worldwide, there were 5 million deaths attributable to smoking in 2000, almost 2 million of which were related to lung cancer and other lung diseases. The WHO projects a doubling of smoking-related deaths by 2020 ([Ezzati, 2003](#)).

Smoking cessation is the most important factor in preventing lung and cardiovascular disease and all-cause mortality. Avoidance of secondary exposure to smoke, especially in the household, is also important in preventing childhood infections and asthma, as well as adult cancers ([US Department of Health and Human Services, 2006](#)). Secondhand smoke is linked to nearly 50,000 deaths per year, most caused by heart disease.

Even simple physician advice to quit smoking provides a marginal benefit of 2.5% of patients quitting successfully ([Lancaster and Stead, 2004](#)). Interventions that combine counseling plus education or group strategies plus pharmacologic treatment with nicotine replacement or specific medications can achieve sustained quit rates of 25% to 30% ([Hughes et al., 2004](#); [Solomon et al., 2005](#); [Stead and Lancaster, 2005](#)). The Agency for Healthcare Research and Quality ([AHRQ, 2008](#)) has provided a comprehensive update to previous clinical guidelines for smoking cessation and treating tobacco dependence. Counseling is most effective when it includes both practical problem solving and social support. Pharmacologic treatment, such as nicotine replacement, bupropion, and varenicline, has proved effective but is most effective when combined with counseling or group programs. The Legacy Foundation reports that ex-smokers have an average of eight quit attempts before ultimately sustaining a tobacco-free lifestyle. [Table 16-1](#) defines a strategy for helping patients to quit smoking by a simple mnemonic of “five A’s” (ask, advise, assess, assist, arrange). Motivational interviewing is an effective and non-judgmental behavioral technique that helps the patient discover their own motivations for quitting. Physicians can also play a key role in community-oriented primary care, helping to establish effective quit smoking groups and other smoking cessation programs, as well as influencing clean indoor air policies and enforcement of laws regarding sale of tobacco to minors.

DIAGNOSTIC TOOLS IN PULMONARY MEDICINE

History and Physical Examination

Diagnosis starts with the patient history and physical examination. Pulmonary symptoms may be evaluated by traditional history-of-present-illness questions, such as the character and quality of the symptoms, duration, onset, timing, exacerbating and alleviating factors, efforts at self-treatment, and the patient’s own understanding of what is causing the symptoms. For example, the symptoms of asthma may be variously described by patients as shortness of breath, wheezing, whistling, “wheezling,”

Table 16-1 The Five A's: Strategies to Help Patients Quit Smoking

Ask	Systematically identify all tobacco users at every visit. Implement an office-wide system that ensures that, for every patient at every clinic visit, tobacco use status is queried and documented.
Advise	Strongly urge all tobacco users to quit. In a clear, strong, and personalized manner, urge every tobacco user to quit.
Assess	Determine willingness to make a quit attempt. Ask every tobacco user if he or she is willing to make a quit attempt at this time (e.g., within the next 30 days).
Assist	Aid the patient in quitting. Help the patient with a quit plan; provide practical counseling; provide intratreatment social support; help the patient obtain extratreatment social support; recommend use of approved pharmacotherapy except in special circumstances; provide supplementary materials.
Arrange	Schedule follow-up contact. Schedule follow-up contact, either in person or via telephone.

From Global Initiative for Chronic Obstructive Lung Disease (GOLD); Global Strategies for the Diagnosis, Management, and Prevention of COPD, Updated 2014. Table 3.2, Brief Strategies to Help the Patient Quit; p. 20; http://www.goldcopd.org/uploads/users/files/GOLD_Report_2014_Jun11.pdf.

chest tightness, tight breathing, or poor exercise tolerance. In addition, patients often self-medicate with nonprescription and prescription medications, as well as using herbal and nonmedicinal alternative therapies, which they typically do not report to their personal physician unless specifically asked (Braganza et al., 2003).

In addition to general history taking, a detailed history of respiratory exposures and risk factors is essential. Smoking is perhaps the most important pulmonary risk factor. A detailed smoking history includes age of first smoking, quantity smoked, number of years as a smoker, other tobacco use, previous attempts to quit, and an assessment of the level of nicotine addiction. Family history can reveal relatives with immunoglobulin E (IgE)-mediated allergy or *atopy* (allergic rhinitis, asthma, eczema, nasal polyps, or aspirin hypersensitivity) or even more serious genetic risk factors, such as cystic fibrosis (CF) or α_1 -antitrypsin deficiency. Perinatal history of premature birth, neonatal respiratory failure, and ventilator care can lead to bronchopulmonary dysplasia and chronic lung disease in children who survive neonatal intensive care.

Taking a good occupational history is also essential, asking about the specific type of work the patient performs, as well as past jobs. In addition, the clinician should ask two key questions:

1. Have you ever been exposed to fumes, gases, or dusts?
2. Do your symptoms get better when you are away from work, during weekends and vacations?

Physical examination begins with vital signs. For example, tachypnea out of proportion to fever may be the first presenting sign of childhood pneumonia. The degree of respiratory difficulty may also be observed in the form of obvious shortness of breath, the work of breathing, the use of accessory respiratory muscles, and the patient's need to take a breath in midsentence (described as *three-to-four-word dyspnea*). General examination can also reveal either peripheral or central cyanosis. Clubbing of the nails can indicate chronic lung disease. Morbid obesity may be associated with obstructive sleep apnea, right-sided heart failure (*cor pulmonale*), or both.

Examination of the chest begins with inspection and progresses to percussion, palpation, and auscultation (Fitzgerald & Murray, 2005). Inspection can reveal chest deformities

(pectus excavatum or flail chest) or spinal deformities (kyphosis or scoliosis) that interfere with breathing, or an enlarged anteroposterior (AP) diameter in adults with chronically hyperexpanded lungs. Adults with morbid obesity or prior chest trauma that restricts chest wall motion can have pulmonary function tests (PFTs) consistent with restrictive lung disease of extrapulmonary origin. Infants and children in respiratory distress may have intercostal retractions.

Palpation can identify thoracic wall abnormalities, mass lesions, or tenderness and show asymmetry of chest wall expansion. Percussion of lung fields should normally be resonant. Dullness to percussion can indicate fluid in the pleural space or consolidation of the lung itself, with fluid filling the normally air-filled alveolar spaces. Both of these conditions also produce decreased breath sounds over the affected area. Hyperresonant lung fields on percussion can indicate the hyperexpansion of obstructive lung disease or even pneumothorax.

Auscultation should include listening over the upper, middle, and lower lung fields of each lung posteriorly, as well as over the apices and mid-lung fields anteriorly. The right middle lobe of the lung and the lingula of the left lung can only be heard anteriorly. In addition to identifying areas of decreased breath sounds, the quality of lung sounds on auscultation can further differentiate underlying lung pathology. Normal (vesicular) lung sounds are continuous. Other continuous breath sounds include wheezing (sibilant or musical rhonchi) and bronchial (tubular) breath sounds (sounds like "Darth Vader" or breathing through a snorkel), which occur normally over the trachea or upper anterior chest wall but indicate pathology when heard in the peripheral lung fields. Discontinuous breath sounds include the sound of small alveolar sacs popping open in fluid-based lung consolidation, which are heard as adventitious lung sounds, such as fine rales or crackles. This can occur in both bases, as in congestive heart failure, or in a more localized area, as in a lobar pneumonia. The sound has been described as similar to tufts of hair being rubbed together close to the ear.

Because decreased breath sounds and dullness to percussion can represent either fluid in the pleural space or consolidation of the lungs themselves, additional physical findings can help differentiate the two conditions. Vocal

Table 16-2 Physical Findings in Common Pulmonary Disorders

Disorder	Inspection	Palpation	Percussion	Auscultation
Bronchial asthma (acute attack)	Hyperinflation; use of accessory muscles	Impaired expansion; decreased fremitus	Hyperresonance; low diaphragm	Prolonged expiration; inspiratory and expiratory wheezes
Pneumothorax (complete)	Lag on affected side	Absent fremitus	Hyperresonant or tympanic	Absent breath sounds
Pleural effusion (large)	Lag on affected side	Decreased fremitus; trachea and heart shifted away from affected side	Dullness or flatness	Absent breath sounds
Atelectasis (lobar obstruction)	Lag on affected side	Decreased fremitus; trachea and heart shifted toward affected side	Dullness or flatness	Absent breath sounds
Consolidation (pneumonia)	Possible lag or splinting on affected side	Increased fremitus	Dullness	Bronchial breath sounds; bronchophony; pectoriloquy; crackles

Modified from Hinshaw HC, Murray JF. *Diseases of the chest*. 4th ed. Philadelphia: Saunders; 1980:23.

fremitus and tactile fremitus are increased in lung consolidation but decreased in pleural effusion. Localized *egophony* (“e-to-a” changes) indicates consolidation of that segment or lobe of the lung; it is not present in pleural effusion except in a small band just above the upper edge of the effusion.

Signs of bronchial inflammation, mucus, and obstruction in the bronchial tree include coarse crackles and wheezes (sonorous or musical rhonchi). Additionally, in normal vesicular breathing, the duration of the inspiratory phase is longer than the expiratory phase, typically 90% of the expired air is exhaled in the first second. Prolongation of the expiratory phase is an early sign of obstruction even before wheezing develops. The diagnostic implications of these physical examination findings are summarized in Table 16-2.

PULMONARY FUNCTION TESTING

Key Points

- Obstructive lung disease is diagnosed by demonstrating a ratio of forced expiratory volume in 1 second (FEV₁) to forced vital capacity (FVC) (or FEV₁/FEV₆ ratio) of less than 70%.
- Improvement in FEV₁ of at least 12% and at least 200 mL from prebronchodilator to postbronchodilator measurement is considered evidence of reversibility of airway obstruction.
- Restrictive lung disease can be diagnosed using office spirometry if the FVC is reduced to less than 80% of predicted while maintaining a normal FEV₁/FVC ratio (i.e., no obstruction).

Pulmonary function testing is essential for detecting lung disease and for differentiating obstructive from restrictive lung disease. PFTs may be done in a hospital-based pulmonary function laboratory or, more often, in the outpatient setting using office spirometry. The simplest PFT is the *peak expiratory flow rate* (PEFR), measured by handheld mechanical peak-flow meters given to patients for self-management and used in office settings and emergency departments (EDs) for quick assessment during acute exacerbations of asthma. PEFR is the maximum flow generated during

Figure 16-1 Time-volume spirometry curve showing measurement of forced expiratory volume in 1 second (FEV₁), forced vital capacity (FVC), and forced expiratory volume in 6 seconds (FEV₆) and curves for obstructive versus restrictive lung disease.

expiration performed with maximal force (“Take a deep breath and blow out as hard and as fast as you can”).

Previous office spirometry units were bulky and required frequent recalibration, but modern units are small, computerized, and often self-calibrating. The quality of testing is important. The patient should be seated comfortably and instructed appropriately. An adequate PFT must include three valid measures (quick start, good effort, maintenance of forced expiration for at least 6 seconds with no cough) and three relatively similar results (FVC varying by <200 mL).

Results of office spirometry are presented both graphically and numerically, with actual values compared with values predicted by the patient’s age, height, and gender. Figure 16-1 shows the points at which two critical values, FEV₁ and FVC, are measured on the time-volume curve. Figure 16-2 shows a typical flow-volume loop for patients that compares normal PFTs with obstructive lung disease and restrictive lung disease (Zoorob et al., 2002). Increasingly, the 6-second end point, or FEV₆, is being used as a

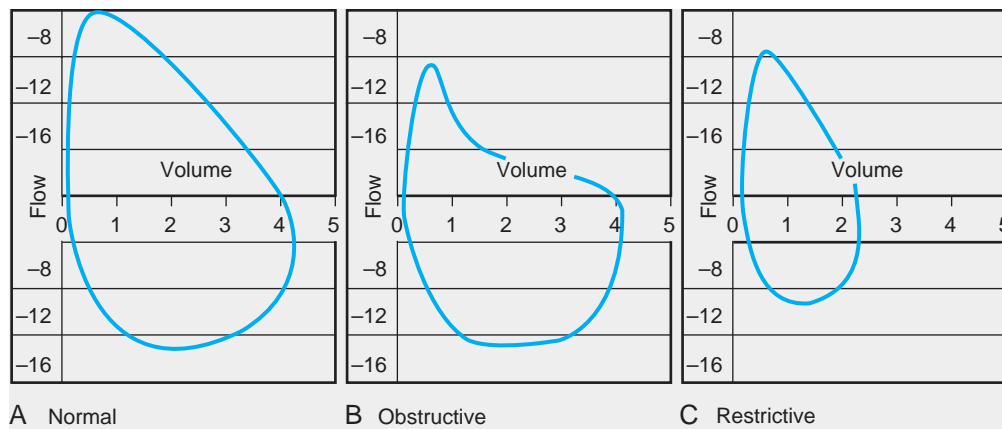

Figure 16-2 Flow-volume loop showing curves for normal (A), obstructive (B), and restrictive (C) lung disease.

reliable and reproducible surrogate measure that can replace FVC for patients who are unable to complete forced expiration beyond 6 seconds.

The key parameters of office spirometry are the FEV₁, the FVC, and the FEV₁/FVC ratio (percentage of exhaled volume blown out in first second of exhalation). The diagnosis of obstructive lung disease is made by demonstrating an FEV₁/FVC ratio (or FEV₁/FEV₆) of less than 70%. This means that the patient has exhaled less than 70% of FVC (full volume of air exhaled) in the first second of exhalation. Other tests of airway obstruction are the *midmaximal expiratory flow rate* (MMEF, or FEF₂₅₋₇₅), which is the average expiratory flow over the middle half of expiration, that is, flow rate during the time when 25% to 75% of the FVC is exhaled. This measure has been described as representing small airway obstruction, but it is less reproducible and has not been included in clinical guidelines for managing patients with obstructive lung disease. However, MMEF can be an early indicator of lung damage caused by smoking or occupational pneumoconioses. The FEF₂₅ and FEF₇₅ are moment-in-time measures of expiratory airflow and are therefore subject to significant patient-to-patient variability unrelated to clinical factors.

One other dimension of office spirometry in diagnosing and managing obstructive lung disease is to measure these parameters before and after a dose of inhaled β_2 -adrenergic agonist is given. Improvement in FEV₁ of at least 12% and at least 200 mL from prebronchodilator to postbronchodilator measurement is considered evidence of reversibility of airway obstruction. Complete reversibility helps establish the diagnosis of asthma, and it is also useful in guiding therapy by establishing the potential efficacy of medications. For example, some patients with COPD are more responsive to anticholinergic medications such as inhaled ipratropium, but others are more responsive to inhaled β_2 -agonists such as albuterol.

For restrictive lung disease, the “gold-standard” test is the *total lung capacity* (TLC), which is a measure of maximal exhaled air (FVC) plus residual capacity (RC). However, this can only be tested in pulmonary function laboratories that can test the patient in a sealed chamber. For practical purposes in the primary care setting, restrictive lung disease can be diagnosed using office spirometry if the FVC is reduced to less than 80% of predicted in the presence of a normal FEV₁/FVC ratio (i.e., no obstruction). One other test

that is available in pulmonary function laboratories but not in office spirometry is the *diffusion capacity* (DLCO), which is a measure of the diffusion of carbon monoxide across the alveolar-capillary membrane. Clinical reductions in DLCO can occur with thickening of the alveolocapillary membrane, which can be a sign of interstitial fibrosis.

CHEST RADIOGRAPHY AND OTHER DIAGNOSTIC IMAGING

Despite major advances in imaging technology, the chest radiograph is still an important diagnostic modality that can clearly reveal signs of pneumonia, COPD, heart failure, tuberculosis (TB), lung masses, and pleural effusion. Figure 16-3 shows a chest radiograph with right middle lobe pneumonia. Although the posteroanterior (PA) radiograph shows some consolidation, it is attenuated by the overlying projection of a normal lower lobe. The lateral radiograph, however, shows the classic wedge-shaped profile of a consolidated right middle lobe.

Chest radiography is also widely used in evaluating patients with suspected exposure to TB because of symptoms, personal contact, or a positive intradermal purified protein derivative (PPD) test result. Figure 16-4 shows the patchy infiltrates and hilar adenopathy typical of pulmonary TB, although TB can have a variety of presentations on chest radiography, including adenopathy, pleural scarring, infiltrates, cavitary lesions, and miliary TB.

Chest radiography can also be helpful in diagnosing non-pulmonary causes of shortness of breath, as in the case of congestive heart failure, with enlarged heart, bibasilar consolidation, small pleural effusions, and prominent pulmonary vasculature. In other conditions such as asthma, chest radiography findings can be quite normal despite significant respiratory compromise.

Chest computed tomography (CT) scan plays an important role in diagnosing lung disease. High-resolution CT (HRCT) can identify pulmonary nodules and hilar lymph nodes at much smaller sizes than can chest radiography, and it is therefore important in diagnosing and staging lung cancers. CT can also detect lung abscess, vascular lesions, and pleural scarring or masses. Whereas early COPD or emphysematous changes can be difficult to detect with even HRCT, additional techniques such as minimum-intensity projection can aggregate data from adjacent slices and, by

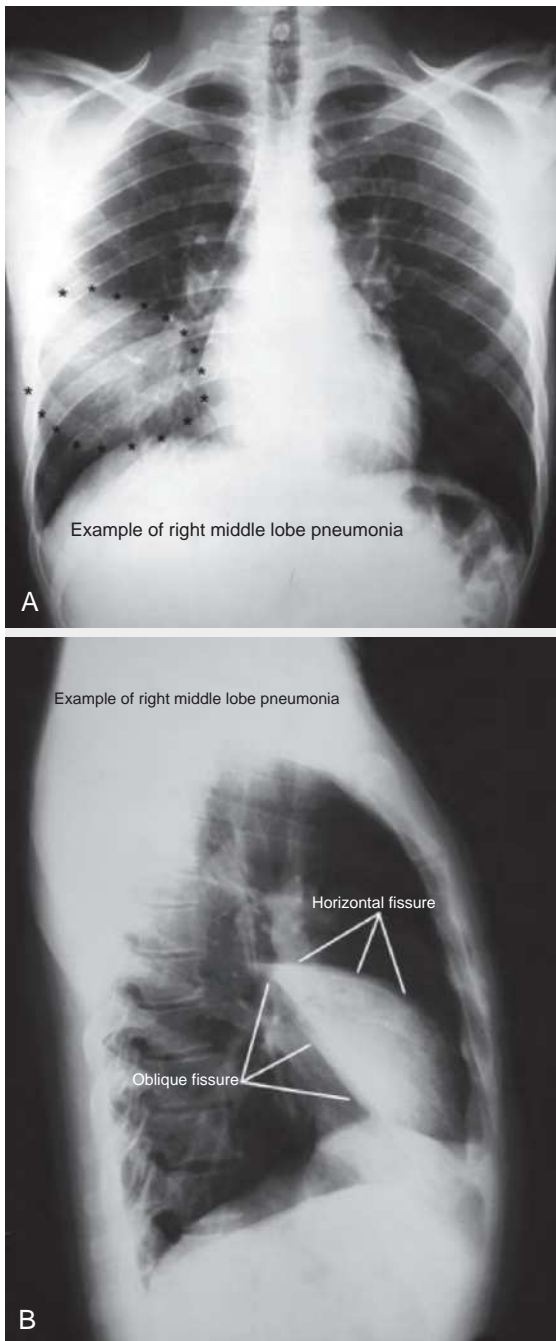

Figure 16-3 Posteroanterior (A) and lateral (B) chest radiographs showing right middle lobe pneumonia. (From Department of Neurobiology and Developmental Sciences, University of Arkansas for Medical Sciences, Little Rock. http://anatomy.uams.edu/anatomyhtml/xrays/xra_atlas39.html and http://anatomy.uams.edu/anatomyhtml/xrays/xra_atlas5.html.)

subtracting vascular and other tissue densities not consistent with lung parenchyma and air, demonstrate small air pockets consistent with early emphysema.

Imaging modalities such as spiral CT have been demonstrated to be effective in detecting early lung cancer in patients with high-risk smoking histories. The United States Prevention Services Task Force (USPSTF) now recommends yearly low-dose CT-scan screening for lung cancer in adults aged 55 to 80 years who have a 30 pack-year smoking

Figure 16-4 Chest radiograph showing tuberculosis with upper lobe fibrotic patchy infiltrates and hilar adenopathy. (From Centers for Disease Control and Prevention, Public Health Image Library, Image 2543. <http://phil.cdc.gov/phil/home.asp>.)

history and currently smoke or have quit within the past 15 years (US Preventive Services Task Force, 2013). When small, noncalcified pulmonary nodules are detected by CT, the likelihood of malignancy is influenced by nodule size, density, number of nodules, and growth over time, combined with patient factors such as age, smoking history, gender, spirometry, occupational history, and endemic granulomatous disease (Libby et al., 2004).

Positron emission tomography scans using ^{18}F -fluorodeoxyglucose (FDG-PET) are becoming increasingly useful in evaluating lung cancers and lymphomas. The ability to define anatomy and metabolism—that is, glucose uptake within the tumor—makes the PET scan useful for staging; detecting node involvement; and defining resectability, tumor response to therapy, and tumor recurrence (Avril and Weber, 2005). Diagnosing solitary pulmonary nodules is a common challenge in primary care. A meta-analysis of studies comparing dynamic CT, magnetic resonance imaging (MRI), FDG-PET, and single-photon emission computed tomography (SPECT) scans based on positive and negative likelihood ratios for identifying malignant versus nonmalignant solitary nodules found that all four were similarly accurate (Cronin et al., 2008). Nuclear medicine studies such as gallium scans are also used extensively in evaluating pulmonary symptoms in patients with human immunodeficiency virus (HIV) infection or acquired immunodeficiency syndrome (AIDS) and are discussed in more detail in the section on HIV-related pulmonary infections.

Other imaging studies have more specific indications. One nuclear medicine study long used in primary care is the ventilation/perfusion (V/Q) scan. This is specifically performed to rule out pulmonary embolism (PE), revealed by focal perfusion defects in adequately ventilated areas. This V/Q mismatch, in the absence of underlying lung pathology, is consistent with a high probability of PE. Unfortunately, patients can also demonstrate matching V/Q defects, which can occur when blood flow is shunted away from an underventilated area of the lung. Scans with no perfusion defect reflect a low probability for significant PE. Other tests

are increasingly taking the place of V/Q scans (see later discussion).

BRONCHOSCOPY

Fiberoptic bronchoscopy allows direct visualization of the bronchial tree. It is useful for diagnosing conditions that require culture of a lower respiratory tract infection by bronchoalveolar lavage (BAL) or conditions such as bronchogenic carcinoma that require tissue diagnosis by transbronchial biopsy. Sometimes these techniques are combined, as in the diagnosis of *Pneumocystis jiroveci* (*carinii*) pneumonia (PCP), for which the sensitivity of bronchoscopy with BAL is approximately 86% and with transbronchial biopsy is 87% (Broaddus et al., 1985). A comparative assessment of different bronchoscopic techniques in obtaining culture specimens in cases of ventilator-associated pneumonia found no significant difference between blind bronchial brushings and bronchoscope-assisted lavage, bronchoscope-directed brushings, or even blind endotracheal aspirates (Wood et al., 2003). Rates of complications (including hemoptysis and pneumothorax) with traditional bronchoscopy are in the range of 0.5% to 1.0% without biopsy and up to 6.8% with transbronchial biopsy (Pue and Pacht, 1995). In a pulmonary fellowship program, the rate of complications for all bronchoscopies performed (with and without biopsy) was 2.06% (Ouellette, 2006). Therapeutic interventions using bronchoscopy are also increasing, and lesions are treated through the bronchoscope with laser, cryotherapy, electrocautery, and stents (Rafanan and Mehta, 2000).

Newer diagnostic techniques include fluorescent bronchoscopy, which can be more sensitive for detecting early endobronchial tumors (Gilbert et al., 2004; Moghissi et al., 2008), and virtual bronchoscopy, which uses sophisticated software to reconstruct images from HRCT scans to create three-dimensional imagery without invasive testing. This technique has been found useful in planning partial lung resection surgery, for example, but it cannot provide bronchoscopy's direct visualization of color, texture, or friability of the bronchial mucosa (Finkelstein et al., 2004).

MEASUREMENT OF BLOOD GASES

Measurement and monitoring of blood gases can be invasive or noninvasive. Transcutaneous pulse oximetry is the most widely used noninvasive test. It provides a fairly accurate measure of oxygen saturation (SO_2) of hemoglobin at values ranging from 70% to 100% by measuring the difference between oxyhemoglobin and reduced hemoglobin in the absorption of light of specific wavelengths. SO_2 of 98% corresponds to an arterial oxygen partial pressure (PaO_2) of 100 mm Hg and 95% to a PaO_2 of 80 mm Hg, demonstrating the challenge of interpreting a test with a 95% confidence interval of $\pm 5\%$. An oxygen saturation of less than 89% corresponds to a PaO_2 of less than 60 mm Hg. Decreased tissue perfusion or color changes caused by jaundice or intravascular dyes can degrade accuracy. Arterial oxygen levels can also be measured transcutaneously ($tcPO_2$) with a skin surface oxygen electrode, but its accuracy is also affected by tissue perfusion, skin temperature, and other factors.

Exhaled carbon dioxide can also be measured noninvasively, most often in the intensive care unit (ICU) for patients on mechanical ventilation or in operating rooms during general anesthesia. Capnography, colorimetric techniques, and CO_2 sensors can detect failure of mechanical ventilation or improper endotracheal tube placement, which generate hypercapnia secondary to hypoventilation.

The invasive technique most often used for measuring oxygen, CO_2 , and acid–base blood chemistries is the arterial blood gas (ABG) measurement. Although it requires an arterial needle puncture and several milliliters of blood, it is highly accurate and reproducible. ABG measurement is indicated in any patient with acute respiratory distress or in managing patients with respiratory failure. In addition to PaO_2 and arterial carbon dioxide partial pressure ($PaCO_2$) measurements, ABG testing also provides a measure of pH, bicarbonate (HCO_3^-), and the anion gap, which can be used to detect respiratory (rather than metabolic) causes of acidosis and alkalosis. Patients with moderate to severe COPD can have chronic hypoxia plus chronic hypercapnia (decreased PaO_2 and increased $PaCO_2$). They can also show signs of primary respiratory acidosis (reduced pH with elevated CO_2) and a compensatory metabolic alkalosis (partial normalization of the pH despite elevated $PaCO_2$) mediated by renal HCO_3^- retention. Nomograms or software used in personal digital assistants allow simultaneous plotting of pH, CO_2 , and HCO_3^- to facilitate interpretation of mixed respiratory and metabolic acid–base disturbances.

COMMON PULMONARY SYMPTOMS

Shortness of Breath

A common presenting symptom in pulmonary disease is shortness of breath. The fundamental question in patients presenting with recent-onset or episodic shortness of breath is this: Is it a lung problem, a heart problem, or something else? The most common pulmonary causes of chronic or repeated episodes of shortness of breath include asthma, smoking-related COPD, chronic lung infections (TB and HIV-related infections), and occupational pneumoconiosis. Acute-onset shortness of breath can be caused by acute exacerbations of any of these chronic conditions, by acute infections such as pneumonia or acute bronchitis, or by spontaneous pneumothorax. Among otherwise healthy children, shortness of breath can be related to asthma, bronchiolitis, pneumonia, or upper airway problems such as croup or epiglottitis. Chronic shortness of breath in children can be related to poorly controlled asthma, bronchopulmonary dysplasia from infancy, or chronic diseases (e.g., CF).

The cardiovascular system is the other organ system most often linked to shortness of breath. In adults, congestive heart failure (CHF) is a leading cause of recent-onset shortness of breath among middle-aged and older adults. In addition to shortness of breath, patients might report symptoms of wheezing from the pulmonary congestion, often referred to as *cardiac asthma*. Differentiating early CHF from pulmonary causes of dyspnea can be a challenge in middle-aged or older patients who smoke or have other chronic medical conditions. Other cardiac conditions associated with shortness of breath include pericarditis and cardiomyopathy, as well as congenital heart defects in

infants presenting with respiratory distress. Vascular conditions include chronic pulmonary hypertension and PE in the setting of acute-onset shortness of breath.

Along with the history and physical examination, testing can help in ruling out pulmonary versus cardiac causes of dyspnea. Physicians often begin diagnostic testing with electrocardiography (ECG) and even echocardiography to rule out cardiac causes of shortness of breath, but simple history, auscultation of the heart and lungs, chest radiography, and office spirometry can also help diagnose or rule out common pulmonary causes of shortness of breath. Improvement on weekends or nonworkdays can suggest an occupational exposure, and a prolonged expiratory phase with expiratory wheezing suggests obstructive lung disease. Orthopnea and pedal edema suggest a cardiac cause. Bibasilar rales suggest fluid in the lower lung fields from CHF. ECG can approximate chamber enlargement and identify arrhythmias that might decrease ventricular filling time. Echocardiography can measure ejection fraction and systolic or diastolic dysfunction indicating heart failure, local wall motion abnormalities suggesting ischemic disease, and valvular abnormalities. Levels of B-natriuretic protein have a 90% sensitivity and 76% specificity for CHF; levels less than 100 pg/mL make CHF unlikely as the principal cause of shortness of breath or wheezing (Mueller et al., 2005). Chest radiography can help rule out pulmonary or other thoracic mass lesions, lung infections, granulomatous or interstitial lung disease (ILD), pleural disease, pneumothorax, and cardiomegaly, supplemented with CT as needed. Although young patients with normal physical examination findings have a low yield on chest radiography, up to 86% of patients older than 40 years with dyspnea have an abnormal chest radiograph (Benacerraf et al., 1981). Spirometry showing an FEV₁/FVC ratio less than 70% is diagnostic of obstructive lung disease, and an FVC less than 80% of predicted value in the presence of a normal FEV₁/FVC ratio suggests restrictive lung disease.

Many patients present primarily with dyspnea on exertion. The 6-minute walking exercise test is a valid measure of exercise tolerance (compared with maximal exercise testing) in patients with COPD and other pulmonary conditions, as well as in various stages of CHF. It can be performed in primary care settings to assess functional disability and response to therapy (American Thoracic Society [ATS], 2002; Lipkin et al., 1986). In patients with pulmonary hypertension, the distance walked with encouragement in 6 minutes in a controlled environment is also a strong independent predictor of mortality (Miyamoto et al., 2000).

Formal cardiac ECG stress testing by exercise treadmill can quantify the level of exercise tolerance and diagnose cardiac ischemia or angina-equivalent conditions, in which a person has ischemia-induced shortness of breath but no chest pain. However, the test has a sensitivity of only 63% and specificity of 74% (86% specificity in the setting of three-vessel or left main coronary artery disease) (Gibbons et al., 1997). Other types of cardiac stress testing, such as exercise echocardiography or the nuclear medicine thallium treadmill test, can be more specific (see Chapter 27) (Mayo Clinic, 1996). The American College of Cardiology and American Society of Echocardiography published a consensus guideline on the appropriate use of stress echocardiography for specific clinical scenarios (Douglas et al.,

2008). For patients unable to exercise, increased cardiac work may be induced pharmacologically, but dipyridamole and adenosine can each cause bronchospasm and should be avoided in patients with asthma or any other obstructive lung disease or undiagnosed pulmonary conditions (Tak and Gutierrez, 2004).

The presentation of patients with acute-onset shortness of breath requires more urgent evaluation. In addition to history and physical examination, a peak-flow test, chest radiography, ECG, complete blood count, and pulse oximetry or ABG testing may be done in short order. Further testing or treatment is guided by the differential diagnosis generated by this initial evaluation. Cardiac isoenzymes and troponin levels can help rule myocardial infarction in or out. If asthma is suspected, responsiveness to a trial of inhaled bronchodilator is both diagnostic and therapeutic. Antibiotics are initiated in cases of pneumonia or other pulmonary infection, and HIV testing can help in cases of suspected opportunistic infections (e.g., PCP).

Any suspicion of PE as a cause of acute shortness of breath requires specific diagnostic evaluation to allow quick intervention in this potentially life-threatening condition. Acute-onset shortness of breath coupled with pleuritic chest pain, hemoptysis, wedge-shaped pulmonary infarct lesions on chest radiographs, and an S1Q3 pattern on ECG can all point specifically to a diagnosis of PE, but most patients have a more nonspecific presentation. All patients with acute-onset shortness of breath with no apparent cause should be evaluated for PE. Physical examination for signs of deep vein thrombosis (DVT) (e.g., asymmetry in calf or thigh diameter, calf tenderness, Homans sign) are relatively insensitive and nonspecific, but other tests (e.g., D-dimer, CT angiography) can more accurately confirm the presence of significant underlying DVT. Clinical decision rules using objective scoring algorithms help establish pretest probability, which in turn enhances the predictive value of other tests for PE (Wells et al., 2000) (see later discussion).

Cough

Cough is also a common presenting symptom in primary care. Although cough can be part of a constellation of symptoms that leads to a specific diagnosis, it can also be the primary symptom in an undifferentiated patient. In these cases, the diagnosis must be obtained through a combination of careful history, physical examination, limited diagnostic testing, and often a trial of empiric therapy. Several elements of the history guide the initial differential diagnosis, especially a history of smoking, immunocompromise (HIV/AIDS or cancer chemotherapy), chronic pulmonary disease, medication use (angiotensin-converting enzyme [ACE] inhibitors), specific occupational exposures, or exposure to TB patients or TB-endemic areas.

Acute episodes of cough, defined as less than 3 weeks, are almost always caused by an acute infection (usually viral) or an acute exacerbation of chronic disease such as asthma or COPD, and the first rule should be to “do no harm” (*primum non nocere*) by treating conservatively and using time as a diagnostic test. Most episodes of acute cough caused by infection are viral in origin, mainly viral upper respiratory tract infections or acute bronchitis. Acute bacterial infections include sinusitis as well as bacterial

overgrowth in exacerbations of chronic bronchitis or COPD. Fever, hemoptysis, or significant shortness of breath in association with cough indicates a chest radiograph or other immediate diagnostic evaluation. Frank hemoptysis can require urgent bronchoscopy for diagnosis and potentially for treatment (electrocoagulation of bleeding site). Without evidence of bacterial infection (clear evidence of sinusitis or pneumonia), previously healthy patients should generally be treated symptomatically without antibiotics unless symptoms persist for more than 3 weeks.

Foreign body aspiration is a diagnostic consideration in children with either acute or chronic cough. Exacerbations of asthma, as well as infections by *Bordetella pertussis* (whooping cough) or *Bordetella parapertussis*, can lead to a persistent cough for as long as 3 to 8 weeks. Cough might indeed be the only symptom experienced by some patients with asthma (cough-variant asthma). In patients with underlying chronic bronchitis or COPD, antibiotics may be indicated during episodes of increased shortness of breath, wheezing, hypoxia, or limitations of activity if accompanied by a sudden change in sputum from thin and clear to thick or copious or yellow-green. Other subacute or chronic infections include bronchiectasis, which can manifest with a cough productive of mucopurulent, blood-tinged, or foul-smelling sputum. In children with chronic productive cough or recurrent pulmonary infections, CF must be considered. Survivors of premature birth with mechanical ventilation in neonatal intensive care may have chronic lung disease with acute exacerbations.

In adults, the most common causes of chronic cough in nonsmokers are postnasal drip, asthma, gastroesophageal reflux disease (GERD), and ACE inhibitors (Holmes and Fadden, 2004). Among smokers, chronic bronchitis, bronchiectasis, and bronchogenic carcinoma (lung cancer) must also be considered. Additional elements of the history can suggest other diagnoses. For example, occupational exposures can suggest specific diagnoses such as coal miner's lung or farmer's lung. Immigration from or travel to TB-endemic areas could suggest TB.

After the history and physical examination, chest radiography is the most valuable diagnostic test in evaluating the patient with chronic cough. Chest radiography can reveal infections (atypical pneumonia or TB), mass lesions (carcinoma), granulomatous disease (sarcoidosis), or evidence of occupational lung disease. Radiography can also reveal nonpulmonary causes of chronic cough, such as early CHF or pleural lesions. Office spirometry may also be performed to rule out obstructive lung disease.

In an otherwise healthy nonsmoker with chronic cough and normal chest radiography findings, a trial of simple measures may be indicated. Persons being treated with an ACE inhibitor should be switched to alternative medication. Patients with occupational exposures should avoid the exposure or use protective equipment and should begin keeping a log to document the association of symptoms with days spent in workplace areas of exposure. Patients with signs of allergic rhinitis or postnasal drip may begin a simple trial of antihistamines. Patients with symptomatic GERD may begin taking a proton pump inhibitor (e.g., omeprazole) or H₂ antagonist. In some cases, chronic cough is the only symptom of GERD, and a successful trial of these agents is diagnostic.

Follow-up is essential, and the primary care practitioner must document instructions to patients that those who do not respond to empiric therapy in 2 to 3 weeks need further diagnostic evaluation. If asthma is suspected and initial office spirometry revealed normal pulmonary function, a simple approach is to ask the patient to keep a log of symptoms and morning peak-flow meter readings. In patients with an abnormal chest radiography findings or in smokers with chronic cough that does not respond to empiric therapy, HRCT scan or even bronchoscopy may be indicated to rule out malignancy. Less common conditions may also present as chronic cough. These include sarcoidosis, TB, and other granulomatous or ILDs, as well as pulmonary manifestations of autoimmune disease, such as rheumatoid arthritis (RA) or systemic lupus erythematosus (SLE).

Patients with HIV/AIDS or other compromise of the immune system deserve specific evaluation (Chapter 15). HIV testing may be indicated in patients with any risk factors because pulmonary symptoms can be the first manifestation of symptomatic HIV disease. In patients known to be HIV positive, tests in addition to chest radiography and HRCT could include gallium scan, PET, bronchoscopy with BAL for stains and cultures, PPD, and sputum testing for PCP.

Obstructive Lung Disease

The most common chronic lung diseases that have a major global impact on disability and health care costs are three obstructive lung diseases: asthma, COPD, and chronic bronchitis. Some patients have features of more than one of these conditions, such as a patient with asthma (acute episodes of reversible obstruction) who also has chronic bronchitis (cough productive of phlegm at least 3 months of the year for at least 2 years in a row) or an adult patient with asthma who is developing some level of irreversible decline in pulmonary function. COPD alone can ultimately result in pathologic signs of emphysema, a diagnosis previously made only with tissue pathology or large blebs on radiography but increasingly visible with high-resolution imaging.

ASTHMA

Key Points

- Asthma is defined as an inflammatory, episodic, obstructive lung disease that is completely reversible.
- Self-management is focused on improving symptom-free function and decreasing risk of adverse outcomes through control of environmental triggers, regular peak-flow monitoring, action plans, and long-term controller medications, a combined strategy that can prevent or abort most flare-ups of asthma.
- All patients with persistent asthma (daytime symptoms more than twice a week or nocturnal symptoms more than twice a month) should be treated with daily long-term control medication, preferably an inhaled corticosteroid (ICS).
- Eliminating passive exposure to smokers is the most important intervention in eliminating environmental triggers.

Asthma is a chronic inflammatory airway disease characterized by recurring acute episodes of reversible airway obstruction, with return to normal lung function between episodes. Although bronchospasm is a component of the reversible airway obstruction, recent clinical guidelines have emphasized the inflammatory pathophysiology of asthma (National Heart, Lung and Blood Institute, 2007). Therefore, the clinician must treat and prevent the inflammation that leads to mucosal edema, secretions, histologic remodeling of the airways, and bronchospasm of smooth muscle origin.

Epidemiology and Risk Factors

Asthma is the most common chronic disease of childhood and affects many adult patients as well. The prevalence of asthma is increasing rapidly worldwide. It now affects more than 300 million people and causes the loss of more than 15 million disability-adjusted life-years (DALY) each year (*Global Initiative for Asthma, 2006*). Asthma prevalence is increasing in many countries and is not decreasing globally, despite some indications of decreased emergency care use linked to improved care (*Anandan et al., 2010*). In the United States, National Health Interview Survey (NHIS) data (*National Center for Health Statistics, 2011*) suggest that 20 million Americans would report currently having asthma (72 per 1000 people). Asthma affects an estimated 6.1 million children nationally (83 per 1000). There were 384,588 hospital admissions with a principal diagnosis of asthma in the United States in 2011, with an average charge per hospitalization of more than \$20,000. That same year, total hospital charges for asthma admissions in the United States added up to \$8 billion (*Agency for Healthcare Research & Quality [AHRQ], 2011a*). Focusing on children, asthma was the primary diagnosis for more than 700,000 childhood ED visits in 2011, and one in 10 of these children seen in the ED were hospitalized (*AHRQ, 2011b*).

Asthma is also a high-disparity condition. Low-income, uninsured, and minority patients with asthma consistently receive worse care and have worse outcomes compared with patients with asthma in the general population (*Lang and Polansky, 1994*). Hospitalization rates in the United States are 3.3 times higher for black than for white patients (*National Center for Health Statistics, 2011*). Publicly insured and uninsured patients are significantly more likely to be hospitalized and to seek ED care during acute exacerbations (*Targonski et al., 1995*).

The strongest risk factors for developing asthma are exposure to household smokers and a family history of asthma or atopy (asthma, atopic dermatitis, or allergic rhinitis). A family history of nasal polyps or aspirin hypersensitivity can also suggest a risk for IgE-mediated atopic disease. Data are mixed on the impact of breastfeeding and early exposure to pets as protective factors in the development of asthma (*Adler et al., 2005*), although the benefits of puppies and breastfeeding should be self-evident.

Clinical Presentation and Diagnosis

A complete history in patients suspected of having asthma should include the frequency and severity of recent symptoms and should distinguish between daytime and nocturnal symptom frequency, a factor that is also important in staging asthma. A history of past or present smoking

(tobacco or other drugs) is essential, as is an inquiry about current passive exposure to smokers in the household or occupational secondary exposure to tobacco smoke (e.g., bartenders, restaurant staff). The clinician should also inquire about activities, acute illnesses, or environmental exposures that trigger episodes; a family history of asthma or atopic disease; and a detailed occupational history. Some patients are also exposed to bronchial irritants through hobbies such as woodworking or oil painting.

Symptomatically, patients can present with complaints of chronic or acute episodic shortness of breath, wheezing, chest tightness, or a chronic cough (often at night). If they already have a diagnosis of asthma, they may report relief with rescue inhalers such as albuterol. Some patients, especially children, only have nocturnal cough, a syndrome known as *cough-variant asthma*, but others have symptoms precipitated mostly by exercise or by breathing in cold air.

On physical examination, the patient might have obvious difficulty breathing or audible wheezing during an acute episode. Patients with significant shortness of breath can have difficulty completing a full sentence without taking a breath. Inspection can reveal nasal flaring, breathing through pursed lips, central or acral cyanosis, hyperexpansion of the chest, or use of accessory respiratory muscles. In more extreme cases, patients appear to have respiratory exhaustion, central or distal cyanosis, or even a blunting of mental status.

On auscultation, the earliest sign of airway obstruction is a prolonged expiratory phase (expiratory phase longer than inspiratory phase). A more obvious sign of asthma is expiratory wheezing. Wheezing can sometimes be brought out by forced expiration, performed by asking the patient to blow out forcefully while the examiner listens over the second intercostal space at the right sternal border. More severe cases of obstruction can result in both inspiratory and expiratory wheezing. In the most severe cases, wheezing might not be audible at all because airflow is minimal. In these cases, wheezing becomes much more prominent as airflow improves. Another sign of severity of an acute episode is *pulsus paradoxus*, defined as a decrease in systolic blood pressure of more than 20 mm Hg during inspiration.

A more objective measure of pulmonary function during an acute exacerbation of asthma is to measure the peak flow of air during forced expiration using a simple, low-cost peak-flow meter. Airflow is measured in liters per second. The best of three attempts is recorded as the peak-flow measurement. Results can be measured against nomograms based on the patient's age, gender, and height, but a better measurement is to compare the patient's peak flow during the acute episode against his or her baseline or best performance during a period of complete remission from asthma signs or symptoms.

When patients present with a history of asthma-like symptoms in the primary care setting, the diagnosis can be confirmed with office spirometry, a form of pulmonary function testing. The essential criterion for a diagnosis of airway obstruction is an FEV₁/FVC ratio of less than 70%. To diagnose asthma, the clinician must also demonstrate reversibility with inhaled bronchodilators, either through the patient's history or improvement in the FEV₁ of greater than 200 mL or 12%. Because asthma is defined as an obstructive lung disease that is completely reversible

between episodes, testing in the office during asymptomatic periods might not demonstrate airway obstruction. In this case, it is helpful for the patient to use a peak-flow meter at home, testing three times each morning and recording the best value, as well as testing during symptom episodes. The record of these values can be reviewed with the family physician to aid in diagnosis, as well as for coaching the patient in self-management and prevention of future episodes.

Chest radiography is not always indicated if the patient has a classic history of episodic airway obstruction, especially if it is reversible with β -agonist rescue inhalers. In infants and children, however, the physician must distinguish upper airway causes of obstruction from obstructive lung disease. Examples include croup or laryngotracheobronchitis, epiglottitis, and foreign bodies lodged in the upper airway. In infants and older adults, the clinician must also exclude so-called cardiac asthma, which manifests as wheezing or other signs of airway obstruction related to pulmonary edema or CHF. In these patients, chest radiography is clearly indicated.

Patients older than 40 years who have new-onset asthma should have a complete workup to rule out other causes of airway obstruction. Many clinicians order chest radiography in all patients with new asthma, although there is a low rate of finding pathology in otherwise healthy older children and young adults. Chest radiographs obtained during an acute episode of asthma can give false-positive findings of infiltrates or atelectasis.

Treatment

The National Asthma Education and Prevention Program (NAEPP) guidelines provide a comprehensive and evidence-based approach to the clinical care of asthma (National Heart Lung and Blood Institute, 1997; [NAEPP Expert Panel Report 3, 2007](#)). Unfortunately, there is a large gap between best practice guideline-based care and usual care, as measured by compliance with these national guidelines ([Thier et al., 2008](#)) and by the clinical outcomes achievable when these guidelines are followed.

Acute Exacerbations. The mainstay of treatment for acute exacerbations of asthma is an inhaled β -agonist medication such as albuterol. Although β -agonist medication is typically administered in the ED or physician's office with a nebulizer machine, a meta-analysis of controlled trials showed that a handheld metered-dose inhaler with a spacer device is at least as effective as a nebulizer in delivering albuterol and achieving a clinical response, as measured by pulmonary function and by clinical outcomes such as hospitalization ([Castro-Rodriguez and Rodrigo, 2004](#)). Adding ipratropium bromide to albuterol nebulizer treatments for patients with severe airflow obstruction in the acute ED setting produces additional bronchodilation, resulting in fewer hospital admissions ([Plotnick and Ducharme, 2000](#); [Rodrigo and Castro-Rodriguez, 2005](#)).

Additional modalities of treatment include oxygen by nasal cannula or mask, and intravenous (IV) fluids for hydration. Short-term administration of systemic corticosteroids has also been demonstrated to be effective. Corticosteroids may be given intravenously (methylprednisolone), intramuscularly (dexamethasone or equivalent), or orally (prednisone or methylprednisolone). When given for 3 to 5 days as burst or pulse-dose therapy, steroids do

Table 16-3 MAP for Asthma Care

Management plan	What do I do every day to control my asthma?
Action plan	What do I do when I have acute symptoms or my peak-flow meter values are dropping?
Prevention plan	What can I do to control asthma triggers and prevent acute flare-ups?

not need to be tapered to prevent adrenal suppression. However, patients with chronic or severe exacerbations of asthma may require prolonged tapering to prevent rehospitalization for recurrence of airway obstruction.

Intravenous magnesium sulfate has also shown significant benefit in decreasing the rate of hospitalization of ED patients with acute asthma and in improving pulmonary function and clinical symptom scores ([Cheuk et al., 2005](#)). The most recent NAEPP Expert Panel Report ([NAEPP Expert Panel Report 3, 2007](#)) now recommends considering using IV magnesium sulfate or heliox-driven albuterol nebulizer treatments in patients who have failed to respond to 1 hour of conventional asthma therapy. Heliox alone (in place of oxygen) is not effective ([Rodrigo et al., 2003](#)). Children treated with theophylline during hospitalizations for acute asthma exacerbations required more albuterol treatments and had longer hospital stays than children not treated with theophylline ([Goodman et al., 1996](#)).

Chronic Care and Disease Management. To achieve optimal outcomes, each patient should have a personal asthma care plan, which can be summarized in the mnemonic MAP ([Table 16-3](#)). The *management* plan refers to daily medications or activities such as measuring peak flow; an *action* plan is needed for specific steps to take in the event of increased symptoms or deteriorating peak-flow values; and a *prevention* plan focuses on understanding personal and environmental triggers, such as avoiding passive exposure to cigarette smoke and eliminating dust mite and cockroach antigens. Treatment is focused on reducing symptoms, increasing functional capacity, and reducing the risk of adverse outcomes (missed school days, ED visits, hospital admissions, and death).

Appropriate chronic care requires appropriate staging of the clinical severity of asthma. Stage 1 is intermittent, and stages 2, 3, and 4 all represent persistent (mild, moderate, and severe) disease. Criteria for classification of patients into stages 1 to 4 are shown in [Figure 19-1](#) and [19-2](#). This staging of asthma is done based on the level and frequency of symptoms or airflow obstruction before beginning treatment. The patient's step is determined by the *most severe* feature, and classification refers to symptoms *before* starting treatment. Pharmacologic treatment of asthma is linked to this classification, as shown in the treatment algorithm (see [Figures 19-3](#) and [19-4](#)).

A critical decision point is to decide if the patient has *persistent* disease as described by these criteria. Evidence suggests that primary care clinicians routinely underclassify the severity of asthma and thus undertreat with daily antiinflammatory, long-term control medications. NAEPP guidelines suggest that only patients with truly intermittent disease—that is, patients with normal peak flow readings, daytime symptoms no more than twice a week, and nighttime symptoms no more than twice a month—should be

Table 16-4 Estimated Comparative Daily Doses for Inhaled Corticosteroids for Adolescents (Age 12 Years) and Adults

Drug	Amount	Daily Dose (μg)		
		Low	Medium	High
Beclomethasone HFA	40 or 80 $\mu\text{g}/\text{puff}$	80-240	>240-480	>480
Budesonide DPI	90, 80, or 200 $\mu\text{g}/\text{inhalation}$	180-600	>600-1200	>1200
Flunisolide	250 $\mu\text{g}/\text{puff}$	500-1000	>1000-2000	>2000

From National Heart, Lung and Blood Institute, NHI, Expert Panel 3 (EPR3). Guidelines for the Diagnosis and Management of Asthma. National Asthma Education and Prevention Program (NAEPP) Coordinating Committee, 2007. <http://www.nhlbi.nih.gov/guidelines/asthma/asthgdln.htm>.

treated with intermittent medication alone. All other patients—those with mild, moderate, or severe persistent disease—should be treated with daily antiinflammatory, long-term control medication such as an inhaled corticosteroid (ICS). One study has been cited as providing evidence allowing intermittent therapy of patients with mild to moderate persistent asthma, but the study results actually found that daily budesonide therapy produced greater improvements in prebronchodilator FEV₁, bronchial reactivity, sputum eosinophils, exhaled nitric oxide levels, scores for asthma control, and the number of symptom-free days but not in postbronchodilator FEV₁ or in reported quality of life (Boushey et al., 2005).

A meta-analysis found that ICSs reduced asthma exacerbations by 55% compared with placebo or short-acting β -agonists, and long-acting β -agonists (LABAs) reduced flare-ups by only 26% (Sin et al., 2004). Similarly, a Cochrane Database review found that inhaled steroids at a dose equivalent to 400 $\mu\text{g}/\text{day}$ of beclomethasone are more effective than leukotriene antagonists and that ICSs should be considered first-line monotherapy for persistent asthma. Patients with mild to moderate disease achieve similar levels of asthma control taking low doses (200 $\mu\text{g}/\text{day}$) as high doses (500 $\mu\text{g}/\text{day}$) of fluticasone, and side effects are greater with higher doses. A dose equivalency chart for inhaled steroids is shown in Table 16-4. Unfortunately, adherence to daily ICSs can be as low as 20% in real-world surveillance outside of clinical trials (Rust et al., 2013).

New approaches to monitoring therapy by measuring the fraction of exhaled nitric oxide (FE_{NO}) could theoretically allow better adjustment of inhaled-corticosteroid doses but have not been widely adopted (Smith et al., 2005). High-dose ICSs are useful primarily in weaning patients from oral steroids.

Other second-line long-term control agents include long acting beta agonists (LABAs; salmeterol, formoterol), long-acting anticholinergics (tiotropium), leukotriene receptor antagonists (LTRAs), inhaled mast cell stabilizers (cromolyn, nedocromil), and theophylline. Although each has demonstrated efficacy, none is as effective as ICSs. When low-dose ICSs are not providing complete remission, the clinician may add a second medication or increase the inhaled steroid dose to moderate levels. In a controlled trial

of an inhaled LABA (formoterol) versus theophylline versus a leukotriene antagonist (zafirlukast) as second-line agents added to ICS therapy, Yurdakul and colleagues (2002) found that the LABA was more effective in preventing exacerbations and had fewer side effects than the other options. A Cochrane review of 12 controlled trials also found that LABAs were more effective than leukotriene antagonists as add-on therapy to inhaled steroids (Ram et al., 2005). Concern persists, however, that LABAs can increase mortality rates when used as monotherapy in the absence of ICSs (Abramson et al., 2003b). Adding tiotropium bromide to low-dose ICS therapy is superior to doubling the dose of the ICS and equivalent to adding a LABA (SOR: A; Peters et al., 2010). The leukotriene synthesis inhibitor zileuton appears to improve pulmonary function and decrease need for β -agonist but causes significant elevations of liver transaminases in 2% to 3% of patients (Nelson et al., 2007).

Immunotherapy also appears to be effective. A Cochrane review found that allergen immunotherapy reduces asthma symptoms and use of asthma medications at a level similar to that of ICSs (Abramson et al., 2003a). A third-line therapy is the once- or twice-monthly injection of monoclonal anti-IgE antibodies (omalizumab), an expensive therapy that is associated with a 98% to 99% reduction in free IgE and significantly fewer exacerbations of asthma, even allowing some patients to be weaned from ICSs (Walker et al., 2003).

Prevention

Even though dust mites are usually mentioned as a controllable environmental trigger, a Cochrane review of 49 controlled trials found no evidence that either physical or chemical methods aimed at reducing exposure to house dust mite allergens had any benefit (Gotzsche et al., 2004). On the other hand, a controlled trial of an intervention to reduce cockroach and dust mite allergens and passive exposure to tobacco smoke among urban children with atopic asthma was effective in reducing both allergens in the home and asthma symptom days (Morgan et al., 2004). Teaching patients to self-monitor and self-manage their asthma using an action plan and ongoing review with their physician is effective in reducing exacerbations and symptoms (Gibson et al., 2002). For children, parents of other children with

asthma can serve effectively as peer counselors and may be especially effective in reducing cultural and linguistic barriers (Flores et al., 2009). As with most pulmonary diseases, the most effective preventive strategy is to eliminate smoking as a risk factor from the patient, the household, and the workplace.

KEY TREATMENT

- Daily ICSs significantly reduce exacerbations and hospitalizations in patients with persistent asthma and are significantly more effective as first-line long-term control agents than any alternative agents (Sin et al., 2004) (SOR: A).
- LABAs are more effective than leukotriene antagonists as add-on-therapy to inhaled steroids. Because most benefits of ICS are achieved at lower doses, adding a LABA to a low or medium dose of ICS is preferred over using a higher dose of ICS. LABAs should not be used as monotherapy because of a higher risk of death (Food and Drug Administration black box warning) (NAEPP EPR-3; Ram et al., 2005) (SOR: A).
- Adding ipratropium bromide to albuterol nebulizer treatments for patients with severe airflow obstruction in the acute ED setting produces additional bronchodilation, resulting in fewer hospital admissions (Plotnick and Ducharme, 2000; Rodrigo and Castro-Rodriguez, 2005) (SOR: A).
- Theophylline is an acceptable (but not preferred) alternative to LABA for second-line long-term control treatment in combination with ICSs, but theophylline or aminophylline should not be used in the acute treatment of ED or in-hospital patients (SOR: A).
- Teaching patients to engage in effective self-management improves clinical outcomes (Gibson et al., 2002) (SOR: A).
- Nurse care managers, community health workers, and parents as peer counselors can improve asthma self-management and clinical outcomes (SOR: B).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE AND CHRONIC BRONCHITIS

Consensus statements from the Global Initiative for Chronic Obstructive Lung Disease known as the GOLD guidelines (Global Initiative, Global Strategy, 2014) define COPD as a postbronchodilator FVC of less than 80% of predicted in a patient with evidence of airway obstruction (FEV_1/FVC ratio $<70\%$) that is not completely reversible (Global Initiative Pocket Guide, 2014). Although some patients with asthma, especially those who smoke, can progress to varying degrees of irreversibility consistent with COPD, the underlying pathophysiology and inflammatory mechanisms in asthma are distinct from those found in patients with COPD.

Epidemiology and Risk Factors

In large part because of the global spread of tobacco addiction, WHO estimates that COPD is already the fifth leading cause of death and will soon be the fifth leading cause of disability as well. In the United States, there were 729,030 hospital admissions with a principal diagnosis of chronic

obstructive lung disease in 2011, with an average length of stay of 4.4 days and in-hospital mortality rate of 1.4%. One third of these admissions were in relatively young 45- to 64-year-old adults (AHRQ, 2011c).

Smoking is the most important risk factor for COPD and causes ongoing damage in COPD patients, as measured by an accelerated decline in FEV_1 compared with nonsmokers or ex-smokers. Among COPD patients who have quit smoking, exposure to secondhand smoke can also be a trigger factor for acute exacerbations, as can variation in environmental air quality (ozone and small particulates). In many countries, indoor kitchen smoke can be a major source of damage to the respiratory tract in settings where daily cooking over indoor fires or charcoal is common. Other trigger factors for acute exacerbations include acute upper respiratory infections, sinusitis, exposure to dust or pet dander, and intercurrent illness. However, when patients reach a more severe stage of illness in which pulmonary reserves are minimal, almost any small change (e.g., fatigue, stress, change in weather) can trigger an exacerbation.

The other major risk factor for the development of COPD is the inherited disorder α_1 -antitrypsin deficiency. The recognition of this disease and its cellular mechanisms of injury to the lung have led to a specific understanding of protease and antiprotease imbalance as one mechanism of disease progression of emphysematous COPD. Any patient who develops COPD without a significant smoking history, any patient with a strong family history of COPD, and any patient developing clinically significant COPD before age 45 years should be screened for α_1 -antitrypsin deficiency. A detailed discussion of genetic counseling of patients with α_1 -antitrypsin deficiency or carrier state can be found in the *ATS and European Respiratory Society (2003) consensus standards*.

Clinical Presentation

Chronic obstructive pulmonary disease includes the two overlapping clinical conditions of chronic *bronchitis* and *emphysema*, which can coexist in the same patient. A practical clinical approach is to diagnose COPD by documenting obstruction that is not completely reversible on pulmonary function testing and then assess whether the patient also has a component of chronic bronchitis—that is, cough productive of phlegm at least 3 months of each year for at least 2 years. Some patients meet this criterion for chronic bronchitis before developing clinical or spirometric evidence of obstructive lung disease. The international GOLD guidelines no longer categorize this as stage 0 COPD because of insufficient evidence that patients will inevitably progress to obstructive lung disease.

Often, patients who smoke have had a chronic smoker's cough for years and present for medical treatment only when symptoms such as shortness of breath on exertion or at rest begin to appear. The hallmark symptom of symptomatic COPD is progressive and persistent shortness of breath. Because of the built-in reserve of the pulmonary system, such functional disability often is not noticed until there is a substantial decline in pulmonary function and substantial damage to lung parenchyma. Still, the U.S. Preventive Services Task Force recommends not screening routinely with spirometry for obstructive lung disease or declining lung function.

Comorbidities are often present, and they must be managed with COPD if patients are to have optimal clinical outcomes and quality of life. For example, CHF can eventually occur after years of elevated right-sided pulmonary pressure (right-sided failure leading ultimately to biventricular failure), or patients might simply experience smoking-related myocardial infarctions and coronary ischemia in parallel with their COPD. Symptomatic COPD has a powerful adverse effect on quality of life, and a substantial proportion of patients with COPD develop comorbid depression. Chronic hypoxia and air hunger can also generate significant anxiety.

Diagnosis and Severity Assessment

By the time many patients present for treatment, the diagnosis of COPD is apparent. In addition to symptoms of dyspnea, chronic productive cough, and functional limitations, patients can show physical findings of lung hyperexpansion (increased lung span on percussion, increased thoracic AP diameter, and use of accessory muscles of respiration). Extrathoracic signs include peripheral or central cyanosis, nail clubbing, and signs of increased central venous pressure or even right-sided heart failure. [Table 16-5](#) presents the differential diagnosis and distinguishing features of COPD suggested by the GOLD guidelines. Any patient who develops COPD without a significant smoking history, or any patient developing COPD before age 45 years, should be screened for α_1 -antitrypsin deficiency. HRCT can help identify granulomatous or ILDs or provide evidence of bronchiectasis.

Spirometry is the key to making a formal diagnosis, as well as for grading the severity of illness. COPD may be diagnosed when obstructive lung disease is not fully reversible, defined as a postbronchodilator FVC of less than 80% of predicted in a patient with evidence of airway obstruction (FEV_1/FVC ratio $<70\%$). A pattern of restrictive lung disease (FVC $<80\%$ of predicted in the presence of a normal FEV_1/FVC ratio) would suggest alternative diagnoses, such as pulmonary fibrosis, sarcoidosis, autoimmune conditions, or primary CHE.

Although there are several classification systems for severity of COPD, the ATS guidelines and the international GOLD standards are similar. They are based on spirometric criteria—the presence of obstruction and the level of impairment in FEV_1 —and correlate strongly with exacerbations and 3-year mortality but less so with perceived quality of life and functional limitations. According to the TOWARDS a Revolution in COPD Health (TORCH) study, moderate COPD (GOLD 2) has a 3-year mortality rate of 11% compared with 24% for very severe COPD (GOLD 4) ([Calverly et al., 2007](#)). One validated survey instrument recommended by the Global Initiative on COPD is the eight-item COPD Assessment Test (CAT), which assesses a broader range of symptoms than just breathlessness, which is the focus of the modified British Medical Research Council (mMRC) scale ([GOLD, 2013b](#)). A CAT score greater than or equal to 10 is considered a high score with regard to categorizing symptoms for treatment decisions. The 6-minute walk test is another way to assess COPD by its impact on daily activities. A distance of less than 149 meters walked in 6 minutes of encouraged walking indicates more severe functional limitation, and a distance

Table 16-5 Differential Diagnosis of Chronic Obstructive Pulmonary Disease* (GOLD Guidelines)

COPD	Onset in midlife Symptoms slowly progressive Long smoking history Dyspnea during exercise Largely irreversible airflow limitation
Asthma	Onset early in life (often childhood) Symptoms vary from day to day Symptoms at night and early morning Allergy, rhinitis, or eczema is also present Family history of asthma Largely reversible airflow limitation
Congestive heart failure	Fine basilar crackles on auscultation Chest radiograph shows dilated heart, pulmonary edema Pulmonary function tests indicate volume restriction, not airflow limitation
Bronchiectasis	Large volumes of purulent sputum Often associated with bacterial infection Coarse crackles or clubbing on auscultation Chest radiograph or CT shows bronchial dilation or bronchial wall thickening
Tuberculosis	Onset at all ages Chest radiograph shows lung infiltrate Microbiologic confirmation High local prevalence of tuberculosis
Obliterative bronchiolitis	Onset at a younger age and in nonsmokers May have history of RA or fume exposure CT on expiration shows hypodense areas
Diffuse panbronchiolitis	Most patients are male and nonsmokers Almost all have chronic sinusitis Chest radiography and HRCT show diffuse small centrilobular nodular opacities and hyperinflation

*These features tend to be characteristic of the respective diseases but do not occur in every case. For example, a person who has never smoked may develop chronic obstructive pulmonary disease (COPD), especially in the developing world where other risk factors may be more important than cigarette smoking, and asthma may develop in an adult and even elderly patients.

CT, Computed tomography; HRCT, high-resolution computed tomography; RA, rheumatoid arthritis.

farther than 350 meters indicates minimal limitation ([Celli et al., 2004](#)).

Treatment

Acute Exacerbations. The course of COPD is characterized by patients' daily coping with chronic obstruction, punctuated by episodic exacerbations that can be life threatening and only partially responsive to treatment. Initial evaluation includes the patient's assessment of the severity of symptoms, plus physical examination, chest radiography, and ABG tests. Predicting which patients can be safely discharged from the ED versus those who need to be hospitalized requires evaluation of both clinical and psychosocial indicators ([Smith et al., 2000](#)).

Chest radiography can reveal underlying causes of an acute exacerbation, such as pneumonia or CHF. ABGs are useful in assessing initial hypoxia and hypercapnia but also in monitoring the patient's response to judicious use of supplemental oxygen administered by nasal cannula or mask. Although relief of hypoxia reduces symptoms and improves cardiac function, it can also decrease the respiratory drive in a patient with chronic hypercapnia and partially compensated respiratory acidosis. For this reason, ABGs should be repeated within 30 minutes after starting oxygen, and ongoing hypoxia may be monitored with pulse oximetry (although oximetry becomes less accurate at SO_2 levels $<70\%$).

An immediate response is expected from inhaled β_2 -agonist therapy in asthma, but the response to bronchodilators in acute exacerbations of COPD can be modest. Some patients are more responsive to anticholinergic bronchodilators such as ipratropium, and others respond to β_2 -agonist agents, so these therapies are often combined in the acute setting. At home, patients can increase the dose or frequency of current medications or add a short-term agent to their chronic therapy (e.g., adding albuterol doses to LABA or adding ipratropium to chronic tiotropium therapy). Either spacer devices or mechanical nebulizer delivery systems may be used. Treatment of acute exacerbations of COPD with systemic corticosteroids (administered orally or parenterally) can reduce treatment failures by more than 50% and improve short-term dyspnea and PFT results, but there is some increase in adverse effects (Wood-Baker et al., 2005). Continuing these systemic steroids beyond 2 weeks has not been shown to have a significant benefit.

Other acute treatments for COPD exacerbations include the nonspecific phosphodiesterase (PDE) inhibitors such as theophylline and aminophylline, which have some bronchodilating effect and may also have a positive effect on the central drive to breathe, on diaphragmatic contractility, and on some mechanisms of bronchial inflammation. More specific PDE-4 inhibitors such as roflumilast have anti-inflammatory effects and significantly improve FEV_1 while reducing exacerbations (McIvor, 2007) but have significant gastrointestinal (GI) side effects as well as mental health concerns (depression and suicidal thoughts). Their role in the treatment of COPD remains uncertain.

Antibiotics are indicated if there are signs of pneumonia, sepsis, or other bacterial infection. Recent changes in sputum production (copious, thick, multicolored, or blood tinged) just before the exacerbation can indicate bacterial overgrowth of chronically inflamed bronchial mucosa, another indication for antibiotics. Because of chronic bacterial colonization, second- and third-generation antibiotics may provide greater benefit.

Indications for hospitalization include the severity of underlying illness, significant worsening during this exacerbation, failure of home or outpatient treatment efforts, significant comorbidities (CHF, arrhythmias, or electrolyte imbalance), and underlying pneumonia or other acute causes. Indications for admission to the ICU or perhaps even intubation and mechanical ventilation include severe dyspnea unresponsive to initial therapy; change in mental status (e.g., confusion, lethargy); or severe or worsening hypoxia ($PaO_2 < 40$ mm Hg), hypercapnia ($PaCO_2 > 60$ mm Hg), or respiratory acidosis ($pH < 7.25$). In a

meta-analysis of treatment strategies for patients hospitalized with an exacerbation of COPD, Quon and colleagues (2008) found that systemic corticosteroids decreased treatment failures by 46% and hospital stay by 1.4 days, although risk of hyperglycemia increased almost sixfold. Antibiotics also decreased treatment failures by 46% and the in-hospital mortality rate by 78%. Noninvasive positive-pressure ventilation (NPPV) reduced the risk of intubation by 65%, the in-hospital mortality rate by 55%, and hospital stay by 1.9 days. Noninvasive intermittent positive-pressure ventilation (NIPPV) is an option for treating moderate to severe respiratory failure in patients who have normal mental status, are stable hemodynamically, and do not have a high risk for aspiration. About 80% of patients improve symptomatically within 4 hours of initiating NIPPV (Putinati et al., 2000; Wijkstra, 2003). On the other hand, chronic nocturnal use of NIPPV has yet to show significant benefit (Wijkstra et al., 2003).

Perhaps just as important as managing the pulmonary disease is to make sure other conditions do not complicate the exacerbation. Unless there are specific contraindications, a patient hospitalized for COPD exacerbation should be started on subcutaneous heparin to prevent DVT. Cardiac monitoring is often indicated in the ED and beyond to assess and treat related arrhythmias or cardiac ischemia. Electrolyte abnormalities are quite common, especially in the setting of rapidly changing $Paco_2$ and acid-base balance. The incidence of pneumonia in ICU patients ranges from 7% to 40%, and the mortality rate from ventilator-associated pneumonia can be as high as 50%. Prophylactic antibiotics can reduce the incidence of respiratory infections in ICU patients by up to 50%, but antibiotics do not reduce the mortality rate (Liberati et al., 2004). Comorbid anxiety and depression are both extremely common and can benefit from consultation and collaborative care with behavioral health specialists.

Chronic Care and Disease Management. Each patient with COPD also needs an ongoing care plan, which includes the MAP elements described for asthma patients (daily management plan, action plan for acute exacerbations, and prevention plan). The treatment of acute exacerbations is described earlier, but each patient should have an individual action plan for increasing symptoms to prevent hospitalization. Such action plans might include symptoms or signs that would trigger a call to the physician, as well as use of short-acting β_2 -agonists (albuterol, terbutaline), short-acting anticholinergic (ipratropium), or oral steroids. Use of short-course antibiotics triggered by changes in phlegm (increased sputum or change in sputum from clear to yellow-green) is common but untested by controlled trials.

A meta-analysis of controlled trials assessed the impact of various modalities of treatment for COPD (Sin et al., 2003). Outcome measures included hospitalizations, exacerbation rates, and health-related quality of life. ICSs, long-acting β_2 -agonists (salmeterol, formoterol), and the long-acting anticholinergic tiotropium each decreased exacerbation rates by 20% to 25% in patients with moderate to severe COPD. The greatest effect was in patients with a FEV_1 of 1 to 2 L. Combining ICSs with a long-acting β_2 -agonist provided modest additional benefit (30% reduction

Table 16-6 Treatment Guidelines for COPD Symptoms and Risk

Category	Symptoms	Risk	First Choice Treatment	Alternative Treatments
A Low symptoms / low risk	Low (CAT score < 10)*	Low Low = GOLD grade 1-2 and 0-1 exacerbations per year	Short-acting inhaled β-agonist or anticholinergic prn*	Long-acting inhaled β-agonist or anticholinergic (or combine both short-acting classes)
B High symptoms / low risk	High (CAT score > 10)	Low Low = GOLD grade 1-2 and 0-1 exacerbations per year	Long-acting inhaled β-agonist or long-acting anticholinergic	Long-acting inhaled β-agonist and long-acting anticholinergic
C Low symptoms / high risk	Low (CAT score < 10)	High High = GOLD grade 3-4 or > 2 exacerbations per year	Inhaled corticosteroid plus long-acting inhaled β-agonist or plus long-acting anticholinergic	Long-acting inhaled β-agonist and long-acting anticholinergic or either of these plus a PDE-4 inhibitor
D High symptoms / high risk	High (CAT score > 10)	High High = GOLD grade 3-4 or > 2 exacerbations per year	Inhaled corticosteroid plus long-acting inhaled β-agonist and plus long-acting anticholinergic	Inhaled corticosteroid plus either long-acting inhaled β-agonist or long-acting anticholinergic and plus a PDE-4 inhibitor

*Short-acting inhaled β-agonist or anticholinergics (or both) may be considered for add-on as needed (prn) use at any level. Consider theophylline in special circumstances (cost, tolerance of or response to other therapies).

CAT, Chronic obstructive pulmonary disease assessment test; PDE, phosphodiesterase.

Table summarizing Global Initiative (GOLD) guidelines for treatment of COPD, see Tables 4 and 7 (pp. 10,19) of Global Initiative Pocket Guide, 2014.

in exacerbations). Tiotropium may be added to ICSs and LABAs as triple therapy (Decramer et al., 2009). Oral theophylline also appears to have some beneficial effects as an antiinflammatory nonspecific PDE-inhibiting bronchodilator but perhaps also in increasing the central drive to breathe. As a result, there are improvements in FEV₁, PaO₂, and PaCO₂, although these must be weighed against potentially significant side effects of theophylline, such as nausea, tremors, and palpitations.

Pharmacologic therapy of COPD is guided by focusing on the parallel goals of decreasing symptoms (to enhance functional capacity and quality of life) and reducing the risk of adverse outcomes (hospitalization and death). Based on high versus low symptoms (measured by CAT or mMRC scales) and high versus low risk (measured by spirometry and exacerbations), patients are placed in A, B, C, or D categories in the GOLD treatment guidelines. For example, some patients may have a high symptom burden but be categorized as low risk based on spirometric pulmonary function measures (GOLD grade 1 or 2) and a low frequency of hospitalization; they would be category B for treatment purposes. Other patients may have a relatively low daily symptom burden, but based on spirometry (GOLD 3 or 4) or frequency of hospitalization (two or more per year), they are categorized as high risk and therefore treatment category C. High-symptom, high-risk patients are category D in this schema. Treatment guidelines for each category of COPD symptoms and risk are summarized in Table 16-6.

Nonpharmacologic therapies have shown mixed results. Home oxygen therapy decreases dyspnea and increases survival time significantly in those with hypoxia at rest (PaO₂ < 60 mm Hg) but not in those with only exertional or nocturnal hypoxia (Crockett et al., 2000). NPPV has not been shown to improve COPD outcomes except in severely

hypercapnic patients (PaCO₂ >55 mm Hg, or 50-54 mm Hg in presence of nocturnal oxygen desaturation or multiple hospitalizations in past year). Pulmonary rehabilitation focuses on improving strength, cardiopulmonary fitness, and exercise tolerance, and nutrition improves health status, as measured by the St. George's Respiratory Questionnaire (SGRQ) and Chronic Respiratory Questionnaire (CRQ) but does not appear to decrease hospitalization or mortality rates (Lacasse et al., 2001). Pulmonary rehabilitation appears to be beneficial in COPD and other chronic pulmonary diseases and is recommended by joint guidelines published by the American College of Chest Physicians (ACCP) and the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) Evidence-Based Clinical Practice Guidelines (Ries et al., 2007).

One disease management program using self-management and telephone follow-up showed a 36% reduction in hospitalizations and a 45% reduction in mortality in COPD patients (Bourbeau et al., 2003), but other trials of disease management programs have not shown such benefit. Despite evidence of significant nutritional deficits in patients with moderate to severe COPD, neither nutritional supplements to increase antioxidants (vitamin E or beta-carotene) nor nutritional supports to increase caloric intake have been demonstrated to improve outcomes or functional status in patients with COPD.

Surgical therapy using lung volume reduction surgery can improve quality of life and exercise tolerance in selected patients with FEV₁ less than 30% to 40% of predicted values (Fishman et al., 2003; Geddes et al., 2000; Goldstein et al., 2003). However, surgery does not improve 5-year mortality rate and can actually worsen the short-term mortality rate (National Emphysema Treatment Trial Research Group, 2001).

Prevention

Smoking cessation is the most important factor in preventing COPD and is the cornerstone of COPD treatment to prevent exacerbations and progressive loss of pulmonary function (Man et al., 2003). The decline in pulmonary function as measured by FEV₁ can be halved (from 60 to 30 mL/year) if COPD patients quit smoking (Anthonisen et al., 1994). Physician advice to quit smoking alone has some impact, and combined interventions (counseling plus education or group strategies plus pharmacologic treatment with nicotine, bupropion) can achieve at least 25% long-term quit rates even in COPD patients. Use of spirometry for screening and early diagnosis of COPD to enhance smoking cessation interventions among smokers does not improve smoking cessation rates or other clinical outcomes. Avoidance of secondary exposure to smoke, especially in the household, is also important. In two thirds world settings, this can mean replacing indoor open fire cooking with kitchen stoves or chimneys.

Influenza vaccine should be administered every year; it can reduce hospitalizations and deaths from pneumonia, cardiovascular disease, and all causes by 30% to 40% (Govaert et al., 1994; Nichol et al., 2003). Because the influenza vaccine is now recommended for all persons older than 6 months of age, special attention should be paid to immunizing child and adult family members, caregivers, health professionals, and other contacts of the person with COPD. Pneumococcal vaccine is also indicated in all patients with COPD, and patients should be revaccinated after 10 years if the first pneumococcal vaccine was administered before age 65 years. Vaccination rates are increasing nationwide, but they are still significantly lower among uninsured people and among racial and ethnic minority populations (CDC, 2003b). Family physicians can improve vaccination rates in their own practice by establishing standing orders for influenza and pneumococcal vaccination (CDC, 2003c, 2009) and can play a key role in encouraging high vaccination rates in schools, senior health centers, and the community.

One critical role for family physicians in the chronic management of COPD is to facilitate open discussions with patients and family members about end-of-life issues such as therapy during acute exacerbations. Although this has become routine in the management of cancer patients, the 5-year survival rate of patients with severe stages of COPD (as well as heart failure and other chronic organ failure) is often worse than that of many cancers. Many patients have a strong desire to avoid mechanical ventilation, only to end up intubated, unconscious, and having difficulty being weaned from the ventilator. Often, family members are asked to assist in end-of-life decision making after complications occur in the course of COPD even though they have not previously discussed such issues with the patient. Facilitating such family discussions, providing templates for living wills and health care power of attorney forms, and referring for legal or psychological or pastoral counseling can dramatically ease a family's confusion and pain during these episodes and in the panoply of issues associated with death and dying.

KEY TREATMENT

- Smoking cessation is the best intervention to slow the long-term rate of decline in FEV₁ (Anthonisen et al., 1994) (SOR: A). All patients should be counseled on smoking cessation; combining effective behavioral therapies (behavioral group therapy, social support) with pharmacologic therapy (nicotine replacement therapy, antidepressants) (Hughes et al., 2004; Lancaster and Stead, 2004; Stead and Lancaster, 2005) (SOR: A).
- To increase efficacy and reduce side effects, inhaled bronchodilators are preferred over oral formulations, and long acting are preferred over short acting. (SOR: A).
- LABAs provide significant benefits in airflow limitation measures, health-related quality of life, and use of rescue medication but have no effect on mortality or decline of pulmonary function (GOLD, 2013; Rodrigo et al., 2008) (SOR: A).
- Long-acting anticholinergics such as tiotropium reduce exacerbations and hospitalizations while improving health status but do not slow the progressive decline in pulmonary function (SOR: A).
- Among patients with COPD, ICS use for at least 24 weeks is associated with a significantly increased risk of serious pneumonia but not death, especially among those using the highest dose of ICS and those with the lowest baseline FEV₁ (Drummond et al., 2008; Singh et al., 2009) (SOR: A).
- Triple therapy, adding tiotropium to a combined LABA and ICS inhaler, appears to add incremental benefit in improving lung function and quality of life and reducing exacerbations (SOR: B).
- Pulmonary rehabilitation, including patient education and cardiopulmonary exercise training, significantly improves clinical outcomes and health-related quality of life and decreases hospital admissions as well as COPD-related anxiety and depression (SOR: A), with some evidence for survival benefit (SOR: B).
- Home oxygen therapy decreases dyspnea and increases survival significantly in patients with resting PaO₂ less than 60 mm Hg but not in patients with normal oxygen levels or with hypoxemia only on exertion (Crockett et al., 2000) (SOR: A).

ACUTE RESPIRATORY FAILURE

Acute respiratory failure can be the result of acute pulmonary infections; exacerbations of chronic pulmonary disease; or other conditions, such as PE, tension pneumothorax, or sepsis.

Clinical Presentation and Diagnosis

The clinical presentation of acute respiratory failure is usually obvious, although some patients slip into respiratory failure while being treated for initially less serious conditions such as pneumonia or acute exacerbations of CHF, asthma, or COPD. Acute respiratory failure can have either or both of two components: inadequate oxygenation (hypoxia) and inadequate ventilation (resulting in hypercarbia and respiratory acidosis). Although patients might

initially present with severe shortness of breath, the hypoxia and increased PaCO_2 can ultimately lead to suppression of respiratory centers in the brain, as well as lethargy, stupor, or coma.

An especially serious form of respiratory failure that can occur is acute respiratory distress syndrome (ARDS), which can occur in patients with severe trauma, especially those who have received massive blood transfusions, overwhelming pneumonia, septic shock, and the acute chest syndrome associated with sickle cell disease.

Indications for intubation and mechanical ventilation include hypoxia and hypoventilation unresponsive to pharmacologic intervention and supplemental oxygen delivery by mask or cannula. Patients unable to protect their own airway because of central nervous system (CNS) depression or inadequate gag reflex might also need intubation. The detailed management of mechanical ventilation is beyond the scope of this chapter, but ventilation can be thought of in terms of ventilator settings that increase or decrease *ventilation* (ventilator mode, respiratory rate, and tidal volume) and ventilator settings that improve *oxygenation*: forced inspiratory oxygen concentration (FiO_2) and continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP).

Weaning patients from the ventilator, especially those with chronic lung disease, can be challenging. Reintubation carries risks of trauma and of ventilator-associated pneumonia. Protocols based on objective criteria (vs. individual clinical judgment) significantly reduce time, costs, and complications related to weaning patients from mechanical ventilation.

OTHER CHRONIC BRONCHIAL DISEASES

Bronchiectasis

Bronchiectasis is both a chronic airway infection and a disease of chronic lung inflammation. Bronchiectasis might be more common outside the United States (Tsang and Tipoe, 2004). Clinical course can be progressive or indolent. Cough is the predominant symptom, and some patients have significant hemoptysis, shortness of breath, or both. Malodorous (fetid) breath is a characteristic symptom. Bronchiectasis not associated with a genetic disorder is designated non-CF bronchiectasis.

Antibiotics are given over the long term using antipseudomonal antibiotics either orally or as aminoglycosides nebulized for inhalation. Macrolide antibiotics such as azithromycin appear to have antibiotic and antiinflammatory effects in treating bronchiectasis. A Cochrane review found a small but significant benefit for prolonged antibiotic therapy in the treatment of patients with purulent bronchiectasis (Evans et al., 2003). Sputum cultures should be monitored for the presence of fungal (*Aspergillus*) and mycobacterial organisms as well because they can complicate the polymicrobial mix of organisms in these patients (Morrissey and Evans, 2003). Bronchodilators, oxygen, and even non-invasive pulmonary ventilation may be tried when bronchial obstruction becomes a major component of pulmonary impairment. Surgical resection of affected lung segments can be helpful in patients with localized disease (Greenstone, 2002).

Cystic Fibrosis

Cystic fibrosis is a genetic disease attributed to autosomal recessive defects on a single gene of chromosome 7. It affects membrane functions in mucus-secreting glands (e.g., sweat glands), the pancreas, and GI and respiratory tracts. Diagnosis of CF is suspected in the presence of pancreatitis and chronic or recurrent lung infections in infants or children. Definitive diagnosis may be made with a sweat chloride test. Treatment of CF has improved significantly over the past decades. Patients now routinely live into adulthood, and now more adults are living with CF than children. Family physicians and internists (in partnership with subspecialists) are increasingly involved in the care of patients with this complex condition.

Specific treatment modalities for CF include physical therapy; nutrition therapy; mucolytics; antibiotics; and increasingly, antiinflammatory therapies. Self-administered airway clearance techniques appear to be as effective as chest physiotherapy (Main et al., 2005). Antibiotics must be broad-spectrum and antipseudomonal agents and often are given in combination during exacerbations or acute infections. In recent years, inhaled tobramycin has become effective antibiotic therapy in bronchiectasis and CF. Antiinflammatory therapy includes oral corticosteroids and ibuprofen; azithromycin has both antibiotic and antiinflammatory properties. ICSs, methotrexate, and protease replacement do not appear to be effective (Prescott and Johnson, 2005). Delivery of gene therapy directly to the respiratory tract is the ultimate hope to achieve cure or long-term remission in CF patients.

Acute Infectious Diseases

BRONCHIOLITIS IN CHILDREN

Bronchiolitis is a viral infection associated with bronchial obstruction. It occurs most often in the fall and winter. About half of all children experience bronchiolitis during the first 2 years of life, with a median age of 6 months. *Respiratory syncytial virus* (RSV) is the most common causative organism, but other viruses (adenovirus, influenza, parainfluenza, and rhinovirus) can also cause bronchiolitis.

Clinical Presentation

Typically, an infant or toddler presents with routine signs and symptoms of upper respiratory infection, such as cough, sneezing, rhinitis, and low-grade fever. Dyspnea and irritability and perhaps audible wheezing soon follow. Tachypnea and nasal flaring are typical, along with signs of airway obstruction, such as a hyperexpanded chest and wheezing on auscultation, with a prolonged expiratory phase. Chest radiographs can show air trapping, peribronchial thickening, atelectasis, and patchy infiltrates. Premature infants and children with chronic disease are at special risk for respiratory failure or complications such as bacterial pneumonia, and up to 5% of patients require hospitalization for severe respiratory distress.

Treatment

Infants with mild bronchiolitis may be managed at home using fluids, antipyretics, and β_2 -agonists if needed. Indications for hospitalization of children with bronchiolitis include age younger than 6 months, hypoxemia ($\text{PaO}_2 < 60$ mm Hg or $\text{SO}_2 < 92\%$), rapid deterioration, apnea, or poor oral intake.

Hospitalized infants should receive fluids (orally or intravenously) and supplemental humidified oxygen. Aerosolized bronchodilators, including aerosolized epinephrine, decrease airway obstruction. Aerosolized ribavirin may be used in infants or children with underlying risk factors, but a meta-analysis of eight randomized controlled trials (RCTs) found no benefit for antiviral agents in general use. A systematic review of glucocorticoid treatment found no benefit in any subgroup of patients with bronchiolitis (Patel et al., 2004), and glucocorticoids do not appear to prevent post-bronchiolitic wheezing (Blom et al., 2007). Epinephrine treatment is better than placebo and might have a slight advantage over salbutamol in treating bronchiolitis in outpatient settings, but benefit has not been proved in hospitalized patients (Hartling et al., 2004). A Cochrane review concluded that nebulized hypertonic (3%) saline may significantly reduce the length of hospital stay and improve other clinical indicators in infants with acute viral bronchiolitis (Zhang et al., 2008).

Some patients ultimately have asthma, with the first episode diagnosed as bronchiolitis, but RSV has not been shown to be a causative agent of chronic asthma. A systematic review found treatment with RSV immune globulin to be effective in preventing hospitalizations and admission to the ICU but not in lowering mortality rates (Wang and Tang, 1999). Children with severe apnea or respiratory failure might require intubation and mechanical ventilation. Antibiotics are only indicated if secondary bacterial infection occurs.

Prevention

Smokers in the household predispose infants to bronchiolitis, and families should be counseled to make all homes with infants or children smoke free. In a small group of infants with underlying lung disease, heart disease, or low birth weight, monthly RSV hyperimmune gamma globulin has been proved to offer some protection from severe disease. Although influenza is a relatively infrequent cause of bronchiolitis, expanded recommendations for influenza vaccination include all children age 6 to 23 months as well as all close contacts of children from birth through 23 months of age.

ACUTE BRONCHITIS

A frequently diagnosed infection in children and adults, acute bronchitis is typically a viral respiratory infection with lower tract symptoms, such as cough, phlegm, hoarseness, or wheezing. This syndrome should be distinguished from acute exacerbations in patients with chronic bronchitis, who are more vulnerable, who might be colonized with different bacterial flora in the respiratory tract, and who might require more aggressive treatment. In acute bronchitis in otherwise healthy patients, viral causes

predominate. RSV and rhinovirus are common causative organisms even during influenza season.

Treatment of acute bronchitis in otherwise healthy patients should be primarily supportive because the condition is largely self-limited. Patients with underlying pulmonary disease or even smokers may have a higher rate of pulmonary complications (e.g., secondary pneumonia) or exacerbation of COPD. Options for symptomatic treatment include air humidifiers, cough suppressants, and antipyretic analgesics. Although β -agonists are sometimes prescribed, there is no evidence for a treatment benefit in the absence of measurable airway obstruction.

Antibiotic use is controversial. Because the most frequent cause is viral, bronchitis has often been overtreated with antibiotics, which would be a preventable source of antibiotic resistance. However, in patients with a productive cough persisting beyond 10 to 14 days, treatment with antibiotics may be indicated to treat bacterial co-infection, especially in smokers or in patients with underlying pulmonary disease. In a study of community-acquired acute bronchitis in France, polymerase chain reaction (PCR) testing revealed that 4.1% of patients were infected with *Chlamydia pneumoniae* and 2.3% with *Mycoplasma pneumoniae* (Gaillat et al., 2005).

A systematic review of RCTs comparing antibiotic therapy with placebo in the treatment of acute bronchitis or acute productive cough without underlying cause found a significant benefit for the antibiotic therapy, as measured by days of illness, persistent cough, and abnormal lung findings on examination (Smucny et al., 2004). An increase in adverse effects in the antibiotic-treated group compared with the placebo group outweighed many of these benefits, however, and caution in using antibiotics unnecessarily to prevent the spread of antibiotic-resistant bacteria is still valid at the population level. The specific choice of antibiotic seems to have little impact, despite known patterns of bacterial resistance in most communities. A systematic review of controlled trials that compared azithromycin with amoxicillin or amoxicillin-clavulanic acid in patients with clinical evidence of acute bronchitis, pneumonia, and acute exacerbation of chronic bronchitis found no significant advantage for using the macrolide antibiotic (Panpanich et al., 2004).

PNEUMONIA

Key Points

- Pneumonia causes more than 1 million hospitalizations per year in the United States.
- Influenza vaccine should be administered every year to patients older than 50 years and to those with chronic lung disease, diabetes, immune dysfunction, or other chronic organ failure.
- Patients should be revaccinated with pneumococcal vaccine after 10 years if the first vaccine was administered before age 65 years.
- Although atypical pathogens commonly cause community-acquired pneumonia (CAP), controlled trials show that β -lactam antibiotics are as effective as macrolides and quinolones in most cases.

Pneumonia is an infection of the lungs that leads to consolidation of the usually air-filled alveoli. It occurs in all age groups and can be caused by various agents, including viruses, bacteria, mycobacteria, mycoplasma, and fungi. Systemic viral infections such as influenza A or B in adults and measles or varicella in children can also lead to bacterial pneumonia.

Epidemiology and Risk Factors

Pneumonia or influenza is the primary diagnosis in over a million hospital admissions per year in the United States, with an in-hospital death rate of 3.3%. Aggregate charges (“the national bill”) for these hospitalizations add up to over \$35 billion per year (AHRQ, 2011d).

Clinical Presentation

Patients with pneumonia can present with cough, fever, dyspnea, or malaise. Cough can be productive or non-productive and blood tinged or with frank blood. The clinical presentation of pneumonia in otherwise healthy patients often follows one of two patterns that can indicate the cause. A rapid onset of cough and shortness of breath with a high fever can indicate classic bacterial lobar pneumonia such as that produced by a pneumococcus. Physical findings after consolidation occurs include decreased breath sounds, dullness to percussion, and egophony on the affected side. The white blood cell (WBC) count is often elevated ($>15,000 \times 10^3/\text{mm}^3$), with a predominance of neutrophils. A smoldering onset with low-grade fever and fewer constitutional symptoms can indicate an atypical pneumonia, which can be caused by organisms such as respiratory viruses or by *Mycoplasma*, *Chlamydia*, or *Legionella* spp.

Patients with new-onset pneumonia can be categorized by whether they are living at home in a community setting or living in a nursing home or other institutional setting. Patients who have had prolonged hospitalizations or who live in nursing homes may be colonized with gram-negative organisms (e.g., *Serratia*, *Pseudomonas* spp.), anaerobes, or multidrug-resistant (MDR) bacteria.

Patients with pneumonia can be further categorized by whether they are immunocompetent or immunocompromised. Patients with immunodeficiencies (including HIV/AIDS) can present with opportunistic organisms including *P. jiroveci* (carinii), cryptococci, *Coccidioides immitis*, atypical mycobacteria, and fungi. Alcoholism can predispose patients to lung infections with *Haemophilus influenzae* or to aspirated anaerobic organisms such as *Peptostreptococcus* or *Bacteroides* spp.

In children, signs of pneumonia can include malaise, cough, chest pain, tachypnea, and intercostal retractions. Children with viral pneumonias have a less toxic appearance, with low-grade fever, wheezing, and cough. Children with bacterial pneumonia appear more acutely ill, with a high-grade fever, chills, cough, and dyspnea. The earliest diagnostic clue in children may be tachypnea disproportionate to degree of fever.

In infants, potential causes of pneumonia are tied to specific periods in the first few months of life. Pneumonia in the newborn is often linked to bacteria that colonize the mother’s vaginal flora. Group B streptococcal infections can occur within the first 48 hours of life or appear at 7 to 10 days after birth. Other neonatal infections include

gram-negative organisms such as *Escherichia coli*. Although *Chlamydia* infections of the eye can appear in newborns at 1 to 2 weeks of age, chlamydial pneumonia is typically diagnosed in infants age 6 to 8 weeks. Other causes of pneumonia in infants age 1 to 3 months include *Ureaplasma urealyticum* and cytomegalovirus (CMV).

Viral pneumonias are most common in preschool and older children. Viral upper respiratory infections or bronchiolitis can also predispose to a bacterial pneumonia. Bacterial pathogens are responsible for only 10% to 30% of all cases of infectious pediatric pneumonia. *Streptococcus pneumoniae* has been the most common bacterial cause of childhood pneumonia, but it is declining in the face of universal pneumococcal vaccination. *H. influenzae* type B pneumonia is associated with bacteremia and other deep tissue infections (e.g., meningitis, arthritis, cellulitis) but also has declined significantly with universal immunization. *Staphylococcus aureus* causes an aggressive pneumonia that can be complicated by acute respiratory failure, pneumatoceles, or empyema. Staphylococcal pneumonia typically occurs after a staphylococcal skin infection or a systemic viral illness such as varicella (chickenpox) or measles.

Diagnosis

Cases of pneumonia are often diagnosed presumptively based on the clinical presentation and perhaps a radiograph. Chest radiography findings in viral pneumonias include patchy or streaky, often bilateral, interstitial patterns and hyperinflation of the lungs. Bacterial pneumonias show classic lobar consolidation and alveolar infiltrates, although radiography findings typically lag behind the clinical course by 1 to 2 days and can be completely normal on day 1. Parapneumonic pleural effusions can also occur.

Sputum Gram stain and culture may be performed but have a low yield. Some bacterial agents such as *Legionella* may be identified by antigen detection from blood samples. *Mycoplasma pneumoniae* infection may be diagnosed with a positive cold agglutinin test of peripheral blood. Sputum smears and cultures for acid-fast bacilli (AFB) are appropriate when there has been possible contact with TB patients, in TB-endemic areas, or when clinical findings suggest TB. Invasive procedures (e.g., BAL, lung aspiration, bronchoscopy) are reserved for special circumstances, such as diagnosing pneumonia in the immunocompromised host or in ventilator-associated pneumonias.

Treatment

Although treatment of CAP is common in primary care, there are many controversies. Clearly, many patients may be managed on an outpatient basis (Segreti et al., 2005). Use of a formal instrument such as the pneumonia severity index (PSI) or CURB-65 can more accurately identify patients eligible for outpatient treatment (IDSA/ATS, 2007). The choice of oral antibiotic in the outpatient setting must cover common causes of bacterial pneumonia. Many treatment guidelines suggest using antibiotics that cover atypical organisms such as *Mycoplasma* and *Legionella* spp., but there is insufficient evidence to support any specific antibiotic strategy in the outpatient treatment of CAP (Bjerre et al., 2004). Treatment should be continued for a minimum of 5 days and at least 48 to 72 hours beyond the patient’s last signs of fever or clinical instability.

In cases of pneumococcal pneumonia with bacteremia, there is limited evidence to suggest that dual therapy with a β -lactam antibiotic and an antibiotic with coverage of atypical organisms results in lower case-fatality rates than using a β -lactam alone. A meta-analysis of studies comparing the effectiveness of a β -lactam antibiotic with antibiotics active against atypical pathogens in nonsevere CAP found no advantage for the antibiotics that were active against atypical pathogens (Shefet et al., 2005). This was true even on subgroup analysis for patients infected with *M. pneumoniae* and *C. pneumoniae*, but there was a significantly lower treatment failure rate in the small number of patients with *Legionella* infections (relative risk [RR], 0.40) treated with a macrolide antibiotic (Mills et al., 2005). Patients with significant comorbidities or chronic organ failure and those at risk for drug-resistant *S. pneumoniae* should be treated with a respiratory fluoroquinolone or combination of β -lactam and macrolide antibiotic (IDSA/ATS, 2007).

Indications for hospitalization of any patient include failure to respond or tolerate oral antibiotics, moderate to severe respiratory distress, significant deficit in oxygenation (alveolar-arterial [A-a] O_2 gradient), more than one area of lobar consolidation, empyema, immunosuppression, abscess formation, pneumatocele, underlying cardiopulmonary disease, and high-risk PSI score. Two additional factors are the patient's age (e.g., infants younger than age 2 months, elderly patients) and comorbidities (underlying pulmonary or cardiovascular disease).

Even in the hospital, not all patients must be treated with IV antibiotics (Marras et al., 2004). The patient might require hospitalization for dehydration or oxygen therapy, but in select cases, oral antibiotics may be equally effective, cost less, and require fewer days in the hospital than IV antibiotic therapy. Other patients may start receiving IV antibiotics in the hospital, but an algorithm that provides for an early switch to oral antibiotics and early discharge can reduce hospital stay.

Treatment of neonatal pneumonia should target group B streptococci and gram-negative organisms such as *E. coli*. Older children with suspected bacterial pneumonia should be treated with antibiotics that provide appropriate coverage for *H. influenzae* and *S. pneumoniae*. Pneumonia in children older than 5 years should also include macrolide coverage for *M. pneumoniae*. When symptoms recur or persist for longer than 1 month, further evaluation for an underlying condition should be undertaken (TB skin test, serum immunoglobulin, bronchoscopy, barium swallow, sweat chloride test).

Prevention

Approximately half of all cases of adult pneumonia can be prevented by annual administration of influenza vaccine plus a one-time pneumococcal vaccine when indicated (Vu et al., 2002). Vaccination with inactivated influenza vaccine is appropriate for all age groups, but the live, attenuated influenza vaccine given by nasal spray is approved for use only in healthy patients ages 5 to 49 years. To prevent community spread of influenza, the CDC recommends that influenza vaccine be given to all persons older than 6 months of age.

Health care workers are an important source of transmission of influenza from infected patients to other

medically vulnerable patients. Therefore, they also should be immunized, preferably with inactivated vaccine if they have close contact with severely immunocompromised persons. Health care workers or family members vaccinated with live, attenuated influenza vaccine should avoid contact with severely immunosuppressed patients for at least 7 days after vaccination.

A systematic review suggests that pneumococcal vaccination does not significantly reduce all-cause mortality or overall rates of pneumonia, but it is specifically effective in preventing invasive pneumococcal disease (Dear et al., 2003).

Two types of vaccine are available for immunizing against invasive pneumococcal disease. Pneumococcal conjugate vaccine (PCV13) is recommended for all children younger than 5 years old and for adults with specific risk factors. All adults age 65 years and older and younger adults and children with specific risk factors should receive pneumococcal polysaccharide vaccine (PPSV23) covering 23 serotypes of the disease. The Advisory Committee on Immunization Practices (ACIP) recommends that "those who received one or more doses of PPSV23 before age 65 years for any indication should receive another dose of the vaccine at age 65 years or older if at least 5 years have elapsed since their previous PPSV23 dose. If a dose of PPSV23 was received at age 65 years or later, no additional doses of PPSV23 are recommended." Elderly persons with unknown vaccination status should be administered one dose of vaccine. Specific indications for pneumococcal vaccines are listed in Table 16-7.

KEY TREATMENT

- Treating uncomplicated CAP with a macrolide or respiratory quinolone has no proven treatment advantage over cephalosporin or aminopenicillin therapy (Mills et al., 2005; Shefet et al., 2005), unless patients have significant comorbidities or other risk factors (IDSA/ATS, 2007) (SOR: A).
- Oral antibiotic therapy for uncomplicated CAP is safe and effective in outpatient or inpatient settings in patients younger than 65 years with no preexisting lung disease or other chronic disease with stable vital signs and no evidence of hypoxia or sepsis (Bjerre et al., 2004; Marras et al., 2004) (SOR: A).
- Influenza vaccination and pneumococcal vaccine are demonstrably effective among elderly patients and those with chronic disease (Vu et al., 2002) (SOR: A).

Chronic Infectious Diseases

TUBERCULOSIS

Tuberculosis is caused by infection with *Mycobacterium tuberculosis*, transmitted by airborne exposure from close contact with infected patients. Pulmonary infection is the most common form, although extrapulmonary TB from hematogenous spread (meningitis, peritonitis, renal or adrenal TB, spinal TB [Pott's disease], others) can occur in young children, elderly people, persons in high-endemic areas, and patients with impaired immunity or malnutrition.

Table 16-7 Medical Conditions or Other Indications for Administration of PCV13 and Indications for PPSV23 Administration and Revaccination for Adults 19 Years of Age or Older

<http://www.cdc.gov/vaccines/vpd-vac/pneumo/vac-PCV13-adults.htm#recommendations.#>

Key Points

- Eighty percent of TB cases come from 22 high-burden nations.
- Sputum cultures can confirm the diagnosis of TB, but they also are important for identifying patterns of drug resistance.
- PCR techniques looking for genetic polymorphisms can provide more rapid diagnosis of drug-resistant TB.
- Latent infection (positive skin test result in asymptomatic patient with normal chest radiograph) is treated with 6 to 9 months of isoniazid or 4 months of rifampin.
- Treatment of active pulmonary TB requires a multidrug regimen for 6 to 12 months; cultures should be negative in 80% of patients within 2 months.

Epidemiology and Risk Factors

In many parts of the world, TB is one of the most common causes of fatal respiratory infection; 80% of cases come from 22 high-burden nations. WHO (2005) estimated 8.8 million new TB cases worldwide in 2003, including 674,000 HIV-infected patients, with 1.7 million deaths attributed to TB. TB cases are falling or stable in most regions but increasing in Africa. In North America, TB rates

rose during the 1980s, but since 1992, TB rates have been in decline. MDR TB is a rising problem. Worldwide, 3% of newly diagnosed TB cases are MDR TB, as are 15% of previously treated TB cases.

Children, elderly people, and immunocompromised patients are especially vulnerable. In the United States, 22% of TB cases occur in older adults, with the highest rates in elderly residents of long-term care facilities (Thrupp et al., 2004). The most important risk factor for developing TB is having household or other close contact with a patient who has active TB.

Clinical Presentation

Tuberculosis can be a life-threatening infection. For pulmonary TB, symptoms include cough, fever, dyspnea, night sweats, and weight loss or failure to gain weight. The few physical findings other than weight loss can include wheezes, rales, or signs of consolidation in the affected lung field. Hematogenous spread can lead to signs of extrapulmonary infection. Patients with an initial diagnosis of CAP might instead have TB. Patients with CAP who have symptoms suggesting TB or who do not respond to antibiotic treatment, who have upper lobe infiltrates or cavitory lesions, who come from endemic areas, or who have persistent cough or hemoptysis should be evaluated for TB (Kunimoto and Long, 2005).

For patients with symptoms or with a positive PPD result, chest radiograph and sputum cultures for AFB are required. Typical chest radiograph findings include hilar or mediastinal lymphadenopathy, patchy infiltrates, apical scarring, and pleural effusions, but a cavitary lesion or miliary pattern (typical millet-seed granulomas scattered diffusely throughout lung fields) more specifically suggests TB.

Diagnosis

Skin testing is still the best method of testing for latent infection by prior exposure to *M. tuberculosis*. Intradermal testing with 5 tuberculin units (0.1 mL) of PPD is more accurate than multiprong tine testing. Interpretation depends on the patient's risk of disease. Patients with a history of direct exposure to active cases of TB, or with impaired immunity such as HIV, should be considered to have a positive test if the area of induration is greater than 5 mm at 48 to 72 hours. Most other patients should be considered positive with induration greater than 10 mm. Very-low-risk patients (age > 5 years, no history of exposure, normal immune system, low rates of TB in population) may be considered positive only with induration greater than 15 mm. These criteria are summarized in Table 16-8 (Centers for Disease Control and Prevention, 2000). Persons vaccinated with bacille Calmette-Guérin (BCG) vaccine may still be accurately tested with PPD skin testing. For high-risk populations, a percentage tuberculin response higher than 15 on the QuantiFERON-TB test (QFT) performed on venous whole blood is moderately correlated with a positive skin test result. Neither PPD nor QFT is recommended as routine screening in low-risk populations (Centers for Disease Control and Prevention, 2003a).

Clinical diagnosis in endemic areas is often based on history of exposure, clinical signs, AFB smears, and chest radiography findings (see Fig. 16-4). Sputum cultures can confirm the diagnosis and also are important for identifying patterns of drug resistance. In infants and young children, sputum AFB smears and cultures plus gastric aspirates each morning for 3 days yield the diagnosis only 50% of the time. Other cases may need to be treated presumptively based on exposure, symptoms, and chest radiographs. In culture-negative cases of TB, it is essential to find the index case and to obtain sputum cultures and drug sensitivities from that patient to guide therapy for patients with negative cultures but active disease.

Laboratory diagnosis of TB historically has relied on the use of sputum smears for AFB and culturing of the *M. tuberculosis* organism. Culture results can require 2 to 8 weeks, but more rapid methods can detect early growth within 5 to 14 days (Katoch, 2004; Schluger, 2003). Gene amplification using PCR techniques can be performed on sputum samples for rapid results, as well as on cerebrospinal fluid (CSF), gastric or pleural aspirates, and urine. PCR is highly sensitive (95%-98%) for diagnosing TB from sputum in smear-positive and culture-positive cases, but it has lower sensitivity (57%-78%) for smear-negative and culture-positive cases (Rattan, 2000). PCR may also be used on organisms obtained from early growth on positive cultures to detect drug resistance more rapidly, taking advantage of the genetic polymorphisms in the *M. tuberculosis* organism, which are almost always associated with drug resistance. Although positive results are highly specific,

Table 16-8 Criteria for Tuberculin Positivity by Risk Group

Reaction > 2 mm of induration	<ul style="list-style-type: none"> ■ HIV-positive patients ■ Recent contacts of TB patients ■ Fibrotic changes on chest radiograph consistent with prior TB ■ Patients with organ transplants and other immunocompromised patients (receiving equivalent of >15 mg/day of prednisone for >1 mo)*
Reaction > 10 mm of induration	<ul style="list-style-type: none"> ■ Recent immigrants (i.e., within last 5 yr) from high-prevalence countries ■ Injection drug users ■ Residents and employees† of high-risk congregate settings <ul style="list-style-type: none"> ■ Prisons and jails ■ Nursing homes and other long-term care facilities for elderly persons ■ Hospitals and other health care facilities ■ Residential facilities for AIDS patients ■ Homeless shelters ■ Mycobacteriology laboratory personnel ■ Persons with high-risk conditions <ul style="list-style-type: none"> ■ Silicosis ■ Diabetes mellitus ■ Chronic renal failure ■ Some hematologic disorders (e.g., leukemias, lymphomas) ■ Other specific malignancies (e.g., head or neck or lung carcinoma) ■ Weight loss >10% of ideal body weight ■ Gastrectomy ■ Jejunioileal bypass ■ Children younger than 4 yr of age or infants, children, and adolescents exposed to high-risk adults
Reaction > 15 mm of induration	<ul style="list-style-type: none"> ■ Persons with no risk factors for TB

*Risk of tuberculosis (TB) in patients treated with corticosteroids increases with higher dose and longer duration.

†For persons who are otherwise at low risk and are tested at the start of employment, a reaction of >15 mm of induration is considered positive. Centers for Disease Control and Prevention, 2000. Table 7, Criteria for Tuberculin Positivity by Risk Group. Morbidity and Mortality Weekly Report (MMWR), Targeted Tuberculin Testing and Treatment of Latent Tuberculosis Infection; June 9, 2000. 49(RR06);1–54.

failure to detect mutations does not entirely rule out drug resistance (Hazbon, 2004; Nachamkin et al., 1997).

Treatment

A positive PPD skin test result in an asymptomatic patient with a normal chest radiograph and negative HIV test result represents latent infection with no active disease. A 6- to 9-month course of isoniazid is effective in treating this latent infection and in preventing the development of active TB. Isoniazid therapy is associated with clinical hepatitis in approximately 0.6% of treated patients (Smieja et al., 1999). An effective alternative is rifampin for 4 months. The short course of two drugs, rifampin and pyrazinamide, for 2 months is no longer recommended because of evidence of increased liver toxicity with this combination (CDC, 2001). Treatment of positive PPD latent infection is indicated even in patients with a history of BCG vaccination and is also effective in patients co-infected with HIV (Wilkinson et al., 1998).

Treatment of active pulmonary TB requires a multidrug regimen for 6 to 12 months. For new drug-sensitive cases of uncomplicated pulmonary TB, the WHO recommends a 6-month protocol of four drugs (isoniazid, rifampin, pyrazinamide, and ethambutol) for the first 2 months, continuing with two drugs (isoniazid, rifampin) for the next 4 months (SOR: A) (WHO, 2009). Culture and drug susceptibility testing (DST) should be performed on all previously treated TB patients, with DST focusing at least on sensitivity to isoniazid and rifampin. In settings where rapid molecular-based DST is available, the results should guide the choice of drug treatment regimen. Rapid molecular-based DST or culture-based DST is strongly recommended in guiding treatment for HIV-positive patients.

In countries with high prevalence of isoniazid resistance and no routine DST, ethambutol may be continued throughout the 6-month course along with isoniazid and rifampin. Whenever possible, treatment should be taken daily unless dosing is directly observed. Treatment with intermittent therapy 2 days per week has been less effective than daily therapy in RCTs (Mwandumba and Squire, 2001). Repeat cultures should be obtained after 2 months of treatment, when 80% of patients have negative cultures. Cavitory lesions, or persistent positive cultures after 2 months of therapy, are indications for an extended 9-month course of treatment.

Directly observed therapy (DOT) is indicated for patients with specific risk factors for treatment failure caused by noncompliance, but RCTs in a variety of settings have not clearly demonstrated benefit over traditional public health strategies (Volmink and Garner, 2003). Enhanced DOT appears to be more effective. Table 16-9 lists strategies of social supports, barrier reduction, compliance monitoring, and incentives that can be blended in a broad-based strategy to ensure treatment compliance and cure (American Thoracic Society, CDC, IDSA, 2003). The WHO reports an 82% success rate for TB treatment worldwide, although the prevalence of MDR TB is increasing.

Treatment of patients who have positive PPD and radiography evidence of TB but negative sputum smears depends on the level of clinical suspicion for active TB. When suspicion is high, multidrug therapy should be initiated pending culture results. If cultures come back negative but the patient shows clinical or radiographic signs of improvement after 2 months of treatment, the patient is assumed to have culture-negative TB, and treatment should be completed using isoniazid and rifampin. If culture remains negative and there is no sign of clinical or radiographic improvement, treatment may be discontinued after 2 months. For patients at low suspicion of TB, no treatment is indicated pending culture results. If cultures remain negative and the patient is asymptomatic with no progression on chest radiography, a standard course of treatment for latent TB (isoniazid for 9 months or rifampin for 4 months) is indicated.

Prevention

The most important elements of prevention are screening for exposure, detection and follow-up of active cases, and prophylaxis of infected but clinically asymptomatic patients. PPD testing and treatment of latent infection is a more effective strategy than BCG vaccination in patient

Table 16-9 Broad-Based Strategy to Ensure Tuberculosis Treatment Adherence and Cure

Enablers	Incentives
Interventions to assist the patient in completing therapy	Interventions to motivate the patient, tailored to individual patient wishes and needs and thus meaningful to the patient
Transportation vouchers	Food stamps or snacks and meals
Child care	Restaurant coupons
Convenient clinic hours and locations	Assistance in finding or provision of housing
Clinic personnel who speak the languages of the populations served	Clothing or other personal products
Reminder systems and follow-up of missed appointments	Books
Social service assistance (referrals for substance abuse treatment and counseling, housing, and other services)	Stipends
Outreach workers (bilingual or bicultural as needed; can provide many services related to maintaining patient adherence, including provision of DOT, follow-up on missed appointments, monthly monitoring, transportation, sputum collection, social service assistance, and educational reinforcement)	Patient contract
Integration of TB care with care for other conditions	

DOT, Directly observed therapy; TB, tuberculosis.

Table 16-10 Latent Tuberculosis Infection Treatment Regimens

Drugs	Duration	Interval	Minimum no. of Doses
Isoniazid	9 mo	Daily	270
		Twice weekly with DOT	76
Isoniazid	6 mo	Daily	180
		Twice weekly with DOT	52
Isoniazid and rifapentine	3 mo	Twice weekly with DOT	12
Rifampin	4 mo	Daily	120

DOT, Directly observed therapy.

Centers for Disease Control and Prevention, 2014. Treatment of Latent TB Infection (updated Feb 7, 2014); <http://www.cdc.gov/tb/topic/treatment/tbi.htm>.

populations with a relatively low incidence of pulmonary TB, but in highly endemic areas, infant BCG vaccination strategies can reduce childhood TB infection rates by as much as 50% (Colditz et al., 1995). Patients with a positive PPD result but no symptoms and negative chest radiography findings should be treated with an effective regimen such as isoniazid daily for 9 months or rifampin for 4 months or other regimens as listed in Table 16-10.

Maintaining an effective public health infrastructure, including TB surveillance, screening, and contact tracing, is essential. Sputum culture and sensitivity testing is an increasingly relevant component of an effective public health strategy to identify and contain the spread of MDR TB.

KEY TREATMENT

- A 9-month course of isoniazid or a 4-month course of rifampin is effective in preventing development of active TB in asymptomatic patients with a positive PPD test result and negative chest radiography findings (i.e., latent infection) even in patients with HIV co-infection (Smieja et al., 1999; Wilkinson et al., 1998) (SOR: A).
- Treatment with intermittent therapy 2 days per week has been less effective than daily therapy in RCTs (Mwandumba and Squire, 2001) (SOR: A).
- BCG vaccine effectively reduces infection rates by about 50% in highly endemic populations (Colditz et al., 1995) (SOR: B).
- Positive PPD test results require diagnostic evaluation even in patients with prior BCG vaccination.

AIDS-RELATED INFECTIONS**Key Points**

- Specific opportunistic infections are associated with HIV, and bacterial CAPs are also common.
- More than half of HIV-infected patients with CD4+ counts less than 200 cells/ μ L experience an AIDS-related opportunistic infection within the next 2 years.
- TB is common in HIV patients. TB worsens the clinical course of HIV infection, and HIV infection complicates TB management.
- HRCT scan is the best imaging study for diagnosing HIV-related pulmonary infections.
- Inactivated influenza and pneumococcal vaccines are recommended for HIV-infected patients who are still able to mount a significant immune response.

HIV/AIDS by definition compromises our host defense capacity for fighting otherwise benign infections. Some of the most common opportunistic infections in patients with HIV/AIDS affect the lungs as their target organ.

Epidemiology and Risk Factors

Table 16-11 shows the relationship between opportunistic infections and specific levels of immunocompromise as measured by CD4+ lymphocyte counts; 200 cells/ μ L is a critical threshold for prophylactic treatment (CDC, NIH, IDSA, 2013). More than half of HIV patients with CD4+ counts below this level experience an AIDS-related opportunistic infection in 2 years.

Human cases of PCP are now understood to be caused by *P. jiroveci*. Most healthy children have been infected asymptotically with *P. jiroveci* by age 4 years (Pifer et al., 1978), allowing cases in HIV patients to occur either by reactivation or by new exposure. Without antiretroviral therapy (ART) or PCP prophylaxis, more than 70% of HIV-infected patients could be expected to experience PCP, with a 20% to 40% mortality rate (Phair et al., 1990). With widespread use of effective antiretroviral therapy, the incidence of PCP among HIV-infected patients in Western nations is now less than one case per 100 person-years (Buchacz et al., 2010).

Table 16-11 Risk Factors Associated with Development of Major Opportunistic Infections in HIV-Infected Patients

Infection	CD4+ Count Risk Threshold (cells/mm ³)	Other Risk Factors
<i>Pneumocystis jiroveci</i> (carinii) pneumonia (PCP)	≤ 200	Prior PCP Present CD4+ cells <14% Fever of unexplained etiology Presence of oral candidiasis
<i>Mycobacterium tuberculosis</i>	Any	Tuberculin skin test (PPD) positive Exposure to infectious contact
<i>Mycobacterium avium</i> complex	≤ 50	Prior respiratory or GI colonization Prior opportunistic disease High viral load (>105 copies/mL)
CMV disease	≤ 50	Seropositive (IgG antibodies to CMV) CMV viremia Prior opportunistic disease High viral load (>105 copies/mL)
Cryptococcal meningitis	$\approx 50-100$	Environmental exposure
Toxoplasmosis	$\approx 100-200$	Seropositive (IgG antibody to <i>Toxoplasma gondii</i>)
<i>Candida</i> esophagitis	≤ 100	Prior <i>Candida</i> colonization High viral load (>105 copies/mL)
Cryptosporidiosis	≤ 100	Environmental exposure (contaminated water, soil, animal exposure)
Histoplasmosis	≤ 100	Exposure (endemic areas: Midwest, Southwest United States)
Coccidioidomycosis	≤ 100	Exposure (endemic areas: Southwest United States, Mexico)

CMV, Cytomegalovirus; GI, gastrointestinal; PPD, purified protein derivative. Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents, 2013

Clinical Presentation

A wide range of clinical presentations can occur with opportunistic infections in HIV/AIDS. PCP can manifest with cough, tachypnea, and fever. Chest radiographs may be relatively normal early in the course of disease but eventually may show diffuse, bilateral, symmetric interstitial infiltrates in a butterfly pattern or ground-glass appearance. Hypoxia, PaO₂ less than 70 mm Hg, and an increased A-a O₂ gradient are typical. Pneumothorax occurring in a patient infected with HIV suggests PCP, which typically produces pneumatoceles as lung tissue is destroyed.

Clinicians should also have a high index of suspicion for pulmonary TB in HIV-infected patients. Presentation of pulmonary TB is fairly typical (upper lobe patchy infiltrates with or without cavitation) in patients with normal CD4 counts, but patients with more severe immune suppression often have atypical lung presentations (lobar infiltrates or miliary pattern) or extrapulmonary forms of TB. In severely immunocompromised patients, sputum AFB cultures

can be positive even in the presence of normal chest radiograph.

The attention to opportunistic infections should not diminish clinical suspicion for bacterial pneumonia as a cause of significant morbidity and mortality in HIV-infected patients. *S. pneumoniae*, *H. influenzae*, *Pseudomonas aeruginosa*, and *S. aureus* are the most frequently isolated organisms (Rimland et al., 2002). Patients present with typical symptoms such as fever, tachypnea, cough, and constitutional symptoms and a pattern of lobar pneumonia or other infiltrates on chest radiography.

Diagnosis

Diagnosis of PCP may be obtained from laboratory testing, histopathology, and imaging studies. Histochemical stains and direct immunofluorescent studies can confirm the organism's presence in induced sputum, but sensitivities are much greater (90%-99%) when specimens are obtained from BAL or transbronchial biopsy (Cruciani et al., 2002). Open lung biopsy is the gold standard and may be safer than bronchoscopic techniques for patients with bleeding disorders.

Nuclear medicine and CT studies are also used extensively in evaluating pulmonary symptoms in patients with HIV/AIDS. For example, HRCT scan can show a patchy, ground-glass appearance or characteristic pneumatoceles in PCP. Gallium-67 scintigraphy is also useful. In a study of 57 immunocompromised patients with pulmonary infections, the first-choice diagnosis suggested by CT was accurate in most fungal infections (95.0%) and PCP (87.5%) but was less accurate for bacterial (73.7%) and viral (75.0%) infections and missed both cases of mycobacterial infection (Demirkazik et al., 2008). A gallium scan showing diffuse increased uptake in the lungs of an HIV-infected patient can also suggest PCP. Sensitivity is high (>90%), but specificity can be as low as 51%. Features of an abnormal gallium scan that increase specificity and positive predictive value include increased uptake in the lungs in the presence of a normal chest radiograph, intensity of uptake in the lung (greater than liver uptake), and a diffuse heterogeneous pattern. In a comparative study of gallium scanning versus HRCT in HIV/AIDS patients with pulmonary symptoms but normal or near-normal chest radiographs, HRCT resulted in both higher positive predictive values (86%) and negative predictive values (88%) than gallium scintigraphy (62% and 73%) (Kirshenbaum et al., 1998).

Sequential thallium and gallium scanning may be performed when Kaposi sarcoma is suspected. The combination of a positive thallium and negative gallium scan is highly specific for Kaposi sarcoma, but sensitivity is decreased by the presence of opportunistic infections, which can make the gallium scan positive as well. Other nuclear imaging studies include cell-surface peptide receptor-binding molecules radiolabeled with indium or technetium (van de Wiele et al., 2002).

Prevention and Treatment

The treatment of HIV is covered in Chapter 15. However, there are specific opportunities for preventing pulmonary opportunistic infections in HIV-infected patients (Clumeck and Wit, 2003; Guidelines for Prevention & Treatment, 2013). ART has transformed HIV/AIDS into a chronic disease in which CD4⁺ counts can often be maintained

above levels at which opportunistic infections are likely. However, PCP prophylaxis is still indicated for patients with CD4 counts below 200 cells/mm³ or a history of oropharyngeal candidiasis.

When an opportunistic infection leads to the initial diagnosis of HIV/AIDS, treatment with ART and agents effective against the opportunistic infection may be begun simultaneously. Fever and worsening of clinical symptoms several weeks after ART initiation may be related to recovery of the patient's immune function, described as an "immune reconstitution or reactivation syndrome," and must be differentiated from treatment failure or progression of disease by measuring serial CD4⁺ counts and RNA viral loads.

Trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis has been demonstrated to prevent episodes of *P. jiroveci* pneumonia and to enhance survival in patients with low CD4 counts (D'Egidio et al., 2007). Oral dapsone, inhaled pentamidine, or atovaquone are alternatives for patients unable to tolerate TMP-SMX. It is also used to treat PCP infections, although the side effects of TMP-SMX are significantly higher in HIV/AIDS patients. Corticosteroids are added for patients with significant respiratory distress or hypoxemia.

Tuberculosis worsens the clinical course of HIV infection, and HIV infection complicates the management of TB (Sharma et al., 2005). All HIV-infected patients should undergo PPD testing for latent infection with *M. tuberculosis*. A PPD reaction greater than 5 mm is considered positive in an HIV-infected patient. If the PPD result is negative but the CD4 count is below 200 cells/mm³, then the patient should be retested after treatment reduces viral load and restores adequate CD4 levels to greater than 200 cells/mm³. The interferon- γ release assay (IGRAs) for TB may be more sensitive than the TB skin test and less cross-reactive with BCG, but its role in routine practice (e.g., to replace or combine with the PPD) has not been fully established. If chest radiograph findings are negative and there are no other signs of active pulmonary or extrapulmonary TB, an appropriate treatment regimen for latent TB should be initiated. Treatment of latent TB reduces significantly the risk of developing active TB in HIV patients with a positive skin test result (Volmink and Woldehanna, 2004). Regimens are similar to those used in HIV-negative patients, but if isoniazid is chosen, the duration of treatment is 9 months rather than 6 months and given with pyridoxine supplements. Standard treatment regimens for active TB appear to be effective in HIV patients as well, but trials will determine the optimum duration, regimen, and dosing frequency in patients with TB and more severe HIV-related immunocompromise. Detailed guidelines for the combined treatment of TB and HIV to maximize outcomes while minimizing drug-drug interactions are available and frequently updated on the CDC's website (CDC, 2013b).

Mycobacterium avium complex (MAC) infections can be prevented with clarithromycin or azithromycin. Disseminated MAC infection often manifests with signs in multiple organ systems, and typically occurs in patients with severe immunocompromise (CD4 count <50 cells/mm³). Localized pneumonia can occur in patients with more intact immune function receiving ART.

Although other prophylactic regimens are available to prevent systemic viral or fungal infections, a survival benefit has not been demonstrated. Inactivated influenza and

23-valent pneumococcal vaccines are recommended for HIV patients who are still able to mount a significant immune response and should be initiated early in the disease, with annual influenza vaccine each year thereafter. Live vaccines should not be used.

KEY TREATMENT

- Treatment of latent TB (positive skin test result) reduces risk of progression to active TB in HIV/AIDS patients (Volmink and Woldehanna, 2004) (SOR: A).
- Influenza vaccine is indicated for HIV/AIDS patients (SOR: A).
- Treatment of asymptomatic HIV-infected patients with TMP-SMX significantly reduces pulmonary infections with *Pneumocystis pneumonia* (Grimwade et al., 2003) (SOR: A).

Fungal Infections of the Lung

Endemic mycoses (histoplasmosis, coccidioidomycosis, and paracoccidioidomycosis) can cause primary pulmonary infections in exposed patients as well as reactivation syndromes in patients with HIV or other causes of immune suppression. The incidence of these infections has decreased with the widespread use of ART for HIV infection. Fungal infections related to *Aspergillus* spp. are more widespread geographically, but the incidence of aspergillosis has also decreased with increasing ART use.

EPIDEMIOLOGY AND RISK FACTORS

Histoplasmosis (*Histoplasma capsulatum*) is most common in basins of the Ohio and Mississippi rivers. Blastomycosis (*Blastomyces dermatitidis*) is found in this same area of the United States as well as in portions of Canada. Coccidioidomycosis (*Coccidioides immitis*) is prevalent in desert areas of the southwestern United States, and paracoccidioidomycosis (*Paracoccidioides brasiliensis*) is the most common endemic mycosis in Central and South America. Airborne exposure to local soil is a risk factor. In South Asia and Southeast Asia (especially India, China, Thailand, and Vietnam), *Penicilliosis marneffei* is another significant endemic mycosis affecting HIV/AIDS patients (Randhawa, 2000).

Aspergillosis occurs most often in the context of immune suppression, especially in HIV-infected patients with CD4⁺ lymphocyte counts less than 50 cells/μL. Leukopenia, systemic corticosteroids, bone marrow transplantation, and broad-spectrum antibiotic therapy also increase risk for aspergillosis.

CLINICAL PRESENTATION

Presentation of any of the endemic mycoses depends on the patient's underlying immune status, as well as on the degree of exposure. For example, in patients with significant immune suppression (CD4⁺ lymphocyte counts <150/μL), histoplasmosis can manifest with signs and symptoms of disseminated multiorgan infection, but patients with more intact immune symptoms can have more localized pulmonary symptoms and signs. Blastomycosis is often a

self-limited infection, but it can lead to chronic pneumonia or skin, musculoskeletal, or CNS involvement (Pappas, 2004). Cough, dyspnea, and fever, with or without weight loss or night sweats, are the most common symptoms (Baumgardner et al., 2004). Coccidioidomycosis similarly can manifest as a self-limited pulmonary infection. In the case of intense exposure or in immunosuppressed patients, it can manifest as a severe fulminant pulmonary infection with ARDS or as a disseminated infection (peritonitis, lymphadenopathy, skin nodules, meningitis, musculoskeletal or liver involvement).

Respiratory disease caused by *Aspergillus* can take the form of pseudomembranous tracheitis or invasive pneumonia. Pseudomembranous tracheitis can lead to airway obstruction. Both respiratory syndromes are associated with cough, fever, dyspnea, and hemoptysis, and pneumonia also produces hypoxia. Chest radiography can show diffuse interstitial infiltrates or even signs of pulmonary infarction caused by fungal invasion of vascular tissue.

DIAGNOSIS

In disseminated histoplasmosis, *Histoplasma* antigen is detectable in blood or urine with 85% to 95% sensitivity. For isolated pulmonary histoplasmosis, BAL or transbronchial biopsy may be required. *Coccidioides* organisms may be cultured or seen on histopathologic tissue stains or detected by serologic tests of blood or CSF. *Aspergillus* spp. may be cultured from sputum samples, which is sufficient for diagnosis in the presence of a typical clinical syndrome and no alternative diagnosis. More definitive diagnosis may be made by BAL (50% sensitivity) or open-lung biopsy.

TREATMENT

Acute, uncomplicated pulmonary histoplasmosis may be treated with watchful waiting in patients with normal immune systems (Wheat et al., 2004). Severe disseminated histoplasmosis or severe diffuse pulmonary histoplasmosis is treated with the liposomal form of amphotericin B initially followed by 12 weeks of oral itraconazole therapy and then lifelong itraconazole prophylaxis. New antifungal agents such as voriconazole, posaconazole, caspofungin, and micafungin are potential alternatives (Herbrecht et al., 2005; Ruhnke, 2004). Detailed treatment guidelines for the management of histoplasmosis and blastomycosis infections are available from IDSA (Chapman et al., 2008; Wheat et al., 2007).

For coccidioidomycosis and blastomycosis, amphotericin B is usually chosen for initial therapy. Less serious infections might respond to fluconazole or itraconazole, and some treatment success has been demonstrated with voriconazole (Bakleh et al., 2005). Meningitis is treated with fluconazole or intrathecal amphotericin B. The CDC recommends treatment with voriconazole for invasive aspergillosis.

PREVENTION

The most important means of preventing fungal pulmonary infections is the ART of HIV/AIDS. HIV patients treated for histoplasmosis or coccidioidomycosis require chronic suppressive therapy with itraconazole or alternative antifungal therapy for life. TMP-SMX prophylaxis

for PCP might also be protective against paracoccidioidomycosis. Education and protective gear (protective masks) during digging, excavation, and construction projects or cave exploration in endemic areas can help prevent acute pulmonary infections caused by high-level environmental exposures.

Vascular Disease

PULMONARY EMBOLISM

Key Points

- Clinical decision rules using objective scoring algorithms help establish pretest probability and enhance the predictive value of other tests for PE.
- A negative *quantitative* D-dimer test result by enzyme-linked immunosorbent assay (ELISA) less than 500 µg/L can effectively rule out PE in patients with low or intermediate pretest probability of disease.
- HRCT scan with contrast can be performed on the lungs and the deep veins of the legs at the same time in a PE protocol.
- Hemodynamically stable patients with submassive PE may be treated with dose-adjusted IV or fixed-dose subcutaneous heparin.
- Hemodynamically unstable patients with massive PE may be treated with thrombolytics or embolectomy.
- Prophylactic therapy is not effective if initiated after a clot has begun to form, so venous thromboembolism (VTE) prophylaxis with subcutaneous heparin should be part of standard hospital admitting orders unless specifically contraindicated.

In the 19th century, Rudolf Virchow defined the pathologic process of PE, in which blood clots, usually from DVTs in one or both legs, break off and are trapped in the pulmonary arterial system, leading to pulmonary infarct, decreased oxygenation of venous blood returning from the periphery, and elevated right-sided pressures in the heart (Dalen, 2002). Two thirds of emboli reach both lungs and lodge in large or intermediate pulmonary arteries, most often in the lower lobes.

Epidemiology and Risk Factors

In 2003, there were 98,921 hospitalizations in the United States during which PE was diagnosed, generating charges of nearly \$2 billion. The in-hospital mortality rate was 3% (Health Care Utilization Project, 2003). The importance of rapid diagnosis and treatment was underscored by Dalen and Alpert in 1975, who estimated that only 6% of PE deaths at that point in medical history occurred in patients diagnosed and treated for PE (Dalen, 2002).

The most important cause of PE is DVT, and both conditions are included under the broader term *venous thromboembolism*. Virchow's triad of risk included hypercoagulability, stasis, and vascular injury. Patients can develop DVT after surgery (especially hip or pelvic surgery), major trauma, prolonged hospitalization or bed confinement, or even prolonged sitting in a confined space (air travel, bus or car trips,

medical school lectures). Patients at highest risk are those with a past history of DVT. Additional risk factors include smoking, cancer, obesity, pregnancy, heart disease, stroke, burns, and medications (e.g., estrogen therapy). Patients with inherited risk include those with antithrombin III deficiency, hyperhomocysteinemia, protein C or protein S deficiency, and factor V Leiden mutation, as well as those with acquired hypercoagulable states such as the antiphospholipid syndrome.

Clinical Presentation

Any suspicion of PE as a cause of acute shortness of breath requires specific diagnostic evaluation and quick intervention in this potentially life-threatening condition. Acute-onset shortness of breath coupled with pleuritic chest pain, hemoptysis, wedge-shaped pulmonary infarct lesions on chest radiograph, and S1Q3 pattern with tachycardia on ECG can all point specifically to a diagnosis of PE, but most patients have a nonspecific presentation. Collateral circulation from bronchial arteries makes pulmonary infarction relatively uncommon. Massive PE can lead to acute right ventricular failure and cardiovascular collapse. PaO₂ greater than 80 mm Hg in room air and a normal A-a O₂ gradient make the diagnosis less likely but do not completely exclude PE. All patients with acute-onset shortness of breath with no apparent cause should be evaluated for PE.

Diagnosis

Diagnosing PE includes an evaluation for DVT. Physical examination for signs of DVT (asymmetry in calf or thigh diameter, calf tenderness, Homans sign) are relatively insensitive and nonspecific, and other tests (venous Doppler ultrasonography or spiral CT with contrast) can more accurately confirm the presence of significant underlying DVT.

When suspected, PE must be confirmed or ruled out with a high degree of certainty. Failure to treat could be life threatening, but treatment carries significant risks as well. Clinical decision rules using objective scoring algorithms help establish pretest probability (high, intermediate, or low), which in turn enhances predictive value of other tests for PE (Ebell, 2004). One common decision tool uses only history and physical examination variables (Wells et al., 2001), and another scoring system adds variables from chest radiography and ABG measurements (Wicki et al., 2001).

Several qualitative, semiquantitative, and quantitative laboratory methods are available for measuring D-dimer. Any negative D-dimer test result can help exclude the diagnosis of PE in patients with low pretest probability of disease, but for patients with moderate pretest probability, only quantitative D-dimer test by ELISA less than 500 µg/L can effectively rule out PE. Spiral CT with contrast and magnetic resonance angiography (MRA), two alternative imaging studies widely replacing V/Q scan, are more accessible and accurate in patients with underlying heart or lung disease, and perhaps more accurate for centrally located than peripheral emboli. Spiral CT also offers the advantage of potentially diagnosing other conditions, and when ordered in a PE protocol may be combined with CT of the lower extremities to evaluate possible DVTs. Table 16-12 summarizes the results of strategies for excluding the diagnosis of PE (using criteria of posttest probability <5%) or for

Table 16-12 Diagnostic Tests to Exclude or Confirm Diagnosis of Pulmonary Embolism

Pretest Probability Based on Objective Clinical Decision Rules	Exclude Diagnosis (PE < 5%)	Confirm Diagnosis (PE > 85%)
Low clinical probability (10%)	Negative D-dimer (quantitative or semiquantitative) Negative spiral CT scan Negative MRA Low-probability V/Q scan	Positive pulmonary angiogram (no other test is adequate to confirm positive diagnosis of PE in a patient with low prior probability)
Moderate clinical probability (35%)	Quantitative D-dimer < 500 µg/L (by ELISA method) Normal or near-normal lung scan Negative spiral CT scan <i>in combination with</i> negative venous Doppler ultrasonography of leg veins	Positive spiral CT scan High-probability V/Q scan Positive MRA Positive venous Doppler ultrasonography of leg veins
High clinical probability (70%)	Negative pulmonary angiogram (no other test is adequate to exclude or rule out diagnosis of PE in a patient with a high prior probability)	Positive spiral CT scan High-probability V/Q scan Positive MRA Positive echocardiogram ultrasound

CT, Computed tomography; ELISA, enzyme-linked immunosorbent assay; MRA, magnetic resonance angiography; PE, pulmonary embolism. V/Q, ventilation/perfusion ratio.

confirming the diagnosis (posttest probability >85%) (Roy et al., 2005).

Treatment

The options for treatment of PE include anticoagulation, thrombolysis, and (rarely) surgery. With controlled trials ongoing, no clear recommendation yet exists for thrombolysis in all cases of PE. One trial of alteplase plus heparin showed significantly decreased mortality in patients with submassive PE compared with patients treated only with heparin (Konstantinides et al., 2002). However, a meta-analysis of all RCTs comparing thrombolytic therapy with heparin in patients with PE showed a survival benefit only in studies that included hemodynamically unstable patients (patients with massive PE). In trials that excluded these patients, there was no benefit found for thrombolysis (mortality rate slightly worse for thrombolytic therapy) (Wan et al., 2004). Treatment of DVT with thrombolytics has also been studied, and although venous blood flow may be improved and post-DVT syndrome decreased, there is a significant risk of hemorrhagic complications such as stroke.

In massive PE with cardiovascular collapse, thrombolysis is often used, but emergency pulmonary embolectomy is an option in settings in which cardiothoracic surgery can be mobilized rapidly. Dauphine and Omari (2005) reported on 11 patients with massive PE treated with emergency embolectomy. Of the seven patients who did not have preoperative cardiac arrest, all survived to hospital discharge. One of the four patients who experienced cardiac arrest preoperatively also survived to discharge.

For patients who are hemodynamically stable and have less than massive pulmonary emboli, the initial treatment choice is dose-adjusted, IV unfractionated heparin or fixed-dose, subcutaneous low-molecular-weight heparin (LMWH). A meta-analysis comparing these two therapies in VTE treatment found odds ratios favoring LMWH in both the rate of recurrence and the rate of bleeding complications, but these differences were not statistically significant (Erkens and Prins, 2010). LMWH by fixed-dose subcutaneous injection is at least as safe and effective as traditional dose-adjusted, unfractionated heparin therapy. Anticoagulation with warfarin is indicated for at least 3 to 6 months after an initial PE episode, and lifetime therapy may be warranted for patients with hypercoagulability or

recurrent episodes. Patients with recurrent episodes unresponsive to anticoagulation might benefit from surgical placement of an inferior vena cava filter.

Prevention

Primary prevention of PE begins with prevention of DVT. Trauma, hip or pelvic surgery, general surgery, and hospitalization or prolonged bed rest put patients at significant short-term risk. Many cases of VTE can be prevented in these patients if prophylaxis is initiated promptly. Prophylactic therapy is not effective if it is initiated after a clot has begun to form, so it is crucial to include VTE prophylaxis (subcutaneous heparin as well as mechanical interventions) on admitting orders for most patients admitted to a hospital for surgery or for serious medical conditions. Clinicians currently underuse prophylactic therapies recommended in various clinical guidelines. They should order heparin prophylaxis on admission automatically unless there is a specific contraindication or the patient is clearly not at risk rather than ordering prophylaxis only when risk factors are obvious (Tooher et al., 2005). When DVT begins in the legs, prompt diagnosis and therapy can provide effective secondary prevention of the more life-threatening PE.

KEY TREATMENT

- DVT prophylaxis begun routinely on hospital admission, unless specifically contraindicated, can prevent many in-hospital PE episodes (Tooher et al., 2005) (SOR: A).
- An algorithm using clinical indicators, quantitative D-dimer test, and various imaging studies (spiral CT with contrast, MRA, venous Doppler ultrasonography) can effectively rule in (>85% probability) or rule out (<5% probability) PE (Roy et al., 2005) (SOR: A).

PULMONARY HYPERTENSION

Pulmonary hypertension is diagnosed when pulmonary artery pressures exceed normal levels, and symptoms ensue. The condition may be either primary or secondary to other causes, which can be pulmonary, cardiac, or systemic in origin.

Epidemiology and Risk Factors

Secondary causes of pulmonary hypertension include chronic lung disease (COPD and chronic bronchitis), cardiac disease (congenital defects, mitral stenosis, left atrial myxoma), autoimmune or inflammatory conditions such as scleroderma and SLE (Paolini et al., 2004), and granulomatous disease such as sarcoidosis. Certain drugs (fenfluramine) can also cause the condition, as can chronic liver disease with portal hypertension. Some patients experience pulmonary hypertension as a complication of arterial clotting or chronic damage from single or multiple episodes of PE.

Primary pulmonary hypertension is diagnosed when there is no obvious cause of the condition, and there is a familial form of the disease as well. Persistent pulmonary hypertension of the newborn occurs in 1.9 neonates per 1000 live births and results from shunting through a patent foramen ovale and ductus arteriosus, with or without pulmonary hypoplasia (Greenough and Khatriwal, 2005).

Clinical Presentation

Symptoms include easy fatigability, exertional dyspnea, chest pain, dizziness or lightheadedness, and syncope. Underlying pulmonary or cardiac disease can mask the diagnosis in early stages. Pulmonary hypertension is often diagnosed late with signs of right-sided heart failure. Patients with COPD, pulmonary fibrosis, sarcoidosis, or recurrent PE who have evidence of right-sided heart failure (cor pulmonale) should be evaluated for pulmonary hypertension as well.

Diagnosis

In the primary care office, patients can have signs of right-sided chamber enlargement on ECG. Echocardiography may also suggest increased right-sided pressures and decreased cardiac index and can be performed both at rest and during exercise. It may also reveal cardiac causes of secondary pulmonary hypertension (Bossone et al., 2005). Definitive diagnosis is made by recording of a pulmonary artery pressure greater than 25 mm Hg on catheterization.

Treatment

Nonspecific treatments of pulmonary hypertension include loop diuretics, digoxin, and anticoagulant therapy with warfarin when indicated. Traditional therapies include dihydropyridine calcium channel blockers such as nifedipine or amlodipine, which can modestly decrease pulmonary arterial pressures in vasoresponsive patients but can also cause sudden death in nonvasoresponsive patients (Humbert, 2004; Malik et al. 1997).

Other therapies include prostacyclins such as epoprostenol and treprostinil; both are pulmonary and systemic vasodilators but must be given by continuous IV infusion through an indwelling catheter or by subcutaneous injection (treprostinil) (Paramothayan et al., 2005b). Iloprost is an inhaled form of prostacyclin apparently with fewer side effects that can improve exercise capacity and symptom scores, but it requires frequent dosing (Baker and Hockman, 2005). Side effects and economic costs are significant obstacles to the use of all these agents. Bosentan is a nonselective endothelin receptor antagonist, and sitaxsentan is a

selective endothelin receptor antagonist. Both improve functional status and physiologic measures in pulmonary hypertension (Liu and Cheng, 2005).

Sildenafil, which inhibits PDE-5 in the pulmonary vasculature, has also been approved for this indication based on results of a controlled trial that showed it improved 6-minute walk distance, New York Heart Association functional class, pulmonary artery pressure, cardiac index, and oxygenation. Sildenafil (2005) is also less expensive than the prostacyclins and endothelin receptor antagonists. Dipyridamole also has some PDE-5 activity.

Inhaled nitric oxide is a selective pulmonary vasodilator that is often used to treat persistent pulmonary hypertension of the newborn. In adults with pulmonary hypertension, a 2-year trial of inhaled nitric oxide therapy combined with dipyridamole demonstrated improvements in exercise capacity, symptoms, and hemodynamic measures (Perez-Penate et al., 2005). A European consensus panel has released guidelines for the use of nitric oxide in this condition (Germann et al., 2005).

Surgical therapies may be general (lung transplant) or specific, as in the repair of congenital shunting lesions, mitral stenosis, or atrial defects. Pulmonary thromboendarterectomy is effective in some patients with pulmonary hypertension associated with saddle pulmonary embolus (Olsson et al., 2005).

OTHER PULMONARY DISEASES OF THE PULMONARY VASCULATURE

Wegener granulomatosis is a small-vessel vasculitis that can manifest either with shortness of breath or hemoptysis or with progressive pulmonary fibrosis caused by repeated small hemorrhages at the alveolar level. It usually combines pulmonary features with glomerulonephritis. Tissue biopsy of either the lung or the kidney may be diagnostic. Clinical manifestations result from the combination of vasculitis, glomerulonephritis, and necrotizing granulomas of the respiratory tract. CT may be more sensitive than MRI for diagnosis of pulmonary lesions.

Diffuse alveolar hemorrhage may result from autoimmune collagen vascular disease or vasculitis, Goodpasture syndrome, and other vasculitides. *Goodpasture syndrome* results from the formation of anti-glomerular basement membrane antibodies, which can also attack the lung capillary membranes. Primary pulmonary vasculitides affect mostly small vessels, but systemic conditions can affect vessels of all sizes. *Churg-Strauss syndrome* is a small-vessel vasculitis that often manifests first as asthma. Most patients also have maxillary sinusitis, allergic rhinitis, or nasal polyps. GI, neurologic, and cardiac involvement often follows. The condition responds well to systemic steroids, but patients can require long-term low-dose prednisone as maintenance therapy (Guillevin et al., 2004).

Pulmonary Complications of Sickle Cell Disease

Patients with sickle cell disease have complications that can manifest with pulmonary signs and symptoms. For example,

patients with sickle cell disease are especially vulnerable to capsular bacteria such as *Streptococcus pneumoniae* (pneumococcus) and *Haemophilus influenzae*, and they can present with acute lobar pneumonia, sepsis, or even pneumonia-related ARDS. Pneumococcal and *H. influenzae* type b vaccines, in combination with penicillin prophylaxis, have significantly reduced (but not eliminated) rates of serious infections with these organisms (Hord et al., 2002).

Acute chest syndrome is an acute syndrome of varying origins in patients with sickle cell disease. One third of patients with this syndrome have an identified infectious cause. Fewer than one in 10 has a documented fat embolism. Postulated mechanisms in most patients with no identified cause include hypoxia-induced pulmonary vasoconstriction, with microclot formation and decreased levels of nitric oxide and other chemical mediators of vasodilation, inflammatory response, and cellular protection (Stuart and Setty, 2001). Hydroxyurea therapy promotes production of hemoglobin F and appears to decrease the likelihood or severity of acute chest syndrome. Nitric oxide therapy might be of use acutely in acute chest syndrome or chronically in the treatment of pulmonary hypertension, but there is inadequate evidence from controlled trials.

Among adults with sickle cell disease, pulmonary hypertension is a significant cause of morbidity and appears to be a significant predictor of mortality, even with relatively modest elevations of pulmonary artery pressure. The pulmonary hypertension can be caused by widespread thrombosis of small arteries, although the cause is uncertain in many cases (Adedeji et al., 2001). Pulmonary hypertension complicates other chronic hemolytic anemias as well (Machado and Gladwin, 2005).

Malignant Disease

LUNG CANCER

Key Points

- Lung cancer is the leading cause of cancer deaths in U.S. men and women.
- Smoking is the most serious and prevalent risk factor for lung cancer.
- Any pulmonary symptoms persisting beyond 3 weeks are indications for diagnostic evaluation. Smokers and patients older than 40 years should receive a more aggressive workup.
- HRCT is more sensitive than chest radiography for diagnosing lung cancer. CT also provides anatomic detail for staging and operability.
- Patients with stage I, non–small cell carcinoma have 50% 5-year survival rate with appropriate surgical resection.
- The family physician plays a central role in facilitating family conversations about diagnostic and treatment options, advance directives, palliative care, and other end-of-life decisions.

Epidemiology and Risk Factors

Although not the most common cancer, lung cancer is the leading cause of cancer deaths in men and women in the

United States. Lung cancer surpassed breast cancer as a cause of death among women in the 1990s because of increased smoking among women and better detection, treatment, and survival of breast cancer. Smoking is clearly the most serious and prevalent risk factor for the development of lung cancer. According to the CDC, from 2000 to 2004, smoking resulted in an estimated annual average of 269,655 deaths among men and 173,940 deaths among women in the United States. The top three smoking-attributable causes were lung cancer, ischemic heart disease, and COPD (CDC, 2008).

Clinical Presentation

Smokers are at significant risk for lung cancer, but other patients can develop lung cancers as well, especially if they have significant secondary exposure to tobacco smoke or other carcinogens. A history of asbestos exposure is a specific risk factor for the development of mesothelioma. Patients can present with respiratory symptoms such as a cough, hemoptysis, or shortness of breath, or they can present with constitutional symptoms such as fatigue and unexplained weight loss. In some cases, a chest radiograph done for other reasons reveals a pulmonary nodule or mass lesion. In patients with metastatic pulmonary lesions, the symptoms of the primary cancer may be predominant or occult.

Diagnosis

Any pulmonary symptoms persisting beyond 3 weeks are an indication for a more extensive evaluation, and smokers and patients older than 40 years should receive a more aggressive workup. Diagnostic evaluation can begin with chest radiograph, but negative results do not rule out lung cancer or provide tissue diagnosis or staging. HRCT scanning is a more sensitive test for identifying lung cancers even at asymptomatic stages. HRCT can also provide some anatomic detail for staging and determining operability of the cancer. Tissue diagnosis is essential not only for confirming the presence of malignancy but also for determining the histopathology. Fiberoptic bronchoscopy with biopsy brushings and washings is highly accurate for diagnosing centrally located bronchogenic carcinoma in the proximal bronchial tree. Transbronchial biopsy can reach deeper tissues for diagnosis of metastatic pulmonary nodules or even lymph node biopsy. Peripheral pulmonary lesions or pleural lesions can be reached by CT-guided needle biopsy or by surgical open-lung biopsy.

The combination of tissue biopsy and imaging studies yields both the histopathologic type and the stage of cancer. The non–small cell lung cancers may be further classified into various histopathologic cell types, such as adenocarcinoma and squamous cell carcinoma. Staging of non–small cell cancers is summarized in [Table 16-13 \(American Cancer Society, 2005\)](#).

Treatment

General treatment principles and guidelines provide a framework for primary care practitioners. Histopathology and stage at diagnosis drive treatment options. For example, surgical resection is not generally effective in treating small cell carcinomas of the lung, which may respond better to chemotherapy. On the other hand, a stage I, non–small cell

Table 16-13 Staging and 5-Year Survival Related to Lung Cancers

Clinical Stage	Defining Characteristics	Average 5-Year Survival Rate (%)
NON-SMALL CELL CANCERS		
I	Carcinoma confined to lung tissue; no spread to other organs or adjacent structures, and no lymph node involvement Substages A and B refer to size of tumor.	51
II	Carcinoma confined to lung tissue; no spread to other organs or adjacent structures but positive lymph node involvement Substages A and B refer to size of tumor.	26
III	Carcinoma with spread to adjacent structures, such as chest wall, diaphragm, mediastinum, or contralateral lung Stage IIIA may still be operable; IIIB is inoperable.	8
Stage IV	Metastatic to distant organs or tissue beyond the thoracic cavity	2
SMALL CELL CANCERS		
Limited	Limited to one lung or one side of the chest with no distant spread	10-20
Extensive	Spread beyond one lung to distant organs	1-2

From Lung and bronchus cancer: survival rates by race, sex, diagnosis-year, stage and age. SEER Statistics in Review, 1975–2003. National Cancer Institute. http://seer.cancer.gov/csr/1975_2003/results_merged/sect_15_lung_bronchus.pdf.

carcinoma might have as much as a 50% 5-year survival rate with appropriate surgical resection. The European Respiratory Society and European Society of Thoracic Surgeons have published extensive clinical guidelines for evaluating any lung cancer patient's fitness for combined surgery and chemoradiotherapy (Brunelli et al, 2009).

Treatment options in addition to surgery include radiation therapy and chemotherapy. Response to any therapy differs by cell type (e.g., squamous cell vs. adenocarcinoma), stage of disease, and whether the tumor is primary or secondary. Some genetic polymorphisms are associated with certain lung cancers in nonsmokers and can be responsive to more specific chemotherapeutic treatment regimens. Patients with metastatic pulmonary nodules from estrogen receptor-positive breast cancer may be treated quite differently from those with primary adenocarcinoma of the lung, although both generally receive some form of chemotherapy. The primary care practitioner must maintain a close working relationship with medical and surgical oncologists to help guide patients and families through various treatment options.

One specific role for the family physician is to help the patient and family address psychosocial needs in a proactive manner. The family physician may facilitate the first conversation between the patient and the patient's family in which the word "cancer" is mentioned or an ongoing conversation in which issues of death and dying can be addressed. The family physician must find the balance in

encouraging the family to maintain hope but also in helping the family to develop contingency plans for potential crises, such as respiratory arrest or loss of function that leave the patient unable to live independently at home. Health care power of attorney and advance-directive documents are a much-needed complement to living wills, which cover only a narrow set of circumstances at the end of life. The family physician can help ensure that pain and other forms of discomfort are managed appropriately and can work closely with the patient, family, oncologist, nurses, hospice, and the patient's faith community to manage proactively the balance between preserving life and preventing suffering, especially in a patient with a terminal illness.

Prevention

Smoking causes lung cancer. Never smoking is the most important preventive measure available, but smoking cessation reduces the risk of all of the major histologic types of lung cancer (Khuder and Mutgi, 2001). Beta-carotene and vitamin E do not prevent lung cancer, and in therapeutic doses, beta-carotene might be associated with a slight increase in cancer (Albanes et al., 1995).

Regular chest radiography screening with or without sputum cytology does not improve mortality rates (Manser et al., 2003). Studies suggest that routine screening of smokers with spiral CT every 6 months does increase detection of early stage cancer and might improve mortality rates by increasing the percentage of non-small cell cancers that are operable (Gohagan et al., 2005). Patients with stage I, non-small cell lung cancers may have a 5-year survival rate of 50%, but only 15% of lung cancers are found at this stage without routine screening.

Another aspect of preventing lung cancer deaths is the rate at which patients of different racial and ethnic groups receive potentially curative surgery in stage I disease. African American patients, for example, have significantly lower rates of surgery and significantly higher mortality rates. Causes of these racial disparities include patient factors (locus of control, acceptability of surgery, health beliefs about risks of opening such cancers to air during surgery); provider factors (biased treatment recommendations or assumptions about what patients might want); systemic or institutional factors (lack of insurance, poverty); and perhaps most important, the patient-physician dyad (issues of respect, trust, and effective communication influence the outcome of negotiating the treatment plan).

KEY TREATMENT

- Smoking causes lung cancer. Never smoking is the most important preventive measure available, but smoking cessation also reduces the risk of all the major histologic types of lung cancer (Khuder, 2001) (SOR: A).
- Routine screening of smokers with chest radiography or sputum cytology does not improve survival. Use of frequent spiral CT suggests increased detection of early-stage cancer and improved mortality in non-small cell cancers (Gohagan et al., 2005; Manser et al., 2003) (SOR: A).
- Beta-carotene and vitamin E do not prevent lung cancer and in therapeutic doses might be associated with a slight increase in cancer (Albanes et al., 1995) (SOR: B).

Occupational Lung Disease

Key Points

- At least 10% of asthma cases in adults can be attributed to occupational causes.
- The two key questions are, “Have you ever been exposed to fumes, gases, or dusts?” and “Do your symptoms get better when you are away from work, such as during weekends and vacations?”
- Asbestosis passed coal miner’s lung as the leading cause of death from occupational pneumoconiosis in the United States.
- Because most occupational masks or respirators are imperfect and workers often remove them, preventive strategies should focus on worksite air-quality improvement.

Exposure to fumes, gases, or dusts in the workplace are a common source of pulmonary symptoms and disease. Taking a good occupational history is essential. In the occupational history, ask the specific type of work the patient performs and other jobs the patient has performed in the past. Two key questions are, “Have you ever been exposed to fumes, gases, or dusts?” and “Do your symptoms get better when you are away from work, such as during weekends and vacations?” Clinically, occupational lung diseases can be divided into five major groups (National Institute for Occupational Health and Safety [NIOSH], 1999): work-related asthma, pneumoconiosis, hypersensitivity pneumonitis, acute irritant or inhalant toxicity, and work-related cancers.

WORK-RELATED ASTHMA

At least 10% of asthma cases in adults can be attributed to occupational exposures, so an occupational history should be obtained in every patient with asthma. Diagnostic criteria are the same as for other causes of asthma or airway obstruction, including spirometry (FEV₁/FVC ratio <0.7) and evidence of reversibility.

Chemical and natural agents can cause asthma or aggravate preexisting asthma. These include chemicals used in

cleaning or manufacturing processes. Occupational exposures causing work-related asthma include dust exposures (e.g., cotton dust, wood sawdust, cement powder, bakery flour), organic exposures (e.g., molds and fungi in agricultural grains), chemical exposures (e.g., solvents, plastics, epoxies, ammonia, chlorine, petroleum vapors), and fumes from welding or other industrial sources (van Kampen et al., 2000), as shown in Figure 16-5 (NIOSH, 2004a). Peak-flow meter readings measured at the same time each day on workdays, weekends, and vacation days can help establish the occupational cause of disability for insurance purposes.

OCCUPATIONAL PNEUMOCONIOSES

The occupational pneumoconioses are diffuse parenchymal lung diseases caused by airborne exposure to inorganic materials such as asbestos, silica, and coal dust. In 1998 and 1999, asbestosis passed coal workers’ pneumoconiosis (coal miner’s lung) as the leading cause of death from occupational pneumoconiosis in the United States. Men accounted for 98% of these deaths. The rise in deaths caused by asbestosis is illustrated in Figure 16-6 (NIOSH, 2004b). Other occupational lung diseases are linked to heavy metal dust or fumes in specific syndromes such as berylliosis (beryllium) and stannosis (tin). Byssinosis, or brown-lung disease, occurs most often among workers in yarn, thread, and fabric mills from exposure to cotton dust.

Patients with occupational pneumoconioses may first develop symptoms of cough and dyspnea, with signs of small-airway disease or overt airway obstruction on pulmonary function testing. As the disease progresses, patients may also develop spirometric evidence of restrictive lung disease as well as chest radiography changes. Removing the patient from the exposure or workplace is the most important step for preventing progression of disease. These pneumoconioses respond poorly to corticosteroids. Smoking significantly worsens the progression of occupational pneumoconiosis (Wang and Christiani, 2000).

HYPERSENSITIVITY PNEUMONITIS

Exposure to organic materials such as fungi, plant proteins, animal danders, or other organic dust can cause a similar type of diffuse parenchymal lung disease known as

Figure 16-5 Causes of work-related asthma, 1993 to 1999. NOS, Not otherwise specified. (From National Institute for Occupational Safety and Health. Distribution of agent categories most often associated with work-related asthma cases for all four SENSOR reporting States [California, Massachusetts, Michigan, New Jersey], 1993–1999. Worker Health Chartbook, 2004. <http://www2a.cdc.gov/niosh-Chartbook/imagdetail.asp?imgid=206>.)

Figure 16-6 Asbestos as a contributing or underlying cause of death in the United States, 1968 to 1999. (From National Institute for Occupational Safety and Health: Number of deaths of U.S. residents aged 15 or older with asbestosis recorded as an underlying or contributing cause on the death certificate, 1968–1999. Worker Health Chartbook, 2004. <http://www2a.cdc.gov/NIOSH-Chartbook/imagetdetail.asp?imgid=217>.)

hypersensitivity pneumonitis. Examples include farmers' lung, mushroom workers' lung, and bird fanciers' disease. Although fewer than 100 deaths per year in the United States are directly attributed to hypersensitivity pneumonitis, the number of cases and resulting short- or long-term disability are potentially much higher.

ACUTE IRRITANT OR INHALANT TOXICITY

A number of acute pulmonary exposures each year are related to inhaled exposures to irritant chemicals. For example, when certain household chemicals such as bleach and ammonia are mixed, chlorine gas can be produced. Chlorine and chlorinated chemicals cause direct injury to tissues throughout the respiratory tract, including the bronchial mucosa. Injury can fill the alveolar sacs with fluid in a noncardiac form of pulmonary edema, or "chemical pneumonitis."

The large surface area of the alveolar sacs in close approximation to the pulmonary capillary system also provides a portal of entry to systemic toxicity from certain inhaled agents. For example, organophosphate and carbamate chemicals, whether used as nerve gas or as agricultural pesticides, can be absorbed readily throughout the respiratory tract. More than 5000 persons died within 1 week after inhaling methyl isocyanate gas released from a factory in Bhopal, India, in 1984. Pulmonary toxicity can also occur as a consequence of systemic exposures. For example, patients exposed to the toxic pesticide paraquat through skin absorption or by ingestion through the GI tract often die from pulmonary hemorrhage or progressive pulmonary fibrosis.

WORK-RELATED CANCERS

The most obvious form of cancer associated with occupational inhalation exposures is mesothelioma, which is most often linked to asbestos exposure. Asbestos-related malignant mesothelioma accounted for an estimated 21,500 deaths in the United States from 1985 to 2009 (Lilienfeld et al., 1988). Persons with an occupational history of welding, pipefitting, shipbuilding, or other exposure to asbestos are at risk.

Lung cancers have also been associated with various occupational exposures, including welding or smelting fumes, coal dust, silica dust, and organic solvents. A more common exposure that has more recently been recognized as occupational is secondary exposure to tobacco smoke. Bartenders, restaurant staff, and others who work in smoke-filled environments are at significant risk for tobacco-related disease, including lung cancers, even if they have never personally smoked.

PREVENTION

Smoking significantly worsens the progression of occupational pneumoconioses such as black lung disease (coal miner's lung) and silicosis. Because most occupational masks or respirators are imperfect even when worn (and workers often remove masks intermittently for comfort), preventive strategies that rely on daily consistent use of respirators or masks in occupational settings are less effective than worksite air-quality improvement (e.g., increased ventilation, air filters, decreased dust or toxin production) in preventing occupational lung disease.

Granulomatous Diseases

SARCOIDOSIS

Sarcoidosis is the most common granulomatous disease of the lungs not attributed to a known infectious cause. Sarcoidosis is defined as a multisystem granulomatous inflammatory disease of unknown etiology, most likely caused by an aberrant immune response to an environmental or infectious agent in a genetically susceptible host. There may be multiple causes of sarcoidosis, based on specific arrangements of antigen, HLA molecules, and the T-cell receptor within individuals (Baughman, 2011; Spagnola, 2013).

Risk Factors

Sarcoidosis can be found worldwide, but regional and racial or ethnic variations in epidemiology and clinical manifestations are intriguing. For example, it affects persons of Scandinavian origin and African Americans at much higher rates than other populations, with an incidence of 35.5 per 100,000 in African Americans and a slight female predominance. Several occupational and environmental exposures have been studied as possible risk factors for sarcoidosis, but none has been conclusively identified. The Sarcoidosis Genetic Analysis (SAGA) study suggested specific genetic loci related to sarcoidosis susceptibility in African Americans (Gray-McGuire et al., 2006). Other studies show promise of characterizing susceptibility loci in a broader range of racial or ethnic groups (Iannuzzi, 2007).

Clinical Presentation

Sarcoidosis typically presents in early adulthood, between the ages 20 and 40 years. Although the disease is systemic, a spectrum of clinical manifestations may suggest the prognosis. The onset of fever; arthralgias; bilateral hilar adenopathy on chest radiography; and a raised, reddish skin lesion along the anterior tibial surfaces (erythema nodosum) characterize *Löfgren syndrome*, an acute, self-limiting form of sarcoidosis that often undergoes spontaneous remission and has a favorable prognosis. The insidious onset of dyspnea, dry cough, hilar adenopathy and infiltrates on chest radiography, new skin lesions of the trunk and extremities, and complaints of recent vision changes characterize a chronic progressive form of sarcoidosis marked by multiple flares of disease requiring repeated treatment throughout the patient's lifetime.

Symptoms that bring patients to medical attention most often emanate from the lungs, skin, or the eyes (uveitis and lacrimal gland enlargement). Diagnosis of sarcoidosis may be delayed when pulmonary symptoms present that are identical to more common lung diseases such as asthma or chronic bronchitis (Judson et al., 2003). The presence of airflow obstruction on pulmonary function testing and airway hyperreactivity have been identified in some subgroups of sarcoidosis patients, making differentiation from asthma difficult (Kalkanis, 2013; Young, 2012). Pulmonary symptoms may result from bronchial obstruction, either external compression caused by adenopathy or granulomas within the airways. Progressive disease may cause damage to the lung parenchyma, with a restrictive pattern of pulmonary function and decreased diffusion capacity

consistent with progressive interstitial lung damage. Clinical features associated with a worse outcome include the presence of lupus pernio, chronic uveitis, hypercalcemia or nephrocalcinosis, nasal mucosal involvement, and bone cysts. Neurosarcoidosis and cardiac involvement, though not common, often carry increased morbidity and a more severe disease course for patients.

Diagnosis

The diagnosis of sarcoidosis is one of exclusion. The disease is established when clinical and radiographic findings are supported by a tissue biopsy specimen showing *noncaseating granuloma* (NCG). It is necessary to rule out known causes of NCG inflammation that may be seen in biopsies from fungal infection, foreign body inclusions, and other noninfectious granulomatous diseases such as Langerhans cell histiocytosis (also referred to as eosinophilic granulomatosis or pulmonary histiocytosis X) and Wegener granulomatosis. Tissue biopsy can usually be obtained from the lung, a palpable lymph node, a skin lesion, or the eye (conjunctiva or lacrimal gland). Percutaneous fine-needle aspiration specimen is less frequently obtained from the liver or from retroperitoneal or abdominal nodes by CT guidance. Biopsy from a CNS or cardiac location requires specialty consultation.

Along with clinical symptoms and biopsy, chest radiograph findings are added to support the diagnosis of sarcoidosis. The Scadding staging system classifies chest radiographs into stage 0 (normal), stage 1 (bilateral hilar adenopathy), stage 2 (adenopathy and infiltrates), stage 3 (infiltrates alone), and stage 4 (fibrosis and retractions). A chest radiograph showing bilateral hilar adenopathy in HIV-negative patients with negative skin test result and cultures for TB is suggestive, but lymphoma and other causes must be ruled out. HRCT can confirm the size and location of adenopathy as well as granulomas and early pulmonary fibrosis.

Transbronchial biopsy can document pathology and endobronchial involvement of the respiratory mucosa. Fine-needle aspiration of endobronchial lymph nodes is being used increasingly. Endobronchial ultrasonography to localize more peripheral adenopathy enhances accuracy. Analysis of BAL fluid showing a C4/C8 lymphocyte ratio greater than 3.5 has high specificity for sarcoidosis. Open-lung biopsy is usually not needed but can be diagnostic. Several biomarkers and cytokine profiles that may be helpful in the diagnosis and disease activity in sarcoidosis are under investigation (Bargagli et al., 2008). The serum ACE level has historically been used and is often elevated in initial cases, but it is not fully reliable as the disease progresses. A sarcoidosis assessment instrument has been developed to help clinicians better characterize organ involvement in patients with sarcoidosis (Judson et al., 1999).

Treatment

Some patients with sarcoidosis may require no treatment or only intermittent nonsteroidal antiinflammatory drugs for joint and constitutional symptoms. Topical corticosteroids may be effective for anterior uveitis and some skin lesions. ICSs and bronchodilators are often used when cough is a prominent symptom in patients with pulmonary involvement, but response has been equivocal. Systemic therapy is

needed for the majority of patients. Systemic corticosteroids are first-line therapy and, for patients with pulmonary involvement, improve symptoms, pulmonary function, and chest radiographic signs of disease (Paramothayan, 2005a).

Second-line therapies include cytotoxic agents and other immunomodulating agents (Baughman et al., 2008). Methotrexate and hydroxychloroquine can be used as steroid-sparing agents. In patients with cardiac or neural sarcoidosis, treatment regimens that include cytotoxic therapy (e.g., cyclophosphamide) are needed. Other treatment strategies include agents that inhibit tumor necrosis factor α (infliximab, adalimumab, etanercept) (Nunes et al., 2005). Comorbid illnesses and multiorgan involvement are common in sarcoidosis (Cox et al., 2004; Westney et al., 2007), so health-related quality-of-life instruments should be used to monitor global response to therapy (DeVries and Drent, 2007), and multidisciplinary team-based care is recommended.

Interstitial Lung Diseases

The ILDs represent a broad range of acute and chronic lung disorders. The pathology may display varying degrees of pulmonary inflammation and fibrosis, leading ultimately to end-stage lung disease. ILDs are classified under the larger designation of *diffuse parenchymal lung disease*, which includes disorders from known causes (occupational and environmental exposures, as well as progressive infections) and unknown causes (sarcoidosis, lymphangioleiomyomatosis, pulmonary histiocytosis X, eosinophilic pneumonia, idiopathic ILDs). The idiopathic ILDs have been subclassified by the *ATS and European Respiratory Society (2002)* into the following clinicopathologic entities, in order of relative frequency: idiopathic pulmonary fibrosis (IPF), nonspecific interstitial pneumonia, cryptogenic organizing pneumonia, acute interstitial pneumonia, respiratory bronchiolitis-associated ILD, desquamative interstitial pneumonia, and lymphoid interstitial pneumonia.

EPIDEMIOLOGY AND RISK FACTORS

Occupational risk factors and specific occupational lung diseases are reviewed in previous sections. Various medications, chemotherapeutic agents, and radiation therapy can all cause diffuse parenchymal lung disease and may result in end-stage lung disease with pulmonary fibrosis. Other causes include autoimmune connective tissue disorders (SLE, RA), granulomatous diseases (sarcoidosis, pulmonary Langerhans cell histiocytosis, eosinophilic granuloma), and metabolic diseases (Gaucher disease, Niemann-Pick disease), congenital neoplasia (tuberous sclerosis, neurofibromatosis) malignancy (lymphangitic carcinomatosis, bronchoalveolar carcinoma, pulmonary lymphoma), and certain drugs (bleomycin, nitrofurantoin, amiodarone). Among the ILDs, idiopathic pulmonary fibrosis occurs more often in patients older than age 60 years and in men more than women. Cigarette smoking, chronic aspiration, various environmental exposures (metal and wood dust), and numerous viruses (Epstein-Barr, influenza, CMV) have been implicated as potential risk factors. The remaining ILDs rarely occur and are designated as separate disease entities

based on specific clinicopathologic differences (Lynch et al., 2005).

CLINICAL PRESENTATION

The hallmark symptoms of ILDs are the insidious onset of progressive shortness of breath and exertional dyspnea with paroxysmal dry cough. A careful history may elicit symptoms of an earlier viral prodrome in patients that may also include cough with varying sputum production and systemic symptoms such as fever or weight loss. On physical examination, most patients can have the typical dry, end-inspiratory (“Velcro”) crackles most appreciable in the lung bases. The finding of cyanosis and accentuated second heart sound, right ventricular heave, and lower extremity edema suggest late phases of the disease caused by chronic hypoxemia and pulmonary fibrosis.

DIAGNOSIS

The usual diagnostic approach for all ILDs is a thorough history and physical examination along with chest radiographic and pulmonary function studies. Assessment of serum antinuclear antibody titer with associated autoantibodies can implicate the presence of a connective tissue disease, which presages a better long-term survival than IPF (Cottin, 2013). The chest radiograph typically shows bilateral, often asymmetric reticular opacities in the peripheral and basal lung areas. A normal-appearing radiograph may rarely be encountered but does not exclude microscopic presence of an ILD. Often, radiographic abnormalities can be seen years before the development of symptoms, so past films should be reviewed. HRCT features of idiopathic pulmonary fibrosis may be distinct and include bibasilar subpleural honeycombing, traction bronchiectasis (as illustrated in Fig. 16-7), thick intralobular septa, and minimal ground-glass opacities. If the HRCT pattern shows a predominance of ground-glass opacification, especially located away from the subpleural areas, diagnoses such as

Figure 16-7 Computed tomography scan of a patient with idiopathic pulmonary fibrosis.

nonspecific interstitial pneumonia, bronchiolitis obliterans organizing pneumonia, or hypersensitivity pneumonitis should be considered. In some cases, fibrotic scarring and nodules create a mass lesion that must be distinguished from carcinoma or other neoplasm.

The typical PFT pattern is that of a restrictive ventilatory defect with decreased lung flow and volume, increased FEV₁/FVC ratio, and decreased DLCO. Biopsy may be necessary to exclude malignancy or to rule in specific conditions such as sarcoidosis. Documenting pulmonary function, exercise capacity (6-minute walk test), and relationship of the ILD to any occupational or environmental exposure are all essential for helping patients receive appropriate worker's compensation or disability support when needed.

TREATMENT

Smoking cessation is essential, and pulmonary rehabilitation may improve quality of life and functional capacity for patients with any ILD. Pharmacologic options include single-agent or combination corticosteroid therapy and immunomodulating or antifibrotic agents (azathioprine, cyclophosphamide, colchicine, D-penicillamine). Overall, whereas these therapies have shown marginal to no benefit in cases of idiopathic pulmonary fibrosis, patients with other ILDs may have a better response (Davies et al., 2003). A meta-analysis of 390 patients with pulmonary fibrosis did find that interferon- γ -1b therapy significantly reduced the mortality rate (Bajwa et al., 2005). Causes of death identified for pulmonary fibrosis in one study included respiratory failure (39%), cardiovascular disease (27%), lung cancer (10%), and pulmonary infection or emboli (6%) (Panos, 1990).

Unilateral lung transplantation may enhance survival and functioning in patients with advanced interstitial fibrosis with chronic respiratory failure, but pulmonary fibrosis with pulmonary hypertension may require bilateral lung transplantation (Alalawi et al., 2005). The 1-year survival rate after lung transplantation is 75%, with 44% of patients surviving 5 years or longer (Trulock, 2001).

Lung Manifestations of Autoimmune Connective Tissue Disorders and Other Systemic Diseases

Many connective tissue diseases can have an impact on the lungs and pleura or on pulmonary function. RA, for example, can cause ILD because of a fibronodular inflammatory response or even larger rheumatoid nodules. Inflammation can also lead to pleural effusion or scarring, and pleural biopsy can reveal rheumatic nodules. Patients with RA can also develop one of several varieties of inflammatory interstitial pneumonia.

Systemic lupus erythematosus can affect the lungs. The inflammatory response of SLE is more vasculitic in nature, which can manifest as pulmonary hemorrhage, thromboembolic disease, or an inflammatory pleuritis with effusion.

Other autoimmune diseases with pulmonary manifestations include mixed connective tissue disease, Sjögren syndrome, and progressive systemic sclerosis (scleroderma). Progressive systemic sclerosis can manifest with thickening and tightening of the skin of distal extremities; sclerodactyly; Raynaud phenomenon; and multiorgan involvement of the lungs, skin, kidney, heart, and GI tract. Sixty percent of patients have shortness of breath; others have cough, pleuritic chest pain, or hemoptysis. Lung CT scan in progressive systemic sclerosis and other autoimmune conditions can show pleural scarring and ILD, especially a ground-glass fibronodular pattern and honeycombing.

Diseases of the Pleura and Extrapulmonary Space

Key Points

- In international settings, the most common cause of pleural disease is TB.
- More than 200 mL of pleural fluid may be detected by physical examination or by blunting of the costophrenic angles on upright chest radiography. Decubitus positioning of the patient can reveal as little as 10 mL of fluid on the dependent side.
- Thoracentesis may be done blindly if pleural fluid layers out to at least 1 cm on decubitus radiograph. Otherwise, ultrasound-guided thoracentesis may be indicated.
- An exudate is diagnosed in pleural fluid by finding a pleural/serum protein ratio greater than 0.5 and a pleural/serum LDH level greater than 0.6 (or pleural LDH > 200 IU/dL) or pleural protein greater than 3 g/dL.
- Purulent fluid in the pleural space is indicated by a high neutrophil count and pH less than 7.2, which can require a chest tube along with antibiotics.
- Rapid drainage of more than 1 L of fluid from large pleural effusions (or air from pneumothorax) can result in reexpansion pulmonary edema.

The lungs are lined by visceral pleura, and the inside of the thoracic cavity is lined by parietal pleura. Normally, these two are closely adjacent, with only enough fluid for lubrication in the space between them.

EPIDEMIOLOGY AND PRESENTATION

Outside the United States, the most common cause of pleural disease is TB. In the United States, TB is still significant, but other disorders, such as pneumonia, HIV-related infections, connective tissue disease (especially lupus), and malignancies (mesothelioma, peripheral lung cancer) must also be considered. Pleural effusions can be caused by systemic sources of transudate (CHF, hepatic failure with ascites, autoimmune disease) or by local inflammatory processes (parapneumonic effusion, pancreatitis, neoplasia).

Four major categories of pathology arise from the pleura or pleural space: pleural fluid (transudate, exudate, hemorrhage, or chylous effusion), pneumothorax, pleural scarring, and pleural mass.

DIAGNOSIS

Pleuritic disease is suggested by thoracic pain on inspiration. More than 200 to 300 mL of fluid in the pleural space may also be detected by physical examination. Decreased breath sounds with dullness to percussion could suggest pleural fluid or lung consolidation, but pleural effusion may be distinguished by the presence of decreased tactile and vocal fremitus. Often, there is a small (1-2 cm) zone at the top edge of the pleural effusion where traditional signs of consolidation may be heard, including egophony. A pleural rub may be heard in areas of inflammation but disappears when significant fluid cushions the movement of visceral pleura against parietal pleura. For pneumothorax, significant air must be present in the pleural space to detect hyperresonance, although breath sounds are often decreased on the affected side. In the 1% to 2% of cases producing *tension pneumothorax*, in which air is able to enter the space but not equilibrate with either extrathoracic or bronchial air pressures, the clinician may detect tracheal shift, cardiac shift, or decreased heart sounds.

Chest radiography reveals blunting of the costophrenic angles and visible fluid when about 200 mL of fluid has accumulated in the pleural space. Decubitus positioning of the patient can reveal as little as 10 mL of fluid on the dependent side on chest radiography. Thoracentesis may be done blindly if the fluid layers out to at least 1-cm thickness on decubitus radiography. Otherwise, ultrasound-guided thoracentesis may be indicated.

Pneumothorax is also visible on chest radiography, especially when it exceeds 10% or more than 100 mL of air is present in the pleural space. On radiographs, 2.5 cm of air space between the thoracic wall and the lung is equivalent to a 30% pneumothorax. This is best visualized on upright PA and lateral radiography or occasionally on the nondependent side when patients are in the decubitus position. Other imaging studies (CT, MRI) can give more anatomic detail in patients with mass lesions or scarring. These studies are also somewhat more sensitive than radiography in detecting small amounts of air in pneumothorax.

Diagnostic thoracentesis can help determine the type of fluid and potential causes. *Transudates* are serous fluids often associated with inflammatory conditions. Transudative fluid is thin and mildly yellow or straw colored, through which one can read newsprint. More specific laboratory criteria for differentiating exudate from transudate include a pleural/serum protein ratio greater than 0.5, pleural/serum lactate dehydrogenase (LDH) level greater than 0.6 (or measured pleural LDH >200 IU/dL), and pleural protein greater than 3 g/dL.

Exudates indicate the presence of WBCs and often a response to infection such as pleural abscess or TB. Parapneumonic effusions may be inflammatory transudates initially or may progress to exudative fluid as WBCs and even the infectious organism itself spread to the pleural space. Infectious exudates are suggested by pH higher than 7.2, which can be an indication for chest tube drainage. More specifically, TB may be suggested by an exudative pleural effusion with elevated WBC count, more lymphocytes than granulocytes, and pleural glucose/serum glucose ratio less than 0.5. Hemorrhage into the pleural space is indicated by the gross or microscopic presence of red

blood cells, although poor technique can result in a bloody tap that is not diagnostic. For mass lesions or scarring, pleural biopsy may be obtained (revealing granulomas or malignancy) either percutaneously with needle or surgically in an open biopsy.

TREATMENT

Treatment most importantly targets the underlying condition. For example, the inflammatory pleural effusions of SLE may be treated with systemic corticosteroids or other antiinflammatory agents. Antibiotics treat pneumonia and parapneumonic effusions, although purulent fluid or abscess in the pleural space can require chest tube drainage in addition to antibiotics.

Other indications for chest tube placement include pneumothorax compromising ventilation, exceeding 25%, or recurring after initial needle thoracostomy. Trauma with hemorrhage into the pleural space can also require a chest tube or even open-chest surgery to identify and treat the source of bleeding. Some pleural effusions may be treated with therapeutic pleural tap rather than chest tube. In these cases, up to 1 L of fluid may be drained through a pleural needle and catheter. For these therapeutic taps, attaching the thoracostomy needle to a tube and vacuum bottle is an alternative to the traditional technique of using a large syringe and stopcock to remove 30 to 50 mL at a time. Rapid drainage of large pleural effusions or pneumothorax can result in reexpansion pulmonary edema.

Patients with recurrent pneumothorax may require surgery to repair a specific defect. Patients with malignant pleural effusion that has recurred after complete reexpansion may benefit from pleural sclerosis, instilling agents such as bleomycin or tetracycline. Pleural stripping is rarely used because of the high rate of complications.

Disorders of Breathing

Sleep apnea may be obstructive or central in origin or a combination of both. The effects of recurrent apnea extend well beyond simple fatigue or sleep deprivation, causing significant cardiovascular and neurologic disease. Patients with *obstructive* sleep apnea are often but not always obese. They experience episodes of intermittent apnea, often associated with snoring, especially during deeper stages of sleep. In addition to obesity, adenoidal or tonsillar enlargement, macroglossia, and laxity of the soft palate and pharyngeal tissue can contribute to sleep apnea. Stroke, brain tumors, trauma, cerebral edema, and other CNS disorders can affect breathing at the *central* level as well. Brainstem infarctions can lead to respiratory arrest and death. *Cheyne-Stokes respirations* describe an undulating pattern of breathing of increased depth and frequency alternating with waves of shallow, slower breathing and even apnea.

Many patients with obstructive sleep apnea have elements of central apnea as well. For example, alcohol and sedatives can exacerbate the respiratory depression and contribute to pharyngeal muscle laxity. In addition, patients with chronic obstructive sleep apnea can develop chronic CO₂ retention that further depresses respiration. Patients with the classic “pickwickian syndrome” (obesity and

hypoventilation syndrome) have a constellation of signs, including morbid obesity, obstructive apnea, polycythemia, pulmonary hypertension, and right-sided heart failure. Patients can present with symptoms of daytime drowsiness, sleepiness, or feeling inadequately rested. Family members often bring the problem to the attention of the patient or the family physician, having observed loud snoring and interruptions in breathing during sleep. Sometimes a motor vehicle crash resulting from somnolence while driving brings the condition to light. Depression can also develop.

In addition to symptoms related to loss of sleep or upper airway obstruction, sleep apnea can contribute to other major causes of morbidity and mortality. Bradyarrhythmias are common, and hypoxia can lead to ventricular arrhythmias or even myocardial ischemia or stroke. When episodic hypoventilation becomes frequent or chronic, with resultant hypoxia and hypercapnia, a metabolic response may counteract the respiratory acidosis associated with hypoventilation; the kidneys retain bicarbonate to foster a compensatory metabolic alkalosis. Systemic and pulmonary hypertension may be intermediate outcomes that lead to more serious cardiac complications.

Formal diagnosis of sleep apnea can be made in a sleep laboratory using multichannel recording (polysomnography) of electroencephalography, ECG, airflow, upper airway muscle tone, and oximetry. Home oximetry alone might not be adequately sensitive. The most essential treatment is significant weight reduction to decrease obesity. Other behavioral treatments include avoiding supine sleep and avoiding alcohol and sedatives. Nasal CPAP is effective for patients who tolerate it. Various oral or dental devices are also available, but data on effectiveness are limited. Surgical procedures attempt to reduce airway obstruction at the palate or tonsillopharyngeal or adenoidal levels. The American Academy of Sleep Medicine has published clinical guidelines with evidence-based recommendations

and algorithms for the evaluation, diagnosis, treatment, and follow-up of patients with sleep disorders (Epstein et al., 2009).

Ophthalmology

EARL R. CROUCH, Jr., ERIC R. CROUCH, and THOMAS R. GRANT, Jr.

CHAPTER OUTLINE

Red Eye, 274
Ocular Trauma and Other Emergencies, 282

Pediatric Ophthalmology, 285
Adult Ophthalmology, 293

Patients present to family physicians with a limited set of symptoms, often with subtle differences to indicate mild or serious ocular conditions. To decide when to treat patients and when to refer them to an ophthalmologist, family physicians must possess a complete appreciation of these subtle differences. Knowledge of the basic anatomy of the eye is essential in determining these diagnostic differences (Figure 17-1).

Red Eye

Family physicians frequently encounter patients who complain of “red eye.” Usually, the condition causing the red eye is a simple disorder, such as conjunctivitis or subconjunctival hemorrhage. These conditions improve spontaneously or are readily treated. A red eye, however, may be a symptom of a more serious disorder, such as herpetic dendritic ulcer, iritis, acute angle-closure glaucoma, ophthalmia neonatorum, or congenital glaucoma. These conditions must be clearly distinguished from the much more common conjunctivitis and subconjunctival hemorrhage because *immediate referral* to the ophthalmologist is paramount. To evaluate the red eye, the family physician needs to have available a penlight, magnifying glasses, a visual acuity chart, fluorescein dye, anesthetic drops, and a tonometer.

EVALUATION

Symptoms and Signs

Patients who complain of a red eye generally can tell the physician whether the eye irritation occurred rapidly or progressed slowly. This information is important because a small foreign body, such as a grain of sand, lodged in the conjunctival sac produces a rapid hyperemia, but a viral or allergic conjunctivitis, or an iritis, generally produces a slowly progressive redness. Ocular pain is an important symptom (Table 17-1). Irritation of the superficial layer of the cornea, as caused by a small foreign body, is accompanied by a superficial “grain of sand” sensation in the eye. Deeper inflammatory processes, such as iritis or iridocyclitis, or a deeper penetrating foreign body in the cornea present with more severe, dull pain in the eye.

Abnormal light sensitivity (photophobia) is a third danger symptom that must be elicited by the family physician. Photophobia occurs with corneal inflammation, iritis, and

angle-closure glaucoma. Patients who have conjunctivitis usually do not have abnormal light sensitivity (Table 17-2).

Patients who complain of a red eye often complain of discharge from the eye (Table 17-3). If they do not complain of eye discharge spontaneously, the physician must inquire about the presence, type, and quantity of discharge. Purulent (creamy white or yellow watery) discharge suggests a bacterial cause. A serous or clear discharge suggests a viral cause. Scanty, white, stringy exudate occurs most often with allergic conjunctivitis. The absence of discharge indicates an unusual cause for red eye, such as iridocyclitis, ultraviolet (UV) light keratitis (snow blindness), or acute angle-closure glaucoma. A complaint of diminished visual acuity is a serious danger sign and must be elicited in the history.

Physical Examination

It is important to examine both eyes because many patients with conjunctivitis in one eye have clear signs of early conjunctivitis in the other. The type of infection must be closely inspected; whereas *conjunctival* infection is characterized by individually visible vessels in the conjunctiva branching from the sclera toward the cornea, *ciliary* infection appears as a red ring surrounding the cornea in which individual vessels are not clearly visible. The significance of ciliary infection is that the deep ciliary vessels are involved, indicating a much more serious inflammatory condition of the eye, such as a deep corneal infection, iritis, or iridocyclitis. Inspect the palpebral conjunctiva carefully with magnification to determine whether lymphoid hyperplasia (cobblestone appearance) exists. The type and quantity of discharge are assessed by pulling down the lower eyelid. The appearance of the punctum should be examined to determine whether pus is coming out of the tear duct. Palpation of the tear sac on the upper portion of the nose (lacrimal crest) demonstrates tenderness in cases of acute dacryocystitis.

Carefully examine the cornea. Normally, the cornea is perfectly transparent. Excessive fluid within the stroma of the cornea results in partial opacification that can be observed by direct illumination with a penlight. A diffuse corneal haze can occur with congenital glaucoma and angle-closure glaucoma. After inspection with a penlight under magnification, corneal staining is performed with fluorescein using sterile filter paper strips. The stained part of the strip is moistened with water and touched to the conjunctiva away from the cornea. With blinking, the fluorescein spreads over the cornea. A UV light source

Figure 17-1 Anatomy of the right eyeball. (From Scheie HG, Albert DM. *Textbook of ophthalmology*, 9th ed. Philadelphia, Saunders, 1977.)

Table 17-1 Red Eye: Differential Diagnosis

Parameter	Conjunctivitis, Bacterial	Iritis	Keratitis	Acute Glaucoma
Vision	Normal	Blurred	Blurred	Marked blurring
Pain	None	Moderately severe; intermittent stabbing	Sharp, severe	Severe; sometimes nausea or vomiting
Photophobia	None	Moderate	Moderate	Moderate
Discharge	Usually significant with crusting of lashes	None	None to mild	None
Conjunctival injection	Diffuse	Circumcorneal	Circumcorneal	Diffuse
Appearance of cornea	Clear	Clear	Cloudy	Cloudy
Pupil size	Normal	Constricted	Normal	Dilated
IOP*	Normal	Normal or low	Normal	Elevated

*Caution: Do not measure intraocular pressure (IOP) with discharge present.

From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.

Table 17-2 Approach to a Patient Presenting with Red Eye (No History of Trauma)

1. Check for the following symptoms or signs:
 - a. Reduced vision
 - b. Pain
 - c. Photophobia
 - d. Corneal staining
 - e. Corneal edema
 - f. Unequal pupils
 - g. Elevated intraocular pressure
2. Refer to ophthalmologist if any of these signals are present.
3. If none of the above is present, the diagnosis is probably conjunctivitis.
4. The triad of a red eye, pain, and loss of vision should *always* alert the examiner to a potentially blinding condition.

Table 17-3 Conjunctivitis Clues

Finding	Cause
Purulent discharge	Bacterial
Serous or clear discharge	Viral
Stringy, white discharge	Allergic
Preauricular lymph node enlargement	Viral

enhances fluorescence. Areas of bright-green staining denote absent or diseased epithelium. Corneal staining readily demonstrates a corneal abrasion and helps identify corneal foreign bodies and infectious epithelial defects, such as herpetic dendritic keratitis (Figure 17-2).

Examine the pupils carefully for size and shape. In most people, the pupils are of equal size; a small percentage have congenital variation in the size of the pupils (anisocoria). These patients are often aware that their pupils are unequal. In patients with previously equal pupils, inequality of the

Figure 17-2 Corneal abrasion. The patient had a fingernail injury caused by the daughter (*left*). Characteristic fluorescein staining is displayed in the adjacent photomicrograph (*right*).

pupil may indicate iritis, typically with the affected pupil partially constricted. In acute angle-closure glaucoma, the pupil is usually partially dilated and may not be round. Unequal pupil size is an important sign of significant ocular trauma or third nerve palsies.

Estimate the anterior chamber depth by side illumination with a penlight. If the anterior chamber is normal or deep, the entire surface of the iris is well illuminated. When the anterior chamber is shallow, the iris on the more distant side of the pupil is in shadow. A shallow anterior chamber in a red eye may indicate acute angle-closure glaucoma or ocular trauma. The anterior chamber appears deep in patients with congenital glaucoma.

If the red eye does not have an obvious infection, the *intraocular pressure* (IOP) should be measured with a tonometer. IOP is normal in most patients with red eye, except for those with acute angle-closure glaucoma. With iritis and traumatic, perforating ocular injuries, IOP is generally low. Sterilize the tonometer before and after application to a red eye, preferably by heat sterilization.

Preauricular lymph node enlargement is a frequent sign of viral conjunctivitis and usually is not present with acute bacterial conjunctivitis (see [Table 17-3](#)).

RED EYE IN INFANTS

Key Points

- Red eye in infants requires special attention to differentiate ophthalmia neonatorum, congenital glaucoma, conjunctivitis, and dacryocystitis.
- Cultures should be obtained in neonates with symptoms suggestive of ophthalmia neonatorum.
- Febrile children with acute dacryocystitis should have cultures tested to direct management.
- Infants with symptoms of congenital glaucoma should be promptly referred to an ophthalmologist.
- For chronic dacryocystitis, the best age for surgical intervention is 6 to 12 months.
- Infants with a dacryocystocele require prompt ophthalmologist referral and systemic antibiotics.

Several conditions occur specifically during the first year of life. They include ophthalmia neonatorum, acute and chronic dacryocystitis, bacterial conjunctivitis, and congenital glaucoma.

Table 17-4 Management of Ophthalmia Neonatorum

Disease	Diagnosis	Treatment
Gonococcal conjunctivitis	Gram-negative intracellular diplococci <i>plus</i> Growth on chocolate agar or Thayer-Martin agar <i>plus</i> Fermentation glucose negative and maltose negative	Ceftriaxone, 125 mg IM single dose <i>plus</i> one of the following: Oral tetracycline, 500 mg qid Oral doxycycline, 100 mg bid Oral erythromycin, 500 mg qid Ophthalmology consultation
Other bacterial conjunctivitis	Gram stain <i>plus</i> Growth on blood agar or chocolate agar	Gram positive: erythromycin ointment qid, or fluoroquinolone qid for 2 wk Gram negative: gentamicin, tobramycin, or fluoroquinolone qid for 2 wk
Chlamydial conjunctivitis	Giemsa stain—basophilic intracytoplasmic inclusion bodies <i>plus</i> Chlamydial culture	Tetracycline, 500 mg qid for 3-4 wk Erythromycin, 250-500 mg for 3 wk bid Doxycycline, 100 mg bid for 2 wk Azithromycin, 1 g (one dose)

bid, Twice daily; *IM*, intramuscular; *qid*, four times daily.

Ophthalmia Neonatorum

Ophthalmia neonatorum is an infection or inflammation of the conjunctiva that occurs during the first 4 weeks of life. Possible causes include chemical conjunctivitis, *Neisseria gonorrhoeae*, and chlamydial infection. The increased incidence of venereal disease and shortcomings in silver nitrate prophylaxis are significant factors in the constantly evolving clinical picture. Ophthalmia neonatorum frequently is a manifestation of a systemic infection, requiring determination of the exact cause in all but the most transient cases. [Table 17-4](#) outlines the management of the various types of ophthalmia neonatorum. At present, erythromycin is the medication of choice. Povidone-iodine ophthalmic solution (0.5%) is less toxic, inexpensive, and

effective but is not generally used because of confusion over povidone solution versus povidone soap.

Silver nitrate has been replaced by erythromycin, so the incidence of chemical conjunctivitis has decreased significantly. Before the neonatal prophylaxis, gonorrhea was a common cause of ophthalmia neonatorum. Half of patients with *gonococcal* conjunctivitis develop corneal clouding, a major cause of blindness. Gonococcal conjunctivitis still occurs, despite erythromycin prophylaxis. Frequently, the infant with gonococcal conjunctivitis presents with swollen eyelids, purulent exudates, beefy-red conjunctiva, and conjunctival edema. The gonococcal organism can rapidly penetrate the intact corneal epithelium and produce corneal perforation if recognition and treatment are delayed. When gonococcal conjunctivitis is suspected, referral to an ophthalmologist is critical. Patients may also have systemic involvement, with associated central nervous system (CNS) signs. Both parents should be examined for venereal disease and treated, if necessary.

A recommended regimen for ophthalmia neonatorum prophylaxis is a single application of silver nitrate 1% aqueous solution, erythromycin 0.5% ophthalmic ointment, or tetracycline 1% ophthalmic ointment (Centers for Disease Control and Prevention [CDC], 2002b).

CHLAMYDIAL INFECTION

Chlamydial infections are a leading cause of ophthalmia neonatorum. There is a high incidence of this type of infection because of the frequent exposure to newborns during delivery and the lack of effective prophylaxis. The onset of infection can occur at any time. The typical picture is a mild unilateral or bilateral mucopurulent conjunctivitis with moderate eyelid edema, chemosis, and conjunctival injection. Systemic involvement may include rhinitis, vaginitis, and otitis media.

Treatment is with tetracycline ointment or erythromycin four times daily for 4 weeks. In addition, both parents should be treated with oral tetracycline or azithromycin. Alternative treatments include oral erythromycin or doxycycline for 3 weeks. Systemic tetracycline should be avoided in breastfeeding women with this infection.

Conjunctival cultures are indicated in all cases of suspected infectious neonatal conjunctivitis (CDC, 2002a).

Bacterial Conjunctivitis

The most common gram-positive bacteria that are causative agents of conjunctivitis include *Staphylococcus aureus*, *Streptococcus pneumoniae*, and group A and B streptococci (Figure 17-3). Gram-negative organisms include *Haemophilus influenzae*, *Escherichia coli*, and *Pseudomonas aeruginosa*. Bacterial conjunctivitis can occur at any age from the first day of life. Chemosis (edema of bulbar conjunctiva), purulent discharge, eyelid edema, and injection are common signs. Associated systemic septicemia can occur, especially with *Pseudomonas* infection. Cultures should be prepared on blood and chocolate agar.

A topical fluoroquinolone often provides effective treatment for severe cases before culture results (Leibowitz, 1991). Gram-negative organisms are best treated with tobramycin or a topical fluoroquinolone. Systemic antibiotics are recommended when there is evidence of systemic

Figure 17-3 Purulent conjunctivitis may indicate infection with *Staphylococcus* spp., *Haemophilus influenzae*, *Streptococcus* spp., or *Pseudomonas* spp. (From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.)

Figure 17-4 Acute dacryocystitis in a neonate with fever and malaise. Lacrimal sac massage and systemic antibiotics relieved the acute infection.

disease. Physicians should use caution with gentamicin, neomycin, and sulfacetamide eye medications because these drugs may cause a toxic chemical conjunctivitis and complicate management. Patients with mild conjunctivitis generally respond to erythromycin or bacitracin ointment.

Acute Dacryocystitis

Neonates may present with acute dacryocystitis, an inflammation of the lacrimal sac (Figure 17-4). Pain, tearing, redness, and discharge usually occur. If the child is febrile, culture testing and Gram staining should be done. *S. pneumoniae* and *S. aureus* are the most common pathogens. Systemic antibiotics are indicated for the acute stage. The ophthalmologist should be consulted immediately because irrigation and probing may be necessary to establish drainage as quickly as possible. Severe cases may progress to a dacryocystocele, sepsis, meningitis, or even death, especially in young infants.

Chronic Dacryocystitis and Nasolacrimal Duct Obstruction

Infants with chronic dacryocystitis usually present to the physician with a chronic history of tearing and crusting with a chronic yellow discharge. Topical antibiotics, such as

Figure 17-5 Congenital glaucoma in a 2-month-old infant who presented with a cloudy cornea involving the right eye. Intraocular pressure was elevated. The diagnosis was congenital glaucoma.

a fluoroquinolone four times daily, should be used. The parent should be taught to compress or massage the lacrimal sac four to six times daily. Approximately 80% of these inflammations resolve spontaneously by age 6 to 12 months. If treatment is not successful or if dacryocystitis persists, the patient should be referred and the nasolacrimal duct system irrigated between 6 and 10 months of age. Before age 14 months, a single probing is curative in about 90% of cases.

Congenital Glaucoma

Congenital glaucoma is a potentially blinding condition with an incidence of one per 10,000 births. It is often confused with chronic dacryocystitis. About two thirds of these cases are bilateral. These patients, similar to those with dacryocystitis, present with excessive tearing. The infants usually are light sensitive (photophobic) and frequently bury their heads in pillows or blankets. These infants often have intense blinking or eyelid spasms (blepharospasm). An enlarged cornea or corneal clouding can be detected clinically and measured with a plastic ruler (normal =12 mm) (Figure 17-5). Corneal edema is the result of elevated IOP, which causes breaks in the inner corneal layers (Descemet membrane) and intrusion of anterior chamber fluid into the corneal stroma. Increased IOP causes significant optic nerve damage, which can lead to blindness. Whenever glaucoma is suspected, immediate consultation is indicated. Surgical treatment of congenital glaucoma is successful in approximately 90% of cases. These patients must be followed by an ophthalmologist for life as a precaution against recurrent IOP elevation and amblyopia.

KEY TREATMENT

- Newborns should be prophylactically treated with erythromycin 0.5% or tetracycline 1% ophthalmic ointment to reduce the risk of ophthalmia neonatorum (CDC, 2002a) (SOR: A).
- Ciprofloxacin 0.3% ophthalmic solution is effective empiric treatment of bacterial conjunctivitis (Leibowitz, 1991) (SOR: A).
- A broad-spectrum antibiotic for 5 to 7 days is generally effective for most cases of bacterial conjunctivitis (American Academy of Ophthalmology [AAO], 2008) (SOR: A).

Figure 17-6 Seborrheic blepharitis is characterized by greasy, dandruff-like scales on the eyelashes. (From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.)

- Children with nasolacrimal duct obstruction may undergo nasolacrimal duct surgery between 6 and 12 months of age or sooner if clinically indicated (Katowitz et al., 1987) (SOR: C).
- Children with congenital glaucoma should be promptly referred to a pediatric ophthalmologist or glaucoma specialist (AAO, 2008) (SOR: A).

RED EYE IN ADULTS AND OLDER CHILDREN

Key Points

- Red eye in adults and older children requires careful evaluation to differentiate the various causes of inflammation.
- Purulent conjunctival discharge warrants culturing and broad-spectrum antibiotics.
- Allergic conjunctivitis generally responds well to topical treatment; symptoms may manifest or worsen on initiation of systemic antihistamines.
- Orbital cellulitis requires prompt computed tomography and systemic antibiotics. Cultures should be obtained from the nasopharynx, conjunctiva, and blood.
- Iritis is characterized by pain, photophobia, miosis, and circumciliary injection and generally occurs after blunt trauma.
- A red eye in a contact lens wearer requires prompt evaluation for a corneal ulcer.
- Acute angle-closure glaucoma is an ocular emergency and requires immediate treatment by an ophthalmologist.

Blepharitis

Blepharitis is a chronic eyelid inflammation that involves abnormalities of the glands surrounding the eyelashes. The two most common types are chronic staphylococcal infections of the eyelid and seborrheic blepharitis (Figure 17-6). *Staphylococcal blepharitis* is the most common inflammation of the external eye. It is frequently asymptomatic initially, but as the disease progresses, the patient complains of

Figure 17-7 Acute hordeolum, or stye. The swollen, tender, red eyelid includes an acute, boil-like lesion. Treatment includes warm compresses and topical antibiotics. (From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.)

Figure 17-8 Chalazion of right upper eyelid in 10-year-old girl. (From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.)

foreign body sensation, matting of the lashes, and burning. Eyelid crusting, discharge, redness, and loss of the eyelashes are observed. *Seborrheic blepharitis* is associated with seborrhea of the scalp, lashes, eyebrows, and ears, characterized by greasy, dandruff-like scales on the eyelashes. Blepharitis is not associated with skin ulcerations. Treatment of both these conditions is long and laborious. Eyelid hygiene is recommended for both conditions. Topical antibiotics are prescribed for staphylococcal blepharitis. Both conditions are recurrent and require repeated therapy.

Stye

A stye is the most common localized infection of one of the glands of the eyelid margin (Figure 17-7). It is an acute boil-like lesion, and the patient usually has a swollen, tender, red eyelid. There may be a moderate amount of conjunctival injection. Treatment includes warm compresses for 15 minutes four times per day and topical antibiotics. Systemic antibiotics are usually not indicated unless there is a preseptal cellulitis component. Generally, the stye drains spontaneously within several days. If resolution does not occur within 2 weeks, the patient should be referred.

Chalazion

A chalazion is a chronic swelling of the eyelids not associated with conjunctivitis (Figure 17-8). The chalazion, a granulomatous inflammatory reaction, may persist for weeks or even months. Chalazia are generally not amenable to oral or topical antibiotics unless the lesion is secondarily infected. Chalazia are usually rubbery, cystic, and non-tender on palpation. When the upper eyelid is involved, vision may be temporarily blurred. If the chalazion persists for more than 4 to 6 weeks, it may require incision and curettage. Recurrent chalazia may be caused by an underlying sebaceous carcinoma, so the lesion should be biopsied and sent for pathologic testing.

Bacterial Conjunctivitis

All common bacteria may cause acute conjunctivitis. Presently, *S. pneumoniae*, *H. influenzae*, *S. aureus*, and *P. aeruginosa* are the most common pathogens. The most frequent causes of hyperacute conjunctivitis are *N. gonorrhoeae* and *N. meningitidis*. Risk factors for bacterial conjunctivitis include contact lens wear, exposure to infectious persons, compromised immune systems, nasolacrimal duct obstruction, and sinusitis. In the presence of a severe purulent discharge, culture of the conjunctiva is mandatory (see Figure 17-3). Subconjunctival hemorrhage may occur with bacterial conjunctivitis and is especially common with *H. influenzae* conjunctivitis.

Treatment of conjunctivitis is with a topical antibiotic, such as erythromycin or bacitracin. Tobramycin ophthalmic ointment may be used for many gram-positive and gram-negative conjunctivitis cases. Ciprofloxacin and ofloxacin also provide effective broad coverage of most types of conjunctivitis. Gonococcal and *Haemophilus* conjunctivitis require systemic and topical therapy. If the conjunctivitis does not improve within 2 to 3 days or the worsening symptoms develop, the patient should be referred to an ophthalmologist.

Ciprofloxacin and ofloxacin provide effective broad coverage of most causative organisms. Newer fluoroquinolones such as gatifloxacin and moxifloxacin provide more potent coverage and better penetration for gram-positive organisms than earlier types of fluoroquinolones. Topical steroids or antibiotic-steroid combinations for conjunctivitis or other causes of red eye should not be used unless the patient is under the care of an ophthalmologist.

Topical corticosteroids have four potentially serious ocular side effects and are contraindicated for conjunctivitis, as follows:

1. Steroids can facilitate penetration of an undetected corneal herpetic infection to the deeper corneal layers and cause corneal perforation.
2. Prolonged local use of the corticosteroids (usually >2 weeks) can cause chronic open-angle glaucoma.
3. Prolonged use of topical corticosteroids can cause cataracts.
4. Topical corticosteroids are capable of potentiating the development of fungal corneal ulcers.

In general, topical steroids should be reserved for patients under the care of an ophthalmologist.

KEY TREATMENT

- Cultures of the conjunctiva are indicated in all cases of suspected infectious neonatal conjunctivitis (SOR: A).

Viral Conjunctivitis

Viral conjunctivitis, in contrast to bacterial conjunctivitis, has a less prominent discharge that is usually watery. The condition is highly contagious, and handwashing is important to avoid infection. When infected, hospital personnel, daycare workers, and institutional personnel should avoid contact with others. Palpable preauricular lymph nodes frequently are present with viral conjunctivitis and represent an important sign that can differentiate it from bacterial conjunctivitis. An associated upper respiratory infection may occur. In advanced cases, true photophobia and blurred vision caused by corneal involvement may be present and require consultation. However, most viral conjunctivitis is self-limiting, and no specific treatment is indicated. Topical steroids are contraindicated. Most viral infections resolve within 10 to 14 days, and specific serologic diagnosis is not necessary. If the conjunctivitis persists or there is any pain or change in vision, the patient should be referred.

Allergic Conjunctivitis

Allergic conjunctivitis is frequently found in pediatric patients and adults. It is usually seasonal, most often the spring and fall. Although often associated with allergic rhinitis, allergic conjunctivitis may occur without systemic symptoms. There is an increase in itching, redness, and swelling, which is variable from day to day. Seasonal allergic conjunctivitis is related to tree and grass pollens, each of which has a distinct season and severity. The condition may be asymmetric. Chronic allergic conjunctivitis is most often related to various indoor allergens, including dust mites, animal dander, molds, and cockroaches. Cats are especially irritating to the eye for the allergic patient.

Treatment for allergic conjunctivitis involves avoidance procedures for outdoor allergens, keeping windows closed at night during allergy season, and wearing eye protection (even sunglasses can reduce exposure to allergens). Washing the face after coming indoors, washing the hair when showering, and keeping the patient's hands away from the eyes can reduce allergen exposure. Bed linens should be washed weekly. Occasionally, allergy testing and allergy shots may be necessary in severe recalcitrant cases.

Symptomatic treatment of allergic conjunctivitis includes cool compresses, artificial tears, and nonprescription antihistamines. Topical antihistamine–decongestant combinations include naphazoline hydrochloride–antazoline phosphate (Vasocon-A) and naphazoline hydrochloride–pheniramine maleate (Naphcon-A), which are reasonably safe and effective. However, rebound vasodilation can occur and cause chronic hyperemia and conjunctival injection.

Cromolyn sodium 4% and olopatadine hydrochloride (Patanol) are effective mast cell stabilizers. Ketorolac tromethamine (Acular), azelastine hydrochloride (Optivar), and lodoxamide tromethamine (Alomide) are also reasonable options for managing allergic conjunctivitis. Systemic allergy medications may cause allergic conjunctivitis to manifest because of reduced tear film production.

Subconjunctival Hemorrhage

A patient may present with a bright-red eye, normal vision, and no pain. Usually, no obvious cause exists, but in some patients, there is a history of coughing, sneezing, or straining before the hemorrhage is present. The patient should be reassured that it is nothing more than hemorrhage of the conjunctiva. There is no therapy except reassurance that the blood will clear within 2 to 3 weeks. Hematologic blood coagulation studies are usually of limited value in patients with subconjunctival hemorrhages unless there is a history of recurrence. Additionally, it is unusual for a hemorrhage to involve the relatively avascular sclera. If trauma is suspected, the patient should be referred to an ophthalmologist to rule out more serious injuries, such as perforation, contusion, or occult rupture of the globe. Subconjunctival hemorrhage may indicate that the patient is a battered child or adult, and other signs of bodily trauma should be investigated.

Corneal Herpetic Infections

Herpetic infections of the eye can produce conjunctivitis, corneal inflammation (keratitis), and uveitis (inflamed iris, ciliary body, and choroid). The herpes simplex virus (HSV) is the most common cause of corneal opacification in temperate-zone countries. Humans are the only natural host for this DNA virus. Approximately 90% of the population has systemic antibodies to HSV. The incubation period of HSV infection is 2 to 12 days. HSV type 1 (HSV-1) is the most common cause of ocular infection, but transmission of HSV-2 also can occur. Although classically HSV-1 is the oral type and HSV-2 is the genital type, current epidemiologic studies indicate that either type may be the source of corneal infection, and therefore cultures and viral titers are often sent for both types.

Primary Herpes Simplex Infection. Primary ocular infection in a nonimmune subject usually presents as conjunctivitis with a clear watery discharge, skin vesicles on the eyelids, and preauricular nodes. Associated vesicles and ulcers on the oral mucosa and skin are common. Corneal involvement also may occur with single or multiple dendrites. If dendrites are present, the patient should be referred for treatment. Particular attention should be given to inspecting the nose for possible lesions. A lesion at the tip of the nose indicates involvement of the cornea through the nasociliary branch of cranial nerve V. Treatment generally

Figure 17-9 Orbital cellulites in 3-year-old patient. (From American Academy of Ophthalmology. *The red eye*. San Francisco: AAO Professional Information Committee; 1986.)

involves trifluridine 1% (Viroptic) drops five times daily for 10 to 14 days. If other regions are involved, oral acyclovir is added to trifluridine, as in eyelid or corneal involvement. These patients should be managed by an ophthalmologist.

Recurrent Corneal Herpetic Infections. At the time of the primary herpetic infection, the virus gains access to the CNS, where it resides in a latent state in the trigeminal and other ganglia. Recurrent attacks occur when the latent state is reversed. The virus travels via the sensory nerves to target tissues, one of which is the eye. Recurrent corneal involvement also includes the development of single or multiple dendritic ulcers. After a brief period, the plaque of epithelial cells desquamates to form a linear branching ulcer (dendrite). When a corneal dendrite is detected by corneal staining with fluorescein, the patient should be referred.

Preseptal Cellulitis. Preseptal cellulitis involves the eyelid and periorbital soft tissues and is characterized by acute eyelid erythema and edema. The infection usually occurs in the setting of an upper respiratory tract infection, external ocular infection, or trauma to the eyelids. Patients may have a mild fever and tend to complain of epiphora, conjunctivitis, and localized tenderness. However, the signs of orbital cellulitis are generally absent unless a preseptal cellulitis evolves into an orbital cellulitis. Treatment is initiated empirically in most cases with cefuroxime, ceftriaxone, or nafcillin.

Orbital Cellulitis

Orbital cellulitis, most frequently caused by an extension of infection from the ethmoid sinus, can occur in adults and

children (Figure 17-9). It is the most common cause of exophthalmos in children. It may be difficult to differentiate a periorbital or anterior eyelid cellulitis from a true posterior orbital cellulitis. With a true orbital cellulitis, the child or adult has pain on movement of the eye, conjunctival edema, and limited extraocular movements. The most common causative organisms are *S. aureus*, *Streptococcus* spp., and *H. influenzae*. Cultures should be obtained from the nasopharynx, conjunctiva, and blood.

Immediate hospitalization and ophthalmic consultation are necessary. Emergent computed tomography (CT) should be performed to rule out orbital cellulitis. If orbital cellulitis is diagnosed, immediate hospitalization with intravenous (IV) antibiotics and ophthalmologic consultation should be undertaken. Appropriate systemic antibiotic treatment depends on the causative organism. Cavernous sinus thrombosis, meningitis, and blindness are serious complications of orbital cellulitis.

Iritis

Iritis is an inflammatory process of the anterior chamber, often associated with blunt trauma or infection. Redness, pain, and photophobia occur with iritis. No discharge is seen, and the pupil is constricted. Circumcorneal (ciliary) injection may occur. IOP is normal or low. Initial treatment may include dilation with homatropine and loteprednol etabonate (Lotemax) for patient comfort, with immediate referral to an ophthalmologist. Consultation should be obtained for all such patients as soon as possible.

Corneal Ulcers

The most common causes of corneal ulcers include gram-positive organisms, such as staphylococci and streptococci; and gram-negative organisms, such as *Pseudomonas aeruginosa* and *Enterobacteriaceae*. Less common gram-negative organisms include *Bacteroides*. Risk factors for corneal ulcers include patients with corneal erosions, persistent epithelial defects, impaired immunologic mechanisms, contact lenses, chronic topical or systemic steroid use, diabetes, and alcoholism. Corneal ulcers require consultation with an ophthalmologist for appropriate culture and antibiotic therapy.

Angle-Closure Glaucoma

Acute elevations in IOP can occur when the outflow of aqueous humor is suddenly blocked. The condition is more common in Asians but may occur in any patient. An acute angle-closure attack may follow an episode of emotional or physical stress; dilation of the pupil in dim lighting; or rarely, after instillation of dilating eyedrops. A patient having an acute attack usually has severe ocular pain, redness, blurred vision, rainbow-colored halos around lights, and sometimes nausea and vomiting. On examination, the eye is usually red, pupil mid-dilated and poorly reactive, and IOP greatly elevated. Generally, only one eye is affected at a time. Corneal clouding or corneal edema may be present in advanced cases.

An acute episode of angle-closure glaucoma is an ocular emergency and requires immediate treatment to lower IOP by medical treatment. After IOP is under control, yttrium-argon-garnet (YAG) or argon laser peripheral iridectomy is performed.

Figure 17-10 Central retinal artery occlusion of left eye with Hollenhorst plaque in the right eye. The patient has a characteristic cherry-red spot involving the macula of left eye (*left*). Hollenhorst plaque with a retinal arcade in right eye suggests bilateral carotid disease and cardiovascular disease (*right*).

Ocular Trauma and Other Emergencies

Key Points

- Chemical burns require immediate evaluation and treatment to stabilize the ocular surface.
- Central retinal artery occlusion requires immediate intervention to return oxygenation to the retina. Patients should be thoroughly evaluated to determine the source of the retinal artery occlusion.
- HypHEMA should be carefully managed with bed rest, shielding the injured eye, and appropriate pharmacologic or surgical treatment to minimize potential complications. Patients with hypHEMA and angle recession require lifelong evaluation for possible glaucoma.
- Ocular foreign bodies of the surface can be conservatively managed with removal of the foreign material and appropriate antibiotic ointment. Care should always be taken to rule out an occult ruptured globe.
- The early signs of a retinal detachment include an increase in floaters or flashing lights. Retinal detachments warrant careful evaluation and prompt intervention.

EMERGENCIES

True emergencies can be classified as those for which therapy should be instituted within minutes. Two true emergencies in the eye are chemical burns of the cornea and central retinal artery occlusion.

Chemical Burns

Most acids produce the extent of their damage immediately on contact—the more concentrated the acid, the more severe the immediate effect. Alkali burns are more devastating to the eye because they continue to cause damage long after the initial chemical contact. Corneal melting can lead to perforation, and severe chronic glaucoma can occur as a

later complication. Burns of the eye by acids or alkalis are true ocular emergencies. An alkaline substance, such as lye, can cause permanent and irreversible blindness.

The immediate treatment of chemical burns must be continual irrigation of the eyes, with up to 1000 mL of normal saline or lactated Ringer solution. If these solutions are not available, water from a shower, spigot, bathtub, or drinking fountain is appropriate. The conjunctival pH should be assessed after irrigation and again 30 minutes later to confirm stabilization of the ocular surface; pH value should be 7.5 to 8. If the pH remains abnormal, irrigation should be repeated until the pH is normal. Patients are managed with aggressive antibiotic ointment therapy and lubrication after a chemical burn. After the initial ocular irrigation, ophthalmologic consultation must be immediate.

KEY TREATMENT

- Chemical burns of the ocular surface should be washed with at least 1 L of fluid and tested until the pH returns to normal. An ophthalmologist should evaluate the affected eye within 24 hours after treatment (AAO, 2007) (SOR: C).

Central Retinal Artery Occlusion

With an incidence of about one in 10,000 people, central retinal artery occlusion is generally not the result of trauma. Risk factors include atrial fibrillation, mitral valve disease, atherosclerosis, a hypercoagulable state, and hypertension. Additionally, prolonged intraorbital swelling can cause occlusion of the central retinal artery. Such situations occur particularly in patients who are having surgery in the face-down position. The characteristic fundus appearance with central retinal artery occlusion is narrow arterioles and a pale optic disc. In addition, there is diffuse retinal whitening. A cherry-red spot occurs only several hours after the initial retinal artery occlusion (Figure 17-10).

Treatment of central retinal artery occlusion must be immediate, including breathing into a small paper bag to help increase the patient's carbon dioxide level. Emergency

paracentesis is a rapid method to decompress the eye and may actually provide immediate restoration of vision. However, most physicians are reluctant to perform paracentesis on a patient within a few minutes. Ocular massage is another means of decompressing the eye. Some centers have hyperbaric oxygen available, which may also be helpful in restoring retinal perfusion for some patients. Treatment should be instituted within 90 minutes if any realistic hope of possible visual recovery can be expected. Patients with central retinal artery occlusion should be thoroughly evaluated for cardiac and carotid disease.

URGENT SITUATIONS

Urgent situations include those for which therapy should be instituted within minutes or a few hours. They include penetrating injuries of the globe, acute angle-closure glaucoma, papillary block, orbital cellulitis, corneal ulcer, corneal foreign body, gonococcal conjunctivitis, ophthalmia neonatorum, and acute iritis. In addition, trauma with retinal tears, vitreous hemorrhage, retinal detachment, and hyphemas constitute urgent situations.

Ocular Foreign Body and Other Eye Injuries

The most common eye injury encountered in family practice is a foreign body in the eye. The most common causes of a foreign body in the conjunctival sac or one embedded in the cornea are particles blown in by the wind; occupational or work-related injuries; and metallic foreign bodies that may fly into the eye, such as after a person hits a metal object with a hammer. It is important to evaluate the location of the foreign body and, in the case of corneal foreign bodies, the depth of penetration. Symptoms may be helpful; superficial foreign bodies in the cornea generally present with the complaint of a dust particle in the eye. Foreign bodies that have penetrated deeper into the corneal stroma produce a dull, aching pain perceived in or behind the eye.

On examination, it is important to look carefully at the inflammatory response of the eye. A purely localized conjunctival inflammation pattern is generally associated with superficial foreign bodies. Ciliary injection is a warning sign that a deep penetration may have taken place, and an ophthalmologic consultation should be sought immediately. Examine the eye after the instillation of ophthalmic local anesthetic to avoid blepharospasm and evasive eye movements. Inspect the cornea with a penlight or ophthalmoscope in a darkened room. Use of the slit on the ophthalmoscope can help visualize irregularities in the corneal surface. Staining with fluorescein demonstrates abrasions and helps identify otherwise transparent foreign bodies.

The family physician may elect to remove a foreign body in the conjunctival sac by irrigation with a sterile solution or after eversion of the upper eyelid with a moistened cotton swab. In the case of superficial corneal foreign bodies, a physician may attempt to remove it with a moist sterile swab, but embedded foreign bodies should be referred to an ophthalmologist.

Corneal Abrasions. Corneal abrasions are often caused by foreign bodies underneath the upper eyelid or inadvertent injury from a finger or small object. Evert the eyelid and examine for conjunctival foreign bodies. To evert the eyelid,

the patient is seated and asked to look downward. The upper eyelid is grasped by its central eyelashes and pulled downward and slightly outward. The examiner then depresses the upper eyelid with a cotton applicator proximal to the upper tarsus margin. Gentle pressure is maintained until the upper eyelid is flipped into the everted position. Frequently, the foreign body is observed and can be removed with a cotton applicator or forceps. Corneal abrasions generally can be treated with an antibiotic ointment. Small abrasions often do not require patching. Large corneal abrasions may require pressure patching or a bandage contact lens.

If the conjunctival or corneal foreign body is not easily removed with a cotton applicator, the family physician should obtain ophthalmologic consultation. If the abrasion is not healed within 24 hours, an ophthalmic consultation should be obtained. Corneal abrasions should also be carefully inspected for other ocular injury. Any irregularity of the pupil in the presence of a corneal abrasion could signify an underlying occult penetrating injury. In such cases, the patient should be immediately directed to an ophthalmologist for further evaluation.

Contact Lens Overwear. Patients with contact lens overwear syndrome have worn their lenses longer than usual and typically awaken during the early-morning hours with severe pain and tearing. In response to prolonged wear, the cornea becomes swollen and develops epithelial defects. Patients need reassurance that the condition is usually not serious even though the pain is severe. However, occasional contact lens-induced corneal abrasions, especially those associated with soft lenses, can rapidly progress to severe corneal infection. Patients should be seen the next day and referred if they have not improved. Contact lens wear may be resumed only after the corneal epithelium is well healed.

Metallic Foreign Bodies. Metallic foreign bodies, if allowed to stay in the eye for a number of hours, frequently leave a "rust ring" that is clearly visible after removal of the foreign body. Rust rings irritate the cornea and result in long-lasting inflammatory changes in the eye. Follow-up should be done daily, with staining of the cornea to demonstrate the expected rapid healing. If healing does not take place over 24 to 48 hours, suspect an infection in the corneal stroma and obtain consultation. Topical antibiotic ointments are used after removal of foreign bodies in an attempt to prevent this complication.

Corneal and Scleral Lacerations

Corneal and scleral lacerations fall within the realm of the ophthalmologist and should be referred immediately after a shield is placed over the eye. Frequently, signs of corneal and scleral lacerations include unequal pupils, decreased IOP, iris prolapse, and hyphema, and a corneal laceration often also involves the lens. It is important to consider posterior injuries to the globe, including retinal detachment, retinal tear, and vitreous hemorrhage (Figure 17-11). Patients can often be managed as outpatients with oral antibiotics. Intravitreal antibiotics may be given at ruptured-globe repair. Some patients are hospitalized for IV antibiotics, although current intravitreal penetration of many antibiotics is often comparable. Corneoscleral

Figure 17-11 Corneal leukoma in 6-year-old boy. The diagnosis was ocular trauma and a penetrating corneal laceration.

lacerations should be principally repaired at the presenting institution when possible with available ophthalmology services. Hospital transfers delay wound closure or risk wound extension or prolapse of intraocular contents.

Blunt Eye Injuries

Blunt eye injuries are common and may result from relatively trivial injuries or high-velocity impact projectiles. An exact history of the trauma must be obtained to assess the velocity involved, which in turn may indicate the extent of ocular damage. Inquiry must be made to determine whether visual acuity changes occurred immediately after the injury. Flashing lights are often seen at the instant of injury and indicate irritation of the retina because any message to the brain from the retina is perceived as light. Persistent blurred vision is indicative of a more serious injury. It may indicate blood in the anterior chamber that is suspended in the aqueous humor. Free-floating blood in the anterior chamber is generally not appreciated by direct ophthalmoscopy. A slit-lamp examination is necessary to observe the suspended red blood cells in the anterior chamber.

Black Eye (Eyelid Contusion). A black eye may be serious or relatively minor. If accompanied by severe pain, bleeding, or constant blurred vision, more serious eye trauma must be considered. In such patients, orbital CT scan and ophthalmologic consultation may be necessary to rule out a ruptured globe.

Red Eye. Almost all ocular trauma cases include bleeding or dilation of blood vessels on the surface of the eye (subconjunctival hemorrhage). This may be observed with any degree of eye injury. For example, a subconjunctival hemorrhage may be spontaneous and often indicates minor injury. In the presence of other findings, a subconjunctival hemorrhage suggests more serious injury, particularly if a concomitant hyphema or vitreous hemorrhage is present.

Pupillary Change. Blunt trauma to the eye may result in lacerations of the sphincter muscle of the pupil. These are manifested by traumatic mydriasis. Unlike the unequal pupils seen with congenital anisocoria, traumatic mydriasis is characterized by recent onset of unequal pupils and by the irregularity of the dilated pupil. Although traumatic mydriasis by itself is not harmful, it suggests severe blunt trauma and is an indication for a careful assessment of

other ocular structures, including the vitreous and retinal periphery.

Traumatic Hyphema. Blunt trauma to the eye may cause injury to the iris, angle structures, and other intraocular structures. Hemorrhage into the anterior chamber, or *hyphema*, is most often found in children. The agent producing the hyphema is usually a projectile that strikes the exposed portion of the eye. A great variety of missiles and objects may be responsible, including balls, rocks, projectile toys, air guns, paint balls, bungee cords, and human fists. With the increase of child abuse, fists and belts have started to play a prominent role. Boys are involved in 75% of cases.

Rarely, spontaneous hyphemas occur and may be confused with traumatic hyphemas. *Spontaneous* hyphemas are secondary to neovascularization, ocular neoplasms (retinoblastoma), and vascular anomalies (juvenile xanthogranuloma). Vascular tufts that exist at the pupillary border have been implicated in spontaneous hyphema. A *traumatic* hyphema may be graded by measuring the height of the layered hyphema in the anterior chamber in millimeters. A hyphema is an ocular emergency and should be referred immediately.

Cataract, choroidal rupture, vitreous hemorrhage, angle recession glaucoma, and retinal detachment are often associated with traumatic hyphema and compromise the final visual acuity prognosis. It is important to recognize that the prognosis for visual recovery from traumatic hyphema is directly related to three factors: (1) amount of associated damage to other ocular structures (e.g., choroidal rupture or macular scarring); (2) presence or absence of secondary hemorrhage; and (3) presence or absence of complications of glaucoma, corneal blood staining, or optic atrophy. With treatment, most hyphema patients have a good visual outcome. (See [eAppendix 17-1](#) online for a discussion of hyphema grading and complications, treatment, and prognosis.)

KEY TREATMENT

- Hyphemas are generally well managed with bed rest, shielding of the injured eye, and medical control of the hyphema and IOP ([Crouch, 2009](#)) (SOR: A).
- If IOP remains elevated or hyphema occupies more than 50% of the anterior chamber, surgical evacuation of the clot may be required to lower IOP, preserve corneal clarity, and reduce optic atrophy ([Sheppard et al., 2009](#)) (SOR: A).

Nonaccidental Inflicted Neurotrauma (Formerly “Shaken Baby Syndrome”)

The true incidence of nonaccidental inflicted neurotrauma is unknown because of the difficulty collecting statistical data. An estimated 1300 children in the United States experience fatal head trauma from child abuse annually. The findings of nonaccidental inflicted neurotrauma involve repetitive, violent, unrestrained, acceleration–deceleration head and neck movements. Neurotrauma can occur without blunt head trauma. Cases primarily occur in children younger than 3 years old, usually during the first year of life. Typically, patients present with fracture and

intracranial or intraocular hemorrhages; not all findings are required to establish the diagnosis. An ophthalmologic consult should be obtained for all patients with suspected nonaccidental inflicted neurotrauma, with carefully documented retinal drawings or preferably fundus photography. Approximately 20% of cases are fatal within the first few days of presentation. Traumatic *retinoschisis*, if present, is highly specific for nonaccidental inflicted neurotrauma, particularly if the child is younger than 5 years.

Retinal Detachment

An increase in previous floaters or the onset of new floaters may occur in a retinal detachment. Traumatic detachment of the retina can be observed after blunt eye injury, especially in older adults. Retinal detachment may also occur spontaneously, especially in patients with high myopia. The patient may complain of reduced overall brightness in the involved eye or may have continuous light flashes, indicating retinal traction. After eye trauma, it is imperative to inspect not only the central portions of the retina but the peripheral portions as well. This examination should be performed in a darkened room after instillation of a short-acting mydriatic agent. Any questionable findings should be referred to an ophthalmologist immediately.

Other serious injuries are traumatic tears of the iris, subluxation or dislocation of the lens that occasionally displaces into the anterior chamber, and blowout fracture of the orbit, with impaired upward eye movement caused by entrapment of the inferior rectus muscle. These injuries are usually readily identified.

Pediatric Ophthalmology

Key Points

- Children should be screened at birth, birth to 3 months, 3 to 6 months, 6 to 12 months, 3 years, 5 years, and then every 1 to 2 years.
- Amblyopia and strabismus are distinct but may be associated. Children can have amblyopia without having strabismus. All children with amblyopia or strabismus should be referred to a pediatric ophthalmologist.
- Cataracts are an important cause of amblyopia in children and require prompt intervention.
- Pediatric cataracts may be a sign of a metabolic disorder, TORCH infection (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex), or chromosomal abnormality.
- Leukocoria warrants further investigation; significant causes include cataracts, *Toxocara canis* infection, retinal disease, and retinoblastoma.

EVALUATION OF VISION WITHIN FIRST 4 MONTHS OF LIFE

Parents may report that their baby does not appear to look at them. This statement requires the physician to document a history of prematurity, fetal distress, anoxia, or birth trauma carefully. A failure to reach developmental

milestones may indicate neurologic abnormalities. A history of seizure disorder, cerebral palsy, or chromosomal abnormalities helps identify potentially serious causes. In these cases, visual acuity or the child's ability to fixate must be assessed. Normal newborns follow faces. By age 2 or 3 months, infants normally follow light and high-contrast objects. Assessment of vision can be achieved by using an optokinetic nystagmus drum. Oculomotor disturbances may be the underlying cause of the child's apparent visual inattention. Bilateral cranial nerve III palsy, congenital fibrosis syndrome, or partial cranial nerve III palsy may give this impression as well.

Searching or roving eye movements are a form of profound nystagmus, with little foveal perception. Nystagmus is an important sign of decreased vision, indicating visual acuity often in the range of 20/200. The onset is usually at birth or shortly thereafter. The nystagmus can be a jerk or pendular nystagmus. The direction should be characterized as horizontal, vertical, or rotary.

Abnormalities of the anterior portion of the eye can cause profound visual loss and are easily visible with a +10 magnification. They include corneal opacities (leukoma) caused by congenital glaucoma; *Peter's anomaly* (abnormal cornea and lens); and *leukocoria* (white pupil) related to congenital cataracts, inflammatory disease, or retinal disease.

Evaluation of the posterior aspect of the eye, including examination of the red reflexes, may indicate an early retinal detachment or retinoblastoma. Optic nerve abnormalities may be associated with midline CNS defects, such as an absent septum pellucidum, agenesis of the corpus callosum, or hypopituitarism. Optic nerve abnormalities such as optic nerve hypoplasia are associated with nystagmus. CT or magnetic resonance imaging (MRI) can identify these abnormalities. Electroretinography (ERG) may be helpful for determining the cause of decreased visual acuity. An abnormal ERG is seen with Leber's congenital amaurosis, congenital achromatopsia, and congenital stationary night blindness. Visual-evoked potential testing may be necessary to determine whether vision is intact.

Some infants who have completely normal eye examination results but demonstrate poor fixation may actually have a delay in maturation of the visual system. Normally, the initial visual system development matures by 4 to 6 months of age. Visual-evoked potential acuities are about 20/400 during the first few days of life and improve to about 20/40 by 6 months of age. In some patients, visual-evoked responses and clinically assessed visual function may be abnormal, only to improve between 4 and 12 months of age. Although incompletely defined, in delayed visual maturation, the vision is decreased, but the ocular examination appears normal, including brisk pupillary response to light. Typically, there is no nystagmus, and ERG results are normal.

VISION SCREENING AND OCULAR EXAMINATION

Appropriate vision screening is one of the most important factors in pediatric eye care. Because focused visual stimuli are critical to normal development, early detection and correction of visual problems reduce serious vision impairment or blindness. The AAO, American Academy of

Pediatrics (AAP), and American Association of Pediatric Ophthalmology and Strabismus (AAPOS) strongly support the goal of early detection and treatment of eye problems in children. In particular, vision screening is needed to detect four major conditions: strabismus, amblyopia, ocular disease, and refractive errors. Family physicians are ideal vision screeners because of their ability to detect abnormalities at an early age. Essential components of vision screening are age, testing format, testing procedures, efficacy, and referral criteria. On a practical level, vision screening must be cost effective and time efficient. The testing devices must be readily available and relatively easy to use. High sensitivity is essential to keep overreferrals and underreferrals to a minimum.

Four Stages of Screening

The AAO and AAPOS recommend that children be examined for eye problems in the following four stages (Table 17-5):

1. In the newborn nursery, physicians should examine all infants. Ophthalmologists should be consulted to examine patients at high risk for conditions such as retinopathy of prematurity (ROP), cataracts, congenital defects, and other ocular pathology.
2. At 6 months
3. At 3 years
4. At 5 years and older

The AAO statement recommends that family physicians establish a close working relationship with a local ophthalmologist who is familiar with children's eye problems. The collaboration can help clarify questions about vision screening and the need for referral. (See [eAppendix 17-2](#) online for specific information on different stages of vision screening.)

Table 17-5 Recommended Vision Screening by Family Physicians

Age	Examination	Referral Criteria
Newborn	Penlight examination of cornea Rule out nystagmus Red reflexes	Any ocular pathology Nystagmus Abnormal red reflexes or white reflex
6 months	Fixation to light and small toys Penlight examination Corneal light reflex test, cover test Red reflexes	Object to occlusion Nystagmus; any ocular pathology Strabismus Abnormal red reflexes or white reflex
3 years	Visual acuity: Snellen letters, tumbling E, or HOTV wall chart Corneal light reflex test, cover test Fundus examination	Acuity of 20/40 or less in one or both eyes Strabismus Any ocular pathology
≥5 years	Visual acuity: Snellen letters, tumbling E, or HOTV wall chart (see online text) Corneal light reflex test, cover test Fundus examination	Acuity of 20/30 or less in one or both eyes Strabismus Any ocular pathology

Also, special groups may need additional vision screening. The following children should also be screened even if they are not due to be examined by their age: all children at high risk of having vision disorders, including those who are mentally retarded or who have trisomy 21 or cerebral palsy and all children who show signs or symptoms of visual problems, experience school failure, or have reading difficulties or other learning problems (e.g., dyslexia). It is important to note that children with learning disabilities such as dyslexia have the same incidence of ocular abnormalities (strabismus, refractive error) as children without such disabilities. Dyslexia involves interpretation by cortical processing centers and does not generally indicate any ocular pathology. Eye defects do not cause letter, number, or word reversal.

TESTING VISUAL ACUITY

Several diagnostic tests are used to detect strabismus, amblyopia, ocular disease, and refractive errors. These include visual acuity and fixation preference tests, corneal light reflex test, cover test, simultaneous red reflexes test, fundus examination, stereoscopic tests, and photorefractive techniques.

The best way to screen for possible visual loss caused by amblyopia is to measure the visual acuity or fixation preference of each eye separately. The covered eye should be firmly occluded during the assessment to avoid any peeking. When there is no apparent sign of amblyopia, the only clue to poor vision may be the child's objection to having the better eye occluded. Additionally, the child may demonstrate a fixation preference of the better-seeing eye, with an inability to fixate on distance objects in the amblyopic eye. Both are common signs of amblyopia that may be caused by a refractive error, media opacities, retinal or optic nerve abnormality, or cortical processing problem.

Equipment required for testing children older than 42 months consists of standard wall charts containing Snellen letters, Snellen numbers, tumbling Es, and HOTV wall charts, as well as some means of occluding the nontested eye, ideally, occluder patches (Optclude, Coverlet).

Stereoscopic and Photorefractive Tests

The visual acuity test is the most widely used vision screening test, but use of this test alone will underrefer many patients with amblyopia and undiagnosed strabismus. Stereoscopic tests such as the random dot E stereogram are relatively inexpensive, fairly accurate, and easy to use. Stereopsis tests are complementary and offer additional information regarding a patient's visual health.

The use of photorefractive apparatus is relatively new. Reproducible results of photography of the red reflex can screen nonverbal infants and children. The sensitivity is high (95%) for refractive error in the range of 1.00 to 2.00 diopters. A problem with this technique is that cycloplegia is usually required to prevent obtaining false-positive results, especially for myopia. In addition, two photographs are needed to avoid missing an astigmatic refractive error. The technology offers great promise, but it must be cost effective. As newer, more rapid and accurate vision tests are developed, these may be incorporated into the screening process.

STRABISMUS AND AMBLYOPIA

Strabismus and amblyopia are two of the most common visual problems affecting children. Strabismus occurs in 4% and amblyopia in 4% of the population. Half of all amblyopia patients have a concomitant strabismus. Conversely, half of all amblyopia patients have no demonstrable strabismus.

Movements of the eyes horizontally and vertically are controlled by the six muscles attached to the sclera of each eye. Movement of both eyes in unison allows vision of singular images. Through a blending process called *fusion*, the brain combines the two images into a single, three-dimensional image. As long as the eye muscles are able to work together, the brain can process incoming visual information. When the eye muscles are not coordinated, one eye deviates inward, outward, or upward, and the other eye remains straight. When this occurs, the brain receives a different image from each eye and cannot combine the two disparate images into a single image frame.

Misalignment of the eye muscles results in strabismus. In addition to a breakdown or absence of fusion, the causes of strabismus may include refractive errors, anatomic anomalies, and abnormal tonic innervation. Adults with acquired strabismus frequently develop double vision, but children with strabismus quickly learn to ignore or suppress the image seen by the deviated eye. As a result of suppression, the straight eye takes over most of the work of seeing, and the crossed eye develops reduced central vision because of lack of use. There are various types of strabismus, including horizontal, vertical, or rotational (cyclotorsional). (See [eAppendix 17-3](#) online for additional information on specific types of strabismus.)

Loss of vision in a relatively normal eye is called *amblyopia*. The phrase “lazy eye” should not be used in diagnosing patients because it can be confused with amblyopia and strabismus. As mentioned earlier, these two distinct clinical entities are associated with each other in only 50% of cases. In children younger than 4 years, amblyopia is the most frequent cause of unilateral vision loss ([Figure 17-12](#)). The condition is usually unilateral, although bilateral high myopia, hyperopia, or astigmatism may occur. Unless treatment begins early, loss of vision in the affected eye may be permanent. Amblyopia is usually treatable if detected at age 3 to 4 years but is generally considered irreversible after 13 years; however, treating amblyopia in patients older than 13 years has had some success. The earlier treatment

Figure 17-12 Amblyopia. This 5-year-old patient also required patching of the better-seeing eye to improve vision in the amblyopic eye.

begins, the better the prognosis for the patient. The primary treatment of amblyopia includes the use of patches, glasses, or both. The better eye is occluded, and underlying conditions such as cataracts or refractive errors are treated.

Testing for Strabismus

The corneal light reflex test, cover test, red reflex, and extraocular rotations are four basic tests for strabismus. To perform the corneal light reflex test, project a penlight onto the cornea of both eyes simultaneously while the child looks straight ahead. Compare the placement of the two corneal reflections. When the eyes are straight, the light appears at the same point on each cornea. If a muscle deviation is present, the reflected light appears slightly off center in one eye. [Figure 17-13](#) illustrates the placement of corneal reflections as they would appear for each direction of deviation. In part *A*, note that the light is centered on the cornea of the left eye but is displaced laterally, or outward, on the right cornea, indicating that the right eye is turned inward, or is *esotropic*. In *B*, note that the light is centered again on the left cornea but is displaced medially, or inward, on the right cornea, demonstrating an outward-turning, *exotropia* of the right eye. In part *C*, the light indicates that the right eye is turned upward, or is *hypertropic*, and the left eye is straight.

The cover test is performed by having the child look straight ahead at an object 20 feet away ([Figure 17-14](#)). An eye chart is usually used to test children older than 3 years. For younger children, it is helpful to use a colorful, moving object or toy. As the child looks at the target, cover the

Figure 17-13 Strabismus of right esotropia (*A*), right exotropia (*B*), and right hypertropia (*C*). (From American Academy of Ophthalmology. *The child's eye: strabismus and amblyopia*. San Francisco: American Academy of Ophthalmology, Professional Information Committee; 1982.)

child's right eye and look for movement of the uncovered eye. If the left eye moves to pick up fixation, it was deviated before placing the cover over the right eye. Repeat the procedure for the left eye and watch for any movement in the uncovered right eye. If the eye moves inward to pick up fixation, the eye is exotropic. If the eye moves outward to pick up fixation, the eye is esotropic.

The third test involves simultaneous examination of the pupillary red reflexes. This is a useful test to assess ocular alignment and rule out abnormal ocular media, such as cataracts. The test should be performed in a darkened room with the examiner approximately 18 to 24 inches from the patient. Both red reflexes should be simultaneously assessed and compared using the direct ophthalmoscope. If an abnormality exists in the ocular media, the red reflex will be asymmetric or a white reflex may be present. An abnormal reflex may also signify a high refractive error or a small strabismus. The red reflexes should be equal and symmetric. Ophthalmoscopy also permits direct visualization of the fundus and optic disc. The fourth test checks the extraocular movements in the cardinal positions of gaze (Figure 17-15). The results of these tests provide a good basis for determining whether there is any misalignment present. This is an important screening for all family physicians to learn because early intervention can help improve the overall visual and binocular status of the patient.

Figure 17-14 Cover-uncover test. The unoccluded eye is evaluated for strabismus. (From American Academy of Ophthalmology. *The child's eye: strabismus and amblyopia*. San Francisco: American Academy of Ophthalmology, Professional Information Committee; 1982.)

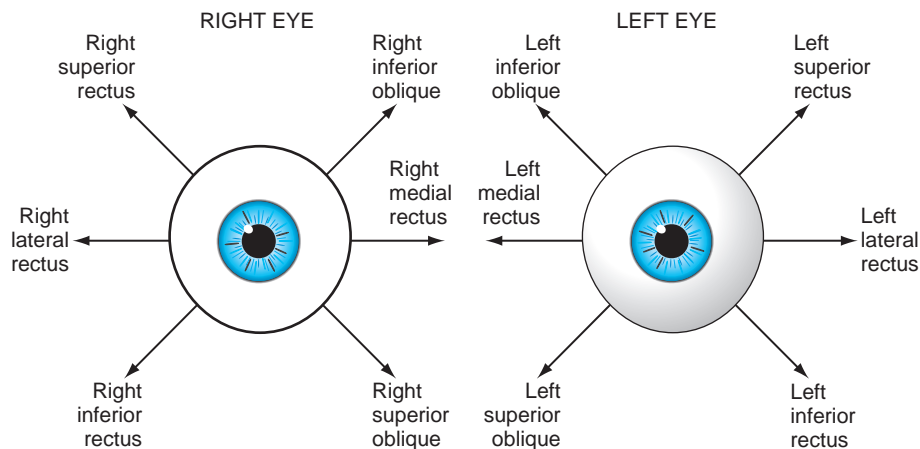

Figure 17-15 Ocular muscle movement in cardinal fields of gaze.

Table 17-6 lists several forms of strabismus. For congenital esotropia, surgery is the primary treatment for this condition and is performed between 6 and 12 months of age (Figure 17-16). Esotropia may also be related to refractive error and managed with spectacle correction (Figures 17-17 and 17-18). Large deviations of exotropia and hypertropia are also managed surgically (Figures 17-19 to 17-23). (See eAppendix 17-3.)

Pseudostrabismus

A common misconception is that children with cross-eye (esotropia) outgrow the condition, but this is generally not the case. This belief stems from confusion between true strabismus and what is known as pseudostrabismus, or false strabismus. A child with pseudostrabismus has broad folds of skin that partially cover the top of each eye and a flat nasal bridge that creates the illusion of crossed eyes. As the child ages and the skin fold becomes less apparent, the condition becomes less noticeable. When a child's eyes are truly crossed, it is always a serious condition and requires the care of an ophthalmologist.

Other Causes of Strabismus

Acute strabismus may be brought on by a viral upper respiratory tract infection, which can cause acute cranial nerve VI palsy. With the advent of antibiotics, middle ear infections with associated petrositis and cranial nerve VI palsies are relatively uncommon. Sudden-onset strabismus may also indicate underlying neurologic disease. Another cause is spasm of the near reflex. A hallmark of spasm of convergence is a constricted pupil. Paralytic or mechanical causes

Table 17-6 Classification of Strabismus		
Type	Cases (%)	Age of Onset
Congenital or infantile esotropia	20	Birth to 6 mo
Accommodative esotropia	45-50	6 mo to 7 yr (usually 2 yr)
Nonaccommodative (acquired) esotropia	10	Variable, depending on cause
Exotropia	20	Variable (usually during infancy to 4 yr)
Hypertropia	<5	Variable, depending on cause

Figure 17-19 Exotropia in 8-year-old patient with right exotropia.

Figure 17-17 Accommodative esotropia and anisometric amblyopia in 5-year-old patient who has unequal refractive errors between the two eyes as well as accommodative esotropia.

Figure 17-20 Positive angle kappa, which appears similar to exotropia, in 8-year-old patient. This patient has retinopathy of prematurity, with bilateral dragged maculas.

Figure 17-18 Accommodative esotropia in 3-year-old patient uncorrected (top) and corrected by hyperopic (farsighted) glasses (bottom). (From American Academy of Ophthalmology. *The child's eye: strabismus and amblyopia*. San Francisco: American Academy of Ophthalmology, Professional Information Committee; 1982.)

Figure 17-21 Patient with diagnosis of Crouzon syndrome who presented with proptosis, amblyopia, and left exotropia.

of strabismus occur with trauma and Duane syndrome. In addition, neurologic trauma accounts for paralysis to cranial nerves III, IV, and VI (Figure 17-24).

The proper corrective treatment for strabismus includes nonsurgical treatment, such as patching and glasses, and surgical treatment, when indicated. Eye muscle surgery is performed when nonsurgical methods cannot correct the misalignment, as well as with worsening misalignment, no effect on the deviation or stereopsis, or progressive loss of

fusion. Four aspects of strabismus surgery should also be stressed, as follows:

1. The surgery is safe and effective.
2. The eyeball is never removed from the orbit to perform the surgery.
3. More than one procedure may be required to establish alignment.
4. Both eyes may require surgery to correct the strabismus.

Figure 17-22 Positive head tilt in 4-year-old child could indicate a vertical deviation, especially superior oblique palsy. (From American Academy of Ophthalmology. *The child's eye: strabismus and amblyopia*. San Francisco: American Academy of Ophthalmology, Professional Information Committee; 1982.)

Figure 17-23 Ocular torticollis in 34-year-old patient. Note the abnormal head tilt.

The goals when treating strabismus include the ability to provide and maintain equal vision in both eyes, enable the eyes to work together rather than independently, and improve depth perception whenever possible.

KEY TREATMENT

- Surgical and nonsurgical treatment of strabismus is beneficial to appropriate visual development, reduction of amblyopia, and rehabilitation of sensorimotor function or depth perception (AAO, 2007) (SOR: A).

REFRACTIVE ERRORS AND COLOR VISION

Some eyes are either too long or too short and need help focusing light onto the retina. If an eye is too long, the light rays focus in front of the retina, and the image is blurred; the person can move things closer to see better or can wear glasses. This condition is called nearsightedness (*myopia*). With farsightedness (*hyperopia*), the light focuses behind the retina because the eye is too short and causes a blurred image. Both conditions are corrected by glasses or contact lenses. *Astigmatism*, another common error in the eye's focusing abilities, is caused by unequal curvature of the front surface of the cornea. Corrective glasses are necessary if it causes blurred vision or discomfort. Unless there is a marked amount of myopia (nearsightedness), hyperopia (farsightedness), or astigmatism, or a significant refractive difference between the eyes, eyeglasses can adequately

Figure 17-24 Chief presenting complaint of underaction of the left lateral rectus muscle and left esotropia after upper respiratory infection in 14-month-old patient, who had cranial nerve VI palsy related to the viral syndrome.

compensate for these problems. Refractive errors requiring eyeglasses affect almost 20% of the pediatric population before full growth is attained.

Color vision defects rarely result in significant visual difficulties. About 8% of white males have some red-green color deficiency, but fewer than 1% of females are affected. In isolation, this defect rarely results in any real drawback to normal function, especially during childhood. Although the identification of such defects can be helpful in a classroom situation, emphasis should not be placed on these minor abnormalities at this age. Color vision testing is not required unless a retinal dystrophy or optic nerve disease is

suspected, the family history is positive, or the family specifically requests it.

HEADACHES

Headache is one of the most common conditions of humans, and children seem to complain less about headaches than adults. Most headaches are not serious and frequently are caused by tension. Many people believe incorrectly that eye strain and the need for glasses are common causes of headaches, although this is certainly possible. Headaches caused by eye disease are usually felt in the eye or in the eyebrow on the same side as the involved eye. Frequently, these headaches are associated with some other symptom, such as blurred vision, halos around lights, or extreme sensitivity to light. Most headaches are related to stress.

LEARNING DISABILITIES AND THE EYE

Although reading may be easier and faster when sight is clear, visual problems generally do not cause learning disabilities, and eye defects are not responsible for reversal of letters. In the past, reading problems were blamed on the eyes, although children with a learning disability have no greater incidence of eye problems than the rest of the population. Other issues, such as dyslexia, attention-deficit hyperactivity disorder, social issues, or family problems are often found to be contributing to a child's poor attention in class or learning difficulties.

It is important that a thorough medical eye examination be performed. The presence or absence of visual defects can be diagnosed and corrected. After vision is corrected, no other examinations or therapies involving the eyes diminish a learning disability. Meta-analysis shows that children with learning disabilities do not benefit from visual training, muscle exercises, perceptual training, or hand-eye coordination exercises ([AAO/AAP/AAPOS Policy Statement, 2009](#)). It may be difficult to diagnose a learning disability definitively before a child is 6 to 7 years old. However, after a diagnosis is made, educational assistance is needed promptly.

PEDIATRIC CATARACTS

Approximately 40% of acquired pediatric cataracts are secondary to trauma, and as many as approximately one third of pediatric cataracts are inherited. The basic approach to the patient with pediatric cataracts is to determine whether the cataract is an isolated finding, part of a systemic abnormality, or associated with ocular disease. When several members of the same family are affected by congenital cataracts, a hereditary origin may be assumed. Autosomal dominant hereditary patterns are the most frequent mode of transmission. X-linked cataracts are rare and occur primarily with the oculocerebrorenal syndrome. Congenital or infantile cataracts have been described in association with a large number of congenital anomalies. (See [eTable 17-1, Pediatric Cataracts: Causes and Associated Conditions](#)).

History and Ocular Examination

In patients with pediatric cataracts, the physician should determine the age when the cataract or decreased vision

occurred. A detailed history of maternal intrauterine infections should include rubella, toxoplasmosis, herpes simplex, cytomegalovirus, and varicella. Drug and medication use during pregnancy and birth trauma should be ruled out.

A complete ocular examination should be performed, including visual acuity assessment using fixation and following responses. Infants with complete bilateral congenital cataracts usually demonstrate decreased visual interest and may have delayed development. Nystagmus results from early visual deprivation and is an ominous sign of poor vision. Ocular fixation and following movements may be decreased or absent. In some cases, strabismus is a presenting sign, especially in children with monocular cataracts.

Glaucoma and other ocular disorders must be ruled out. Examination of the red reflexes by retinoscopy can reveal even minute lens opacities. Direct ophthalmoscopy or retinoscopy through the child's nondilated pupil is helpful for estimating potential vision in an eye harboring a cataract. Any central opacity or surrounding cortical distortion larger than 3 mm can be visually significant. Generally, a more posterior lens opacity carries more visual significance. The presence of retinal detachment, retinoblastoma, or other ocular pathologies that preclude good visual outcome must be ruled out by indirect ophthalmoscopy or ultrasonography.

Most *anterior polar cataracts* are small, smaller than 1 to 2 mm, and are usually not progressive. Surgery is seldom required for small, anterior polar cataracts, and the visual prognosis is excellent. If the cataracts increase in size, visual acuity may be compromised and may require surgical intervention.

Nuclear cataracts are typically congenital, dense axial opacities 3 mm or larger. Nuclear cataracts are frequently associated with microphthalmos and are inherited as autosomal dominant traits. Visual results are generally only fair, even if surgery is done early, and poor if done late. Aphakic glaucoma has a much higher incidence in these patients. *Rubella cataracts* may occur as a manifestation of the classic rubella syndrome—the triad of cardiac defects, hearing impairment, and cataracts.

Partial Lens Opacities

The evaluation of partial lens opacities is related to the location of the cataract. *Anterior cataracts* include anterior lenticonus, polar cataracts, persistent pupillary membrane opacities, and those occurring with anterior segment dysgenesis. *Posterior cataracts* include posterior polar, posterior lenticonus, persistent hyperplastic primary vitreous, and posterior subcapsular lens opacities. Posterior subcapsular cataracts are typically associated with corticosteroid use, atopic dermatitis, or inflammatory diseases and are generally bilateral.

Traumatic and Posterior Lenticonus

Traumatic cataract, the most common cause of unilateral cataract in children, is caused by penetrating or blunt trauma. Posterior lenticonus cataracts are the second most common cause of unilateral acquired cataract in children. *Posterior lenticonus* is a circumscribed oval or round bulge in the infant's or child's posterior lens capsule and cortex,

eTable 17-1 Pediatric Cataracts: Causes and Associated Conditions

Intrauterine Infection	Metabolic Disorders
Rubella	Galactosemia
Toxoplasmosis	Galactokinase deficiency
Herpes simplex	Hypoparathyroidism
Cytomegalovirus	Pseudohypoparathyroidism
Varicella	Diabetes mellitus
	Hypoglycemia
	Hyperalimentation (vacuoles)
	Mannosidosis
Drug Induced	Inflammatory
Corticosteroids	Juvenile rheumatoid arthritis
Chlorpromazine	Sarcoidosis
Ergot	Pars plana
Naphthalene	Atopic dermatitis
Ocular Disease	Genetic Causes and Syndromes
Retinitis pigmentosa	Autosomal dominant
Aniridia	Autosomal recessive
Persistent	X-linked recessive
■ Hyperplastic	Down syndrome (trisomy 21)
■ Primary vitreous	Trisomy 13
Leber congenital amaurosis	Trisomy 18
Retinopathy of prematurity	Lowe syndrome
Retinoblastoma	Dubovitz syndrome
	Hallermann-Streiff syndrome
	Alport syndrome
	Cri du chat syndrome
	Cerebrotendinous xanthomatosis
	Marinesco-Sjögren syndrome
	Myotonic dystrophy

Radiation Injury	Trauma

restricted generally to a 2 × 7–mm axial diameter. The bulge increases progressively, and cataractous changes occur in the cortex surrounding the posterior lenticonus. Generally, there is a reduced red reflex initially with posterior lenticonus, and cataractous changes occur in the surrounding cortex. In 21 patients with posterior lenticonus, only 2 had bilateral posterior lenticonus. The interval between the “oil droplet” posterior lenticonus and cataract development is variable. The eyes are normal in size, and visual results are good with surgery. Posterior lenticonus cataracts occur as early as 3 months of age or as late as 15 years. If the vision becomes worse than 20/70, the cataract should be removed by specialized instrumentation followed by contact lens fitting or an intraocular lens.

Complete Lens Opacities

Workup for complete cataracts includes systemic evaluation, ocular ultrasonography, metabolic evaluation, serum chemistry, and chromosomal analysis. Congenital cataract causes include intrauterine infection, metabolic disorders, chromosomal anomalies, and systemic syndromes. Workup for congenital cataracts includes urinalysis for reducing substances and amino acids. Serum chemistry for calcium, phosphorus, glucose, and blood urea nitrogen levels and TORCH titers should be obtained. When warranted, genetic and pediatric consultations should be requested. Radiologic imaging, including CT or MRI, may be needed.

Surgical Issues

Prompt clearing of the visual axis with immediate optical correction offers the best chance for visual recovery in pediatric patients with unilateral or bilateral cataracts. The surgical procedure recommended depends on the patient's age, risk of amblyopia and expected ocular growth, and reactivity to surgery. In patients younger than 6 months to 2 years old, the best option is to clear the visual axis and have it remain clear throughout the critical period of vision development with a lensectomy–vitrectomy procedure and 6-mm posterior capsulectomy with anterior vitrectomy. This procedure eliminates reopacification of the posterior capsule, which occurs in more than 90% of pediatric patients younger than 2 years. In children older than 2 years, lensectomy with vitrectomy and a 4-mm posterior capsulectomy are performed. Most of these children can be fitted with contact lenses, although an intraocular lens is indicated for some traumatic cataract patients. Traumatic unilateral cataracts present the least controversial situation in which intraocular lenses are considered in young children. Advances in intraocular lenses and surgical techniques have afforded significant improvements in pediatric cataract management.

The prognosis for children with monocular and binocular congenital and pediatric cataracts has improved markedly. Ongoing clinical studies will determine the best indications and procedures for use in pediatric cataract patients.

KEY TREATMENT

- The decision for cataract surgery with intraocular lens implantation depends on the degree of vision loss and potential for amblyopia. Among newborns and infants

with cataracts, visually significant cataracts should be removed and corrected with intraocular lens, aphakic contact lens, or aphakic spectacles (AAPOS, 2007) (SOR: C).

- The decision for cataract surgery with intraocular lens implantation in older children depends on the degree of vision loss, comorbidities, and systemic disease (AAPOS, 2007) (SOR: C).

RETINOBLASTOMA

Retinoblastoma is the second most common primary intraocular malignancy in all age groups (melanoma is most common in adults) and is the most common intraocular malignancy of childhood. Its incidence is approximately 1 in every 14,000 births. Generally, there are 250 to 300 new cases in the United States annually.

The tumor occurs bilaterally in as many as 40% of cases. It is generally diagnosed between 14 and 18 months of age, and more than 90% of the tumors are diagnosed by the age of 3 years. Familial retinoblastoma accounts for 6% of patients, but 15% of unilateral cases are carriers for the retinoblastoma gene. The remaining 94% of cases are sporadic. Germinal mutations account for 25% of retinoblastoma cases and somatic mutations for 75%. Most bilateral cases are caused by germinal mutations. The disease is inherited through an autosomal recessive tumor suppressor gene; thus, the phenotype appears similar to that of autosomal dominant inheritance with incomplete penetrance. It is difficult, if not impossible, to differentiate the genetic mutations clinically and to determine which tumors will be passed on to offspring. There are occasional rare cases of retinoblastoma related to chromosomal abnormalities (partial deletion of long arm of chromosome 13). It has also been associated with trisomy 21.

The diagnosis of retinoblastoma is made by the patient presenting with a white pupil (leukocoria) in 61% of cases; strabismus in 22% of cases; and sometimes with a retinal detachment, red painful eye, or spontaneous hyphema (Figure 17-25). Generally, patients with small retinoblastomas have problems with vision or strabismus. More advanced lesions present with leukocoria and occasionally secondary glaucoma. The advanced lesions may metastasize to the orbit and produce proptosis through the orbital spread. In addition, patients with retinoblastoma may have systemic metastases to the CNS, skull bones, lymph nodes, and other organs.

The treatment of retinoblastoma is generally enucleation for patients with advanced retinoblastoma involving more than 50% of the eye. If the second eye is involved, treatment depends on the size of tumor and whether there is extraocular extension. External-beam irradiation treatment may be performed on the second eye or bilaterally, when necessary. Photocoagulation and cryotherapy are equally effective for small retinoblastomas confined to the retinal periphery. Newer modalities are incorporating chemoreduction and radioactive plaque therapy for localized retinoblastoma and possible vision preservation. Systemic chemotherapy may be indicated after enucleation for advanced unilateral or bilateral cases.

Figure 17-25 Total retinal detachment and advanced retinoblastoma in 23-month-old infant who presented with leukokoria (white reflex).

KEY TREATMENT

- Patients with retinoblastoma should receive long-term follow-up for evaluation of associated systemic cancers ([Children's Oncology Group, 2006](#)) (SOR: C).
- Surgery for retinoblastoma requires specialist services and should be referred to supraregional centers when possible ([National Institute for Health and Clinical Excellence, 2005](#)) (SOR: C)

Adult Ophthalmology

Key Points

- Refractive errors in adults may be corrected with glasses or contact lens or more recent advanced techniques in refractive surgery. Risks and benefits associated with each option vary considerably.
- Patients with an acquired unilateral ptosis should be evaluated for Horner syndrome, myasthenia gravis, and cranial nerve III palsy.
- Patients with recurrent anterior uveitis should be evaluated for ankylosing spondylitis, inflammatory bowel disease, sarcoidosis, juvenile rheumatoid arthritis, Reiter syndrome, herpetic keratitis, and Lyme disease. Patients should be seen by an ophthalmologist for further evaluation.
- Common causes of posterior uveitis include toxoplasmosis, sarcoidosis, cytomegalovirus, Epstein-Barr virus (EBV), Behçet disease, and *Bartonella* infection.
- Ocular medications, particularly antiglaucoma medications, are well known for having a variety of systemic side effects. Medications such as β -blockers may have implications for patients with heart or lung disease.

CORRECTION OF REFRACTIVE ERRORS

Contact Lenses

A major use of contact lenses is to correct myopia, aphakia, and astigmatism. It is critical to have a well-motivated patient who will wear contacts successfully. The many types of contact lenses mainly fall into four groups: (1) daily-wear hard lenses; (2) daily-wear soft lenses; (3) rigid, gas-permeable lenses; and (4) extended-wear soft lenses. Hard lenses have generally been constructed of polymethyl methacrylate. The material absorbs less fluid than soft contact lenses. Soft contacts may become 80% or more hydrated. New materials for hard and soft lenses continue to be developed. Complications of contact lenses, particularly extended-wear contacts, include infection, ocular allergies, follicular conjunctivitis, contact lens opacification, corneal edema, and corneal vascularization. Therefore, patients wearing contacts and complaining of red eyes require urgent evaluation.

Refractive Surgery

The latest treatment option for myopia, hyperopia, and astigmatism is laser refractive surgery with the excimer laser. Photorefractive keratectomy (PRK) and laser-assisted in situ keratomileusis (LASIK) use excimer lasers to remove corneal tissue to flatten the cornea or make it steeper. In the PRK procedure, the laser cuts through the surface cornea. Myopia of -1.00 to -10.00 diopters can be successfully corrected with PRK. This procedure does not involve a corneal flap, unlike LASIK, and has good visual recovery response. However, it is more painful than LASIK. The LASIK procedure is performed under a corneal flap. A 6-mm zone is cut with a microkeratome and the laser treatment directed to the exposed stromal tissue. LASIK is the preferred procedure for more than 6 to 8 diopters of myopia; its benefits are greater accuracy with the laser, reduced postoperative complications, quicker recovery of vision, and predictable healing. Some studies have suggested that LASIK has a slightly higher retreatment rate.

Hyperopia and astigmatism can now also be corrected with laser refractive surgery. The LASIK procedure is the preferred treatment for these conditions; PRK and LASIK are widely available. In the past several years, refractive surgery for myopia, hyperopia, and astigmatism has been considered instead of contact lenses or glasses. Recently, conductive keratoplasty has been advanced for treating presbyopia. However, there may be a compromise in balancing distance and near-vision postoperatively. Potential surgical complications include infections, epithelial ingrowth, halos, and loss of contrast sensitivity. In a patient with moderate cataracts, cataract surgery is more advisable than refractive surgery because the patient will often have only a few years of vision correction before needing cataract surgery.

Decisions regarding refractive surgery procedures should be based on surgeon expertise, patient refraction, and available equipment. The patient should be informed about the possible options. For patients who are not candidates for laser refractive surgery, other surgical methods can correct refractive error. For example, implantable collamer lenses are particularly useful for high myopic patients, are generally well tolerated, and have a lower incidence of postoperative symptoms (e.g., halos).

OCULAR MEDICATIONS

Ocular medications may have significant systemic side effects, such as many of the glaucoma medications. Glaucoma medications can generally be classified into β -blockers, prostaglandins and prostamides, carbonic anhydrase inhibitors, α -blockers, and older medications (e.g., epinephrine and pilocarpine).

Systemic absorption of β -adrenergic blockers, such as timolol (Timoptic), may exacerbate asthma. β -Blockers may also cause problems with breathing, bradycardia, and hypotension. These medications are contraindicated in patients with heart block, congestive heart failure, asthma, or obstructive lung disease.

Carbonic anhydrase inhibitors, such as methazolamide (Neptazane), lower IOP and decrease aqueous production. Carbonic anhydrase inhibitors, such as acetazolamide (Diamox), cause increased urination, decreased appetite, headache, nausea, malaise, and kidney stones. Additionally, these medications lower the serum potassium level, particularly in patients taking diuretics. Potassium supplements should be prescribed to prevent hypokalemia.

α -Adrenergic agonists, such as brimonidine tartrate (Alphagan), can lower blood pressure as well as IOP. Side effects include dry mouth and fatigue. Additionally, brimonidine can cross the blood–brain barrier and produce somnolence. Apraclonidine (Iopidine) induces allergy in 20% to 25% of patients and is found to be ineffective in about 25% of all patients.

A newer class of glaucoma medications includes the prostaglandins and prostamides. These medications, such as latanoprost (Xalatan), travoprost (Travatan), and unoprostone isopropyl (Rescula), are associated with increased eyelash growth and increased pigmentation of the iris, conjunctiva, and eyelids. Additionally, these medications can induce conjunctival hyperemia and can increase the risk of postoperative retinal edema.

Other ocular medications include antibiotics, antiinflammatory agents, and steroids. Patients are occasionally given an antibiotic–steroid combination, such as tobramycin–dexamethasone (TobraDex), that may increase IOP, cause cataracts, or potentiate fungal ulcers. Steroid glaucoma is a form of open-angle glaucoma. If the condition is undetected and the patient continues to refill the medication, damage may occur to the optic nerve, including glaucomatous optic atrophy. Generally, IOP is lowered after the steroids have been discontinued. However, it may take several months for IOP to return to a normal level. Vision loss that occurs during this period may be permanent. Because of the relative frequency of steroid glaucoma, cataract, and exacerbations of viral infections, topical corticosteroids should be avoided for minor ocular inflammations. Generally, ocular conditions that warrant the use of topical steroids also warrant consultation with an ophthalmologist.

OPHTHALMIC CONDITIONS IN OLDER ADULTS

The most important causes of central and peripheral visual impairment in older adults include glaucoma, cataract, diabetic retinopathy, and macular degeneration. Most of these conditions can be controlled or, as in the case of cataracts,

Figure 17-26 Blepharospasm in 68-year-old woman with a history of uncontrollable eyelid spasm resulted in her being unable to drive.

vision can be restored to a significant level to improve the quality of life. Glaucoma and macular degeneration progression may be slowed with proper treatment. Regular eye examinations for older adults can detect early signs of ocular abnormalities and ensure that proper treatment is initiated. Generally, adults older than 40 years should have a complete examination at least every 3 years. After age 65 years, the examination should be at 1- to 2-year intervals.

Diseases of the Eyelid

Entropion is a turning in of the eyelid margin so that there is a rubbing of eyelashes or cilia, with resultant ocular irritation. An *ectropion* is a turning out of the eyelid margin so that the eye builds up excessive tears and becomes inflamed. Both conditions are more common in the older adult population. Entropion and ectropion can cause symptoms of irritation and corneal changes.

Basal cell carcinoma is much more common in older adults. It occurs more often on the lower eyelid. Generally, basal cell carcinomas have pearly edges and a central depression that becomes ulcerated.

Dermatochalasis, or baggy eyelids, may interfere with vision, covering part of the eye. This condition is caused by atrophy of the eyelid skin and elasticity changes. Dermatochalasis causes no permanent damage to vision.

Blepharospasm is a chronic spasm of the eyelid in older adults (Figure 17-26). It may interfere with reading and driving. Botulinum toxin (Botox) injection in small doses is presently the treatment of choice.

Herpes Zoster and Herpes Simplex

Herpes zoster occurs more frequently in the older adult population. When the skin lesions involve the eyelids and tip of the nose, the ophthalmologist should be consulted for evaluation. Corneal dendrites and ulcers can occur with herpes zoster virus and HSV infection (Figure 17-27). HSV infection is more frequently associated with uveitis. Herpes simplex infection responds to trifluridine (Viroptic) eye-drops, whereas HSV infection requires topical steroids.

Ptosis

Ptosis can occur in a number of forms, including congenital ptosis, pseudoptosis, and acquired ptosis (Figure 17-28). Congenital ptosis can occur as a unilateral or bilateral ptosis. A Marcus Gunn jaw-winking ptosis results from a

Figure 17-27 Herpes zoster keratitis. Photomicrograph shows pseudodendrites.

Figure 17-28 Congenital ptosis in 4-year-old patient with congenital bilateral ptosis.

Figure 17-29 Ptosis of left upper eyelid in 8-year-old patient who had ocular myasthenia and subsequently developed ptosis of right upper eyelid and exotropia.

misdirected cranial nerve III. Acquired forms of ptosis include *myogenic* forms, such as myasthenia gravis and progressive external ophthalmoplegia, and *neurogenic* forms, such as Horner syndrome and cranial nerve III palsy (Figure 17-29). *Pseudoptosis* is caused by conditions giving the appearance of a ptosis. It is particularly common with

microphthalmia (small eye, or phthisis bulbi). Pseudoptosis may also be secondary to hypotropia.

Congenital ptosis generally is corrected with bilateral fascia lata brow suspension or a levator resection in patients with good levator function. Treatment of adult forms of ptosis includes correction with a tarsoconjunctival resection, strengthening of the levator aponeurosis, and levator resection.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease. It can occur at any age and is more common in women. There are some genetic associations, but usually it is sporadic. In myasthenia gravis, acetylcholine receptor antibodies decrease postsynaptic receptor activity at the neuromuscular junction. The muscle cannot receive the message propagated by the action potential. The clinical effect is muscle weakness, which may be variable, chronic, localized, or diffuse. The immunologic component (B and T cells produced in the thymus) plays a role. About 75% of patients have thymic abnormalities, and 10% have thymomas.

Common ocular findings include unilateral or bilateral ptosis, which is usually asymmetric eyelid fasciculations, and eyelid retraction. Patients with myasthenia gravis frequently have eye muscle deviations with double vision. Systemic manifestations include involvement of the jaw and neck, an inability to hold the body erect because of weakness of the spinal muscles, and limb weakness. In addition, symptoms may include choking on food and shortness of breath, which is considered a *myasthenic crisis*. Speech difficulties may also occur. A neurologist usually prescribes treatment for myasthenic patients. The prognosis is generally good in patients who present with ocular abnormalities initially.

Strabismus in Adults

Adult strabismus results in both visual and psychosocial disabilities. Adults with strabismus may not be offered appropriate surgical treatment because of misconceptions regarding surgical and nonsurgical correction. Successful strabismus surgery can relieve diplopia and visual confusion, restore or establish depth perception, expand the visual field, eliminate an abnormal head posture, and improve psychosocial function and employability.

Adults with strabismus should be referred to an ophthalmologist who specializes in surgical and nonsurgical correction of adults. Patients should understand the management of strabismus, if possible, and can be educated regarding the relative risks and benefits of surgery.

KEY TREATMENT

- The surgical and nonsurgical treatment of strabismus in adults results in improved binocular visual function, visual rehabilitation of the sensorimotor system, and improved psychosocial benefits (AAO, 2007) (SOR: A).

Dry Eye (Keratitis Sicca)

Tears, because of their lubricating and bacteriostatic properties, are essential for maintaining a healthy cornea and

conjunctiva. A deficiency in tear production may result in a dry eye, also known as keratitis sicca. *Keratoconjunctivitis sicca* is an acquired disorder seen frequently during the fifth decade of life that occurs more often in women. Initial symptoms include a foreign body sensation, dryness, and burning, which often worsens as this condition progresses. Paradoxical tearing from reflex stimulation of the lacrimal gland occurs. Symptoms usually exceed the signs of this common condition. Examination reveals a lack of corneal and conjunctival luster, with punctate erosions. With a decrease in aqueous tears, there is an attempt to compensate by an increase in mucin production, leading sometimes to a stringy, ropelike discharge.

Some cases of keratoconjunctivitis sicca are related to an autoimmune cause, particularly in patients with dryness of other mucous membranes. It also often occurs with rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome. Initial treatment includes lubrication with artificial tears and ointments to supplement or replace the tear film deficit. In moderate or severe cases, an ophthalmologist may need to occlude the eyelid punctum surgically and perform a tarsorrhaphy to protect the corneal surface. Moisture chambers may also be prescribed. Topical antibiotics are required only if secondary infection occurs. Cyclosporine 0.05% (Restasis) is also useful in addressing inflammatory components of tear film insufficiency when other treatments are insufficient.

Exposure keratitis is a condition symptomatically similar to dry eyes that is caused by incomplete eyelid closure during blinking or with sleep. It may result from Bell palsy, scarred or malpositioned eyelids, or thyroid exophthalmos. Management involves the use of ophthalmic lubricating solutions and ointments. Mechanical measures designed to assist normal eyelid closure may be necessary, including frequent manual massage of the eyelids during the day to assist closure, forceful blinking exercises to elicit the Bell reflex, and taping the eyelids shut at night. Merely patching the eye should be avoided because of an increased risk of corneal abrasion if the eyelids do not cover the eye underneath the patch.

Thyroid Eye Disease (Thyroid Orbitopathy)

Hyperthyroidism may induce an orbitopathy in some patients. In such cases, there is diffuse hyperplasia of the thyroid and infiltrative ophthalmopathy. Thyroid eye disease is seen in association with thyroid dysfunction, although thyroid function test results may be normal. With thyroid orbitopathy, the extraocular muscle becomes infiltrated; this may occur even when the disease appears to be under good systemic control. The precise extraocular mechanism is unknown and the genetic predisposition uncertain.

Graves ophthalmopathy occurs in approximately 95% of patients with Graves thyroid disease but is only rarely seen with Hashimoto thyroid disease. The diagnosis of *euthyroid* Graves ophthalmopathy is primarily a clinical diagnosis, confirmed with orbital CT imaging. Clinical characteristics include hypotropia, esotropia, or a combination of vertical and horizontal strabismus. Many patients are euthyroid at diagnosis, but there may be a history of previous thyroid dysfunction. Thyroid myopathy is a common cause of acquired vertical deviation in adults but relatively uncommon in children. Werner has classified eye involvement in

Graves' disease by the NO-SPECS mnemonic: *no* signs of symptoms, *only* signs of eyelid retraction or gaze palsy with or without eyelid lag or proptosis, signs and symptoms of soft tissue involvement, *proptosis*, extraocular muscle involvement, *corneal* involvement with corneal drying, and *sight* loss with optic nerve involvement.

The total muscle volume of the extraocular muscles increases as the disease worsens. The volume can be computed by averaging serial CT sections. Indications for treatment of thyroid ophthalmopathy include diplopia, abnormal head position, a large horizontal or vertical strabismus, and loss of vision. Generally, the preferred treatment is orbital decompression if loss of vision is threatened. Nonsurgical management of the patient includes prisms to alleviate the diplopia in primary position. Eye muscle surgery can be performed with adjustable sutures.

Ocular Changes with Aging

Arcus senilis, or corneal arcus, is a hazy, white or yellow arc or deposit in the peripheral cornea. It has many causes and is more common in older adults. The deposit is composed of cholesterol and other lipids and does not generally indicate an underlying systemic abnormality. It does not interfere with vision or eye function. In white patients, this finding may indicate lipid abnormalities and an increased propensity for cardiovascular disease. No such clear correlation has been identified in African Americans, who are much more likely to have an arcus. The pupil becomes miotic and does not respond well to dilation or darkness. The vitreous body detaches from the retina, resulting in the perception of flashing lights secondary to retinal traction. The retinal pigment epithelium atrophies, making the choroidal vessels more visible. The lens becomes progressively stiffer with age. Symptoms begin in the mid-40s, with increasing difficulty in near-vision focusing. By age 60 years, most patients have had a major reduction in accommodative amplitudes. The universal stiffening of the lens with age causes the well-known symptoms of presbyopia, requiring the use of reading glasses.

Cataracts

A cataract is a condition that affects a large percentage of the population. As a result, cataract surgery is the most common U.S. surgery performed. Currently, cataracts affect approximately 40 million people in the United States. Generally, the normal aging and cataractous changes in the lens are related to its metabolic activity. *Acquired cataracts* may be caused by penetrating trauma, irradiation, heat, or blunt trauma. Metabolic cataracts occur particularly in association with diabetes. Changes in the blood glucose concentration may alter the refractive power of the lens. With hyperglycemia, glucose byproducts enter the lens, causing it to swell and inducing a myopic shift. *Nuclear sclerosis cataract* is the most common cause of lens opacity seen by ophthalmologists; an increased central density makes lens power stronger. As a result, frequent changes in the eyeglass prescription are necessary to correct the changing lens power. This type of cataract develops slowly, and surgery may not be necessary for several years.

The decision for cataract surgery with intraocular lens implantation depends on the degree of vision loss and the daily requirements of the patient. In patients with

cataracts, indications for surgery include the patient's preference and needs, functional disability by Snellen visual acuity test and visual field testing, and concomitant ocular problems.

Cataract surgery involves removal of the cataractous lens and insertion of an intraocular lens. Generally, the procedure is performed under local anesthesia, although the patient may have general anesthesia. Modern cataract surgery primarily entails removing the lens through an extracapsular technique, which can be done en bloc or through a small corneal incision with phacoemulsification. In children, cataracts are generally soft and often require aspiration equipment.

Phacoemulsification is a technique that uses ultrasonic energy to break up the lens material so that it may be withdrawn through a small needle. Unfortunately, phacoemulsification has been confused with laser treatment for cataract removal. It is important to emphasize to patients that the laser is not used to remove the cataractous lens. Part of the confusion lies in the fact that secondary cataracts or opacification of the posterior capsule can be eliminated using the YAG laser. With the YAG laser, there is photodisruption of the capsule, which creates an opening and provides good visual acuity. Cataract removal is one of the most successful operations performed. Generally, adult patients are treated with intraocular lenses after cataract removal. If the patient has bilateral aphakia, contact lenses or cataract spectacles may be worn. However, moderate visual distortion occurs with aphakic spectacles, as well as restriction of peripheral vision. Routine preoperative testing does not improve clinical outcomes for healthy patients undergoing cataract surgery.

Uveitis

A red painful eye with photophobia and increased tearing often occurs with the presentation of anterior uveitis. In addition, the patient may have decreased vision. *Vascular injection*, a circumcorneal injection involving the deep vessels of the sclera, is one of the primary signs of anterior uveitis. Generally, patients with uveitis are moderately light sensitive. In addition, the inflammatory process may hinder aqueous production and reduce IOP.

Patients suspected of an *anterior uveitis* should be referred to an ophthalmologist for consultation and treatment. The most common cause of anterior uveitis is idiopathic; other common causes include ankylosing spondylitis, inflammatory bowel disease, sarcoidosis, juvenile rheumatoid arthritis, Reiter syndrome (urethritis, polyarthritis, and ocular inflammation), herpetic keratitis, and Lyme disease.

Patients with *posterior uveitis* usually present with a reduction in vision and vitreous floaters. They may have clinical signs of retinal vasculitis, retinal ischemia, optic nerve edema, and exudative retinal detachment. On careful inspection, cells may be visible floating in the vitreous. Common causes of posterior uveitis are toxoplasmosis, sarcoidosis, cytomegalovirus, EBV, Behçet disease, and *Bartonella* infection. *Toxoplasmosis* accounts for up to 30% of cases and may destroy the macula or other important visual structures. Characteristically, there is an exudation in the retina caused by an inflammatory process. *Toxocara canis* may also present as uveitis.

Diseases of the Retina and Optic Nerve

Key Points

- Glaucoma is a leading cause of blindness and is managed medically and surgically.
- Choroidal melanoma is the most common intraocular malignancy.
- Posterior vitreous detachment is a common cause of vitreous floaters but may present similar to retinal detachment.
- Age-related maculopathy represents a significant cause of central vision loss in older adults.
- Some patients with macular degeneration may benefit from advances in therapeutic laser treatments.
- Vitamin supplements have been shown to be beneficial for some patients with macular degeneration.
- Routine funduscopy should be performed to evaluate for hypertensive retinopathy and diabetic retinopathy.
- Diabetic retinopathy is the most common cause of blindness in Americans age 20 to 74 years.
- Giant cell arteritis generally occurs in patients 55 years and older, with headache, scalp tenderness, jaw claudication, malaise, fatigue, and amaurosis fugax.
- Carotid artery disease is an important cause of transient ischemic attacks; 50% of patients with transient ischemic attack (TIA) involving carotid artery disease have a major stroke within 1 month of the first attack.
- About 75% of women and 34% of men with optic neuritis will develop multiple sclerosis within 15 years.

Retinal diseases account for 10% to 15% of blindness. Common retinal diseases include macular degeneration, diabetic retinopathy, retinal detachment, and retinal vascular disease. Sudden loss of vision can have various causes; four common causes are retinal detachment, temporal arteritis, ischemic optic neuropathy, and optic neuritis (Table 17-7).

Vitreous Floaters. The vitreous gel degenerates during middle age and forms microscopic strands within the eye. An increase in previous floaters, acute flashing lights, or the appearance of a veil or curtain over a patient's vision may signify a retinal detachment. Posterior vitreous detachment is a common cause of vitreous floaters. The sudden onset of vitreous floaters can be alarming for the patient. Generally, they are simply the result of the normal aging process. Vitreous floaters may interfere with clear vision, particularly reading. Although generally benign, posterior vitreous detachments can create retinal hemorrhages and are associated with retinal tears and detachments.

Melanoma. Choroidal melanoma, a pigmented elevated mass in the choroid, is the most common intraocular malignancy. As the tumor spreads, it may produce a retinal detachment. In addition, retinal pigment epithelial alterations can occur in the form of *drusen* or *lipofuscin* (Figure 17-30). The differential diagnosis of choroidal melanoma includes choroidal nevus, retinal detachment, and metastatic tumor to the choroid. All patients with intraocular tumors should have an extensive physical examination and laboratory testing to exclude metastatic spread of

Figure 17-30 Choroidal melanoma. Increased pigmentation involves the choroid, with characteristic lipofuscin overlying the lesion, which is slightly elevated with bowing of the overlying vessels. This melanoma was locally treated.

Figure 17-31 Age-related maculopathy in 73-year-old woman who demonstrated evidence of geographic atrophy with her macular degeneration.

Table 17-7 Systematic Approach to Patient Presenting with Rapid or Sudden Loss of Vision

Presentation	Symptoms	Signs	Treatment
Painful: Acute narrow, angle-closure glaucoma	Pain, tearing, headache Halos around light with intermittent blurring of vision Nausea, vomiting	Shallow anterior chamber Sudden rise of IOP Circumcorneal injection Cornea edematous and cloudy	Refer immediately. If no ophthalmologist available, begin oral glycerin (1 mL/kg), IM acetazolamide (500 mg) and topical pilocarpine (1%-4%) every 15 min
Painless: Central retinal artery occlusion	Sudden unilateral visual loss (may be preceded by transient blurring)	Cherry-red spot in macula Narrowed arteries Pale optic nerve head Edematous retina	Digital ocular massage Elevation of blood CO ₂ level through rebreathing into paper bag or breathing 95% O ₂ and 5% CO ₂ (carbogen) if available
Painless: Cranial (giant cell) arteritis	Sudden unilateral visual loss preceded by vague migrating joint pains Low-grade fever, depressed appetite No localized pain in eyeball but scalp pain; severe, boring headaches	Enlarged and painful temporal artery Increased ESR is key to diagnosis	Refer immediately. Definitive treatment is high doses of systemic corticosteroids. Involvement of other eye in relatively short time; therefore, immediate referral is imperative
Retinal detachment	Usually rapid loss of vision but <i>may vary</i> Frequently preceded by flashing lights and floaters; more common in patients with myopia; after cataract extraction; after blunt trauma	Retinal elevation on ophthalmoscopic examination	Refer to ophthalmologist promptly

ESR, Erythrocyte sedimentation rate; IM, intramuscular; IOP, intraocular pressure.

the neoplasm. Many ocular melanomas have already metastasized at diagnosis. Treatment modalities generally involve radioactive plaques, and enucleation is performed less frequently. When a small, melanotic lesion is detected, observation is indicated in older adults with slow-growing lesions.

Macular Degeneration. *Age-related macular degeneration* (ARMD) is the most common form of breakdown in the macular area, accounting for 70% of all cases. *Age-related maculopathy*, formerly called “macular degeneration,” leads to loss of fine or central vision but not side vision. Laser

treatment is of benefit in select patients. Macular degeneration begins with nonexudative changes (Figure 17-31). However, many people with macular degeneration have an abnormal vascularization that is not always amenable to laser therapy (Figure 17-32). The condition occurs in the other eye within 1 year in 10% of cases. Another form of macular degeneration is *exudative macular degeneration*, which accounts for 10% of cases.

Normally, the macula is protected by thin tissue that separates it from the fine blood vessels that nourish the posterior aspect of the eye. When these blood vessels break or leak, scar tissue may form, often leading to abnormal

Figure 17-32 Age-related maculopathy with choroidal neovascularization. Abnormal blood vessels have formed in the area of macular degeneration and require further studies to determine whether laser treatment is indicated.

growth of new blood vessels (neovascularization). These new vessels are particularly fragile, and leakage and bleeding may occur. If macular degeneration involves both eyes, near activities become difficult. If an individual loses central vision related to macular degeneration, generally the peripheral vision is unaffected.

An ophthalmologist can confirm the diagnosis of macular degeneration; assessment includes color vision testing, ophthalmoscopy, and fluorescein angiography, when indicated. Examination reveals an accumulation of membranous debris on the posterior aspect of the retinal pigment epithelium, the presence of drusen, and atrophy of the retinal pigment epithelium. In addition, there may be detachment of the retinal pigment epithelium and choroidal neovascularization.

There is no cure for patients with ARMD. Ophthalmic laser surgery may be beneficial in reducing the spread of the exudative macular degeneration, but it is successful only in the early stages. Laser therapy and anti-VEGF (vascular endothelial growth factor) medications have been helpful in treating membranes and neovascularization. Advanced cases of macular degeneration have been treated with macular translocation with some success. At present, use of multivitamins with beta-carotene and vitamin E may delay progression for many patients with ARMD. However, beta-carotene supplements in smokers have been associated with an increase in lung cancer. Vitamin supplements have no impact on cataract formation.

KEY TREATMENT

- Patients with intermediate ARMD had a 25% reduction in the progression of ARMD with the following vitamin and mineral supplements: vitamin C (500 mg), vitamin E (400 IU), beta-carotene (15 mg [25,000 IU]), zinc oxide (80 mg), and cupric oxide (2 mg) (*Age-Related Eye Disease Study Research Group, 2001*) (SOR: A).

- Management options for macular degeneration include observation, antioxidant vitamin and mineral supplements, intravitreal injection of anti-VEGF agents, PDT, and laser photocoagulation surgery (*AAO, 2008*) (SOR: A).

Hypertensive Retinopathy. Routine ophthalmoscopy in patients with hypertension affords the physician a direct view of the arterioles and helps assess the long-term duration and severity of the hypertension as well as evidence of accelerated or malignant hypertension. In the vascular system, arterioles serve as the resistance vessels, and the overall cross-section of the arteriolar bed determines peripheral resistance. With the fundus examination, the physician can directly observe the degree of spasm in arterioles and the effects of long-term hypertension on the arteriolar wall. Severe hypertensive retinopathy can lead to profound vision loss, although usually the patient is completely asymptomatic.

The normal arteriolar wall is transparent, and the visible image is of the blood column as it passes through the arteriolar lumen. An additional anatomic consideration is that at the point of crossing of the arteriole and venule, the vasculature shares a common adventitial layer. Therefore, when arteriolar thickening occurs, the venule is compressed, resulting in arteriolar-venous nicking. It is practical to divide the changes in the fundus seen in hypertension into two scales: a hypertensive scale and an arteriole-sclerotic scale (see [eAppendix 17-4](#) online, Hypertensive Retinopathy Grading).

Diabetic Retinopathy. Diabetic retinopathy is the most common cause of blindness in Americans 20 to 74 years old. Patients with diabetes are at 25 times greater risk of becoming blind from diabetic retinopathy than nondiabetic persons of becoming blind from all other causes. Diabetic retinopathy is more common in women, but men appear to develop a more complicated and severe proliferative retinopathy. Findings have shown that in type 1 diabetes mellitus, it is unusual to detect diabetic retinopathy before 5 years after onset of disease. After 15 years from diagnosis, most patients with type 1 diabetes have some diabetic retinopathy, with incidence of proliferative disease greater than 40%. In type 2 diabetes, with onset after age 30 years, diabetic retinopathy is often detectable at the initial diagnosis. Diabetic patients requiring insulin have a higher incidence of diabetic retinopathy and proliferative disease.

The precise pathogenesis of diabetic retinopathy remains unclear, but the target tissue is the retinal capillary. Localized ischemia has been shown to increase levels of VEGF and result in a corresponding area of vascular proliferation. The vascular complications evolve through states defined by ophthalmoscopic findings.

The first stage is called *nonproliferative* or “background” retinopathy ([Figure 17-33](#)). Capillaries leak and later become occluded. The retinal findings include aneurysms, hard exudates, intraretinal hemorrhages, and macular edema. In the nonproliferative stage, patients only experience visual loss if there is macular involvement. Visual loss from macular edema is present in 5% to 20% of patients with diabetes, depending on the type and duration of

disease. With progression, patients will develop *preproliferative* diabetic retinopathy. This stage frequently progresses to proliferative diabetic retinopathy. The most readily recognized abnormality of preproliferative retinopathy is the cotton-wool spot, a white opacity with feathery edges indicative of localized retinal infarct of the nerve fiber layer.

Proliferative diabetic retinopathy (PDR) is responsible for most serious vision loss in patients with diabetes. As a result of continued retinal ischemia, new blood vessels form in the area of the optic disc or elsewhere on the retinal surface (Figure 17-34). Without laser photocoagulation, these vessels typically progress to retinal detachment and form vascularization within the vitreous cavity. Neovascularization results in vitreous hemorrhage and retinal traction. After fibrous proliferation has detached the retina, surgical repair can be challenging. Prophylactic

laser photocoagulation is the best way to avoid this complication for diabetic patients with PDR.

SCREENING RECOMMENDATIONS

- Screening eye examinations for patients with type 2 diabetes reduce the chance of vision loss (Tubbs et al., 2004) (SOR: A, 1).
- Patients with type 1 diabetes should have their first eye examination 5 years after onset.
- Patients with type 2 diabetes should have their first eye examination at diagnosis.
- Patients with diabetes should have a baseline eye examination before becoming pregnant or early in the first trimester.
- On initiation of ophthalmic screening, all patients with diabetes should have annual dilated fundus examinations by an ophthalmologist or sooner if poor diabetic control or visual symptoms develop (AAO, 2007) (SOR: A, 1).

Figure 17-33 Nonproliferative diabetic retinopathy of left eye. There is extensive nonproliferative disease with macroaneurysms, hemorrhages, and exudates. Although there is no neovascularization, this patient is at risk of developing proliferative disease.

Retinal Detachment. Retinal detachment is separation of the retina from its blood supply. It usually follows a tear or hole in the retina. Retinal tears may be caused by trauma or retinal disease, but the cause of most tears is unclear. When the retina is detached, vision is lost from the involved area of the retina. If the macula detaches, irreversible loss of vision may occur unless the detachment is treated within 24 hours. Anatomic reattachment of the retina is successful in up to 90% of cases.

Giant Cell Arteritis (Temporal Arteritis)

Temporal arteritis is a systemic autoimmune disorder. Pathologically, there is a granulomatous inflammation of large and medium-sized arteries. It generally occurs in patients older than 55 years, with no gender predilection. Involvement may occur in any organ system. Ocular involvement is generally associated with inflammation of the posterior ciliary arteries. General symptoms include amaurosis fugax, headaches, scalp tenderness, jaw claudication, occasional ear pain or arthralgias, pain and tenderness on one or both temples, malaise, and intermittent fevers. Ocular symptoms include loss of vision, diplopia, pain, red eye, and ocular-ischemic syndrome. The workup

Figure 17-34 Proliferative diabetic retinopathy. The patient has severe disease, with diffuse retinal hemorrhages in all quadrants and evidence of neovascularization, and requires urgent panretinal photocoagulation. There is evidence of neovascularization of the optic disc in the left eye.

of patients suspected to have giant cell arteritis includes a careful history of nonvisual symptoms, examination, and laboratory studies to include erythrocyte sedimentation rate (ESR), C-reactive protein, and complete blood count with differential. Using the Westergren method, the value for a normal ESR is 30 mm/hr for a 60-year-old man; for women, top of normal range is age plus 10 divided by 2, so 35 mm/hr is the upper range of normal for a 60-year-old woman. The differential diagnosis of sudden vision loss also includes emboli, central retinal artery occlusion, and retinal detachment.

The visual loss of giant cell arteritis is caused by an ischemic process in the optic nerve. Central retinal artery occlusion may also occur with giant cell arteritis. It is important to diagnose giant cell arteritis as early as possible. Without corticosteroid treatment, patients often develop permanent vision loss bilaterally. When one eye is involved with giant cell arteritis, the second eye loses vision in 65% of untreated patients. Generally, involvement of the second eye occurs within 10 days of onset. When the diagnosis is suspected on the basis of clinical symptoms and signs, temporal artery biopsy is necessary to confirm the diagnosis. The ESR is often greatly elevated, although it may be normal for age. If there is any doubt regarding the diagnosis, a temporal artery biopsy is warranted.

After the diagnosis is established, steroid therapy should be instituted immediately. Up to 100 mg of prednisone (1.0-1.5 mg/kg/day) should be given orally if giant cell arteritis is suspected. Some physicians recommend IV steroids. Patients often require treatment for several months pending a positive biopsy or strong suspicion of giant cell arteritis. Steroids should not be delayed because of the temporal artery biopsy. Biopsy results will remain positive for up to 1 week after beginning steroid therapy. The patient can be monitored by symptoms occurring after institution of treatment and by ESR. Because of the severe systemic effects of giant cell arteritis, the patient should be followed closely.

KEY TREATMENT

- Giant cell arteritis should be promptly treated with oral or IV steroids before obtaining a temporal artery biopsy; treatment should not be delayed for laboratory confirmation (Turbin et al., 1999) (SOR: A).

Glaucoma

Glaucoma is responsible for at least 10% of cases of blindness in the United States. Glaucoma is four times more common in African Americans, who are also eight times more likely to develop blindness from glaucoma. Glaucoma appears to increase with age in the United States and decreases with age in Japan. Patients with diabetes also have an increased risk for developing glaucoma.

The most common form of glaucoma in the United States is primary *open-angle glaucoma*, which accounts for about two thirds of all cases. In Asia, the most common form of glaucoma is *angle-closure glaucoma*. Open-angle glaucoma tends to be genetically based, with multifactorial inheritance or as an autosomal recessive trait, with a high prevalence of carriers. Glaucoma is bilateral and occurs

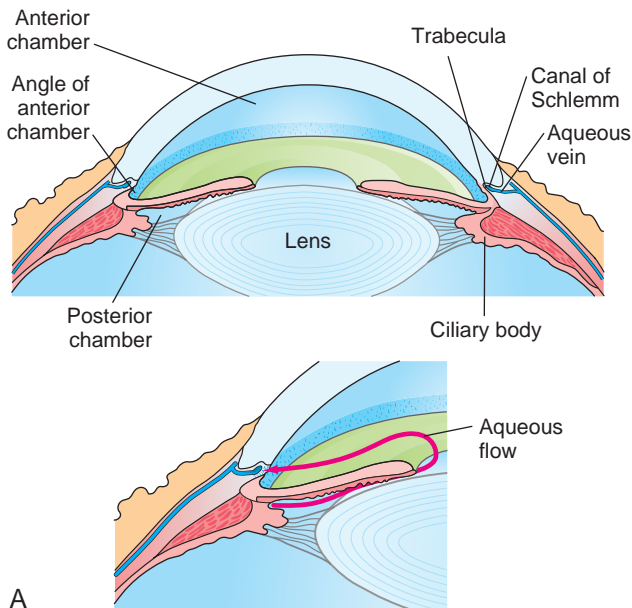

predominantly after age 50 years, although incidence is significant during the 30s and 40s, and it may even occur during the teenage years. Glaucoma is more severe in the African American population. Current incidence of glaucoma is 2% in the United States. The family physician can measure IOP using tonometry to detect elevated IOP. Tonometry can be performed with a Schiøtz tonometer, Perkins applanation tonometer, Tono-Pen XL tonometer, or Goldmann applanation tonometer held horizontally. This test should be performed at least every 3 years, beginning at age 35 years.

The damage to vision caused by glaucoma is irreversible. If the glaucoma can be detected early, it can usually be controlled and is curable by medical treatment, laser surgery, trabeculectomy, or some other filtering procedure. It is important to emphasize that glaucoma may occur at any age. Causes include congenital glaucoma, chronic open-angle glaucoma, narrow-angle glaucoma, or other forms of glaucoma, including pigmentary glaucoma.

One of the most common forms of secondary glaucoma is *steroid glaucoma*, which occurs in a substantial number of patients who use corticosteroid eyedrops or ointment for several weeks or longer. This condition also may occur with oral or systemic corticosteroid use, although it is rare. Steroid glaucoma is a form of open-angle glaucoma and, similar to primary open-angle glaucoma, can be effectively treated if detected early. If IOP is not lowered in time, there may be permanent damage to the optic nerve. Treatment for this type of glaucoma is discontinuation of corticosteroids and initiation of topical glaucoma medications. The IOP elevation is reversible after the steroids have been discontinued, but it may take 2 to 3 months or longer for pressure to return to a normal level. Any visual loss that occurs during this period may be permanent. There is no reliably safe dose of topical steroids that can ensure the prevention of steroid glaucoma. Even topical medications that consist of a combination of steroids and antibiotics or other type of medication can increase IOP. Because of the relative frequency of steroid glaucoma, as well as other ocular complications resulting from steroid use (e.g., cataract, exacerbation of viral infections), topical steroids should not be used for minor ocular inflammations, except in special circumstances.

Secondary glaucoma also may be caused by ocular trauma, intraocular inflammations, intraocular tumors, and carotid vascular disease. Regardless of cause, any patient suspected of having secondary glaucoma should be referred to an ophthalmologist as soon as possible for further evaluation and therapy. Management depends on the cause of the disease and character of the IOP elevation. Some medications can also result in glaucoma and include a warning related to developing angle-closure glaucoma. Additionally, topiramate (Topamax) is associated with an idiosyncratic acute glaucoma caused by uveal effusions.

With increased IOP, damage to the optic nerve and visual field abnormalities can occur. Almost all elevated pressures are caused by an obstruction to the outflow of aqueous humor. *Aqueous humor*, formed inside the eye in the ciliary body, circulates around the lens and through the pupil into the anterior portion of the eye. The aqueous humor exits through the anterior angle structures (trabecular

A

B

Figure 17-35 A, Flow of aqueous from the ciliary body, leaving the eye through the trabecula and canal of Schlemm via a normal, open, wide angle. B, Chronic open-angle glaucoma. (From Scheie HG, Albert DM. *Textbook of ophthalmology*. 9th ed. Philadelphia: Saunders; 1977.)

meshwork and Schlemm canal) (Figure 17-35). About 10% of glaucoma cases occur in the setting of normal IOP, suggesting that these eyes are particularly susceptible to pressure changes. Glaucoma management involves more than controlling IOP. Possible sources of damage to the optic nerve involve mechanical factors affecting the optic nerve, decreased optic nerve perfusion, and blockage of axoplasmic flow in the lamina cribrosa. Carotid artery stenosis can also cause problems because of decreased perfusion to the optic nerve. Occasionally, elevations result from impeded outflow caused by elevated venous pressure, such as in patients with Sturge-Weber syndrome.

The most serious consequence of elevated IOP is damage to the optic nerve (Figure 17-36). As IOP rises, retinal nerve fibers are destroyed at the optic nerve head, resulting in permanent visual loss. Peripheral vision is usually affected first, followed by progressive visual loss involving the entire visual field (Figure 17-37).

Figure 17-37 Testing peripheral fields by confrontation. (From American Academy of Ophthalmology. *The athlete's eye*. San Francisco: AAO Professional Information Committee; 1986.)

KEY TREATMENT

- Long-term monitoring is essential for successful management of glaucoma (AAO, 2000) (SOR: A).
- For chronic open-angle glaucoma, initial treatment is topical medications (AAO, 2000) (SOR: C).
- For uncontrolled chronic open-angle glaucoma, surgical treatment should be considered (AAO, 2000) (SOR: C).
- For acute angle-closure glaucoma, medical treatment and surgery (laser or incision) should be implemented as soon as medically possible (SOR: A).

Anterior Ischemic Optic Neuropathy

The clinical characteristics of ischemic optic neuropathy include age at onset generally older than 60 years, painless vision loss, and afferent pupillary defect (Marcus Gunn pupil). These patients also usually have a visual field abnormality. Examination of the optic disc reveals edema in almost all cases. Pathology appears to be related to a diseased ciliary circulation. It is generally difficult to determine whether the disc edema will result in a mild peripheral (side) visual field defect and good visual acuity or reduced central acuity and a significant visual field defect. Giant cell arteritis must be ruled out in these patients. A general physical examination and associated blood work are indicated. No treatment prevents the progression of ischemic optic neuropathy, including steroids and anticoagulants.

Transient Ischemic Attacks in Carotid Artery Disease

Transient ischemic attacks are neurologic deficits lasting less than 24 hours and are reversible. The most common ophthalmologic TIA is *amaurosis fugax*, which is a fleeting monocular blindness caused by an embolic event. There is a sudden graying or reduction of vision, often moving from the peripheral vision to the center to cover the entire visual field within a few seconds. After 1 to 5 minutes, the central vision begins to return first. Other causes of TIAs include chronic disc edema (in which vision loss lasts seconds, not minutes), chronic papilledema with bilateral blackouts based on optic nerve disease (often also lasting a few seconds and caused by postural changes), and basilar artery insufficiency. TIAs related to basilar artery insufficiency are usually bilateral blackouts lasting seconds or minutes, often with changes in the posterior circulation.

The most important mechanisms involving carotid TIAs with stroke are embolization from the carotid artery or its branches, reduced perfusion caused by carotid stenosis or occlusion, or a combination of the two. In most patients (up to 90%), the site of the obstruction is the carotid sinus. Hollenhorst plaques are bright-yellow cholesterol emboli that may occlude the retinal arterioles (see Figure 17-10). Fibrin platelet emboli can occur near retinal arterioles and produce visual symptoms. A cholesterol or fibrin platelet embolus is indicative of ulcerative disease in the carotid arteries and is associated with a high incidence of ischemic heart disease, peripheral vascular disease, stroke, and aortic abdominal aneurysm. A rarer form of carotid TIA is related to valvular heart disease, particularly with a prolapsed mitral valve or cardiac arrhythmia. Approximately 30% to

50% of patients with TIAs and carotid artery disease have a major stroke within 1 month of the first attack.

Optic Neuritis

Optic neuritis is localized inflammation of the optic nerve sheath, resulting in reduced neuronal transmission and decreased visual acuity. Generally, there is a loss of color vision and red desaturation noticed by the patients. The symptoms generally worsen during the first few days and progressively improve over several weeks. In children, optic neuritis has various causes, typically associated with viral infections. In young adults, optic neuritis has a high association with multiple sclerosis (MS). Approximately 75% of women and 34% of men with optic neuritis will develop MS within 15 years of the onset of optic neuritis. Patients should undergo MR neuroimaging to investigate for plaque formations. They should be questioned regarding constitutional symptoms of fatigue, weakness, difficulty moving or seeing after strenuous activity, and previous attacks.

Intravenous methylprednisolone (1 g/day for 3 days) followed by oral prednisone (1 mg/kg/day for 11 days) reduced the rate of MS development for 2 years (Beck, 1988). Patients at high risk had a 44% reduction in the rate of developing MS when treated with interferon (Controlled High Risk Avonex Multiple Sclerosis Trial [CHAMPS]). Newer treatments with interferon- β -1a (Avonex) and interferon- β -1b (Betaseron, Copaxone) have shown significant improvement in quality of life for patients and reduction in relapses. The Optic Neuritis Treatment Trial recommendations included giving patients with optic neuritis IV methylprednisolone (1 g/day) for 3 days followed by 11 days of oral prednisone (1 mg/kg/day) (Beck et al., 1993). The dose is generally modified for children with 1 mg/kg/day whether using IV or oral steroids. Patients who receive oral rather than IV steroids for the first 3 days generally have more relapsing of their symptoms. Additionally, although corticosteroids hasten visual recovery, administration of steroids does not affect the overall visual acuity. The main benefit is delay of onset of multiple sclerosis.

17-1 Hyphema

Corneal blood staining occurs primarily in patients who have a total hyphema and associated elevation of intraocular pressure (IOP). Factors that may increase the likelihood of corneal blood staining include the following:

1. Initial state of the corneal endothelium (decreased viability resulting from trauma or advanced age, e.g., cornea guttata)
2. Surgical trauma to the endothelium
3. Large amount of formed clot in contact with the endothelium
4. Prolonged IOP elevation

Grading

Alternatively, a hyphema may be graded by the following system:

- Grade 1—layered blood occupying less than one third of anterior chamber
- Grade 2—blood filling one third to half of the anterior chamber
- Grade 3—blood filling more than half but less than the total anterior chamber
- Grade 4—total clotted hyphema filling anterior chamber (“black ball” or “eight ball” hyphema)

Secondary hemorrhage associated with traumatic hyphema results in a much worse prognosis. Eventual visual recovery to an acuity of 20/50 (6/15) or better occurs in approximately 64% of patients with secondary hemorrhage compared with 79.5% of those with no rebleeding. True secondary bleeding into the anterior chamber is indicated by an increased amount of blood in the chamber. Secondary hemorrhage occurs in approximately 25% of all hyphema patients (range, 7%-38%). The incidence of secondary hemorrhage is higher in hyphemas that occupy 50% or more of the anterior chamber.

Complications

Four complications of traumatic hyphema are directly attributed to the retention of blood in the anterior chamber: posterior synechiae, peripheral anterior synechiae, corneal blood staining, and optic atrophy. *Optic atrophy* may result from acute, transiently elevated IOP or chronically elevated IOP. *Posterior synechiae* may form in patients with traumatic hyphema and are secondary to iritis or iridocyclitis. Posterior synechiae are uncommon in patients treated medically but occur more frequently in patients who have had surgical evacuation of the hyphema. *Peripheral anterior synechiae* occur frequently in medically treated patients in whom the hyphema has remained in the anterior chamber for a prolonged period (=9 days).

Corneal blood staining occurs primarily in patients who have a total hyphema and associated IOP elevation. Each of these factors affects endothelial integrity. Corneal blood staining may occur with low or normal IOP, as well as in hyphemas that are less than total. Corneal blood staining is more likely in patients with a total hyphema that remains for at least 6 days with concomitant, continuous IOP greater than 25 mm Hg. Corneal blood staining may require several months or more to clear.

Nonglaucomatous optic atrophy in hyphema patients may be caused by the initial trauma or by transient periods of markedly elevated IOP. Diffuse optic nerve pallor is the result of transient periods of greatly elevated IOP; it occurs with constant pressure of 50 mm Hg or higher for 5 days or 35 mm Hg or higher for 7 days. Patients with sickle cell trait with hyphema are more difficult to manage and require vigorous control of IOP and sometimes anterior chamber paracentesis. Patients with sickle cell hemoglobinopathies and hyphemas have more sickled erythrocytes in the anterior chamber than in the circulating venous blood. The sickled erythrocytes obstruct the trabecular meshwork more effectively than normal cells, with concomitant IOP elevation to higher levels with hyphema of lesser degree. Moderate elevation of IOP in patients with sickle cell hemoglobinopathy may produce rapid deterioration of visual function caused by profound reduction of central retinal artery and posterior ciliary artery perfusion.

Prognosis and Treatment

Cataract, choroidal rupture, vitreous hemorrhage, angle recession glaucoma, and retinal detachment are associated with traumatic hyphema and compromise the final visual acuity prognosis. It is important to recognize that the prognosis for visual recovery from traumatic hyphema is directly related to three factors: (1) amount of associated damage to other ocular structures (e.g., choroidal rupture or macular scarring); (2) presence or absence of secondary hemorrhage; and (3) presence or absence of complications of glaucoma, corneal blood staining, or optic atrophy.

Treatment modalities should be directed at reducing the incidence of secondary hemorrhage and the risk of corneal blood staining and optic atrophy. The success of hyphema treatment, as judged by recovery of visual acuity, is good in approximately 75% of patients. About 80% of hyphema patients with less than one-third filling of the anterior chamber regain visual acuity of 20/40 (6/12) or better. Approximately 60% of those with more than half but less than total hyphema regain 20/40 or better, but only approximately 35% of those with initially total hyphema have good visual results. Approximately 60% of hyphema patients younger than 6 years have good visual results; those in older age groups have progressively higher percentages of good visual recovery.

17-2

Vision Screening in Children (see Table 17-5)

Newborn Screening

Vision screening of all infants in the newborn nursery should include two elements: a penlight examination to inspect corneal clarity and evaluate for nystagmus and a simultaneous examination of both red reflexes. Infants at high risk for eye problems such as *retinopathy of prematurity* (ROP) and those with a family history of congenital cataracts, retinoblastoma, and metabolic or genetic disease should undergo a detailed ophthalmologic examination.

Premature infants with a birth weight less than 1500 g or less than 31 weeks' gestation are at greater risk of developing ROP. Newborns with respiratory distress syndrome are also at greater risk of developing ROP. Each year, ROP causes some degree of visual loss in approximately 1300 infants in the United States and severe impairment in 400 to 800 infants. In most infants, ROP is a transient disease with spontaneous regression. Some patients, however, have progressive ROP. The current recommendation is that premature babies be examined by 4 weeks of age or at 32 weeks of gestational age.

Cataracts are the most common cause of a white pupil (*leukocoria*) at birth; other common causes are:

- Retinoblastoma
- Persistent hyperplastic primary vitreous
- Retinal detachment
- Vitreous hemorrhage (from coexisting disease or ocular trauma)
- Intraocular inflammation, as with *Toxocara canis* (less common)

The incidence may be as high as one in every 5000 live births in the United States. A positive family history of congenital cataracts is present in about 55% of infants with congenital cataracts. Because they interfere with the normal development of the visual system, cataracts in infants must be approached more aggressively than cataracts in adults. Some patients require no treatment, but others may require surgery within the first few weeks of life followed by fitting of contact lenses or aphakic glasses and treatment for amblyopia.

Retinoblastoma is a life-threatening cause of leukocoria that can be detected within the first few weeks of life. It is the most common intraocular malignancy in children and occurs once in every 16,000 to 20,000 live births, resulting in 250 to 300 new cases annually in the United States. About 25% of affected patients have a family history of retinoblastoma, usually bilateral. Some 60% of patients with retinoblastoma present with a white fundus reflex and 20% with strabismus. The prognosis for vision and life is directly related to the size and extension of the retinoblastoma.

Persistent hyperplastic primary vitreous, also called “persistent fetal vasculature,” is a congenital developmental abnormality that causes leukocoria. It results from persistence of embryonic remnants of the eye’s vascular system. The affected eye is often smaller than the other eye, and the lens may become opaque. Clinical management is similar to that for pediatric cataracts. Other causes of leukocoria include retinal detachment and vitreous hemorrhage caused by coexisting disease or ocular trauma. Intraocular inflammation, such as that caused by *T. canis*, is another cause of leukocoria.

Screening at 6 Months

All infants should have a routine eye examination by a family physician at 6 months of age. The examination should assess the baby’s ability to fixate and follow a light or small toy. Each eye should be tested separately. Screening should also assess objection to occlusion of either eye, a frequent sign of amblyopia. To screen for ocular alignment, the corneal light reflex, cover test, and alternate cover test should be performed. Simultaneous examination of the red reflexes is useful to rule out abnormalities of the lens and retina. These and other tests are described in detail later in this section (see “[Testing Visual Acuity](#)”).

By about 6 months of age, the infant’s eyes reposition themselves with a jerking motion after following a series of presented objects to one side. This phenomenon, which has been called “railroad” or “telephone” nystagmus, is an entirely normal reaction. It can be elicited by having the subject watch a rotating drum that is painted with vertical stripes (optokinetic drum).

An optokinetic tape is useful for examining babies with possible diminished vision. The tape can be used to assess horizontal and vertical nystagmus. It is helpful for determining whether vision is present when the parents believe that the child may be blind.

Screening at 3 Years of Age

The early developmental years are the most important for detecting strabismus and amblyopia. A misalignment of the eye muscles is called *strabismus*. Any constant misalignment before 6 months of age should be referred to an ophthalmologist. An ophthalmologist should also evaluate any intermittent misalignment after 4 months of age. Adults who have acquired strabismus frequently develop double vision, but children with strabismus quickly learn abnormal neuroadaptation to suppress the image seen by the wandering eye. *Amblyopia* refers to the development of poor

central vision in an otherwise anatomically normal eye and may occur from deprivation, strabismus, or unbalanced refractive errors. Many cases of amblyopia may occur with or without strabismus. Also, most children with amblyopia do not have visual complaints.

As early as 36 months of age, visual acuity testing can be performed using Snellen letters or the “tumbling E” game. The child must identify every character on each line; if a child this age can read most of the characters on the line, it is considered acceptable. Other methods include HOTV matching letters and Allen picture cards. In addition to acuity testing, a fundus examination, cover test for strabismus, and corneal light reflex test should be performed.

Children with a visual acuity of 20/40 or less or a two-line difference in acuity between the two eyes (even within the passing range) should be referred for ophthalmologic examination. Children with strabismus or any ocular pathology should also be referred.

Children with esotropia after 10 weeks of age have a low incidence of spontaneous resolution ([Pediatric Eye Disease Investigator Group, 2002a, 2002b](#)).

Screening and Eye Examinations at Age 5 Years and Older

The child should be screened before kindergarten, again in first grade (age 6 years), and every other year thereafter until 11 or 12 years of age. Visual acuity should be assessed, preferably with the Snellen acuity test. Family physicians have also used binocular instruments, including the Titmus stereo test and telebinocular instrumentation. Binocular instruments are used to test for visual acuity, hyperopia (farsightedness), and muscle balance. Recently, computer-assisted testing of visual acuity is being used more often in family medicine. It takes up little space and can be administered by one person. However, the child’s eye cannot be observed during the screening process. Titmus testing is useful in children older than 5 years.

In this age group, children with a visual acuity of worse than 20/30 or a two-line difference between the two eyes should be referred to an ophthalmologist, as should children with strabismus or any ocular abnormality. *Myopia*, or nearsightedness, usually occurs by the third or fourth grade (age 9–10 years). In patients with a family history of high myopia (more than -6 to -7 diopters), myopia may occur at birth. *Hyperopia*, or farsightedness, generally does not need to be corrected with glasses, particularly when it is $+2.50$ diopters or less, unless there is a component of strabismus or accommodative difficulty. Glasses are usually prescribed, however, if hyperopia is more than $+4.00$ diopters. Glasses may also be needed to correct astigmatism, a common error in the focusing ability of the eyes.

The American Academy of Ophthalmology (AAO) statement on vision screening has indicated that 20% of children need glasses before they attain full growth. Recommended ages for vision screening include newborn to 3 months, 3 to 6 months, 6 to 12 months, 3 years, 5 years, and every 1 to 2 years after age 5 years. Abnormal findings should be referred to an ophthalmologist ([American](#)

[Academy of Ophthalmology Pediatric Ophthalmology/Strabismus Panel, 2012](#)).

History as a Screening Tool

Before you begin objective testing of visual acuity, obtain an ocular history from the parents to determine whether a visual problem might exist. The symptoms of potential eye problems include the following:

1. Rubbing the eyes
2. Shutting or covering one eye
3. Tilting or turning the head
4. Squinting
5. Unable to see distant objects clearly
6. Bumping into objects

The typical patient’s complaints include (1) inability to see well at distance, (2) blurred vision, and (3) double vision. Pertinent questions to ask the parents follow:

- Does your child hold objects unusually close to his or her face when trying to focus?
- Do your child’s eyes appear to cross?
- How well do you think your child sees?

Ask the parents whether the child can grasp and pick up small objects easily and whether his or her eyes follow them across the room. A family history of eye disease, particularly amblyopia and strabismus, is an important clue.

Importance of Family History

A positive family history can be an important clue for detecting vision problems in children. Charts of 500 randomized patients in a referral practice for pediatric ophthalmology were reviewed; 220 had strabismus disorders, which included exotropia (congenital and acquired) and esotropia (congenital, accommodative, and nonaccommodative). One study found that 42% of esotropic patients and 39% of exotropic patients had a positive family history of the condition in one or both parents ([AOA, 2002](#)). Subdividing these patients into specific strabismus subgroups, there was a positive family history of strabismus in 57% of patients with congenital esotropia, 34% of patients with accommodative esotropia, 67% of those with congenital exotropia, and 38% of other exotropic patients. Patients who did not have a positive family history were those with nonaccommodative esotropia that developed after 18 months of age.

Also, a positive familial history of congenital cataracts is found in up to 55% of patients with congenital cataracts.

Testing Visual Acuity

Some children 3 to 5 years old might not yet be able to perform vision testing with letters and numbers. For these children, the “illiterate E” test may be used. Information is available for home use by parents to prepare children for this test; it includes the practice Es, an illiterate E wall chart, and specific instructions for parents on their use. Another

excellent test for this age group is the HOTV test, which consists of a wall chart composed only of H, O, T, and V. The child is provided with an 8.5 × 11.0-inch board containing a large H, O, T, and V. The examiner points to a figure on the wall chart, and the child identifies the correct figure on the testing board. Both the illiterate E test and HOTV test are excellent for this age group. Examiners may determine which test is most useful in their practice and use that test preferentially. Neither the illiterate E test nor the HOTV test should be used for children capable of being tested with letters and numbers.

However, these tests may be used as confirmation of a letter or number in those circumstances in which the examiner believes that poor performance on testing may be caused by issues other than visual acuity. Some children between ages 3 and 4 years may not be able to perform the illiterate E or HOTV test. In such cases, a flash card-type picture test, such as the Allen card test, may be used. The Allen card test consists of four flashcards containing seven figures. It is a good idea with a very young child to play with the cards initially and to be certain that the child is able to identify all seven pictures. Sometimes the child may not know one or two of the figures. In this case, testing should be performed with the remaining figures.

All Allen figures are 20/30 size figures. The farthest distance at which the child is able to identify the pictures accurately becomes the numerator and 30 becomes the denominator. For example, if the child can identify the pictures accurately at 15 feet, the visual acuity would be recorded as 15/30, equivalent to 20/40 or 10/20 vision. The procedure is then repeated with occlusion, first of the left eye and then the right eye.

17-3 *Specific Types of Strabismus*

Several forms of strabismus may occur (see [Table 17-6](#)). *Congenital esotropia*, or infantile esotropia, accounts for almost 25% of all patients who present with strabismus. This condition is usually apparent shortly after birth or during the first 6 months of life. The deviation is generally constant and may be accompanied by a reduced ability to abduct (move the eyes outward). Babies with congenital esotropia usually do not have associated systemic findings. Surgery is the primary treatment to correct this condition and is performed at 6 to 12 months of age (see [Figure 17-16](#)).

Accommodative esotropia is the most common cause of esotropia and accounts for almost 50% of cases. This type of esotropia is caused by excessive focusing or accommodation. Generally, accommodative esotropia is intermittent initially and gradually becomes constant. The age of onset is at about 2 years, but it may occur as early as 6 months or as late as 7 years. Generally, patients with accommodative esotropia have a moderate amount of hyperopia. Usually, glasses are prescribed to relieve the need to accommodate (see [Figure 17-17](#)). In this way, focusing is done by the glasses, enabling the eyes to straighten. Glasses are generally worn at all times to effectively straighten the eyes. If the inward turning is greater nearer than at a distance, bifocals may be required (see [Figure 17-18](#)).

Nonaccommodative (acquired) *esotropia* is not caused by excessive accommodation. The most common causes of nonaccommodative esotropia include unequal refractive errors, cataracts, and corneal scars. Generally, the

treatment is directed to the underlying condition, including the correction of amblyopia. Eye muscle surgery may be needed to correct the misalignment.

Exotropia accounts for approximately 20% of strabismus cases. About 75% of exotropic cases begin on an intermittent basis, which could confuse or delay the diagnosis. Frequently, the parents note that the child closes one eye in bright sunlight or has an outturned eye when fatigued or sick. It is important to test patients with exotropia at near and distant positions when this condition is suspected. Other causes of exotropia include cranial nerve III palsy, neurologic disease, and abnormalities in the bony orbit. Patients with Apert-Crouzon disease frequently present with exotropia. Small exotropic deviations are kept under observation. Larger deviations require surgery (see [Figures 17-19 to 17-21](#)).

Hypertropia, or vertical deviation, accounts for fewer than 5% of patients with strabismus (see [Figure 17-22](#)). It can occur at any age. Vertical deviations are important because they frequently occur in conjunction with serious conditions such as trauma, tumors of the brain and orbit, and thyroid disease. A vertical deviation is usually named for the higher eye. Patients with vertical deviations may have a head tilt, which must be differentiated from ocular torticollis (see [Figure 17-23](#)). Prisms are used to correct small hypertropic deviations, whereas surgery is indicated for large deviations. When diplopia (double vision) occurs with strabismus, it may be treated with surgery, prisms, or both.

17-4 Hypertensive Retinopathy Grading

The hypertensive scale reflects a degree of spasm within the arteriolar system. There is no universally accepted classification of fundus changes in hypertension. Scheie's classification considers arteriolar vascular leakage changes and arteriolar sclerosis separately (Scheie and Albert, 1977).

Hypertensive retinopathy is graded as follows:

- Grade 1—generalized attenuation of retinal arterioles
- Grade 2—more pronounced attenuation and focal arteriolar attenuation
- Grade 3—generalized and focal arteriolar attenuation with retinal exudates, cotton-wool spots, and hemorrhages
- Grade 4—grade 3 changes plus papilledema

Grading of the arteriolar changes is as follows:

- Grade 1—broadening of the arteriolar reflex and minimal arteriolar-venous (A-V) crossing defects
- Grade 2—increased arteriolar light reflex and A-V crossing changes
- Grade 3—copper wire arterioles and marked A-V crossing changes
- Grade 4—silver wire arterioles and severe A-V crossing changes

Emergencies

EPIGLOTTITIS

Epiglottitis (or “supraglottitis”) is a condition that requires prompt attention by the physician. Epiglottitis results from bacterial (and rarely viral) infection of the supraglottic structures—that is, the epiglottis and arytenoid cartilages. A high level of suspicion is necessary to make a diagnosis and avoid significant morbidity. Rapid decompensation and complete loss of the airway are the sequelae of most concern. The physician should always be suspicious when a patient presents with fever, sore throat, and difficulty swallowing and when the severity of oropharyngeal

physical findings is not in proportion to the symptoms. Croup, tonsillitis, peritonsillar abscess, and other neck infection may be incorrectly diagnosed in these patients. Epiglottitis occurs mainly in children age 2 to 7 years, although infants, older children, and adults can be affected. Mortality rates of 6% to 7% have been reported in adults.

Signs and symptoms of epiglottitis include a rapidly developing sore throat, high fever, restlessness, and lethargy. A “supraglottic,” muffled voice is common. Many patients have difficulty with their saliva and drool. Classically, these patients are in a sitting position leaning forward because this position tends to alleviate obstructive symptoms from the supraglottic swelling. They may show signs of “air hunger” or may have stridor.

Key Points

- Drooling, posturing, and air hunger are classic signs of epiglottitis.
- Epiglottitis is much less common in the pediatric population with routine *Haemophilus influenzae* type b (Hib) vaccination and is now more often seen in adults. It is often more insidious in adults but can still progress to airway obstruction.
- A lateral neck radiograph showing a thumbprint sign can be diagnostic of epiglottitis, but visualization of the larynx is paramount.
- A high index of suspicion is required for the timely diagnosis of retropharyngeal abscess. The physical findings can be subtle.
- Sudden sensorineural hearing loss (SSNHL) should be considered in a patient who presents with a new complaint of hearing loss or tinnitus and no evidence of cerumen impaction or middle ear effusion.
- Acute onset of wheezing in a child with no history of asthma should alert the clinician to a possible airway foreign body.
- Esophageal foreign body in children often presents with drooling and refusal of oral intake and absence of signs of infection.
- Whereas esophageal foreign bodies are more often radiopaque on radiographs, airway foreign bodies are more likely to be radiolucent food material. With both, history and physical examination are paramount.
- Risk factors for epistaxis include nasal sicca, nasal trauma, hypertension, sinonasal neoplasia, and coagulopathy. Often the coagulopathy is iatrogenic and “therapeutic.”
- Epistaxis can rarely progress to respiratory embarrassment or hypovolemic shock, especially in a patient with comorbid conditions.
- Adolescent boys with recurrent epistaxis may have a juvenile nasopharyngeal angiofibroma.
- Proper setup is necessary for effective treatment of epistaxis. This includes a headlight, suction, an epistaxis treatment kit, silver nitrate for cautery, and packing material.
- Nasal packing can cause toxic shock syndrome.
- Nasal packing can lead to hypoxemia, especially in a patient with cardiopulmonary disease or sleep apnea.
- Definitive diagnosis of an aerodigestive tract foreign body may require endoscopy.
- Suspicion of a disc battery esophageal foreign body requires emergent endoscopy because significant tissue necrosis can quickly occur.
- Epistaxis often responds to correction of risk factors (e.g. hypertension, sicca, and coagulopathy).
- If nasal packing is not effective, more invasive procedures may be necessary. These procedures include endoscopy with cautery, vessel ligation, and angiography and embolization.

Table 18-1 Distinguishing Features of Epiglottitis and Croup

Feature	Epiglottitis	Croup
Cause	Bacterial	Viral
Age	1 year to adult	1-5 years
Location of obstruction	Supraglottic	Subglottic
Onset	Sudden (hours)	Gradual (days)
Fever	High	Low grade
Dysphagia	Marked	None
Drooling	Present	Minimal
Posture	Sitting	Recumbent
Toxemia	Mild to severe	Mild
Cough	Usually none	Barking, brassy, spontaneous
Voice	Clear to muffled	Hoarse
Respiratory rate	Normal to rapid	Rapid
Larynx palpation	Tender	Not tender
Clinical course	Shorter	Longer

From Berry FA, Yemen TA. Pediatric airway in health and disease. *Pediatr Clin North Am.* 1994;41:153.

The differential diagnosis includes tonsillitis, peritonsillar abscess, retropharyngeal abscess, airway foreign body, and croup. Physical examination with laryngoscopy is extremely useful in differentiating these diagnoses. Endoscopy should not be performed if there is concern of impending airway obstruction. Endoscopy typically shows erythema and edema of the epiglottis and arytenoid cartilages. Other findings include laryngeal tenderness on neck palpation, although palpation should be avoided when the diagnosis is being considered. Placement of a tongue depressor has been known to precipitate acute airway obstruction and should be avoided entirely if epiglottitis is strongly suspected.

Any time the diagnosis of epiglottitis is in question, otorhinolaryngologic (ear, nose, and throat [ENT]) and infectious disease consultations are warranted. Differentiation from croup can be difficult because there is considerable overlap of symptoms (Table 18-1) (Berry and Yemen, 1994). A lateral extended neck radiograph can help in the diagnosis. Radiographic evidence includes the classic “thumbprint” sign. If epiglottitis is suspected or lateral neck radiography is confirmatory, the patient should be taken to the operating room (OR) for orotracheal intubation in the presence of an anesthesiologist and an otorhinolaryngologist. In any case of airway obstruction, cricothyrotomy or tracheotomy can be lifesaving because orotracheal intubation can be difficult and sometimes impossible. Some patients, usually adults, may be treated expectantly with intravenous (IV) medications and intensive care unit (ICU) observation as long as personnel are available for control of the airway if necessary. If airway stability is questionable, observation is not recommended.

After control of the airway is achieved, cultures of the epiglottis should be obtained and directed antibiotics instituted. *Haemophilus influenzae* type b (Hib) is common and can be β -lactamase producing. The incidence of epiglottitis in children is decreasing since the introduction of the Hib vaccine in the late 1980s. However, the incidence has

Figure 18-1 Large left peritonsillar abscess (arrow) that required surgical drainage.

remained stable or slightly increased in adults. The relative incidence of *Staphylococcus aureus* has also increased since the widespread use of the Hib vaccine. Antibiotics should be administered parenterally; effective antibiotics include cefotaxime, ceftriaxone, ampicillin plus sulbactam, or ampicillin plus chloramphenicol. Steroids can be useful for edema and inflammation, but their effectiveness has not been proved in controlled studies.

PERITONSILLAR ABSCESS

A peritonsillar abscess is the accumulation of pus in the peritonsillar space that surrounds the tonsil. The same organisms responsible for common tonsillar infections—*Streptococcus* and *Staphylococcus* spp. and anaerobes—are also found in peritonsillar abscesses.

The typical signs and symptoms of peritonsillar abscess include fever, increasing sore throat, dysphagia, odynophagia, and a muffled “hot potato” voice. Trismus is extremely common. Examination confirms asymmetric tonsils and peritonsillar edema and erythema. The soft palate and uvula are swollen and displaced away from the side of the abscess. It is often difficult to distinguish between abscess and peritonsillar cellulitis. If possible, it is helpful to palpate because fluctuance indicates a loculation of pus. Diagnosis is often made by clinical impression, but computed tomography (CT) can be confirmatory and useful when the diagnosis is uncertain (Figure 18-1).

If untreated, a peritonsillar abscess may spontaneously drain, progress to involve the deep neck space or sepsis, or even lead to airway obstruction. The most important part of the treatment is drainage of the abscess cavity by needle aspiration, incision and drainage, or tonsillectomy. Cultures

of the aspirate can be obtained, and broad-spectrum antibiotics should be started. Appropriate antibiotics include ampicillin–sulbactam (Unasyn) or clindamycin (Cleocin). Many patients present with dehydration, and parenteral fluids should be given if necessary. Analgesics should be prescribed as needed with careful monitoring of the airway and oxygenation. One or two doses of IV corticosteroids may be given to decrease inflammation and pain.

Children presenting with peritonsillar abscess should be admitted to the hospital. Treatment with IV hydration and parenteral antibiotics is appropriate initially. Patients with peritonsillar cellulitis/phlegmon or early abscess often demonstrate a rapid response to treatment, whereas those with a well-formed peritonsillar abscess do not typically improve. Drainage is necessary in nonresponders. Abscesses in cooperative adults can be drained under local anesthesia in the emergency department (ED) or office and treated in an outpatient setting. Children usually require general anesthesia for drainage, and a tonsillectomy may also be performed. Later, an elective tonsillectomy may be recommended to prevent recurrence, especially for patients with a history of recurrent tonsillitis, although few, if any, controlled studies support this recommendation.

SUDDEN SENSORINEURAL HEARING LOSS

Although most types of hearing loss are nonurgent problems, SSNHL deserves special note because it is considered an otologic emergency. Any patient complaining of sudden hearing loss requires prompt evaluation. An obvious cause such as cerumen impaction or middle ear fluid can be treated appropriately and routinely. If a cause is not identified, SSNHL should be suspected and prompt ENT referral arranged. SSNHL is thought to be secondary to vascular, thromboembolic, viral, or autoimmune causes. It may also be the result of ototoxicity. A viral etiology is thought to be the most common. Without treatment, hearing returns in one third of patients, partial hearing returns in one third, and there is no improvement in the remaining third. Early intervention with oral corticosteroids appears to improve outcomes and is recommended in patients without significant contraindications to oral steroids. Many steroid regimens are described. A 10- to 14-day course of prednisone beginning at 60 mg/day with a short taper is reasonable. The hearing loss needs to be followed. Finally, for patients who do not respond to systemic steroids, controlled studies do support the use intratympanic infusion of corticosteroids, demonstrating improved outcomes (Xenellis et al., 2006). Intratympanic steroids are also appealing for patients with contraindications to oral steroids (e.g., those with “brittle diabetes”). For patients who do not have complete return of hearing, magnetic resonance imaging (MRI) is necessary to rule out a vestibular schwannoma (acoustic neuroma), which can rarely present with sudden hearing loss.

FOREIGN BODIES

Swallowing or aspiration of objects is most common in children but also occurs in the adult population. These objects can become lodged anywhere in the upper aerodigestive tract.

Esophagus

The most common location for esophageal foreign bodies is at the level of the cricopharyngeal muscle. Other regions include the anatomic narrowings of the esophagus, such as the gastroesophageal junction, and the area of indentation of the esophagus by the left main stem bronchus and the arch of the aorta. Coins are by far the most common objects found in the esophagus in children. Chicken or fish bones are more common in adults.

The diagnosis of an esophageal foreign body is primarily based on the medical history and physical examination, with the aid of radiologic studies. Parents might witness ingestion of the foreign body and subsequent coughing, gagging, refusal to eat, or drooling. Often, however, the incident goes unwitnessed, and reliance on other diagnostic techniques is necessary.

Plain radiographs (including lateral radiographs) are often diagnostic in pediatric patients because most esophageal foreign objects are radiopaque (Figure 18-2). Other radiologic findings that can suggest a foreign body include increased soft tissue density in the prevertebral space, mediastinal widening, air-fluid levels in the esophagus, and paraesophageal air. Disk batteries *require a high index of suspicion* because they can cause significant tissue injury and lead to esophageal perforation *if they are not removed emergently*. They have a classic appearance when viewed laterally, approximating a dime resting on a nickel (similar to the appearance of Figure 18-2).

If there is sufficient evidence of an esophageal foreign body, consultation is indicated for esophagoscopy and removal. When radiolucent objects have been ingested, contrast esophagography might be indicated, although esophagograms can give a false-negative result and can also complicate visualization during rigid esophagoscopy.

Figure 18-2 Lateral neck radiograph of a child presenting with gagging and drooling, showing two coins (arrow) in the esophagus near the cricopharyngeal junction.

Figure 18-3 Inspiratory (A) and expiratory (B) radiographs of an 8-year-old boy with a left airway foreign body (peanut). No foreign object is visible on plain radiographs, but the expiratory radiograph shows overinflation of the left lung with mediastinal shift to the contralateral side.

Airway

As with esophageal foreign bodies, airway foreign bodies are much more common in infants and young children. Many deaths from foreign body aspiration occur in the home before medical intervention can be administered. The most frequently aspirated foreign bodies are foods, with nuts leading the list. Foreign bodies aspirated into the airway are usually found lodged in the bronchial tree but can also be found in the larynx or trachea. If the event is witnessed and results in complete airway obstruction, a Heimlich maneuver should be administered; however, the event is often not witnessed. Symptoms can include hoarseness, persistent cough, wheezing, or stridor if the foreign body is lodged in the trachea or larynx. Because the potential for morbidity and mortality is substantial, this condition requires urgent diagnosis and timely intervention to prevent catastrophe.

Any time a small child presents with wheezing or noisy breathing without a history of reactive airway disease, an airway foreign body should be included in the differential diagnosis. Typically, patients and parents recount a transient episode of coughing during eating that then subsided; the patient might even be symptom free for a time and then later have symptoms such as coughing or wheezing.

The most important diagnostic step for identifying a foreign body is a high index of suspicion. Careful auscultation of the lung fields is essential because subtle asymmetric differences may be found. Because most airway foreign bodies are radiolucent, chest radiographs can be normal, but abnormalities such as hyperinflation, atelectasis, or pneumonia can be present (Figure 18-3). If plain radiographs are equivocal or normal and the patient is in stable condition, airway fluoroscopy can be helpful.

Consultation with a physician experienced in foreign body removal is required. Definitive treatment of airway foreign bodies is direct laryngoscopy and rigid bronchoscopy to identify and remove the object.

EPISTAXIS

Although epistaxis is usually nothing more than a minor annoyance, some episodes are severe enough to require

urgent medical attention and intervention. In rare cases, epistaxis can also be a life-threatening emergency.

Predisposing factors for epistaxis include trauma, frequent cleaning or picking, dry weather, hypertension, bleeding dyscrasias (factor deficiencies, hereditary hemorrhagic telangiectasia, lymphoproliferative disorders), anticoagulation therapy (e.g., acetylsalicylic acid, heparin, warfarin, clopidogrel), and intranasal tumors. Special consideration should be given to adolescent boys with recurrent epistaxis and nasal obstruction because these symptoms might be the result of a juvenile nasopharyngeal angiofibroma. These are benign but locally aggressive tumors. All of these potential risk factors should be considered because they must be addressed to treat the patient appropriately. If epistaxis is the result of significant trauma, this affects the algorithm for evaluation and treatment; this is discussed in the “Head and Neck Trauma” section of this chapter.

Epistaxis is classified according to its location. Bleeding from the anterior nasal cavity is most common and usually originates from a rich plexus of vessels at the anterior septum called the *Kiesselbach plexus* (Figure 18-4). Bleeding from this location, although troublesome, is less likely to be severe and is usually easier to control than posterior epistaxis. Posterior epistaxis originates from the posterior two thirds of the nasal cavity and can be quite severe and much more difficult to control.

Initial management of epistaxis includes assessment and stabilization of vital signs. Rarely, severe bleeding can lead to airway compromise, hemodynamic compromise, or both, especially in patients with underlying cardiopulmonary dysfunction. The airway should be assessed and stabilized, urgently if necessary. Hypertension, if severe, should be controlled, with care taken to avoid subsequent *hypotension*. Hematologic studies, including a complete blood count (CBC), prothrombin time, and partial thromboplastin time, should be ordered. IV access should be established, allowing administration of fluids as well as IV medications, if necessary, during treatment.

Treatment

Effective treatment requires adequate visualization and patient cooperation. The level of intervention by the primary

Figure 18-4 Kiesselbach plexus. 1 and 2, Anterior and posterior ethmoid arteries; 3, septal branch of the sphenopalatine; 4, greater palatine; 5, branch from superior labial; 6, Kiesselbach plexus. (From Colman BH, Hall IS, eds. *Hall and Colman's diseases of the ear, nose and throat*. 15th ed. Philadelphia: Churchill Livingstone; 2000:82.)

care physician depends on level of experience, comfort level, and availability of appropriate supplies and equipment. ENT consultation should be considered when any of these prerequisites cannot be met. The patient should be reassured and given an explanation of the planned treatment. This results in better cooperation and decreases patient anxiety, improving treatment success. A bright headlight, nasal speculum, large nasal (Frazier tip) suction, and bayonet forceps are required. If the patient is monitored and stable, a small dose of IV narcotics titrated for analgesia and anxiolytic effect may be given. Extreme caution should be taken not to oversedate the patient. Also, instrumentation of the nose can lead to a significant vasovagal response that may be accentuated in a hypovolemic patient given narcotics. It is advised to err on the side of caution with regard to narcotic medication both during and after treatment.

All clots should be suctioned. They can be quite tenacious and require forceps for removal. The nasal cavity should next be topically anesthetized and decongested (a mixture of 4% lidocaine and phenylephrine applied with cotton balls or spray works well). If a bleeding site is easily identified, it may be cauterized with a silver nitrate stick.

Anterior Packing. If suction, decongestion, and cautery do not stop the bleeding and the site is still thought to be anterior, an anterior nasal pack should be placed. This can be done with 0.5-inch petroleum gauze coated in antibiotic ointment. A better option, if available, is to use a preformed pack. Merocel nasal packs or prepackaged inflatable packs are usually readily available and quite effective. Remembering that the nasal cavity extends *posteriorly* from the nostril and not *superiorly* facilitates placement. The pack should be coated in antibiotic ointment before placement. It is best to use the smallest pack that is effective.

Placement of the pack can be quite uncomfortable for the patient. Discomfort can be minimized by ensuring optimal decongestion and topical anesthesia of the nasal cavity. If

using a Merocel pack, it is sometimes helpful to hydrate and expand the pack *before* placing it. This can be done with sterile saline or phenylephrine. Although the pack appears quite large after it is expanded, it decompresses readily and slides in easily when it is covered in antibiotic ointment. The entire length of the pack needs to be grasped with the bayonet forceps if this technique is used. Preexpansion of the pack also minimizes further abrasions and bleeding that can occur with placement of the firm, nonexpanded pack. This technique is especially advantageous if a septal deviation is on the bleeding side. Regardless of what type of pack is used, care must be taken not to distort or overstretch the nasal ala (nostril) when the pack is in place. This causes significant discomfort and can result in necrosis of the nostril.

After the pack is in place, the patient should be observed for further bleeding. If the patient remains stable, is tolerating the pack well, has no significant comorbid conditions, and has only a unilateral anterior pack, the patient may be discharged with mild narcotic pain medications and antibiotics for prophylaxis against toxic shock syndrome and sinusitis. If these conditions are not met, admission may be necessary. The pack should be removed 2 to 5 days later, with instructions to use nasal saline and nasal ointment liberally for the next 2 weeks. Recurrent bleeding should prompt an ENT consultation.

Posterior Packing. If the bleeding is not controlled with a smaller anterior pack, the origin of the bleeding may be posterior, requiring a larger anterior pack or *anteroposterior pack*. A very effective and commonly used pack is the Rapid Rhino (ArthroCare ENT) pack. The Rapid Rhino comes as a shorter *anterior* or a longer *anteroposterior* balloon tampon. It acts as a platelet aggregator and forms a lubricant upon contact with water. It has a cuff that is inflated by air. The prepackaged kit comes with detailed instructions for insertion. These packs are used in many EDs nationwide. They are effective for severe anterior as well as posterior nose bleeds. If a preformed anteroposterior pack is not available or not effective, a traditional anteroposterior pack may be placed. The posterior pack is necessary essentially to seal off the posterior nasal cavity and provide a buttress to prevent the anterior pack from slipping posteriorly.

Placement of a posterior pack requires experience, and even if it is successfully done, ENT consultation is indicated to assist with further bleeding, pack removal, and to monitor for pack complications. Anterior-posterior packs are associated with significant patient discomfort and potential complications during and after insertion. Local complications, including necrosis of the alae, septum, and palate, can occur, and close observation is required to prevent them. Hypoxemia can also result. Supplemental oxygen and monitoring of oxygen saturation is indicated. Patients with preexisting cardiopulmonary disease require closer observation, often in the ICU. The patient might require judicious doses of narcotics for pain and antibiotics for infection prophylaxis.

Other Techniques. Rarely, epistaxis cannot be controlled with packing, requiring further intervention. This can include intraoperative endoscopic cautery, endoscopic or open arterial ligation, or angiography with selective

embolization of the offending vessel. There are advantages and disadvantages to each of these techniques. In general, the surgical techniques are usually favored over embolization if there are no significant contraindications to surgery. All of the surgical techniques have very high success rates. Embolization is also effective when performed by an experienced interventional radiologist, but it does carry the relatively low risk of inadvertent embolization of the internal carotid artery system and subsequent ischemic cerebral injury, which can be devastating.

KEY TREATMENT

- If there is ever concern about impending airway obstruction, steps should be taken rapidly to prepare to stabilize the airway (SOR: C).
- Interventions for airway obstruction include mask ventilation followed by endotracheal intubation or cricothyrotomy or tracheotomy (SOR: C).
- Patients with epiglottitis typically respond to IV steroids and IV antibiotics directed at *H. influenza* and *S. aureus*. Patients should be closely monitored for impending airway obstruction (SOR: B).
- Most peritonsillar abscesses should be drained, although patients with smaller or early abscesses may respond to medical therapy (SOR: C).
- Early treatment of SSNHL with corticosteroids appears to improve outcomes. The risks and contraindications of steroids need to be considered (SOR: B).

Head and Neck Trauma and Respiratory Embarrassment

Key Points

- The ABCs of trauma include *airway, breathing, circulation, and cervical spine clearance*.
- Laryngeal and pharyngoesophageal injuries must be suspected in blunt or penetrating neck injuries.
- Isolated facial injuries can result in significant bleeding and can be associated with orbital or central nervous system (CNS) injury.
- Overlooked facial fractures can result in long-term functional and cosmetic defects.

The ABCs of trauma should be remembered when treating a patient with cervicofacial trauma. This includes evaluation and treatment of *airway, breathing, circulation, and cervical spine*. The most pressing issue after significant face, head, or neck trauma is the potential for respiratory compromise secondary to several causes. Altered mental status can lead to aspiration of blood or secretions with or without central hypoventilation. Comminuted facial fractures (midface or mandibular) can distort the oral and pharyngeal airway sufficiently to cause obstruction. An undetected expanding pharyngeal or neck hematoma can cause airway obstruction by extrinsic compression of the

trachea or pharynx. Blunt or penetrating neck injuries can cause laryngeal fracture, bleeding, or hematoma, leading to critical airway obstruction.

Potential airway obstruction must be addressed quickly because complete obstruction can progress rapidly. The diagnosis is clinical because hypoxemia and carbon dioxide retention are late signs. Extensive facial edema or ecchymosis should arouse concern for facial fracture. A muffled voice can be the result of expanding hematoma. Laryngeal or tracheal injury should be suspected if the patient has a change in the voice, hemoptysis, subcutaneous emphysema, or stridor.

Stabilization of a compromised airway should be accomplished as soon as possible. Endotracheal intubation may be attempted, with plans for emergent cricothyrotomy as necessary. If time permits, the on-call anesthesiologist, trauma surgeon, or otorhinolaryngologist should be consulted to assist in airway management. Blind intubation (especially nasotracheal) or insertion of a laryngeal mask airway is not recommended because this further compromises the already tenuous airway if intubation is unsuccessful. Although tracheotomy is the preferred procedure when endotracheal intubation is impossible or contraindicated, cricothyrotomy is also acceptable and can be lifesaving.

There is potential for significant blood loss after severe head and neck trauma. IV access should be established and volume replacement initiated quickly. Bleeding from facial wounds can be controlled with direct pressure and suture ligation of arterial bleeding. Management of epistaxis is discussed earlier. Bleeding from the neck or evidence of expanding hematoma implies a major vessel injury and requires immediate operative exploration by a trauma surgeon, vascular surgeon, or otorhinolaryngologist.

Unrecognized pharyngeal and esophageal injury can result in life-threatening infection. These injuries might not be obvious on initial evaluation and require a very high index of suspicion. Contrast studies and endoscopy are usually required to confirm the diagnosis. Treatment can include repair of the injury or external drainage to allow healing.

Isolated facial injuries are rarely life threatening but still can result in significant bleeding and, rarely, airway compromise and permanent disability. Significant facial trauma should be evaluated in the ED. The potential for intracranial and cervical spine injuries should be considered when major facial injuries are present. Trauma of the periorbital region requires ophthalmologic evaluation. All lacerations should be inspected, cleaned, and sutured. Antibiotics should be used if contamination is likely.

Deeper injuries can result in facial nerve transection. If facial nerve weakness is detected, plastic surgery or ENT consultation is necessary for expedient nerve exploration and repair. The parotid salivary duct can also be injured and requires repair over a stent. Facial fractures should be evaluated with CT (both axial and coronal images). Possible mandibular fractures should be evaluated with plain radiographs, including panoramic (Panorex) films. Overlooked and untreated facial fractures can result in significant long-term functional and cosmetic deficits. Oral surgery consultation is sometimes required, especially with injury to the teeth or altered dental occlusion.

KEY TREATMENT

- If there is ever concern about impending airway obstruction, steps should be taken to secure the airway (SOR: B).
- If injuries prevent adequate visualization, intubation should not be attempted. In these cases, tracheotomy or cricothyrotomy should be performed (SOR: C).
- IV access should be established and volume replacement initiated quickly (SOR: C).
- Deep facial lacerations might require exploration to ligate vessels or repair an injury to the facial nerve or parotid salivary duct (SOR: C).

Nasal Trauma

Traumatic injuries to the nose are extremely common and usually of little long-term significance. In some patients, however, trauma can result in significant cosmetic and functional problems. In severe cases, nasal trauma can result in severe bleeding and cerebrospinal fluid (CSF) leakage and can even be life threatening.

Evaluation of a patient who has sustained nasal trauma requires a thorough history. The mechanism of injury must be understood. If the injury was recent, the patient must be examined for signs of cervical, mandibular, maxillary, orbital, and intracranial injury. Bleeding can be quite severe after isolated nasal trauma but usually stops spontaneously or with only digital pressure.

Initial evaluation includes assessment of the gross appearance of the face, with special attention to the possibility of other facial fractures (orbital, zygomatic, mandibular). Obvious deformity of the nose should be noted, although marked edema obscures this in some cases. Radiographs may be ordered, but their utility is variable because nondisplaced fractures usually require no treatment, and displaced nasal fractures are usually obvious on examination.

Intranasal examination is done to rule out the presence of a septal hematoma or CSF leakage. A septal hematoma results when bleeding occurs between the septal perichondrium and the underlying cartilage. The hematoma can be unilateral or bilateral. It results in a widened septum with nasal obstruction. Successful treatment requires prompt diagnosis followed by incision and drainage and packing to prevent reaccumulation. If untreated, and especially if bilateral, the hematoma leads to ischemic necrosis of the cartilage or can result in abscess formation. This can ultimately result in loss of enough septal cartilage to cause external nasal collapse, called *saddle nose deformity*. Because it is extremely difficult to repair, avoiding saddle nose deformity is paramount.

Severe bleeding after nasal trauma can result from a vascular injury of the ethmoidal, the sphenopalatine, or rarely the carotid arteries. Techniques for controlling epistaxis described in this chapter can be used, but ENT consultation should be obtained if the trauma is severe or if severe bleeding persists. *CSF leakage* is diagnosed when clear drainage is seen dripping from one or both sides of the nose. Leakage can increase in a more dependent position. Nasal CSF leakage requires urgent ENT and neurosurgical

consultation. It often resolves spontaneously but can lead to life-threatening problems such as pneumocephalus (air within the cranial vault), meningitis, and brain abscess.

Isolated nasal deformity after nasal trauma results from displacement of the nasal bones, the external nasal cartilages, or the septum. The nasal bones can often be repositioned with excellent results by performing a *closed reduction*. This is done under local or general anesthesia, usually after the initial edema has subsided and before the bones have set (7-10 days after injury). Sometimes an *open reduction*, which involves refracturing the nasal bones, is required. If the septum is significantly deviated, it can be repaired at the same time. If residual nasal deformity persists, a formal *rhinoplasty*, which more precisely addresses all aspects of the external nose, can be done later. In children with nasal fractures, closed reduction is usually recommended sooner than for adults because their fractures heal more quickly. Repair should be done within 7 days of the injury, if possible. Open reduction is generally not recommended in children because of concern for affecting future nasal growth. If necessary, rhinoplasty is delayed until nasal growth is complete, which is shortly after puberty.

The Ear

Key Points

- Otolgia may be from a referred source when the physical examination does not support an ear problem.
- In smokers with otalgia, the clinician should suspect laryngopharyngeal carcinoma when a presumed infection does not respond to antibiotics.
- Pneumatic otoscopy or tympanometry is most useful in confirming middle ear fluid.
- The most common cause of vertigo is a peripheral vestibular disorder (38%-56%).
- Benign paroxysmal positional vertigo (BPPV) is the most common cause of peripheral vertigo and is twice as common in women as in men.
- Unless the diagnosis of BPPV is uncertain, radiographic imaging and vestibular testing are not recommended.
- Pneumatic otoscopy can cause nystagmus and vertigo in the presence of a perilymph fistula.
- Tinnitus is primarily caused by sensorineural hearing loss (SNHL) but occasionally can be a symptom of a vascular abnormality, a hypermetabolic state, medications, or an intracranial mass.
- The most common infection in children seen in a physician's office is acute otitis media (AOM).
- Three criteria necessary for the diagnosis of AOM are acute onset, middle ear effusion, and signs and symptoms of middle ear inflammation.
- Severe AOM is defined as moderate to severe otalgia and fever greater than 39°C (102.2°F).
- Tympanic blistering (bullous myringitis) is simply a variant of AOM and should be treated as such.
- All traumatic perforations of the tympanic membrane require audiologic evaluation to rule out SNHL.
- SSNHL is an otologic emergency.

PHYSICAL EXAMINATION

See [eAppendix 18-1](#) online.

OTALGIA

Although the vast majority of patients with otalgia have an otologic cause, the clinician must recognize that otalgia may be *referred*. Sensory innervation of the ear includes cranial nerves V, VII, IX, and X; therefore, disorders of structures with similar innervation can cause otalgia. It is imperative that the physician not simply attribute otalgia to an ear infection unless the physical examination supports this diagnosis. Otalgia can result from dysfunction of the nose, sinuses, oral cavity, pharynx, larynx, dentition, temporomandibular joints, and salivary glands. These structures must be thoroughly assessed, especially if the results from examination of the ear appears normal. This is especially true in smokers, whose initial symptom of laryngopharyngeal carcinoma may be otalgia. Otolaryngologic referral for laryngoscopy may be indicated with suspected referred otalgia. (See [eTable 18-1](#) and [eTable 18-2](#) online for the differential diagnosis of otalgia.)

TUMORS OF THE EAR

Tumors of the ear are rare. Classification is based on their location (external ear, middle ear, inner ear). A tumor of the external or middle ear is often easily diagnosed by visualizing a lesion on otoscopy. In some cases, symptoms may mimic infection (pain, otorrhea). Tumors of the inner ear can manifest with symptoms of hearing loss, tinnitus, disequilibrium, or facial weakness. ([eTable 18-3](#) online lists tumors of the ear by location.)

VERTIGO

The sense of balance or equilibrium occurs when there is normal and harmonious function of several systems and organs in the body. These include the musculoskeletal system, the cardiovascular system, the CNS, the eyes, and the ears. Abnormal function of any of these can result in the sensation of dizziness or disequilibrium. The term *vertigo* is reserved to describe a perceived sensation of motion, usually spinning, of the person relative to the environment or vice versa. Causes of disequilibrium can be categorized into one of three groups: *peripheral* (inner ear or labyrinthine), *CNS*, or *systemic* (e.g., cardiovascular, metabolic). Although not pathognomonic of a labyrinthine disorder, true vertigo most often indicates aberrant function of the inner ear.

Because patients use “dizzy” to describe many sensations, the actual sensation is best clarified by a detailed history ([Table 18-2](#)). The major studies on the causes of persistent dizziness, from [Drachman and Hart \(1972\)](#) to [Davis \(1994\)](#), all describe four diagnostic categories: lightheadedness, presyncope, disequilibrium, and vertigo. The investigators all conclude that the most common cause of persistent dizziness is a peripheral vestibular disorder (38%-56% of cases) followed closely by a psychogenic disorder (6%-33%). In about 25% of patients, the complaint is the result of the combined effects of multiple sensory deficits, medications,

Table 18-2 History for “Dizziness”

Description of the sensation (including associated symptoms)
Onset (acute, gradual)
Duration (date sensation was first noted, length of time it lasts)
Intensity (how troubling is it?)
Exacerbations (activities, positions, circumstances that worsen the situation)
Remissions (activities, positions, circumstances that make sensation better)
Medications (prescription, herbal, over the counter)
Other medical problems (e.g., diabetes, hypertension, heart disease)
Psychosocial (any stressors?)

or orthostasis, leading to complaints of presyncope, lightheadedness, or disequilibrium. Finally, central vestibular etiologies are unusual and represent fewer than 10% of all causes.

A thorough medical history allows the physician to distinguish between true vertigo (a sensation of spinning) and other sensations, such as presyncope, lightheadedness, and unsteadiness. The physical examination and laboratory evaluation are guided by the accuracy of the history. A sensation of vertigo originates from within the vestibular system but can be either *peripheral* (vestibular nerve and inner ear) or *central* (cerebellum, brainstem, thalamus, and cortex).

Questions regarding hearing and neurologic deficits can help elicit which part of the vestibular system is involved (see [eTable 18-4](#) online). Whereas peripheral vertigo tends to be episodic, central vertigo is constant. Neurologic symptoms or loss of consciousness do not occur with peripheral vertigo but are possible with central vertigo. Nystagmus, which is labeled by the direction of the fast component, can be present in both types of vertigo and can be horizontal or rotary; vertical nystagmus occurs only in central vertigo.

The physical examination should include assessment of orthostatic blood pressure changes, a complete ocular examination, tuning fork tests (Weber and Rinne), pneumatic otoscopy (elicits vertigo in patients with perilymphatic fistula), balance tests (Romberg), gait (including tandem walking), and cranial nerve evaluation. The Dix-Hallpike maneuver (see [eFigure 18-3](#)) is especially helpful in diagnosing BPPV. Head movement almost always worsens the feeling of true vertigo. If it does not, the dizziness may be attributed to a cause other than vestibular dysfunction.

Laboratory testing can include an audiogram if no specific cause of vertigo can be found after the medical history and physical examination. Electronystagmography (ENG) is an objective study of the vestibular system and can help localize a vestibular lesion. Electrodes placed about the eye sense the movements of nystagmus as either spontaneous or initiated by maneuvers such as caloric testing, positioning, optokinetics, and pendulum tracing. A brain MRI scan is indicated in patients with unilateral otologic symptoms and in those unresponsive to treatment. Blood tests, when necessary, can include CBC, rapid plasma reagin (RPR), vitamin B₁₂ level, folate level, drug screens, and heavy metal testing when indicated.

18-1 Ear: Physical Examination

The typical symptoms associated with an otologic problem include hearing loss, ear pain (otalgia), tinnitus, vertigo, and drainage (otorrhea). The clinician should ascertain the timing, severity, duration, associated symptoms, and modifying factors.

Examination of the ear begins with inspection of the external ear, which includes the auricle and ear canal (Lucente and Har-El, 1999) (eFigure 18-1). In children, overly prominent ears, or *macrotia*, can result in significant teasing and may be surgically correctible with an otoplasty. The skin of the auricle should be carefully inspected for signs of infection, actinic changes, obvious lesions, or trauma. The ear canal is best inspected with an otoscope using the largest speculum that easily fits in the canal. The canal should have a small amount of brownish cerumen that need not be removed unless causing symptoms or obscuring the view of the entire tympanic membrane. The canal should be inspected for ulcerations, masses, erythema, drainage, or foreign bodies. Some patients have bilateral smooth, raised areas in the canal called *bony exostoses*. These are of no consequence unless they obstruct the ear canal. They are common in cold-water swimmers and surfers.

The tympanic membrane and middle ear can also be assessed with the otoscope (eFigure 18-2). The middle ear includes the tympanic membrane and the ossicles (malleus, incus, and stapes). The tympanic membrane should appear translucent, with fine vascularity along the part of the malleus that is attached to the membrane. A normal light reflex may be noted at the anterior-inferior portion of the tympanic membrane. The tympanic membrane should be

inspected for dullness, erythema, retraction, bulging, perforation, or drainage. An attempt should also be made to look for any masses that might be visible behind the tympanic membrane. Whitish areas *on* the tympanic membrane (*tympanosclerosis* or *myringosclerosis*) are usually secondary to previous trauma or infection and are rarely of clinical significance. However, a white mass that is *behind* the tympanic membrane may be a cholesteatoma.

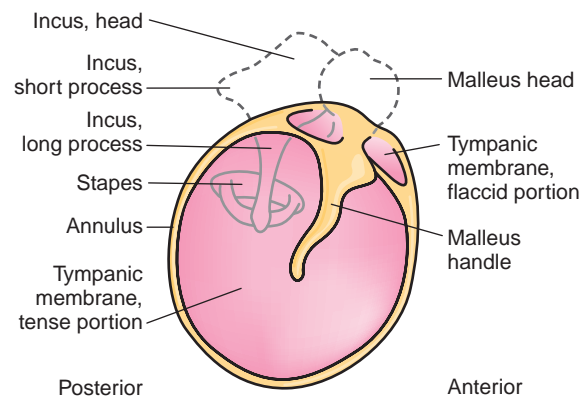

Clinicians should be comfortable with *pneumatic otoscopy*, which should be performed if middle ear effusion is suspected. A slightly larger otoscope tip or special soft tip is used so that the canal will be completely sealed. A small amount of positive and negative pressure is applied with either a small bulb attached to the otoscope handle or a small silicone elastic (Silastic) tube (a tourniquet tube) placed in the examiner's mouth. If the middle ear pressure is normal, the tympanic membrane moves equally back and forth. In cases of middle ear fluid or perforation, the tympanic membrane is sluggish or immobile.

Although the same principles of an adult examination apply, otologic examination of young children and infants may be compromised by small ear canals and poor cooperation. Because crying may result in tympanic membrane erythema and obscure the diagnosis of acute otitis media, the otologic examination should be done first. Assistance from the parent or medical assistant is often required. Obstructing cerumen should be removed if the tympanic membrane is not well visualized. Pneumatic otoscopy may be necessary to confirm the presence of middle ear fluid.

A tuning fork examination using the Weber and Rinne tests should be done if hearing loss is suspected. These tests help distinguish *conductive* (middle ear) and *sensorineural* (inner ear) loss. A 512-Hz tuning fork usually suffices, with additional tuning forks (256 and 1024 Hz) increasing

eFigure 18-1 Coronal section of the ear. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:2.)

eFigure 18-2 Tympanic membrane and middle ear ossicles. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:3.)

sensitivity and specificity. The *Weber test* is performed by gently striking the tuning fork and placing it against the patient's forehead or upper incisors. If the patient hears the tone louder in one ear (referred to as *lateralizing* to that ear), there may be either a conductive hearing loss in the same ear or a sensorineural hearing loss in the contralateral ear. The *Rinne test* compares air conduction with bone conduction and complements Weber's test to help determine which ear is affected. The Rinne test is performed by gently striking the tuning fork and alternating placement against the mastoid tip (bone conduction) with placement directly in front of the ear (air conduction). With normal hearing or a sensorineural hearing loss, the patient will hear the tone louder in front of the ear (positive Rinne test result). In an ear with a conductive hearing loss, the patient will hear the tone louder over the mastoid tip (negative Rinne test result).

A *Dix-Hallpike test* is a specific examination technique to evaluate for benign paroxysmal positional vertigo (BPPV) (eFigure 18-3). The test is done by having the patient sit on an examination table with the legs outstretched. The patient's head is turned to one side, and the patient is assisted back into a supine position, with the head still turned and allowed to gently extend past the edge of the table. The patient is asked to direct the eyes downward toward the floor and left open. The patient is asked to report any feeling of disequilibrium while the examiner inspects the eyes for any sign of nystagmus. After the test is performed on one side, it is repeated on the other. A positive Hallpike test result includes all the following: brief latency before subjective vertigo, rotatory nystagmus with the fast component directed toward the floor, spontaneous cessation of symptoms and nystagmus after several seconds (usually 15-30 seconds), and fatigability on repeat test. Some of these findings may be absent in BPPV. However, lack of spontaneous cessation or fatigability of vertigo or nystagmus is concerning for central nervous system (CNS) dysfunction.

eFigure 18-3 Dix-Hallpike maneuver (A and B). (From Andreoli TE. *Cecil essentials of medicine*. Philadelphia: Saunders; 1997:926.)

Although not technically part of the otologic examination, a complete neurologic examination should always be done, especially in a patient with a complaint of disequilibrium. This should include assessment of cranial nerve function, cerebellar testing, and the Romberg test. In addition, a cardiovascular assessment, including orthostatic vital signs, can also provide clues to a nonotologic cause of dizziness.

Audiometry and Tympanometry

Audiometry and tympanometry are objective tests of the auditory system. They are essential and often complementary parts of a complete otologic evaluation. Audiometry consists of two parts: pure-tone and speech audiometry (eFigures 18-4 to 18-7).

Pure-tone audiometry tests the patient's awareness of tones of various pitches that are presented to each ear individually. The measure of loudness is based on the decibel scale, which is logarithmic. Normal hearing is defined as hearing each tone (ranging from 250-4000 Hz) at levels at or below 20 dB. The tones are presented in each ear through air conduction via an earphone or through bone conduction via a bone-conduction vibrator placed at the mastoid tip. Presenting the tones in these two ways allows the conductive components of hearing (i.e., external and middle ear structures) and the sensorineural components (i.e., inner ear structures and cranial nerve VIII) to be assessed independently in each ear. The external ear canal should be cleared of cerumen before testing. Pure-tone audiometry allows an audiogram to be created, which graphically depicts both conductive and sensorineural hearing in both ears.

Speech audiometry is a test of inner ear function. It is performed by asking the patient to repeat single-syllable words (presented at an adequate volume to each ear individually).

A score, called the *discrimination score*, is given to each ear. A discrimination score of less than 90% is considered

eFigure 18-4 Sensorineural hearing loss. RE ANSI, Revision of American National Standards Institute standards. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:73.)

eFigure 18-5 Degree of hearing loss. *RE ANSI*, Revision of American National Standards Institute standards. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:74.)

eFigure 18-6 Conductive hearing loss. *RE ANSI*, Revision of American National Standards Institute standards. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:75.)

abnormal. Asymmetry of the discrimination scores is suspicious of unilateral inner ear pathology (acoustic neuroma). Audiometry is an excellent, reliable test in cooperative patients. It has limitations for those who cannot (or will not) follow instructions (e.g., infants, young children, mentally impaired patients, malingers). An abnormal audiogram result should always be confirmed by tuning fork examination. An accurate audiogram clearly depicts hearing acuity and, most important, shows if any variation exists between the two ears. Special audiometric tests are done in cases of suspected malingering and are quite helpful in these cases.

eFigure 18-7 High-frequency hearing loss. *RE ANSI*, Revision of American National Standards Institute standards. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:76.)

Impedance audiometry or *tympanometry* measures resistance and compliance of the middle ear structures. It is also an indirect test of eustachian tube function. It is done by placing a pressure probe with an airtight seal in the meatus of the ear. The probe is capable of producing a small amount of positive and negative pressure while delivering a stimulus and measuring small changes in volume, thereby measuring compliance of the tympanic membrane (eFigure 18-8). The result produces a *tympanogram*, the configuration of which can be compared with standard patterns.

If eustachian tube and middle ear function are normal, the normal pressure and compliance yield a *type A* tympanogram. If there is negative middle ear pressure or middle ear fluid, abnormal tympanic membrane compliance and middle ear pressure yield an abnormal *type C* or *type B* (flat) tympanogram, respectively. A tympanic membrane perforation causes a type B (flat) tympanogram but with a higher measured volume because the middle ear is in communication with the external ear canal.

Special Tests

Auditory brainstem response (ABR) is a test of nerve conduction of the auditory nerve (cochlear division of cranial nerve VIII) in response to auditory stimuli. A normal ABR result produces a characteristic waveform reflecting normal neural transmission from the eighth nerve to the brain. It can be done on conscious or unconscious patients. Although its evaluation is not as precise as with an audiogram, ABR is a completely objective test and does not require patient cooperation. It is most often used to test hearing in patients who cannot be tested with routine audiometry, including infants or young children who have failed infant hearing screening or otoacoustic emission (OAE) testing or those who are suspected of or at risk for hearing loss. Because it requires no patient feedback, ABR can be done on unconscious patients and possible malingers. It may be ordered as a screening test for some patients with relatively low suspicion of an acoustic neuroma or for those not able to undergo magnetic resonance imaging.

eFigure 18-8 Type A is a normal tympanogram. If there is negative middle ear pressure or middle ear fluid, tympanic membrane mobility will be impaired. A type B tympanogram indicates middle ear fluid, and type C indicates negative middle ear pressure. (From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999:77.)

Otoacoustic emission is also an objective test that measures the cochlea's response to noise. When presented with certain acoustic stimuli, the hair cells within the cochlea produce a predictable noise that can be measured. Assuming there is no conductive hearing loss, lack of production of stimulated OAEs indicates cochlear dysfunction and probable hearing loss. The test provides accurate information regarding hearing. OAE has been recommended to screen all infants for hearing loss and has been implemented in most U.S. states. Abnormal OAE testing in a neonate requires further evaluation, including repeat testing, possible ABR, and ear, nose, and throat evaluation.

Electronystagmography is a test of the vestibular (balance) portion of the inner ear that relies on the neural relationships between the cranial nerve innervating the ears (cranial nerve VIII) and those innervating the eyes (cranial nerves III, IV, and VI). Placement of electrodes around the eyes allows detection of nystagmus (both spontaneous and elicited) that might not be visible to the observer. Abnormal nystagmus indicates CNS or peripheral (labyrinthine) dysfunction, or both. The test can also be performed using special goggles and video assessment referred to as *videonystagmography*.

eTable 18-1 Differential Diagnosis of Otogenic Otalgia

External Ear	Middle Ear or Mastoid
Diffuse external otitis	Acute otitis media
Furunculosis	Acute mastoiditis
Necrotizing (malignant) external otitis	Barotrauma
Impacted cerumen	Acute eustachian tube obstruction
Perichondritis	Chronic otitis media
Foreign bodies	Subperiosteal abscess
Bullous myringitis	Petrositis
Herpes zoster oticus	Extradural abscess
Neoplasm	Lateral sinus thrombosis
Otomycosis	Neoplasm
Trauma	Trauma
Keratosis obturans	Postsurgical otalgia
Cholesteatoma of ear canal

eTable 18-4 Comparative Features of Peripheral Vestibular Disorders

Feature	BPPV	Meniere Disease	Vestibular Neuronitis	Perilymphatic Fistula
Hearing loss	No	Low frequency initially	Ultrahigh frequency (>8 kHz) or none	Variable
Tinnitus	No	Yes	Predominantly no	Variable
Type of vertigo	Positional	Spontaneous	Spontaneous	Variable
Duration of vertigo	1-2 min	20 min to 24 hr	24-48 hr	Variable
Physical examination	Positive Dix-Hallpike test	Nystagmus present in acute stage only	Nystagmus present in acute stage only	66% of patients have positive fistula test
Treatment	Repositioning maneuvers; surgery if dizziness persists	Diuretic as maintenance therapy; diazepam (Valium) for intractable vertigo	Diazepam during acute stage; vestibular exercises 72 hr after disease onset	Bed rest initially; surgery if dizziness persists

BPPV, Benign paroxysmal positional vertigo.

Meniere Disease

Meniere disease is characterized by episodic severe vertigo lasting hours, with associated symptoms of unilateral roaring tinnitus, fluctuating low-frequency hearing loss, and aural fullness. The typical age of onset is in the fifth decade of life. The cause is uncertain but is speculated to result from allergic, infectious, or autoimmune injury. The histopathologic finding includes *endolymphatic hydrops*, which is thought to be caused by either overproduction or underresorption of endolymph in the inner ear.

Meniere disease is a clinical diagnosis mostly based on history. Testing may be obtained to support the diagnosis and rule out other disorders. Audiometry often demonstrates a low-frequency SNHL. An FTA-ABS (fluorescent treponemal antibody-absorption) test may be obtained to rule out syphilis. ENG may demonstrate a unilateral peripheral vestibular weakness on caloric testing. When the diagnosis is uncertain, a brain MRI with contrast is obtained to evaluate for a retrocochlear lesion. The differential diagnosis of Meniere disease includes acute labyrinthitis, neurosyphilis, labyrinthine fistula, autoimmune inner ear disease, vestibular neuronitis, and migraine-associated vertigo.

Although Meniere disease has a highly variable clinical course, most patients have long symptom-free periods between clusters of episodes. The majority of patients have an excellent prognosis, with symptoms burning out over several years. However, some patients have a disabling course with frequent and severe attacks. On average, a moderate SNHL is the end result. The disease may become bilateral in about 45% of cases (wide variability exists).

Treatment of an acute episode involves vestibular suppressants and antiemetics. As with any vestibular disorder, vestibular suppressants should be limited for use during acute symptoms because of their addictive potential and impairment of central compensation. Maintenance therapy includes reduction of sodium intake to less than 1500 mg/day and a diuretic such as hydrochlorothiazide–triamterene (Dyazide). Patients are also instructed to minimize caffeine, alcohol, nicotine, and chocolate. Allergy treatment may be helpful in some patients. Most patients have adequate control of symptoms with this regimen. Several studies have indicated that a short course of steroids is not likely to improve Meniere disease (Fisher et al., 2012).

Patients who fail conservative measures may be candidates for procedures and surgical treatment. Gentamicin, a vestibulotoxic aminoglycoside antibiotic, may be injected transtympanically into the middle ear to permeate into the inner ear. Control of vertigo may result in 90% of patients but with a risk of hearing loss. Endolymphatic sac decompression or shunting through a mastoidectomy appears to benefit most patients with minimal risk to hearing. Although a generally accepted procedure, adequate studies are lacking on its effectiveness. More invasive interventions, including vestibular nerve section and labyrinthectomy, are reserved for patients with severe disease who do not respond to other measures (Sajjadi and Paparella, 2008).

Vestibular Neuronitis

Acute vertigo associated with nausea and vomiting (but without neurologic or audiologic symptoms) that originates

in the vestibular nerve is known as *vestibular neuronitis*. Vestibular neuronitis can occur spontaneously or can follow viral illness. Horizontal nystagmus shows the fast component beating away from the affected side. The symptoms peak within 24 hours and usually last for 3 to 4 days. Autopsy studies have shown cell degeneration of one or more vestibular nerve trunks, a finding similar to that seen in Bell palsy, which affects the facial nerve. A short course (3-5 days) of vestibular suppressants (e.g., meclizine [Antivert], diazepam [Valium]) and antiemetics such as promethazine (Phenergan) can provide symptomatic relief in the acute setting.

Distinguishing between vestibular neuronitis and bacterial labyrinthitis or labyrinthine ischemia is important. The diagnosis of *bacterial labyrinthitis* is based on hearing loss and otitis media or meningitis, and *labyrinthine ischemia* can be distinguished by hearing loss plus associated neurologic symptoms with a history of vascular disease.

Benign Paroxysmal Positional Vertigo

The most common cause of peripheral vestibular vertigo in adults is BPPV. BPPV occurs in all age groups but more often between ages 50 and 70 years. The incidence of BPPV is 11 to 64 per 100,000 persons per year and is twice as common in women as men (Froehling et al., 1991). It is caused when otoconia particles from the utricle or saccule lodge in the posterior semicircular canal and is also referred to as *canalithiasis*. This causes the canal to be a gravity-sensing organ, and head movement results in displacement of the otoconia and a sensation of vertigo.

The Dix-Hallpike maneuver reproduces this vertigo in the patient, resulting in nystagmus (see eFigure 18-3). Characteristics of the nystagmus of BPPV include fatigability, a latency period of 1 to 5 seconds before nystagmus begins after the head is moved, a short duration of nystagmus from 5 to 30 seconds, and reversal of the nystagmus components when the patient is returned to the sitting position. If these characteristics are not present and treatment is not successful, BPPV cannot be diagnosed. In such a case, a CNS lesion is possible. BPPV can be the residual effect of Meniere disease, ear surgery, vestibular neuronitis, or ischemia of the inner ear. Head trauma, even when it is minor, can lead to BPPV. However, one third of cases are idiopathic.

Treatment of BPPV consists of performing repositioning maneuvers with the goal of returning the otoconia to the utricle or saccule (Nguyen-Huynh, 2012). In addition, the patient may attempt to reposition the otoconia at home by sitting upright on the bed and rapidly lying supine with the affected ear facing downward. After 1 minute, the head should be repositioned with the opposite ear facing downward, and the patient should wait another minute. The patient should then return slowly to the upright seated position and repeat this exercise four more times. The entire process is completed twice daily until the symptoms have abated (Hilton and Pinder, 2010).

An expert panel convened by the American Academy of Otolaryngology–Head and Neck Surgery Foundation recommended against “routinely treating BPPV with vestibular suppressant medication such as antihistamines or benzodiazepines” (Bhattacharyya et al., 2008). Because of the variability of symptoms, the clinician must judge each

case independently. Resolution occurs in a few weeks or months, and the condition is benign, although it can recur.

Perilymph Fistula

Rapid changes in air pressure (barotrauma), otologic surgery, violent nose blowing or sneezing, head trauma, or chronic ear disease may cause leakage of perilymph fluid from the inner ear into the middle ear and result in episodes of vertigo. Associated signs and symptoms are variable but can include a sudden pop in the ear followed by hearing loss, vertigo, and sometimes tinnitus. Diagnosis can be determined by a fistula test, in which negative and positive pressures are applied to the tympanic membrane using pneumatic otoscopy, causing nystagmus and vertigo.

Labyrinthitis

As with vestibular neuronitis, labyrinthitis causes sudden and severe vertigo. In contrast to vestibular neuronitis, the patient also has tinnitus and hearing loss. The hearing loss is sensorineural, is often severe, and can be permanent. Labyrinthitis is caused by inflammation within the inner ear. The cause is most often a viral infection but can be bacterial. Bacterial labyrinthitis usually results from extension of a bacterial otitis media into the inner ear. A noninfectious *serous* labyrinthitis can also occur after an episode of AOM. Other, less common causes include treponemal infections (syphilis) and rickettsial infection (Lyme disease).

Symptomatic treatment of labyrinthitis is similar to that for vestibular neuronitis. Antibiotics are recommended if a bacterial cause is suspected. As with AOM, bacterial labyrinthitis can, in rare cases, lead to meningitis. Few other conditions cause the constellation of hearing loss, tinnitus, and vertigo, but cerebrovascular ischemia, meningitis, brain abscess, and encephalitis should all be considered. Although the vertigo should resolve over days to weeks, hearing loss and tinnitus can persist.

Drugs known to be ototoxic can cause acute onset of hearing loss and disequilibrium, although this is not true labyrinthitis. These drugs include salicylates, aminoglycosides, loop diuretics, and various chemotherapeutic agents. This cause should be considered in patients who complain of hearing loss or dizziness while taking these medications.

TINNITUS

Tinnitus is a term used to describe an internal noise perceived by the patient. It is usually, but not always, indicative of an otologic problem. Tinnitus is most often subjective (that is, heard only by the patient). However, it can be objective and heard by the patient and the examiner. In most cases, tinnitus is secondary to bilateral SNHL and requires no further evaluation. In rare cases, tinnitus can be a symptom of a vascular abnormality (aneurysm or arteriovenous malformation), hypermetabolic state, or intracranial mass that, if not evaluated, could result in delayed treatment. Middle ear and rarely external ear pathology can also cause tinnitus, as can numerous medications (Table 18-3). The patient's medications should be reviewed.

Evaluation of tinnitus begins with a complete medical history, including duration of symptoms, possible inciting event (e.g., acoustic trauma), and accompanying symptoms (e.g., vertigo, hearing loss, headache, vision changes).

Table 18-3 Causes of Tinnitus

Subjective	Otologic: presbycusis, noise-induced hearing loss, Meniere disease, otosclerosis Metabolic: hyperthyroidism, hypothyroidism, hyperlipidemia, vitamin deficiency Neurologic: basilar skull fracture, whiplash injury, multiple sclerosis, meningitic effects Pharmacologic: aspirin, NSAIDs, aminoglycosides, TCAs, loop diuretics, heavy metals, oral contraceptives, caffeine, cocaine, marijuana Dental: temporomandibular joint syndrome Psychologic: depression, anxiety
Objective	Vascular abnormalities: AVM, glomus tumors, stenotic carotid artery, vascular loops, persistent stapedial artery, dehiscent jugular bulb, hypertension Tympanic muscle disorders: palatomyoclonus, idiopathic stapedial muscle spasm Patulous eustachian tube CNS anomalies: congenital stenosis of the sylvian aqueduct, type 1 Arnold-Chiari malformation

AVM, Arteriovenous malformation; CNS, central nervous system; NSAID, nonsteroidal antiinflammatory drug; TCA, tricyclic antidepressant.

Specific questions regarding the tinnitus are critical: Is it unilateral or bilateral? What is the quality of the tinnitus (pitch, volume)? Does it sound like a heartbeat or rushing blood? Does it change? A complete ENT evaluation should be performed, and audiometry is mandatory.

In general, if the tinnitus is bilateral, not particularly intrusive, not pulsatile, and associated with symmetric hearing loss, it is likely secondary to the hearing loss itself. The hearing loss requires further evaluation with MRI with contrast if it is asymmetric.

In cases of *pulsatile* tinnitus with normal otoscopy, magnetic resonance angiography (MRA) is performed to evaluate for vascular abnormalities. If otoscopy identifies a retrotympanic mass, temporal bone CT is obtained to evaluate for a vascular mass or abnormality. Blood tests can be performed to rule out anemia or hyperthyroidism, which can result in a hypermetabolic state and cause tinnitus secondary to increased blood flow near the cochlea. Auscultation of the neck, periauricular area, and chest may identify a bruit or murmur, indicating a need for a carotid duplex ultrasound study or echocardiogram, respectively. Most cases of arterial pulsatile tinnitus are secondary to atherosclerotic carotid artery disease. Venous pulsatile tinnitus often improves with digital pressure over the internal jugular vein. Etiologies include idiopathic venous hum, a high-riding jugular bulb, or benign intracranial hypertension.

Effective treatment of tinnitus is difficult and usually requires various approaches. Finding and eliminating potential causes (especially pharmaceutical) is imperative. Patients should be counseled to avoid caffeine and nicotine. A research review by the Agency for Healthcare Research and Quality's (AHRQ's) Effective Healthcare Program found that sertraline was the one selective serotonin reuptake inhibitor that consistently improved reducing loudness, improving quality of life and alleviating severity of tinnitus (Pichora-Fuller et al., 2013). IV lidocaine eliminates tinnitus in some patients but is not practical and has obvious potential side effects. Various homeopathic treatments and nutritional supplements are effective in some cases, but most have not been evaluated in controlled studies. Hearing

aids are beneficial in *masking* the tinnitus if hearing loss exists. Tinnitus maskers can be purchased that essentially drown out the tinnitus with various distracting noises. Biofeedback and a technique called *tinnitus retraining therapy* are helpful for some patients. These techniques can be learned through various publications or at a tinnitus treatment center. All patients with obtrusive tinnitus are encouraged to join the American Tinnitus Association, the largest tinnitus support group and an excellent source of reliable information (Newman et al., 2011).

DISORDERS OF THE EXTERNAL EAR

Otitis Externa

The most common cause of pain in the external ear is acute otitis externa. It affects 3% to 10% of the patient population. The pain is caused by inflammation and edema of the ear canal skin, which is normally adherent to the bone and cartilage of the auditory canal. The inflammatory reaction can be caused by bacteria, fungi, or contact dermatitis (see eTable 18-5 online).

Cerumen protects the canal by forming an acidic coat that helps prevent infection. Factors that predispose to otitis externa include absence of cerumen, often from excessive cleaning by the patient; water, which macerates the skin of the auditory canal and raises the pH; and trauma to the skin of the auditory canal from foreign bodies or use of cotton swabs.

When a bacterial organism is suspected, treatment consists of cleaning the ear canal of any debris or drainage and then instilling antibiotic drops with or without steroids. Because the most common bacterial organisms in this infection are *Pseudomonas aeruginosa*, *Peptostreptococcus*, *Bacteroides fragilis*, and *S. aureus*, drops containing ciprofloxacin or neomycin-polymyxin B (Ciprodex, Cortisporin, Coly-Mycin, Pediotic) are effective against these pathogens, combined with a steroid to decrease inflammation, pain, and pruritus. A recent study found Ciprodex to be more effective against *P. aeruginosa* than neomycin-polymyxin B-hydrocortisone (Dohar et al., 2009).

The clinician must use judgment in assessing the severity of the infection and treat accordingly. If the infection spreads beyond the auditory canal, oral antimicrobials are indicated. If clinical improvement is not apparent after 48 hours, the patient needs to be reexamined for additional treatment or referral to an otorhinolaryngologist.

Fungal infections comprise fewer than 10% of external otitis cases. The most common fungi are *Aspergillus niger* and *Candida* spp. and are more prevalent in tropical climates. Itching is a more common complaint than pain in fungal ear infections. Thorough cleaning of the ear canal is the primary duty of the physician in this infection. Drops that are effective include 2% acetic acid with or without a steroid. Clotrimazole drops or powder can also be used to treat fungal infections of the ear canal (van Bolen et al., 2003).

Approximately 90% of necrotizing (malignant) otitis externa is seen in immunocompromised patients such as patients with diabetes, patients with acquired immunodeficiency syndrome (AIDS), and those receiving chemotherapy. Systemic antibiotics are mandatory in these cases. Antipseudomonal antimicrobial agents should be administered intravenously in the hospital setting, and surgical

debridement is often necessary. Complications from necrotizing otitis externa include facial nerve palsy, mastoiditis, meningitis, and even death (Quick, 1999).

Other conditions that affect the external auditory canal include impacted cerumen, seborrheic dermatitis, psoriasis, contact dermatitis, and staphylococcal furunculosis. Symptoms and signs include pruritus, edema, scaling, crusting, oozing, and fissuring of the external auditory canal. Treatment of the underlying disease is the primary goal. Corticosteroid preparations are indicated for seborrheic dermatitis, psoriasis, and contact dermatitis. Oral antibiotics and sometimes incision and drainage are required for staphylococcal furunculosis.

Auricular Hematoma

Blunt auricular trauma, most commonly in wrestlers and boxers, may shear the perichondrium from the underlying cartilage, leading to a hematoma. The presence of a fluctuant swelling with loss of normal auricular landmarks helps to distinguish a hematoma from ecchymosis. If left untreated, an auricular hematoma may cause fibrosis and neocartilage formation, leading to a deformity of the auricle termed *cauliflower ear*. Therefore, treatment in a timely manner is recommended.

Although a Cochrane review could not define the best treatment for an acute auricular hematoma, a frequently successful treatment involves incision and drainage with dental rolls sutured to the anterior and posterior auricle (Figure 18-5). Needle aspiration alone often leads to recurrences. The bolster is usually left in place for 4 to 7 days, with the patient permitted to return to wrestling or boxing with headgear. Prophylactic antistaphylococcal antibiotics are given. For a long-standing hematoma or a cauliflower ear, debridement of fibrosis and cartilage is necessary (Jones and Mahendran, 2008).

Figure 18-5 Photograph of 16-year-old boy who sustained auricular hematoma in a wrestling match. He underwent incision and drainage with placement of dental rolls.

eTable 18-5 Otorrhea from the External Ear Canal

Cause	Physiologic Process	Diagnostic Clue	Treatment
Cerumen	Accumulation of cerumen in external ear canal with possible infection	Impacted cerumen in external ear canal	Cerumen removal
Otitis externa	Inflammation of external ear canal, usually by <i>Pseudomonas aeruginosa</i>	Purulent drainage in external ear canal Edema or erythema of external ear canal Recent history of water in external ear canal History of diabetes mellitus History of canal trauma (with cotton swabs) Otalgia Polyp in external ear canal	Otic antibiotic drops with or without oral antibiotics Aural cleaning Dry-ear precautions Consider ear wick if unable to visualize tympanic membrane
Foreign body	Foreign body impacted in external ear canal	Foreign body visualized in external ear canal History of inserting foreign body History of ear cleaning with cotton swabs Young person or person with mental retardation having had foreign body in nose	Removal of foreign body Otic antibiotic drops if evidence of infection or bleeding Referral to ENT if foreign body cannot be removed
Canal trauma	Trauma to skin of external ear canal caused by, e.g., cotton swab or bobby pin; possible head trauma	History of instrumentation such as ear cleaning Bloody otorrhea Laceration or bleeding visualized in external ear canal	Otic antibiotic drops Temporal bone CT if history of head trauma Complete audiologic evaluation Referral to ENT
Neoplasia	Neoplasms originating in or extending to external ear canal	Unilateral involvement Mass seen in external ear canal Polyp in external ear canal	Temporal bone CT Referral to ENT
Malignant otitis externa	Fulminant infection, almost always caused by <i>Pseudomonas</i> spp.	Severe pain Patient has diabetes or is old Polyp in external ear canal	<i>Pseudomonas</i> -specific IV antibiotics Aural cleaning Temporal bone CT
Fungal otitis externa	Fungal infection	Visible hyphae Refractory to antibiotic therapy Patient has diabetes or is old or immunocompromised	Acetic acid otic drops Dry-ear precautions
Dermatosis	Allergic or irritant dermatosis	History of contact with known allergen or irritant Erythema and itching	Removal of causative agent Topical steroids Systemic steroids if severe Antibiotics if secondary infection is present
Psychogenic factors	Psychogenic condition	Continued reports of wet or crawling sensations in the external canal Irritated or possibly secondarily infected external canal Normal findings at evaluation for cause after patient has been treated for infection	Topical steroids Antibiotics if secondary infection is present Psychiatric referral

CT, Computed tomography; ENT, ear, nose, and throat; IV, intravenous

External Auditory Canal Foreign Bodies

A common problem seen in family physicians' offices is a patient with an external auditory canal foreign body. A wide variety of objects can be found. In one study of 191 patients with aural foreign bodies, 27 different objects were discovered (Ansley and Cunningham, 1998). The most common were beads, plastic toys, pebbles, insects (especially cockroaches), popcorn kernels, earrings, paper, peas, cotton, pencil erasers, and seeds. When a patient presents with a chronic dry cough that has not responded to the usual measures, the physician should look for an aural foreign body (causing irritation of the ninth cranial nerve).

Removal of an external auditory canal foreign body is simplified if the object is in the lateral third of the external auditory canal. Objects within the medial two thirds pose a greater challenge. A variety of instruments can be used, depending on the object, including cerumen loops, alligator forceps, and otologic-tip suction. Irrigation with body-temperature sterile water often dislodges the object. Hygroscopic objects such as vegetables, beans, and other food matter can swell and make the object even more impacted and should not be irrigated. Disk batteries should be removed immediately because of the possibility of liquefaction necrosis of the external auditory canal. Aural irrigation is contraindicated because wetting of the battery leads to leakage of electrolyte solution.

Smooth, round objects pose a difficult problem because, in trying to remove them, they are often pushed farther into the canal. Aural irrigation or even cyanoacrylate glue on the tip of a straightened paperclip is effective in removing objects that are difficult to retrieve. Methods to remove cockroaches or other insects include microscope immersion oil, mineral oil, or lidocaine. The effect of mineral oil or microscope immersion oil is to drown the insect, and lidocaine tends to make cockroaches crawl rapidly out of the ear canal (Bressler and Shelton, 1993). Otomicroscopy is often required for safe removal.

Depending on their age, fewer than 35% of patients should require anesthesia. The younger the patient, the more likely anesthesia will be required. Objects with sharp edges are best removed with an operating microscope with the patient under general anesthesia. Complications of foreign body removal include canal wall trauma and tympanic membrane perforation. Immobilization of the patient is the key to successful removal of aural foreign bodies, and at least two assistants are necessary.

Cerumen

Glandular secretions from the outer third of the external auditory canal and desquamated epithelium combine to form cerumen. Cerumen is necessary to provide a hydrophobic and acidic environment to protect the underlying external ear canal epithelium and prevent infection. The external auditory canal is self-cleaning, with cerumen slowly pushed laterally to the external meatus.

Cerumen impaction is the symptomatic accumulation of cerumen in the external canal or an accumulation that prevents a needed assessment of the ear. Complete occlusion is not necessary. Symptoms may include hearing loss, tinnitus, pruritus, fullness, otalgia, cough, odor, and dizziness. Impaction often results from instrumentation with

cotton-tipped applicators, which should be discouraged. Elderly patients with changes to external canal epithelium, patients with external canal abnormalities (e.g., osteomas, exostoses, stenosis), and users of hearing aids and earplugs are also at risk for impaction. Excessive cerumen production as a primary problem is relatively rare.

In most people, cleaning the external meatus with a finger in a washcloth while bathing is sufficient to maintain the ear canals. Treatment of cerumen impaction by the clinician may involve ceruminolytic agents, irrigation, or manual removal. Ceruminolytic agents include water-based; oil-based; and non-water-, non-oil-based solutions. A Cochrane review found that any type of ear drop (including water and saline) is more effective than no treatment, but the study quality was lacking (Burton and Glasziou, 2009). Office irrigations may be performed using a large syringe with a large angiocatheter tip. The type of irrigant solution used is probably not critical, although a tepid or warm temperature is important to prevent the patient from becoming vertiginous from a labyrinthine caloric response. Instilling a ceruminolytic 15 minutes before irrigation may improve the success rate. Irrigations should not be performed in those with tympanic membrane perforations or previous ear surgery. Of note, irrigation with tap water has been implicated as a causative factor in malignant otitis externa. Therefore, instilling an acidifying ear drop after irrigation in patients with diabetes is recommended. Manual removal requires knowledge of ear anatomy and special care to avoid trauma. A handheld otoscope with a curette and other instruments may be used. Otolaryngologists often use binocular microscopy to aid with visualization. Patients inquiring about ear candling should be informed that it has not been shown to be effective and presents a risk of thermal injury to the ear (Burton and Doree, 2008).

Frostbite

The ears, nose, and cheeks, in that order, are most at risk for frostbite. Exposure to subfreezing temperature is the main risk factor, but wind chill also greatly affects heat loss from the skin by convection. Protective clothing greatly diminishes the risk.

There are three grades: grade I frostbite, in which the skin is erythematous and edematous; grade II frostbite, in which the skin blisters and forms bullae; and grade III frostbite, which results in local necrosis of the dermis over 1 to 2 weeks. To assess the severity of frostbite, the physician must examine the tissue from several hours up to 2 days after the typical skin blanching occurs.

Treatment consists of quickly warming the ear with gauze soaked in saline at 38° to 40° C (100.4°-104.0° F). Any blisters that form should be allowed to reabsorb spontaneously. Topical antibiotic ointment can be applied, and viability of the tissue should be assessed periodically.

Lacerations

When there is trauma to the ear requiring suture closure, careful realignment is mandatory to maintain the auricular contour. The extent of the injury should be evaluated thoroughly with the tissue anesthetized with 1% lidocaine (without epinephrine). This allows a careful evaluation of the wound as well as a meticulous suture closure. Lacerations involving only the skin can be closed with

everting nonabsorbable sutures. An earlobe that is torn from earring trauma can be closed in layers using absorbable chromic gut suture to close the dermis and nonabsorbable 5-0 or 6-0 suture to close the skin. Lacerations that involve cartilage, perichondrium, and skin must also be closed in layers but might best be referred to a specialist in otorhinolaryngology or to a plastic surgeon.

DISORDERS OF THE MIDDLE EAR

Bullous Myringitis

Bullous myringitis refers to painful inflammatory bullae on the tympanic membrane. The blebs appear hemorrhagic. It was formerly thought that bullous myringitis was caused by *Mycoplasma pneumoniae* infection. Roberts (1980), however, summarized six studies involving 858 patients with bullous myringitis, and *M. pneumoniae* was isolated from only one. The cause is usually viral but can be bacterial in some cases. Studies have confirmed that bacterial cultures from bullous fluid are similar to cultures from middle ear fluid taken from patients with AOM. The main isolates are *Streptococcus pneumoniae*, *H. influenzae*, and β -hemolytic streptococci. The tympanic blistering is probably a nonspecific reaction and simply a variant of AOM that should be treated as such.

It is important to distinguish bullous myringitis from acute otitis externa, which requires topical treatment, and from herpes zoster oticus, which can lead to cranial neuropathy and requires antiviral treatment. Neither of these conditions is usually limited to only tympanic membrane involvement.

Otitis Media

Acute Otitis Media. The most common infection for which children are seen in a physician's office is AOM. The annual cost of AOM in the United States is an estimated \$2.88 billion (Ahmed et al., 2014). By age 7 years, 93% of children have had at least one episode of AOM, and 75% have had recurrent infections. AOM can occur at any age, but the highest incidence is between 6 and 24 months in the United States.

The primary cause of bacterial colonization of the middle ear is eustachian tube dysfunction. Abnormal tubal compliance in addition to delayed innervation of the tensor veli palatini muscle leads to collapse of the eustachian tube. Aerobic and anaerobic organisms, as well as viruses, can contribute to middle ear infection (Lieberthal et al., 2013). The three most common bacteria involved in AOM are *S. pneumoniae* (25%-40% of cases), *H. influenzae* (10%-30%), and *Moraxella catarrhalis* (2%-15%) (Klein, 2004). Risk factors most often associated with AOM are child care outside the home and parental smoking. Table 18-4 lists the common risk factors for AOM. A viral upper respiratory infection usually precedes an episode of AOM.

The criteria necessary to confirm the diagnosis of AOM are: acute onset of ear pain (holding, tugging, rubbing of the ear in a nonverbal child) or intense erythema of the TM, moderate to severe bulging of the TM, or new onset of otorrhea not due to OE. If there is no middle ear effusion (MEE), AOM may not be diagnosed (Lieberthal et al., 2013; Level of evidence [grade]: B). Middle ear effusion can be diagnosed by direct visualization of air-fluid levels behind the

Table 18-4 Common Risk Factors for Acute Otitis Media

Male gender
Bottle feeding, especially in the supine position
Exposure to upper respiratory tract infections (e.g., daycare setting, winter season)
Genetic factors
Ethnic factors (e.g., Inuit or Native American)
Parental smoking
Allergy
Craniofacial abnormalities (e.g., cleft palate)
Previous episode of acute otitis media, particularly during the preceding 3 months
Use of a pacifier

Table 18-5 Causes of Otagia Other than Acute Otitis Media

Temporomandibular joint disorders

tympanic membrane, a bulging drum, lack of movement on pneumatic otoscopy, or a flat tympanogram readout that indicates no tympanic membrane movement and therefore the presence of middle ear effusion. Redness of the tympanic membrane, pain, and fever are the most common signs and symptoms of middle ear inflammation (see eTable 18-6 online). Erythema of the tympanic membrane without middle ear effusion is myringitis or tympanitis and is a separate diagnosis from AOM. Ear pain in the presence of a normal-appearing, flaccid tympanic membrane indicates causes other than AOM (Table 18-5).

The standard of care for the treatment of AOM in children older than 6 months depends on the severity of the symptoms. Antibiotics should be prescribed for children 6 months and older with severe symptoms (moderate or severe otalgia or temperature 102.2°F or higher (Grade B). When the symptoms are nonsevere, the parents can be given the option of observation or antibiotics (Grade B). The decision either to begin antibiotics or to observe the patient without them is based on the certainty of diagnosis, severity of symptoms, and age of the patient (Lieberthal et al., 2013) (Table 18-6).

When the criteria for the diagnosis of AOM are met and the symptoms are bilateral, the diagnosis is certain, and antibiotic therapy is indicated for any child 2 years old or younger (Lieberthal et al., 2013). Observation is allowed for this age group if the symptoms are not severe and unilateral. For children older than 2 years, observation is an option if the illness is not severe and the parents can be relied on to report the patient's status and can obtain medication if necessary. Severe illness is defined as moderate to severe otalgia and fever higher than 39°C (102.2°F). When two or fewer diagnostic criteria are present, diagnosis is considered uncertain, and observation is allowed for children 6 months and older with nonsevere illness (Toll and Nuñez, 2012).

Table 18-6 Treatment of Acute Otitis Media

Features	Treatment
LOW-RISK PATIENTS	
Older than 6 yr, no antimicrobial therapy within past 3 mo, no otorrhea, not in daycare, and temperature <38°C (<100.5°F)	Amoxicillin: 40-50 mg/kg/day in divided doses for 5 days
HIGH-RISK PATIENTS	
Younger than 2 yr, in daycare, treated with antimicrobials within past 3 months, otorrhea, or temperature >38°C (>100.5°F)	Amoxicillin: 80-90 mg/kg/day in divided doses for 10 days
TREATMENT FAILURE	
Signs and symptoms persisting after 3 days	Amoxicillin-clavulanic acid (Augmentin): 80-90 mg/kg/day for 7-10 days Cefuroxime axetil (Ceftin): 20-30 mg/kg/day bid for 7-10 days Ceftriaxone (Rocephin): 50 mg/kg intramuscularly for 1 dose not to exceed 1 g for children <12 yr for 1-3 days or for >12 yr 1-2 g/day for 3-4 days depending on severity of symptoms
PENICILLIN-ALLERGIC PATIENTS	
Any	Cefuroxime axetil: 2 mo-5 yr, 30 mg/kg/day divided q 12 hr, max: 1000 mg/day Cefpodoxime: 2 mo-5 yr, 5 mg/kg/day, divided q 12-24 hr, max: 1000 mg/day; 6-12 yr, 10 mg/kg/day, max: 400 mg/day Ceftriaxone (see above)

bid, Twice a day; q, every;

Resistance of *S. pneumoniae* to penicillin is an increasing problem and ranges from 15% to 50% depending on the area. The mechanism of resistance is based on an alteration of penicillin-binding proteins rather than the production of β -lactamase, as occurs with *H. influenzae* and *M. catarrhalis* infections. Resistance rates are higher in children than in adults, especially if the children are in daycare or have received antimicrobial therapy in the previous 3 months.

The dose to treat AOM is 80 to 90 mg/kg/day in two divided doses (Lieberthal et al., 2013). This allows the drug to overcome resistance in the causative organism. For patients with a penicillin allergy or those who have been treated with amoxicillin in the past 30 days, alternative medications include cefuroxime, cefpodoxime, cefprozil, or ceftriaxone. A meta-analysis found that first-generation cephalosporins have cross-allergy with penicillin, although the cross-allergy with second- and third-generation cephalosporins is negligible (Pichichero and Casey, 2007). Macrolides are not recommended for AOM in children because *H. influenzae* is the dominant organism causing AOM in this age group. Middle ear fluid becomes sterile 3 to 6 days after starting treatment, so the duration of therapy for uncomplicated AOM in children older than 2 years of age is 5 to 7 days.

If the initial antibiotic fails to resolve symptoms in 72 hours (pain, fever, redness and bulging of the tympanic membrane, otorrhea), high-dose amoxicillin-clavulanic acid is recommended. Alternatives in penicillin-allergic patients include the antibiotics cited earlier. Patients who do not respond to amoxicillin-clavulanic acid therapy should be treated with intramuscular ceftriaxone for 3 days. This antibiotic in a single dose can also be used initially if the child is vomiting or unable to keep down oral medication. Doses of antimicrobials are given in Table 18-6.

Influenza vaccine has been shown to decrease the number of cases of AOM in immunized patients compared with control participants and is recommended for all children according to the Advisory Committee on Immunization Practices, AAP and AAFP. Breastfeeding should be

Table 18-7 Guidelines for Treatment of Otitis Media with Effusion in children 2 months to 12 years

Duration of Otitis Media with Effusion	Treatment
6 wk	Observation Hearing evaluation optional
3 mo	Hearing evaluation; if 20-dB hearing loss
4-6 mo	Referral for polyethylene tube if there is hearing loss

Adapted from Rosenfeld RM, Andes D, Bhattacharyya N, et al. Clinical practice guideline: adult sinusitis. *Otolaryngol Head Neck Surg.* 2007;137 (3 suppl):S1-S31.

encouraged for the first 6 months of life, and tobacco smoke should be avoided.

Otitis Media with Effusion. Otitis media with effusion (OME) is defined as persistent middle ear fluid without pain, fever, or redness of the tympanic membrane. It is often the result of AOM but can occur de novo. About 90% of children have OME before they reach school age. About 80% to 90% of cases resolve within 3 months and 95% within 1 year. Table 18-7 provides the AHRQ guidelines for treatment of OME.

Tympanometry can be used to judge the presence of middle ear fluid. It is important to document the affected ear, the duration of the effusion, and the presence and severity of symptoms associated with OME. The latter include a feeling of fullness in the ear, popping, mild pain, hearing loss, balance problems, and delayed language development.

If OME persists for 3 months, a comprehensive hearing evaluation should be performed. A 40-decibel (dB) loss (or worse) in hearing bilaterally mandates referral for evaluation for polyethylene (PE) tube placement. Management of hearing loss between 6 and 39 dB depends on parent or caregiver preferences and can include strategies

to improve the listening and learning environment or referral for tube placement. If the hearing loss is 5 dB or less, repeat testing in 3 months may be performed if the middle ear effusion continues at that time. Follow-up testing is recommended every 3 to 6 months until the effusion resolves unless significant hearing loss occurs or there is evidence for structural abnormalities of the eardrum or middle ear. In these patients, PE tube placement is the preferred course.

When referring to a surgeon, the primary care physician must provide an adequate history of the duration of the middle ear effusion, developmental state of the child, and pertinent information such as a history of AOM. Physician and parental expectations for the referral should be clarified. Ultimately, the decision for PE tube placement should be based on a consensus among all parties involved. The possibility of repeat surgery after tube extrusion is 20% to 50%, and with reoperation, adenoidectomy is recommended in children with normal palates because it reduces the need for future surgery by 50%.

Recurrent Otitis Media. Three episodes of AOM within 6 months with complete resolution between episodes or four episodes in 12 months defines recurrent otitis media. Although the evidence is conflicting, a Cochrane review in 2006 showed only minimal improvement in recurrences, and this decrease in episodes only occurred when the antibiotic was continued. The authors recommended discouraging amoxicillin prophylaxis in children with recurrent otitis media not only because it is minimally effective but also to prevent antibiotic side effects and the acquisition of resistant pneumococci (Lieberthal et al., 2013). Pneumococcal vaccination has no beneficial effect on either health-related quality of life or functional health status in children 1 to 7 years old with recurrent AOM (Brouwer et al., 2005).

Tympanostomy tubes and also adenoidectomy may be offered to patients and may be beneficial in cases of recurrent AOM requiring multiple rounds of antibiotics within 6 to 12 months, especially if the episodes are severe.

Chronic Suppurative Otitis Media. Chronic suppurative otitis media (CSOM) is the presence of persistent purulent otorrhea through a perforated tympanic membrane or tympanostomy tube. A persistent tympanic membrane perforation may result from AOM, chronic eustachian tube dysfunction, or trauma. A cholesteatoma or rarely a tumor may also result in CSOM. Otorrhea may also be from chronic otitis externa, which may be difficult to distinguish from CSOM until treatment is initiated. Causes of otorrhea from the middle ear may not always be from middle ear bacterial infection (see eTable 18-7).

Associated symptoms often include hearing loss and tinnitus. Increasing pain, vertigo, or facial palsy imply a possible impending complication of CSOM (discussed later) and require urgent otolaryngologist consultation. Binocular otomicroscopy allows better visualization and suctioning of purulent material compared with routine otoscopy. Imaging is reserved for medical treatment failures or if a complication is suspected. CT is helpful to evaluate for bony erosion. MRI is indicated with suspicion of CNS involvement.

Initial management should include culture and sensitivity of the discharge to allow appropriate antibiotic selection.

If chronic otitis externa is suspected, the specimen should also be sent for fungal culture. Empiric antimicrobials should be started with coverage against the usual pathogens, which include *S. pneumoniae*, *H. influenzae*, *S. aureus*, *Pseudomonas* spp., and anaerobes. A Cochrane review demonstrated that ototopicals are superior to oral antibiotics. Quinolone ototopicals are safe for use in the middle ear. Topical aminoglycosides carry a risk of ototoxicity, but in some cases their use outweighs the risk. Systemic antibiotics may be required in severe cases or when copious drainage impairs administration of ototopicals. Aural toilet with an acetic acid solution (1 part distilled water, 1 part white vinegar) may be helpful to clear debris and provide antiseptics (Macfadyen et al., 2006a, 2006b).

If otorrhea resolves but a tympanic membrane perforation persists, the patient may be offered a tympanoplasty (tympanic membrane repair) to reduce the risk of recurrence and to improve hearing. If medical therapy fails to control inflammation, a tympanomastoidectomy may be indicated to eradicate infection, aerate the middle ear and mastoid, and repair the tympanic membrane. *Chronic tympanostomy tube otorrhea* is treated the same as typical CSOM. In recalcitrant cases, however, tube removal or replacement may be indicated. Also, adenoidectomy may be considered because chronic adenoiditis may act as a nidus for infection.

Complications. Although rare since the advent of antibiotics, complications of otitis media must be recognized early to avoid significant potential morbidity and mortality (Table 18-8). Chronic or recurrent otitis media can result in scarring of the tympanic membrane (*myringosclerosis* or *tympanosclerosis*), which alone is usually of no consequence. If scarring involves the ossicles, however, hearing loss can result. Tympanic membrane retraction or perforation can also occur.

INTRATEMPORAL COMPLICATIONS. Extension of the infection into the mastoid air cells can lead to *acute mastoiditis*. The signs and symptoms of acute mastoiditis are fever and postauricular tenderness, erythema, and edema. It is important to recognize that acute mastoiditis is a clinical and not a radiologic diagnosis. Therefore, inflammatory changes on a temporal bone CT must be correlated with examination findings to be called acute mastoiditis. Furthermore, acute mastoiditis must be distinguished from an auricular cellulitis secondary to acute otitis externa. *Facial paralysis* may result from AOM or CSOM because of inflammation along the facial nerve as it courses through the middle ear space.

eTable 18-7 Otorrhea from the Middle Ear

Cause	Pathophysiologic Process	Diagnostic Clue	Treatment
Acute otitis media with perforation	Purulent effusion in middle ear space with subsequent perforation	Antecedent upper respiratory infection Otalgia preceding otorrhea Purulent drainage	Otic antibiotic drops with oral antibiotics Aural cleaning Dry-ear precautions
Chronic otitis media with perforation with or without cholesteatoma	Chronic inflammation of middle ear space and mastoid, usually caused by <i>Staphylococcus</i> and <i>Pseudomonas</i> organisms	Purulent drainage White or pearly appearing mass behind tympanic membrane Unresponsive to prior antibiotic therapy Polyp in external ear canal	Otic antibiotic drops Complete audiologic evaluation Temporal bone CT Culture of drainage if not responding to prior antibiotic therapy Referral to ENT
Trauma	Head trauma with temporal bone fracture and possible CSF leakage	History of head trauma or ear trauma Bloody drainage Clear drainage that continues to accumulate Facial nerve weakness	Otic antibiotic drops Complete audiologic evaluation Temporal bone CT Dry-ear precautions Referral to ENT
Tuberculosis of middle ear	Hematogenous spread of <i>Mycobacterium tuberculosis</i> organisms to middle ear space	Positive result of PPD or anergy test History of pulmonary TB Thin, odorless drainage (chronic) No response to prior antibiotic therapy	AFB stain and culture Antituberculosis medications if positive PPD test result or if high index of suspicion
Neoplasia	Neoplasm originating in or extending to middle ear space	Unilateral Pulsatile tinnitus Mass visualized Polyp in external ear canal	Complete audiologic evaluation Temporal bone CT Referral to ENT

AFB, Acid-fast bacillus; CSF, cerebrospinal fluid; CT, computed tomography; ENT, ear, nose, and throat; PPD, purified protein derivative; TB, tuberculosis. From Lucente FE, Har-El G. *Essentials of otolaryngology*. Philadelphia: Lippincott, Williams & Wilkins; 1999.

Treatment of acute mastoiditis and facial nerve paralysis includes IV antibiotics, insertion of a tympanostomy tube for drainage, and sometimes emergent mastoidectomy. Infection within the middle ear space can extend into the inner ear, leading to labyrinthitis. Symptoms may include vertigo, tinnitus, and SNHL. Expedient initiation of broad-spectrum antibiotics and in some cases insertion of a tympanostomy tube may be necessary. *Petrositis* is a rare complication involving inflammation of the petrous apex mastoid air cells. *Gradenigo syndrome*, which includes retro-orbital pain, otorrhea, and cranial nerve VI palsy, may result. Treatment includes IV antibiotics and surgical drainage.

INTRACRANIAL COMPLICATIONS. The most serious complications of otitis media involve CNS extension of the infection and include sigmoid sinus thrombosis, meningitis, and brain abscess. Warning signs of an impending CNS complication include increasing pain, headache, spiking fever, or altered mental status. Evaluation may include MRI and lumbar puncture. Suspicion of CNS complication often requires urgent neurosurgical, ENT, and infectious diseases consultations. High-dose IV antibiotics and sometimes urgent surgery (mastoidectomy or craniotomy) are required to prevent significant morbidity or mortality. *Otitic meningitis* is a major cause of morbidity in the pediatric population. Fortunately, vaccines against Hib and *Pneumococcus* spp. (Prevnar) have decreased these occurrences.

A “cholesteatoma” is a destructive epithelial cyst in the middle ear that may extend to the mastoid air cells. The term is a misnomer because of the lack of cholesterol and presence of only squamous epithelium and keratin debris. The external ear canal and outer layer of the tympanic membrane are lined with squamous epithelium. Keratin debris is continuously sloughed as new epithelial cells mature. In a normal ear, the debris slowly migrates to the external meatus, where it is washed away. In contrast to the external ear, the middle ear space is lined with respiratory epithelium, which produces no keratin debris. Cholesteatomas form when squamous epithelium is abnormally located within the middle ear space, allowing the keratin debris to accumulate.

Cholesteatomas often result in CSOM with findings of purulent otorrhea, polyps, and granulation. However, some cholesteatomas are dry, with the finding of a white mass visible behind the tympanic membrane or a white mass or crusting on the tympanic membrane itself. A cholesteatoma must be differentiated from *myringosclerosis*, which is usually flat, white scarring on the tympanic membrane. Enzymatic properties, inflammation, and pressure may lead to bone erosion and hearing loss. If left untreated, serious problems may result, including facial nerve paralysis, labyrinthine fistula, and intracranial complications (see [Table 18-8](#)).

Congenital cholesteatomas occur without a history of tympanic membrane perforation or retraction and are postulated to result from congenital rests of epithelium in the middle ear space. These may occur in children with no significant history of otitis media and are usually diagnosed as an incidental white mass behind the tympanic membrane.

Primary acquired cholesteatomas result from prolonged eustachian tube dysfunction. Negative middle ear pressure results in a *retraction pocket* of the tympanic membrane,

usually at the region of the pars flaccida. Squamous epithelium may become trapped and accumulate in the retraction pocket, resulting in a cholesteatoma. Any retraction pocket of the tympanic membrane requires further evaluation to prevent progression to cholesteatoma.

Secondary acquired cholesteatomas occur as a result of a tympanic membrane perforation. In some cases, a perforation of the tympanic membrane may allow the outer squamous epithelium to migrate into the middle ear space, leading to cholesteatoma formation.

Although aggressive medical treatment may reduce inflammation, surgical treatment is necessary for almost all cholesteatomas. In less advanced cholesteatomas, the external auditory canal is spared in surgery, a “canal wall up” tympanomastoidectomy. Close follow-up is required because of the risk of recurrence from microscopic disease or persistent eustachian tube dysfunction. In more advanced disease, the posterior canal is removed, termed a “canal wall down” tympanomastoidectomy (modified radical and radical mastoidectomy). The canal wall-down procedures are more likely to result in a conductive hearing loss (CHL), but the mastoid cavity becomes accessible through a larger external canal, thereby exteriorizing the cholesteatoma. Typically, semiannual mastoid bowl debridement is necessary to remove squamous and ceruminous debris to prevent inflammation.

Traumatic Tympanic Membrane Perforations

Traumatic perforation of the tympanic membrane may result from barotrauma (water skiing or diving injuries, blast injuries, blows to side of head), ear canal instrumentation (cotton-tipped applicators, bobby pins, paper clips, cerumen curettes), or otitis media (see earlier discussion). The patient usually complains of acute pain that subsides quickly, associated with bloody otorrhea. Severe vertigo can occur but is transient in most cases. Persistent vertigo suggests inner ear involvement (perilymphatic fistula). Hearing loss and tinnitus are also common.

Findings may include fresh blood in the canal and around the perforation. Any medial canal clots or debris should not be removed or irrigated except under microscopy. Secondary bacterial infection may require treatment with ototopical antibiotics. Topical fluoroquinolones are safe for use in the middle ear. Audiologic evaluation is necessary to rule out SNHL. If a tuning fork examination indicates SNHL or is unreliable, the patient should be referred for complete audiologic and ENT evaluation.

In uncomplicated cases, the perforation is expected to heal spontaneously over days to weeks. The patient should be instructed to keep the ear dry during this time. If the perforation has not healed after several weeks, a tympanoplasty to close the perforation and, if necessary, repair ossicles is indicated. Repair of the perforation may improve hearing, reduce infection, and prevent cholesteatoma formation.

Barotrauma and Barotitis

Changes in altitude while flying (or scuba diving) can lead to rapid changes in middle ear pressure, leading to accumulation of serous middle ear fluid or blood. Symptoms may include aural fullness, otalgia, and CHL. In most cases, the fluid is resorbed, although this may take several weeks. *Autoinflation* maneuvers (popping the ears) may hasten

recovery. Oral and topical decongestants, nasal steroid sprays, or a short course of corticosteroids may be helpful. Antibiotics are indicated only if there are signs of infection. If fluid persists or is troublesome to the patient, a myringotomy allows the fluid to be drained. Tympanostomy tube insertion may be indicated for persistent middle ear fluid.

Rarely, a rapid change in middle ear pressure can lead to the creation of a *perilymphatic fistula* between the inner and middle ear. The patient complains of severe vertigo and hearing loss (sensorineural) (see “Vertigo”). Urgent ENT consultation is indicated.

HEARING LOSS

Hearing loss results from an interruption in the transmission of sound or subsequent nerve impulses in one or more areas of the ear. Recognition and treatment of hearing loss are imperative; unrecognized or untreated hearing loss may result in severe psychosocial ramifications in both adults and children. In the elderly population, hearing loss may lead to social withdrawal and depression. In the pediatric population, hearing loss may cause speech or cognitive delays. Hearing loss also has significant safety implications when it interferes with awareness of warning sounds (e.g., car horns, sirens, fire alarms). The four types of hearing loss are:

1. *CHL* occurs when there is a failure of normal propagation of acoustic energy through the conducting portions of the ear, which include the external auditory canal and the middle ear.
2. *SNHL* occurs from dysfunction of the inner ear, which may be caused by a failure of the generation of nerve signals in the cochlea by the cochlear hair cells or propagation of electrical signals along the cochlear division of the eighth cranial nerve.
3. *Mixed hearing loss (MHL)* occurs when hearing loss results from both CHL and SNHL.
4. *Central hearing loss* can result from ischemic or traumatic brain injuries.

Hearing loss may be subclassified according to whether it is *acquired* or *congenital*. Hearing loss is further classified based on its *severity* (mild, moderate, severe, profound), *side-ness* (right, left, bilateral), *stability* (stable, progressive, fluctuating), and *cause*.

Evaluation includes noting the onset and duration of the hearing loss, any inciting events, the subjective severity of the hearing loss, and any psychosocial impact. Associated ear symptoms, medical history, and a history of ototoxic medication exposure are also important. Although history and examination provide clues to the etiology of the hearing loss, comprehensive audiometric evaluation is essential to making a diagnosis. [Table 18-9](#) lists the most common types of CHL and SNHL.

Otosclerosis

Otosclerosis is caused by sclerotic fixation of the stapes and is the most common cause of CHL in the adult population with no previous history of trauma or infection. It is autosomal dominant in inheritance and more common in women than in men. Otosclerosis is usually bilateral and progressive. Treatment options include no treatment, amplification (hearing aid), fluoride treatment (stabilizes

Table 18-9 Common Types of Conductive and Sensorineural Hearing Loss

Conductive Hearing Loss	Sensorineural Hearing Loss
Cholesteatoma	Acoustic neuroma
Cerumen impaction	Diabetes
Foreign body in ear canal	Hereditary (congenital) loss
Ossicular problems	Idiopathic loss
Otitis media with effusion	Meniere disease
Otosclerosis	Multiple sclerosis
Retracted tympanic membrane (eustachian tube dysfunction)	Noise-induced loss
Tumor of the ear canal or middle ear	Ototoxicity
Tympanic membrane perforation	Perilymphatic fistula
Tympanosclerosis	Presbycusis
	Syphilis

but does not improve hearing), and surgery (stapedectomy). Stapedectomy involves removing and replacing the stapes with a tiny prosthesis. This procedure has a success rate of greater than 95%. Risks of surgery, although rare, include worsened hearing, tympanic membrane perforation, changes in taste, and disequilibrium.

Sudden Sensorineural Hearing Loss

See “[Emergencies](#).”

Presbycusis

Presbycusis is an all-inclusive term to describe the process of hearing loss related to aging. An estimated 30% to 35% of adults age 65 to 75 years and 40% to 50% of adults older than 75 years have hearing loss. Symptoms of presbycusis include gradually decreasing hearing acuity, especially for higher pitch tones (women’s and children’s voices) and in certain situations (with background noise). Tinnitus is common.

The cause of presbycusis is likely multifactorial, but ultimately the loss of cochlear *hair cell* function is thought to be the cause in most cases. Hair cell damage or loss can result from chronic noise exposure, genetic predisposition, and ototoxic medications. The hearing loss may also be caused by neurovascular injury from chronic conditions such as hypertension or diabetes, which can affect the cochlea or cochlear nerve. Hormonal conditions such as hypothyroidism should be considered, as should unusual conditions such as tertiary syphilis. Central auditory problems might be the cause, from dementia, cerebrovascular disease, or cerebrovascular accident (cerebrovascular accident [CVA], stroke).

Although the term “presbycusis” implies sensorineural loss, CHL should also be considered, including cerumen impaction, chronic OME, and otosclerosis (see [Table 18-9](#)).

Acoustic Neuroma

An acoustic neuroma (or more precisely, *vestibular schwannoma*) is a benign tumor that arises from the Schwann cells of cranial nerve VIII. Acoustic neuromas account for about 10% of all intracranial tumors. They are most commonly diagnosed in middle age. They are slightly more common in women than men. They are usually sporadic but may be associated with neurofibromatosis 1 or 2 (NF-1, NF-2). Most patients with NF-2 will develop bilateral

acoustic neuromas. Acoustic neuromas in NF-1 are much less common.

The primary symptoms of vestibular schwannoma are asymmetric hearing loss (sensorineural) and tinnitus. The hearing loss is usually gradual in onset and progressive but can occur suddenly. Disequilibrium is not usually the chief complaint on presentation, but patients often admit to mild unsteadiness. Larger tumors can cause dysesthesia around the ear, facial weakness, or both. If the neuroma is diagnosed late, patients can manifest cerebellar symptoms and symptoms of mass effect and obstructing hydrocephalus.

After a complete neuro-otologic examination and audiologic evaluation, an MRI scan of the brain with fine cuts through the internal auditory canal with gadolinium contrast is necessary for diagnosis.

Treatment options include observation, surgery, or stereotactic radiotherapy. Most vestibular schwannomas require treatment to prevent cerebral complications from future growth. If the patient is aged or infirm, watchful waiting may be considered. Very small tumors may be observed because the rate of growth is often slow. Surgical treatment involves either a translabyrinthine resection if hearing is poor or a craniotomy for hearing preservation. Stereotactic radiotherapy has the obvious advantage of avoiding major surgery. Success is similar to surgery for smaller tumors. Shortcomings of this treatment include delayed facial palsy, tumor recurrence (which requires routine monitoring), and the potential for radiation-induced malignancies in the future.

Hearing Loss from Acoustic Energy

Excessive noise exposure is an important and usually preventable cause of hearing loss. Hearing loss can result from chronic or acute noise exposure, usually causing injury at the level of the cochlear hair cells. However, acute acoustic trauma can also cause injury to the tympanic membrane and middle ear structures.

Chronic noise exposure may be recreational or vocational. The Occupational Safety and Health Administration (OSHA) has established guidelines for safe limits for acute and chronic noise exposure to prevent occupational noise-induced hearing loss. Exposure to noise of 90 dB or less is permissible for up to 8 hours per day. As the noise intensity increases, the permissible duration of exposure decreases. OSHA outlines procedures for hearing protection and monitoring. These standards also can help provide guidelines to minimize excessive recreational noise exposure. Recreational activities known to cause excessive noise include hunting or target shooting with firearms; use of power tools or power lawn equipment; attendance at sporting venues, motor racing events, action movies, or concerts; and listening to loud music on headphones. Hearing protection or avoidance is recommended for such activities.

Acute exposure to excessively loud noise can cause CHL or SNHL. CHL can result from a blast-type injury that leads to tympanic membrane perforation or ossicle injury. The conductive component of the hearing loss is usually reparable, but severe acoustic trauma can also cause sensorineural loss. SNHL from acute acoustic trauma is usually the result of temporary hair cell dysfunction or permanent injury, leading to transient or permanent *threshold shifts*, respectively. A concussive or blast injury (e.g.,

slap, airbag deployment to ear) can result in the formation of a labyrinthine fistula from the inner ear into the middle ear, which causes severe vertigo and SNHL. Most fistulas close spontaneously with bed rest, but some require middle ear exploration and repair. However, the SNHL is usually permanent.

Hearing Loss in the Pediatric Population

Congenital hearing loss is often hereditary but may be secondary to an intrauterine insult or infection. Of the hereditary variety, the majority are autosomal recessive and nonsyndromic. Risk factors for congenital hearing loss include a family history of hearing loss, facial abnormalities, ICU admission, history of meningitis, syndromes known to be associated with hearing loss, low Apgar scores at birth, medications known to cause hearing loss (e.g., aminoglycosides), elevated bilirubin, some prenatal maternal infections, or suspicion of hearing loss.

Universal newborn hearing screening using otoacoustic emissions and auditory brainstem response allows early identification of impaired children. Intervention by age 6 months appears to improve language development. A temporal bone CT is often obtained to evaluate for inner ear malformations that would predispose the patient to further hearing loss with even mild head trauma. A genetics evaluation and counseling may be indicated. Mutations of the Connexin-26 gene, an autosomal recessive disorder, account for a significant percentage of nonsyndromic hereditary hearing loss. Hearing loss may coexist with other conditions (e.g., renal, ophthalmologic, thyroid, infectious, cardiac), so other testing may be indicated based on clinical suspicion.

In children with a significant hearing loss, hearing aids are recommended. A cochlear implant may be indicated for those with hearing so poor to be considered unaidable. A cochlear implant is a surgically implanted device that receives sound, converts it to electrical signals, and directly stimulates the cochlea. Results are excellent in properly selected patients.

An important and often unrecognized cause of hearing loss in children is chronic OME. Children with either unilateral or bilateral middle ear effusions refractory to medical treatment for more than 3 months should have audiometric testing. Myringotomy with tube insertion is indicated if bilateral CHL is found and should be considered in some cases of unilateral loss as well.

Treatment of Hearing Loss

Individual treatments for specific causes of hearing loss vary greatly. This section gives a brief overview of options available to improve hearing in patients with the most common causes of hearing loss.
