laboratory monitoring but with higher initial cost and inability to achieve emergent reversal. These newer oral anticoagulant agents tend to have less bleeding risk overall but a slightly higher risk of gastrointestinal bleeding than warfarin (Hankey, 2014).

These predictive tools can be found online and are useful in helping guide therapy:

- **ABCD2:** Estimates risk of stroke after a TIA (<http://www.mdcalc.com/abcd2-score-for-tia/>).
- **CHAD2S2-VASc:** Estimates risk of stroke in those with atrial fibrillation and guides anti-platelet vs. anticoagulation therapy. A score greater than 2 suggests benefit from anticoagulation therapy (<http://www.mdcalc.com/cha2ds2-vasc-score-for-atrial-fibrillation-stroke-risk/>).
- **HAS-BLED:** Estimates risk of major bleeding with anticoagulation therapy. If the score is greater than 3, the risk of bleeding is significant with anticoagulation therapy (<http://www.mdcalc.com/has-bleed-score-for-major-bleeding-risk/>).

Hypercholesterolemia. Modest stroke risk reduction has been demonstrated by the achievement of lower lipid levels. Statins are effective for the primary prevention of ischemic stroke for patients with a history of occlusive arterial disease, coronary artery disease (CAD), or diabetes without a history of cerebrovascular disease. Statins reduce the risk of ischemic stroke in hypertensive patients with multiple cardiovascular risk factors and nonfasting cholesterol levels lower than 250 mg/dL, reduce stroke risk for patients with CAD or equivalent (e.g., diabetes, peripheral artery disease), and prevent recurrent ischemic stroke in CAD patients (Busch et al., 2004). Statins have also been shown to reduce the incidence of stroke and TIA in patients without preexisting CAD (Amarenko et al., 2006).

Carotid Artery Stenosis. Patients with internal carotid artery stenosis of less than 75% have an annual risk of stroke of approximately 1.3%. In contrast, patients with internal carotid stenosis greater than 75% have annual TIA risk of 7.2% and annual stroke risk of 3.3%. Patients with asymptomatic carotid stenosis have a relatively low rate of ipsilateral stroke, probably about 2% per year (Norris et al., 1991). Select patients with asymptomatic carotid stenosis may benefit from carotid endarterectomy. The Asymptomatic Carotid Atherosclerosis Study (ACAS) showed a benefit from endarterectomy in patients with a stenosis more than 60%, although the overall benefit was relatively small (Young et al., 1996). A low perioperative complication rate is crucial if endarterectomy is to offer asymptomatic patients a beneficial option. Carotid angioplasty and stenting are viable alternatives to carotid endarterectomy but are limited to patients at high risk for endarterectomy. When used with an embolus protection device, the safety and efficacy of carotid stenting have been established, and the noninferiority of carotid stenting compared with endarterectomy has been demonstrated. When medical management is elected, it should include control of hypertension, smoking cessation, education regarding the symptoms of TIA, efforts to identify and treat existing CAD, antiplatelet therapy, statin therapy, and serial carotid ultrasound studies to monitor the progression of carotid stenosis.

The management of symptomatic carotid artery stenosis—that is, cervical carotid stenosis associated with ipsilateral focal ischemic events—is less controversial. Clinical trials consistently demonstrate the benefits of carotid endarterectomy for patients with high-grade (70%) cervical carotid stenosis who are symptomatic. Conversely, symptomatic patients with mild (<50%) carotid stenosis do not benefit from surgery. Patients with moderate stenosis obtain a moderate benefit from surgery. These patients may be appropriately treated with surgery or medical therapy, depending on the clinical judgment of the treating physicians. Physicians should remember that women have a lower incidence of subsequent stroke than men with similar degrees of carotid stenosis. Women also have higher rates of perioperative complications than men.

Diabetes. Patients with diabetes who have strokes tend to be younger and have a higher incidence of intracerebral bleeding. Diabetes is an established risk factor for initial strokes, but there is no evidence that intensive control of hyperglycemia decreases the incidence of recurrent stroke. Usual glycemic control remains a reasonable endeavor.

Acute Intervention

When oxygen deprivation occurs, neuronal cellular death occurs within minutes. Thus, in nonperfused areas of the brain, necrosis begins within minutes. These areas of necrosis are typically surrounded by areas of decreased blood flow. This diminished blood flow may be barely enough to keep the neurons in these areas alive. Such areas of hypoperfusion are electrically silent and are referred to as the *ischemic penumbra*. If timely reperfusion of the ischemic penumbra occurs, these neurons can recover. However, failure to reperfuse the ischemic penumbra promptly results in time-related neuronal cell death and transformation of an area of hypoperfusion into an area of frank infarction. Resuscitation of the ischemic penumbra is therefore a primary goal of acute stroke management. Because of the time-related cellular death that occurs in areas of hypoperfusion, interventions aimed at reperfusing the ischemic penumbra must be instituted expeditiously if maximal benefit is to be realized.

Many agents and interventions have been under investigation for the treatment of acute stroke. Although therapeutic options for acute stroke management are expanding, *tissue plasminogen activator* (t-PA) is currently the only specific medication validated for this purpose by clinical trials and labeled for this use by the U.S. Food and Drug Administration (FDA). The National Institute of Neurologic Disorders and Stroke recommends t-PA for acute intervention in select stroke patients (NINDS, 1995). The t-PA trials showed substantial improvement in long-term functional outcome for patients treated with t-PA within 3 hours of ischemic stroke onset compared with the placebo group (NINDS t-PA Stroke Study Group, 1997). For every 100 patients given t-PA, 12 more experienced complete neurologic recovery than those receiving placebo. However, there was an approximately 6% increase in intracerebral hemorrhage in t-PA recipients. This risk of intracerebral hemorrhage increased significantly if computed tomography (CT) demonstrated early infarction changes. More recently, the European Cooperative Acute Stroke Study III has

Table 41-4 Criteria for Tissue Plasminogen Activator Use in Patients with Thromboembolic Stroke

Considering t-PA as a treatment option	Age \geq 18 years Noncontrast CT without evidence of hemorrhage Time since onset of symptoms clearly <3 hr (4.5 hr for select patients) before t-PA administration would begin
Excluding t-PA as a treatment option	HISTORICAL AND CLINICAL FINDINGS Clinical presentation suggests subarachnoid hemorrhage even if CT is normal: Sudden, severe headache, often with loss of consciousness at onset Vomiting common Active internal bleeding, increased risk of bleeding, or known bleeding diathesis, including: Recent use of warfarin with prolonged INR Use of heparin within 48 hr with prolonged aPTT Platelet count <100,000 cells/mm ³ History of intracranial hemorrhage Known arteriovenous malformation or aneurysm GI or GU bleeding in past 21 days Arterial puncture in past 7 days at noncompressible site Recent LP Stroke, intracranial surgery, or head trauma in previous 3 months Major surgery or serious trauma in preceding 14 days Persistent SBP >185 or DBP >110 mm Hg Seizure at stroke onset Rapidly improving neurologic signs Isolated, mild neurologic deficits Acute MI Post-MI pericarditis Blood glucose <50 mg/dL or >400 mg/dL Patient pregnant or lactating CT FINDINGS Evidence of intracranial hemorrhage Hypodensity or effacement of the sulci in one third of the region of the middle cerebral artery

aPTT, Activated partial thromboplastin time; CT, computed tomography; DPB, diastolic blood pressure; GI, gastrointestinal; GU, genitourinary; INR, international normalized ratio; LP, lumbar puncture; MI, myocardial infarction; SBP, systolic blood pressure; t-PA, tissue plasminogen activator (alteplase [Activase]).

demonstrated that the time window for administration of t-PA can be safely and effectively extended to 4.5 hours in select patients. Those older than 80 years, those with a history of stroke and diabetes, those taking oral anticoagulants, and those with NIH Stroke Scale score greater than 25 are excluded from this extended timeframe.

The administration of t-PA for the treatment of acute stroke requires strict adherence to established eligibility criteria, emergency CT capability with experienced interpretation, and 24-hour intensive care unit monitoring (Table 41-4). The limit from stroke onset to treatment with t-PA must be respected, whether the patient meets criteria for the 3-hour time window or the 4.5-hour time window. If a patient wakes from sleep with a neurologic deficit, the stroke must be assumed to have had its onset at the time sleep commenced. If the exact time of stroke onset is in question, t-PA should not be given. Patients and their families should understand that although treatment of acute ischemic stroke with t-PA is potentially beneficial, there is an approximately 1 in 15 chance of sustaining a serious cerebral hemorrhage even if t-PA is used in accordance with strict

guidelines. They should also understand that although patients with severe ischemic strokes have the most to gain from t-PA, they also have a higher risk of t-PA-associated intracerebral hemorrhage. Finally, the CT must not demonstrate intracranial bleeding if t-PA is to be given, and some experts recommend withholding t-PA if the CT demonstrates evidence of early infarction.

In some referral centers, intraarterial t-PA is also a treatment option. Such intervention extends the treatment window to 6 hours, principally because of the lower dose of t-PA administered and the ability to deliver the agent directly into the clot. Additionally, mechanical removal of intraarterial thrombus is also a treatment option using a variety of devices such as a corkscrew-like mechanism (Merci device), a suction mechanism (Penumbra device), or a self-expanding stent retriever (Solitaire or Trevo device) to extract the clot and thereby reestablish blood flow to the ischemic penumbra. Whereas small series of patients and individual centers have shown favorable results using such revascularization techniques, no large randomized clinical trials have demonstrated improved outcomes. Additional studies to determine appropriate patient selection for intraarterial revascularization are ongoing.

Pharmacologic Therapy

Published studies to date overwhelmingly support the ability of *aspirin* to reduce stroke incidence and death in patients who present with TIA or CVA. Aspirin and other agents that affect platelet function are frequently used for long-term secondary stroke prevention. It therefore seems reasonable, after hemorrhage has been excluded by CT, to begin aspirin therapy in the setting of acute stroke, provided the patient does not have a contraindication to aspirin therapy. Aspirin doses between 50 and 1300 mg/day have been shown to be effective for stroke prevention. In the absence of convincing evidence favoring a specific dosage, most clinicians prescribe 81 or 325 mg/day. The FDA recommends that aspirin doses of 50 to 325 mg/day be used for stroke prevention.

Clopidogrel (Plavix) inhibits platelet function by irreversibly binding to adenosine diphosphate receptors. Compared with aspirin, clopidogrel significantly decreases the constellation of stroke, myocardial infarction (MI), and vascular death and has a toxicity comparable with that of aspirin. Thrombotic thrombocytopenic purpura has been reported after the initiation of clopidogrel, often within the first 2 weeks of therapy (Bennett et al., 2000).

Dipyridamole (Persantine) was widely used in combination with aspirin in the early 1980s for the prevention of stroke until critical analysis cast doubt on its efficacy. A European study found high-dose sustained-release dipyridamole plus aspirin to be superior to aspirin alone for the prevention of stroke (Diener et al., 1996). The side effects of this therapy included headache and required discontinuation in approximately 6% of patients.

Selection of the appropriate antiplatelet agent for stroke prevention can become complicated, especially for patients with comorbid cardiovascular disease. Both extended-release dipyridamole plus aspirin (Aggrenox) and clopidogrel (Plavix) are reasonable first-line antiplatelet agents for secondary stroke prevention, shown to be more effective than aspirin alone. Randomized controlled trials (RCTs)

Table 41-5 Cardiac Conditions Substantially Associated with Embolism

Atrial fibrillation
Mitral stenosis
Mechanical cardiac valves
Recent myocardial infarction
Left ventricular thrombus, especially if mobile and protruding
Atrial myxoma
Infective endocarditis
Dilated cardiomyopathy
Marantic (nonbacterial thrombotic) endocarditis

have shown no additional benefit of the combination of clopidogrel and aspirin, which only increase the risk of hemorrhage.

The use of *heparin* therapy for the prevention of recurrent TIA or stroke progression is limited. Progression of stroke is common, occurring in 15% to 20% of carotid-distribution strokes and 35% to 40% of vertebrobasilar strokes. Even in patients with angiographically minimal or absent cerebral artery occlusion, clinical worsening of neurologic findings frequently occurs. Furthermore, heparin has not been shown in adequate clinical trials to improve clinical outcome among patients with stroke. The [International Stroke Trial Collaborative Group \(1997\)](#) reported that patients receiving subcutaneous (SC) heparin had fewer recurrent ischemic strokes, but this improvement was offset by an increase in hemorrhagic strokes. There was no net benefit. Trials with heparinoids have also failed to demonstrate a clear benefit and have shown an increased risk of non-CNS bleeding. Studies have also failed to demonstrate a clear benefit for low-molecular-weight heparin (LMWH).

Currently, *warfarin* (Coumadin) cannot be recommended as initial therapy for most patients with stroke of primarily cerebrovascular origin. In two large-scale RCTs of warfarin compared with aspirin in the prevention of recurrent stroke (SPIRIT, WARSS), warfarin was not superior to aspirin for patients without cardioembolic disease or operable carotid stenosis (Sacco et al., 2006). Furthermore, the hemorrhagic risk with warfarin was higher than with aspirin. In contrast to ischemic stroke, there is good evidence that warfarin is beneficial for patients with several major cardiac disorders predisposing them to embolic stroke. [Table 41-5](#) summarizes cardiac conditions that are substantially associated with cardioembolic stroke and often warrant prophylactic therapy with warfarin. Other cardiac conditions, such as mitral valve prolapse with or without myxomatous changes, severe mitral annular calcification, and calcific aortic stenosis, have a low or uncertain risk of embolism, and warfarin therapy is generally reserved for secondary prevention.

Management of Acute Stroke

Initial Management in Emergency Department.

Patients suspected of having sustained an acute stroke should be stabilized in accordance with usual emergency management, which focuses initially on basic cardiopulmonary resuscitation and support. All patients should have a thorough but timely physical examination, looking especially for head and neck trauma and cardiovascular abnormalities, followed by neurologic evaluation, including assessment of mental status, CN function, cerebellar

Table 41-6 Initial Treatment Considerations for Stroke Patients

Provide initial care.	Stabilize the patient, secure the airway, and provide adequate oxygenation. Assess level of consciousness, language, visual fields, eye movements, and pupillary movements. Obtain history and perform physical examination. Perform CT of head without contrast. Obtain CBC with platelets and differential, electrolytes, creatinine, BUN, glucose, PT/PTT, and oxygen saturation.
Consider toxicology screen.	Consider special coagulation studies such as antiphospholipid antibodies, factor V Leiden assay, protein C and protein S, antithrombin III, ANA, fibrinogen, RPR, homocysteine, serum protein electrophoresis, prothrombin gene 20210.
Consider acute intervention with t-PA.	
Consider the following with admission orders.	TEE Carotid duplex ultrasonography Cardiac telemetry Supplemental oxygen and appropriate oxygen saturation monitoring Antiplatelet therapy Fluid restriction if infarct is large to reduce cerebral edema Close monitoring of intake and output Regular determinations of blood glucose levels to avoid hyperglycemia NPO until there is certainty about the gag reflex pending swallowing evaluation Elevate head of bed 20 to 30 degrees to reduce cerebral edema Bed rest for first 24 hr with fall precautions; then advance as appropriate Vital signs and neurologic checks every 2 hr × 4; then every 4 hr for 24 hr Prophylaxis for DVT while immobile Speech therapy consultation to evaluate swallowing Neurology, physical therapy, occupational therapy, nutrition, and social services consultations

ANA, Antinuclear antibodies; BUN, blood urea nitrogen; CBC, complete blood count; CT, computed tomography; DVT, deep vein thrombosis; NPO, nothing by mouth; PT/PTT, prothrombin time/partial thromboplastin time; RPR, rapid plasma reagin; TEE, transesophageal echocardiography; t-PA, tissue plasminogen activator.

function, and motor and sensory function using the NIH Stroke Scale. Initial laboratory studies should generally include determination of a complete blood count (CBC) with differential and platelet count; prothrombin time and partial thromboplastin time (PT/PTT); electrolyte, blood urea nitrogen (BUN), creatinine, and glucose levels; oxygen saturation by pulse oximetry; and a metabolic panel. Depending on the clinical history, some patients should have studies for possible altered coagulation or connective tissue diseases. A CT scan of the head should be obtained expeditiously to evaluate for hemorrhage. Most patients should have additional studies, including electrocardiography (ECG), chest radiography, echocardiography, and carotid duplex ultrasonography. Consultation with neurology, speech therapy, physical therapy, occupational therapy, and social services should be considered (Table 41-6).

Elevated Blood Pressure. During the first day after an ischemic stroke, elevated BP should not be treated unless the SBP is consistently higher than 220 mm Hg or the DBP is consistently higher than 120 mm Hg. There are exceptions to this recommendation. Patients who have received t-PA should have BP maintained below 185/110 mm Hg, and patients with MI, heart failure, aortic dissection, or renal failure should have more aggressive BP control. Areas of cerebral ischemia lose their normal autoregulatory capacity, and tissue perfusion becomes directly linked to mean arterial pressure. When cerebral ischemia occurs, BP elevations are often transient, and spontaneous declines common. Overzealous BP treatment can therefore convert an area of ischemia that retains the potential for recovery into an area of frank infarction with no potential for recovery.

When antihypertensive agents are used shortly after stroke, one with rapid action and predictable response, such

Table 41-7 Antihypertensive Agents for Patients with Acute Stroke

Labetalol (Normodyne)	10 mg IV over 1 to 2 min; may repeat or double dosage every 10 to 20 min until BP is controlled or a maximum dose of 300 mg has been reached
Nicardipine (Cardene)	100 mg orally twice daily 5 mg/hr IV, titrated upward as necessary, typically to a maximum of 15 mg/hr
Sodium nitroprusside (Nipride)	0.3 µg/kg/min IV, titrated upward as necessary, typically to a maximum of 10 µg/kg/min

BP, Blood pressure; IV, intravenous.

as nicardipine (Cardene), labetalol (Normodyne), or sodium nitroprusside, should be chosen (Table 41-7). Nicardipine is currently considered the first-line treatment in this setting. Labetalol is preferable to sodium nitroprusside because of nitroprusside's ability to cause cerebral vasodilation, which can worsen cerebral edema in some patients. Sublingual calcium channel antagonists should be avoided because of their ability to cause precipitous BP declines, which could significantly reduce cerebral blood flow and result in further ischemic damage.

Cerebral Edema. Cerebral edema usually peaks within 2 to 4 days after a stroke. It is seldom a problem during the first 24 hours, except in cases of large cerebellar strokes. Steroids are not used to treat cerebral edema related to thromboembolic strokes. Steroids are generally ineffective and may exacerbate hyperglycemia and raise BP. Cerebral edema related to thromboembolic stroke is first treated by raising the head of the bed 20 to 30 degrees. Hyperventilation can work rapidly to reduce *intracranial pressure* (ICP) but has

only a transient effect. Mannitol can be given to lower ICP at 0.25 to 1 g/kg intravenously (IV) over 30 minutes, but its use is controversial because of possible pooling in the area of ischemia and potential worsening of edema. Mannitol can rapidly lower ICP and can be repeated every 6 hours. The maximum dose of mannitol is 2 g/kg IV. Hypertonic saline has also been used to reduce cerebral edema in this context. Hemicraniectomy with durotomy is performed for malignant middle cerebral artery-distribution infarct in select cases and has been shown to improve survival and functional outcome.

Other Management Issues. *Hypoxia* should be avoided. Any circumstance that is likely to impair oxygen delivery to the ischemic penumbra needs to be avoided. Patients with acute stroke should therefore have their oxygen saturation monitored and supplemental oxygen provided if desaturation occurs.

The use of SC heparin for the prevention of *deep vein thrombosis* (DVT) in nonhemorrhagic stroke patients has been well accepted. Heparin should be dosed based on weight. LMWH is a reasonable alternative in this setting. Intermittent pneumatic compression stockings are the best prophylactic alternative for patients unable to receive anticoagulants. Patients able to ambulate 50 feet daily are at low risk for venous thromboembolism.

Fever is seen quite often after an acute stroke. Regardless of cause, fever should be reduced because ischemic cerebral insults accompanied by even mild elevations in body temperature have been associated with less favorable outcomes in both experimental models and clinical studies.

Hyperglycemia can be harmful for the ischemic penumbra because it permits anaerobic metabolism, which results in local generation of lactic acidosis. Serum glucose levels should generally be maintained below 150 mg/dL. Nevertheless, it should be recognized that controlling blood glucose has not been shown to improve stroke outcome in humans.

Patients who have a *seizure* after a stroke have a higher mortality rate. Some believe that such patients should receive anticonvulsant therapy indefinitely, but others note that a trial off medication after several years without seizure activity seems reasonable.

DELERIUM

Key Points

- A confused older adult patient should generally be assumed to have delirium until proved otherwise.
- Delirium is a transient, global disorder of cognition and consciousness; changes in consciousness typically develop quickly and fluctuate during the day.
- Underlying dementia is a significant risk factor for delirium.
- The history, physical examination, and test results usually suggest a cause for delirium.
- Delirium is best managed by correction of the causative disturbances.
- Primary prevention of delirium is the most effective treatment strategy.

Table 41-8 Common Causes of Delirium

Vision impairment

Delirium is a common problem encountered in patients seen by family physicians, especially in hospitals and skilled nursing facilities. Delirium is characterized by a change in cognition and attention that develops rapidly, usually over hours to days, and fluctuates throughout the day. It may present as *hyperactive delirium*, with agitation, disorientation, and delusions; *hypoactive delirium*, demonstrated by a lethargic patient who is difficult to arouse and engage in conversation; or a mixed-type delirium with features of both. Hypoactive delirium is the most common encountered form of delirium, which may explain why it goes unrecognized in up to 70% of patients experiencing delirium (Gillis and MacDonald, 2006). Because of this, any confused older adult patient should generally be assumed to have delirium until proven otherwise. Delirium is a serious condition that has long-term ramifications, including increased hospital lengths of stay, increased mortality rates, failure to return to baseline cognitive and functional status, and increased need for prolonged, skilled nursing facility care. Table 41-8 summarizes risk factors for the development of delirium. Two thirds of delirium cases occur in patients with underlying dementia, placing these patients at significant risk when being treated for other health problems (Cole, 2004).

The mainstay of treatment for delirium is to identify and correct the underlying cause. This cause can usually be determined through a thorough history, physical examination, and evaluation of selected laboratory test results. Table 41-9 summarizes some of the common causes that should be considered. Special attention should focus on

recently started medications. Although almost any medication can precipitate delirium, analgesics, antiarrhythmics, antidepressants, Parkinson medications, anticholinergic medications such as antihistamines, benzodiazepines, β -blockers, calcium channel blockers, steroids, diuretics, clonidine, and digoxin are common culprits. A targeted laboratory evaluation should be undertaken, including a CBC, determination of electrolytes, BUN, creatinine, glucose, calcium, magnesium, phosphate, and liver function tests (LFTs). Oxygenation should be assessed by oximetry or arterial blood gases (ABGs). ECG should be considered, especially for patients with angina, dyspnea, or a cardiac history. Chest radiography and urinalysis to evaluate for occult infection, especially in older adult patients, should also be considered.

If this evaluation does not elicit a likely cause for a patient's delirium, further testing may be necessary. Additional laboratory studies to consider include thyroid function tests, human immunodeficiency virus (HIV) testing, rapid plasma reagin (RPR) test, drug levels, toxicology screening, serum ammonia level, and serum vitamin B₁₂ level. LP is usually reserved for patients with fever and signs suggesting meningitis. Neuroimaging may be indicated for patients with new neurologic signs or a history of head trauma. EEG may be helpful in the evaluation of patients with a suspected seizure disorder or to differentiate delirium from a functional psychiatric disorder.

Delirium can be treated with both nonpharmacologic and pharmacologic measures. Environmental modifications should be instituted early, before pharmacologic intervention or mechanical restraint is considered. A supportive and familiar environment should be created for the patient. Family members should be encouraged to remain nearby as much as possible. The staff should visit the patient frequently or move the patient to be near them. The room should be well illuminated, with a large, easily read clock and calendar. The family should bring familiar items from home to be placed in the patient's room. Whenever possible, normal sleep hygiene patterns should be maintained with minimal interruptions during the night hours.

Pharmacologic management of delirium should be considered when the previous treatments have failed to control agitation and should involve the use of antipsychotic medications. Among the antipsychotic agents, haloperidol (Haldol) at 1 to 2 mg orally every 4 hours as needed, or 0.25 to 0.5 mg orally every 4 hours for elderly patients, is recommended ([American Psychiatric Association, 1999](#)). Other antipsychotic medications, such as risperidone (Risperdal), 0.5 to 1 mg orally daily, and olanzapine (Zyprexa), 2.5 to 5 mg orally daily, may also be used; as yet, no RCTs have established the safety and effectiveness of one antipsychotic medication over another for the management of delirium symptoms ([Seitz et al., 2007](#)). Risperidone and olanzapine do not work as quickly as haloperidol, often require slow titration, and can be associated with significant orthostasis. Studies have also demonstrated a potentially elevated risk of death in older adults with dementia who were treated with atypical antipsychotics ([Schneider et al., 2005](#)). Therefore, these risks must be considered when initiating pharmacologic treatment for delirium. Further recommendations for initiating antipsychotics for the treatment of delirium include using the lowest possible doses, frequent

reassessments to limit the duration of antipsychotic use, and a baseline ECG to rule out susceptibility to an arrhythmia from a prolonged QT interval ([Seitz et al., 2007](#)). Lorazepam (Ativan), a benzodiazepine, has also been used for the treatment of agitation associated with delirium, although a Cochrane review concluded that benzodiazepines cannot be recommended for the treatment of non-alcohol-related delirium ([Loneragan et al., 2009](#)). Physical restraints should be a last resort, reserved for the protection of patients who do not adequately respond to environmental and pharmacologic interventions.

Studies have shown that a multicomponent approach to reduce risk factors is the most effective for the prevention of delirium. Intervention strategies should be targeted toward orientation and therapeutic activities for cognitive impairment, early mobilization to avert immobilization, interventions to prevent sleep deprivation, eyeglasses and hearing aids if needed, early intervention for dehydration, minimization of the use of psychoactive drugs, pain management, nutrition, bowel and bladder function, oxygen delivery to the brain, and appropriate environmental stimuli ([Inouye, 2006](#)).

DEMENTIA

Key Points

- Dementia is a gradual, progressive impairment of memory and other cognitive functions that is severe enough to impact work, social activities, or relationships.
- Dementia can be divided into four categories: Alzheimer disease (60% of cases), dementia with Lewy bodies (15%), vascular dementia (15%), and all other causes (10%).
- Comprehensive, longitudinal, well-coordinated care delivered by the family physician for both the patient and the caregiver is the cornerstone of effective management of patients with dementia.
- The cholinesterase inhibitors are effective in slowing the progression of cognitive and functional decline and may be used in conjunction with memantine (an N-methyl-D-aspartate [NMDA] receptor antagonist) to treat moderate to severe dementia.

Dementia is characterized by the development of an acquired impairment in memory associated with impairment in one or more cognitive domains, including executive function, language (expressive or receptive), *praxis* (learned motor sequences), or *gnosis* (ability to recognize objects, faces, or other sensory information). The impairments are severe enough to interfere with work, social activities, or relationships ([American Psychiatric Association, 1994](#)). The course is usually one of gradual, progressive decline and causes impairment in the ability to perform activities of daily living (ADLs). The incidence of dementia increases with age. By 75 years, 10% to 15% of people have dementia, increasing to 35% to 50% for those older than 85 years.

Classification and Pathophysiology

Dementia is usually divided into four main categories. Dementia of the Alzheimer type accounts for approximately

60% of cases; dementia with Lewy bodies, 15%; and vascular dementia, 15%. The remaining category includes multiple other forms, including mixed dementias that exhibit components of both Alzheimer and vascular dementia and dementias resulting from CNS trauma, Parkinson disease, Pick disease, Creutzfeldt-Jakob disease, and Huntington disease.

Patients with *Alzheimer disease* have brains that demonstrate atrophy with ventricular and sulcal enlargement. They reveal evidence of neuronal loss as well as the presence of amyloid plaques and neurofibrillary tangles. Amyloid plaques are composed of misfolded β -amyloid that initiates a pathogenic cascade, resulting in neurotoxicity and nerve cell death.

Dementia with Lewy bodies is similar to Alzheimer disease, but visual hallucinations and motor symptoms similar to parkinsonism develop early in the course of the disease. Histologically, Lewy bodies are present; these are cytoplasmic inclusions found in the temporal, parietal, and paralimbic regions of the brain.

Vascular dementia is usually subdivided into multi-infarct dementia and subcortical vascular dementia. *Multi-infarct dementia* should be suspected when focal, asymmetric neurologic abnormalities accompany dementia. Neuroimaging may show multiple strokes. *Subcortical vascular dementia* should be suspected if the patient manifests significant problems with gait early in the course of the dementia. CT and magnetic resonance imaging (MRI) scans are usually normal in these patients, except for increased signal in the deep white matter, a nonspecific sign.

Evaluation

The diagnosis of dementia is still made clinically, so the evaluation of a patient with suspected dementia begins with a complete history and physical examination. The history should include questions regarding the time frame surrounding symptom progression. The relation to any recent vascular events such as stroke should be noted. Risk factors for vascular disease (hypertension, diabetes, hyperlipidemia, atrial fibrillation, smoking history) should be reviewed. Changes in the ability to perform ADLs should also be addressed. The patient's ability to perform dressing, eating, ambulating, toileting, and bathing tasks should be recorded as independent, requiring assistance, or dependent. The physical examination should include a thorough neurologic examination for signs of underlying vascular disease and stroke. Cognitive testing should be done, ideally with the Mini-Mental State Examination, which allows for quantification of cognitive impairment over time (Table 41-10). A score less than 24 is considered abnormal, but because of educational bias, highly educated patients may have inflated scores and those with limited education artificially low scores (Tombaugh, 1992).

When considering which tests to perform as part of the evaluation of a patient with dementia, physicians have traditionally been taught to search for reversible causes of dementia. It is now recognized that reversible dementia rarely occurs (Sloane, 1998). Current recommendations for laboratory testing generally recommend that all patients be evaluated with a CBC, thyroid-stimulating hormone (TSH), serum calcium, electrolytes, and fasting glucose, as well as a serum B₁₂ level. Selective testing based on the presenting

Table 41-10 Mini-Mental Status Examination

Maximum Score*	Task
5	Orientation: year, season, date, day, and month
5	Orientation: state, county, town, building, and floor (as applicable)
3	Registration: Name three objects. Record the number of trials required to learn.
5	Attention and calculation: Serial 7 subtraction: Subtract from 100 by 7 (stop after 5 answers) or spell the word "world" backward (score number of correct letters in correct location).
3	Recall: Recall the three objects registered above.
2	Language: Name two objects (pencil and watch).
1	Repeat "No ifs, ands, or buts."
3	Follow a three-step command.
1	Read and obey: "Close your eyes" written in print large enough for patient to see clearly.
1	Write a sentence.
1	Copy a picture of intersecting pentagons.

*Total possible score: 30.

Modified from Folstein MF, Folstein SE, McHugh PR. Mini-Mental State: a practical method for grading the cognitive state of patients for the clinician. *J Psychiatr Res.* 1975;12:189.

medical history, physical examination, and cognitive testing may include a red blood cell (RBC) folate level, RPR for syphilis screening, and HIV antibodies. Testing for homocysteine levels and genetic testing for apolipoprotein E gene is not recommended (Feldman et al., 2008). Although neuroimaging is not recommended for all patients in the workup of dementia, selective use of CT or MRI is recommended for patients with suspected tumor, subdural hematoma, or normal-pressure hydrocephalus (NPH) (Feldman et al., 2008). ¹⁸F-florbetapir (Amyvid) was recently approved by the FDA for the detection of amyloid- β in the brain. Positive scans can be found in up to 30% of cognitively normal persons older than the age of 70 years. It is known that it can take up to 15 to 20 years for amyloid plaque density to increase to clinically apparent dementia. Thus, the majority of normal elderly persons with a positive scan are still normal in 5 to 10 years' time. The Society of Nuclear Medicine and Molecular Imaging and the Alzheimer's Association Joint Amyloid Imaging Task Force 2012 published appropriate use criteria to help guide cost-effective usage of this new modality (Rowe and Villemagne, 2013).

Management

Comprehensive, longitudinal, well-coordinated care delivered by the family physician for both the patient and the caregiver is the cornerstone of effective management of patients with dementia. Patients should be seen regularly in the office, and the physician should be readily available by telephone. The family should maintain frequent contact with the patient and physician. The family physician should update vaccinations, monitor visual acuity and hearing, and address other appropriate health issues. Families should be counseled regarding behavioral and environmental modifications that may be helpful, including reducing hazards in the home for falls and injuries. A discussion regarding the timing of cessation of driving should be undertaken early in the course of treatment. Decisions regarding advanced directives and planning for the later

stages of the disease should begin early in the process as well. The patient should legally designate a durable power of attorney for health care. The discussion of the placement of feeding tubes should begin before difficulties with feeding develop. Families should be aware that feeding tubes do not prolong life, are associated with discomfort and medical complications, and are generally not recommended for patients in the final stages of a dementing illness (Li, 2002). The role of palliative care and hospice care should also be discussed early in the course of the illness, when the patient has the opportunity to participate in the decision-making process.

Pharmacotherapy

The cholinesterase inhibitors donepezil (Aricept), galantamine (Razadyne), and rivastigmine (Exelon) have received FDA approval for the treatment of patients with Alzheimer disease. Tacrine (Cognex), which is associated with elevated liver transaminase levels in about 30% of patients, is rarely used. The cholinesterase inhibitors act by blocking acetylcholinesterase breakdown of acetylcholine, believed to increase acetylcholine in affected areas of the brain. All of these agents show comparable response rates, and choice is therefore individualized according to patient and caregiver needs as well as the drug's side effect profile. Pharmacologic effectiveness is measured by a slowing of the decline in cognitive and global functioning over 6 to 12 months. The cholinesterase inhibitors are generally well tolerated, although side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, weight loss, bradycardia, and agitation. When these medicines are discontinued, the patient may experience a rapid decline in global functioning.

Another medication, memantine (Namenda), an NMDA receptor antagonist, has been FDA approved for the treatment of moderate to severe dementia as monotherapy or in combination with a cholinesterase inhibitor (Reisberg et al., 2003). Memantine appears to have fewer side effects than the cholinesterase inhibitors, although dizziness, insomnia, and hallucination may be seen. Data for efficacy of alternative agents such as Ginkgo biloba, nicotine, vitamin C, and vitamin E for the treatment of Alzheimer disease has been mixed. A recent study found that long-term use of Ginkgo biloba failed to reduce the risk of progression to Alzheimer disease in elderly adults with memory complaints compared with placebo (Vellas et al., 2012). A Cochrane review in 2012 concluded that vitamin E should not be used for the treatment of mild cognitive impairment and Alzheimer disease. There is evidence that maintaining healthy vitamin C levels can have a protective function against age-related cognitive decline and Alzheimer disease, but maximal benefit is likely realized by avoiding vitamin C deficiency (Harrison, 2012). Because of the negative correlation between tobacco smoking and Alzheimer disease, there has been interest in nicotine as a potential therapeutic agent, but its use is limited because of toxicity and addictive properties. However, cotinine, the active metabolite of nicotine, has the benefits of nicotine and a much better safety profile, making it an ideal candidate for further study. At present, aside from avoiding vitamin C deficiency, no other prescribed medication, supplement, or herbal preparation can be recommended for the cognitive or functional manifestations of dementia.

SEIZURES

Key Points

- Febrile seizures usually occur between age 3 months and 5 years and represent the most common convulsive disorder of young children (2%-5%).
- Risk factors for a first febrile seizure include family history, developmental delays, high fever, and child care attendance.
- Initiation of treatment with anticonvulsant medication after a single seizure is not usually indicated if the initial workup is benign.
- Newer anticonvulsant medications tend to be better tolerated and have fewer adverse reactions than older, traditional medications and can be considered early in the course of treatment.

One in 11 Americans who lives to the age of 80 years experiences at least one seizure. About 1% of the U.S. population has epilepsy or recurrent unprovoked seizures. Treatment of patients with epilepsy reduces the risk of recurrent seizures while optimizing quality of life. This requires minimizing the adverse effects of antiepileptic medications and maximizing the patient's ability to engage in normal activities and responsibilities (Scheuer and Pedley, 1990).

Seizures are a manifestation of disturbed neurologic function and therefore are often associated with acute neurologic disorders such as meningitis. In some patients, the seizures are self-limited and resolve when an acute neurologic disturbance resolves. In others, the seizures persist and result in a diagnosis of epilepsy. Some patients who appear medically and neurologically normal after appropriate evaluation may experience a single seizure, and the cause is never determined. Such patients do not have epilepsy.

Seizures are typically classified as partial or generalized. Whereas *partial*, or *focal*, seizures arise in a portion of one cerebral hemisphere and are accompanied by focal EEG abnormalities, *generalized* seizures appear to involve simultaneously all or large parts of both cerebral hemispheres from their onset. Partial seizures are subclassified according to whether consciousness is preserved (simple partial seizures) or impaired (complex partial seizures). Generalized seizures are subclassified by their associated patterns of convulsive movements (Table 41-11).

It is not always possible to classify accurately a seizure based exclusively on clinical observations. A seizure with generalized convulsive activity may have a focal onset with rapid generalization. Such a seizure would best be classified as a partial seizure with secondary generalization rather than as a generalized tonic-clonic seizure. Accurate classification of such a seizure could not be accomplished, however, without EEG. Also, not every paroxysmal event that appears to be a seizure is actually a seizure. Movement disorders, psychological disorders, and sleep disorders can produce activity that is similar to seizure activity. Thus, accurate seizure diagnosis often requires both clinical observation and corroborative EEG. Because EEG is usually done in the absence of seizures, certain steps should be taken to increase its diagnostic yield. Both sleep and sleep deprivation increase the likelihood of recording

Table 41-11 Seizure Classification

Partial seizures	Simple (consciousness is preserved)
	Complex (consciousness is impaired)
	Secondarily generalized
	Simple partial seizures evolving to generalized tonic-clonic
	Complex partial seizures evolving to generalized tonic-clonic
Generalized seizures	Simple partial seizures evolving to complex partial, then to generalized tonic-clonic
	Tonic-clonic
	Absence
	Atypical absence
	Myoclonic
	Tonic
	Atonic

epileptiform abnormalities by EEG. Obtaining multiple recordings can also increase the diagnostic yield. In some cases, accurate diagnosis can be accomplished only with continuous video and EEG monitoring over several days during which the event of interest is recorded. Typically, this is accomplished in specialized epilepsy centers. A small number of patients with seizure disorders have normal interictal EEG recordings despite efforts made to record epileptiform abnormalities.

Febrile Seizures

Febrile seizures are seizures without a definite cause that are associated with fever. Febrile seizures, by definition, do not include seizures occurring in patients with an intracranial infection, such as meningitis or encephalitis, toxic encephalopathy, or any other neurologic illness. The definition also excludes seizures associated with fever that occur in patients who have a history of a previous nonfebrile seizure. Febrile seizures usually occur in children between the ages of 3 months and 5 years and represent the most common convulsive disorder of young children, affecting 2% to 5% of U.S. children. The most common age of onset is in the second year of life, and boys are affected slightly more often than girls (Freeman and Vining, 1995; Hirtz, 1997).

Risk factors for a first febrile seizure include a family history of febrile seizures, developmental delays, very high fever, and child care attendance. Approximately one third of children who experience a first febrile seizure will experience at least one more. The younger the child when the first febrile seizure occurs, the more likely the child is to have another febrile seizure. Most recurrences occur within 1 year. A family history of febrile seizures also increases the likelihood of recurrence. Fortunately, fewer than 5% of children who experience a febrile seizure develop epilepsy.

Febrile seizures can be of any type but are most often tonic-clonic. Febrile seizures are usually shorter than 6 minutes, and fewer than 8% last longer than 15 minutes. Most children therefore do not come to the attention of the family physician until after the seizure is over. Although it is commonly believed that the rate of fever increase is an important factor in the development of febrile seizures, no data support this as being more important than fever severity.

The evaluation of a child who has had a febrile seizure should begin with a careful history and physical examination. The history should include symptoms of infection, medication use, toxic ingestions, developmental and health problems, prenatal and birth history, family history, and detailed descriptions of the seizure by witnesses. The physical examination should pay particular attention to signs of severe illness, including petechiae, meningismus, tense or bulging fontanelle, Kernig and Brudzinski signs, and signs of neurologic abnormality (including decreased alertness or cognition and deficits of motor strength or tone). Even in children with a previous history of febrile seizures, a seizure associated with fever may be a sign of an intracranial infection. If intracranial infection is suspected, an LP should be performed. Otherwise, LP is not necessary. Children older than 18 months who have meningitis or encephalitis usually demonstrate typical clinical signs and symptoms. Many of these children lack histories, symptoms, or signs suggesting meningitis and thus do not require LP. However, children younger than 12 to 18 months may lack the typical clinical signs and symptoms of intracranial infection and are more likely to require LP. If a child is already taking antibiotics and experiences a seizure associated with fever, partially treated meningitis should be considered. The presence of a source of infection, such as otitis media, does not exclude the possibility of meningitis. Other features in the history that should also raise suspicion of meningitis in children with seizures and fever include evaluation for illness by a physician within the past 48 hours, a seizure that occurs in the office or emergency department (ED), or a focal seizure.

Most children with febrile seizures do not require routine laboratory testing. The only laboratory studies needed are those that will assist in evaluating the source of the child's fever. Radiography of the skull, neuroimaging studies such as CT and MRI, and EEG are not usually indicated. Children who are diagnosed with a febrile seizure should be observed in the ED or physician's office for several hours. These children may then be sent home, provided (1) they demonstrate satisfactory clinical improvement and are alert, (2) the fever has been appropriately evaluated and treated, and (3) close outpatient follow-up is possible. If there is any question about intracranial infection, if a child does not demonstrate expected clinical improvement during observation, or if follow-up cannot be ensured, hospital admission is recommended.

One of the most important components of outpatient management of children with febrile seizures is education of the parents. Seizures are frightening events for most parents. They should be reassured that febrile seizures do not result in brain damage and that the risk of epilepsy is very low. Slightly more than one in six children, however, experience another seizure within 24 hours, and about one in three experiences another febrile seizure at some point. If another seizure occurs, parents should be advised to place the child on his or her side or face down on the abdomen. Contrary to common belief, they should not attempt to place anything between the child's teeth during a seizure. The parents should carefully observe the child, and if the seizure does not spontaneously resolve after 10 minutes, they should call 9-1-1. Parents may have concerns about routine vaccinations for children with a history of febrile

seizures. The diphtheria and tetanus toxoids and acellular pertussis (DTaP) and measles, mumps, and rubella (MMR) vaccinations are most likely to produce fever associated with seizure. If a febrile seizure is going to occur after vaccination, it is most likely to occur within 48 hours of the DTaP vaccination or within 10 days of the MMR vaccination.

Initial Diagnostic Evaluation of a First Seizure in Adults

A careful history and physical examination, along with routine blood work, can detect many medical problems that may be associated with seizures. Such problems include infection, electrolyte and glucose abnormalities, impaired hepatic or renal function, and cardiopulmonary disease. Most patients with new-onset seizures should have a CBC with platelet count and differential; toxicology screen; thyroid function testing; PT/PTT; determination of serum transaminase, electrolytes, calcium, magnesium, phosphorus, BUN, creatinine, and glucose; ABGs; or pulse oximetry. If cardiopulmonary disease is suspected, ECG and chest radiographs should be obtained. Meningitis or encephalitis suspected clinically indicates LP, which is otherwise not necessary. Patients usually recover rapidly after a first seizure, and their clinical progress can be gauged after several hours of observation. Hospitalization is not usually necessary after a first seizure unless an underlying illness is suspected and injury has been sustained or there are concerns about the patient's clinical progress, inadequate social support or observation, or a lack of the patient's ability or motivation to complete outpatient follow-up.

Patients with new-onset seizures should be scheduled for appropriate EEG and neuroimaging studies. MRI and CT are important complements to EEG because of their ability to identify structural abnormalities that may be related to the development of seizures. MRI is preferable to CT because of its superior ability to identify cortical architectural abnormalities, visualize the temporal lobes, detect gliomas, and identify cavernous malformations. CT, however, is appropriate in the emergency setting because it is readily available and can detect hemorrhages acutely. If the patient is seen in the office shortly after a first seizure, neuroimaging does not need to be performed immediately unless the history and physical examination suggest focal brain injury or marked cognitive impairment. In contrast to MRI and CT, positron emission tomography and single-photon emission CT can provide functional views of the brain. These studies can identify areas of relative hypoperfusion or hypometabolism that appear to be structurally normal but might play an important role in the development of partial seizures. Although such studies can be useful, especially for patients with conditions such as localization-related epilepsy, they are not routinely obtained or widely available.

Pharmacologic Therapy

Whether antiepileptic drug therapy should be initiated after a first seizure remains a topic of debate. The data regarding the likelihood of recurrent seizures after a first seizure are wanting or questionable, and estimates of the rate of recurrence after a single unprovoked seizure range widely. Certain

findings and characteristics do seem to increase the likelihood of recurrence after a first seizure, including EEG abnormalities, previous neurologic injury, partial seizures, and a family history of seizures. Also, it is not known whether antiepileptic pharmacologic therapy after a single seizure alters the subsequent risk of epilepsy. Because of these uncertainties and because antiepileptic pharmacologic therapy is associated with a significant incidence of adverse effects, often exceeding the risk of recurrent seizures, many family physicians elect not to prescribe antiepileptic medications for most patients after a single seizure. Nonetheless, because of the unpredictable course of first-time seizures, patients should be cautioned against driving, according to local regulations, and engaging in other activities, which can present a danger should another seizure occur.

Although many agents are available for the treatment of seizures, carbamazepine (Tegretol), phenytoin (Dilantin), phenobarbital, and divalproex (Depakote) have been traditional first-line therapies for most patients with epilepsy. Increasing availability of newer agents to treat seizures has often resulted in more favorable side effect profiles. Phenobarbital is the oldest agent but has certain disadvantages. Its adverse effects include irritability, decreased cognition, and hyperactivity or lethargy. The degree of sedation and cognitive effects produced at therapeutic dosages are frequently significant enough that many family physicians do not prescribe phenobarbital as a first-line agent. The recommended dosage for common antiepileptics and adverse effects are summarized in [Table 41-12](#). Most patients with epilepsy can achieve remission with the use of a single medication. Because the addition of another antiepileptic agent is usually associated with an increase in adverse drug effects, patients not controlled with one agent should be given a trial of a different agent rather than combining agents early in the course of treatment. Treatment with more than one agent is usually attempted only after a number of trials of monotherapy have failed.

Family physicians should exercise caution when measuring levels of antiepileptic drugs. Therapeutic ranges for most antiepileptics are only guidelines for treatment. Some patients achieve therapeutic remission without significant side effects with drug concentrations ordinarily toxic. Other patients develop intolerable side effects with subtherapeutic serum levels. Serum levels of most antiepileptic drugs should generally be determined when remission of seizures is achieved or the patient develops significant side effects. Drug concentrations can also provide evidence of compliance. More frequent serum testing is necessary for patients taking more than one agent, pregnant women, older adults, patients with hepatic or renal dysfunction, and patients taking medications for other medical problems. [Table 41-13](#) lists drugs used to treat other medical conditions that can lower the seizure threshold. Nevertheless, serum levels should not be the primary basis for decisions regarding antiepileptic drug dosing. Seizure control and the development of adverse effects related to drug therapy are more important than serum levels alone.

Status Epilepticus

Status epilepticus is generally defined as more than 30 minutes of unconsciousness and continuous or

Table 41-12 Common Antiepileptic Agents

Agent	Usual Dosage	Adverse Effects
Carbamazepine (Tegretol)	Start: 200 mg twice daily (adults), 5 mg/kg/day (children) Maintenance: Increase by 200 mg/day weekly to max 1600 mg/day (adults), 20-35 mg/kg/day to max 1000 mg/day (children) Usually divided QID	Drowsiness or agitation, diplopia and blurred vision, disequilibrium, benign leukopenia, hepatic failure, rare SIADH, rare aplastic anemia
Phenytoin (Dilantin)	Oral loading dose: 400 mg, then 300 mg in 2 h and 4 h (adults) Maintenance: 300 mg/day (adults), 5 mg/kg/day to max 300 mg/day (children) Usually divided TID	Dose related: nausea and vomiting, nystagmus, ataxia Not dose related: gingival hyperplasia, hirsutism, acne, coarsening of features, hepatic failure, osteomalacia
Divalproex (Depakote)	Start: 10-15 mg/kg/day Maintenance: 15-60 mg/kg/day Usually divided BID-QID	Transient GI side effects Toxic effects: tremor, thrombocytopenia Side effects: weight increase, alopecia, hepatotoxicity (controversial whether LFTs detect in time to avoid), pancreatitis
Phenobarbital	Starting and maintenance: 100-300 mg/day (adults), 3-5 mg/kg/day (children) Usually given in single or divided doses	Lethargy, sedation, decreased cognition, decreased attention, hyperactivity, depression
Levetiracetam (Keppra)	Start: 1000 mg/day (adults), 20 mg/kg/day (children) Maintenance: maximum, 3000 mg/day (adults), 60 mg/kg/day (children) Usually divided BID	Depression, hostility, aggressive behavior, psychosis, somnolence, headache, URI symptoms, infection, fatigue, irritability
Oxcarbazepine (Trileptal)	Start: 600 mg/day (adults), 8-10 mg/kg/day (children) Maintenance: maximum, 2400 mg/day (adults), 45 mg/kg/day (children) Usually divided BID	Hyponatremia, hypersensitivity reaction, leukopenia, thrombocytopenia, angioedema, Stevens-Johnson syndrome, dizziness, somnolence, diplopia, headache, nausea, ataxia
Lamotrigine (Lamictal)	Start: dosing varies with concomitant antiepileptics Maintenance: maximum, 400 mg/day Usually divided BID	Rash, Stevens-Johnson syndrome, angioedema, neutropenia, pancreatitis, dizziness, headache, ataxia, nausea, somnolence
Tiagabine (Gabitril)	Start: 4 mg/day (adults and children >12 yr) Maintenance: maximum, 56 mg/day (adults), 32 mg/day (children) Usually divided BID-QID	CNS depression, seizures, weakness, rash, dizziness, asthenia, somnolence, nausea, diarrhea, tremor, confusion, impaired concentration
Gabapentin (Neurontin)	Start: 300 mg/day (adults), 10-15 mg/kg/day (children) Maintenance: up to 3600 mg/day (adults), 35 mg/kg/day (children) Usually divided TID	Leukopenia, depression, dizziness, somnolence, ataxia, fatigue, peripheral edema, weight gain, tremor, diarrhea
Topiramate (Topamax)	Start: 25 mg BID (adults, children >10 yr) Maintenance: up to 200 mg/day Usually divided BID	Nephrolithiasis, paresthesias, anorexia, ataxia, cognitive dysfunction
Zonisamide (Zonegran)	Start: 100 mg/day for 2 weeks (adults) Maintenance: up to 600 mg/day Usually divided BID	Nephrolithiasis, somnolence, anorexia, cognitive dysfunction
Pregabalin (Lyrica)	Start: 150 mg/day (adults) Maintenance: up to 600 mg/day Usually divided BID-TID	Thrombocytopenia, hypersensitivity reaction, angioedema, dizziness, somnolence, ataxia, peripheral edema, weight gain
Lacosamide (Vimpat)	Start: 100 mg/day (adults) Maintenance: up to 600 mg/day (300 mg/day in mild-mod hepatic failure or CrCl <30 mL/min) Divided BID	Syncope, atrial fibrillation (rare), dizziness, headache, diplopia, vomiting, fatigue, ataxia
Ezogabine (Potiga)	Start: 300 mg/day Maintenance: up to 1200 mg Divided TID	Psychosis, dependency, dizziness, somnolence, fatigue, cognitive dysfunction, weight gain
Rufinamide (Banzel)	Start: (Lennox-Gastaut) 400-800 mg/day (adults), 10 mg/kg/day (children) Maintenance: up to 3200 mg/day (adults and children) Usually divided BID	Suicidality, seizures, QT shortening, hypersensitivity reaction, leukopenia, somnolence, vomiting, headache, dizziness, nausea
Clobazam (Onfi)	Start: (Lennox-Gastaut) 10 mg/day (weight >30 kg) Maintenance: 40 mg/day Divided BID	Respiratory depression, dependency, suicidality, Stevens-Johnson syndrome, anemia, somnolence
Vigabatrin (Sabril)	Start: (infantile spasms) 40 mg/kg/day (children) Maintenance: up to 100-150 mg/kg/day Usually divided BID	(Restricted in United States) Permanent vision loss, anemia, neuropathy, headache, dizziness, fatigue, somnolence, weight gain

BID, Twice a day; CNS, central nervous system; CrCl, creatinine clearance; LFT, liver function test; QID, four times a day; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; TID, three times a day; URI, upper respiratory infection.

Table 41-13 Drugs That Can Lower Seizure Threshold

intermittent, generalized seizure activity. However, because most seizures last 2 minutes or less, any seizure longer than 5 minutes may progress to status epilepticus. Patients with recurrent seizures without recovery to wakefulness should also be considered to be in status epilepticus. Status epilepticus can be alarming to observe, even for experienced clinicians. A systematic approach to patients in status epilepticus can facilitate optimal patient care during such an episode. The first step in the management of patients with status epilepticus is to support vital functions. The airway should be protected. Although the patient should be intubated if necessary, this usually requires neuromuscular blockade, and bag and mask ventilation is often preferable. The patient's vital signs should be closely monitored, including continuous oximetry and ECG. Supplemental oxygen at a rate of about 4 L/min is recommended. IV access should be secured for the administration of parenteral medications and blood drawn for a CBC; toxicology screen; and determination of electrolyte, glucose, calcium, magnesium, and anticonvulsant drug levels. The patient should receive thiamine, 100 mg IV, followed by 50 mL of dextrose 50% with water.

If the patient continues to seize, parenteral agents may be given, including lorazepam, 0.1 mg/kg IV at 2 mg/min, or diazepam, 0.2 mg/kg (maximum, 10 mg) at a maximum rate of 5 mg/min. These agents have a relatively rapid onset and short duration of action. Simultaneous loading with phenytoin is therefore recommended. Phenytoin is loaded at 20 mg/kg IV at a rate of less than 50 mg/min through a line infusing glucose-free saline to avoid precipitation of phenytoin in the line. Fosphenytoin (Cerebyx) is the prodrug of phenytoin and has a more favorable safety profile than phenytoin, can be given at a faster rate (150 mg/min), and converts to phenytoin after first-pass metabolism, but it is more costly than phenytoin. BP and cardiac rhythm must be closely observed because of the ability of phenytoin to precipitate hypotension and heart block. If these side effects appear, they often resolve when the rate of administration is decreased. If seizures continue despite these measures, phenobarbital may be administered parenterally. As a last resort, barbiturate coma or general anesthesia can be instituted. Propofol (Diprivan) and midazolam (Versed) administered as continuous IV drips are often used in neurocritical care settings to induce coma for status epilepticus.

CENTRAL NERVOUS SYSTEM INFECTION AND INFLAMMATION

Key Points

- Bacterial meningitis is a neurologic emergency.
- Acute bacterial meningitis has high morbidity and mortality rates.
- Antibiotic therapy should be started as soon as possible after meningitis is considered likely, usually by cerebrospinal fluid (CSF) analysis.
- Knowing the most prevalent organisms that cause bacterial meningitis in different age groups is important in guiding therapy.
- Gram stain of CSF is recommended for all patients with suspected bacterial meningitis.
- Adjunctive dexamethasone therapy for infants, children, and adults who have already received antibiotics is not recommended.

Bacterial Meningitis

Acute bacterial meningitis has high morbidity and mortality rates even under the best circumstances. For this reason, prompt recognition of the clinical syndrome, performance of appropriate testing to confirm the diagnosis, and initiation of appropriate therapy are essential.

Most adult patients (85%) present with the classic triad of fever, headache, and neck stiffness (Roos et al., 1997). Other symptoms include nausea and vomiting (35%), seizures (30%), CN palsies, and other focal neurologic signs (10%-20%). Meningismus (50%) may be subtle or marked, as with Kernig sign (resistance to knee extension after flexion of hip and knees by examiner) or Brudzinski sign (involuntary flexion of knees in supine patient in response to rapid neck flexion by examiner) (Tunkel and Scheld, 1997). Other symptoms include nuchal rigidity, lethargy, photophobia, confusion, sweats, and rigors. Papilledema occurs in fewer than 1% of patients during the early phases of the disease. When papilledema is present early, an alternative diagnosis such as a brain abscess or mass lesion should be sought.

Not all patients present with the classic signs and symptoms. Neonates may present with poor feeding or weak sucking response, irritability, vomiting, temperature instability (hyperthermia or hypothermia), diarrhea, and apnea. Nuchal rigidity and meningismus are not reliable signs in children younger than 1 year (Prober, 1996). A bulging fontanelle may occur late in the disease, and seizures occur in 40% of neonates. A maculopapular rash that later becomes petechial and purpuric on the extremities should suggest meningococcal meningitis. Older adult patients may have a more insidious presentation, with variable meningeal signs, change in mental status, lethargy, obtundation, and no fever.

The host is an important determinant of susceptibility to meningitis. Obvious risk factors include a history of recent open trauma, surgery (especially neurosurgery), and burns. Closed-head trauma can cause CSF leaks, which have been associated with pneumococcal meningitis. Common predisposing factors include otitis media (most common);

Table 41-14 Common Pathogens of Bacterial Meningitis Based on Age

Age	Pathogens
0-1 mo	Group B streptococci, <i>Listeria monocytogenes</i> , <i>Streptococcus pneumoniae</i> , <i>Escherichia coli</i>
1-3 mo	Group B streptococci, <i>L. monocytogenes</i> , <i>S. pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i> , <i>E. coli</i>
3 mo-18 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>H. influenzae</i>
18-50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>H. influenzae</i>
>50 yr	<i>S. pneumoniae</i> , <i>L. monocytogenes</i> , gram-negative bacilli

sinusitis; mastoiditis; alcoholism; perinatal exposure; and nonimmunized, immunocompromised, or asplenic status (Swartz, 1997).

Knowing the most prevalent organisms that cause bacterial meningitis in the various age groups is important in guiding empiric therapeutic choices (Table 41-14). The three most common pathogens for community-acquired bacterial meningitis are *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae*, accounting for about 80% of cases in the United States. Until the development of the *H. influenzae* type b (Hib) vaccine in the early 1990s, this was the most common bacterial meningitis, occurring in almost 50% of cases. As a result, *S. pneumoniae* and *N. meningitidis* have become relatively more common, especially in the pediatric population. *Escherichia coli* has been superseded by group B streptococci as the most common cause in infants during the first months of life. Other common pathogens include *Listeria monocytogenes*, *Klebsiella pneumoniae*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, other gram-negative bacilli, and other streptococci.

Initial Management. The Infectious Disease Society of America (IDSA) practice guidelines call for prompt blood cultures and LP for most patients with suspected acute bacterial meningitis (Tunkel et al., 2004). Nevertheless, emergency LP may not be successful or prudent because of overriding concerns about a CNS mass lesion or other cause of increased ICP, necessitating CT before LP. In these patients, blood samples should be drawn and appropriate antibiotic and adjunctive therapy provided before LP or CT (Table 41-15).

The LP is the foundation of the diagnosis of bacterial meningitis. In adults, opening pressure is typically 80 to 210 mm H₂O, although lower values may be observed in infants and children. Table 41-16 illustrates typical CSF findings. Gram stain is recommended for all patients because it permits rapid organism identification in 60% to 90% of patients with community-acquired bacterial meningitis, with a specificity of more than 97% (Tunkel et al., 2004). Other rapid diagnostic tests, such as latex agglutination, and limulus lysate assay have not shown clinical usefulness in diagnosis or management of bacterial meningitis. Polymerase chain reaction (PCR) assay to amplify DNA may be helpful, particularly for patients with negative Gram stains. The serum C-reactive protein (CRP) concentration may be particularly helpful for patients with findings consistent with meningitis but for whom the Gram stain is

Table 41-15 Criteria for Adult Patients with Suspected Bacterial Meningitis Recommended for Computed Tomography before Lumbar Puncture

Criterion	Comment
Immunocompromised state	HIV infection or AIDS, receiving immunosuppressive therapy, or after transplantation
History of CNS disease	Mass lesion, stroke, or focal infection
New-onset seizure	Within 1 week of presentation; some authorities would not perform LP on patients with prolonged seizures or would delay LP for 30 minutes in patients with short, convulsive seizures
Papilledema	Presence of venous pulsations suggests absence of increased ICP
Abnormal level of consciousness	—
Focal neurologic deficit	Includes dilated nonreactive pupil, abnormalities of ocular motility, abnormal visual fields, gaze palsy, arm or leg drift

AIDS, Acquired immunodeficiency syndrome; CNS, central nervous system; CT, computed tomography; LP, lumbar puncture; HIV, human immunodeficiency virus; ICP, intracranial pressure.

From Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 2004;39:1267.

Table 41-16 Typical Cerebrospinal Fluid Findings in Bacterial and Viral Meningitides

Parameter	Bacterial Meningitis	Viral Meningitis
Opening pressure (mm H ₂ O)	>180	Often normal or significantly elevated
Leukocyte count (cells/mm ³)	1000-10,000 Median: 1195 Range: 100-20,000	<300 Median: 100 Range: 100-1000
Neutrophils (%)	>80	<20
Glucose (mg/dL)	<40	>40
Protein (mg/dL)	100-500	Often normal
Gram stain (% positive)	60-90	Negative
Culture (% positive)	70-85	50

negative and withholding antibiotics is being contemplated because a normal CRP result has a high negative predictive value (Tunkel et al., 2004).

Additional laboratory studies include CBC, platelet count, PT, PTT, and ABGs, as well as determination of electrolyte, protein, glucose, BUN, and creatinine levels. Further laboratory workup and imaging studies (chest radiography, sinus series, skull radiography) may be indicated, depending on the clinical setting.

Bacterial meningitis is a neurologic emergency. Accordingly, if the diagnosis is considered likely, antibiotic therapy should be started as soon as possible, usually immediately after the LP has been performed or as soon as blood cultures have been obtained if a CT of the head is warranted. Antibiotic therapy is generally targeted by the results of the Gram stain (Table 41-17) or may be chosen empirically based on age and predisposing conditions (Table 41-18). Table 41-19 outlines recommendations for specific

Table 41-17 Antimicrobial Therapy in Adult Patients with Presumptive Pathogen Identification by Positive Gram Stain Results

Microorganism	Recommended Therapy	Alternative Therapies
<i>Streptococcus pneumoniae</i>	Vancomycin plus third-generation cephalosporin*†	Meropenem (C), fluoroquinolone‡ (B)
<i>Neisseria meningitidis</i>	Third-generation cephalosporin*	Penicillin G, ampicillin, chloramphenicol, fluoroquinolone, aztreonam
<i>Listeria monocytogenes</i>	Ampicillin [§] or penicillin G [§]	TMP-SMP, meropenem (B)
<i>Streptococcus agalactiae</i>	Ampicillin [§] or penicillin G [§]	Third-generation cephalosporin* (B)
<i>Haemophilus influenzae</i>	Third-generation cephalosporin*	Chloramphenicol, cefepime, meropenem, fluoroquinolone
<i>Escherichia coli</i>	Third-generation cephalosporin*	Cefepime, meropenem, aztreonam, fluoroquinolone, TMP-SMP

*Ceftriaxone or cefotaxime.

†Some experts would add rifampin if dexamethasone is also given (B).

‡Gatifloxacin or moxifloxacin.

§Addition of an aminoglycoside should be considered.

Note: All recommendations are (A) unless otherwise indicated. In children, ampicillin is added to the standard therapeutic regimen of cefotaxime or ceftriaxone plus vancomycin when *L. monocytogenes* is considered and to an aminoglycoside if a gram-negative enteric pathogen is of concern.

TMP-SMP, trimethoprim-sulfamethoxazole.

Modified from Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 39;1267, 2004.

Table 41-18 Empiric Antimicrobial Therapy for Purulent Meningitis Based on Patient Age and Specific Predisposing Condition (A)

Predisposing Factor	Common Bacterial Pathogens	Antimicrobial Therapy
AGE		
<1 mo	<i>Streptococcus agalactiae</i> , <i>Escherichia coli</i> , <i>Listeria monocytogenes</i> , <i>Klebsiella</i> spp.	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside
1-23 mo	<i>Streptococcus pneumoniae</i> , <i>Neisseria meningitidis</i> , <i>S. agalactiae</i> , <i>Haemophilus influenzae</i> , <i>E. coli</i>	Vancomycin plus third-generation cephalosporin*†
2-50 yr	<i>N. meningitidis</i> , <i>S. pneumoniae</i>	Vancomycin plus third-generation cephalosporin*†
>50 yr	<i>S. pneumoniae</i> , <i>N. meningitidis</i> , <i>L. monocytogenes</i> , aerobic gram-negative bacilli	Vancomycin plus ampicillin plus third-generation cephalosporin*†
HEAD TRAUMA		
Basilar skull fracture	<i>S. pneumoniae</i> , <i>H. influenzae</i> , group A β -hemolytic streptococci	Vancomycin plus third-generation cephalosporin*
Penetrating trauma	<i>Staphylococcus aureus</i> , coagulase-negative staphylococci (especially <i>Staphylococcus epidermidis</i>), aerobic gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>)	Vancomycin plus cefepime, vancomycin plus ceftazidime, or vancomycin plus meropenem
Postneurosurgery	Aerobic gram-negative bacilli (including <i>P. aeruginosa</i>), <i>S. aureus</i> , coagulase-negative staphylococci (especially <i>S. epidermidis</i>)	Vancomycin plus cefepime, vancomycin plus meropenem
CSF shunt	Coagulase-negative staphylococci (especially <i>S. epidermidis</i>), <i>S. aureus</i> , aerobic gram-negative bacilli (including <i>P. aeruginosa</i>), <i>Propionibacterium acnes</i>	Vancomycin plus cefepime,† vancomycin plus ceftazidime,‡ or vancomycin plus meropenem‡

*Ceftriaxone or cefotaxime.

†Some experts would add rifampin if dexamethasone is also given.

‡In infants and children, vancomycin alone is reasonable unless Gram stain reveals gram-negative bacilli.

CSF, Cerebrospinal fluid.

Modified from Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 2004;39;1267.

antimicrobial therapy based on isolates and susceptibility, and [Table 41-20](#) recommends doses.

Role of Corticosteroids. The theoretic goal of using corticosteroids in bacterial meningitis is to minimize meningeal inflammation, thereby decreasing the severity and incidence of brain injury. However, the IDSA recommends adjunctive dexamethasone therapy in certain patients based on age.

NEONATES. There are currently insufficient data to make recommendations involving newborns ([Tunkel et al., 2004](#)).

INFANTS AND CHILDREN. Available evidence supports the use of adjunctive dexamethasone in infants and children with Hib meningitis initiated 10 to 20 minutes before (or at least concomitant with) the first doses of antibiotic at a dose

of 0.15 mg/kg every 6 hours for 2 to 4 days. However, adjunctive dexamethasone should not be given to infants and children who have already received antimicrobial therapy because it is unlikely to improve patient outcome ([Tunkel et al., 2004](#)). Adjunctive dexamethasone in infants and children with pneumococcal meningitis is controversial. On the use of steroids for pneumococcal meningitis, the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP) stated, "For infants and children 6 weeks of age and older, adjunctive therapy with dexamethasone may be considered after weighing the potential benefits and possible risks. Experts vary in recommending the use of corticosteroids in pneumococcal meningitis; data are not sufficient to demonstrate clear benefit in children" ([AAP, 2003](#)). Also, data support adjunctive corticosteroids in children from high-income countries but

Table 41-19 Specific Antimicrobial Therapy in Bacterial Meningitis Based on Isolated Pathogen and Susceptibility Testing

Microorganism, Susceptibility	Standard Therapy	Alternative Therapies
STREPTOCOCCUS PNEUMONIAE		
Penicillin MIC <0.1 µg/mL	Penicillin G or ampicillin	Third-generation cephalosporin,* chloramphenicol
0.1-1.0 µg/mL [†]	Third-generation cephalosporin*	Cefepime (B), meropenem (B)

Ampicillin susceptible	Ampicillin plus gentamicin	—
Ampicillin resistant	Vancomycin plus gentamicin	—
Ampicillin and vancomycin resistant	Linezolid (B)	

*Ceftriaxone or cefotaxime.

[†]Ceftriaxone- or cefotaxime-susceptible isolates.[‡]Consider addition of rifampin if the MIC of ceftriaxone is >2 µg/mL.[§]Addition of an aminoglycoside should be considered.[¶]Consider addition of rifampin.^{||}Choice of a specific antimicrobial agent must be guided by in vitro susceptibility test results.

Note: All recommendations are (A) unless otherwise indicated.

MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

Modified from Tunkel AR, Barry J, Hartman SL, et al. Practice guidelines for the management of bacterial meningitis. *Clin Infect Dis*. 2004;39:1267.

show no beneficial effect for children in low-income countries (Cochrane review; van de Beek et al., 2007).

ADULTS. Adjunctive dexamethasone, 0.15 mg/kg every 6 hours for 2 to 4 days, with the first dose administered 10 to 20 minutes before (or at least concomitant with) the first dose of antibiotic, should be initiated in all adult patients with suspected or proven pneumococcal meningitis. Although data are insufficient to make this recommendation for other bacterial pathogens, many experts initiate dexamethasone in all adults because the cause of meningitis is not always ascertained at the initial evaluation. As in children, dexamethasone should not be given to adult patients who have already received antibiotics (Tunkel et al., 2004).

Dexamethasone should only be continued if the CSF stain reveals gram-positive diplococci or if the blood or CSF cultures are positive for *S. pneumoniae*.

ANTIMICROBIAL THERAPY. Prompt and accurate treatment of meningitis is essential to increase survival and reduce morbidity. Treatment recommendations for a known pathogen of community-acquired bacterial meningitis and for selected clinical settings are listed in Tables 41-21 and

41-22. Duration of therapy is based more on tradition than on clinical evidence and varies depending on the pathogen. Repeat LP for CSF analysis of response to therapy is not necessary for most patients who demonstrate clinical improvement within 24 to 48 hours. Patients who do not demonstrate significant clinical improvement and show high resistance on culture and sensitivity, as well as neonates with meningitis caused by gram-negative bacilli, should undergo repeat LP (Tunkel et al., 2004).

Prophylaxis and Prevention. Prophylaxis is indicated for any close contacts of persons with documented meningococcal meningitis or Hib meningitis. For meningococcal meningitis, adults should receive 600 mg of rifampin orally twice daily for 2 days; children older than 1 month should receive 10 mg/kg (up to 600 mg) every 12 hours orally for 2 days (5 mg/kg every 12 hours if younger than 1 month). Rifampin is not recommended for pregnant women, and the reliability of oral contraceptives may be affected by rifampin therapy. An alternative to rifampin is ceftriaxone intramuscularly as a single dose, 125 mg for those 15 years and younger and 250 mg for those older than 15 years.

Table 41-20 Recommended Dosages of Antimicrobial Therapy in Patients with Bacterial Meningitis (A)

Antimicrobial Agent	Total Daily Dose (dosing interval in hr)			
	Neonates (age in days)		Infants and Children	Adults
	0-7*	8-28*		
Amikacin	15-20 mg/kg (12)	30 mg/kg (8)	20-30 mg/kg (8)	15 mg/kg (8)
Ampicillin	150 mg/kg (8)	200 mg/kg (6-8)	300 mg/kg (6)	12 g (4)
Aztreonam	—	—	—	6-8 g (6-8)
Cefepime	—	—	150 mg/kg (8)	6 g (8)
Cefotaxime	100-150 mg/kg (8-12)	150-200 mg/kg (6-8)	225-300 mg/kg (6-8)	8-12g (4-6)
Ceftazidime	100-150 mg/kg (8-12)	150 mg/kg (8)	150 mg/kg (8)	6 g (8)
Ceftriaxone	—	—	80-100 mg/kg (12-24)	4 g (12-24)
Chloramphenicol	25 mg/kg (24)	50 mg/kg (12-24)	75-100 mg/kg (6)	4-6 g (6) [‡]
Ciprofloxacin	—	—	—	800-1200 mg (8-12)
Gatifloxacin	—	—	—	400 mg (24) [§]
Gentamicin [†]	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5 mg/kg (8)
Meropenem	—	—	120 mg/kg (8)	6 g (8)
Moxifloxacin	—	—	—	400 mg (24) [§]
Nafcillin	75 mg/kg (8-12)	100-150 mg/kg (6-8)	200 mg/kg (6)	9-12 g (4)
Oxacillin	75 mg/kg (8-12)	150-200 mg/kg (6-8)	200 mg/kg (6)	9-12 g (4)
Penicillin G	0.15 MU/kg (8-12)	0.2 MU/kg (6-8)	0.3 MU/kg (4-6)	24 MU (4)
Rifampin	—	10-20 mg/kg (12)	10-20 mg/kg (12-24)	600 mg (24)
Tobramycin [†]	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5 mg/kg (8)
TMP-SMX [§]	—	—	10-20 mg/kg (6-12)	10-20 mg/kg (6-12)
Vancomycin ^{**}	20-30 mg/kg (8-12)	30-45 mg/kg (6-8)	60 mg/kg (6)	30-45 mg/kg (8-12)

*Smaller doses and longer intervals of administration may be advisable for very-low-birth-weight neonates (<2000 g).

[†]Need to monitor peak and trough serum concentrations.

[‡]Higher dose recommended for patients with pneumococcal meningitis.

[§]No data on optimal dosage are needed in patients with bacterial meningitis.

^{||}Maximum daily dose of 600 mg.

**Maintain serum trough concentrations of 15 to 20 µg/mL.

MU, Million units; TMP-SMX, trimethoprim-sulfamethoxazole.

Dosage based on trimethoprim component.

Table 41-21 Specific Antibiotic Treatments for Known Pathogens

Pathogen	Primary Therapy	Alternative*
Group B streptococci	Penicillin G or ampicillin	Vancomycin or third-generation cephalosporin [†]
<i>Streptococcus pneumoniae</i> (MIC <0.1)	Third-generation cephalosporin [†]	Meropenem penicillin
<i>S. pneumoniae</i> (MIC >0.1)	Vancomycin plus third-generation cephalosporin*	Substitute rifampin for vancomycin; or meropenem; or vancomycin as monotherapy if highly allergic to other alternatives
<i>Haemophilus influenzae</i> (β-lactamase negative)	Ampicillin	Third-generation cephalosporin [†] or chloramphenicol or aztreonam
<i>H. influenzae</i> (β-lactamase positive)	Third-generation cephalosporin [†]	Chloramphenicol or aztreonam or fluoroquinolones [‡]
<i>Listeria monocytogenes</i>	Ampicillin plus gentamicin	TMP-SMX
<i>Neisseria meningitidis</i>	Penicillin G or ampicillin	Third-generation cephalosporin [†]
Enterobacteriaceae	Third-generation cephalosporin [†] plus aminoglycoside	TMP-SMX or aztreonam or fluoroquinolones or antipseudomonal penicillin [§] (or ampicillin) plus aminoglycoside
<i>Pseudomonas aeruginosa</i>	Ceftazidime plus aminoglycoside	Aminoglycoside plus aztreonam or aminoglycoside plus antipseudomonal penicillin [§]
<i>Staphylococcus aureus</i> (methicillin sensitive)	Antistaphylococcal penicillin ± rifampin	Vancomycin plus rifampin or TMP-SMX plus rifampin
<i>S. aureus</i> (methicillin resistant)	Vancomycin plus rifampin	
<i>Staphylococcus epidermidis</i>	Vancomycin plus rifampin	

*If patient is highly allergic or intolerant of primary therapy.

[†]Ceftriaxone or cefotaxime.

[‡]Ciprofloxacin or levofloxacin.

[§]Piperacillin, mezlocillin, or ticarcillin.

^{||}Nafcillin, oxacillin, or methicillin.

MIC, Minimum inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

Table 41-22 Common Pathogens of Bacterial Meningitis and Empiric Treatment Based on Age

Age	Common Pathogens	Treatment*	Duration (days)
0-1 mo	Group B streptococci	Ampicillin <i>plus</i> third-generation cephalosporin [†]	14-21
	<i>Listeria monocytogenes</i>	or ampicillin <i>plus</i> aminoglycoside	14-21
	<i>Escherichia coli</i>		21
	<i>Streptococcus pneumoniae</i>		10-14
1-3 mo	Group B streptococci, <i>E. coli</i> , <i>L. monocytogenes</i>	Ampicillin <i>plus</i> third-generation cephalosporin [†]	14-21
	<i>S. pneumoniae</i>		10-14
	<i>Neisseria meningitidis</i> , <i>Haemophilus influenzae</i>		7-10
3 mo-18 yr	<i>H. influenzae</i> , <i>N. meningitidis</i>	Third-generation cephalosporin [†] or meropenem	7-10
	<i>S. pneumoniae</i>	or chloramphenicol	10-14
18-50 yr	<i>H. influenzae</i> , <i>N. meningitidis</i>	Third-generation cephalosporin [†] or meropenem	7-10
	<i>S. pneumoniae</i>	or ampicillin <i>plus</i> chloramphenicol	10-14
>50 yr	<i>S. pneumoniae</i>	Ampicillin <i>plus</i> third-generation cephalosporin [†]	10-14
	<i>L. monocytogenes</i>	or ampicillin <i>plus</i> fluoroquinolone [‡] or meropenem	14-21
	Gram-negative bacilli (other than <i>H. influenzae</i>)		21

*Add vancomycin in areas where there is greater than 2% incidence of highly drug-resistant *S. pneumoniae*.

[†]Ceftriaxone or cefotaxime.

[‡]Ciprofloxacin or levofloxacin.

Ciprofloxacin, 500 mg orally as a single dose, is another alternative to rifampin in nonpregnant, nonlactating adults (Advisory Committee on Immunization Practices [ACIP], 2013; Centers for Disease Control and Prevention, 2000; Pickering, 2003).

Prevention of nasopharyngeal carriage in patients treated for meningitis is achieved by starting prophylaxis doses (same as earlier) before discharge. Prevention is also achieved by immunoprophylaxis. The Hib vaccine is now part of the primary vaccination series for children and has been immensely successful at almost eliminating *H. influenzae* meningitis. A vaccine for meningococcal disease is now a part of the standard immunization regimen for all children between the ages of 11 and 12 years, with a booster dose at age 16 years. It should also be administered to children between the ages of 13 and 18 years if not previously vaccinated (ACIP, 2013).

The 13-valent pneumococcal conjugate vaccine (PCV-13) is recommended for all children as part of the ACIP's immunization schedule. PCV-13 is also recommended for adults age 19 years or older with immunocompromising conditions, functional or anatomic asplenia, CSF leaks, or cochlear implant (ACIP, 2013).

KEY TREATMENT

- Evidence supports the use of adjunctive dexamethasone in infants and children with Hib meningitis (IDSA; Tunkel et al., 2004) (SOR: A).
- Adjunctive dexamethasone is recommended for adult patients with suspected or proven pneumococcal meningitis (IDSA; Tunkel et al., 2004) (SOR: A).

Recurrent Meningitis

Recurrent meningitis can have both infectious and noninfectious causes. A CSF leak accounts for approximately 75% of cases of recurrent meningitis. Clinically, it presents similar to aseptic meningitis. A careful history may detect a drug exposure, structural lesion, or associated systemic disorder. To be truly recurrent, the CSF must confirm

pleocytosis. Between episodes, the CSF must also be documented to return to normal. The interval between recurrences can be months to years. Unless the source is bacterial, the course of recurrent meningitis is usually self-limited, and spontaneous recovery is generally the rule. Optimal treatment is aimed at the underlying cause.

Chronic Meningitis

There are no pathognomonic features of chronic meningitis. The classic symptoms, if present, may be extremely subtle and variable. There may be unusual symptoms such as psychoses, movement disorders, and parkinsonian syndrome. The average duration of symptoms is 17 to 43 months, during which symptoms may fluctuate or remain static. CSF that shows a mildly decreased glucose level in the setting of mononuclear pleocytosis should always raise the suspicion of chronic meningitis. The causes are numerous, and attention should be paid to a history of previous systemic diseases, specific infections that could involve the meninges, possible exposures, geographic risk factors, immunologic compromise, and concurrent extraneural involvement (Tables 41-23 and 41-24).

Viral Meningitis

Viral meningitis is actually a subset of aseptic meningitis. *Aseptic meningitis* antedates the modern science of virology and signifies an infection of the subarachnoid space and meninges with no obvious bacterial cause. *Encephalitis* occurs when there is inflammation of brain tissue. *Viral meningitis* presents with similar signs and symptoms as bacterial meningitis but with less severity. A history of a preceding viral respiratory infection is common. Obtaining LP for CSF evaluation is the only method for determining the difference. There are numerous causes of viral meningitis (Table 41-25). Outbreaks are often seasonal.

Treatment is mainly supportive, with the exception of herpes simplex virus (HSV) and HIV, for which specific antiviral therapy is available. Data regarding herpes meningitis treatment are limited, and both high-dose acyclovir (60 mg/kg/day) and lower-dose therapies have been advocated (Kohlhoff et al., 2004). For HIV and acquired

Bacterial	Tuberculosis Brucellosis Nocardiosis Syphilis Lyme disease Actinomycosis Listeriosis Subacute bacterial endocarditis Tularemia Leptospirosis Meningococcal infection
Fungal	Cryptococcosis Coccidioidomycosis Histoplasmosis Blastomycosis <i>Candida</i> <i>Aspergillus</i> spp. <i>Zygomycetes</i> spp. <i>Sporothrix</i> spp.
Viral	Retroviruses Herpesvirus Enteroviruses Lymphocytic choriomeningitis Mumps
Parasitic	Cysticercosis Schistosomiasis Trichinosis Paragonimiasis Echinococcosis Toxoplasmosis Visceral larva migrans
Noninfectious	Neoplasm Vasculitis Chemical meningitis Collagen vascular disease Behçet disease Sarcoidosis Systemic lupus erythematosus Fabry disease Foreign body in central nervous system Vogt-Koyanagi-Harada syndrome
Other	Parameningeal focus Chronic lymphocytic meningitis

immunodeficiency syndrome (AIDS)–dementia complex (ADC), many antiviral combinations have been suggested. The factors to be considered when choosing a combination therapy for ADC include toxicity, the many potential drug interactions, CNS penetration, and resistance. Because the treatments for HIV and its complications are often changing, consultation with an infectious disease specialist should be considered.

With the exception of HSV encephalitis and ADC, the prognosis is generally very good for other viral meningitides. Children seem to recover within 1 to 2 weeks, but adults may take several months.

Brain Abscess

Brain abscess, a rare disease in the United States, can occur in single or multiple sites. It usually arises from a secondary focus outside the CNS. Examples may include upper or lower respiratory infection, intracardiac infection, penetrating skull trauma, local osteomyelitis, any source of bacteremia, or no source (20%). Risk factors include IV drug use, HIV infection, and any other immunocompromised

Blood	Complete blood count, differential Chemistries, ESR, ANA HIV serology RPR Consider ACE, antineutrophilic cytoplasmic antibodies, specific serologies, blood smears

Human immunodeficiency virus

state. Common pathogens include streptococci, staphylococci, enteric gram-negative organisms, and anaerobes.

Clinically, brain abscess usually has a more aggressive onset of symptoms than bacterial meningitis. Symptoms usually present as typical meningeal irritation along with mental status changes that progress to stupor or coma, seizures, and focal neurologic findings. Laboratory studies are not impressive. Caution should be exercised before performing LP because brain edema is often present. Once past the initial cerebritis stage, CT or MRI of the brain often identifies the abscess. A search for a secondary cause is important. A radionuclide-labeled leukocyte scan may be needed to differentiate a brain tumor from infection. Aspiration or biopsy of the area in question usually confers a definitive diagnosis.

Treatment is directed toward the cause and lasts for 4 to 6 weeks. Drainage of the abscess is achieved by CT-guided needle aspiration or craniotomy. Recurrence can be expected in 5% to 10% of patients. Morbidity is significant and includes the risk of epilepsy (10%-70%), focal neurologic sequelae (25%), and cognitive impairment (15%). The overall mortality rate is 5% to 10%.

DIZZINESS

Key Points

- Dizziness is a risk factor for falls and functional decline in older adults.
- Characterizing the type of dizziness can narrow the differential diagnosis.
- Benign paroxysmal positional vertigo patients complain of episodic vertigo without aural symptoms.

Dizziness is a common problem encountered by family physicians. It is a typical complaint of elderly patients and has a broad differential diagnosis. Fortunately, dizziness is usually benign and self-limited. Nevertheless, it is a risk factor for falls and functional decline in the geriatric population and, in a small subset of patients, can signal a life-threatening condition.

Evaluation

The evaluation of dizziness is often frustrating for both patients and physicians. This frustration arises from the vast differential diagnosis, the potential for multiple etiologies, and the lack of a dependable method of diagnosing the more serious causes of dizziness. The initial step in the evaluation of a patient with dizziness is a thorough history. First, the physician should clarify the category of dizziness reported by the patient. Dizziness can be categorized as *vertigo*, which is the sensation of spinning or motion; *presyncopal lightheadedness*, which is a sensation of impending faint; *disequilibrium*, a sensation of unsteadiness and imbalance; or dizziness that cannot be adequately quantified, reported by patients as a feeling of lightheadedness or floating sensation. Categorizing the type of dizziness can limit the differential diagnosis (Table 41-26). Many patients, however, are unable to limit their dizziness symptoms to one specific category. Classically, the category of vertigo was further defined as peripheral or central vertigo based on

Table 41-26 Types of Dizziness

Category	Differential Diagnosis
Vertigo (sensation of spinning)	Inner ear, vestibular, brainstem and cerebellar abnormalities, sinusitis, drug toxicity, panic disorder, cervical spine disease
Presyncopal lightheadedness	Cerebral hypoperfusion, venous pooling in extremities, low blood volume, cardiac abnormalities (arrhythmia, cardiac insufficiency), vasovagal phenomenon
Disequilibrium (unsteadiness more prominent when standing)	Broad differential—any disturbance of the neurosensory system
Other (vague descriptions of lightheadedness without presyncope, or a floating sensation)	Broad differential but often associated with psychological disorders

Table 41-27 Substances Associated with Dizziness

Alcohol

 Psychotropic medicines
 Vasodilating agents

symptoms and signs, including nystagmus. This is not clinically useful, especially in the older adult population, because many of these findings are seen in normal patients as well.

After categorizing the type of dizziness experienced by the patient, the physician should next determine the temporal pattern of the symptoms. *Continuous* dizziness is typically produced by a stroke. *Episodic* dizziness lasting a few seconds to a minute and associated with head movement is usually a sign of benign positional vertigo. Meniere disease tends to cause dizziness lasting hours to days. Finally, the history should focus on the onset of the symptoms, alleviating or aggravating factors, and a review of the patient's medications (Table 41-27).

The physical examination should include orthostatic BP and pulse determinations; examination of the ears, nose, and throat for signs of infection; cardiovascular examination for murmurs and arrhythmias, with auscultation for carotid bruits; and neurologic examination, including evaluation of CNs, hearing and vision screening, observation of gait, cerebellar testing, and neuromuscular assessment of extremities. A Dix-Hallpike maneuver should be tested if the differential diagnosis includes benign positional vertigo because a positive test result confirms this diagnosis. Screening audiometry should be considered to rule out

Figure 41-2 Epley maneuver. (Reused with permission from Jones HR, Allam G, Srinivasan J. *Netter's neurology*. 2nd ed. Philadelphia: Saunders; 2011:117.)

Meniere disease and acoustic neuroma if warranted by the type of dizziness described by the history.

Laboratory and imaging studies should be ordered based on history and physical examination findings. Laboratory tests frequently include CBC, electrolytes, BUN, creatinine, glucose, serum calcium, LFTs, and TSH. If neuroimaging is indicated, MRI is the preferred modality because of its superior ability to evaluate the posterior fossa and brainstem. In some patients, carotid Doppler evaluation, cardiac event monitoring, or echocardiography may be necessary. Subspecialty consultation should be considered before proceeding with further, extensive testing.

Conditions Associated with Dizziness

Benign Positional Vertigo. Benign positional vertigo is believed to be caused by a dislodged otolith from the semicircular canal. Symptoms include episodic vertigo without aural symptoms. Nausea and vomiting may also be present secondary to the vertigo. Common histories include vertigo precipitated by rolling over in bed or bending over to tie

shoes. The diagnosis can usually be made by the history and eliciting a positive Dix-Hallpike maneuver. Patients can be expected to have gradual resolution of their symptoms over 4 to 6 weeks with supportive therapy. The canalith repositioning (Epley) maneuver (see Figure 41-2) provides short-term resolution of the vertiginous symptoms (Cochrane review; Pinder, 2004).

Postural Dizziness. Nonvertiginous postural dizziness suggests postural hypotension. *Orthostatic hypotension* is usually defined as a 20-mm Hg drop in systolic BP or 10-mm Hg drop in diastolic BP 2 minutes after moving from a recumbent to standing position. Older adult patients, however, can develop postural dizziness without apparent postural hypotension. In some cases, no BP decline occurs, although enough blood pools in the older adult's lower extremities to impair cerebral perfusion. When postural dizziness without postural hypotension is suspected, an evaluation of the cardiovascular system should be considered. If significant cardiovascular pathology, such as congestive

heart failure, is not identified, a therapeutic trial of support stockings and optimized hydration can be contemplated.

Labyrinthitis, Vestibular Abnormalities, and Meniere Disease. A comprehensive review of these topics is beyond the scope of this chapter but should be considered when evaluating any patient with dizziness. Patients with the abrupt onset of a single episode of vertigo that gradually resolves over several days often have *labyrinthitis* or *vestibular neuronitis*, usually distinguished clinically by the presence or absence of hearing changes. Patients with labyrinthitis usually experience hearing changes, but those with vestibular neuronitis do not. Whereas a viral infection is the usual cause in younger patients, infarction becomes more likely in older adults. Older adult patients may recover more slowly and experience feelings of imbalance for several months. Treatment during the symptomatic period may include vestibular rehab exercises and pharmacologic agents such as meclizine, promethazine, or low-dose benzodiazepine (e.g., lorazepam). *Meniere disease* should be suspected when an older adult reports recurrent episodes of vertigo, tinnitus, gradual development of low-frequency hearing loss, and in some cases ear fullness before onset of vertigo.

Dizziness of Cervical Origin. Cervical spine problems, especially osteoarthritic changes, can cause dizziness that may be vertiginous in nature and of vascular or proprioceptive origin. In cases of vascular origin, flow through one or both of the vertebral arteries is temporarily disrupted by an osteoarthritic spur that compresses the vessel when the patient turns the head or looks up. In cases of proprioceptive origin, overstimulation of the proprioceptive receptors in the facet joints produces the sensation of dizziness. Either of these conditions can cause a “drop attack.” These patients should avoid the position that precipitates the symptoms, and in some cases, cervical collars or cervical traction may be helpful.

Vertebrobasilar Transient Ischemic Attacks and Stroke. The TIAs that produce vertigo of abrupt onset lasting minutes to hours are a manifestation of ischemia in the distribution of the vertebrobasilar arteries, not the carotid arteries. Unfortunately, the TIA diagnosis can be difficult to make because vertigo may be the only symptom reported, and more definitive neurologic symptoms suggestive of a vertebrobasilar event may be absent, such as blurred vision, visual field deficits, diplopia, dysarthria, and unilateral motor or sensory changes. When a patient presents with symptoms of a vertebrobasilar TIA, the physician should consider causes such as cardioembolic disease, polycythemia, and subclavian steal syndrome. A significant BP difference in the arms and symptoms with arm abduction may signal subclavian steal syndrome, which may be corrected surgically. If the cause of these symptoms is related to vertebrobasilar vascular disease, treatment is usually medical with aspirin or other antiplatelet agents.

Vertigo is also a component of several well-recognized *vertebrobasilar stroke syndromes* (Table 41-28). *Lacunar strokes*, particularly those affecting the cerebellum, are also an important cause of dizziness. The dizziness associated with lacunar strokes is often reported as a sense of

Table 41-28 Vertebrobasilar Stroke Syndromes

Anatomy	Symptoms
Occlusion of vertebral artery	Lateral medullary syndrome: vertigo, nausea, ipsilateral facial numbness, Horner syndrome, contralateral body loss of pain and temperature sensation, tendency to fall to affected side
Occlusion of anterior inferior cerebellar artery: affects labyrinth, pontomedullary region, and inferolateral cerebellum	Lateral pontomedullary syndrome: severe vertigo, nausea, vomiting, unilateral hearing loss, tinnitus, facial paralysis, asymmetric cerebellar testing
Cerebellar infarction	Severe vomiting, vertigo, and ataxia; brainstem signs may be absent, making differentiation from labyrinthitis difficult or impossible

disequilibrium that is difficult to explain clinically. Such patients often report a sense of imbalance when standing that started when they were not feeling well and persists even after they return to their otherwise usual state of health. CT imaging is subject to excessive artifact in the posterior cranial fossa and is often inadequate to identify small cerebellar or brainstem infarcts. MRI is more useful for imaging this portion of the brain and should be considered as the initial imaging modality. Aggressive efforts to control BP are advised for patients believed to have experienced lacunar strokes.

PERIPHERAL NEUROPATHIES

Key Points

- In developed countries, diabetes and alcoholism are the most common causes of peripheral neuropathy in adults.
- Polyneuropathies are often inflammatory and caused by HIV infection, Lyme disease, and leprosy; no cause can be found in up to 20% of cases.
- There is no specific laboratory study or serum marker for the diagnosis of peripheral neuropathy.
- Electromyography (EMG) and nerve conduction studies (NCS) are most useful for evaluation of peripheral neuropathy and should be considered early.
- Mononeuropathies are usually caused by entrapment, compression, or other physical injury to a specific nerve.
- Carpal tunnel syndrome (CTS) is a common mononeuropathy caused by decreased tunnel size (Colles fracture, rheumatoid arthritis), enlargement of median nerve (diabetes, amyloidosis), or increased volume of other structures (tenosynovitis, gout).
- Common symptoms of CTS include numbness and paresthesias in the median nerve sensory distribution, pain at rest (especially at night), weakness in the thumb, and thenar atrophy.

The incidence of peripheral neuropathy is not known, but it is a common feature of many systemic diseases. In developed countries, diabetes and alcoholism are the most common causes of peripheral neuropathy in adults

(Poncelet, 1998). Worldwide, leprosy is the primary treatable cause of peripheral neuropathy, and HIV is one of the fastest growing causes (Sabin et al., 1993).

Peripheral neuropathies are frequently overlooked. The evaluation can be time consuming and costly without a systematic approach based on a careful history, clinical evaluation, and select studies. Despite a thoughtful approach, however, no cause can be found in up to 20% of cases (Dyck et al., 1981; McLeod et al., 1984). The goal in treating peripheral neuropathy should be to identify the treatable cause or underlying medical condition, such as diabetes, alcohol, drugs, or nutritional disorder. Hereditary neuropathies are uncommon but underdiagnosed; thus, a careful family history (e.g., long-standing distal neuropathy) should not be neglected.

Anatomy

The peripheral nervous system (PNS) consists of CNs III to XII, spinal roots (dorsal and ventral), spinal nerves, dorsal root ganglia, and most autonomic ganglia and roots. Because the motor neuron cell bodies are located in the spinal cord or CNS, diseases affecting these are considered separately. Peripheral nerves consist of different types of fiber bundles called *axons*. Large- and medium-sized axons are normally myelinated and carry information about proprioception, vibration, and light touch. Small axons, consisting of myelinated and unmyelinated types, are responsible for light touch, pain, and temperature, as well as autonomic information. These small, unmyelinated fibers of the autonomic PNS travel within most peripheral nerves and convey poorly defined visceral sensations and monitor autonomic functions. Most peripheral nerves carry incoming sensory information (afferent fibers) and outgoing motor and autonomic messages (efferent fibers).

Clinical Pathophysiology

Sensory Changes. Large- and small-fiber neuropathies can often be distinguished clinically by whether they affect proprioception and vibration or pain and temperature, respectively. Because processes that affect small fibers cause pain and sensory changes, symptoms may include reduced sensitivity to stimuli (hypoesthesia) or burning and tingling sensations (dysesthesias and paresthesias, respectively). There may also be impaired pain or temperature sensation and autonomic dysfunction. When large fibers are damaged, vibratory sense and proprioception are affected. This can lead to unsteady gait; complaints of coolness in the extremities; or *allodynia*, in which non-noxious stimuli such as light touch are perceived as pain. In polyneuropathies, pain and sensation are commonly affected in a stocking-glove distribution.

Motor Changes. Symptoms are usually most pronounced distally. This is especially true with polyneuropathies, in which symptoms of stumbling, clumsiness, and weakness are most common because of the effects on the intrinsic muscles. Motor symptoms can range from mild weakness to complete paralysis. Diminished DTRs may be one of the early signs of motor dysfunction. Denervation of muscles causes eventual atrophy. An example is the “sharp shin” sign, whereby atrophy of the tibialis anterior muscle gives a prominent appearance to the tibia. As the intrinsic

muscles deteriorate, the wasting gives the hands and feet a skeletal appearance. In long-standing neuropathies, trophic changes such as high-arched feet (*pes cavus*), hammertoes, kyphoscoliosis, and hair loss with or without ulcerations can be seen. Cramps, fasciculations, and restless legs may also be present.

Autonomic Changes. Autonomic changes are especially common with diabetes. The skin may become smooth, cold, and shiny. It may be unusually dry and devoid of perspiration. Orthostatic hypotension is one of the most common autonomic symptoms associated with neuropathy from systemic disease. The genitourinary and gastrointestinal systems are also often affected.

Classification. Peripheral neuropathies are often categorized in terms of the anatomy affected, pathophysiologic process, temporal development, and functional outcome.

Anatomic Classification. The major anatomic patterns of peripheral nerve disease can be distinguished by the clinical presentation of mononeuropathy, multiple mononeuropathy, and polyneuropathy. *Mononeuropathies* occur when there is damage to a single peripheral nerve or root. This is seen with local entrapment from causes such as trauma (acute or chronic), tumor infiltration, or infarction. *Multiple mononeuropathies* (mononeuropathy multiplex) occur when several nerves are individually affected by a disease process. Involvement is usually asymmetric and noncontiguous. These mononeuropathies are much less common than other peripheral neuropathies and are more difficult to recognize and treat. Multiple mononeuropathies are usually seen with systemic diseases such as vasculitis, diabetes, and rheumatoid arthritis. *Polyneuropathies* occur in a symmetric, diffuse, bilateral pattern and produce a characteristic stocking-glove pattern of sensory changes. However, most polyneuropathies affect both sensory and motor nerves. Some can affect peripheral autonomic nerves. Many common peripheral neuropathies fall into this category.

Pathophysiologic Classification. Based on the primary site of involvement, peripheral neuropathies can be classified as neuronopathies, axonal neuropathies, and myelinopathies. Electrodiagnostic studies can help define this in a clinical setting. *Neuronopathies* result from damage to the sensory cell bodies in the dorsal root ganglia or motor neuron cell bodies in the spinal cord. Their location in the CNS usually results in a degenerative process that produces incomplete recovery. Diseases that specifically affect the motor neuron cell bodies in the CNS are usually not categorized as peripheral neuropathies. *Axonal neuropathies* occur when damage occurs at the level of the axon. When the axon is disrupted (e.g., by trauma), the axon and distal myelin sheath may degenerate distal to the site of injury (wallerian degeneration). In toxic or metabolic injuries, when the distal axon is injured and myelin degeneration spreads proximally, it is known as “dying back” neuropathy. With the dying back process, the longer nerves tend to be affected earlier and more severely. *Myelinopathies* (demyelinating neuropathies) result from a process affecting primarily the myelin sheath. They can result from

Table 41-29 Neuropathies Classified by Temporal Presentation

Acute onset (within days)	GBS Vasculitis Porphyria Diphtheria Thallium toxicity Ischemia Penetrating trauma Rheumatoid arthritis Diabetic plexopathy or cranial neuropathy Acute nerve compression Polyarteritis nodosa Burns Iatrogenic (e.g., improper injection techniques)
Subacute onset (weeks to months)	Most toxins Most drugs Nutritional deficiencies Abnormal metabolic state Diabetic plexopathy Neoplasms Uremia
Chronic course (months to years)	CIDP Alcohol Diabetes Hereditary neuropathies
Relapsing	GBS HIV Porphyria Refsum's disease CIDP

GBS, Guillain-Barré syndrome; *HIV*, human immunodeficiency virus.

acute conditions such as Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs), and certain hereditary neuropathies.

Temporal Classification. Acute peripheral neuropathies develop over a few days. When motor signs are predominant, GBS should be suspected first. Vasculitic or toxic processes can also present acutely. A subacute presentation may be seen in toxic, inflammatory, infiltrative, or carcinomatous processes that develop over weeks. A chronic-onset neuropathy may develop gradually and progress over months to years, as is the case in metabolic or hereditary neuropathies. Peripheral neuropathies may also have a relapsing course (Table 41-29).

Laboratory Evaluation

There is no specific laboratory study or serum marker for the diagnosis of peripheral neuropathy. Information from the history and physical examination may direct specific laboratory tests (e.g., testing for specific toxins, infections, or inflammatory disorders). If the cause of neuropathy is not obvious, some screening laboratory studies should be considered, including ESR, CBC, LFTs, and determination of fasting blood glucose, glycosylated hemoglobin, BUN, creatinine, serum vitamin B₁₂, and TSH levels. Additional studies may be warranted, depending on the initial workup, such as chest radiography to rule out sarcoidosis, pulmonary function tests for GBS, or ECG for processes that affect cardiac conduction. may indicate an acquired inflammatory neuropathy (GBS or CIDP).

Electromyography and NCS are probably the most useful laboratory studies for the evaluation of peripheral neuropathy and should be considered early. They can confirm the presence of peripheral neuropathy and provide information about the type of fibers involved (sensory, motor, or both) and whether the problem is symmetric, asymmetric, or multifocal. EMG can define entrapment neuropathies and differentiate these from more proximal radicular compression. It can also help differentiate muscle wasting caused by neuropathic or myopathic disorders from simple disuse atrophy. NCS can help define pathophysiology (axonal loss vs. demyelination). EMG and NCS are useful but have limitations and should complement the history and examination. EMG is usually not as helpful in diseases that cause a diffuse small-fiber peripheral neuropathy, in which only pinprick and temperature sensation are affected (Table 41-30). In fact, the electromyography result may be normal. EMG needles also mildly inflame the muscles into which they are inserted. Thus, if a muscle biopsy is anticipated, that muscle should not be tested with EMG (Corse and Kuncl, 1999). NCS are most diagnostic with diseases affecting large, fast fibers and thus may be normal in patients with small-fiber neuropathies. Evaluation of small, proximal sensory nerves is not reliably done using EMG or NCS.

Nerve biopsy is helpful only in specific cases and is usually a last step in the workup. This includes patients with suspected amyloidosis, vasculitis, leprosy, leukodystrophies, sarcoidosis, or demyelinating disorders. Because the sural nerve, a sensory nerve, is generally used, disease affecting only motor nerves may be missed. Possible complications include permanent numbness or dysesthesia in the distribution of the excised nerve (typically lateral heel and ankle), infection, and poor wound healing.

In the evaluation of neuropathies, a carefully performed history that identifies key features of the presentation correlated with the findings of electrodiagnostic studies is the critical first step in developing a reasonable diagnosis. Questions include the following:

- Is the pattern of involvement focal or multifocal (Table 41-31)?
- Is the pattern symmetric (Tables 41-32 and 41-33)?
- Did symptoms evolve acutely, subacutely, or chronically? Was there a predilection for the upper extremities (Table 41-34)?
- Were the extremities affected in a distal versus a proximal distribution (see Tables 41-32 and 41-33)?

Table 41-31 Neuropathies by Pattern of Involvement

Focal	Multifocal
Common entrapment neuropathies: endocrine	Diabetes mellitus
Myxedema	Vasculitis
Acromegaly	Polyarteritis nodosa
Hypothyroidism	Churg-Strauss syndrome
Infection or inflammation	Giant cell arteritis

- Are the symptoms sensory, motor, or both (Table 41-35; see also Tables 41-32 and 41-33)?
- Is there autonomic or CN involvement (Tables 41-36 and 41-37)?
- What did the EMG and NCS show? Were other significant laboratory studies done?

Taking this approach to peripheral neuropathies will prove to be more efficient and fruitful than less ordered approaches despite the often elusive nature of these diagnoses.

Mononeuropathies

Mononeuropathies are usually caused by entrapment, compression, or other physical injury to a specific nerve. Peripheral nerves most at risk are those that occupy spaces with confining borders. Electrodiagnostic studies are useful in confirming the diagnosis and quantifying the degree of injury. Treatment is generally conservative, involving protection of the affected nerve from further injury by the use of activity avoidance or modification, ergonomic workplace correction, and bracing. Local (by injection) or systemic antiinflammatory treatment is often helpful. Surgical intervention is usually reserved for patients who fail conservative therapy, have evidence of progressive weakness and atrophy, or have a significant focal conduction block on electrodiagnostic examination.

Brachial Plexus Neuropathy. Brachial plexus neuropathy (plexopathy) can result from blunt or penetrating trauma. The typical injury is directed into the axilla or violently increases the angle between the shoulder and head. In the latter case, *stingers* or *burners*, which frequently occur in football players, result in temporary paresthesias and diffuse weakness in the upper extremity. Recurrent stretch injuries to the brachial plexus can result in permanent

Table 41-37 Neuropathies with Cranial Nerve Involvement

Primary	Bell palsy Trigeminal neuralgia
Secondary	Diabetes mellitus Diphtheria Lyme disease Sarcoidosis with cranial invasion Guillain-Barré syndrome Human immunodeficiency virus

weakness and atrophy. Also, apical lung tumors with direct extension or compression can cause pain in the upper extremity and hand numbness. Radiation therapy also can result in brachial plexopathies. *Idiopathic brachial plexopathy* (Parsonage-Turner syndrome) often occurs abruptly without any clear precipitating factor, although it can develop after an infection, injection, surgery, or childbirth. It typically begins with an aching sensation in the neck or shoulder and progresses over days to produce weakness, sensory loss, and diminished reflexes. Patients with brachial plexopathy often have considerable pain. Recovery is usually spontaneous but can take weeks to months. Some residual weakness may be present in a few patients.

Median Neuropathy (Carpal Tunnel Syndrome).

Carpal tunnel syndrome is one of the most common mononeuropathies. It typically occurs within the confines of the carpal tunnel in the wrist. The median nerve can also be entrapped in the forearm as a pronator or interosseous syndrome. The entrapment can be caused by anything that causes a decrease in the size of the carpal tunnel (e.g., Colles fracture, rheumatoid arthritis, congenital carpal tunnel stenosis), enlargement of the median nerve (e.g., diabetes, amyloidosis, thyroid disease, neuroma), or an increase in the volume of other structures within the carpal tunnel (e.g., tenosynovitis, ganglion, gout, urate deposits, lipoma, hematoma, fluid retention in pregnancy).

Other risk factors include any tasks that require repeated or sustained stress over the base of the palm. Low-frequency vibration exposure is another well-recognized risk factor for CTS. Repetitive wrist and hand movements such as knitting, typing, painting, woodworking, and weightlifting are also implicated as high-risk factors.

Common symptoms include numbness and paresthesias in the sensory distribution of the median nerve (palmar surface of thumb, index finger, and middle finger; radial side of ring finger; radial two thirds of palm). The patient may also have pain at rest (especially at night), weakness in the thumb, and thenar atrophy. Signs include a positive Tinel sign at the wrist (tingling in median nerve distribution on percussion over ventral wrist), positive Phalen sign (similar findings within 45 seconds after placing patient's wrist in maximal flexion), pain or paresthesias in a median distribution with thumb pressure over the median nerve for up to 30 seconds, and thenar atrophy. CTS can present with many variations, including proximal pain in the arm and shoulder, and with normal EMG.

Ulnar Neuropathy. The most common place to have ulnar nerve injury is at the elbow, where the nerve is

anatomically most exposed and vulnerable as it traverses superficially in the ulnar groove. Pressure at the elbow such as with prolonged elbow weight bearing, coma, intoxication, or anesthesia can account for this problem.

Cubital tunnel syndrome occurs when the nerve is compressed as it runs beneath the aponeurosis of the flexor carpi ulnaris just distal to the medial epicondyle (cubital tunnel). Activities that involve repetitive or sustained elbow flexion, such as baseball pitching, can injure and stretch the nerve. This results in hypermobility of the ulnar nerve and allows recurrent subluxation over the medial epicondyle. Common symptoms include paresthesias or pain in the ring and small fingers and dorsoulnar aspect of the hand and forearm. There may be generalized loss of grip or fine motor control in the hand because of impairment of the intrinsic muscles. Symptoms may improve with elbow extension. Recurrent subluxation of the ulnar nerve at the elbow, especially in young throwing athletes, often requires surgical intervention.

Ulnar neuropathy distal to the elbow usually presents as *ulnar tunnel syndrome* when the nerve is compressed within the Guyon canal in the wrist. Prolonged pressure over the hypothenar eminence, as occurs with cycling, is a common cause, as are similar causes listed for CTS. Dysesthesias may or may not be present in the ulnar regions. Depending on where the specific entrapment occurs, all the intrinsic hand muscles may be weak, or hypothenar function may be selectively preserved.

Radial Neuropathy. Radial nerve injuries are much less common than other upper extremity neuropathies. Proximally, the radial nerve is most vulnerable in the axilla, where it can be injured by hyperabduction of the arm, which puts traction on the nerve. This is the case with “Saturday night palsy,” when an intoxicated person sleeps with an arm draped over a chair. A similar circumstance occurs when the nerve is compressed against the humerus at the spiral groove. It is also seen with improper fit or use of crutches. Other sources of compression that can injure the radial nerve along its course include lipoma, fibroma, and new or previous (from callus) humerus fracture.

The radial nerve is predominantly a motor nerve, so symptoms depend on the level of injury. If the compression is proximal enough, there will be sensory loss over the dorsum of the hand along with weakened triceps (elbow extension) and brachioradialis (elbow extension and supination) motor function. The most obvious finding in radial palsy is wristdrop and drop finger (digital extensor paralysis).

In *posterior interosseous syndrome* (radial tunnel syndrome) the compression is more distal; the purely motor branch of the radial nerve, the posterior interosseous nerve, is entrapped at the supinator muscle, causing only weakness in the finger extensors without affecting wrist extension.

Lumbosacral Neuropathy. Compared with the brachial plexus, the lumbosacral plexus is less susceptible to trauma. Injury caused by trauma or compression from surgery, pregnancy, childbirth, tumors, or aortic aneurysm can occur. Diabetes can also cause multiple mononeuropathy of the plexus (see later).

Meralgia Paresthetica. Compression of the lateral femoral cutaneous nerve as it passes over the anterior superior iliac spine at the lateral end of the inguinal canal is common. It is seen in those who have diabetes, are obese, or wear their pants too tight. Patients experience numbness, paresthesias, and pain over the anterolateral aspect of the thigh without weakness.

Femoral Neuropathy. Any blunt or penetrating trauma, surgery or angiography in the groin, prolonged lithotomy position, or hyperextension during dance or gymnastics can injure the femoral nerve. A tumor or inguinal hernia involving the plexus can also compress the nerve. The femoral nerve supplies the quadriceps muscles for knee extension and provides sensory information from the anterior medial thigh and medial leg. Dysfunction in this nerve can result in pain in the groin that radiates to the thigh, buckling of the knee caused by quadriceps weakness, and sensory loss over its area of distribution. Weakness in the hip flexors indicates a more proximal lesion in the lumbar plexus or roots. Diabetic lumbosacral plexopathy should also be distinguished from femoral neuropathies. With the former, patients are older than 50 years, have diabetes, and develop acute severe pain in the thigh that progresses over days to weakness in the femoral nerve distribution. Sensory symptoms are mild. EMG helps distinguish these different conditions.

Sciatic Neuropathy. The sciatic nerve arises from the sacral portion of the plexus. It leaves the pelvis through the sciatic notch and divides into the tibial and peroneal nerves at the popliteal fossa. The sciatic nerve provides sensation to the perineum, posterior thigh, lateral calf, and foot. It innervates the thigh extensors, hamstrings, and all the muscles of the lower leg and foot. Pain, weakness, and sensory changes caused by injury of the sciatic nerve or one of its two branches can be caused by trauma from gunshots, hip fracture or dislocation, compression from surgery or prolonged sitting on a hard edge, tumor, endometriosis, lipoma, aneurysm of the gluteal artery, or improper intramuscular injection into the gluteus. Symptoms of sciatic nerve compression can mimic L5 to S1 radiculopathy. Again, EMG is helpful in these clinical situations.

Peroneal Neuropathy. The common peroneal nerve is most often compressed as it passes close to the fibular head. Such compression occurs from prolonged leg crossing, squatting, or kneeling; an improperly fitted cast or stockings; or prolonged pressure in an intoxicated or comatose patient. Symptoms of peroneal palsy consist of sensory loss over the lateral calf and dorsum of the foot and a weakness of ankle dorsiflexion (footdrop) and foot eversion without pain. If a clear history of trauma or compression cannot be elicited, imaging of the posterior fossa is necessary to rule out a mass lesion. Patients with a more permanent injury to the peroneal nerve may need an ankle-foot orthotic device to provide ankle stability and prevent plantarflexion contractures.

Tibial Neuropathy (Tarsal Tunnel Syndrome). The tarsal tunnel is located at the inferoposterior margin of the medial malleolus. Its boundaries include the bones of

the ankle and fibrous flexor retinaculum. The posterior tibial nerve and three flexor tendons of the foot and vessels lie within this tunnel. Compression can occur within the tunnel from tenosynovitis, enlarged veins, and fracture or dislocation of the ankle. Prolonged standing or walking may lead to vascular stasis and engorgement within the tunnel. A horse jockey is one of the few occupations associated with this syndrome. The primary symptom of tarsal tunnel syndrome is painful, burning paresthesias in the sole of the foot that are worse after a day of activity and may extend into the night. The symptoms can be reproduced or exacerbated by gentle percussion over the tarsal tunnel (Tinel sign). The patient may also have weakness in the intrinsic muscles of the foot, making it difficult to push off during walking. Definitive treatment is surgical decompression involving release of the retinaculum.

Interdigital Neuropathy. A common cause of foot pain, entrapment of an interdigital nerve is often caused by a Morton neuroma or benign swelling of the nerve. Tenderness is appreciated in the web space between the metatarsal heads. Any space can be affected, but the second and third web spaces are most often involved. Running, ballet dancing, and wearing tight shoes or high heels are all risk factors. Modifying risk factors, local corticosteroid injection, and surgical release are treatment options.

Polyneuropathies

Inflammatory Neuropathies. With inflammatory neuropathies, an inflammatory process is directed against the peripheral nerve; the most common causes follow. Treatment is usually directed toward the causative agent.

HUMAN IMMUNODEFICIENCY VIRUS. Several opportunistic infections of the PNS may result from HIV infection. HIV itself, cytomegalovirus, and herpes zoster are most common. Painful sensorimotor polyneuropathies or demyelinating polyradiculoneuropathies occur during the early and late stages of HIV disease. Symptomatic relief of neuropathic pain may be achieved with antidepressants (e.g., amitriptyline) or anticonvulsants (e.g., carbamazepine).

LYME DISEASE. The early stages of disseminated Lyme disease have resulted in Bell palsy or an inflammation of CN VII (facial nerve) in approximately 11% of patients with Lyme disease (Wilkinson, 1998). In the later stages of Lyme disease, a neuropathy mimicking CIDP can occur.

LEPROSY. Although uncommon in the United States, leprosy is the most common worldwide treatable cause of neuropathy. Symptoms of neuropathy can occur before the systemic manifestations of disease are present. As leprosy progresses, with its characteristic skin lesions, the risk for peripheral nerve injury increases. Sensory loss of some degree is expected. Treatment is directed toward the disease itself.

ACUTE INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY. *Guillain-Barré syndrome*, or acute inflammatory demyelinating polyradiculoneuropathy, is a rapidly progressive paralytic syndrome affecting persons of all ages. GBS seems to occur through an immune-mediated process. Many cases follow a mild gastrointestinal or upper respiratory viral illness by 1 to 3 weeks. Other risk factors include pregnancy, influenza immunization, the postoperative period, and HIV infection. A particularly strong link between

Campylobacter jejuni infection and GBS has been suggested in up to 20% of cases (Dyck et al., 1993).

The traditional description of a rapid progression of ascending symmetric weakness starting in the lower extremities and moving to the upper extremities is often useful, *but variations are quite common*. Indeed, early development of proximal weakness is frequently seen, and involvement of upper extremities before lower extremities is not rare. In general, the presentation is one of rapid progression of an ascending symmetric weakness, usually starting in the lower extremities and moving to the upper extremities. Patients may initially complain of pain and paresthesias in the back and proximal limbs. The progressive weakness that involves the legs as well as the upper extremities, trunk, intercostals, head, and neck muscles may take several days to 4 weeks and often results in paralysis. There may be mild sensory impairment in the extremities, early loss of DTRs, and bilateral facial nerve palsy in up to 40% of patients. NCS demonstrate demyelination, and the CSF may show an increased protein level, with normal cell counts.

The differential diagnosis of a rapid-onset polyradiculoneuropathy includes botulism, diphtheria, hypophosphatemia, acute intermittent porphyria, poliomyelitis, Lyme disease, poisoning from contaminated shellfish (e.g., tetrodotoxin), and toxic neuropathies (e.g., arsenic, mercury, thallium).

Because of the rapidly progressive nature of GBS, patients should be monitored in the hospital for signs of respiratory failure and autonomic instability (arrhythmias, hypotension, hypertension, and hyperpyrexia in two thirds of patients). Treatment usually consists of plasmapheresis or intravenous human immune globulin (IVIG). There is no role for steroids in the acute treatment of GBS. In most patients, recovery is complete or nearly complete, although it may take a few weeks to 18 months. About 10% of cases result in severe permanent disability. Even under the best circumstances, 3% to 5% of patients do not survive.

CHRONIC INFLAMMATORY DEMYELINATING POLYRADICULONEUROPATHY. Chronic inflammatory demyelinating polyradiculoneuropathy is an acquired motor and sensory neuropathy of unknown cause. As with GBS, an immune-mediated pathogenesis is suspected. Unlike GBS, CIDP usually occurs in the absence of a preceding illness. Unusual exceptions include HIV infection, dysproteinemias, and lupus erythematosus. CIDP is predominantly a motor polyneuropathy affecting those of all ages, with a progressive or relapsing course. Weakness can be proximal or distal but usually develops in the legs over at least 2 months, distinguishing CIDP from GBS. Sensory changes include numbness or paresthesias but can be variable. DTRs are decreased or absent. Electrodiagnostic and CSF findings are similar to those found in GBS. Treatment includes prednisone, along with plasmapheresis or IVIG. CIDP should be distinguished from other acquired and hereditary neuropathies.

Metabolic Neuropathies

DIABETIC NEUROPATHY. Diabetes is the cause of the most common polyneuropathy seen by family physicians, occurring in up to 50% of all patients with diabetes. Its incidence usually rises with disease progression. Diabetic peripheral neuropathy has a widely variable presentation but usually is seen as a symmetric polyneuropathy, with predominant

sensory signs and mild motor signs. Patients experience burning dysesthesias and pain in the soles of the feet. Impaired position sense leading to ataxia and arthropathy (Charcot joints) implies the involvement of large, myelinated sensory fibers. Patients with diabetic neuropathy experience bilateral symptoms that include burning pain in the back and thigh with proximal muscle weakness, decreased patellar DTRs, and normal sensory function. This is thought to be caused by microvascular ischemia of the proximal motor trunks. Diabetes is also associated with autonomic neuropathies. Symptoms may include postural hypotension; gastroparesis; intestinal dysmotility; atonic bladder; impotence; and loss of pain fibers in the cardiac sympathetic system, permitting silent MI.

UREMIC NEUROPATHY. Patients with chronic renal disease develop a symmetric sensorimotor neuropathy involving the upper and lower extremities. They complain mostly of burning paresthesias. Uremic neuropathy is thought to be secondary to a toxic effect on the peripheral nerves. Because many chronic renal patients also have diabetes, it is often difficult to isolate a single cause. However, patients with true uremic neuropathy who have undergone renal transplantation can have dramatic improvement of symptoms (Rees, 1995).

Nutritional Neuropathies. Most nutritional neuropathies involve one of the B-complex vitamins. Patients at risk for these neuropathies usually have chronic alcoholism, malabsorption syndrome, eating disorder, or unusual diet (food faddist). It presents as a symmetric polyneuropathy with burning in the feet. Weakness, atrophy, and hypoaffective reflexes may also occur.

Alcoholic neuropathy is caused from inadequate intake and poor absorption. Treatment with multivitamin supplementation is usually adequate but may take time to be effective. Thiamine (vitamin B₁) deficiency, or beriberi, is seen most often with chronic alcoholism. It may present as a distal polyneuropathy or as a more serious Wernicke-Korsakoff encephalopathy, with mental status changes. In the latter case, intramuscular thiamine (100 mg/day) is preferred initially over oral administration. Pyridoxine (vitamin B₆) deficiency can be associated with the use of dapsone or isoniazid, which interfere with vitamin B₆ metabolism. Prevention requires supplementation with 50 mg of pyridoxine three times daily. Prolonged intake of pyridoxine of more than 2 g/day has also been associated with sensory neuropathy (Rostami, 1995). Vitamin B₁₂ deficiency may present only with vague paresthesias. Determining the serum vitamin B₁₂ level is the best way to assess a patient when this problem is suspected because abnormal RBC indices may not be apparent until irreversible neurologic symptoms have already occurred.

Hereditary Neuropathies. The hereditary neuropathies are often missed by family physicians and even by those close to the affected patient. These indolent, slowly progressive polyneuropathies may present with motor, autonomic, and less often, sensory symptoms. These include pes cavus, absent tendon reflexes, a high-stepping or slapping gait, footdrop, slowly progressive wasting and weakness of peroneal muscles, foot ulcers, joint arthropathy, and absence of sweating. Without a specific treatment for these

Table 41-38 Neuropathies Caused by Drugs and Toxins

Drugs	
Axonal	Amitriptyline Chloroquine Cimetidine Colchicine Dapsone Didanosine Disulfiram Ethambutol Hydralazine Interferon alfa Isoniazid Lithium Metronidazole Nitrous oxide Nitrofurantoin Paclitaxel Phenytoin Pyridoxine Procainamide Vincristine
Demyelinating	Amiodarone Colchicine Gold
Neuronopathy	Cisplatin Pyridoxine Thalidomide
Toxins

Euphorants	Glue Solvents

neuropathies, efforts are focused on management of physical disabilities, education, genetic counseling, and reassurance. Hereditary neuropathies and CIDP can both have a familial pattern, the important difference being that CIDP is treatable.

Toxic Neuropathies. Toxic neuropathies occur from repeated exposure to drugs, industrial toxins, or heavy metals (Table 41-38). The presentation depends on the exact exposure and what part of the nerve is affected. It may present as a progressive, symmetric, ascending polyneuropathy, as in many occupational exposures, or with vague sensory changes similar to those of nutritional neuropathies. Lead intoxication creates a motor neuropathy starting in the upper limbs, affecting the radial nerve and causing wristdrop. Many of these neuropathies slowly improve when the offending agent is removed; however, this is not always the case. A careful medical and occupation history is important. Treatment is directed accordingly.

Dysproteinemic Neuropathies. Dysproteinemias such as cryoglobulinemia, myeloma, amyloidosis, lymphoma, monoclonal gammopathies, and some leukemias are associated with peripheral neuropathy. In patients with idiopathic peripheral neuropathies, a *monoclonal gammopathy* can be identified in up to 10% (Kissel and Mendell, 1996).

Plasma exchange is useful as a treatment option for some of the dysproteinemic neuropathies.

CARCINOMATOUS NEUROPATHIES. Carcinomatous neuropathies may result from direct compression by a solid tumor or local infiltration of nerves. The most common association is lung carcinoma. Some chemotherapeutic agents, such as vincristine and cisplatin, have neurotoxic side effects. The most common presentation is that of a distal sensorimotor polyneuropathy. In up to 16% of patients with lung carcinoma and 4% of those with breast carcinomas, peripheral neuropathy preceded the actual signs of the disease.

CRANIAL NEUROPATHIES

Key Points

- Bell palsy is an acute unilateral paralysis of the facial nerve and involves the forehead muscles.
- Trigeminal neuralgia is usually a unilateral severe lancinating pain lasting a few seconds, triggered by innocuous stimuli (light touch to face, toothbrushing).
- Trigeminal neuralgia is rarely seen in patients younger than 40 years of age.

Many conditions or infections may affect the CNs and cause a peripheral neuropathy. Two common problems encountered by family physicians are idiopathic acute peripheral facial paralysis (Bell palsy) and trigeminal neuralgia (tic douloureux).

IDIOPATHIC ACUTE PERIPHERAL FACIAL PARALYSIS. *Bell palsy* is an acute, unilateral paralysis of the facial nerve of unknown etiology but possibly linked to an antecedent herpes infection (Adour, 1975). Bell palsy is likely the most common isolated cranial neuropathy (23 per 100,000) seen by family physicians (Hauser et al., 1971). Symptoms tend to develop over hours to days and may be associated with recent upper respiratory infection. Symptoms include partial or complete paralysis of the ipsilateral facial muscles, forehead involvement, otalgia, phonophobia, and cephalgia. If the forehead muscles are spared, one must consider a central etiology to the symptoms. Bilateral findings of Bell palsy should prompt consideration of GBS, sarcoidosis, disseminated Lyme disease, or diabetes.

Most patients with Bell palsy recover with only supportive therapy within a few days to a few months. This makes aggressive treatment controversial. A recent meta-analysis showed that whereas high-dose corticosteroids (>450 mg total dose) were associated with greater benefit and decreased risk of unsatisfactory recovery, antiviral agents showed no benefit alone but may have additional benefit when used with corticosteroids (de Almeida et al., 2009). A typical corticosteroid regimen may include oral prednisone, 60 mg/day (or 1 mg/kg/day) for 7 days, then tapering by 10 mg/day, with or without valacyclovir, 1 gram twice daily for 7 days.

KEY TREATMENT

- High-dose corticosteroids (>450 mg total dose) help reduce the risk of unsatisfactory recovery from Bell palsy (de Almeida et al., 2009) (SOR: A).

TRIGEMINAL NEURALGIA. Trigeminal neuralgia (tic douloureux) usually involves the second and third (maxillary and mandibular) divisions of the trigeminal nerve, causing pain of the innervated structures (lips, gums, teeth). It is almost always unilateral, with the pain sudden, sharp, and severe, lasting a few seconds at a time. This cycle of pain can occur hundreds of times a day. It may be described as lancinating, ice pick-like, or an electric shock and characteristically is precipitated by innocuous stimuli such as light touch to the face or toothbrushing. It is rarely seen in patients younger than 40 years. Pain that is longer in duration, bilateral, or described as more aching or pressure-like is usually not related to trigeminal neuralgia and should cause the physician to search for another cause. Other conditions that should be considered include multiple sclerosis (MS), acoustic neuroma, aneurysm, meningioma, trigeminal neuroma, and early herpes zoster or postherpetic neuralgia. Herpes zoster should be suspected in patients younger than 40 years who present with pain following the upper division of the trigeminal nerve (forehead and eye). Neuroimaging with MRI scanning of the brain is recommended to exclude these causes from idiopathic disease.

A common initial pharmacologic treatment for idiopathic trigeminal neuralgia is carbamazepine (Tegretol), up to 1200 mg/day. Usually, it is started at relatively low doses (100–200 mg once or twice daily) and increased at 7- to 10-day intervals until adequate symptom control is achieved. Other medications that have been used but are not FDA approved include oxcarbazepine (Trileptal), up to 2400 mg/day, gabapentin (Neurontin), amitriptyline, and baclofen. Patients should be educated that these medicines will only work when taken on a consistent basis and not as an analgesic medication. Toxicities from these medications, including allergic reactions, bone marrow suppression, and liver toxicity, may develop and thus require close monitoring. Patients with refractory symptoms or who do not tolerate pharmacologic treatment should be considered for neurosurgical evaluation.

PARKINSON DISEASE

Key Points

- The hallmark clinical features of Parkinson disease include resting tremor, rigidity, and bradykinesia of asymmetric onset.
- Symptoms such as hallucinations, gait abnormalities, paralysis of upward gaze, early dementia, early postural instability, early autonomic dysfunction, involuntary movements other than tremor, and a failure to respond to levodopa suggest a parkinsonism-plus syndrome and require further evaluation.
- Drug therapy for Parkinson disease should be initiated when the symptoms are significant enough to cause functional impairment.

Parkinson disease is the second most common progressive neurodegenerative disorder in the United States after Alzheimer disease. Parkinson affects about 1% of the population older than age 60 years and 4% to 5% of those older than 85 years. The disease is uncommon before age 40

years, and the incidence is higher in men than women. A genetic predisposition to Parkinson disease may be present; up to 15% of patients have a first- or second-degree relative with Parkinson disease. At present, no clear environmental links to Parkinson disease have been identified. The disease is caused by a disruption of dopaminergic neurotransmission in the basal ganglia and the development of eosinophilic intracytoplasmic inclusions (Lewy bodies) in the residual dopaminergic neurons.

Symptoms and Signs

The hallmark clinical features of Parkinson disease include tremor, rigidity, and bradykinesia, usually of asymmetric onset. Tremor is the presenting symptom in up to 70% of patients, and in fact, an asymmetric rest tremor is virtually pathognomonic of Parkinson disease. Many patients present to family physicians complaining of a tremor and the concern they may have Parkinson disease. Most have *essential tremor*, which can be differentiated from the tremor of Parkinson disease in that whereas essential tremor is usually symmetric and exacerbated by action, the tremor of Parkinson disease is usually at rest and asymmetric.

Rigidity is often associated with *cogwheeling*, a ratchety quality during passive movement of the limb. *Bradykinesia* refers to the slowness of movements, which usually begins in an asymmetric fashion, described by the patient as “weakness” of an extremity, although no abnormalities are noted with strength testing. Other clinical features associated with Parkinson disease include micrographia, paucity of facial expression (masked facies), narrow shuffling gait, and postural instability (late finding). Behavioral and cognitive symptoms are frequently seen in patients with Parkinson disease as well.

Differential Diagnosis

Up to 20% of patients initially diagnosed with Parkinson disease ultimately have an alternative diagnosis. The term *parkinsonism-plus syndrome* is used for patients who have similar symptoms but also have additional abnormalities or do not respond to the usual medications. Symptoms that suggest a parkinsonism-plus syndrome include hallucinations, gait abnormalities, paralysis of upward gaze, early dementia, early postural instability, early autonomic dysfunction, involuntary movements other than tremor, and a failure to respond to levodopa (*Italian Neurological Society, 2003*). Conditions that frequently may be confused with Parkinson disease include progressive supranuclear palsy (PSP), dementia with Lewy bodies, multiple-system atrophy, vascular parkinsonism, and drug-induced parkinsonism.

Progressive supranuclear palsy may initially be mistaken for Parkinson disease. Patients have ophthalmoparesis of vertical gaze, primarily downward gaze. Early loss of postural reflexes, predominantly axial rigidity, pseudobulbar palsy, and frontal lobe signs are other characteristics of PSP. Response to dopaminergic medications is minimal.

Dementia with Lewy bodies has motor symptoms similar to those of Parkinson disease, and there may be a response to levodopa. Rigidity is usually more prominent than bradykinesia or tremor. Additionally, patients have early cognitive impairment and hallucinations early in the disease course.

Multisystem atrophy includes a number of diseases, and it is not clear if they represent distinct diseases or a single, pathologic continuum. This group includes olivopontocerebellar atrophy, striatonigral degeneration, and Shy-Drager syndrome. Symptoms are related to autonomic nervous system dysfunction and include orthostatic hypotension, cerebellar dysfunction, bladder dysfunction, and a poor levodopa response.

Vascular parkinsonism may be associated with multiple vascular lesions in the basal ganglia. There is usually a stepwise progression to the disease. Tremor at rest is not a common finding, and the bradykinesia and rigidity tend to be more significant in the legs. The gait is often broad-based. Associated symptoms include dementia, spasticity, and weakness. MRI studies show multi-infarct changes, and the response to levodopa is poor.

A final category of Parkinson-like conditions is *drug-induced parkinsonism*. It is important to identify this cause because it is usually reversible. Drug-induced parkinsonism accounted for 20% of cases of parkinsonism-plus conditions in a population-based study (*Bower et al., 1999*). Medications that can cause these symptoms include neuroleptics, atypical neuroleptics, antiemetic medications (e.g., metoclopramide, prochlorperazine), amiodarone, valproic acid, and lithium. Medicines that block the synthesis of dopamine, such as methyl dopa (Aldomet), or deplete dopamine (e.g., reserpine) can also induce parkinsonism (*Nutt and Wooten, 2005*).

Diagnostic Evaluation

An extensive diagnostic evaluation is not necessary when the history and physical examination reveal classic findings of Parkinson disease. Imaging of the brain with CT or MRI may be performed if the diagnosis is in question and to rule out other conditions such as NPH or vascular parkinsonism. Consultation with a neurologist may be helpful, especially if the diagnosis is in question or a parkinsonism-plus diagnosis is likely.

Treatment

Currently, diagnosis of Parkinson disease does not relegate a patient to pharmacologic treatment. Drug therapy should be initiated when the symptoms are significant enough to cause functional impairment (*Rao et al., 2006*). Current therapies do not appear to slow the progression of the disease, and no studies have clearly demonstrated a best initial treatment for this condition (*Schreck et al., 2003*). *Table 41-39* summarizes the pharmacologic agents available to treat Parkinson disease.

Pharmacotherapy. *Levodopa*, a precursor of dopamine, is the most frequently prescribed agent for the treatment of symptomatic Parkinson disease and is particularly effective at controlling bradykinesia and rigidity (*Miyasaki et al., 2002*). Alone, levodopa is absorbed but is peripherally metabolized to dopamine by dopa-decarboxylase enzymes. This peripheral conversion limits the overall effectiveness of levodopa and increases the side effects, including nausea, vomiting, and hypotension. To remedy this, levodopa is combined with carbidopa, which prevents this peripheral conversion. Dopa-decarboxylase is saturated with 70 to 100 mg of carbidopa. Thus the usual starting dose of

Table 41-39 Medications for Parkinson Disease

Generic Name	Recommended Dosage	Side Effects/Comments
ANTICHOLINERGICS		
Trihexyphenidyl (Artane)	1 mg TID; increase to 2 mg TID	Effective for tremor Side effects include impaired memory, blurred vision, urinary retention
Benzotropine (Cogentin)	0.5 mg at bedtime; increase by 0.5 mg up to a maximum of 6 mg/day	Same as for trihexyphenidyl
CARBIDOPA-LEVODOPA COMBINATIONS		
Immediate release (Sinemet)	25 mg/100 mg initially ½ tablet TID; increase by ½ tablet every 4-7 days up to 1 tablet TID to QID	“Gold standard” of therapy Long-term therapy may result in motor fluctuations, dyskinesias, confusion, hallucinations
Controlled release (Sinemet-CR)	1 tablet BID	Same as for immediate release
Carbidopa-levodopa plus entacapone (Stalevo)	1 tablet TID (dosage based on titration of individual components)	Same as for other carbidopa-levodopa preparations, plus diarrhea
CATECHOL-O-METHYLTRANSFERASE INHIBITORS		
Tolcapone (Tasmar)	100 mg or 200 mg TID	Adjunct to levodopa to prevent motor fluctuations Monitor liver functions
Entacapone (Comtan)	200 mg with each dose of carbidopa-levodopa, up to 8 tabs (1600 mg) daily	Same as for tolcapone
DOPAMINE AGONISTS		
Bromocriptine (Parlodel)	1.25 mg with meals BID; increase by 2.5 mg every 2-4 wk to a maximum of 15 mg/day	Effective in monotherapy or as an adjunct to levodopa
Pramipexole (Mirapex)	0.125 mg TID; maximum, 1.5 mg TID	Side effects include excessive daytime somnolence, hypotension, confusion, hallucinations
Ropinirole (ReQuip)	0.25 mg TID; increase weekly by 0.25 mg TID to 3 mg TID Maximum dose, 8 mg TID	Same as for pramipexole
Rotigotine (Neupro)	Start 2 mg/24 hr patch daily; may increase by 2 mg weekly to a maximum of 6 mg/24 hr (start with 4 mg/24 hr to a maximum of 8 mg/24 hr for severe disease)	Contains sulfites; remove before MRI or cardioversion Side effects: sleep attacks, hypotension, psychosis, application site reactions
MONOAMINE OXIDASE TYPE B INHIBITORS		
Selegiline (Eldepryl)	5 mg at breakfast and lunch	Avoid use with SSRIs, TCAs, and meperidine Side effects: nausea, dizziness, hallucinations, abdominal pain, vivid dreams
Rasagiline (Azilect)	0.5 mg/day to 1 mg/day	Side effects: extrapyramidal symptoms, dyskinesia, hallucinations, hypotension, depression
N-METHYL-D-ASPARTATE ANTAGONIST (RECEPTOR INHIBITOR)		
Amantadine (Symmetrel)	100 mg twice daily	May be used as monotherapy Side effects: dizziness, confusion, livedo reticularis, hallucinations

BID, Twice a day; *MRI*, magnetic resonance imaging; *QID*, four times daily; *SSRI*, selective serotonin reuptake inhibitor; *TCA*, tricyclic antidepressant; *TID*, three times daily.

carbidopa-levodopa is 25 mg/100 mg three times daily (Rao et al., 2006).

Dopamine agonists directly stimulate dopamine receptors, thus bypassing the presynaptic synthesis of dopamine. These medications cause less dyskinesia and fewer fluctuations than levodopa. They can be used alone or in conjunction with levodopa. Currently, bromocriptine (Parlodel), pramipexole (Mirapex), and ropinirole (ReQuip) are oral medications in this class. Transdermal rotigotine (Neupro) is a once-daily patch available for the treatment of Parkinson disease. Apomorphine (Apokyn) is also available as a SC injection for the treatment of sudden, resistant “off” periods (Goetz et al., 2005). It has significant adverse effects and should only be used by individuals experienced with its use. Dopamine agonists should not be used in patients with dementia because of the high likelihood of producing hallucinations (Nutt and Wooten, 2005).

Monoamine oxidase type B (MAO-B) inhibitors were initially thought to provide a neuroprotective effect to patients with Parkinson disease. This has not been supported in the literature. Agents available in the United States in this class include selegiline (Eldepryl), orally disintegrating selegiline (Zelapar), and rasagiline (Azilect). A meta-analysis of 17 trials comparing MAO-B inhibitors with placebo or levodopa revealed that MAO inhibitors reduce disability, the incidence of motor fluctuations, and the need for levodopa (Ives et al., 2004).

Anticholinergic medications primarily work on the muscarinic acetylcholine receptors. These medications have low effectiveness and a high incidence of side effects, which limit their overall usefulness to patients younger than 70 years and with preserved cognitive function.

Degradation of levodopa in the periphery is known to be associated with motor fluctuations and dyskinesia in

Parkinson disease. The enzyme catechol-*O*-methyltransferase (COMT) is responsible for part of this degradation. *COMT inhibitors* prolong the dopamine response. Two medications in this category are tolcapone (Tasmar) and entacapone (Comtan). These medications reduced “off” time, reduced total levodopa dose, and improved motor symptoms in patients with advanced Parkinson disease and motor complications (Cochrane review; [Deane et al., 2004](#)). As such, COMT inhibitors are usually reserved for more advanced cases.

Among *NMDA antagonists* (NMDA receptor inhibitors), amantadine (Symmetrel), originally developed as an antiviral agent, is useful for tremor, rigidity, and bradykinesia associated with Parkinson disease, although few studies demonstrate its clear efficacy. Amantadine may also have a dopamine agonist effect as well as an anticholinergic effect. Side effects include dizziness, insomnia, nausea, and vomiting.

Surgical Treatment. Surgical treatments are options to be considered when tremor, motor fluctuations, and dyskinesia are not adequately controlled with medications alone. Early techniques such as unilateral pallidotomy or thalamotomy have fallen out of favor because of their irreversible nature. There is long-term, high-quality evidence for deep brain stimulation of the globus pallidus interna or subthalamic nucleus for improvement of motor features or stimulation of the thalamic ventralis intermedius for improvement of tremors ([Fasano et al., 2012](#)). Stimulation of other targeted centers needs further study. Patients with symptoms not controlled medically should be referred to specialized centers with surgeons experienced in performing these procedures.

Treatment of Nonmotor Symptoms. Patients with Parkinson disease frequently develop other comorbid conditions such as depression or dementia. In the case of depression, an SSRI can be used. Up to 40% of patients develop dementia ([Aarsland et al., 2003](#)). In these patients, the cholinesterase inhibitors can be effective. Parkinson disease is a progressive illness, so it is important for the family physician to discuss advanced directives, establishment of power of attorney for health care decisions, and the patient’s wishes surrounding the use of artificial nutrition. Living wills and other legal documents should be prepared and appropriate discussions documented. Common symptoms such as constipation, sleep disturbance, and orthostatic hypotension should be aggressively treated.

KEY TREATMENT

- Levodopa, dopamine agonists, and MAO-B inhibitors, alone or in combination, are effective in treating the symptoms of Parkinson disease ([Rao et al., 2006](#)) (SOR: A).
- The usual starting dosage of carbidopa–levodopa is 25 mg/100 mg three times daily ([Rao et al., 2006](#)) (SOR: A).
- Surgical therapies (deep brain stimulation) are effective when medical therapy fails to control Parkinson symptoms ([Fasano et al., 2012](#)) (SOR: A).

MULTIPLE SCLEROSIS

Key Points

- The diagnosis of MS requires evidence of demyelinating disseminated disease.
- Optic neuritis, nystagmus from internuclear ophthalmoplegia, and Lhermitte sign are highly suggestive of MS.
- The currently most widely accepted diagnostic criteria for MS are the McDonald criteria, established by an international panel in 2001 and revised in 2005 and 2010.

Multiple sclerosis is a recurrent, chronic, demyelinating autoimmune disorder that affects the CNS. The mean age of onset for MS is 29 to 33 years, although the range is 15 to 50 years, which makes this the most common cause of neurologic disability in young adults.

Diagnosis

The diagnosis of MS is based on clinical signs and symptoms combined with diagnostic testing, which may include MRI, CSF analysis, and visual-evoked potentials (VEPs). Definitive diagnosis of MS requires evidence of demyelinating disease consisting of at least two attacks, disseminated over time and space ([Polman et al., 2011](#)). That is, clinical symptoms should last at least 24 hours in the absence of fever or infection and should be separated in time, and they should affect two different areas of the CNS: the brain, spinal cord, or optic nerves. The clinical symptoms vary, depending on which part of the CNS is involved. Three symptoms are highly suggestive of MS: optic neuritis, nystagmus resulting from internuclear ophthalmoplegia, and Lhermitte sign, which is an electrical sensation extending down the back and legs with flexion of the neck. The International Panel of the Diagnosis of Multiple Sclerosis developed criteria for the diagnosis of MS ([McDonald et al., 2001](#)), revised in 2005 and 2010 and summarized in [Table 41-40](#) ([Polman et al., 2011](#)). It is important to remember that alternative diagnoses should be considered and excluded. These include CNS vasculitis, paraneoplastic syndromes, sarcoidosis, leukodystrophies, CNS tumors, infections, CNS lymphoma, and nutritional deficiencies (e.g., vitamin B₁₂ deficiency). Neuromyelitis optica is considered a separate, although similar, entity in which there is demyelination predominantly in the spinal cord, often over multiple segments, in conjunction with unilateral or bilateral optic neuritis. Brain MRI is often normal and serum aquaporin-4 (AQP4) antibodies are detectable.

The precise relationship between clinical symptoms and MR findings is not well understood. Thus, MRI alone is not useful in predicting the clinical course of MS. T2-weighted MR images best define the size of white matter lesions, and gadolinium can reveal the disruption of the blood–brain barrier associated with an active MS lesion. In general, MR findings can be used to demonstrate evidence for dissemination in space and time when these features cannot be reliably determined clinically, such as when there is a clinically isolated syndrome. Dissemination in space is demonstrated by at least one lesion in two or more

Table 41-40 Criteria for Multiple Sclerosis

Clinical Presentation	Additional Data Needed
Two or more attacks (relapses); two or more objective clinical lesions	None; clinical evidence suffices (additional evidence desirable but must be consistent with MS)
Two or more attacks; one objective clinical lesion	Dissemination in space demonstrated by at least one T2 MRI lesion in at least two of four areas of the CNS
One attack; two or more objective clinical lesions	Dissemination in time demonstrated by a new T2- or gadolinium-enhancing lesion on follow-up MRI or simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time
One attack; one objective clinical lesion (monosymptomatic presentation)	Dissemination in space demonstrated by MRI findings described above <i>and</i> Dissemination in time demonstrated by MRI findings described above
Insidious neurologic progression suggestive of MS (primary progressive MS)	At least 1 year of progression of disease and two of the following three criteria: <ul style="list-style-type: none"> ■ Positive CSF ■ Dissemination in space demonstrated by MRI evidence of at least one T2 lesion in the periventricular, juxtacortical, or infratentorial region ■ At least two T2 cord lesions

CSF, Cerebrospinal fluid; MRI, magnetic resonance imaging; MS, multiple sclerosis.

Modified from McDonald WI, Compston A, Edan G, et al. Recommended diagnostic criteria for multiple sclerosis: guidelines from the International Panel on the Diagnosis of Multiple Sclerosis. *Ann Neurol*. 2000;150:121.

regions of the CNS, which include the periventricular, juxtacortical, infratentorial, and spinal cord regions. Gadolinium enhancement is no longer a requirement. MRI criteria for dissemination in time are a new T2 or gadolinium-enhancing lesion on repeat MRI compared with a prior MRI (a 30-day interval is no longer necessary) or a single MRI study with simultaneous asymptomatic enhancing and nonenhancing lesions.

The CSF analysis of patients with MS generally demonstrates a normal opening pressure, cell count, glucose level, protein level, and culture. The most clinically useful CSF abnormality is the presence of oligoclonal immunoglobulin G (IgG) bands resulting from intrathecal IgG synthesis, which can be found in up to 90% of patients with MS (Freedman et al., 2005). IgG bands are not specific to MS and are also seen in sarcoidosis, AIDS, and subacute sclerosing panencephalitis. The value of CSF analysis is mainly limited to MS patients with only a few lesions on MRI or to make the diagnosis of primary progressive MS, as discussed later. Visual-evoked responses may also provide supporting evidence for MS, particularly in situations with few abnormalities on MRI. Other VEP analysis offers little in establishing a diagnosis of MS (Gronseth and Ashman, 2000).

Clinical Course

Four subtypes of MS are currently described: relapsing remitting, secondary progressive, primary progressive, and

progressive relapsing. *Relapsing-remitting* MS accounts for about 85% of the initial diagnosis of MS patients and is characterized by acute attacks followed by full recovery. The interval between relapses can be variable and is characterized by a lack of disease progression. *Secondary-progressive* MS is characterized by a pattern that is initially relapsing remitting but then evolves into a pattern of progressive neurologic decline. MRI demonstrates more extensive lesions, and approximately 50% of patients initially diagnosed with relapsing-remitting MS will develop secondary-progressive disease. *Primary-progressive* MS, characterized by a gradual disease progression over at least 1 year from the initial onset, accounts for approximately 10% of MS diagnoses and has limited treatment options. Dissemination in space is demonstrated by at least one T2 lesion in the periventricular, juxtacortical, or infratentorial areas or at least two T2 lesions in the spinal cord, as well as the presence of oligoclonal bands in the CSF. *Progressive-relapsing* MS demonstrates a pattern of steady progression from the time of onset that may be punctuated by clearly defined relapses. The patients may or may not fully recover from these acute relapses.

Treatment

The treatment of MS can be divided into disease-modifying therapies, medications for acute relapses, and symptomatic management. Although there is no definitive cure, disease-modifying therapies may reduce the frequency of relapses, slow the rate of progression, and reduce the acute inflammatory response. Symptomatic therapy can improve the control of many of the functional disabilities and thus improve quality of life.

Disease-Modifying Therapies. It is generally held that disease-modifying therapy should be initiated immediately on the diagnosis of MS (Coyle and Hartung, 2002). Disease-modifying therapy has been shown to be more effective in preventing new lesion formation than repairing old lesions. These therapies include interferon β -1b (Betaseron, Extavia), interferon β -1a (Avonex, Rebif), and glatiramer acetate (Copaxone). The β interferons are immunomodulating medications that also have antiviral activities. They have been shown to reduce relapses in patients with the relapsing-remitting form of MS. Betaseron is given as an alternating-day SC injection, Rebif is a three-times-weekly SC injection, and Avonex is administered as a weekly intramuscular injection. All have similar side effects, including injection site reactions, influenza-like symptoms, and worsening of preexisting depression. Bone marrow suppression and transient elevation of liver enzymes may also occur.

Glatiramer (Copaxone) is a synthetic polypeptide consisting of four amino acids. It is thought to lead to the induction of antigen-specific suppressor T cells. It is administered as a daily SC injection and has been shown to reduce relapses by approximately 30% (Comi et al., 2001). Side effects include postinjection reactions and occasionally a reaction involving flushing, chest pain, anxiety, and dyspnea. The reaction is self-limited and does not require discontinuation of the medication.

Several orally administered disease-modifying treatments are now available. These include fingolimod (Gilenya),

teriflunomide (Aubagio), and dimethyl fumarate (Tecfidera). Of these, fingolimod and teriflunomide require monitoring of baseline CBC and LFTs as well as other indices before the start of treatment because of associated toxicities.

Two other disease-modifying drugs for MS are mitoxantrone and natalizumab. Mitoxantrone is a synthetic anthracenedione given by IV infusion once every 3 months. It has been shown to reduce MS relapses by 67% (Hartung et al., 2002). Mitoxantrone is blue and can lead to transient bluish discoloration of the sclera and urine. It also can cause cardiotoxicity and as a chemotherapeutic agent should only be prescribed for worsening cases of MS not responding to first-line agents. Only health care professionals experienced in the use of cytotoxic chemotherapy agents should administer mitoxantrone.

Natalizumab is a monoclonal antibody that blocks α_4 -integrin. This molecule is involved in moving circulating leukocytes into the brain in response to inflammation. It is administered as a 1-hour infusion every 4 weeks. Natalizumab has been shown to reduce clinical relapses, slow the progression of disability, and reduce the development of new brain lesions (Polman et al., 2006). Complications that limit its use include a hypersensitivity reaction up to 1 hour after infusion. Natalizumab has also been associated with progressive multifocal leukoencephalopathy, a destructive brain infection caused by JC virus. Therefore, the distribution and use of natalizumab is closely monitored, and it can be administered only by registered physicians.

One treatment that has no prophylactic benefit but does potentially improve function is dalfampridine (Ampyra). Its effect is to facilitate nerve conduction by blocking potassium channels, which in the affected axon tend to function in an aberrant fashion. The result is improved motor function, typically assessed by a 25-foot timed walk. There is a risk of seizures, particularly with overdosing, so patients with coexisting epilepsy should not receive dalfampridine.

Medications for Acute Relapses. Glucocorticoids are still widely used for the treatment of acute exacerbations of MS. The principal effects of corticosteroids appear to be related to their antiinflammatory and antiedema effects. It is recommended as standard therapy for any patient with an acute attack of MS (Goodin et al., 2002). Treatment normally consists of 3 to 5 days of a 1-g/day IV infusion of methylprednisolone. Oral prednisone taper may or may not be used after infusion.

Symptomatic Management. Medications used for symptomatic management depend on the specific symptoms encountered by the patient. MS patients frequently develop spasticity, which can be treated with baclofen, tizanidine, or benzodiazepines. Physical therapy can also help with spasticity. Bladder dysfunction can also occur in patients with MS. New bladder symptoms should be evaluated with a urine culture to rule out infection. A postvoid residual should also be obtained, as well as urodynamic testing to determine whether the problem is overflow incontinence from urinary retention or urge incontinence from detrusor instability. In the presence of urge incontinence, the anticholinergics oxybutynin (Ditropan) and tolterodine (Detrol) may be useful. If the problem is urinary retention and overflow incontinence, patients will usually need to be treated with intermittent self-catheterization. Patients may also experience depression, constipation, and sexual dysfunction. The usual evaluation and treatment options should be considered for patients who experience these problems.

KEY TREATMENT

- Both β interferons as well as newly available oral medications have been shown to reduce the number of relapses in patients with the relapsing-remitting form of MS (Coyle and Hartung, 2002) (SOR: A).
- Glucocorticoids are recommended as standard therapy for any patient with an acute attack of MS (Goodin et al., 2002) (SOR: A).
- Disease-modifying therapy should begin at diagnosis of MS (Coyle and Hartung, 2002) (SOR: B).

CHAPTER OUTLINE**Overview, 1039****Sexual Dysfunction, 1041****Female Sexual Dysfunction, 1041****Male Sexual Dysfunction, 1043****Substance- or Medication-Induced Sexual Dysfunction, 1047****Gender and Sexual Orientation, 1047****Sexuality Issues at Specific Times of Life, 1048****Conclusion, 1051**

Overview

Sexuality is a fundamental aspect of human self-concept and a complex biopsychosocial process. Physiologic aspects of sexuality are interpreted within the patient's cultural and social context. Family physicians and primary care providers are well situated to offer patients basic information regarding human sexual health issues and to evaluate and treat most common sexual problems; however, they seldom ask patients about sexual functioning. This chapter describes the basic principles of evaluation of female and male sexual dysfunction and clinical management of common disorders.

SEXUAL SELF-CONCEPT

Humans possess a gender identity and a sexual orientation. *Gender* is the publicly and usually legally recognized perception of an individual as male or female and often is synonymous with chromosomal or genital phenotype (male or female sex). Gender when assigned at birth is an individual's "natal gender." *Gender identity* is a social identity, an internal self-perception of being male or female, masculine or feminine, or occasionally a category neither male nor female. Individuals may be androphilic (sexually attracted to men) or gynephilic (sexually attracted to women) toward sexual partners of their own or the other gender. If desired sexual partners are their own gender, individuals may self-identify as gay or lesbian or, if both genders, bisexual. Someone who falls outside the societal norms of gender or sexual attraction may self-identify as "queer," a more fluid or inclusive term for gender or sexual attraction (or both). Although many people remain either androphilic or gynephilic their entire lives, some individuals may have different predominant sexual attractions at different times in their lives. The terms "men who have sex with men" (MSM) and "women who have sex with women" (WSW) are used because the sexual activity defines the risks, not the gender identity.

MODELS OF HUMAN SEXUAL RESPONSE

Masters and Johnson first described the physiology of the "human sexual response cycle" in 1966. Based on the

physical components of sexual functioning, they described four phases of the sexual response cycle: excitement, plateau, orgasm, and resolution (Figure 42-1). Helen Singer Kaplan subsequently described a more subjective, psychologically oriented sexual responsiveness model with three phases: desire, excitement, and orgasm. Nonlinear alternative models have been suggested, especially for women's sexual response (Basson and Schultz, 2007) (Figure 42-2). In certain settings, men may have similar nonlinear sexual responses.

INITIAL EVALUATION OF SEXUAL PROBLEMS

Many patients would benefit from detection and treatment of sexual problems; however, many clinicians do not ask, and patients may not volunteer the information. In the Global Study of Sexual Attitudes and Behaviors (GSSAB), which surveyed more than 27,000 adults age 40 to 80 years in 29 countries, 49% of women and 43% of men reported experiencing at least one sexual problem; fewer than 20% had sought medical assistance for sexual issues (Moreira et al., 2005). Health care providers should proactively and routinely address sexual health.

The sexual health interview may be approached with a screening or abbreviated method followed by in-depth questioning if necessary (Table 42-1). The answers on the detailed sexual history then direct the physical examination and appropriate laboratory testing. A physician may open the sexual history questioning with an *inclusion* technique. "Sexual health is important to overall health, so I ask all my patients about it. I'm going to ask you a few questions on sexual matters now." The clinician can use *normalization*, introducing emotionally laden or difficult subjects by implying these experiences are quite prevalent: "Many people have been sexually abused or molested as children. Did you have any experiences like that when you were young?" *Universalization* phrases questions as if everyone has done everything, making an affirmative answer easier for sensitive questions. For example, patients may be asked, "How often do you masturbate?" instead of "Do you masturbate?" The clinician should also reassure the patient about physician- or clinician-patient confidentiality. Physicians should avoid terms that make assumptions regarding patients' sexual behaviors. When inquiring about past or recent

sexual encounters, the clinician may inquire “with men, women, or both?” Using the term “partner” instead of “husband,” “boyfriend,” “wife,” or “girlfriend” may allow patients to discuss their sexual orientation openly. Slang words should be redefined in medical terminology so that the clinician and patient may communicate clearly.

Figure 42-1 Female (A) and male (B) sexual response cycles. Desire precedes both cycles in this model. The phases illustrated are excitement, plateau, and orgasm. The length of the plateau phase is variable. Women may have a brief plateau followed by orgasm (cycle C) or a long plateau with no orgasm (cycle B). Women may have multiple orgasms before resolution, although many do not (cycle A). For men with premature ejaculation, the plateau phase is brief. After ejaculation, men enter a refractory period lasting minutes to hours during which they are unable to ejaculate.

In 1976, Jack Annon proposed the PLISSIT model to approach sexual concerns: permission, limited information, specific suggestions, and intensive treatment (Table 42-2). Many clinical cases can be managed with brief education or limited advice, such as discussing normal physiologic sexual changes with aging or recommending books or products (e.g., water-based lubricant for vaginal dryness). When a referral has been made, scheduled follow-up visits support the patient during the process. Counseling may be extremely important, and the physician should research

Table 42-1 Questions for a Detailed Sexual History

- Are you currently sexually active? Have you ever been sexually active?
- Are your sexual partners men, women, or both?
- How many sexual partners have you had in the past month? Past 6 months? Lifetime?
- How satisfied are you with your (or your partner's) sexual functioning?
- Has there been any change in your (or your partner's) sexual desire or the frequency of sexual activity?
- Do you have, or have you ever had, any risk factors for HIV (blood transfusion, needle stick injuries, IV drug use, STIs, partners who placed you at risk)?
- Have you ever had any sexually related diseases?
- Have you ever been tested for HIV? Would you like to be?
- What do you do to protect yourself from contracting HIV?
- What method do you use for contraception?
- Are you trying to become pregnant (or father a child)?
- Do you participate in oral sex? Anal sex?
- Do you or your partner(s) use any particular devices or substances to enhance your sexual pleasure?
- Do you ever have pain with intercourse?
- Women: Do you have any difficulty achieving orgasm?
- Men: Do you have any difficulty obtaining and maintaining an erection? Difficulty with ejaculation?
- Do you have any questions or concerns about your sexual functioning?
- Is there anything about your (or your partner's) sexual activity (as individuals or as a couple) that you would like to change?

Sexual Dysfunction

Sexual functioning involves interactions among the physical, mental, and emotional aspects of an individual. The categorization outlined by the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) is used to define sexual dysfunctions. To be a “disorder,” the condition must cause the individual “clinically significant distress”; if an individual’s sexual response or functioning is outside of the statistical norm but does not cause the person distress, it is not a disorder. The DSM-5 describes subtypes to designate the onset or situation of the sexual dysfunction. Sexual dysfunctions may be “lifelong,” existing since the individual became sexually active, or “acquired,” appearing after an interval of normal sexual functioning. The sexual dysfunction may be “generalized” or “situational,” occurring in all instances or only with certain types of stimulation, situations, or partners, respectively. The DSM-5 also suggests defining the severity of the dysfunction as “mild,” “moderate,” or “severe” based on the distress of the individual regarding the dysfunction.

When evaluating a patient complaining of sexual dysfunction, a number of factors that may contribute solely or collectively to the individual’s sexual dysfunction need to be considered: (1) partner factors, such as a partner’s involvement or sexual response; (2) relationship factors, such as poor communication or emotional abuse; (3) individual vulnerability factors (e.g., body image), psychiatric comorbidity (e.g., depression, anxiety), and life stressors (e.g., unemployment); (4) cultural or religious factors; and (5) medical factors, such as physical disability or medications. Before a sexual dysfunction is diagnosed, the clinician must rule out that the patient’s perceived sexual dysfunction is not better explained by a medical condition or treatment for a medical condition, such as a medication, or by a mental health disorder, such as depression. In addition, an individual’s understanding of sexual functioning must be assessed. Occasionally, a patient complaining of a sexual dysfunction simply lacks the knowledge about effective modes of sexual stimulation or an understanding of

Table 42-3 Female Sexual Interest/Arousal Disorder

To be diagnosed with female sexual interest/arousal disorder, a woman needs to lack or have significantly reduced sexual interest/arousal for at least a 6-month duration manifested by at least three of the following six criteria:	<ol style="list-style-type: none"> 1. Absent or reduced interest in sexual activity 2. Absent or reduced sexual or erotic thoughts or fantasies 3. No or reduced initiation of sexual activity and typically unreceptive a partner’s attempts to initiate 4. Absent or reduced sexual excitement and pleasure during sexual activity in almost all or all sexual encounters (in identified situational contexts or, if generalized, in all contexts) 5. Absent or reduced sexual interest or arousal in response to any internal or external sexual or erotic cues 6. Absent or reduced genital or nongenital sensations during sexual activity in almost all or all sexual encounters
---	--

the normal decrease in sexual response associated with aging and needs education, not a diagnosis of sexual dysfunction.

Female Sexual Dysfunction

Key Points

- Female sexual interest/arousal disorder in the DSM-5 recognizes the interaction between desire and arousal as the trigger for a woman’s sexual response.
- Psychosocial interventions may be efficacious for the treatment of female sexual dysfunction.
- Selective serotonin reuptake inhibitor (SSRI) antidepressants delay or inhibit orgasm in women.
- The prevalence of genito-pelvic pain/penetration disorder ranges from 12% to 21% in the United States.

FEMALE SEXUAL INTEREST/AROUSAL DISORDER

For women, low sexual interest is the most frequently reported sexual problem. Four in 10 women state they have low sexual desire. The lack of or low sexual desire may not be distressing for all women; “distress” prevalence ranges in studies from 23% to 61% (Lindau et al., 2007; Shifren et al., 2008). Whereas in the DSM-IV-TR, women distressed by low or lacking sexual desire were diagnosed with “hypoactive sexual desire disorder,” the DSM-5 recognizes the complex interaction between sexual interest and arousal in women and defines “female sexual interest/arousal disorder.” To be diagnosed with female sexual interest/arousal disorder, a woman needs to lack or have significantly reduced sexual interest or arousal for at least a 6-month duration manifested by at least three of six criteria (Table 42-3).

Female sexual desire is a complex interaction among biologic, psychological, social, interpersonal, and environmental components. Ovarian function, especially ovarian androgens, may play an important role. In women age 20 to 49 years, low or lacking sexual interest/arousal disorder is almost threefold more likely in surgical postmenopausal women than premenopausal women (Leiblum et al., 2006). Life stressors, health problems, and personality

may play significant roles in the decrease in sexual interest or arousal of postmenopausal women, perhaps even more than the hormonal changes themselves (Ornat et al., 2013). Medical illnesses, such as thyroid disease, chronic pain conditions, urinary incontinence, and depression or anxiety, may negatively impact sexual interest or arousal. Medications can affect sexual interest or arousal, especially SSRI antidepressants, antihypertensives, antipsychotics, and narcotics. Fear of pregnancy or sexually transmitted infection (STI) and discord or communication difficulty in a couple's relationship may diminish sexual interest or arousal. The clinician must explore all aspects of the biopsychosocial model when evaluating a woman distressed by her sexual interest or arousal functioning.

Evaluation

Evaluation for female sexual interest/arousal disorder includes a thorough history and physical examination to detect any gynecologic, neurologic, cardiovascular, or endocrine disorders. Laboratory testing should include thyroid function, fasting glucose, lipid profile, and liver function. If a hormonal problem is suspected, prolactin, total and free testosterone, sex hormone-binding globulin, dehydroepiandrosterone (DHEA), and estrogen levels may be drawn. Androgen levels in premenopausal women should be measured at the peak on days 8 to 10 of a 28-day menstrual cycle.

Treatment

The U.S. Food and Drug Administration (FDA) has not approved any medication specifically for treatment of female sexual interest/arousal disorder. Estrogen therapy improves vaginal dryness but may not affect sexual interest. For women within 5 years of amenorrhea (early menopause), treatment with estrogens alone or in combination with progestogens was associated with a small to moderate improvement in sexual function, particularly in pain (Nastri et al., 2013). Because the lack of ovarian androgens is implicated in sexual interest and arousal, testosterone replacement has been investigated for women. No FDA-approved testosterone formulation exists at the time of this writing. A randomized controlled trial (RCT) of sildenafil in postmenopausal women with SSRI-associated sexual dysfunction demonstrated a significant improvement in delayed orgasm and arousal (lubrication) but no improvement in desire (Nurnberg et al., 2008). In small studies, bupropion improves sexual interest and arousal in premenopausal women and women taking SSRIs (Segraves et al., 2004). The FDA-approved Eros Clitoral Therapy Device uses a silicon cup to apply a vacuum to increase blood flow to the clitoris and surrounding tissue. The device appears effective in women without detectable disease and after radiation treatment for cervical cancer (Munarriz et al., 2003; Schroder et al., 2005), although sample sizes have been small.

Given the lack of effective allopathic treatment for low or lacking sexual interest and arousal, many women turn to complementary and alternative therapies. Compared with placebo, daily local intravaginal application of prasterone (DHEA) for 12 weeks improved desire and interest, arousal, orgasm, and pain at sexual activity in 216 postmenopausal women with moderate to severe symptoms of vaginal

atrophy (Labrie et al., 2009). Limited data exist for Ginkgo biloba, damiana leaf, ginseng, and other proprietary herbal blends that are marketed to improve female sexual interest and arousal (Simon, 2009). A review found psychosocial interventions in most published studies were reported efficacious for the treatment of female sexual dysfunction; however, the studies were heterogeneous and few in number, with multiple limitations (Gunzler and Berner, 2012).

FEMALE ORGASMIC DISORDER

Women demonstrate a wide range of orgasmic function, both subjectively and objectively. For a diagnosis of orgasmic disorder, women must have experienced a marked delay in orgasm, marked infrequency of or absence of orgasm, and markedly reduced intensity of orgasmic sensations over a 6-month time frame. Orgasmic dysfunction, the inability to reach orgasm when desired, may be lifelong or acquired. Some women may believe they have lifelong orgasmic disorder because, unlike many men, they do not reach orgasm solely with vaginal intercourse. A basic description of physical orgasm (i.e., pleasurable sensation in the genital area and contractions of the vagina followed by a feeling of physical and psychological relaxation) may facilitate discussion of orgasm. Many women prefer simultaneous vaginal and clitoral stimulation, oral-genital sex, or clitoral stimulation alone to have an orgasm and do not have an orgasmic disorder. In addition, the individual must express clinically significant distress regarding the diminished orgasmic sensations for an orgasmic disorder to be diagnosed.

In both lifelong and acquired orgasmic dysfunction, it is important to ask about past or current experiences of violence, victimization, and abuse. Social factors also affect a woman's experience of orgasm. Women taught negative messages regarding sexuality or with strict religious or cultural prohibitions on sexual attraction and thoughts may experience orgasmic difficulty even if the specified conditions for sexual behavior (e.g., marriage) have been fulfilled. Acquired orgasmic disorder can be caused by other medical illnesses and contributing contextual factors.

Evaluation

The clinical history in acquired orgasmic disorder should focus on the patient's perception of this dysfunction, including the time and circumstances of onset, possible causes, effect on relationship(s), and treatment goals. Physiologic functioning during sexual stimulation, including adequacy of lubrication and ability to sustain states of high arousal, should be explored. Contributing factors such as fatigue, depression, stress, substance abuse, and other medical illnesses should be considered. Contextual and relationship issues, including the possibility of abuse, should be discussed. Medications, especially SSRIs, may delay or inhibit orgasm in women. In most cases of orgasmic dysfunction, no specific physical examination or laboratory testing is necessary.

Treatment

Treatment of female orgasmic disorder usually involves increasing knowledge and sexual options for the patient and partner. Masturbation may provide information about

sexual responsiveness and preferred stimulations. Partner education regarding clitoral stimulation and adequate pre-intercourse lovemaking (foreplay) can change the focus from intercourse to mutual pleasuring, spontaneity, and sexual satisfaction. Referral for more in-depth therapy is indicated if the evaluation reveals significant relationship dysfunction, past abuse, or other severe medical or psychosocial complications.

GENITO-PELVIC PAIN/PENETRATION DISORDER

Genito-pelvic pain/penetration disorder refers to four commonly comorbid symptoms: (1) difficulty having intercourse, (2) genito-pelvic pain, (3) fear of pain or vaginal pain, and (4) tension of the pelvic floor muscles. A diagnosis can be made with marked difficulty in only one of these areas. The prevalence of genito-pelvic pain in large North American studies ranges from 12% to 21% (Landry and Bergeron, 2009). Genito-pelvic pain is often idiopathic but may follow pelvic trauma, such as painful intercourse, childhood or adolescent sexual abuse, sexual assault, rough gynecologic examination, complicated episiotomy, vaginal infections, pelvic inflammatory disease, or pelvic surgery. Often an avoidance of sexual intercourse or even speculum medical examinations occurs in response to the genito-pelvic pain.

Evaluation

The diagnosis is usually made by history. Pain during tampon insertion or the inability to insert a tampon before a woman becomes sexually active may be an important risk factor for genito-pelvic pain/penetration disorder. Patients report pain and difficulty with, or inability to engage in, vaginal intercourse or digital vaginal stimulation, using tampons or vaginal contraceptives, or having a pelvic examination. Patients may demonstrate visible contraction of the pelvic floor musculature with anticipated speculum examination. Physical examination may detect pertinent anatomic abnormalities, such as vaginal septa.

Treatment

Few studies exist on treatment for genito-pelvic pain/penetration disorder. Uncontrolled reports suggest that sex therapy may be helpful (McGuire and Hawton, 2005). If vaginal muscle tightening or spasm is present, therapy must be directed at restoring conscious control of vaginal muscle relaxation under conditions that respect the patient's autonomy and maintain the patient's safety from further trauma. If the patient expresses fear or anxiety, pelvic examination may be deferred, and in severe cases, sedation may be necessary. Any physical abnormalities detected on pelvic examination, such as infections, should first be treated. After this, the patient may begin self-treatment with size-graded plastic or silicone vaginal dilators, gradually teaching her vagina to remain relaxed and receive nonpainful, self-controlled penetration. Specialized physical therapists teach patients to use biofeedback to relax the pelvic floor musculature; this can be more effective than treatment with dilators and is often preferred by patients. Treatment of posttraumatic stress disorder and other sequelae of past trauma may be crucial. Referral to a sex therapist is often helpful.

Male Sexual Dysfunction

Key Points

- The prevalence of erectile dysfunction (ED) increases with age.
- Vascular risk factors (e.g. diabetes, smoking, obesity, sedentary lifestyle) increase the risk of ED.
- Phosphodiesterase-5 (PDE-5) inhibitors (e.g., sildenafil) are the first-line therapy to treat ED.
- Premature (early) ejaculation (PE) is defined as a less than 1-minute intravaginal ejaculatory latency. SSRIs can delay ejaculation and can be used to treat PE.

ERECTILE DYSFUNCTION

The National Institutes of Health Consensus Development Conference (1992) defined ED as “the inability for a male to achieve an erect penis as part of the overall multifaceted process of male sexual function.” The DSM-5 defines “erectile disorder” as ED accompanied by “clinically significant distress” that is not better accounted for by a nonsexual mental health disorder or the direct physiologic effects of a substance (e.g., drug of abuse, medication) or a general medical condition.

Both sympathetic and parasympathetic nerves regulate blood flow into the corpus cavernosum of the penis. Stimulation of the parasympathetic nerves causes release of nitric oxide (NO) from the noradrenergic, noncholinergic nerves and endothelial cells. NO increases the intracellular levels of cyclic guanosine monophosphate (cGMP) in the cavernosal smooth muscle, which relaxes the cavernosal tissues. With the resultant rapid blood flow into the corporal bodies of the penis, the small emissary veins that cross the tunica albuginea are occluded, and blood is trapped inside the corpus cavernosum, leading to an erection. The level of cGMP is also affected by prostaglandins. PDE-5 is the main cGMP-catalyzing enzyme in human smooth muscle. PDE-5 inhibitors increase cGMP levels and facilitate and maintain penile erection. The intact functioning of four body systems—vascular, neurologic, endocrine, and usually psychological—is necessary for a man to experience a penile erection.

Erectile dysfunction can occur at any age, but prevalence increases with age—2% for ages 40 to 49 years, 6% for 50 to 59 years, 17% for 60 to 69 years, and 39% for 70 years or older (Inman et al., 2009). Medical conditions associated with peripheral vascular disease, such as diabetes, coronary artery disease (CAD), stroke, and hypertension, increase the prevalence of ED. In men younger than 60 years, smoking, a sedentary lifestyle, and being overweight increased the risk for ED (Bacon et al., 2003).

Evaluation

Clinicians should carefully evaluate the patient's complaint of ED because some men consider PE as ED. Because penile erection depends on intact vasculature, the medical history is similar to one assessing cardiovascular risk factors: “What is bad for the heart is bad for the penis.” Several common classes of medicines can cause sexual

dysfunctions (Table 42-4). The social history should include the patient's smoking, alcohol, drug and marijuana use and important social and sexual relationships. The physician should also assess psychological factors such as depression and anxiety. Physical factors need to be considered. Some studies have shown that bicycle riding may cause ED

Table 42-4 Medications Affecting Sexual Function

Antihypertensives
β-Blockers (atenolol, metoprolol, bisoprolol, propranolol)
Thiazide diuretics (hydrochlorothiazide, chlorthalidone)
Sympatholytics (clonidine, methyldopa)
Calcium channel blockers (nifedipine, amlodipine)
ACE inhibitors (enalapril, lisinopril)
Antipsychotics
Antidepressants
TCA
Selective and nonselective serotonin reuptake inhibitors
Anxiolytics and Tranquilizers
Alprazolam
Diazepam
Antiandrogens
Ketoconazole
Spirolactone
5α-Reductase Inhibitors
Finasteride
Dutasteride
Digoxin
Gonadotropin-Releasing Hormone Agonists

Simvastatin
Cytotoxic Agent
Methotrexate

ACE, Angiotensin-converting enzyme; HIV, human immunodeficiency virus; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

from perineal compression and hence decreased penile blood flow; however, more investigation is needed (Sommer et al., 2010).

Physical examination focuses on signs related to the vascular, neurologic, and endocrine systems. Peripheral pulses should be palpated and carotids auscultated for bruits. The thyroid should be examined for enlargement or nodular disease. A thorough genitourinary examination should be performed. The clinician can assess perineal enervation with anal sphincter tone, perianal sensation, and the bulbocavernosus reflex. The penile shaft may show Peyronie disease (fibrous plaques of corpus cavernosa affecting erectile function or causing pain with erection). The prostate should be evaluated. Testicular atrophy may indicate low testosterone levels. If secondary sexual characteristics are lacking or the patient has other signs of hypogonadism, further endocrine evaluation should be undertaken.

Vascular risk factors should be assessed with fasting glucose and lipid profile. Blood urea nitrogen (BUN) and creatinine, serum transaminases, thyroid-stimulating hormone, and prostate specific antigen (PSA) levels should be considered. If the patient is young, deficient in secondary sexual characteristics, or has other signs of hypogonadism, a testosterone level should be determined. A low testosterone level, however, cannot be considered a definitive cause of ED. Many men with very low levels of circulating testosterone have normal libido and erectile function. Testosterone is highly protein bound to sex hormone-binding globulin, with only about 2% circulating as free testosterone; therefore, total testosterone levels may not reflect the bioavailable testosterone. The prevalence of abnormally low serum testosterone levels, even among men with ED, is only about 7%. Testosterone supplementation can be considered in men with low testosterone (<300 ng/dl) and ED (Table 42-5).

Treatment

Phosphodiesterase-5 inhibitors are first-line therapy for ED and are effective in most cases. Sildenafil (Viagra),

Table 42-5 Testosterone Replacement Options

Route	Drug Dose	Estimated Monthly Cost	Advantages	Disadvantages
Oral	Testosterone undecanoate, 120-240 mg 2 to 3 times daily	Not approved in the United States	Oral	Serum testosterone levels vary
Intramuscular	Testosterone enanthate, 250 mg every 2-3 wk Testosterone cypionate, 50-200 mg every 2-4 wk	\$100	Lower cost	Testosterone levels vary over the administration interval; higher risk of polycythemia; frequent injections
Subcutaneous	Testosterone pellets, two to six 75-mg implants every 3-6 mo	\$150 plus physician fees	Continuous level	Expensive; needs a procedure to implant; can spontaneously extrude
Buccal	Testosterone, 30 mg every 12 hrs	\$250	Self-administered	Twice-daily dosing oral irritation; bitter taste
Transdermal patch	5-10 mg/day	\$250	Daily administration	Skin irritation; expensive
Transdermal gel—cutaneous	50-100 mg/day	\$300	Daily administration; easy to adjust dose; no patch visible	Can take up to 10 minutes to dry; can transfer to contacts; expensive
Transdermal gel—axillary	2%: 30-120 mg/day 1.62%: 20.25-81 mg/day	\$300	Smaller amount of gel to apply	Can transfer to contacts; expensive

Data from Seftel, 2007 and Corona, 2011.

Table 42-6 Phosphodiesterase-5 Inhibitors

Parameter	Sildenafil (Viagra)	Vardenafil (Levitra)	Tadalafil (Cialis)
Dosages	25, 50, 100 mg	2.5, 5, 10, 20 mg	2.5 mg (taken daily), 5 mg, 10 mg (as needed dosing)
Absorption	Decreased if taken with high-fat foods	Decreased if taken with high-fat foods	Unchanged with food; decreased if taken with antacids
Onset of action (min)	30-60	30-120	16-30
Length of effect (hr)	3-5	4-5	24-72
Side effects	Headache, flushing, nasal congestion, dyspepsia, abnormal color vision	Headache, flushing, dyspepsia, nasal congestion, abnormal color vision	Headache, flushing, nasal congestion, dyspepsia, back pain, myalgia 12-24 hr after dose, color vision changes very rare
Metabolism	Hepatic	Hepatic	Hepatic
Drug interactions	Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole), moderate CYP3A4 (e.g., erythromycin), nonspecific	Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole) increase plasma levels; potential hypotension with nitrates and α -adrenergic blockers	Strong CYP3A4 inhibitors (e.g., ritonavir, indinavir, ketoconazole, itraconazole) increase plasma levels; potential hypotension with nitrates and α -adrenergic blockers
Dose reduction	CYP450 inhibitor (cimetidine) causes significant increase in plasma levels; potential hypotension with nitrates and α -adrenergic blockers	Patients older than 65 yr; hepatic impairment; no adjustment for moderate to severe renal impairment (CrCl <30 mL/min)	No dosage adjustment for age; not recommended in patients with severe hepatic impairment Daily use: no adjustment for moderate to severe renal impairment (CrCl >30 mL/min); not recommended for CrCl <30 mL/min As-needed use; reduce dose for CrCl <50 mL/min
Additional information	Patients older than 65 yr; hepatic impairment; severe renal impairment (CrCl < 30 mL/min)	May prolong QT interval	Nitrates given no sooner than 48 hr after dose; substantial consumption of alcohol (e.g., 6 oz of 80-proof vodka) increases orthostatic hypotension; no blood pressure drop with tamsulosin (selective α -adrenergic blocker)

CrCl, Creatinine clearance
Data from Campbell, 2005.

vardenafil (Levitra), and tadalafil (Cialis) differ in their absorption, potential effective time interval, and some side effects (Table 42-6). All oral PDE-5 inhibitors are more effective than placebo, with tadalafil more effective followed by vardenafil (Yuan et al., 2013). All PDE-5 inhibitors can cause increased vasodilation with nitrates and should not be used concomitantly; fatalities have been reported. Use with α -adrenergic blocker medications should also be avoided because of the risk of significant hypotension. Human immunodeficiency virus (HIV) protease inhibitors significantly increase the half-life of PDE-5 inhibitors by interfering with hepatic metabolism. PDE-5 inhibitors may need titration to an effective dose or dose reduction for age and hepatic or renal impairment. PDE-5 inhibitors have also been found to reduce lower urinary tract symptoms associated with benign prostatic hypertrophy (BPH), and tadalafil was approved for treatment of BPH in 2012 (Miller, 2013). The FDA has issued a warning against consumption of dietary supplements that claim to increase sexual pleasure or claim to have sildenafil or tadalafil.

Prostaglandin E_1 (PGE₁; alprostadil) is second-line treatment for men who have a contraindication for or have failed PDE-5 inhibitors. In all patients with ED, regardless of its etiology, PGE₁ improves the dysfunction (Urciuoli et al., 2004). Intraurethral alprostadil (MUSE—medicated urethral system for erection) is a pellet of synthetic PGE₁ that is absorbed across the urethral mucosa and increases corpus cavernosum blood flow. Intracavernous self-injection of alprostadil (Caverject, Edex) is another alternative, especially for patients with mild to moderate vascular disease not responsive to PDE-5 inhibitors. Alprostadil along with

papaverine (parenteral vasodilator) and phentolamine (an α -adrenergic blocker) (Tri-mix) has been used for ED. Complications, although relatively uncommon, include ecchymosis, hematoma, and painful erection. Although priapism occurs in fewer than 1% of users, patients should be warned to seek prompt medical attention if an erection lasts longer than 4 hours. Injection can also cause minor bleeding, so condom use is advised if bloodborne infection risk is present. Long-term use can result in fibrosis of the corpus cavernosum, and administration more frequently than three times weekly is not recommended.

Vacuum erectile devices (VEDs) can be used by men with ED from any cause. The penis is inserted into a tube in which a vacuum is applied, filling the corpus cavernosum with blood. A soft, constricting ring is placed at the base of the penis to prevent venous drainage from the corpus. Side effects include penile pain and numbness, bruising, and trapped ejaculation. Anticoagulant therapy is a relative contraindication. In men after a prostatectomy or who cannot use a PDE-5 inhibitor, a VED should be first-line therapy (Brison et al., 2013).

Penile prostheses remains an option for men who find traditional treatment undesirable or men who have not responded to or have a contraindication to traditional treatment. The two types of prostheses are malleable rods and inflatable prostheses. Side effects are related to surgery and anesthesia along with mechanical failure, penile shortening, soft or hypoactive glans, or pencil-like penile syndrome (Vitarelli et al., 2013).

Men with ED may seek complementary and alternative medicine for treatment. A systematic review showed some

evidence of effectiveness of red ginseng and yohimbine, although the studies were small and had limitations (Ernst et al., 2011). A study showed *melanocortin receptor agonists* (PT-141) along with a PDE-5 inhibitor to be safe and effective in men with minimal side effects in whom PDE-5 inhibitors were ineffective (Diamond et al., 2005).

Patients with ED primarily (or exclusively) of psychological origin may benefit from individual psychotherapy or pharmacologic therapy. Focused group therapy demonstrates greater efficacy than no therapy for ED. Group psychotherapy alone or with sildenafil significantly improves ED compared with sildenafil alone (Melnik et al., 2007). Men with sexual dysfunction often develop the “spectator effect,” fear of recurrent failure or difficulty, and focus attention on self-performance rather than pleasuring and enjoyment, further decreasing arousal. Similarly, “performance anxiety” increases sympathetic tone, which physiologically impedes erectile function. Sensate focus exercises by both partners directed by a certified sexual therapy counselor can be helpful. Relationship conflicts, contraception or fertility concerns, and religious or moral conflicts regarding sexual activity can affect erectile function. Depression, anxiety, adjustment disorders, substance abuse, and other psychiatric symptoms should be evaluated and treated. Survivors of physical or sexual abuse may require long-term treatment and support with a therapist experienced in this area.

Testosterone Supplementation for Erectile Dysfunction

Testosterone supplementation may or may not improve erectile function in hypogonadal men. One study found that previously unresponsive hypogonadal men using testosterone supplementation responded to sildenafil or apomorphine (Foresta et al., 2004). A double-blind placebo-controlled trial comparing transdermal testosterone versus placebo in men with ED and low testosterone levels demonstrated a 30% increase in total testosterone versus placebo in the treated cohort but no significant difference in erectile function (Allan et al., 2008). Several options exist for testosterone supplementation (see Table 42-5).

PREMATURE (EARLY) EJACULATION

Premature (early) ejaculation is ejaculation that occurs before or shortly after vaginal penetration. Studies in heterosexual men suggest a 60-second or less intravaginal ejaculatory latency to define PE; the duration definition may apply to all men regardless of sexual activities and partners, but research is lacking (American Psychiatric Association, 2013). Using the new DSM-5 definition of ejaculation occurring within 1 minute of vaginal penetration, approximately 1% to 3% of men would be diagnosed with PE. When using the DSM-IV definition, which was ejaculation occurring more rapidly than desired, prevalence was 20% to 30%.

Evaluation

Evaluation of PE is by history. Onset, circumstances, and meaning (personal and relationship) of the dysfunction should be explored, as well as pertinent past sexual experiences. For example, young men whose first sexual

experiences were rushed may later have difficulty establishing ejaculatory control in more relaxed contexts. Men having intercourse infrequently are more likely to ejaculate rapidly. The clinician should determine whether a patient can delay his ejaculation while masturbating. In addition, information regarding the patient’s level of sexual knowledge and his partner’s expectations may be significant. Evaluation for medical conditions such as hyperthyroidism or prostatitis that may shorten ejaculatory should occur.

Treatment

Selective serotonin reuptake inhibitor antidepressants can cause prolongation of the preorgasmic plateau and thus may delay ejaculation. Dapoxetine is a short-acting SSRI that can be taken as needed and is approved by the FDA for treatment of PE. RCTs show dapoxetine, 30 mg and 60 mg as needed, achieved statistically significant improvements in perceived control over ejaculation (Hellstrom, 2009). Using other SSRIs for PE is an off-label use. PDE-5 inhibitors added to SSRIs may further improve PE. Tramadol has been investigated as another oral agent; however, a large, international RCT of tramadol for the treatment of PE was stopped early (McMahon and Porst, 2011). Topical treatments that reduce the sensory stimuli to the penis (e.g., topical eutectic mixture of lidocaine-prilocaine spray) may increase ejaculatory latency time. Only weak or inconsistent evidence exists regarding the effectiveness of psychological interventions for the treatment of PE (Melnik et al., 2007).

DELAYED EJACULATION

Men who can sustain a full erection for a reasonable duration of sexual activity will usually be able to ejaculate. Only 75% of men report always ejaculating during sexual activity. Delayed ejaculation is diagnosed when the man has adequate sexual stimulation and the desire to ejaculate but subjectively has a delay or absence of ejaculation. Actual prevalence is unclear because the subjective definition and the time intervals to ejaculation vary. Alcohol use can cause difficulty with sustaining arousal or with orgasm. Contextual and partner issues may contribute to delaying ejaculation. Fewer than 1% of men will complain of delayed ejaculation lasting the 6 months needed for the diagnosis of delayed ejaculation disorder.

KEY TREATMENT

- PDE-5 inhibitors (sildenafil, tadalafil, vardenafil) are first-line therapy for ED (Yuan et al., 2013) (SOR: A).
- PGE₁, intraurethral or injected into the corpus cavernosum, is second-line treatment of ED (Urciuoli et al., 2004) (SOR: A).
- VEDs may help ED of any cause (Brison et al., 2013) (SOR: B).
- Men receiving group therapy plus sildenafil versus sildenafil alone showed significant improvement in erectile function (Melnik et al., 2007) (SOR: A).
- SSRI antidepressants improve PE by prolonging the preorgasmic plateau (Hellstrom, 2009) (SOR: A).

Substance- or Medication-Induced Sexual Dysfunction

The DSM-5 formalized the diagnosis of the sexual dysfunction that may be caused by medication or another substance. The sexual dysfunction must develop during or soon after the substance intoxication or withdrawal or after exposure to a medication. The substance or medication should be known to produce the symptoms for which the patient complains. Common substances are alcohol, opioid narcotics, amphetamines, and cocaine. Many common medications cause sexual dysfunction (see [Table 42-4](#)). Approximately 25% to 80% of individuals taking antidepressants, especially SSRIs or tricyclics, report sexual side effects, most commonly inhibited or delayed orgasm in both men and women and ED in men. Bupropion and mirtazapine do not appear to cause sexual side effects. For men with ED from SSRIs, administering sildenafil appears effective, but for women, adding bupropion at high doses may help ([Taylor et al., 2013](#)). Anticonvulsants, except for lamotrigine, have adverse effects on sexual desire. Gabapentin may affect orgasm. Chronic opioid use, even with appropriate use for pain management, lowers testosterone levels in men, which may cause decreased libido or ED. After discontinuing opioids, men may experience PE. Clinicians should inquire about sexual functioning in patients on medications or substances known to affect desire, arousal, or orgasm.

KEY TREATMENT

- For men with ED from SSRIs, administering sildenafil appears effective ([Taylor et al., 2013](#)) (SOR: B).
- For women with sexual dysfunction associated with SSRIs, adding bupropion at high doses appears most promising ([Taylor et al., 2013](#)) (SOR: C).
- Sildenafil may be a useful option in the treatment of antipsychotic-induced sexual dysfunction in men with schizophrenia ([Schmidt et al., 2012](#)) (SOR: B).

Gender and Sexual Orientation

Key Points

- Some individuals who have been sexually active with members of their own gender self-identify as heterosexual. Most clinicians overestimate the number of exclusively heterosexual patients in their practices.
- Women with same gender partners are less likely than heterosexual women to have had a mammogram or Pap smear recommended by a clinician in the past 3 years.
- Compared with heterosexual men and women, gay men, lesbian women, and bisexual women (LGB) are much more likely to have major depression and attempted suicide.
- The [U.S. Preventive Services Task Force \(USPSTF\)](#) suggests annual HIV screening in MSM.
- Preventive health care is important for transgendered individuals, and current guidelines should be consulted.

Sexual orientation is a social construct. Customs regarding which sexual acts are acceptable, with whom, and under what circumstances have varied in different cultures and eras. In *Sexual Behavior in the Human Male* in 1948, Kinsey and colleagues hypothesized that sexual orientation might be a continuous spectrum, from exclusive heterosexuality through exclusive homosexuality, and might vary across the life span in different people. Researchers have attempted to measure the prevalence of homosexuality and bisexuality in populations, with varying success and controversy. Some people who have been sexually active with members of their own gender self-identify as heterosexual. In one study, although only 2.8% of male respondents and 1.4% of female respondents self-identified as GLB, 10.9% of men and 4.3% of women ages 40 to 49 years reported having had at least one same-gender sexual experience since puberty ([Laumann et al., 1994](#)). Physicians likely overestimate the number of exclusively heterosexual patients in their clinical practices.

CARE OF LESBIAN, GAY, BISEXUAL, AND TRANSGENDERED PATIENTS

Lesbian, Gay, and Bisexual Patients

Lesbians are less likely to obtain health maintenance services, such as mammography and cervical cancer screening, than heterosexual women. Patients in same-gender couples are often not eligible for spousal health insurance benefits. Even when insurance status was the same, women with same-gender partners were less likely than heterosexual women to have had a mammogram or Pap smear recommended within the previous 3 years ([Buchmueller and Carpenter, 2010](#)). Many clinicians and lesbians mistakenly believe they do not need Pap smears. A woman self-identified as lesbian, however, may have been a victim of childhood sexual abuse, had a history of consensual male sexual contact, or may be bisexual. Nulliparous lesbians are at a high risk for cancers of the breast, endometrium, and ovary. Female-to-female transmission of STIs (including HIV/AIDS infection) is much less efficient than male-to-female transmission; however, genital–oral sex and fomites such as sex toys can transmit gonorrhea and *Trichomonas*, respectively. Mental health screening for depression and suicide should be considered, especially for “closeted” sexual minority women. Lesbians who had not disclosed their sexual orientation to a majority of friends, family, and coworkers were 90% more likely to have ever made a suicide attempt, and bisexual women were three times more likely to have made a suicide attempt than heterosexual women ([Koh and Ross, 2006](#)).

Gay men sometimes report difficulty in obtaining adequate health care caused by providers' bias and fear of discrimination. Any male patient who presents for treatment of urethritis should be asked about participation in oral-genital sex or receptive anal intercourse because some treatment regimens for urethral gonorrhea and chlamydia are not effective against pharyngeal and anal infections. A careful exposure history should be taken, even if the patient self-identifies as heterosexual, because some heterosexual-identified men have same-gender sexual experiences. Sixty percent of new HIV/AIDS infections in the United States are

in MSM. In 2013, the USPSTF recommended universal screening for individuals between ages 15 and 65 years and suggested annual screening in high-risk groups, such as MSM. Men who self-identify as gay or bisexual are more likely than heterosexual men to have major depression, to admit to suicidal ideation, or to have attempted suicide. Mental health screening for depression may be prudent in this population.

Transgendered Patients

Transgendered individuals transiently or persistently identify with a gender different than their natal gender. A *transsexual* individual is one who seeks to take on the social role of the other gender, either full or part time, often with the assistance of hormone therapy, surgery, or both. *Cross-dressers* (previously referred to as “transvestites”) are persons who at times may dress as the other gender to be publicly perceived as such or for sexual pleasure. *Intersex* is a different medical concept and refers to persons born with ambiguous genitalia or for whom phenotypic and chromosomal sex do not match (e.g., 5 α -reductase deficiency). Some persons do not perceive themselves as being fully male or fully female and seek to create new gender identities, similar to those found in many indigenous cultures. The prevalence of transgendered individuals is difficult to assess because of cultural and reporting limitations. One study gives an estimate of one in 11,900 to one in 45,000 for male-to-female (MtF) individuals and one in 30,400 to one in 200,000 for female-to-male (FtM) individuals (De Cuypere et al., 2007). *Gender dysphoria* is clinically distressing incongruence between one’s natal gender and one’s expressed or experienced gender. People may seek medical assistance in changing their physical sex to be congruent with their internal self-perception. People who identify as transgendered or who cross-dress are likely to be more numerous than individuals seeking sexual reassignment surgery.

Family physicians and other clinicians may be involved in the treatment of transgendered individuals, both in their medical transformation to relieve their gender dysphoria and in their overall health. To relieve the distress associated with gender dysphoria, some individuals need hormone therapy and surgery, but others need only hormones or surgery. Transgendered people receiving hormones can present a blend of gender-associated physical characteristics. MtF sex reassignment surgery is currently technically advanced, with postoperative MtF individuals often not identified as such even on cursory gynecologic examination. FtM surgery is more complex and prone to complications with more variable results. Because of the fear of being stigmatized, some patients may seek medical services without revealing their hormone use or operative history. In one study, 26% of respondents reported being denied medical care because they were transgender (Kenagy, 2005).

The management of feminizing or masculinizing hormone treatment for transgendered individuals can be managed by primary care physicians with appropriate education, such as the primary care protocol from the University of California-San Francisco Center of Excellence for Transgender Health (see [Web Resources](#)) or the World Professional Association for Transgender Health Standard

of Care for Gender for Health of Transsexual, Transgender, and Gender-Nonconforming People, seventh edition (Coleman et al., 2012). Establishing routine visits for hormone management provides the opportunity to discuss routine health promotion and preventive services. Current guidelines should be consulted, such as one provided by the University of California-San Francisco’s Center of Excellence for Transgender Health (<http://transhealth.ucsf.edu>). FtM reconstructive chest surgery does not remove all the glandular tissue as with a mastectomy; thus, FtM men who retain the axillary tail should at minimum continue self-examination. Clinicians should be alert for significant risks associated with feminizing or masculinizing hormones, such as increased risk of thromboembolic events with estrogen and increased cardiovascular events with testosterone.

The initiation of hormone therapy for modification of visible sex characteristics and sex reassignment surgery are life-changing medical interventions that should only be undertaken for patients who have completed an appropriate mental health evaluation and are in supportive mental health care. For clinical gender transition, a multidisciplinary team approach is ideal, such as in a comprehensive program or concurrent care from a mental health professional with experience in this area; a primary care physician knowledgeable about hormone supplementation and general transgender medical care; and urology, gynecology, and plastic surgery specialists. The World Professional Association for Transgender Health has resource links for patients (<http://www.wpath.org>).

Sexuality Issues at Specific Times of Life

ADOLESCENCE

Key Points

- Almost half (47%) of high school students report having experience sexual intercourse, with 15% reporting experience with four or more partners.
- Eight-four percent of high school students report being taught about HIV/AIDS in schools; however, only two thirds of sexually active male youth report condom use with their last sexual intercourse. The prevalence of condom use in adolescents has not changed significantly since 2003 (60%-63%).
- Twelve percent of female adolescents and 5% of male adolescents report being forced to have sexual intercourse they did not want. Almost 10% of adolescents report being hit, slapped, or physically hurt on purpose by a partner.
- Gender dysphoria can become apparent in young children or adolescents.
- Eight-four percent of LGBTQ (lesbian, gay, bisexual, transgender, and queer) youth report verbal harassment, 30% report physical abuse, and more than a quarter of them drop out of school because of harassment.

Although shyness, reticence, and embarrassment are common, most adolescents (77% in one survey) would like their health care providers to ask them directly about their sexual knowledge and experience (Rosenthal et al., 1999). Family physicians can use routine outpatient visits for school, camp, sports, or pre-employment physical examinations to offer medical information as it relates to the teenagers' current concerns.

Sexual Activity

The Centers for Disease Control and Prevention (CDC) conducts the Youth Risk Behavior Surveillance (YRBS) surveys every 2 years. In 2011, 15,503 questionnaires were completed in 43 states and 21 large urban school districts (158 high schools) nationally, with an overall response rate of 71%. Nationwide, almost half (47%) of all students reported having experienced sexual intercourse, with the prevalence by state ranging from 37% to 59%. Fifteen percent of teenagers reported experience with four or more sexual partners, ranging from 8% to 23% in the state surveys and 7% to 27% in the urban areas. Significantly more African American boys (32%) reported four or more sexual partners than Hispanic (20%) and white (13%) boys. Twice as many African American girls reported four or more sexual partners than Hispanic girls (18% vs. 9%) and one third more than white girls (13%). About one in five girls and boys report being sexually active (having sex with at least one person in the 3 months before the survey) in ninth grade, but by 12th grade, half of girls and 44% of boys reported being sexually active (Eaton et al., 2012).

Family physicians should remain mindful that teenagers may practice sexual acts other than intercourse. Some teens maintain sexual relationships involving mutual genital touching and masturbation for months or years before beginning intercourse. A significantly greater number of ninth grade students had engaged in oral sex than in vaginal sex (19.6% vs. 13.5%) and perceived fewer health, social, and emotional risks with oral sex than vaginal intercourse (Halpern-Felscher et al., 2005). Risks involved in oral-genital or anal sexual acts, such as oral transmission of gonorrhea or HIV infection with unprotected anal intercourse, should be discussed frankly with adolescents. Eight-four percent of high school students in the 2011 YRBS report being taught about HIV/AIDS in school, with 15% of girls and 11% of boys reported having had HIV testing. The prevalence of condom use has not changed significantly since 2003 (60%-63%), but use diminishes over time; 63% of sexually active 10th grade students reported condom use with sexual intercourse, decreasing to 61% and 56% of 11th graders and 12th graders, respectively (Eaton et al., 2012). Family physicians should remind sexually active adolescents to use a condom with each oral, genital, or anal intercourse to minimize HIV and other STI risk.

Family physicians should not assume that adolescent sexual experiences are consensual or desired. In the YRBS 2011, 8% of youth reported having been forced to have sexual intercourse they did not want (12% female, 5% male). Many teenagers who have had coercive sexual experiences do not identify these as rape or abuse. Asking a neutrally worded question (e.g., "Have you ever done anything sexual when you really didn't want to?") may open

the door to further dialogue regarding exploitive or traumatic sex. Almost one in 10 of adolescents report being hit, slapped, or physically hurt on purpose by a partner (blacks, 12%; Hispanics, 11%; and whites, 8%; 9.4% overall). The prevalence of dating violence may be even higher, with the reported range from 8% to 24% in large urban school districts (Eaton et al., 2012).

For adolescent patients, drug and alcohol use is a significant risk factor for unprotected sexual activity. In the 2011 YRBS, 22% of teenagers reported alcohol or drug use immediately before they last had sexual intercourse. Almost one third of white girls (31%) report using oral contraceptives before their last sexual intercourse, but only one in 10 black and Hispanic girls report that use. Long-acting contraception is often the best option for young women who are at risk for pregnancy because of substance use. Referral for treatment of addiction should be considered for adolescents who combine drinking with driving or sex and who are unable to discontinue this risk behavior without assistance.

Lesbian, Gay, Bisexual, and Transgender and Questioning Youth

Sexual orientation has three dimensions: attraction, self-identification, and sexual behavior. During adolescence, these three dimensions may not be congruent or may be fluid. In pooled data from the 2001 to 2009 YRBS surveys, 53.5% of high school students reported having had sex with the opposite gender, 2.5% reported having had sex with the same gender, 3.3% reported having had sexual contact with both genders, and 40.5% reported having had no sexual contact (Kann et al., 2011). By maintaining an open questioning style, such as asking, "When you think of people to whom you are sexually or romantically attracted, are they male, female, or both, or are you not sure yet?," the health care provider gives the adolescent permission to express their sexual orientation freely. Some adolescents are uncertain of their sexual orientation and are considered "questioning." The inclusive acronym for sexual minority (nonheterosexual) individuals is LGBTQ.

Gender Dysphoria

Awareness of gender occurs very early in life. A toddler can be aware of the physical differences between the genders. By 3 or 4 years, a child self identifies as a boy or girl. Thus, some children may express gender dysphoria as early as preschool. Not all children who express distress over their natal gender continue to have gender dysphoria by adolescence. Gender dysphoric adolescents may have more anxiety and depression or oppositional defiant disorder than non-gender dysphoric adolescents (Coleman et al., 2012). In 2013, the American Academy of Pediatrics published a statement to help guide clinicians in the care of LGBTQ children and adolescents (Levine, 2013).

Health Risks for LGBTQ Youth

In an environment critical of their emerging sexual orientation, LGBTQ adolescents may experience harassment, profound isolation, and fear of discovery, which interfere with achieving the developmental tasks related to self-esteem, identity, and intimacy. Eight-four percent of adolescents

who are open about their LGBTQ sexual orientation reported verbal harassment; 30% reported physical abuse. More than one quarter (28%) dropped out of school because of harassment (Levine, 2013). Censure, alienation, and abandonment by the family of origin represent a particularly devastating consequence for many LGBTQ teenagers. LGBTQ adolescents may become homeless after coming out to their families. Homeless LGBTQ adolescents may resort to the sexual trade to survive, risking STIs, HIV/AIDS, and pregnancy. LGBTQ adolescents are more likely to have had sexual intercourse, to have had three or more sexual partners, and to have experienced sexual intercourse against their will. Between 1997 and 2006, the rate of AIDS diagnoses reported among male adolescents 15 to 19 years nearly doubled, from 1.3 cases per 100,000 to 2.5 cases per 100,000 (CDC, 2009). LGBTQ teenagers are more likely than heterosexual peers to start using tobacco, alcohol, and illegal drugs at an earlier age.

Teenagers seeking family planning or obstetric services are not necessarily heterosexual; bisexual and lesbian respondents are two to seven times more likely to become pregnant than their heterosexual peers (Saewyc et al., 2008). Lesbian or bisexual young women have sexual intercourse with male partners at younger ages, more often engaging in sexual activity while under the influence of drugs or alcohol, and higher rates of forced or coerced sexual contact than heterosexual female adolescents (Tornello et al., 2013). Gay or lesbian youth were about half as likely to use a condom with their last intercourse than heterosexual youth (35.5% vs. 65.5%) (Kann et al., 2011). LGBTQ adolescents are twice as likely to have considered suicide in the past year as heterosexual youth (31% vs. 14%, 2007 YRBS). Primary care providers who care for adolescents, especially gay, lesbian, or bisexual youth, should be alert to the possibility of depression and suicide. For support, clinicians can suggest they contact the Gay, Lesbian, Bisexual, and Transgender National Hotline (888-843-4564 or <http://www.glnh.org>) or the Trevor Helpline (866-488-7386; 866-4UTREVOR), a 24-hour suicide prevention hotline that focuses on the needs of sexual minority youth.

OLDER ADULTHOOD

Key Points

- The likelihood of being sexually active correlates with good health status. Older women may be less likely to have a spouse or intimate partner because of their greater longevity.
- Testosterone levels are lower in men with chronic illnesses than in healthy men.
- Before testosterone replacement, men should have their prostates evaluated with a PSA and digital rectal examination. PSA should be drawn annually. Hematocrits should be monitored in men on testosterone.

Although the likelihood of being sexually active declines steadily with age, many older adults remain sexually active; 84% of men and 62% of women age 57 to 64 years and

67% of men and 40% of women age 65 to 74 years report being sexually active in the previous 12 months, with two thirds of both genders in each cohort sexually active more than two to three times a month. For those age 75 to 85 years, 39% of men and 17% of women reported sexual activity within 12 months (Lindau et al., 2007). Several factors impact the age related decline in sexual activity. As men and women age, physiologic changes in sexual functioning occur. During arousal, older men experience less scrotal vasoconstriction and testicular elevation, erection may be delayed or insufficient, and orgasm may be of shorter duration with less ejaculatory fluid. Women may have decreased labial engorgement and less vaginal lubrication during arousal and fewer and weaker uterine contractions during orgasm. Regardless of these physical changes, many older adults continue to have active sexual lives.

Approximately half of sexually active older adults reported at least one sexual problem, with almost two thirds having at least two bothersome sexual problems. Sexual problems most often reported by women were lack of interest (43%), difficulty with lubrication (39%), inability to climax (34%), finding sex not pleasurable (23%), and pain (17%). Among men, the most common sexual problems were difficulty in achieving or maintaining an erection (37%), lack of interest in sex (28%), climaxing too quickly (28%), anxiety about performance (27%), and inability to climax (20%) (Lindau et al., 2007). The likelihood of being sexually active is associated with good health. Men and women who reported good to excellent health were 80% and 70%, respectively, more likely to be sexually active than men and women with “poor” or “fair” health status (Lindau et al., 2007). Many common health conditions, such as arthritis or back pain, can inhibit sexual activity. Vascular disease and its risk factors, including CAD, stroke, diabetes, hypertension, hyperlipidemia, and smoking, correlate with ED (Laumann et al., 2005). Pudendal nerve disruption after hysterectomy and bladder, rectal, or prostate surgery may cause sexual dysfunction. Because they often take several medications, older adults may be particularly susceptible to medication-induced sexual dysfunction (see Table 42-4).

At all ages, women are less likely to be sexually active than men. However, 37% of women age 65 years or older reported some sexual activity, with 12% reporting at least weekly sexual activity (Huang et al., 2009). For women who reported no sexual activity in the previous 3 months, lack of interest (39%) was the most common reason followed by lack of a sexual partner (36%), physical problem of the partner (23%), and lack of interest by the partner (11%). Women may be more likely not to have a spouse or intimate partner because of their greater longevity. Between 75 and 85 years, men are almost twice as likely as women to have an intimate partner (78% vs. 40%) (Lindau et al., 2007). Lack of privacy may be problematic for elderly adults, who may live with family members or in long-term care settings.

A decline in sex steroid production is a factor in sexual dysfunction for both women and men. Postmenopausal estrogen deficiency is responsible for loss of vaginal lubrication and elasticity. The Women’s Health Initiative raised concerns regarding deleterious effects of systemic estrogen replacement (Rossouw et al., 2002). Clinicians should

counsel women, especially those older than 65 years, desiring long-term oral estrogen supplementation to diminish vaginal atrophy symptoms regarding the increased risk of CAD, thrombotic disease, and breast cancer. Vaginal estrogen supplementation by creams, tablets, or a vaginal ring may be helpful to decrease vaginal mucosal atrophy with much less systemic absorption. Women who remain sexually active may avoid significant vaginal atrophy through continued stimulation of the epithelium and vascular supply.

Testosterone levels do decline with age, eventually by 50% from midlife to old age. Free testosterone declines by 1.7% to 2.8% per year. Testosterone levels are lower in men with chronic illnesses than healthy men. Low testosterone levels associated with signs (increased abdominal fat, reduced muscle and bone mass, decreased body hair, gynecomastia, small testis) and symptoms (fatigue, weakness, decreased libido, decreased energy, erectile dysfunction) comprise the clinical syndrome of late-onset hypogonadism, also called androgen deficiency in the aging male or colloquially “low T.” Testosterone levels above 12 nmol/L (346 ng/dL) do not need supplementation, and testosterone replacement for levels below 8 nmol/L (231 ng/dL) is usually not controversial. Questions remain on treatment for testosterone levels between 8 and 12 nmol/L (231–346 ng/dL). In obese men, weight loss and increased physical activity can raise testosterone levels. Before testosterone replacement therapy (TRT), men should be screened with a PSA and a digital rectal examination and then have a PSA drawn annually. A PSA rise of 0.4 ng/mL over 2 years or an incremental rise of 1.4 ng/mL in 1 year should trigger further urologic examination (Mohr et al., 2005). Other risks of TRT are increased red blood cell mass. The hematocrit should be monitored regularly and TRT stopped if the hematocrit rises above 54%. Testosterone for replacement can be administered intramuscularly, subcutaneously, or transdermally (see Table 42-5). Replacement should only return testosterone levels to the physiologic level. Testosterone supplementation appears to have increased risk for men with cardiovascular disease. A study of testosterone supplementation in older men with CAD was halted early because of increased cardiovascular events in the treated cohort (Basaria et al., 2010). In a retrospective cohort study, men with known CAD by coronary artery catheterization using testosterone had a 5.8% increased absolute

risk of death, myocardial infarction, or stroke than non-users of testosterone, with a 29% increased relative risk of adverse events (Vigeri et al., 2013). More research is needed on testosterone supplementation risks for older men.

Conclusion

Sexuality is a core aspect of personal identity. Knowledge regarding human sexual behavior in health and illness across the life span will enable family physicians to provide appropriate care to patients who are experiencing sexual difficulties. Many patients with sexual problems can be treated by family physicians and other primary health care providers without assistance. Referral to a certified sex therapist should be pursued for more complicated cases. Family physicians should maintain awareness of the health care needs of persons with same-gender sexual experiences or orientation. Transgendered persons may have the health care needs of their former and present gender. Sexual health issues are pertinent for adolescent and older adult well-health care. Family physicians should routinely include questions regarding gender identity, sexual behavior, and relationships during the clinical interview of all patients to help maintain their optimum health.

Genetics in Primary Care Practice: Disease Illustrations, 1058

Overview

Key Points

- Discoveries related to a wide variety of conditions are increasing the prominence of genomics in routine patient care.
- Primary care providers should be aware of what is known and not known about the benefits and harms of emerging genomic clinical technologies.
- Primary care providers should become familiar with supportive resources and, when appropriate, seek out expert consultation to help manage genetic conditions.

We stand at a remarkable time in history regarding our understanding of how variations in the human genome contribute to health and disease. At least some of this progress can be attributed to the technologies developed to complete the Human Genome Project. The tools of genomics and molecular biology are unlocking the fundamental underpinnings of previously enigmatic conditions, shedding light on the fundamental nature of the human species (Feero et al., 2010).

Some of the most exciting developments in genomics over the past decade relate to the genetics of common disease, cancer care, and microbial genomics. In the area of common conditions (e.g., diabetes, heart disease, asthma) in which multiple genes and environmental factors interact to cause disease, genetic scientists have been able to use a powerful technique known as a *genome-wide association study* to identify human genome variations associated with common disease risk. Thousands of risk markers known as *single nucleotide polymorphisms* (SNPs) have now been reliably associated with the presence of a long list of common conditions and traits. Although each individual marker confers only a small risk of disease (which greatly limits their use in the clinic to predict risk in individual patients), many have helped to better define disease pathogenesis (Kraft and Hunter, 2009; Manolio et al., 2013). This may lead to new interventions for multiple common diseases down the road.

Perhaps the biggest initial impacts of the expanding genomic knowledge are novel targeted therapies with

improved efficacy and reduced toxicity compared with traditional chemotherapeutic agents. These are benefiting an increasing number of patients with cancer. This new generation of cancer treatments was made possible by insights into the pathological mutations responsible for tumorigenesis. Most of these insights could not have been achieved without the ability to sequence large numbers of samples of tumor and normal tissues from affected patients (McDermott et al., 2011). Application of rapid, accurate, and low-cost genotyping and sequencing technologies has also led to improved abilities to quickly identify and track emerging infectious disease threats in both the hospital setting and in international outbreaks (Relman, 2011).

We are at an early stage in the discovery process, and our embryonic knowledge of the human genome is not *easily* yielding rapid improvements in aspects of clinical care. This perspective is often lost in the media hype and attention given to the latest genetic discovery. The lack of a rapid translation from a new discovery to a proven clinical application (e.g., genetic test, targeted therapy) frustrates clinicians and patients alike and can lead to unrealistic and potentially harmful expectations. There is peril in the temptation to adopt promising, but as of yet unproven, clinical technologies. Primary care providers should recognize when the application of knowledge from genetic discovery is of proven benefit and when it is not. Perhaps most important, physicians should recognize that a substantial and rapidly expanding number of genomic applications fall into a gray area of unexplored benefit. The number of applications in this grey zone will continue to increase as fields such as epigenomics (the study of the consequences of chemical changes to DNA that don't affect the base pair sequence) mature. It is incumbent on providers to seek additional information from a reputable source when in doubt.

GENETICS VERSUS GENOMICS

The terms *genetics* and *genomics* are often used interchangeably in the literature, and this chapter is no exception. However, *genetics* is best viewed as the study of *single genes*, what they do, and how mutations in these genes cause disease. It is a snapshot of a specific situation, and environmental and behavioral factors often play a subordinate role. A prototypical genetic condition, cystic fibrosis (CF), is usually caused by a deletion mutation $\Delta F508$ in the *CFTR*

Table 43-1 Select Evidence-Based Recommendations for Genetic/Genomic Applications

Condition	Clinical Scenario	Recommendation	Organization, Year of Recommendation
Breast cancer	Screening	Primary care providers screen women who have family members with breast, ovarian, tubal, or peritoneal cancer with one of several screening tools; women screening positive should receive genetic counseling and, if indicated after counseling, <i>BRCA</i> testing	USPSTF, 2013
	Screening	Recommend against using <i>BRCA1</i> and <i>BRCA2</i> testing as screening tool in average-risk populations	USPSTF, 2013
	Treatment	Insufficient evidence to recommend for or against routine use of expression profiles to guide care in specific populations of women with breast cancer	EGAPP, 2008
Colorectal cancer	Case finding	Recommend offering counseling and tumor sample testing for Lynch syndrome to all patients with newly diagnosed colorectal cancer, to reduce morbidity and mortality in relatives	EGAPP, 2009
	Pharmacogenetic testing	Insufficient evidence to recommend for or against <i>UGT1A1</i> testing for patients with metastatic colorectal cancer	EGAPP, 2009
	Pharmacogenetic testing	Recommend <i>KRAS</i> testing for patients with metastatic colorectal cancer who are being considered for treatment with cetuximab or panitumumab	EGAPP, 2013
Hemochromatosis	Screening	Recommend against screening for hemochromatosis in asymptomatic individuals	USPSTF, 2008
Hyperlipidemia	Screening	Recommend earlier screening for hyperlipidemia in patients with family history of premature cardiovascular disease	USPSTF, 2008
Diabetes	Screening	Insufficient evidence to recommend testing for variants <i>TCF7L2</i> to assess risk for type 2 diabetes	EGAPP, 2013
Cardiovascular disease	Treatment	Recommend against routine use in adults with idiopathic VTE and family members to guide anticoagulation therapy	EGAPP, 2011
Prostate cancer	Testing	Recommend against routine use of the <i>PCA3</i> genetic test for prognosis of progression	EGAPP, 2013

VTE, Venous thromboembolism.

From the U.S. Preventive Services Task Force (USPSTF) and CDC Evaluation of Genomic Applications in Practice and Prevention (EGAPP) Working Group relevant to primary care. <http://www.uspreventiveservicestaskforce.org/uspsttopics.htm#Btopics>. EGAPP. <http://www.egappreviews.org/workinggrp/recommendations.htm>.

gene. *Genomics* is the broader study of “the functions and interactions of all the genes in the genome,” including how those genes interact with environmental and behavioral factors (Guttmacher and Collins, 2002). When considering genomics, it is important to recognize that environmental factors may be much more important in determining phenotype than genetic mutations. Common, so-called complex conditions, such as diabetes, cancer, and heart disease, are best considered from the perspective of genomics.

GENETICS AND EVIDENCE-BASED MEDICINE

As a discipline, *clinical genetics* originally developed in an environment that focused on the diagnosis and treatment of rare, or at least uncommon, disease. Often, large numbers of patients were not available for clinical trials, and in many cases, the severity of the conditions made randomized controlled trials (RCTs) untenable. This contrasts with *evidence-based medicine* (EBM), which primarily deals with common conditions and values large, prospective RCTs, as well as the public health consequences of individual medical choices. As genomic discoveries increasingly impact health care for common conditions, new

applications should be evaluated through a lens of *evidence of benefit*. Established groups that follow EBM precepts, such as the U.S. Preventive Services Task Force (USPSTF), for example, have issued recommendations on the potential of genomics for screening and testing for hereditary breast and ovarian cancer (HBOC) syndrome and hemochromatosis. The U.S. Centers for Disease Control and Prevention (CDC) has established newer groups such as the Evaluation of Genetic Applications in Practice and Prevention (EGAPP) specifically to review the evidence supporting genetic and genomic applications intended for health care use. Since 2005, the EGAPP has generated a number of evidence-based guidelines for the use of genomic technologies in patient care (Table 43-1). In 2013, the Office of Public Health Genomics (OPHG) at the CDC established a curated list of genomic technologies arranged into a three-tier system by available evidence of outcome benefits and the existence of guidelines regarding their use (OPHG, 2013). Considerable growing pains will occur as EBM and genomic medicine intersect, largely because the drive to adopt promising technologies outstrips the ability and resources to rapidly generate conclusive evidence of clinical benefit.

Family History: Best Guide to Genetic Components of Disease

Key Points

- Family history remains the best general tool for assessing a patient's risk for heritable conditions.
- Numerous guidelines relevant to primary care providers incorporate family history information.
- Evidence-based reviews have found that family history obtained from patients is generally accurate.
- Patient-completed web-based tools offer a convenient way to gather family history information.

Family history is arguably the single best tool for recognizing genetic components of disease in the primary care setting. Despite this, available evidence suggests it is very much underutilized in clinical care. In the context of single-gene disorders, family history has proved valuable for generations of clinicians and plays a major role in making a diagnosis and identifying at-risk individuals. Family physicians should be familiar with common patterns of inheritance of single-gene disorders, including X-linked recessive, X-linked dominant, autosomal dominant, autosomal recessive, and multifactorial or complex (Table 43-2). Classically, the three-generation genetic history known as a *pedigree* or *genogram* has been taught as the “gold standard” of family history collection. Certainly, after a potential genetic issue has been identified, a family physician should be comfortable in collecting and accurately representing a complete family history. However, taking a complete family history can be time consuming, and on a practical level, it is not always possible to collect in the context of a brief office visit. It is perfectly reasonable to gather, review, and update family history longitudinally.

Common diseases such as type 2 diabetes, coronary artery disease, and cancer also cluster in families. Family history captures both hereditary and environmental risks

and is an important component of many validated risk algorithms for these and other conditions. Recent attention has focused on the systematic collection of family history as a screening tool in primary care settings, particularly via direct entry into electronic medical records. Family history information supplied by patients is generally fairly accurate for a wide range of conditions. However, few well-designed trials have examined health outcomes associated with use of family history as a screening tool (Berg et al., 2009; Wilson et al., 2009).

Given competing demands on family physicians' time and resources, what genetic family history is the most important to capture? A national collaboration of primary care and genetics professionals has developed mnemonics to help clinicians think genetically as they provide patient care (Burke et al., 2001). The mnemonic, “FamilyGENES” highlights “red flags” that signal a genetic concern, as follows (Whelan et al., 2004):

- **F**amily history—multiple affected siblings or individuals in multiple generations
- **G**roups of congenital anomalies
- **E**xtrême (or **e**xceptional) presentation of common conditions
- **N**eurodevelopmental delay or degeneration
- **E**xtrême or **e**xceptional pathology
- **S**urprising laboratory values

Another mnemonic is SCREEN (for familial disease), which uses the following set of family history questions to uncover genetic implications:

- **S**ome concerns: Do you have any (some) concerns about diseases or conditions that seem to run in the family?
- **R**eproduction: Have there been any problems with pregnancy, infertility, or birth defects in your family?
- **E**arly disease, death, or disability: Have any members of your family died or become sick at an early age?
- **E**thnicity: How would you describe your ethnicity? *or* Where were your grandparents born?
- **N**ongenetic: Are there any other risk factors or nonmedical conditions that run in your family?

Table 43-2 Patterns of Inheritance Often Encountered in Primary Care

Pattern of Inheritance	Characteristics of Family History	Example Conditions
X-linked recessive	Males affected more than females, maternal inheritance, 50% risk of female carrier sons affected	X-linked color blindness X-linked muscular dystrophy
X-linked dominant	Males and females may be affected, males more severe, daughters of affected males affected, male and female transmission	Fragile-X syndrome
Autosomal dominant	Affected individuals usually in every generation, 50% probability of affected individuals having affected offspring, M = F	Huntington disease Hyperkalemic periodic paralysis Lynch syndrome Marfan syndrome HBOC syndrome
Autosomal recessive	Often multiple affected individuals in same generation, skipped generations, 25% risk of affected child for carriers, M = F	α_1 -Antitrypsin deficiency Cystic fibrosis Sickle cell disease Usher syndrome
Multifactorial	Clustering of cases in families, risk to first-degree relatives high, consequences of shared environment might be evident	Coronary artery disease Types 1 and 2 diabetes Many cancers

HBOC, Hereditary breast and ovarian cancer.

Electronic health record (EHR) systems seldom offer efficient and complete ways to collect and represent family history information. National efforts are underway to address this deficiency. Patient-completed paper and electronic tools provide another way to obtain a detailed genetic history. The [U.S. Surgeon General's Family History Initiative \(U.S. Surgeon General, 2013\)](#) includes a web-based tool that can be completed by patients, stored on their local computers, and shared with relatives and their health care providers in pedigree or table format (My Family Health Portrait; <https://familyhistory.hhs.gov>). This free, easy-to-use tool is an excellent way for patients with Internet access to record family history and is time saving for clinicians. The family history collected by the tool is now stored using emerging data standards that allow the data to be shared with EHR and personal health record systems. Alternatively, a number of organizations have created paper family history tools for patients and providers that are available on the Internet.

Genetic Testing

Key Points

- Knowledge of the indications for and limitations of genetic testing is relevant to common clinical situations in family medicine.
- The context of testing and its limitations are important for proper interpretation.
- Pretest and posttest counseling are currently recommended for genetic testing, although the need for such counseling in all testing situations is controversial.
- Genetic testing results can have implications for the family, and providers generally have a duty to warn potentially affected members.
- Family physicians should be involved in ordering, interpreting, and managing the consequences of genetic testing with health implications.

Identifying what constitutes a genetic or genomic test can be challenging. Traditionally, a genetic test measures changes in the sequence of DNA, but a “genetic test” can also be a measure of a protein or metabolite ([Table 43-3](#)). From this perspective, a fasting lipid panel could be

considered a genetic test. Also, a genetic test does not always need to be relevant to other family members, as when an individual's cancer cells are tested for mutations that affect prognosis and therapy. In some cases, a family physician's most important role is simply to reassure low-risk individuals that they do not need genetic testing.

The indications for genetic testing include confirming a diagnosis, identifying disease risk, and guiding therapeutic interventions. A genetic test can be done using many types of specimens, although testing for mutations in DNA is often done on DNA extracted from whole blood, saliva, or a cheek swab. Whereas some tests look for only specific mutations, others scan for all mutations in a specific DNA region. Testing costs can range from \$100 to thousands of dollars, depending on the complexity and patent status of the test. Often, testing an affected family member first is the preferred strategy. Without knowing the mutation present in a family, an asymptomatic patient's negative test result may not be informative because the particular test done may not include the mutation affecting that family.

Family physicians should be aware that genetic testing may have implications for the extended family as well as the patient. For example, studies with patients with Huntington have shown that genetic test results, whether positive or negative, have significant implications for patients and their families. This includes depression, lifestyle behavior changes, and relationship changes among family members. Those testing negative may have survivor's guilt or may be treated as being outside the family. Patients can benefit from counseling about implications before undergoing genetic testing that is both highly predictive and associated with profound health consequences ([Martin and Wilikofsky, 2004](#)). For genetic tests that are less predictive or are associated with conditions with less profound health consequences, the benefits of formal genetic counseling are less clear-cut.

Obtaining and interpreting molecular tests for DNA mutations often has unique considerations. First, it is important to order the correct test for the patient's condition; this is not always obvious, particularly when multiple tests are available. Second, the presence of a mutation in an asymptomatic individual only rarely predicts disease onset, course, or severity. This is particularly true for the multitude of recently discovered SNP markers associated with risk for common complex conditions. Third, absence of a known causal mutation in a gene may not mean that an individual

Table 43-3 Types of Genetic and Genomic Testing

Test	Example Methods	Clinical Scenarios	Example Conditions
Chromosomal analysis	Fluorescent in situ hybridization, karyotype, array comparative genomic hybridization	Pediatrics, prenatal testing	Down syndrome, unexplained mental retardation
DNA analysis	Allele-specific oligonucleotide hybridization, sequencing, fluorescent PCR assays, DNA microarrays, high throughput exome or whole-genome sequencing	Adult, pediatric, prenatal testing, pharmacogenetic testing	HBOC syndrome, Huntington disease, CF, warfarin pharmacogenomics, unexplained developmental delay
Biochemical tests	Various	Adult, pediatric, prenatal	Hyperlipidemia, phenylketonuria, quadruple screen
Expression profiling	cDNA measurement on microarrays, quantitative PCR	Adult, pediatric	Breast cancer, melanoma, colorectal cancer

cDNA, Complementary (copy) deoxyribonucleic acid; *CF*, cystic fibrosis; *HBOC*, hereditary breast and ovarian cancer; *PCR*, polymerase chain reaction.

is at no or low risk of disease. For example, in families meeting the clinical criteria for HBOC syndrome, testing for mutations in the *BRCA1* or *BRCA2* occasionally fails to detect a mutation in affected members. The absence of detectable mutations in affected individuals means that the test is essentially uninformative, and the risk to asymptomatic family members needs to be estimated from the clinical scenario and is not that of the average population ([GeneTests, 2013a](#)).

Because of the complex factors involved, genetic tests are frequently ordered by physicians with particular expertise regarding the condition for which testing is being considered. Expert clinicians may be medical geneticists or other medical specialists (e.g., oncologists, neurologists, cardiologists) with specific interest and knowledge of genetic conditions affecting their specialty area; a few primary care physicians have also developed expertise with some genetic conditions. Genetic counselors are individuals with masters level training in genetics who are specifically trained to help manage individuals with genetic conditions. In many health care environments, these professionals provide the required pre and posttest counseling related to genetic testing under the supervision of an overseeing physician. Genetic counselors can be exceptionally valuable partners for primary care providers managing patients with suspected genetic conditions. Currently, there are insufficient genetics professionals in all U.S. regions; as a result, primary care physicians will most likely be providing more genetic counseling and testing in the future. The next section provides a more in-depth look at settings in which different types of genetic testing are relevant to primary care.

EXAMPLES OF GENETIC TESTING

Preconception and Prenatal Screening

Genetic screening or testing can occur either before conception or during the pregnancy. When possible, screening or testing before a pregnancy is ideal because this provides the broadest range of choices if increased risk of a genetic defect is detected. Preimplantation genetic testing is available for an increasing number of conditions but is costly and not accessible to many individuals. Most genetic evaluations occur after the pregnancy is established. The ability to detect genetic defects has grown rapidly over the past decade. Many ethical issues exist in both the preconception and the prenatal screening or testing environment, including the course of action if the fetus is found to have an incurable, life-altering condition. Common indications for prenatal testing are advanced maternal age, previous child with a chromosomal abnormality, family history of abnormality or single-gene disorder, family history of neural tube defect or other structural abnormality, abnormalities identified in pregnancy (e.g., on ultrasonography), parental consanguinity, recurrent miscarriages, previous unexplained stillbirth, parental ancestral origin, and use of certain medications. The American College of Obstetricians and Gynecologists (ACOG), March of Dimes, and American College of Medical Geneticists have developed or compiled guidelines for recommended tests. However, these guidelines are often based on consensus or expert opinion and do not always agree.

High-resolution ultrasonography, maternal serum marker testing, and maternal serum-based cell-free fetal DNA tests are screening tests for congenital anomalies associated with a variety of genetic conditions. More invasive testing, such as chorionic villus sampling and amniocentesis, can provide accurate diagnosis of genetic conditions but at the cost of a higher risk of complications. Available guidelines suggest that amniocentesis be offered to all pregnant women to aid in the detection of Down syndrome ([ACOG, 2007](#)). Rapid advances in cell-free fetal DNA testing of maternal serum may supplant more invasive testing. The family physician should evaluate the risks and benefits of all forms of prenatal genetic screening or testing, discuss them with the patient and her partner, and make referrals to health care providers with genetics expertise as appropriate.

Newborn Screening

The first genetic testing encountered by most individuals is the heel stick at 24 hours after birth. The advent of the Recommended Uniform Newborn Screening Panel and an improved evidence-based process for selecting conditions to add to newborn screening panels in the United States has led to a growing uniformity of newborn screening across the states ([National Newborn Screening and Global Resource Center, 2013](#)). The majority of conditions included on the panel are genetic, although testing for most conditions relies on measuring the presence of metabolites in newborn blood samples using gas chromatography mass spectrometry. DNA-based newborn screening protocols are being adopted nationally for conditions such as CF and severe combined immune deficiency.

Hearing screening in the newborn period has also been remarkably successful, and through such screening programs many heritable forms of congenital hearing loss are identified in time for early intervention and counseling of parents considering additional children. The Recommended Uniform Newborn Screening Panel has also been updated to include routine use of pulse oximetry screening to identify infants with serious congenital heart defects, which occur in up to 1% of newborns.

Pharmacogenetics

Pharmacogenetics is the study of genetically determined variations in response to medication. This can include variations in how a drug is metabolized as well as how drugs interact with intended as well as unintended targets in the body. Pharmacogenetic testing can be useful in ensuring accurate drug dosing, avoiding adverse side effects, and selecting drugs. The U.S. Food and Drug Administration (FDA) mandates that many drugs contain information referencing pharmacogenetic testing in their labeling. Although family physicians should be aware that such labeling exists, the evidence of benefit of testing for these variations is not uniform across drugs. For example, preliminary clinical data suggested that testing for variations in two genes related to warfarin treatment would improve care of patients requiring anticoagulation with this drug. This led to prominent inclusion of information regarding pharmacogenetic testing in the warfarin drug label by the FDA. Subsequently, a major study suggested that there was no appreciable benefit of adding pharmacogenetic testing

Table 43-4 Pharmacogenetic Testing

Drug	Gene	Notes
Abacavir	<i>HLA-B*5701</i>	HIV-1 patients
Aminoglycosides	<i>A1555G</i>	Not routinely
Antifolate chemotherapy	<i>MTHFR</i>	Not routinely
Azathioprine	<i>TPMT</i>	Not routinely
β-Blockers	<i>CYP2D6</i>	Not routinely
Irinotecan	<i>UGT1A1</i>	Not routinely
Opioids	<i>CYP2D6</i>	Not routinely
Oral contraceptives	FVL, prothrombin G20210A, others	Family and personal history of VT can be used
SSRIs	<i>CYP450</i>	EGAPP recommended against, 2007
Carbamazepine	<i>HLA-B*1502</i>	For Asian Americans
Warfarin	<i>CYP2C9</i> and <i>VKORC1</i>	Algorithms may work as well or better

HIV-1, Human immunodeficiency virus type 1; *EGAPP*, Evaluation of Genomic Applications in Practice and Prevention; *SSRI*, selective serotonin reuptake inhibitor; *VT*, venous thrombosis.

to the initiation of warfarin anticoagulation. This being said, a variety of pharmacogenetic tests are routinely used to guide treatment of oncology and infectious disease patients based on evidence of clinical benefit. Current recommendations of pharmacogenomic tests for some conditions common in family medicine are in [Table 43-4](#).

Recent promising applications of pharmacogenomics measure variations relevant to drug responsiveness in cancer. Often, cancer drugs are toxic and expensive, so more individually targeted therapy (personalized medicine) based on the mutations present in a patient's tumor prove valuable over time. Examples include testing breast cancer tumors for overexpression of *HER2* receptor to guide use of targeted therapies and *KRAS* oncogene mutations testing to guide colorectal cancer (CRC) treatment ([Allegra et al., 2009](#)). Testing for mutations in patients' tumors is now a part of routine oncologic care for a growing variety of cancers, including breast, colon, lung, stomach, leukemia and lymphoma, and metastatic melanoma. The availability of low-cost sequencing of patient normal and tumor DNA is driving innovation in cancer care at a very rapid pace, and many more clinical applications of pharmacogenetic testing relevant to cancer care are in the pipeline for clinical release.

Direct-to-Consumer Testing

Since the completion of the Human Genome Project in 2003, more companies now offer direct-to-consumer (DTC) genetic testing. The public profile of DTC testing has increased dramatically over the past several years with the advent of inexpensive, genome-wide scans for SNPs. Tests that measure millions of genetic variations simultaneously can be obtained with a saliva sample and a few hundred dollars. The majority of these markers are probably of little significance to the tested individual's health, and patients may both overestimate and underestimate their personal risk of disease based on the results of such testing.

Other types of DTC genetic tests offered can be grouped into "medical" and "nonmedical" categories. Medical tests

include highly validated DNA testing for specific mutations in classic single-gene mendelian disorders, pharmacogenetic testing, and paternity testing. Nonmedical testing ranges from determining one's ethnic and geographic origins or athletic prowess to ear wax type. DTC testing can offer advantages of anonymity for testing as well as easy access to genetic tests that might be difficult to obtain through routine health care channels. The consumer pays for most DTC genetic testing.

Clinicians should recognize that "buyer beware" applies to DTC genetic testing. National regulatory oversight ensuring the analytic and clinical validity of these tests is inadequate, although some states (California, New York) have enacted laws to increase scrutiny of consumer-oriented tests. Late in 2013, the FDA effectively stopped DTC SNP-based testing for common disease risk in the United States because of potential for harm from inaccurate or misleading results; it remains to be seen if consumer demand and advances in science will change this position. Even with accurate testing, there is no assurance that the result will be clinically useful to the individual. This is particularly problematic when a trained health professional is not available to help individuals appropriately select and interpret genetic testing. Companies now offer phone-based genetic counseling services independent of any testing services. Ideally, a trained health professional should be involved in ordering and interpreting any genetic or genomic testing with health implications.

Ethical, Legal, and Social Issues

Key Points

- Clinicians should consider potential ethical, legal, and social issues (ELSI) when discussing genetic testing with patients.
- The Genetic Information Nondiscrimination Act (GINA) provides national protections against health insurance and employment discrimination based on genetic information. Health Insurance Portability and Accountability Act (HIPAA) provides insurance portability and privacy protections. Some states have more comprehensive statutes to prevent genetic discrimination.
- The Affordable Care Act (ACA) provides protection against discrimination in health insurance for individuals with preexisting genetic conditions.
- Case law suggests that family members have a right to know whether genetic information affects their personal health and that health care providers have a duty to warn family members of health risks.
- Minors incapable of providing informed consent should not be tested for conditions not immediately relevant to their health or not treatable in childhood.

Significant potential ELSIs are associated with the use of genomic technologies in health care, and funding for research regarding ELSIs was part of the Human Genome Project from the outset. ELSIs include concerns regarding potential for discrimination or stigmatization based on

one's genome, the right to know or not know one's genetic status in family settings, potential adverse effects of genetic testing on reproductive decision making, and discomfort with genetic testing of conditions for which treatment in childhood is not recommended or is not available.

Many patients are concerned that genetic information could be used as a tool for discrimination by health insurers and employers. In 2008, the GINA became U.S. law and provides national protection against use of genetic and family history information as a basis for discrimination by health insurers or employers (Hudson et al., 2008). However, the law does not prevent use of genetic information by life, long-term care, or disability insurers. Some states have laws providing for more stringent protections than those afforded by GINA, and physicians should be aware of the protections their states provide. The passage of the ACA of 2010 has provided very important protections to individuals with genetic conditions that often require very costly care, by preventing insurers from denying coverage or setting rates based on preexisting conditions.

Family physicians must remember that a genetic diagnosis affecting a patient may have implications for the entire family. Before genetic testing, they should discuss the need to inform family members of abnormal results that might affect them. When a patient does not want family members to know that they have a genetic disease, the HIPAA has clarified and strengthened the patient's right to privacy of medical information. When knowledge of the patient's condition would not change health outcomes for the relative, the physician has no duty to warn. If the information can affect other family members' health, this presents a quandary. Some courts have ruled that physicians are liable for failure to inform other family members. Physician assistance in informing family members can also help the patient (Offit et al., 2004).

Several national groups of genetics professionals have developed consensus guidelines against genetic testing in *minors* unless there is a potential immediate benefit to the child's health. Experience in adult-onset conditions has revealed that many people choose not to know if they are at risk for a genetically determined condition. Knowing about the risk of developing an adult illness in childhood, when no treatment or intervention is available, may present unnecessary intrusion into normal child and family development. Consequently, rather than test minors, it is often advisable to wait until adulthood so that a fully informed decision can be made about testing.

Reproductive decision making can be complex. It is important to remember that the quadruple screen or high-resolution ultrasound during pregnancy is genetic testing. Before patients undergo preconception or prenatal screening or testing, family physicians need to discuss the patient's expectations about results and subsequent pregnancy planning. Counseling before fetal testing should include detailed information about risks; benefits to parents and infants; probability of abnormal results; and implications of possible results, including inconclusive results or those indicating alternate paternity. Reproductive counseling has followed a nondirective model in which the health professional avoids biasing the woman's or the couple's decision-making process.

Genetics in Primary Care Practice: Disease Illustrations

Key Points

- Health care providers should recognize when genetic factors contribute meaningfully to risk assessment, diagnosis, or disease management for rare conditions as well as common multifactorial conditions.
- Staying current with advances in diagnosis and treatment of genetic conditions challenges both genetic specialists and family physicians.
- Family physicians should identify and utilize credible and current information resources to support their care of patients with heritable conditions because proper diagnosis and management can be lifesaving.

Table 43-5 lists examples of multifactorial, single-gene, and chromosomal disorders seen in family medicine, including genetic information about each disease (Acheson and Wiesner, 2004; Christiansen et al., 2005; Gaston et al., 1986). In aggregate, single-gene and chromosomal disorders are relatively common. Physicians should remain alert for single-gene diseases when seeing patients, which can include causes of cancers, anemia, liver disease, developmental delay, and deep vein thrombosis. Making a correct genetic diagnosis can lead to lifesaving interventions for affected patients and their families.

Much research is needed regarding the genetics of multifactorial disorders, and predispositional genetic testing for such conditions using newer markers (e.g., disease-associated SNPs) is not currently recommended. A few examples illustrate what can currently be done with genetics and genomics in primary care.

HEREDITARY BREAST AND OVARIAN CANCER

A family history of premenopausal breast cancer in a first-degree relative doubles personal breast cancer risk. These women may benefit from earlier screening and should be counseled about the benefits of early detection. An autosomal dominant pattern of inheritance is seen in a much smaller number of families, perhaps 5% of women with breast cancer, known as HBOC syndrome. Current USPSTF guidelines suggest that physicians should recognize individuals from such families because they may benefit from counseling about HBOC and testing for mutations in the *BRCA1* and *BRCA2* genes. Risk factors include breast or ovarian cancer (or both) occurring at an early age in the family, in multiple individuals in the family, the presence of male breast cancer in a family, and Ashkenazi Jewish ancestry. The USPSTF recommends against using *BRCA1* and *BRCA2* mutation testing as a screening tool in the absence of a suggestive personal or family history.

Numerous *BRCA* mutations have been found, and their prevalence in the general population is about 1 in 800 but up to 1 in 40 in people of Ashkenazi Jewish descent. Pretest and posttest counseling is very important for HBOC testing. The ACA mandates that most insurers (with the notable exception of Medicare) cover genetic counseling for at-risk individuals and, when appropriate, *BRCA1* and *BRCA2*

Table 43-5 Multifactorial, Single-Gene, and Chromosomal Disorders Seen in Family Medicine

Condition	Inheritance Pattern	Genes Involved*
SINGLE-GENE DISEASES		
Early-onset Alzheimer disease	Autosomal dominant	<i>APP, PSEN1, PSEN2</i>
Breast cancer	Autosomal dominant with incomplete penetrance	<i>BRCA1, BRCA2</i>
Colon cancer (Lynch syndrome)	Autosomal dominant with incomplete penetrance	<i>MLH1, MSH2, MSH6, and PMS2</i>
Cystic fibrosis	Autosomal recessive	<i>CFTR</i>
Hemochromatosis, adult	Autosomal recessive	<i>HFE</i>
Marfan syndrome	Autosomal dominant	<i>FBN1, TGFBR2</i>
Sickle cell disease	Autosomal recessive	<i>HBB</i>
Tay-Sachs disease	Autosomal recessive	<i>HEXA</i>
β-Thalassemia	Autosomal recessive	<i>HBB</i>
Familial hypercholesterolemia	Various	<i>LDLR, ApoB, PCSK9, LDLRAP1</i>
CHROMOSOMAL DISEASES		
Down syndrome	Sporadic	Trisomy 21
Fragile X syndrome	X-linked dominant with incomplete penetrance	<i>FMR1</i> , with >200 CGG repeats
Turner syndrome	Sporadic	XO karyotype
XXY Males (Klinefelter syndrome)	Sporadic	XXY karyotype
MULTIFACTORIAL DISEASES		
Alzheimer disease	Multifactorial	<i>APOE4</i> , multiple SNPs
Asthma	Multifactorial	Multiple SNPs
Coronary artery disease	Multifactorial	Multiple SNPs
Depression	Multifactorial	Multiple SNPs
Type 1 diabetes	Multifactorial	HLA variants and multiple SNPs
Type 2 diabetes	Multifactorial	Multiple SNPs
Venous thromboembolism	Multifactorial/autosomal dominant	Factor V Leiden (FVL), proteins C and S, prothrombin G20210A, antithrombin III

*Most common mode of inheritance for each condition listed; for many common multifactorial conditions, there are rare instances of mutations in single genes causing a similar disease.

SNP, Single nucleotide polymorphism.

Data from Gene Tests (<http://www.genetests.org>); Online Mendelian Inheritance in Man (<http://www.ncbi.nlm.nih.gov/omim>); and National Human Genome Research Institute Genome Wide Association Study catalog (<http://www.genome.gov/26525384>).

mutation testing. The presence of many rare mutations and mutations of unknown clinical significance in the population can make interpretation of testing complicated, and involvement of a clinician with specialized knowledge is advisable.

Women with *BRCA* mutations may have up to an 80% lifetime risk of breast cancer and a 40% risk of ovarian cancer depending on the mutation. The risk of other cancers is also greater, although less so. It is important to recognize that men with *BRCA* mutations develop breast cancer at much higher rates than the general population. In fact, a diagnosis of male breast cancer should lead to a careful review of family history. Personal risk depends on the specific gene variant involved and other risk factors. Aggressive strategies aimed at early detection (e.g., breast magnetic resonance imaging [MRI]) are frequently recommended, but evidence of comparative effectiveness is not complete. Interventions such as bilateral mastectomy and oophorectomy have an enormous impact on women's lives, but evidence suggests these surgeries may confer up to a 90% reduction in cancer risk (National Comprehensive Cancer Network [NCCN], 2013).

Evidence regarding prophylaxis with tamoxifen or related agents is equivocal and may be related to the specific causal

mutation. Although routinely offered to individuals with *BRCA* mutations, little evidence supports the use of annual CA-125 and transvaginal ultrasonography to screen for ovarian cancer. Options for prevention and treatment are increasing over time, and more targeted and less invasive options may become available.

KEY TREATMENT

- Women with a personal or family history suggestive of HBOC syndrome should be screened for breast cancer risk using a validated tool. Those screening positive should be offered genetic counseling and, when appropriate, testing for mutations associated with HBOC syndrome (USPSTF, 2013) (SOR: A).
- Enhanced breast cancer screening with annual mammograms and breast MRI starting at age 25 years or 10 years earlier than the age of earliest diagnosis in the family are recommended for individuals with *BRCA* mutations (NCCN, 2013; Saslow et al., 2007) (SOR: C).
- Prophylactic mastectomy and oophorectomy dramatically reduce the risk of breast and ovarian cancer in HBOC patients (NCCN, 2013) (SOR: B).

HEREDITARY COLORECTAL CANCER

About 10% of the general population has a first-degree relative with CRC; this history increases personal lifetime risk for CRC from 9% to 16%. Many guidelines recommend early screening for these individuals—by age 40 years or 10 years earlier than the age at diagnosis of a family member. Early detection and removal of adenomatous polyps have made determining family history more difficult. Patients should be asked about removal of polyps in relatives, and those who have adenomatous polyps should be encouraged to tell their families.

A family history that contains many relatives with CRC, adenomatous polyps, or endometrial cancer, especially in more than one generation or with early onset (age <50 years) suggests an autosomal dominant pattern of inheritance. Two relatively common, autosomal dominant, hereditary CRC syndromes account for about 3% to 5% of all CRC cases: Lynch syndrome and familial adenomatous polyposis (FAP).

Lynch syndrome, or hereditary nonpolyposis colon cancer syndrome (HNPCC), occurs in about 1 in 200 to 800 families and is underdiagnosed in primary care settings. Lynch syndrome is caused by mutations in mismatched repair genes and confers an approximately 80% lifetime risk of CRC. Often these cancers are right sided and occur at an earlier age than sporadic CRC. Women with HNPCC have an increased risk for endometrial cancer; the incidence of other gastrointestinal and central nervous system cancers is also increased but to a lesser degree. Evidence-based guidelines suggest that CRC screening with colonoscopy should begin in the 20s for affected individuals. Screening for endometrial cancer is also recommended, but there is less evidence of benefit. Evidence indicates that the disease burden could be reduced by screening tissue samples from all new CRC cases for molecular findings suggestive of Lynch syndrome. Family members of individuals testing positive then could be offered testing and enhanced surveillance if positive (EGAPP Working Group, 2009).

Familial adenomatous polyposis is seen in about 1 in 8000 families, and affected individuals have a 100% lifetime risk of CRC. Management usually involves early screening (age 10-12 years) with sigmoidoscopy and early colectomy. Chemoprophylaxis with nonsteroidal antiinflammatory drugs may also be of benefit.

Family physicians should recognize both FAP and HNPCC and ensure that genetic evaluation is offered to these families. If a specific mutation is identified, early screening of family members can be stopped for those testing negative. In the absence of a known mutation, all family members should be screened at an early age and the screening repeated at shorter intervals.

KEY TREATMENT

- Individuals with a single first-degree relative (parent, sibling, child) affected by colon cancer should be offered screening at 40 years of age or 10 years before the age at diagnosis of the affected relative (NCCN, 2013) (SOR: B).

- All colon cancer tumor samples should be tested for changes suggestive of Lynch syndrome (HNPCC) to reduce morbidity and mortality in family members (EGAPP Working Group, 2009) (SOR: A).
- Accelerated screening for colon cancer is recommended for individuals with Lynch syndrome (NCCN, 2013) (SOR: A).
- Colon cancer screening beginning in the second decade of life and early colectomy are recommended to reduce risk of CRC for individuals with FAP syndrome (NCCN, 2013) (SOR: A).

CYSTIC FIBROSIS

Cystic fibrosis is a relatively common autosomal recessive condition that causes progressive lung disease and exocrine pancreatic insufficiency. CF affects approximately 1 in 3200 U.S. whites but is less common in other population groups. CF results from inheriting two mutated copies of the *CFTR* gene, which is known to play a role in regulating chloride transport across epithelial membranes. More than 1000 *CFTR* mutations have been described, but the $\Delta F508$ mutation accounts for the great majority of classic CF cases.

The diagnosis of CF in symptomatic individuals can be made by the chloride sweat test, transepithelial nasal potential difference measurement, or genetic testing for *CFTR* mutations. Once almost universally fatal in adolescence or early adulthood, improved management has resulted in more CF patients surviving well into adulthood. Patient management in specialized CF centers is common, although it is unclear to what extent management by a specialized center is associated with improved patient outcomes. Lung transplantation has been used as a “cure” for the pulmonary complications of CF.

All women should be offered CF carrier screening as part of prenatal or preconception care to determine risk, so that reproductive planning is an option (ACOG, 2011). It is important to recognize that the common panels offered for prenatal CF screening contain tests for a variety of CF mutations but perform less well in certain ethnic groups. This lowered sensitivity results in residual risk of having an infant with CF despite a negative screening test in certain population groups.

All U.S. states include CF in their newborn screening programs, and evidence suggests that screening is associated with improved outcomes (Grosse et al., 2006; Southern et al., 2009). Newborn screening for CF illustrates some important dilemmas. As a result of this screening, we now know that many patients with nonclassic *CFTR* mutations have only mild disease, such as congenital absence of the vas deferens or chronic sinus infections. Does diagnosis before the onset of symptoms improve outcomes for these individuals? What about the risks of informing parents of a serious disease in their apparently normal newborn—will it change parenting and child development? The answers to these questions are under investigation, but they are important factors to consider when assessing risks and benefits of early CF detection.

KEY TREATMENT

- Newborn screening for CF occurs in some U.S. states and is associated with improved outcomes (Grosse et al., 2006; Southern et al., 2009) (SOR: B).
- It is reasonable to offer CF carrier screening to women in the preconception or prenatal setting, regardless of race or ethnicity (ACOG, 2011) (SOR: C).
- Consensus guidelines suggest sweat chloride testing or genetic testing for *CFTR* mutations for CF diagnosis in symptomatic individuals (GeneTests/GeneReviews, 2013b) (SOR: C).

Crisis Intervention, Trauma, and Disasters

ROBERT E. FEINSTEIN and EMILY COLLINS

CHAPTER OUTLINE

Development of Crisis Intervention, Trauma, and Disaster Theory, 1062

Evaluating the Crisis or Disaster, 1063

Crisis Intervention Treatment in the Office Setting, 1067

Coping Skills and Adaptive Problem Solving, 1070

Other Trauma Treatments, 1071

Medications for Symptoms of Psychiatric Disorders, 1072

Conclusion, 1073

Family medicine physicians are frequently asked to assist a patient who is in a crisis, whether a life-threatening illness; divorce; a sudden infant death; mental health crises such as depression or suicide attempt; or crises resulting from trauma such as rape, automobile accidents, natural disasters, or the trauma from terrorism. The *crisis intervention approach* provides both a theory and a treatment model that can be readily applied to patients in crisis, victims of disaster, and others who have been traumatized. This chapter reviews the development of crisis intervention theory, discusses current thinking about trauma and disasters, and presents a method for evaluation, formulation, and intervention in the biopsychosocial domains of a crisis.

Development of Crisis Intervention, Trauma, and Disaster Theory

HISTORICAL CONSIDERATIONS

Key Points

- A crisis is a brief psychological upheaval, precipitated by a stressor, resulting in an inability to cope, adapt, or function in daily life. A crisis may resolve with improved functioning, return to baseline functioning or stable functioning with a predisposition to a new crisis, or can be stabilized with the patient living at a lower level of functioning (Caplan, 1964).
- Crises can be effectively treated if patients are told that they can expect to recover, are treated immediately, and are returned to daily functioning as soon as possible (Salmon, 1917).
- A crisis typically lasts 6 weeks and can resolve spontaneously. Crisis resolution depends on the severity of precipitant, the personal reaction to the trauma, the support system helping the patient, and the effects of the trauma on the community (Lindemann, 1944).
- Some crises are precipitated by normal development, such as adolescence or marriage (Erikson, 1959).

Thomas Salmon (1917), a British military physician during World War I, was asked to evaluate patients with severe “shell shock” (traumatic neurosis), which was producing psychological paralysis in Allied soldiers. In this first medical description of the psychological effects of war, Salmon noted that French soldiers sustained fewer psychological casualties than British soldiers. Three factors seemed to account for the French advantage: (1) French soldiers were told that they could expect to recover from their psychological traumas; (2) soldiers received immediate psychological treatment close to the battlefield; and (3) soldiers were returned to battle as quickly as possible. These principles became the cornerstone of modern crisis theory and disaster management strategies. Patients entering crisis treatment can expect to be treated immediately in their natural environments with an expectation that they will recover from the crisis, trauma, or disaster. Efforts should be made to return patients to their normal lives and communities as soon as possible.

Eric Lindemann (1944) applied and expanded Salmon’s theories. He studied the acute grief reactions of persons who lost family members in the Coconut Grove fire in Boston, which claimed 500 lives. Lindemann discovered that normal people surviving such trauma develop an emotional crisis of pain, confusion, anxiety, and temporary difficulty in daily functioning. Also, he discovered that the psychological trauma caused by the crisis had little relation to preexisting psychopathology and that only a small group of the victims declined after the event to a lower level of functioning. Generally, the outcome of a crisis was related to the severity of the stressor, personal reaction to the trauma, effect of the trauma on the person’s family and friends, and degree of community disruption. Lindemann found that most crisis survivors recovered spontaneously within 6 weeks.

Erik Erikson (1959), a sociologist, introduced the idea of a life cycle composed of developmental stages and developmental crises. His eight stages were seen as normative processes during which age-specific psychological tasks, transitions, and crises were routinely encountered. A difficulty or inability to negotiate a stage successfully affects the

ability to progress to the next stage. For example, an adolescent seeks an adult identity and redefines social roles that emphasize peer relationships and increasing autonomy from parents. Those who do not successfully traverse adolescence develop a childlike dependence on parental figures and often have difficulty developing a career, getting married, or developing autonomous social relations.

Other crisis practitioners have expanded Erikson's basic concept of eight developmental crises to include other crises, such as leaving home for the first time, the midlife crisis, and parents' experience of the "empty nest syndrome." For many patients, a transition from one life phase to the next, such as marriage, divorce, retirement, or an illness, may bring the potential for a new developmental crisis.

Gerald Caplan (1961, 1964) synthesized many of these earlier ideas into modern crisis theory and treatment. He defined the crisis state as a brief, personal, psychological upheaval precipitated by a stressor, or "hazard." A precipitant produces emotional turmoil so that the person is temporarily unable to cope, adapt, or function in daily activities. Caplan demonstrated that a crisis implies the potential for danger and an opportunity for growth. Although subscribing to Lindemann's theories of acute precipitants, Caplan believed that a person's preexisting psychiatric condition could influence the development, evolution, and resolution of a crisis. A crisis may be based on the failure of a person's individual coping style and ability to adapt. Caplan confirmed that most acute crises resolve in about 6 weeks, with four possible outcomes: improved functioning, functioning restored to precrisis levels, incompletely restored functioning with a susceptibility to the development of future crises, or a severely impaired but stable level of lower functioning. He corroborated Lindemann's findings that some people cope with a crisis by spontaneously and flexibly developing new coping or problem-solving styles. Caplan developed a crisis treatment focused on development of better coping mechanisms and adaptations to life's traumas.

CURRENT UNDERSTANDING OF CRISIS, TRAUMA, AND DISASTERS

Key Points

- Approximately 66% of patients will experience a traumatic event during their lifetimes.
- One-year prevalence rates for all forms of trauma are approximately 20%.
- Approximately 13% of the U.S. population has reported a lifetime exposure to natural or human-generated disaster.
- The U.S. National Comorbidity Survey has estimated that 18.9% of men and 15.2% of women reported a lifetime experience of a natural disaster.
- Posttraumatic stress disorder (PTSD) in the United States has an estimated lifetime prevalence of 8%, with women twice as likely as men to be affected at some time during their lives.
- The most common traumatic events include witnessing an injury, murder, fire, flood, or natural disaster; being in a life-threatening accident; or combat exposure.

The current understanding of "crisis" has been used as one of several core strategies in the management and treatment of trauma and disasters. The type of events which authors called "traumatic" defines the frequency of traumatic experiences. For example, whereas early studies limited traumatic events to wars, natural disasters, and plane crashes, more recent epidemiologic studies include intimate partner violence, car accidents, crime, and foreclosures. Estimates of lifetime trauma exposure vary with the definition of a "traumatic event," so community studies of exposure to lifetime trauma also vary (25%-90%). According to the American Psychiatric Association's (APA's) *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition (DSM-5), the projected lifetime rate of PTSD is 8.7% at age 75 years. Additionally, the DSM-5 notes that the estimated 12-month prevalence rate among U.S. adults is 3.5%.

Natural disasters such as earthquakes, tsunamis, hurricanes, tornadoes, and volcanic eruptions can traumatize individuals, devastate whole communities, and disturb an entire population in a large geographic area. Human-made disasters, such as the September 11 attacks (2001), Oklahoma City bombing (1995), Newtown shooting (2012), suicide bombings, plane crashes, and environmental accidents, are all byproducts of the 21st century and, unfortunately, have become a part of modern life. The most common traumatic events that may cause PTSD include witnessing an injury, murder, fire, flood, or natural disaster; life-threatening accident; and combat exposure.

Evaluating the Crisis or Disaster

Key Points

A comprehensive evaluation of a crisis, trauma, or disaster includes assessment of the following:

- The normal equilibrium state
- The precipitant stressor or trauma
- The personal interpretation or meaning of the events
- The crisis state
- Preexisting personality or psychiatric conditions
- Selective past history
- System of social supports
- Effects on local society or community resources

Figure 44-1 presents an overview of a modern crisis intervention theory that is useful for the treatment of a crisis or trauma.

NORMAL EQUILIBRIUM STATE AND STRESSORS

Under normal circumstances, a person has a sense of internal psychological equilibrium and environmental support that generally permits activities of daily living, working, and experiencing pleasure. A delicate balance among the person's internal wishes and fears, skills and capacities, values, and ideals determines psychological equilibrium. *Environmental equilibrium* refers to a stable balance among basic needs for food, water, shelter, and physical comfort, as

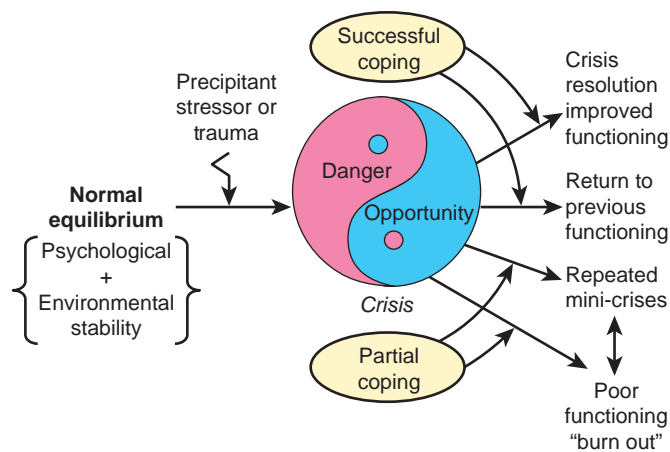

Figure 44-1 Crisis intervention theory.

well as the integrity of community and social supports for job, family, religion, and society.

A patient in crisis enters an emotional storm after a stressor disturbs the normal equilibrium. Environmental precipitants typically seen in a family physician's office include sickness and the stress of coping with death, divorce, marital separation, job loss, a financial crisis, traumas, intimate partner violence, and so forth. *Disasters* are acute environmental crises during which all concerned are focused on basic survival, acute medical care, and provisions of basic human needs. *Psychological stressors* may be related to events such as witnessing a trauma; surviving a disaster; loss of self-esteem; loss of love; a disturbing dream; sexual dysfunction; or sudden overwhelming fear, panic, or rage. *Developmental crises* such as latency, puberty, adolescence, marriage, birth of a child, midlife crisis, chronic medical illness, and retirement are common factors precipitating a crisis or may be comorbid factors.

Hobson and associates (1998) revised the Holmes and Rahe (1967) social readjustment scale. This newer scale lists 51 external life stressors that precipitate significant stress in most people. The top 20 items in this scale were in five separate domains: death and dying, health care issues, stress related to crime and the criminal justice system, financial and economic issues, and family stresses. This scale includes events that range in severity, from the most stressful being death of a spouse (rated as 1), divorce (7), experiencing domestic violence or sexual abuse (11), and surviving a disaster (16). It also includes events that many would consider positive yet stressful, such as getting married (32), experiencing a large monetary gain (42), and retirement (49). This list of stressors represents the most common external events that can cause a crisis. It is these types of stressors and the internally disturbing feelings attached to the events that produce emotional turmoil and a transient inability to adapt during the early stages of a crisis.

Most patients seeking treatment are surprised to discover that a major, unrecognized life stressor may have occurred on the same day or several days before the onset of the crisis. Less often, the stressor occurred sometime in the previous 6 weeks. Generally, events that occurred more than 6 weeks earlier are not acute stressors. Instead, these important past events may represent a previous crisis that was

incompletely resolved and may be linked to the current crisis, as illustrated in [Case Study 44-1](#).

Case Study 44-1

Lisa is a 28-year-old woman who presented to the office with increasing anxiety, irritability, and insomnia. Upon thorough questioning by her physician, Lisa revealed that her symptoms began about 4 weeks earlier when she saw the news and learned about a local shooting. Since seeing that news piece, Lisa has had an increase of anxiety in social settings, been more avoidant of family and friends, and had difficulty falling asleep and staying asleep. She has experienced great difficulty in concentrating at work and in her classes at school. She found that she had trouble focusing and her mind would often wander to an event from her past. She endorsed trying hard not to think about this event. When discussing her sleep, Lisa shared that she started to again have nightmares of this same experience from 10 years before in which a family she was living with was robbed and one of the family members killed by a firearm. Lisa had been out of the home during the robbery but returned to the police scene. She left that living situation shortly after this incident and subsequently developed symptoms of PTSD. She also realized that she had recently bumped into the mother of the family member who was killed in the incident 10 years earlier. She reported she had counseling at that time and was able to work through the trauma. Lisa had been living without symptoms for many years until recently.

Interpretation or Meaning of the Stressor

Whether a crisis is precipitated by an external life event or an internal psychological thought or feeling, each person interprets or adds meaning to the acute precipitant. For Lisa in [Case Study 44-1](#), a news report of a shooting precipitated a major emotional crisis and a recurrence of her PTSD symptoms.

When listening for the precipitant of a crisis, it is important to understand the meaning of all stressors in the context of a patient's life. The report of a shooting in Lisa's local community had a personalized meaning to her that reawakened old wounds and PTSD symptoms, fueling a major emotional crisis. The following sequence of events, filtered through the lens of Lisa's select past personal experiences, created this current crisis. On learning of the shooting, Lisa perceived a personal threat. This current precipitant reawakened traumatic memories of the killing of a family member in the home in which she had lived 10 years earlier. She became avoidant of social situations, had traumatic dreams causing insomnia, and described difficulty with work and school. The report of the local shooting reawakened her internal reactions and her select past memories of the murder that happened 10 years earlier. This culminated in an acute crisis with a relapse of her PTSD symptoms associated with social and occupational dysfunctions.

Lisa presented to her physician with symptoms but was unable to articulate her problem. As they discussed her symptoms and situation, Lisa realized that her current reaction was rooted in PTSD symptoms returning from her past

trauma. Her physician helped her recognize her reaction to the local report of a shooting in light of her past trauma. Lisa also realized with some surprise that meeting the mother of the family member who had been murdered also triggered the reemergence of her PTSD symptoms. With her physician's assistance, Lisa anchored her current fears in a reemergence of older PTSD symptoms. She felt more secure, her symptoms lessened, and she fully recovered.

CRISIS STATE

The crisis state can be defined as a brief psychological upheaval, precipitated by a stressor, that produces an intense state of inner turmoil or disorganization that overwhelms a person's ability to cope and adapt. As with Lisa, the crisis state can be experienced as symptoms of anxiety, nightmares, insomnia, and behavioral changes, resulting in social and occupational dysfunction. For some, the crisis state may be denied or experienced as psychological numbing.

Often, patients in a crisis or suffering from a trauma present to their family physicians with a confusing array of physical complaints (see [Case Study 44-2](#)). Patients typically experience four clusters of symptoms during a crisis or secondary to a trauma ([Table 44-1](#)).

Case Study 44-2

Mark, a 35-year-old real estate broker, presented to his family physician with anxiety and panic attacks, worrying about his performance at work, feeling depressed, and having 2 weeks of suicidal ideation. He noted that he was becoming so preoccupied with his decreasing performance that he was unable to get anything accomplished and feared he would be fired. Through careful questioning by his family physician, Mark admitted that these symptoms began 2 weeks earlier when his long-term girlfriend informed him that they would never get married. Mark became concerned that his girlfriend was going to leave him or be unfaithful. He described similar episodes in the past, noting that his first suicide attempt was in college after his first girlfriend left him for his roommate. He shared with his family physician that he wanted to get help because he did "not want to be like my father." Mark clarified that his mother left his father when Mark was a young boy. Mark's father began drinking and attempted suicide. Mark's father pursued other relationships and was often emotionally absent during those times. Inevitably, when these relationships ended, Mark's father would end up either attempting suicide or would be hospitalized for his recurrent depression.

Typically, a patient in crisis such as Mark cannot explain precisely what is upsetting him, although he was certainly aware that he was panicked and unable to concentrate. Mark's family physician asked, "Why now, at this point in time, are you anxious with suicidal thoughts and in crisis?" When asked, Mark initially felt distressed and confused. As he began to talk about his girlfriend, he recognized that he was panicked with the fear of losing her. He began to cry

Table 44-1 Common Symptoms Associated with a Crisis or Trauma

Physical	General
	Insomnia
	Tremors
	Profuse sweating
	Chills
	Loss of or increased sexual drive
	Increased substance use or abuse
	Gastrointestinal
	Nausea
	Vomiting
	Upset stomach
	Loss of or increased appetite
	Cardiac
Racing heart or palpitations	
Chest discomfort	
Neurologic	
Headaches	
Dizziness	
Numbness, tingling	
Acute or chronic pain	
Thoughts	Recurring traumatic dreams or nightmares
	Difficulty with memory, attention, or concentration
	Difficulty in making decisions
	Obsessions or compulsions related to the trauma
	Reconstructing the events of the crisis in an effort to master the trauma
	Questioning spiritual or religious beliefs
	Psychosis (extreme)
	Suicidal ideation
	Homicidal ideation
	Feelings
Numbness, irritability, restlessness	
Anhedonia	
Fear or anxiety when reminded of the traumatic event	
Feeling sad, blue, or depressed	
Emotional outbursts and angry feelings	
Hopelessness or helplessness	
Behaviors	Overprotection of self and family
	Easily startled
	Isolation from others
	Avoidance of activities associated with the event
	Avoidance of places and people that trigger memories
	Keeping busy to avoid thinking
	Increase in conflict with family members
	Agitation
	Drug seeking
	Suicidal behaviors
	Acting out, violent behaviors

with thoughts that he might be alone again. He became fearful he would follow in his father's footsteps of drinking, depression, repeated bouts of suicidal ideation, and never remarrying.

Frequently, people in crisis may not seek help by themselves and instead are brought in by concerned family members, lovers, friends, or perhaps the police or an ambulance. In these cases, it may take a while for the "Why now?" causes to be identified. Although symptoms often bring patients in to see their physicians, deeper unconscious levels of a crisis are often initially inaccessible to patients. Physician questioning and asking patients to retell the details of their experiences over the past 6 weeks and relevant past history is typically how the "Why now?" of the crisis emerges. This "Why now?" questioning is the first step in treating a crisis.

ACUTE CRISIS RESOLUTION AND ADAPTION TO THE CRISIS (WITHIN 6 WEEKS)

For many patients, the acute nature of the crisis is often resolved within 6 weeks as the patient learns to cope or adapt to the acute stress. The DSM-5 (APA, 2013) has classified the initial 1-month period of a crisis marked by impaired functioning as an “acute stress disorder.” The DSM-5 specifies that the acute symptom picture must last more than 3 days and no more than 4 weeks and must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning. The result of the acute stages of the crisis is one of four possible outcomes, as specified in Figure 44-1. Successful coping and adaptation to a crisis can lead to crisis resolution that ultimately promotes growth and can even lead to improved functioning. For most patients, however, crisis resolution means a return to a previous level of baseline functioning. Still other patients only partially resolve the crisis and instead “seal over” and deny the significance of their feelings or recent events, setting the stage for a future crisis. Those with the worst prognosis typically have poor adaptation skills and, at best, stabilize at a lower level of daily functioning. For example, an adolescent girl swallowed 30 pills after being left by her boyfriend. When questioned, she denied any suicidal intent and instead said, “I just had a headache.” This patient has sealed over her crisis. Denial of her suicidal intent and anger with her boyfriend may lead to poor adaptation called a *missed or unresolved crisis*. This patient may continue to use unsuccessful coping strategies, such as drinking or cutting herself, as a way to deal with painful feelings. Unresolved crises predispose the patient to future episodes that may be caused by even less stressful precipitants. For example, this same patient may again become suicidal after a new date cancels their “hook-up.” Fortunately, future crises often afford new opportunities to work past unresolved crisis, with better adaptation and coping.

SEQUELAE OF CRISIS, TRAUMA, OR DISASTER (6 WEEKS TO LIFETIME)

Although many patients completely recover from a crisis within 4 to 6 weeks, others may suffer with the sequelae of trauma or a crisis. The prognosis generally depends on three groups of factors: pretraumatic, traumatic, and posttraumatic risk factors (Ursano et al., 1995). *Pretraumatic* risk factors include prior psychiatric illness, genetics, typical coping styles, gender, and culture. *Traumatic* risk factors relate to the type of trauma, severity and duration of the trauma, and seriousness of a physical injury. *Posttraumatic* risk factors include dysfunctional coping styles, few resources available for repair, poor individual or community response, some incapacity for problem solving, and adaptation. In general, recovery is more likely if the crisis is not too severe and is short in duration. The crisis is often prolonged in victims of chronic abuse or torture or if a disaster is totally devastating to the fabric of a community (as with a hurricane or earthquake). After the crisis, the resources available for repair and the coping strategies used are the best predictors of outcome.

Table 44-2 Trauma and Crisis-Related Disorders

Adjustment disorder (309.XX; DSM-5, pp. 286-287)
Acute stress disorder (308.3; DSM-5, pp. 280-281)
Posttraumatic stress disorder (309.81; DSM-5, pp. 271-272)
Major depressive disorder (296.xx; DSM-5, pp. 160-161)
Substance-related and addictive disorders (DSM-5, pp. 481-585)
Dissociative disorders (301.14; DSM-5, p. 292)
Generalized anxiety disorder (300.02; DSM-5, p. 222)
Panic disorder (with or without agoraphobia) (300.01; DSM-5, pp. 208-209)
Specific phobia (300.xx; DSM-5, pp. 197-198)
Social anxiety disorder (social phobia) (300.23; DSM-5, pp. 202-203)
Brief psychotic disorder (298.8; DSM-5, p. 94)
Somatic symptom disorder (300.82; DSM-5, p. 311)
Conversion disorder (functional neurological symptom disorder) (300.11; DSM-5, p. 318)

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition. Diagnostic criteria available from American Psychiatric Association.

Diagnostic and statistical manual of mental disorders. 5th ed. Arlington, VA: American Psychiatric Publishing; 2013.

When dealing with a patient who is in a crisis or has recently had a trauma, it is important for the family physician to assess for associated trauma-related conditions. This assessment begins with attention to physical illness or psychosomatic complaints and then focuses on basic health care needs (food, warmth, shelter, clean drinking water, good sanitation). From a psychiatric standpoint, the family physician must remember that it is normal to have symptoms of trauma after a crisis event. Most patients' symptoms will wane gradually or resolve spontaneously, and many patients may not require psychological treatment. At 1 year, however, 30% to 40% of those exposed to a disaster will show lingering evidence of psychiatric morbidity (Raphael, 1986). For example, 1 year after being involved in a car crash, about 25% of patients will show signs of a psychiatric disorder, and 11% will go on to develop PTSD (Mayou et al., 1993). Table 44-2 summarizes the spectrum of psychiatric disorders that can occur in the wake of a crisis or trauma.

PREVIOUS PSYCHIATRIC ILLNESS OR PERSONALITY DISORDER

For many people, there is little correlation between a previous psychiatric illness or personality disorder and their capacity to cope or adapt to an acute crisis or trauma. A person with schizophrenia may be just as capable of handling an acute crisis as others who do not have psychiatric disorders. How well a person handles an acute crisis or trauma depends primarily on the variables discussed earlier, including the precipitant, the meaning of the events, the crisis situation itself, the patient's coping skills and styles, and the effectiveness of the patient's support network.

However, there are many cases in which a preexisting psychiatric disorder or an unresolved trauma or crisis may influence the development of a new crisis. Consider the case of an intellectually disabled boy who becomes severely violent because his mother ran out of his favorite breakfast cereal. This change would be a minor stressor for most people, but for this boy, disruption of his daily breakfast food and routine are perceived as catastrophic. His low IQ and lack of verbal skills related to his intellectual disability

predispose him to a crisis involving violence because he lacks the ability to consider other options. Patients with severe psychiatric illness or personality disorders, those with trauma-related disorders (see [Table 44-2](#)), and those who have rigid coping styles or poor adaptation skills all are at greater risk for future crises.

SELECTIVE PAST HISTORY

For an acute crisis, the patient's past history is relevant only in so far as it can help explain and resolve the current crisis. Many patients, wanting to avoid the pain of the current crisis, may unconsciously lead the family physician "down the garden path" with unexplained symptoms or other chronic problems, avoiding the pain of the current issues. To avoid the past history trap, the physician must try to understand the dynamics of the current crisis and then look for similar events in the patient's past that can be used to understand more about the current situation. For example, a selective past history of violence and the circumstances surrounding those events may provide valuable clues to understanding a current violent crisis. Taking a detailed selective history, discovering past events that are similar to the current crisis, will help the family physician assist in developing a deeper understanding of the "Why now?"

Additional events from the past history that might be helpful in understanding a violent event include a history of cruelty to animals; truancy; living in foster homes; childhood abuse or neglect; sexual abuse; a history of family violence; legal or severe financial problems; previous incarcerations; and a history of depression, substance abuse, or alcoholism. Selective past history that could be relevant for understanding an acute suicidal crisis might include a history of prior attempts, depression, bipolar disorder, substance abuse, chronic pain or disability, or severe neurologic or medical illness.

When dealing with trauma victims, it is important to ask about past trauma, previous successful coping styles or adaptations, and cultural and religious beliefs. This information can help promote recovery. The less severe the current traumatic event, the more critical are predisaster variables, such as prior social and occupational functioning or a history of a psychiatric illness.

Social Systems

Everyone lives within a network of social interaction, social support, and community and national resources. Most of our daily social interactions are with family, friends, and work colleagues. These daily social interactions are made possible by the community supports that enable a person to obtain clean water, adequate sanitation, housing, food, clothing, work, education, finances, and medical care. Community structures are generally made possible because of the support of the country or nation. National resources support the entire infrastructure of the civilization, from roads to a monetary system to constitutional protections. In general, stable social systems at different levels tend to provide the greatest buffers against crises or disasters of all types. An ecologic map (eco map) can be used to represent the patient's social network (review [Figure 44-3](#) and [Case Study 44-3](#)).

Often, a patient goes into a crisis because the immediate social environment is threatened or disrupted by such issues as divorce, a dysfunctional family, drug abuse, unemployment, or an eviction notice. Relative damage to a local support network can have profoundly varied effects on a patient. For example, the death of a spouse produces a more severe crisis if the deceased person was also the sole financial provider. Even a minor disturbance in a small or dysfunctional support network can produce a major crisis. For example, an elderly woman who is housebound and without family, friends, or a telephone can experience a major crisis when her home health aide misses a scheduled visit.

When assessing the local support network of a patient, a family physician should consider whether the patient's network is interested, available, and competent to help. Some networks are helpful and should be included, but other networks may be harmful to the patient and need to be excluded from care. This determination may be especially complicated in intimate partner violence cases in which a marital separation is necessary but may also result in the woman needing to face financial stresses, loss of her home, and the loss of her social network. When a patient is in a crisis, the family physician can help the patient choose and mobilize the most helpful people in the patient's immediate support network and exclude others. Such helpful mobilizations may include calling in a specific family member, speaking to a supportive boss, helping the patient retain an attorney, establishing health care, or obtaining Medicaid.

In general, social disruptions at the local level of support (e.g., job loss) are less damaging than community-level disruptions (e.g., tsunamis). National disruptions such as wars or earthquakes in poor countries cause a devastation from which many never recover. Disasters are long lasting when the needed resources remain greater than the available resources ([Eranen and Liebkind, 1993](#)). During a disaster, the social structure of a society can be damaged to such an extent that the existence and functioning of the entire community or nation can be threatened. This was experienced after Hurricane Sandy in 2012 and the earthquake in Haiti in 2010. Disasters of this magnitude require local, state, national, and even international support if there is to be a chance of restoring the social integrity of the community to predisaster levels of functioning.

Crisis Intervention Treatment in the Office Setting

BASIC CRISIS INTERVENTION APPROACH

Key Points

- Develop a timeline of events, starting with the "Why now?" and working from the initial presentation backward in time.
- Focus on acute risk assessment, including risk of suicide, violence, and acute medical conditions.
- Develop an eco map or support network map. This begins with a three-generational genogram and a list of other psychosocial supports, which may include friends, other medical professionals, medical insurance, religious

or community organization, and other people who could help the patient.

- Select a single problem or symptom to begin the treatment.
- Build a wheel-and-spoke treatment plan with the single problem or symptom in the center. List and prioritize all the spokes, which are the biopsychosociocultural factors that will need to be addressed to resolve the crisis.
- Treat the problem or symptoms by fostering the use of adaptive coping skills.
- Use a crisis resolution strategy.
- Use psychiatric medication for symptom-oriented crises.

The focus of a crisis assessment involves the evaluation and understanding of the precipitants of the crisis or trauma, personal meaning of the events, crisis state itself, selective past history, support network, and current psychiatric illness if relevant. These assessments are subsequently used to help formulate the causes of the crisis so that, if necessary, specific crisis intervention treatment and problem-solving approaches can be implemented.

A tailored crisis intervention treatment is typically one to five sessions offered on a voluntary basis, but this can be extended as needed. The treatment is specifically geared toward helping the patient survive and cope with the acute biopsychosocial or cultural effects of the crisis. The time required for each session depends on the complexity of the case and the practitioner's skill. A family physician can begin the crisis assessment and treatment by exploring the "Why now?" or the acute precipitants of the crisis. This inquiry can be followed by detective-style questioning designed to uncover the specific chronology and sequence of events, feelings, thoughts, and behaviors that led to the development of the acute crisis. Patients seeking help should be encouraged to tell the details of their acute crisis situation.

Helping the patient to describe the stressors and evolution of the acute problem may offer clues to developing problem-solving approaches for crisis resolution. Crises or disasters involving the lack of food, clothing, shelter, poor sanitation, or inadequate medical care should be given first priority. Crises involving violence, suicide, or a life-threatening medical illness have the next highest priority for focusing of the crisis treatment. Crises in everyday life can be treated according to the patient's preferences.

Crisis treatment focuses on the dynamic interplay of events from the most recent precipitants and days, the previous 6 weeks, and selective elements from the patient's past history that help frame the focus of immediate care. Important tools and approaches that can guide a crisis formulation and treatment are the timeline, eco map or support network tool, wheel-and-spoke formulation, symptom-oriented treatment, and assessment and development of more adaptive coping styles. All of these components can be used for the development of a general crisis resolution strategy.

TIMELINE

A timeline is a pictorial representation of the immediate, recent, and selective events from the past history

contributing to the current crisis. A family physician can build a timeline while interviewing the patient. The physician asks the patient to discuss the immediate events and precipitants of the crisis on the day of the office visit or events from the past week. Together, the physician and the patient reconstruct the history by working backward over the previous 6 weeks. Finally, the physician tries to elicit the selective past history that may relate to the current crisis. Use of the timeline is illustrated in [Case Study 44-3](#). Developing a timeline with a patient helps both physician and patient focus on recent events and begins the process of formulating treatment, as illustrated in [Figure 44-2](#) for [Case Study 44-3](#).

Case Study 44-3

Joanne was an insurance adjuster who was assigned to work with families whose homes were destroyed after Hurricane Sandy in 2012. She began her job 6 weeks earlier, having had experience working with Hurricane Katrina families in the past. The fallen trees and damaged homes and cars after Sandy and the load of dealing with traumatized families left her distressed, feeling uncharacteristically anxious and overwhelmed, and with new-onset insomnia. Four weeks ago, she asked for help from work and was told several other adjusters would be available to help in a few weeks. Two weeks ago, her nanny threatened to resign for financial reasons. Her possible resignation raised the specter of a child care problem. This led Joanne to some binge overeating, drinking to help her insomnia, and migraines. She went to her family physician. During the office visit, her family physician helped her build her timeline (see [Figure 44-2](#)). Her family physician recognized the multiple levels of her distress and was able to help Joanne acknowledge that her migraines and insomnia were worsened by her drinking. The timeline also uncovered that 3 weeks earlier was the anniversary of her husband's death during Hurricane Irene. A tree fell on his car as he was returning home. The death of her husband left her alone as the sole provider, caring for her three children; her husband's mother, who had dementia; and her aging parents. Joanne and her physician did some problem solving, during which treatment of her migraines and insomnia was initiated. Exploring her eco map encouraged her to ask her siblings for help and discuss with her boss adding other adjusters to her current work site.

ECOLOGICAL MAP

An eco map is a pictorial representation of the patient's entire support network. Included in the eco map are a genogram and the immediate support network. This map can include the patient's current family, the family of origin for three generations, and all the people and community resources in the patient's immediate living environment (e.g., family, neighbors, nanny, physician, church, social services agencies). An eco map can be used by a family physician to help decide who can help the patient; who needs to be excluded; or what social, religious, legal, or

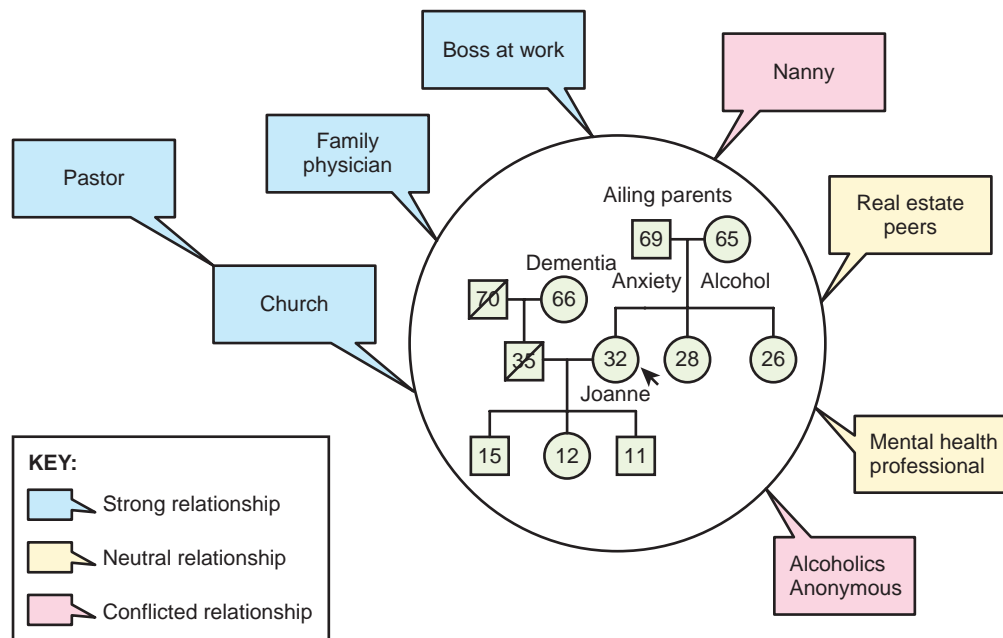

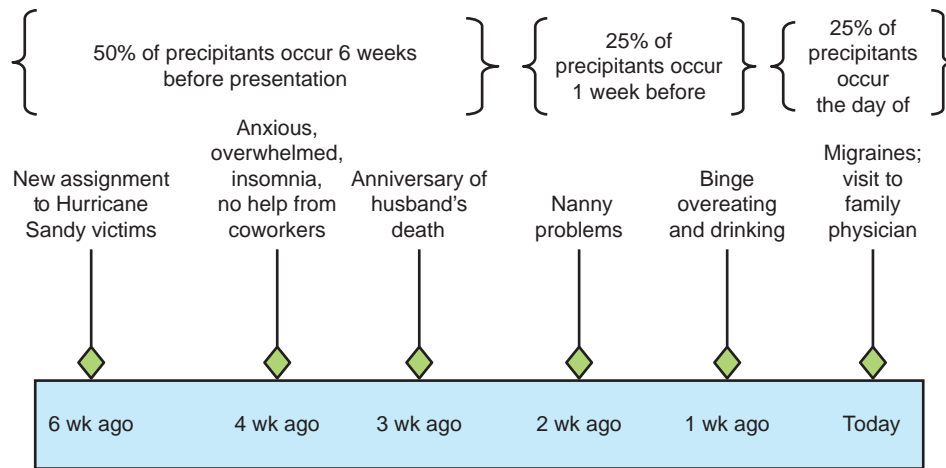

Figure 44-3 Ecologic or support network map: Case Study 44-3. Circles indicate females and squares indicate males. The numbers inside the circles and squares indicate the age. A line across the square indicates that the person is deceased, and the arrow represents the identified patient.

economic resources need to be mobilized to assist the patient in crisis.

Using Case Study 44-3, Joanne’s eco map is illustrated in Figure 44-3. Her siblings, boss, and peers could be called on to assist her during this crisis. The decisions about which support members to use should be negotiated with the patient. Adding support in addition to the care offered by her family physician and the offer of additional mental health services was sufficient to help resolve this acute crisis.

Selecting the Problem or Symptom

Because most crises present with a number of problems and symptoms simultaneously, it is important to select the starting point of the treatment. Immediate survival and safety issues are almost always the first priorities. Providing food, shelter, safety, and medical care and preventing suicide risk or violence must supersede all other concerns. Less severe

problems or symptoms can be handled according to the patient’s preferences.

WHEEL-AND-SPOKE FORMULATION OF THE CRISIS

The wheel-and-spoke format is a useful tool to help develop a formulation that specifies the multiple causes of the crisis and can assist in the development of an effective, prioritized treatment plan. The acute crisis should be pictured as the center of a wheel. The spokes of the wheel are the problems or symptoms that are likely causing or contributing to the crisis. The physician can establish a numbered priority list for problem solving. For each problem listed, the family physician recommends a specific evaluation, test, or treatment approach designed to ameliorate the crisis. An application of the wheel-and-spoke diagram for Joanne’s case is illustrated in Figure 44-4.

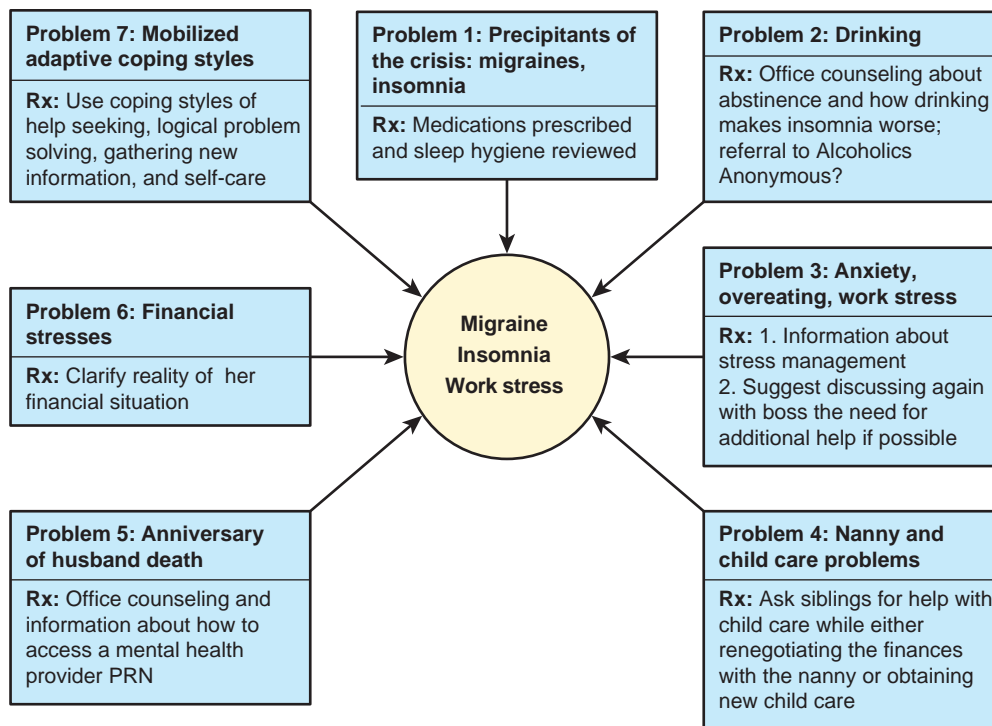

Figure 44-4 Wheel-and-spoke crisis formulation and treatment plan. PRN, As needed; Rx, prescribe.

Table 44-3 Coping Styles

Adaptive coping styles	Intuitive: using imagination, feelings, and perceptions to solve a problem Logical, rational: carefully reasoned, logical, deductive style Trial and error: trying a random solution; if it fails, modifying it and trying again Help seeking: gathering information and then proceeding Self-care: pursuing wellness through nutrition, exercise, stress management, or sleep hygiene Wait and see: allowing time or circumstance to determine the outcome Action oriented: taking action to rectify the problem immediately Contemplative: quietly thinking over the problem before acting Spiritual: asking for God's direction Emotional: using emotions such as tears, anger, or fear to help solve problem Controlling: controlling people or oneself to gain power to solve problem Manipulative: using various manipulative styles to resolve crisis
Pathologic coping styles	Use of alcohol and drugs Anxiety, panic, depression Deceptive, antisocial: use of dishonesty, lying, cheating, or stealing to resolve crisis Suicidal: using threat of suicide or suicide attempts to coerce someone or to solve problem Violent: using threat or actual violence to establish control and solve problem Avoidance or denial: failure to confront or acknowledge problems Somatization: displaying physical symptoms as a method of expressing emotions Impulsive: unpredictable or impulsive responses without anticipation of possible outcomes Random, chaotic: nonproductive and extreme form of trial and error and impulsive style; often seen in prolonged psychotic states

PROBLEM-FOCUSED OR SYMPTOM-ORIENTED TREATMENT

After the physician has formulated the case using the timeline and eco map and developed a wheel-and-spoke treatment plan, the problem-focused or symptom-oriented crisis treatment can begin. A family practitioner may use educational, psychotherapeutic, or supportive approaches with or without medications. The cornerstone approaches to crisis treatment are fostering coping skills and adaptive problem solving using a crisis resolution strategy. Medications may be necessary for symptom relief or as part of the treatment approach to related major psychiatric illness.

Coping Skills and Adaptive Problem Solving

Fortunately, most people find new ways to handle or cope with a crisis. Coping styles are the unique ways that patients deal with stress. For example, some cope with a stressful crisis by analyzing it, asking others for help, or gathering additional information. Some coping styles work better in certain situations than others. Table 44-3 lists some typical adaptive coping styles that can be suggested to patients, as well as pathologic coping styles that should be avoided whenever possible. Crisis resolution can be promoted by

Table 44-4 Crisis Resolution Strategy

Assess safety.	<p>If a patient is in acute danger because of violence, suicide risk, or acute medical problems, more help may be required. Contact medical providers, law enforcement, or other resources as indicated.</p> <ol style="list-style-type: none"> 1. Teach the patient to recognize the early warning signs of a crisis, which typically includes anxiety or depressive symptoms, occasional panic symptoms, feelings of being overwhelmed, a sense of urgency, vigilance, confusion, disorganization, intrusive thoughts, flashbacks, nightmares, self-defeating actions, and suicidal or homicidal feelings. 2. Set the patient's expectations for recovery. 3. Inform the patient that after an acute event, most acute life crises take approximately 6 weeks to subside, stabilize, or resolve. 4. Normalize the patient's symptoms. Patients need to know that, after an acute crisis or trauma, somatic and psychiatric symptoms and atypical daily routines (e.g., not going to work) are part of normal healthy coping. 5. It is important for patients to know that if problems and symptoms do not resolve after 6 weeks, they should obtain further evaluation and treatment as necessary. 6. If the patient desires, he or she can talk over the crisis with the family physician or a trusted friend. It is often best if these friends or family members are not directly involved in the crisis. For prevention or early intervention for the next crisis, the physician can assist the patient in developing a list of contacts of available friends, other physicians or specialists, and available community resources. 7. If a patient is overwhelmed with emotion, is coping poorly, or has a dysfunctional daily routine (beyond the typical norm of a posttraumatic reaction), she or he may benefit by sharing painful feelings or discussing recurrent or intrusive thoughts. This sharing may provide some immediate relief. 8. Identify the specific symptoms, problems, and areas of the patient's functioning that are most affected by the crisis (e.g., work, home, interpersonal, economic). 9. Identify the specific precipitants, other stressors, and symptoms (e.g., insomnia) that are currently contributing to the crisis. This can be done by helping the patient develop a timeline (see Figure 44-2). 10. Evaluate the support system by use of an eco map (see Figure 44-3). Using this support network tool, patients can be assisted in discovering who can help and who might exacerbate the situation. 11. Select the problem(s) or symptom(s) to treat first. This can be the most difficult part because it requires an accurate understanding or formulation of the causes of the crisis to prioritize what problem or symptom to treat first. 12. Use a wheel-and-spoke format (see Figure 44-4) to develop the treatment plan for a core crisis and prioritize the order of problems or symptoms that need to be treated. 13. Teach the patient to understand his or her current coping style and why and how it may not be working. Introduce other, more adaptive coping styles (see Table 44-3). 14. Obtain additional information from others who may be able to assist with crisis resolution. This should only be done after the crisis has been formulated and the focus of the treatment chosen. 15. Make a specific plan for crisis resolution based on additional information, newly discovered feelings, a crisis formulation, and treatment focus. This plan should involve the use of novel coping styles, a specific sequence of actions, and psychopharmacology as clinically appropriate (see Table 44-3). 16. The patient should implement the plan. Initially, it may be less overwhelming to resolve one cause of the crisis at a time instead of trying to handle many problems simultaneously. 17. Assess the results. Has the problem been resolved? If yes, go to step 1 and tackle a new symptom or problem. If not, go to step 18. 18. If the initial plan has not helped, try again, get additional help, or consult with a psychiatrist or other professionals.
----------------	--

evaluating a patient's coping style and, when necessary, suggesting an alternative or more adaptive coping style. These new skills facilitate a patient's adaptation to the stressful life circumstances. In general, those who can flexibly use many coping styles are the most successful at crisis resolution and problem solving. Often, patients in crisis rely too heavily on one coping style, which may not be the most adaptive for a particular situation. Those patients who lack the capacity to develop new, more adaptive coping styles may become dysfunctional when confronted with a crisis.

To illustrate coping styles and new coping skills, review [Case Study 44-3](#). Joanne initially felt anxious and overwhelmed and began binge eating and drinking in her efforts to deal with her work stress, memories of the loss of her husband, and emerging problems with child care. As this progressed to symptoms of migraines and insomnia, she consulted her family physician. She realized she could ask for help from her physician, siblings, boss, and perhaps peers and she could get additional help as needed through a mental health professional or Alcoholics Anonymous. She mobilized her existing abilities to approach problems logically and work through alternative solutions as well as gather additional information about how to get

a new nanny. She also recognized her need to focus on self-care by using sleep hygiene and stress management techniques.

CRISIS RESOLUTION STRATEGY

In addition to teaching coping styles and coping skills, a family physician can provide a patient with general strategies for crisis resolution. A crisis resolution strategy, based on the crisis principles, consists of 18 steps ([Table 44-4](#)). The family physician may need to walk through some or all of these steps with the patient first before encouraging the patient to attempt some steps as a self-help strategy for the future.

Other Trauma Treatments

KEY TREATMENT

- Crisis intervention and psychotherapeutic techniques are a first-line approach for a crisis or mass trauma (Bradley et al., 2005; [National Institute for Health and Care Excellence \[NICE\], 2005](#)) (SOR: A). These include:

- Trauma-focused cognitive behavioral therapy (TFCBT) for adults and children is one of most beneficial forms of psychotherapy (Bisson et al., 2009; Foa et al., 2009; Forbes et al., 2010) (SOR: A).
- Eye movement desensitization and reprocessing is highly effective in some studies and less effective in others (Foa et al., 2009) (SOR: A or B).
- Exposure-based cognitive processing therapy is also one of the most beneficial form of psychotherapy (Bisson et al., 2009; Foa et al., 2009; Forbes et al., 2010) (SOR: A).
- Psychoeducation, breathing, relaxation training, and homework can be helpful for PTSD (Forbes et al., 2010) (SOR: B).
- Psychological first aid is helpful after mass trauma or disaster (Bisson et al., 2007) (SOR: B).
- Critical incident stress management (CISM), sometimes called debriefing, is not helpful (Benedek et al., 2009) (SOR: C).

Patients in an acute crisis or with disaster-related trauma may or may not require treatment. Crisis treatment is often necessary if the patient is suicidal or at risk for violence, has an acute medical emergency, or has a major psychiatric disorder (psychosis, PTSD, bipolar disorder, depression, overwhelming anxiety). All treatment is best when it is offered voluntarily or upon patient request.

Psychological treatment of patients with trauma can be offered immediately, with the patient allowed to pursue treatment voluntarily. Treatment should be vigorously pursued and possibly mandated if a major, life-threatening psychiatric illness appears acutely (APA, 2004; NICE, 2005).

No acute psychiatric treatment is often the best course of action if symptoms and non-life-threatening problems are resolving and if social and occupational functioning has remained intact over the first 6 weeks. Evidence indicates that mandatory crisis intervention in non-life-threatening circumstances, often called *critical incident stress management* (CISM) or “debriefing” (Mitchell et al., 1983), is not helpful (Rose et al., 2004). Patients who have experienced a mass trauma or disaster may benefit from “psychological first aid” (Bisson et al., 2007; Veterans Administration/Department of Defense [VA/DoD] Management of Post-Traumatic Stress Working Group, 2012). This approach fosters safety, calmness, self and community efficacy, social connectedness, and optimism. In addition, psychoeducation, breathing, and relaxation training are often included as intervention that may be useful during the initial phases of exposure to traumas (APA, 2004; Benedek et al., 2009; NICE, 2005).

Seven major evidence-based guidelines are used to treat acute stress disorder and PTSD (Forbes et al., 2010). These practice guidelines do not always agree on the level of evidence for some treatments, which is why some forms of psychotherapy have two ratings in the key treatments crisis, trauma, disaster treatments. The current best recommendation for treatment of PTSD for adults (Foa et al., 2007) and children (AACAP Practice Parameters for PTSD, 2010) is TFCBT (Foa et al., 2009; Forbes et al., 2010) (SOR: A) as first-line preferential treatment rather than

pharmacotherapy (Forbes et al., 2010). TFCBT includes exposure to past traumas through imagined, in vivo, and directed therapeutic, written, verbal, or taped narrative and use of cognitive-behavioral interventions. Exposure-based cognitive processing therapy is an evidence-based treatment with good efficacy (Foa et al., 2009; Forbes et al., 2010).

Eye movement desensitization and reprocessing is rated as either grade A (by Australian National Health, 2007; VA/DoD Management of Post-Traumatic Stress Working Group, 2012) or as grade B (by the Institute of Medicine, 2007). Because there are not enough experienced trauma therapists, pharmacotherapy is often used as the first-line treatment when trauma-based psychotherapy is not available.

Medications for Symptoms of Psychiatric Disorders

KEY TREATMENT

- First-line treatment for PTSD is with selective serotonin reuptake inhibitors (SSRIs), including sertraline and paroxetine, which are both approved by the U.S. Food and Drug Administration for PTSD (Friedman, 2013; Stein et al., 2003) (SOR: A). Venlafaxine (a serotonin-norepinephrine reuptake inhibitor [SNRI]) has also been shown to reduce symptoms similar to SSRIs (Friedman, 2013; Stein et al., 2003) (SOR: A), although the SSRIs and SNRIs may be less effective in combat veterans (Friedman, 2013; Hetrick et al., 2010).
- Mirtazapine and nefazodone are considered second-line agents. However, nefazodone is not often used because of concerns for liver toxicity (Friedman, 2013; Stein et al., 2003) (SOR: B).
- Benzodiazepines are not recommended for the treatment of PTSD unless being used for a comorbid disorder. Evidence has shown that this class of medication does not reduce symptoms and carries a high risk potential (Friedman, 2013; Stein et al., 2003) (SOR: B).
- Bupropion does not have any current consistent evidence as a treatment for PTSD (Friedman, 2013; Stein et al., 2003) (SOR: C).
- Topiramate is the only anticonvulsant that has consistently been shown to have efficacy as favorable as the SSRIs (Stein et al., 2003) (SOR: A).
- For PTSD nightmares, prazosin may be effective (Friedman, 2013; Stein et al., 2003) (SOR: B).
- Evidence is inconclusive regarding adjunctive treatment of PTSD with atypical antipsychotics in the absence of psychotic symptoms. Monotherapy is not recommended (Krystal et al., 2011; Stein et al., 2003) (SOR: B).
- There is currently insufficient evidence to determine if combined psychotherapy and pharmacotherapy is better than either modality alone (Hetrick et al., 2010) (SOR: A).

Although psychotherapeutic techniques are a first-line approach for a crisis or mass trauma (Forbes et al., 2010), use of medications for treatment of specific symptoms

or psychiatric disorders can also be helpful. In general, pharmacology targeting symptom reduction parallels the pharmacology of the treatment for the major psychiatric disorders. For example, if a patient has an isolated sleep disturbance, use of the newer hypnotics is warranted. Similarly, for depressive or psychotic symptoms, antidepressants or antipsychotics can be used. This symptom-oriented approach has not been well studied.

During the acute crisis or immediate posttraumatic state, insomnia or other sleep disturbances may greatly affect coping. Use of a nonbenzodiazepine such as zolpidem, zaleplon, or eszopiclone can be considered as first-line pharmacologic treatment for acute sleep disturbances. The use of benzodiazepines for sleep or anxiety in the acute postcrisis state is questionable, with little support for efficacy and concerns that benzodiazepines may inhibit effective coping. Benzodiazepines also carry the risk of dependence and addiction, and data suggest that they do not reduce the progression to PTSD (Friedman, 2013). Although data are sparse regarding the effectiveness, trazodone is also often used clinically for chronic sleep difficulties because it carries no risk of dependence.

Thus far, no known interventions have prevented PTSD. For the primary treatment of PTSD, medications include SSRIs, prazosin, and topiramate. PTSD symptoms, including reexperiencing the trauma, avoidance, numbing, and hyperarousal, are effectively treated with SSRIs and SNRIs, including sertraline, paroxetine, venlafaxine, and fluoxetine (APA, 2004; Benedek et al., 2009; Forbes et al. 2010; Friedman, 2013; Stein et al., 2006). Prazosin has been shown to be effective in treating nightmares associated with PTSD, but its effects on other PTSD symptoms is not well studied (Friedman, 2013).

A distinction between non-combat-related and combat-related PTSD is warranted when considering pharmacologic therapy (Benedek et al., 2009). Non-combat-related PTSD includes civilian trauma, childhood or adult sexual assault, intimate partner violence, interpersonal trauma, or trauma caused by a motor vehicle crash. For non-combat-related PTSD, sertraline, paroxetine, fluoxetine, and venlafaxine are effective in short-term trials. These medications can either be a primary form of treatment if the patient does not want TFCBT or can be combined with TFCBT; no evidence yet shows that combined treatment is superior to SSRI or CBT alone (Hetrick et al., 2010). More recent studies suggest that topiramate is beneficial in the treatment of PTSD and is similar in efficacy to the SSRIs (Friedman, 2013). The efficacy of the antidepressant mirtazapine is equivocal but reportedly somewhat beneficial (Friedman, 2013). No efficacy for β -blockers or bupropion has been established.

The results for pharmacologic treatment of combat-related trauma are less convincing. It seems that younger veterans with PTSD from more recent wars are responsive to the same SSRIs and SNRIs as non-combat-related patients. However, older veterans from previous wars do not appear to respond to sertraline or fluoxetine. Thus, the common SSRIs may be only somewhat effective for this group (Benedek et al., 2009). For PTSD nightmares in both groups, prazosin (3-15 mg/night) has been used with some success.

Although the SSRIs are the first-line choice for the pharmacotherapy of PTSD, not all patients will have a full treatment response. Previously, it had been thought that adjunctive treatment with risperidone and olanzapine may be helpful. However, a recent large randomized clinical trial of veterans found that risperidone was no better than placebo (Friedman, 2013; Krystal et al., 2011). Augmentation with a mood stabilizer such as divalproex or lithium may be considered, but evidence for success is limited. Buspirone or benzodiazepines may also be used, but only sparingly and adjunctively, to decrease anxiety or panic attacks. These medications are not recommended as monotherapy.

Conclusion

Family physicians are routinely faced with a variety of acute crises, patient-reported traumas, and disaster situations that require a specialized knowledge to understand patient complaints and to successfully develop management and intervention strategies. The goals of crisis intervention and disaster management are to evaluate the precipitants of the crisis, understand the personal meaning of the events, deal with the crisis state itself, and use the selective past history to comprehend the current situation better. It is also important to mobilize the support network and, if relevant, diagnose and treat any comorbid psychiatric illnesses. A crisis evaluation strategy using a timeline, eco map, and wheel-and-spoke formulation can be used to help implement a specific problem-solving approach. Crisis treatment includes problem or symptom-oriented therapy, use of adaptive coping styles, 18-step crisis intervention approach, and medications when indicated. All of these interventions can be helpful when seeking a resolution of the crisis.

Difficult Encounters: Patients with Personality Disorders

ROBERT E. FEINSTEIN and JOSEPH CONNELLY

CHAPTER OUTLINE

Personality Traits versus Personality Disorder, 1074

Classification and Diagnosis, 1074

Management of Patients with Personality Disorders, 1075

General Management Principles for Difficult Patients, 1081

Interventions for Specific Personality Disorders, 1085

Conclusion, 1089

Patients with personality disorders are difficult to manage and can elicit intense reactions in the primary care physicians and medical staff who care for them. Patients with personality disorders have an unintentional ability to create problematic patient–physician–staff relationships. This covert pressure placed on the physicians and staff often affects how the medical team evaluates or diagnoses a patient and frequently affects physician orders, laboratory tests, suggested treatments, and recommendations. Up to 15% of primary care patients have a personality disorder (Moran et al., 2000; National Institute for Mental Health in England, 2003). However, patients with personality disorders often go unrecognized because they do not complain and often do not present with any overt symptoms. However, when interviewed, patients with personality disorders often reveal interpersonal failures and describe multiple social and occupation difficulties. Most patients with personality disorders are recognized after a problematic interpersonal interaction or are secondarily recognized by the complaints of others, especially complaints from spouses, family, or friends. Family physicians see these patients every day. Patients with personality disorders tend to consume a disproportionate amount of family physicians' time and emotional energy. Physicians with high numbers of difficult patients are more susceptible to low morale and burnout (An et al., 2013; Han, 1994, 1996, 2002).

Although family physicians do not treat the underlying personality disorder, recognition and effective management of these difficult patients is routinely possible and often necessary in medical settings. The goal in the management of patients with personality disorders is to provide or assist physicians or staff in the understanding and medical management of these patients so that optimal medical care can be delivered.

Personality Traits versus Personality Disorder

Personality traits are enduring. They describe a habitual way of coping that is manifested in how a patient feels, thinks, behaves, and interacts with others. Genetically determined personality traits are called *temperament*. Personality traits such as shyness or high stimulus barrier (the ability to stay focused and not be distracted by external

stimuli) are often observable from birth and can be readily seen in a newborn nursery. Other personality traits that develop from the interaction with caregivers and the environment are called *character*. Character traits, such as the capacity to empathize or anxious or depressive tendencies, can be environmentally acquired through early parent–child experiences. The distinction between personality traits and a personality disorder is a matter of degree. Personality traits tend to be stable but can be more easily modified according to the needs of external reality. When personality traits combine and become rigid, extreme, and maladaptive and cause interpersonal, social, or occupational dysfunction, they are called *personality disorders* (Oldham et al., 2009; Skodal, 2009). These disorders are much harder to modify and typically require long-term psychotherapy, with or without pharmacotherapy, to facilitate change. Although everyone is unique, there seems to be a continuum of personality traits and disorders that are commonly encountered. Some personality disorders can be recognized in the movies. These include the narcissistic personality disorder as portrayed by Sharon Stone in *Basic Instinct*, the antisocial personality disorder played by Robert DeNiro in *Cape Fear*, and the schizotypal personality disorder portrayed by Karen Allen in *The Glass Menagerie*.

Classification and Diagnosis

Key Points

- A personality disorder is an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual's culture.
- Problems are in at least two of these areas: cognition, affectivity, interpersonal functioning, and impulse control.
- An enduring pattern is inflexible and pervasive across a broad range of persona and social situations.
- The enduring pattern leads to clinically significant distress or impairment in social, occupational, or other areas of functioning.
- The pattern is stable and of long duration; onset can be traced back to adolescence or is diagnosed in adulthood.
- To diagnose, begin with dimensional measures: Cluster A, odd eccentric; Cluster B, dramatic emotional; and Cluster C, avoidant fearful (Table 45-1).

Table 45-1 Personality Clusters and Disorders

Cluster A (Odd, Eccentric)	Cluster B (Dramatic, Emotional)	Cluster C (Anxious, Fearful)
1. Paranoid (301.0; DSM-5, p. 649)	1. Antisocial (301.7; DSM-5, p. 659)	1. Avoidant (301.82; DSM-5, pp. 672-673)
2. Schizoid (301.20; DSM-5, pp. 652-653)	2. Borderline (301.83; DSM-5, p. 663)	2. Dependent (301.6; DSM-5, p. 675)
3. Schizotypal (301.22; DSM-5, pp. 655-656)	3. Histrionic (301.50; DSM-5, p. 667)	3. Obsessive-compulsive (301.4; DSM-5, pp. 678-679)
	4. Narcissistic (301.81; DSM-5, pp. 669-670)	

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition.

Personality disorder criteria are available from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th Ed. Washington, DC: American Psychiatric Association; 2013

- Use the categorical classification systems to identify the specific personality disorder.
- A particular patient may have traits from different clusters and may meet criteria for more than one personality disorder.

Patients with personality disorders are typically diagnosed using a categorical or a dimensional approach. The quasi-dimensional and *categorical* approach described in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM IV-TR; [American Psychiatric Association, 2005](#)) and maintained in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; [American Psychiatric Association, 2013](#)), begins by identifying the appropriate dimensional cluster of a personality disorder. Each of these clusters broadly describes personality dimensions of the patient as either Cluster A, odd or eccentric; Cluster B, dramatic, emotional, or erratic; or Cluster C, anxious or fearful. After the dimensional cluster has been identified, the categorical approach describes 10 discrete “prototypes” or easily recognizable categories of personality disorders. This predominately categorical approach colorfully describes and differentiates 10 distinct personality disorders. This categorical approach has the advantage that it is easiest for clinicians to use. However, because personalities are complicated and often not discrete entities, it is not unusual for a patient to meet DSM-5 criteria for two cluster diagnoses and more than one specific personality disorder diagnosis. Because of these limitations in the current categorical system, the evolution within personality disorder research is to move toward a dimensional model for classification.

The DSM-5 has a dimensional “alternative DSM-5 model for personality disorders.” This complex dimensional model describes Criteria A as the “level of personality functioning,” which includes disturbances in the self (e.g., disturbances in experiences of self and others, problems with self-esteem, difficulty in regulating emotions, and difficulty being self-directed toward meaningful life goals) and disturbances in interpersonal functioning (e.g., problems with empathy and intimacy). Criteria B describes personality traits in five broad domains (e.g., negative affectivity, antagonism, detachment, disinhibition, and psychoticism). These domains consist of 25 specific personality traits that are described in detail. Although the DSM-5’s *dimensional* approach has much to offer to psychiatrists and other mental health professionals who treat personality disorders, the approach is not yet validated for extensive or official use. Because the dimensional approach is still in development, this chapter uses the categorical approach

adopted by DSM-5, which is likely more useful for family physicians.

Management of Patients with Personality Disorders

Key Points

The following five-step process is useful as a management strategy for family physicians who wish to create therapeutic relationships with personality-disordered patients who might otherwise be experienced as difficult. (Tables 45-1 and 45-2 outline this process using the DSM-5 classification.)

1. Strive to understand the patient’s core beliefs, irrational thoughts, and fears.
2. Identify the patient’s defense mechanisms and coping style and use confrontation, clarification, and interpretation to modify these.
3. Recognize recurrent patient behaviors and how these will likely affect patient adherence and use of medical services.
4. Learn to use your own reactions to the patient to help identify the diagnosis and management strategy.
5. Recognize that specific interventions are helpful for different types of patients (Table 45-3).

PATIENT CORE BELIEFS, IRRATIONAL THOUGHTS, AND FEARS

Key Points

- Patients have identifiable core beliefs (or worldviews) and fears.
- These interact and can feed off each other in difficult patients.
- Stress activates these core beliefs and precipitates intense and dysfunctional emotions, fears, thoughts, physical symptoms, or maladaptive behaviors that are characteristic for each specific personality disorder (see Table 45-2).
- Adherence to medical recommendations and use of medical services are somewhat predictable based on the particular personality disorders.

The family physician can apply the principles of cognitive-behavioral therapy (CBT) to facilitate their management skills when working with patients with personality

Table 45-2 Schema for Managing Patients with a Personality Disorder

DSM-5 Disorder	Patient Core Beliefs	Patient Fears	Defenses	Coping Styles	Patient Health Behaviors
Paranoid	Others are adversaries and are to blame; I am being examined; They are out to get me; I can't trust anyone	Exploitation; slights; betrayal; humiliation; physical intrusions from medical procedures	Projection: ascribe one's impulses to others Projective identification: project one's impulse plus control of others as way to control one's own impulses Denial: refusal to admit painful realities Splitting: self and others seen as all good or all bad	Guarded and protective of their autonomy, often with an arrogant belief in their own superiority	Wariness, suspicion, mistrust, jealousy, self-sufficiency, counter-attacking, anger, violence
Schizoid	I need space; I need to be alone; people are replaceable or unimportant	Emotional contact; warmth; intimacy; caring; intrusions or violation of privacy	Isolation of affect: thoughts stored without emotion Intellectualization: replace feelings with fact Denial and splitting: see above Regression: revert to childlike thoughts, feelings, or behaviors	Inner world insulated from others	Withdrawal; seeking isolation and privacy
Schizotypal	Idiosyncratic, magical, or eccentric beliefs; I know what they're thinking or feeling; premonitions	Emotional contact; warmth, caring; violation of privacy	Schizoid fantasy: retreat to idiosyncratic fantasy when faced with painful experience Undoing: symbolic magical action designed to reverse or cancel unacceptable thoughts or actions Regression, denial, splitting: see above	Chaotic, disorganized	Withdrawal; odd, autistic, or magical behaviors and movements; seeks isolation and privacy
Antisocial	People are there to be used and exploited; I come before all others	Boredom; loss of prestige, power, or esteem	Acting out: expression in action or behavior rather than in words or emotions Splitting: see above	Seeks autonomy, freedom; seeks advantage or secondary gain	Lies, deceit, and manipulation; violence; seeks secondary gain
Borderline	I am very bad or very good; Who am I? I can't be alone	Separations, loss, emotional abandonment; not being loved and cared for; fluctuating self-esteem	Splitting, projection, projective identification, dissociation, regression, acting out (see above) Omnipotence: seeing self, others as all-powerful Idealization or devaluation: vacillates between seeing self or others as ideal and then deprecating self or others Mini-psychotic experiences	Hostile dependency; chaotic lifestyle; threatening or intimidating; seeking intimacy, dependency, or pseudo-autonomy	Impulsive behaviors; suicidal actions; cutting; anger or violence; panic; anxiety; poor reality; stormy relationships
Histrionic	I need to impress and to be admired or loved; I need to be taken care of or helped	Loss of love, admiration, attention, or dependent care	Sexualization: functions or objects changed into sexual symbols to avoid anxieties Regression, acting out, splitting: see above Dissociation: disrupted perceptions or sensations, consciousness, memory, or personal identity Somatization: physical symptoms caused by mental processes Repression: involuntary forgetting of painful memories, feelings, or experiences	Self-centered, emotion driven, flirtatious, flighty	Dramatics; exhibitionism; expressiveness; impressionistic
Narcissistic	I am special; I am important; I come first; The world should revolve around me	Loss of prestige, image, power, or esteem	Splitting, projection, projective identification, acting out, denial regression: see above	Superior and arrogant, self-aggrandizing, self-centered, self-protecting, demeaning, demanding, critical	Self aggrandizement; inflated or deflated self view; entitled; devalue or idealize; viciousness; envy; competitive
Avoidant	I must avoid harm or be cautious because I may get rejected or exposed or be humiliated	Rejection; embarrassment in social situations; humiliation; exposure of inadequacies	Inhibition: restriction of thoughts, feelings, behaviors to avoid shame, exposure of inadequacies, rejection or humiliation Phobias: fears of objects, people, situations; avoided to prevent anxiety Avoidance, withdrawal, regression, Somatization: see above	Withdraw or escape; avoid criticism	Avoidance; withdrawal; social timidity; caution; fear or anxiety

Table 45-2 Schema for Managing Patients with a Personality Disorder (Continued)

DSM-5 Disorder	Patient Core Beliefs	Patient Fears	Defenses	Coping Styles	Patient Health Behaviors
Dependent	I am helpless without others; I can't make a decision; I need constant reassurance and care	Separation, independence, making decisions, anger	Dependent: yearning for care, clinging, needing direction Passive-aggressive: superficial compliance and passivity disguising stubbornness and anger Reaction formation: unacceptable impulses expressed as the opposite Regression, splitting: see above	Passive, dependent, helpless	Unusually submissive; clinging; indecisive; childlike; needing to be taken care of
Obsessive-compulsive	People should do better or try harder; I must be perfect; I must make no errors or mistakes; details, not feelings, rule	Disorder, mistakes, imperfection, afraid of feelings, (especially rage or anger), anxiety, self-doubt, dependency	Isolation of affect, intellectualization, reaction formation, undoing: see above Controlling: efforts to regulate objects or others to avoid anxiety Displacement: transfer of one's feelings from one person on to another Dependent: see above Inhibition: restricting thoughts, feelings, or behaviors for fear that unacceptable impulses will erupt and create anxiety or damage Phobias, repression: see above	Inflexible; constricted; governed by rules, safety, or security concerns	Perfectionism; driven orderliness; logical; compulsions; controlling; critical; stubbornness or stinginess; workaholic; rational

DSM-5, *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition.

Table 45-3 Personality-Disordered Patients: Adherence, Utilization, Physician Reactions, and Interventions

DSM-5 Disorder	Adherence	Utilization	Physician Reactions	Interventions
Paranoid	Difficult when requested by the physician because the patient is suspicious of the need for compliance Problematic but may be easier when the patient is seeking relief from symptoms	Limited utilization, or as a condition for medical service utilization, the patient may seek detailed explanations or reasons for the diagnostic testing or needs for other services	Fearful; sense of danger; mistrust; feeling accused, blamed, or threatened	<ol style="list-style-type: none"> 1. Empathize with patient's fear of being hurt; acknowledge complaints without arguing or ignoring. 2. Openly and honestly explain medical illness. 3. Correct reality distortions and unreasonable patient expectations. 4. Gently question irrational thoughts and suggest more rational ones. 5. Do not confront delusions. 6. If the patient refuses care out of mistrust, rather than insist, ask if it is OK if you can disagree about the need for the test. 7. Interpret projection (blame) and other defenses.
Schizoid	May be difficult Will need reinforcement and monitoring; may need outreach services	Underutilization; outreach, if not too frequent, may help foster appropriate use of medical services	Detached or removed; wish to involve patient with others or to break through the isolation	<ol style="list-style-type: none"> 1. Empathize with the patient's need for privacy and contact. 2. Accept the patient's unsociability. 3. Reduce the patient's isolation as tolerated. 4. Neutrally impart medical information. 5. Do not demand involvement nor permit total withdrawal. 6. Correct reality distortions and unreasonable patient expectations. 7. Gently question irrational thoughts and suggest more rational ones. 8. Interpret isolation and other defenses.
Schizotypal	May be difficult; may need outreach, visiting nurse, community resources, or case management	Underutilization; may need outreach to gain reasonable and appropriate utilization of medical services	Detached; removed; "weird and alone" feelings; wish to involve patient with others or to break through the isolation	<ol style="list-style-type: none"> 1. Empathize with the patient's idiosyncratic style, magical thinking, and perceptions without directly confronting them. 2. Recognize the need for privacy and contact. 3. Accept the patient's unsociability; reduce the patient's isolation, as tolerated. 4. Neutrally impart information. 5. Do not demand involvement or permit total withdrawal. 6. Correct reality distortions and unreasonable patient expectations. 7. Gently question irrational thoughts and suggest more rational ones. 8. Interpret regression and other defenses.

Continued on following page

Table 45-3 Personality-Disordered Patients: Adherence, Utilization, Physician Reactions, and Interventions (Continued)

DSM-5 Disorder	Adherence	Utilization	Physician Reactions	Interventions
Antisocial	May be resistant, problematic, and intolerant of the need for ongoing compliance	May misuse medical resources for secondary gain	Used, exploited, or deceived; anger; a wish to uncover lies, punish, or imprison	<ol style="list-style-type: none"> 1. Empathize with the patient's fear of exploitation and low self-esteem. 2. Determine if you are being used for secondary gain. If you suspect dishonesty, verify symptoms and illness progression with others. 3. Do not moralize. Explain that deception results in your giving the patient poor care. 4. Correct reality distortions and unreasonable patient expectations. 5. Gently question irrational thoughts and suggest more rational ones. 6. Interpret defenses. 7. Medications as adjunctive treatment.
Borderline	Inconsistent as adherence is easily influenced by emotional storms, interpersonal conflicts, or chaotic lifestyles	Misuse or high use for maladaptive behaviors such as suicidal or disruptive behaviors	Feeling manipulated, angry, impotent, depleted, self-doubting; wish to rescue or get rid of the patient; guilty	<ol style="list-style-type: none"> 1. Empathize with patient's fear of abandonment and separation and plan for absences by arranging coverage. 2. Express a wish to help and satisfy reasonable needs. 3. Ask the patient to monitor impulsive behaviors with a diary or log. 4. Set firm limits and do not punish. 5. Correct reality distortions and unreasonable patient expectations. 6. Gently question irrational thoughts and suggest more rational ones. 7. Interpret splitting and other defenses. 8. Negotiate emergency procedures in advance. If suicidal, the patient must go to the emergency room, if not safe. If the patient refuses emergency help when you offer, let the patient know in advance that this therapeutic breach may end the relationship. 9. Medications as adjunctive treatment.
Histrionic	Often dependent on others or inconsistent	May misuse or overuse medical resources to gain attention from the physician or staff	Flattered, captivated, seduced, or aroused; flooded by emotions; depleted; wish to rescue	<ol style="list-style-type: none"> 1. Empathize with patient's fear of losing love or care. 2. Interact in a friendly way, not too reserved or too warm. 3. Discuss patient's fears; reassure when possible. 4. Use logic to counteract an emotional style of thinking. 5. Set limits if patient regresses. 6. Correct reality distortions and unreasonable patient expectations. 7. Gently question irrational thoughts and suggest more rational ones. 8. Interpret sexualization, regression, and other specific defenses.
Narcissistic	Can be problematic; intolerant of the need for ongoing compliance requirements	Entitled to use, or may abuse, medical services when needed	Devalued/overvalued; inferior/superior; fearful of patient's criticism or anger; wish to retaliate, devalue, or get rid of the patient	<ol style="list-style-type: none"> 1. Empathize with patient's vulnerability and low self-esteem. 2. Don't mistake patient's superior attitude for <i>real</i> confidence and don't confront entitlement. 3. When devalued or attacked, acknowledge the patient's hurt, your mistakes, and express your continued wish to help. 4. If devaluing continues, offer a referral as an option, not as punishment. 5. Correct reality distortions and unreasonable patient expectations. 6. Gently question irrational thoughts and suggest more rational ones. 7. Interpret splitting and other defenses.
Avoidant	Diverted or delayed by avoidant behavior; guided by a wish to avoid disapproval of medical staff	Seeks medical services to secure approval or avoid criticism, not necessarily seeking the health benefits	Frustrated because the patient often cannot articulate fears; annoyed at the patient's weakness	<ol style="list-style-type: none"> 1. Empathize with patient's social fears, shame, shyness, and fears of revealing inadequacies, rejection, embarrassment, humiliation, and anger. 2. Help the patient describe in detail the feared situation(s). 3. Encourage and support the need for the patient to gradually face the fears and the tendency to avoid. If this seems overwhelming, choose smaller fears to confront or refer. 4. If frustrated or unclear about the nature of the fears, ask for detailed descriptions of the problem. 5. Gently elicit irrational thoughts and suggest more rational ones. 6. Correct reality distortions. 7. Interpret avoidance, phobias, and other defenses. 8. Medications as adjunctive treatment.

Table 45-3 Personality-Disordered Patients: Adherence, Utilization, Physician Reactions, and Interventions (Continued)

DSM-5 Disorder	Adherence	Utilization	Physician Reactions	Interventions
Dependent	Dependent on others for medical supervision and easily overwhelmed by the demands of self-monitoring compliance	Underuse when left to themselves, but may overuse service when physician or medical staff becomes the source of needed gratification	Depleted; annoyed at the patient's dependence; may deny the patient's reasonable needs	<ol style="list-style-type: none"> 1. Empathize with the patient's need for care. 2. Frustrate total dependence. 3. Be careful to avoid telling the patient what to do. 4. Encourage independent thinking and action. 5. Realize that what the patient says that he or she wants (caretaking) is not necessarily what he or she needs. 6. Ask the patient what it is about independence that is so frightening. 7. Don't abandon or threaten termination because some very dependent patients need regular physician contact for life. 8. Correct reality distortions and unreasonable patient expectations. 9. Gently elicit irrational thoughts and suggest more rational ones. 10. Interpret regression and other specific defenses. 11. Prescribe medications as adjunctive treatment (see Table 45-4).
Obsessive-compulsive	Rigid and inflexibly follows the rules; disrupted or anxious if unexpected changes are required	Conflicted about utilization; fears of uncertainty may drive increased use, and fears of loss of control may decrease use	In a battle of control with negative reactions to patient stinginess, need for order, and stubbornness; distanced from feelings; bored with details	<ol style="list-style-type: none"> 1. Empathize with the patient's logical, detailed, unemotional style of thinking. 2. If obsessive thoughts are interfering with medical care, ask about the patient's feelings. 3. Do not struggle with the patient over control or critical judgments. 4. Avoid abandoning the patient. 5. Correct reality distortions and unreasonable patient expectations. 6. Gently elicit irrational thoughts and suggest more rational ones. 7. Interpret specific defenses.

disorders. The theory of CBT ([Beck and Freeman, 1990](#); [Greenberger and Padesky, 1995](#)) is that patients have a "worldview," or a set of "core beliefs," and personality-specific fears that can be identified and directly managed by the family physician who brings those worldviews to the patient's conscious awareness. When an environmental stress occurs against the background of the patient's core belief, a reinforcing feedback loop ensues. An external environmental stress or internal stress interacts with the core beliefs, and this triggers an irrational fear or thought. Irrational fears create negative emotions (e.g., depression or anxiety) that can lead to maladaptive behaviors or physical symptoms. Behaviors or symptoms can also feedback directly to confirm the patient's worldview and fears. Core beliefs and fears are readily activated in medical settings where patients are sick and vulnerable. For example, a patient with stomach distress may fear or believe that she has cancer. She may be anxious that she is dying as her mother recently did of a gastrointestinal cancer. By inquiring about the severity of the patient's fears and uncovering her irrational thoughts (that she too must have cancer), the physician can reassure her that this is unlikely and reduce her worry while also proceeding with the workup as indicated. Empathizing with the patient's core beliefs and fears will likely improve the doctor-patient relationship, which may allow the physician to help the patient recognize his or her irrational thoughts. The physician can then correct these distortions with facts, thereby relieving suffering and possibly improving the quality of medical care that takes place. The CBT sequences for each of the specific personality disorders are described in [Table 45-2](#).

DEFENSES AND COPING STYLES

Key Points

- Defense mechanisms are automatic internal psychological processes that protect the patient from anxiety and stressors and help with adaptation to the environment.
- Patients with specific personality diagnoses use a known range of particular defense mechanisms (see [Table 45-2](#)).
- Patients with unexplained somatic symptoms tend to use denial, externalization, and somatization, converting psychosocial distress and problematic interpersonal relationships into unexplained physical complaints.
- Coping styles are typical behavioral ways of dealing with the external world.
- Patients with specific personality diagnoses tend to use a known range of coping styles (see [Table 45-2](#)).
- Patients with severe unexplained somatic symptoms tend to use high- or low-anxious coping styles or manipulative coping styles (see [Table 45-2](#)).

A family physician can attempt to relieve a core problem or a symptom presenting for medical care by fostering the patient's awareness of his or her problems. To do this, it is important to appreciate the unconscious psychological processes known as *defense mechanisms*. These unconscious psychological processes (e.g., denial, projection) are

used to resolve internal conflicts, manage moods, mediate external dangers, and facilitate adaptations to reality. *Coping styles*, on the other hand, are typically behavioral patterns and methods of coping with the external environment.

Patients with personality disorders often present with unexplained symptoms. They tend to use defense mechanisms such as denial, externalization, and somatization, converting psychosocial distress and problematic interpersonal relationships into unexplained physical complaints. Patients with severe unexplained symptoms tend to use high- or low-anxious coping or manipulative coping styles (see [Table 45-1](#)). By understanding the constellation of defenses and coping styles used by personality-disordered patients, the physician may be able to modify the pathologic defenses or coping style that is interfering with the patient-physician alliance and the delivery of medical care. A physician can use clarification, confrontation, and interpretation (see [Table 45-1](#)). For example, a borderline patient may feel hurt and abandoned by the physician's vacation plans and accuse the physician of not caring. This patient may use a defense mechanism called *devaluation* (physician is deprecated as uncaring) and a coping style of manipulation (threatening suicide). With this understanding, the physician can begin to help the patient by not taking personally the patient's efforts to devalue or manipulate. The physician can respond to the patient by empathizing with the patient's fears of abandonment. The physician may clarify that the patient has a distorted belief and that the vacation is being incorrectly experienced as a personal abandonment of the patient. The physician may further clarify that the vacation does not communicate anything about the physician's future ability or wish to care for the patient. The patient can be reassured of the physician's return, future realistic medical availability, specific limits of availability, and medical coverage by another physician. In a preventive effort to allay a crisis and help a borderline patient manage separation fears, the physician (before the vacation) could also suggest that the patient use a new active coping style and schedule a meeting with a designated medical colleague who will provide coverage while the physician is away. Often, it is helpful to anticipate issues that may arise for the patient and suggest specific problem solving and coping.

PATIENT BEHAVIORS, ADHERENCE, AND USE OF MEDICAL SERVICES

Key Points

- Cluster A personality disorders (paranoid, schizoid, and schizotypal) tend not to adhere to medical recommendations and to underuse medical services.
- Cluster B patients (antisocial, histrionic, borderline, narcissistic) tend to have variable adherence to medical recommendations and may misuse, overuse, or underuse medical care.
- Cluster C patients (dependent, obsessive-compulsive, avoidant) tend to adhere to medical recommendations because of fear of the consequences of nonadherence.

Patients with personality disorders often display characteristic behaviors that affect their adherence to medical recommendations and use of medical services ([Soeteman et al., 2008](#)). Understanding these behaviors can also help physicians manage the expectations of these difficult patients and improve the chances for effective interventions that might improve medical adherence and health outcomes. In general, patients with Cluster A personality disorders (paranoid, schizoid, and schizotypal) tend not to adhere to medical recommendations and underuse medical services. They may require outreach to involve them in their own medical care. Cluster B patients (antisocial, histrionic, borderline, narcissistic, and self-defeating) tend to have variable adherence to medical recommendations and may misuse, overuse, or underuse medical care. Cluster C patients (dependent, obsessive-compulsive, avoidant) tend to adhere to medical recommendations because of fear of the consequences of nonadherence. They are ambivalent users of the medical system and tend to use medical services appropriately when others are involved in their care.

PHYSICIAN REACTIONS TO PATIENTS WITH PERSONALITY DISORDERS

Key Points

- Physician reactions are useful in recognizing, diagnosing, and managing difficult patients.
- Reactions stirred by the patient are referred to as *patient-generated countertransferences*.
- Physician reactions are often similar or shared in common by all physicians seeing the patient, with some elements peculiar to each individual physician.
- Difficult patients often generate intense physician feelings.
- There may be fantasies or thoughts about the patient that are uncharacteristic for the physician.
- The physician may engage in behaviors that would normally not be typical for him or her (see [Table 45-3](#)).

Although the DSM-5 is a useful aid for making a diagnosis, family physicians often recognize a patient with a personality trait or unexplained physical complaint by their own reactions to the patient. Physicians working with personality-disordered patients seem to have specific and characteristic reactions to these patients that need to be recognized, understood, and used for the patient's benefit. Patient-generated feelings provoked in the physician are created through the interpersonal interaction between patient and physician. These reactions to a patient should alert the physician to a possible diagnosis of a difficult patient. Typical physician reactions to patients that are provoked by the patient are also called *patient-generated countertransferences*. These include intense feelings, uncharacteristic fantasies, or atypical behaviors by the physician.

Intense Affects

Intense physician feelings elicited through patient interactions may include negative feelings such as active dislike,

fury, or frustration toward a patient (Groves, 1978; Strous et al., 2006). Alternatively, the physician may have strong positive feelings of attraction, sexual arousal, wanting to rescue the patient, or wanting to provide exceptionally good medical care. These may alternate with other wishes to avoid the patient, terminate the relationship, or transfer the patient to a colleague. In extreme cases, intense feelings aroused in a physician can become a focal point for leading the physician into boundary violations with a patient. These are extremely damaging to both parties and violate the tenets of professional behavior.

Fantasies

Physicians may also recognize that they are interacting with a patient who has a personality disorder by recognizing their own fantasies. Fantasies described by family physicians that are commonly generated by patients with personality disorders may include excessive worrying about a patient after normal work hours; a wish to rescue a patient; a wish that a patient might die; dreaming about a patient; or experiencing unusually exaggerated, intrusive, angry, sexual, or curious fantasies about the patient when not at work and during personal private time.

Atypical Behaviors

A physician may also notice behaviors with certain patients that are atypical for his or her usual customary medical practice. These unusual physician behaviors should trigger self-examination by the physician and consideration that the patient may have a personality disorder. Frequently, difficult patients are capable of arousing unconscious reactions that lead to new and unusual physician behaviors.

Common atypical physician behaviors include ordering tests to placate a patient, asking for more than the usual number of consults on a patient whose care does not seem medically complicated, suggesting aggressive diagnostic testing or procedures when the yield of these tests is likely to be low, repeatedly extending the time spent with a particular patient or family, lowering the customary fee, offering free treatment, or developing a personal (not professional) relationship with a patient. Common physician reactions associated with difficult patients are reviewed in Table 45-2.

Physicians can use the scope of patient-generated countertransferences (their feelings, fantasies, and atypical medical behaviors) as a valuable diagnostic aid because difficult patients tend to provoke the same feelings in most physicians who deal with them. For example, a patient with a borderline personality disorder (BPD) often leaves many physicians exhausted and worried about the patient's suicidal threats. A patient with obsessive-compulsive personality disorder (OCPD) may argue over details of the treatment, fees, or scheduling. Physicians who learn to recognize feelings provoked by patients will find it easier to identify the subtype of personality disorder according to the feelings elicited. More important, physicians who can recognize their unusual reactions will be better able to tolerate them and avoid acting out their feelings with a patient. This will improve the physician-patient relationship, medical decision making, and ultimately patient care (Feinstein et al., 1999).

General Management Principles for Difficult Patients

ATTENDING TO A PROBLEMATIC ALLIANCE

To establish a good working alliance based on trust, acceptance, and confidence, the family physician should begin each patient encounter by listening, asking open-ended questions, and continually striving for empathy. The alliance is also fostered by the physician's own self-awareness, ability to acknowledge mistakes, and efforts to adapt to the patient's wishes or needs that will foster improved health outcomes. Problems often occur in developing an alliance with a patient who has a personality disorder. If tension develops in the alliance, the physician should ask what the patient thinks of the current problem. If the patient expresses the problem clearly, the physician should join with the patient in solving the problem to deliver effective medical care. If the problem is the physician-patient relationship, nondefensive reflective listening, clarifications, admitting mistakes, and initiating new efforts to improve the situation are often helpful. If the physician believes that there is a different problem affecting the alliance, the physician may say, "I believe that there is a different problem [identify the problem, e.g., psychosocial distress, problem drinking] that is affecting my ability to help you get well and offer you the best medical care available. We need to think about this problem and come up with some solutions."

CHOOSING A FOCUS FOR THE INTERVIEW

When delivering medical care with a patient with a personality disorder, it is important to be consistent, reliable, and predictable to avoid future problems. Patients with personality disorders often experience an inability to verbalize or prioritize their most important medical or psychosocial concerns. For these patients, it is particularly important to strive for a mutually agreed upon focus for short- and long-term medical treatment goals. It is often helpful to use a process called *informed shared decision making*, in which the physician takes time with the patient to discuss and negotiate the acute focus of medical care, short- and long-term medical goals, strategies to achieve these goals, and specific timelines for accomplishing the prioritized medical plan (Feinstein et al., 1999).

USING BASIC PSYCHOTHERAPY TECHNIQUES FOR INTERVIEWING A PATIENT

As is often the case, a general medical approach may not be sufficient to help a difficult-to-manage patient. After a brief period of immersion in the patient's complaints, the family physician can respond with empathic responses, initially acknowledging the patient's fears, core beliefs, and symptoms (see Table 45-1). If this is not helpful, the physician can use general psychotherapeutic techniques such as confrontations, clarifications, or interpretations directed toward the current problem interfering with medical care (Stoffers et al., 2012).

A *confrontation* is an observation by the physician offered to a patient for examination. It is usually a comment

that draws attention to contradictions in the patient's beliefs, thoughts, feelings, or behaviors. For example, one might say to an anxious-somatic patient who denies that psychosocial factors might be contributing to her symptomatology that her physical complaints may be caused by medical, psychological, or social stresses and that her high levels of anxiety could be making her physical symptoms worse.

A *clarification* adds new information or perspective or elucidates misunderstandings, miscommunications, or other information that seems vague or confusing. The need for repeated clarifications occurs regularly with difficult patients. It is important to use clarifications before suggesting a new plan to correct the problem.

Interpretations are integrating comments that link confrontations and clarifications with the patient's current problem that is interfering with medical care. Interpretations can be made about the immediate medical situation and may address the patient's core beliefs, irrational thoughts, fears, maladaptive symptoms or behaviors, defense mechanisms, or coping style. Interpretations can also be directed at a difficulty in the physician–patient interaction, problems with the patient coping with the disease, problems in the patient's life circumstances, or patient refusal of a necessary medical workup or treatment. For example, an interpretation to a borderline patient with chronic pain might be:

I think you want relief from your pain. However, your refusal to adhere to my treatment recommendations makes relief from your pain unlikely (confrontation). You then get angry and suicidal with me because your pain is not relieved, so you do not keep your scheduled appointments (clarification). Instead of enlisting my help and using our services when the pain is overwhelming, you blame us for your pain and feel frustrated and suicidal. Your anger helps you avoid dealing with the chronic reality of your medical condition (interpretation), which is that we can make your pain manageable but not cure it.

Making interpretations takes practice but can powerfully restore a realistic and helpful physician–patient relationship.

ATTENDING TO THE PATIENT'S EMOTIONAL NEEDS

Patients with personality disorders are often exquisitely sensitive and distressed by internal emotional states, moods, desires, and physical complaints. At a basic level, attending to the patient's emotional needs means listening empathically, reflectively, and carefully before attempting an intervention. With many personality-disordered patients (e.g., avoidant, dependent, histrionic, or borderline), it may be initially more important to attend to the patient's emotional needs for contact, reassurance, or validation before addressing physical or somatic complaints. Alternatively, some other personality-disordered patients (paranoid or obsessive-compulsive personalities) may need the family physician to attend to pain or address physical complaints first before the patient can discuss anxious, depressed, or agitated moods.

MODIFYING THE PATIENT'S SURROUNDINGS

Patients with personality disorders often show fewer symptoms and a dramatic improvement in their acute emotional, physical, and behavioral functioning when the physician recruits additional support from the environment. This may mean bringing in a helpful spouse, friend, or other personal support into the patient's medical care. Other approaches to improving the patient's external environment may include allowing the nurse or office staff to spend more time with the patient, adding social services, offering self-help support groups, or recommending psychiatric care. In extreme situations, using psychiatric or medical emergency services can be helpful interventions. Some patients with personality disorders need to be managed with the help of the police.

IMPROVING THE PATIENT'S CAPACITY TO TEST REALITY

Patients with personality disorders typically have distorted views of reality. Stressed patients from the Cluster A and B groups may transiently hear voices, hallucinate, have brief episodes of delusional thinking, or have paranoia. Impairment in reality testing can occur with paranoid, schizoid, schizotypal, and borderline personality disorders. If psychotic disturbances in reality are present, assess and treat these first before providing the requested medical care. Mobilizing external supports, using medications, or placing the patient in a safe and calm environment is often sufficient.

A stressed patient can also present with a tenuous or disturbed relationship to reality. Cluster B patients may have a disturbance in the sense of reality, such as *derealization* (watching his or her own life as if it were a movie), *depersonalization* (not feeling a part of one's own life), dramatic distortions of what has been said, transient misperceptions of real events (interpreted according to core beliefs or irrational thoughts), or misunderstanding the physician or patient role. Such reality distortions are not usually dangerous but can lead to severe problems in the physician–patient relationship if they are not recognized and addressed. Helpful verbal techniques to improve reality testing include uncovering and clarifying the patient's irrational thoughts or core beliefs and using confrontation, clarification, and interpretation to improve the patient's reality distortions.

EMPATHIZING WITH THE PATIENT'S WORLDVIEW

Many patients need a focal physical examination first to believe that the physician is taking them seriously. Afterward, all psychological interventions used depend on the patient's feeling understood by the physician. Listening and reflecting back the problems identified by the patient while empathizing with the patient's worldview can be extremely helpful in management.

For example, an avoidant personality-disordered patient may refuse a prostate examination while having complaints of urinary hesitation and dribbling. The physician could say:

I am not trying to criticize you for your preference to avoid a physical exam. I understand your wish to avoid dealing with this problem. The testing (urinalysis and rectal examination) takes only a few minutes and is not terribly uncomfortable. This information will guide my treatment. I think it is in your interest to get these examinations. Could we do this today? Then we can plan a way to relieve your symptoms.

ACCEPTING THE PATIENT'S LIMITATIONS AND STRENGTHS

Patients with severe personality disorders are often rigid in their approach to the world and limited in their capacity for social and occupational functioning. They typically do not seek or make changes easily. In patients with the most severe personality disorders, it may be most effective to accept the patient's fixed and irrational beliefs and limited functioning. Focusing on the patient's strengths and how external circumstances (not the patient's beliefs) can be modified may be better strategies to help these most difficult patients.

MANAGING UNREASONABLE EXPECTATIONS AND SETTING REASONABLE LIMITS

Patients with personality disorders often have unreasonable expectations. They may expect an unrealistic cure, never-ending diagnostic testing, constant availability of the medical team, special treatment, an unwarranted disability diagnosis, excessive pain medication, or many consultations. The physician must set limits on a patient's unreasonable expectations. Effective limit setting involves exploring why the patient believes that his or her particular expectation can or should be met. This involves a reasonable physician response about what can or cannot be done. Ultimately, limit setting is about agreeing to a reasonable approximation of the patient's request and tactfully saying "no" to requests that are not appropriate.

QUESTIONING ILLLOGICAL FEELINGS, THOUGHTS, AND BEHAVIORS

Patients often have irrational thoughts about their illnesses and the care that they will receive. They may also misunderstand the physician's efforts to communicate. For example, some patients may think that nothing can be done to ameliorate their physical complaints or that a prescribed medication may make them sick. Other patients may think that magnetic resonance imaging (MRI) will cure them or that the MRI may give them cancer. These types of irrational thoughts should be explored and the reality clarified. If done tactfully, this usually reduces anxiety in most patients. If a patient is frankly delusional, it is not useful to confront a patient's fixed belief. It is better to accept the patient's viewpoint while asking the patient's permission to have a different viewpoint.

DISCUSSING DEFENSE MECHANISMS AND COPING STYLES

Patients may benefit from discussing their maladaptive defenses and coping styles and exploring ways of effectively

dealing with their situations. For example, an obsessive-compulsive patient has a high cholesterol level and is calling the physician's office for more details about other laboratory tests. The results of the lipid profile are given to the patient, who now wants to know whether a lifestyle change or a statin medication would work better. With the recommendation for an initial lifestyle plan of more exercise and nutritional counseling, the patient becomes concerned about how to pay for this. Repeated efforts to help the patient with additional information do not make the patient feel any better. In fact, more information just raises more requests for additional information. The patient is asked to come for another visit. At this visit, the physician might say, "I can continue to give you more information, but it seems that anxiety is driving your questions. What are you worried about?" In essence, this says, "Your coping style of seeking information and details is not helping you. If you can recognize your anxiety about this subject, you may feel calmer." Review [Table 45-1](#) for specific defenses and coping styles. Interpreting defenses or modifying a coping style requires the ability to recognize these and then to implement the preparatory confrontations and clarifications before making an interpretation and subsequently suggesting new ways to cope with the situation.

KEY TREATMENT

- Attend to the doctor–patient relationship.
- Focus the interview on manageable goals within the time frame available.
- Use psychotherapeutic techniques of confrontation, clarification, and interpretation when interviewing the patient ([Davanloo, 1990, 2001](#)) (SOR: A).
- Attend to the patient's emotional needs (SOR: C).
- Modify the patient's surroundings (SOR: C).
- Improve the patient's capacity to test reality ([Kernberg, 1975, 1984, 1992](#)) (SOR: C).
- Empathize with the patient's worldview ([Beck, 1990](#)) (SOR: C).
- Accept the patient's limitations and strengths (SOR: C).
- Manage unreasonable patient expectations and set limits (SOR: C).
- Question illogical feelings, thoughts, and behaviors ([Greenberg & Padesky, 1995](#)) (SOR: C).
- Discuss defenses and coping style and interpret them (see [Table 45-2](#)) (SOR: C).
- Prescribe medications as needed ([Markovitz, 2004](#); [Soloff, 2000](#); [Soloff, 2009](#)) (SOR: A).
- Use specific interventions for each kind of difficult patient as detailed in [Table 45-3](#) (SOR: C).

PSYCHOPHARMACOLOGY FOR PERSONALITY DISORDERS

Medication can be helpful at times in treating patients with personality disorders. Prescribing medication can be focused on (1) treating targeted traits or symptoms within the personality disorder, (2) the personality disorder itself, or (3) the comorbidity of any major psychiatric illnesses that coexists with the personality disorder.

Table 45-4 Pharmacotherapy for Symptomatic Treatment of Personality Traits and Disorders*

Anger and Impulsive Aggression	Suicidal Ideation	Psychotic Symptoms	Mood Instability and Interpersonal Problems	Anxiety	Depression
BORDERLINE PERSONALITY DISORDER (SOR: B)[†]					
Haloperidol	Flupenthixol	Aripiprazole	Aripiprazole	Aripiprazole	Aripiprazole
Aripiprazole	decanoate	Olanzapine	Olanzapine	Olanzapine	Divalproex sodium
Olanzapine	Olanzapine		Divalproex sodium	Topiramate	Amitriptyline
Lamotrigine	Fluphenazine		Topiramate		
Topiramate	decanoate				
	Paroxetine				
ANTISOCIAL PERSONALITY DISORDER (SOR: C)[‡]					
Lithium					
Phenytoin					
Citalopram					
Sertraline					
SCHIZOTYPAL PERSONALITY DISORDER (SOR: B)[‡]					
	Olanzapine	Olanzapine			
	Risperidone	Risperidone			
AVOIDANT PERSONALITY DISORDER (SOR: B), DEPENDENT TRAITS (SOR: C)[‡]					
			Brofaromine	Brofaromine	
			Citalopram	Citalopram	
			Sertraline	Sertraline	

*Doses of these medications are in the standard range that are used for the major psychiatric illnesses.

Psychopharmacology targeting traits or symptoms of BPD has the most robust literature (Stoffers et al., 2010). The older approach of primarily using antidepressants and selective serotonin reuptake inhibitors for treating the multiple symptoms of BPD has not been replicated in the most recent literature. Medications shown to be somewhat effective in treating the multiple symptoms of anger and impulsive aggression, psychotic symptoms, and anxiety in BPD include aripiprazole and olanzapine. A medication somewhat effective at treating anger and impulsive aggression, disturbed interpersonal relationships, and anxiety of BPD is the mood stabilizer topiramate. Treatment of suicidal behaviors is best targeted with flupenthixol or fluphenazine decanoate, paroxetine, or olanzapine. Other medications that may be useful for treating a single targeted symptom of BPD are detailed in Table 45-4.

There is also some evidence for prescribing medication to treat antisocial personality disorders, avoidant personality disorder with dependent traits, and schizotypal personality disorder. These medications are also detailed in Table 45-4.

When using psychopharmacology to treat a patient with comorbid major psychiatric illness and personality disorder, it is most important to focus initial medication trials on the primary psychiatric illness, not the personality disorder. This is because many symptoms seen in major psychiatric disorders are the same as those seen in personality disorders. Some of the symptoms related to a personality disorder will completely remit when the primary psychiatric illness is treated first. If symptoms of the personality disorder remain after treatment of the primary psychiatric

disorder, then the patient can be treated using the targeted symptom approach detailed in Table 45-4.

KEY TREATMENT

- Medications can target anger and impulsive aggression, suicidal ideation, psychotic symptoms, mood instability, interpersonal problems, anxiety, and depression (see Table 45-4) (Markovitz, 2004; Soloff, 2000; Soloff, 2009) (SOR: A).
- Doses for treating symptoms are the same as doses used for major psychiatric conditions (Markovitz, 2004; Soloff, 2000; Soloff, 2009) (SOR: B).
- Anger and impulsive aggression, psychotic symptoms, and anxiety in BPD can be treated with aripiprazole and olanzapine (Lieb et al., 2010) (SOR: A).
- Anger and impulsive aggression, disturbed interpersonal relationships, and anxiety of BPD can be treated with the mood stabilizer topiramate (Lieb et al., 2010; Nose et al., 2006; Ypriitham, 2004.) (SOR: A).
- Treatment of suicidal behaviors is best targeted with flupenthixol or fluphenazine decanoate, paroxetine, or olanzapine (Lieb et al., 2010; Soloff, 2009) (SOR: B).
- Irritability, anger, and mood symptoms in patients with personality disorders are *not* generally responsive to selective serotonin reuptake inhibitors (SSRIs) (Soloff, 2009) (SOR: A).
- Psychotic symptoms can be treated with low doses of typical or atypical antipsychotic medications (Soloff, 2009) (SOR: B).

Interventions for Specific Personality Disorders

Using specific interventions for each subtype of personality disorders is the art of medicine. A basic specific approach is outlined for each disorder in [Tables 45-1](#) and [45-2](#). This schema includes choosing the correct DSM-5 cluster; identifying the specific personality diagnosis; understanding the patient's core beliefs, irrational thoughts, specific fears, main defense mechanisms, and coping style; and recognizing common physician reactions to each personality disorder. Using this knowledge, interventions are then tailored for each disorder (see [Table 45-3](#)). This conceptual framework allows the formulation of helpful interventions for the primary care management of specific personality disorders.

PARANOID PERSONALITY DISORDER

When interacting with a paranoid patient, the physician typically reacts with fear, mistrust, and a sense of danger. The physician may also feel blamed or accused. The patient may have a similar fear of being hurt, exploited, or invaded. Patients often react to suggestions for medical care with mistrust, excessive fault finding, sensitivity to criticism, or hypervigilance. They may collect small insults as proof of the world's injustices. When invasive medical procedures are performed, a paranoid patient may react with full-blown panic and anxiety; many paranoid patients unconsciously experience a body invasion as a homosexual assault. Patients with paranoid personality disorder rely most heavily on projection as their main defense. Using projection, they accuse the physician of hurts that reflect their own aggressive style of hurting others.

A physician working with the paranoid patient needs to empathize with the patient's mistrust and hypersensitivity. The physician should avoid arguing or attempting to reason the patient out of the paranoid worldview. It is extremely important to use confrontations and clarifications to help correct the patient's distorted perceptions about his or her medical care. Unfortunately, direct confrontation of a delusion or hallucinations (the most troubling deficits in reality testing) often has the paradoxical effect of making these patients more suspicious of the physician.

Acknowledging that the patient's suspicion has an emotional reality can be helpful. Rather than confronting mistrust or suspicions directly, the physician can acknowledge responsibility for any actions that the patient might have perceived as mistakes. For example, the physician could say, "I did not appreciate how it might hurt you when I ordered that lab test." It may also help to express understanding and concern for the patient's rights. If there is a medical need for special testing of which the patient is suspicious, acknowledge the patient's fears and describe openly and honestly the details of the procedures, potential for pain, and likely risks and benefits. If the patient still refuses to comply, do not use direct persuasion. Ask the patient, "Is it all right with you if we have different opinions?" With the patient's consent to hearing a different opinion, openly discuss the medical necessity of the testing without trying to resolve the problem. At future office visits,

attempt new and ongoing discussions of the patient's fears of complying with the request for specialized testing. It may take months for the paranoid patient to trust enough to consent to the appropriate treatment. Counterprojective statements by the physician can diffuse the projections and distortions directed at the physician. The physician can use counterprojective remarks to help the patient access his or her feelings while focusing angry or suspicious feelings away from the physician toward others who are not present. For example, a physician harassed by an angry, suspicious, or blaming patient could use a counterprojective statement such as, "You felt angry and hurt when the lab technician drew your blood. You must be fearful of the results of these tests."

SCHIZOID AND SCHIZOTYPAL PERSONALITY

Physicians typically feel uninvolved or detached or have a desire to break through the aloofness of schizoid and schizotypal patients. *Schizoid* patients may give the physician the impression that they are loners. A common physician reaction to *schizotypal* patients is a feeling that the patient is alone and "weird or strange." Superficially, patients with either diagnosis fear personal contact, emotional involvement, and invasion of their privacy. At the deepest level, they long for emotional contact that is not overwhelming. They may react to suggestions for medical care with avoidance, withdrawal, apparent emotional detachment, or denial of the medical problem. Schizotypal patients often function with impaired reality testing manifested by magical, odd, or psychotic modes of thinking. Schizotypal patients use regression to schizoid fantasy and, to a lesser extent, denial as their main defenses. They appear increasingly idiosyncratic and withdrawn when stressed. Schizotypal personality disorder appears to increase the risk for the future development of schizophrenia.

Schizoid patients do not appear psychotic or idiosyncratic in their behavior. They are disinterested in intimate contacts with others, appear detached and unemotional, and wish to be left alone. More infrequently than schizotypal personality disorder, the schizoid personality may also be associated with the future development of schizophrenia. When stressed by a medical problem, schizoid patients use isolation and intellectualization to hide their emotions. If necessary, they regress to childlike functioning or use psychotic denial of their illness as their main defenses.

Patients with schizotypal and schizoid personalities tend to experience their physicians as intruding into their privacy, which may drive them away from the physician. They are relieved when the physician is not present and prefer fewer medical appointments and contacts. It is generally helpful to accept their lack of sociability at a level that does not demand involvement or permit total withdrawal. Neutral or unemotional expressions of medical information are most likely to be heard and used.

ANTISOCIAL PERSONALITY DISORDER

Common physician reactions to a patient with antisocial personality disorder are feelings of being used, exploited, or deceived. This can lead to physician anger and wishes to be

free of the patient, uncover lies, or punish or imprison the patient. These patients fear that they will become vulnerable, lose respect or admiration from others, and become easy prey to manipulation when they become ill. They expect to be exploited, demeaned, or humiliated. Similar to a narcissistic patient, they often have low self-esteem, excessive self-love, compensatory feelings of superiority, grandiosity, recklessness, and emotional shallowness, and they show a lack of concern for others. They often react to medical care with entitled demands for special treatment. When caught in dishonesty, they may angrily attack or devalue the physician. They may resort to other psychopathic manipulations of deception, lying, cheating, or stealing. In fact, their friendly, facile, slick, superficial charm and intelligent appearance is often beguiling for the physician. They can lose reality testing when stressed by the potential of getting caught in their deceptive practices. This is typically manifested by impulsive actions that reveal severely impaired or sometimes psychotic judgments. When receiving medical care for a legitimate illness, they typically function at the same level and often appear to have the same characteristic issues as the narcissistic personality disorder (Kernberg, 1992). They can often be managed similarly (see “Narcissistic Personality Disorder”).

To intervene with an antisocial patient, the family physician needs to be alert and anticipate that the patient may be requesting unnecessary medical care or malingering or may present with a factitious disorder. Although setting strict limits and reasonable expectations is important when treating all patients with personality disorders, it is particularly important when dealing with a patient with antisocial personality disorder. This patient may be seeking the secondary gain of illegal disability benefits or money, excuses for work absenteeism, or avoidance of legal problems or may be just seeking caretaking. It is important not to inadvertently collude with the patient’s plans for secondary gain. For example, if the physician thinks that a patient’s request for disability is fraudulent or unwarranted, the patient should not be referred for additional disability evaluations. If deception is suspected, the physician can ask for verification of symptoms from other reliable sources. There is often dishonesty in a patient’s communication in the form of withholding important information, partial truths, or outright lying, cheating, or stealing. If this occurs, avoid the common reaction of moralizing. Instead, grant the patient the reality that he has the ability to fool all the physicians if he or she wants. The patient can be told that the result of deception is that the physician may make poorly informed medical decisions. This will ultimately result in the patient’s receiving inadequate or poor medical care. The physician can explore with the patient why he or she needs to act self-destructively. Patients may need to be reminded that the physician’s role is to help with medical problems and not to pass judgment or help the patient obtain unfair medical benefits.

BORDERLINE PERSONALITY DISORDER

Patients with BPD have a high prevalence of somatic symptom and substance abuse disorders (Grant et al., 2004; Lubman et al., 2011). They frequently become dependent on their physicians in an extremely demanding, clinging, and helpless or self-destructive manner. Physicians may feel

manipulated, angry, depleted, exhausted, or self-doubting. They may want to end the patient relationship or rescue patients from themselves, or they can be drawn into a cycle of extensive medical testing to try to explain many somatic complaints. Patients with BPD fear separation or abandonment and may react to potential losses with panic, emotional instability, anger, or impulsive (suicidal or self-destructive) actions. They may seek care and use defenses that appear as a somatic symptom disorder. These somatic symptoms and borderline personality structure often represent the sequelae of childhood abuse, sexual abuse, or other trauma (Kernberg, 1975; Sansone et al., 2001).

Use of parallel inquiry to uncover a history of trauma is often most helpful for a patient complaining of multiple somatic complaints. Borderline patients often react to medical care with an aggressive or dependent clinging to their physicians and other caretakers (Gross et al., 2002). They may angrily devalue a physician who does not adequately explain their symptoms and may make entitled demands for special treatment when they become worried or frustrated. They tend to relate to others as “all good or all bad,” which significantly contributes to their poor life functioning.

Typically, reality testing is intact. However, under stress, patients with BPD may temporarily lose reality testing and have mini-psychotic breaks lasting minutes or hours. These patients may at times manifest severe distortions in perceptions or sense of reality. They may misunderstand the physician’s intentions or instructions. They may also experience episodes of derealization or depersonalization. Patients with BPD have *identity diffusion*, extreme fluctuations in self-perception from the grandiose to an excessively harsh underestimation of their abilities. They also have stormy and chaotic relationships with others. They rely heavily on splitting, projective identification, projection, and devaluing.

Office management of patients with BPD involves an empathic understanding of their fears. These fears revolve around the threat to their security or fears of separation or abandonment and, secondarily, sensitivity to rejection or fears of humiliation. They require firm limit setting (e.g., what the physician can realistically offer). Attempts to satisfy these patients’ intense needs often result in an exhausted or angry physician. This can be avoided by setting realistic limits while offering the patient different ideas or options for medical care and more adaptive behaviors. Initial interventions should attempt to establish reality testing or correct reality distortions. If reality testing is intact, the most helpful interventions can be aimed at attending to medical care while decreasing the pathologic splitting defenses by using confrontation, clarification, and interpretations of the problematic situation.

The primary treatment for BPD is psychotherapy complemented by symptom-targeted pharmacotherapy (APA, 2001). Four types of psychotherapy have been shown to be effective in treating this personality disorder (Stoffers et al., 2012). These are dialectical behavior training, transference-focused psychotherapy, mentalization-based psychotherapy, and supportive psychotherapy in conjunction with medications. Most patients with BPD need extended psychotherapy (twice per week for 1 to 2 years) with specially trained mental health professionals to attain and maintain lasting improvement in their personalities, interpersonal

problems, and overall functioning. Pharmacotherapy often has an important adjunctive role, especially for diminution of symptoms such as affective instability, impulsivity, psychotic-like symptoms, and self-destructive behavior (see [Table 45-4](#)). Although caring for these patients can be exhausting for family physicians, it is important to know that the long-term remission rates for patients with BPD are quite good.

HISTRIONIC PERSONALITY DISORDER

Patients with histrionic personality disorder have an emotionally expressive style, seek excessive attention, are often dramatic, and may present with a conversion disorder. Physicians may feel flattered, captivated, seduced, or sexually aroused by these patients. Alternatively, the physician may feel overwhelmed by the patient's exaggerated or excessive emotions, embarrassed by the sexual overtures, depleted, or confounded by unexplained physical symptoms (e.g., pseudoseizures, paralysis, and mutism). These patients may unconsciously use their symptoms to elicit attention or support from the physician ([Bornstein and Gold, 2008](#)). They may also use their sexuality to recruit others to satisfy their needs to be taken care of or romantically pursued. They fear that they are not desired and will lose the care or admiration of others.

There are two different levels of functioning with the histrionic personality disorder. [Kernberg \(1984, 1992\)](#) describes a neurotically functioning "hysteric" who shows intact reality testing, defenses centered on repression, and stable and mature relations with others. The female hysteric has a flirtatious, clinging, childlike dependence in intimate relationships but can function at mature levels in social and work situations. Male hysterics have similar psychological conflicts but may appear as "macho" or "effeminate" ([Kernberg, 1992](#)). The hysteric of either sex often reacts to medical care with regression to a childlike, sexualized, dependent, and clinging position. They seek to gratify their wishes for dependent care by seducing or flattering others. Outside the office, they usually function well.

By contrast, a "histrionic patient" ([Kernberg, 1984, 1992](#)) can display transient losses of reality testing, defenses centered on splitting, chaotic sexualized relations with others, and a range of unexplained physical or somatic complaints. The histrionic patient is self-centered and self-indulgent, with a pervasive childlike dependence that extends from intimate relationships into all aspects of social and occupational functioning. Female histrionics typically act flirtatiously but may become indignant when a man shows sexual interest. Male histrionics also show the self-centered and dependent pattern but may also have hypochondriacal and antisocial features. Histrionics of both genders may seek medical care because of unexplained medical symptoms. They may react to medical care with regression but, unlike the hysteric, use defenses centered on "splitting"; they may see the physician as "all good or all bad" and can be extremely devaluing. They may appear severely self-centered, attention seeking, diffusely sexual, hypochondriacal, somatic, and exploitative. All of this may be coupled with an exhausting dependency on the physician.

In working with hysterics and histrionic patients, a physician needs to be friendly, neither overly warm nor reserved.

Hysterics and histrionics often are helped when the physician uses parallel diagnostic inquiry when they present with somatic complaints. Parallel diagnostic inquiry is a technique in which the clinician simultaneously explores potential physical and psychological factors involved in the patient's complaints. Hysterics also may benefit from some gratification of their dependent wishes and a free discussion of their fears and emotions. They can often be reassured by an educational and informational approach to their medical illnesses and are capable of expressing gratitude to the physician. In contrast, the intense dependency of histrionics is often made worse by gratifying the patient's needs. Offering excessive emotional care may make them greedy or demanding for satisfaction of their needs. Histrionics benefit from firm, kind limit setting (especially to their sexual overtures), with neutral acknowledgment and gratification of their reasonable needs. They may be further helped by focusing on their distortions in reality perception and through interpretation of their splitting mechanisms.

NARCISSISTIC PERSONALITY DISORDER

The family physician's reactions to the narcissistic patient are often difficult to manage. The superior, entitled, self-loving, arrogant attitude of these patients can be intimidating. They may elicit feelings in the physician of being devalued and inferior. The physician may have concerns about the patient's anger and criticism. Alternatively, the lack of empathy and interpersonal exploitation of these patients can readily provoke the physician to anger, a wish to retaliate with harsh criticism, or a desire to end the patient-physician relationship.

The core fears of narcissistic patients are the result of a fragile self-esteem and their need for constant approval and praise from others. They fear loss of admiration, potency, and power, and they fear being exploited when vulnerable. Any perceived insult to their "grandiose self" ([Kernberg, 1984, 1992](#)) makes them feel rejected, deflated, and criticized and frequently results in feelings of rage, shame, or humiliation.

A narcissistic patient generally has intact reality testing but can undergo severe reality distortions when he or she perceives slights, rejection, or competition from others with talent. Those narcissistic patients who have paranoid and antisocial features ([Kernberg, 1992](#)) have a worse prognosis. They often have a fragile identity that can swing from the grandiose to the worthless. They rely heavily on splitting mechanisms to regulate their self-esteem. They portray themselves as grandiose and superior. This helps defend against feelings of extreme inadequacy and vulnerability. They can devalue, viciously attack, or degrade those around them when they act in a self-important way. Alternatively, as splitting operates, they may idealize or be envious of others who are, for the moment, seen as more powerful or successful. In this position, their self-esteem plummets, as evidenced by their sense of worthlessness and their reports of deprecating and degrading self-attacks.

Office management of narcissistic patients, as well as many antisocial patients, requires that the physician not mistake the patient's superior and entitled manner for genuine confidence. When being verbally devaluing, it may help the physician to view the demeaning or verbally attacking patient as a wounded child having a "temper

tantrum.” This may prevent the physician from retaliating by demeaning the patient, which only escalates a maladaptive interaction. Intervening in the face of a devaluing attack involves acknowledging that the patient feels hurt and that the patient has a right to his or her opinions. If the patient can discuss his or her hurt feelings with a nonjudgmental and empathic physician, the problems generally resolve, and a good physician–patient alliance can be restored. If this is not possible, offer the patient the right to seek another expert for consultation. This offer needs to be made without malice, defensiveness, or apology. This may help the patient calm down and reconsider his or her position.

In a long-term relationship with a narcissistic patient, splitting can be interpreted. This can be done by reminding patients who are demeaning that they previously praised the skill and abilities of the physician. If hostile, patients can be asked why they are now so critical and angry. When this is effective, it will allow patients to discuss their perception of insults to their self-esteem.

AVOIDANT PERSONALITY DISORDER

Patients with avoidant personality disorder have feelings of inadequacy and fear of criticism. They have low self-esteem and believe that they are inept and inadequate. They believe that others are critical and disapproving until proved otherwise. Although avoidant patients crave human relationships and affection, their fear of being criticized, rejected, embarrassed, or hurt causes them to initially avoid social situations or meeting new people. Their shyness and avoidance protect them from their fears of being rejected or humiliated. In medical encounters, they often can seek psychosocial help through somatic complaints. This somatic approach of physical complaints can conceal psychological issues and makes them feel safer than revealing unconscious or unexpressed emotions. They prefer not to divulge personal aspects of themselves because this may leave them vulnerable. Their timidity, hypersensitivity, and cautiousness can generate feelings of frustration or annoyance in the physician. Patients with avoidant personality disorder typically use defense mechanisms based on denial; repression, including inhibition; phobia; and isolation.

Managing avoidant patients is more effective when the physician uses both parallel diagnostic inquiry and emotion-focused interviewing. It is most helpful when the physician can recognize and empathize with the patient’s social fears, including the fear of the physician’s criticism. Patients may minimize symptoms or delay seeking help because of fear of the physician or the feeling that they are unworthy or unimportant. Some avoidant patients do the reverse by asking for emotional help through their somatic symptoms. The physician should help the patient understand his or her symptoms and any specific fears revolving around the diagnostic or therapeutic plan. Irrational fears and thoughts can be gently corrected and alternative interpretations offered. Patients should be encouraged, with appropriate support, to face their somatic and other fears as the best way of mastering them. If the physician feels frustration or annoyance, it is often helpful to encourage the patient to describe what he or she is finding most difficult in the medical care or proposed medical plan.

DEPENDENT PERSONALITY DISORDER

Patients with dependent personality disorder may be characterized by an exaggerated need for care or a need for direction from another person (or both). Dependent patients may present initially with a physical illness. These initial medical complaints often elicit exaggerated caretaking response from physicians and may introduce into the medical relationship a tendency to return to the physician with increasing somatic complaints (Bornstein and Gold, 2008). Dependent patients often feel helpless and inadequate in making even minor decisions, such as what to do next medically, what to wear, or whom to befriend. They have a core belief that they cannot function alone, are completely incapable of taking care of themselves, and must have someone else provide care and make decisions. Their major fear is of independence.

Although both borderline patients and dependent patients are extremely dependent on others, they react very differently to the threat of losing a significant other. Whereas a borderline patient becomes angry or enraged, a dependent patient becomes submissive and obsequious. Patients with dependent personality disorder use defenses that include regression, passive aggression, and reaction formation.

Patients with dependent personality disorder are submissive and clinging with their caretakers because of fear of losing them. The dependence of these patients can make physicians feel annoyed, drained, or depleted. Physicians may tend to deny reasonable needs of an excessively dependent patient. The secondary gains that patients with dependent personality receive from an illness also create extra challenges for the physician. Use of parallel diagnostic inquiry and emotion-focused interviewing is helpful. The physician must understand and empathize with the patient’s need for being taken care of while encouraging and fostering independent thinking and action by the patient. Because these patients often use medication, alcohol, food, and other means to satisfy their dependency needs, the physician must exercise caution in how these are used in the therapeutic plan. Unreasonable expectations for being taken care of should be gently discouraged by the physician.

OBSESSIVE-COMPULSIVE PERSONALITY DISORDER

Patients with OCPD are preoccupied with details, order, and control. Although their labels are similar, these patients differ in substantial ways from patients with obsessive-compulsive disorder (OCD). OCD patients have recurrent disturbing thoughts or obsessions that create marked subjective distress.

The core adaptive traits of patients with OCPD are orderliness, attention to detail, and an emphasis on rational thinking and logic. These traits are lifelong patterns that many patients use adaptively in their professional lives. Patients with OCPD often view these traits as a personal strength. However, often their attention to detail leads them to perfectionist beliefs, worry, or ruminations that they must not make mistakes or be imperfect. They can interpret rules, regulations, and values rigidly and stubbornly. Patients with OCPD often ruminate and are prone to inter-

pret minor physical changes as worrisome somatic complaints (McGuire and Shore, 2001).

Because they are uncomfortable with feelings and emotions, patients with somatic presentations may be unconsciously motivated to seek reassurance from their physicians. They may fear disorderliness and dirt. The compulsive, critical, controlling, self-righteous side of their personalities often creates difficulty in relationships with physicians, coworkers, friends, and family. They can be stingy, orderly, and obstinate. Physicians, who often have obsessive-compulsive traits themselves, may feel irritated and competitive with these patients about who controls the diagnostic workup or treatment plan.

Patients with OCPD use defense mechanisms such as intellectualization, isolation, displacement, doing and undoing, and reaction formation. Using reaction formation, they may behave in a superficially deferential or obsequious manner to repress from themselves and hide from others their critical and self-righteous and indignant feelings. These defenses are used against their anger and dependency needs, which are often unconsciously denied. Illness may represent a dangerous threat to the sense of self-control in OCPD patients. A past illness can lead to a future somatic presentation. The physician should understand and empathize with this loss of self-control while helping patients regain some control in the management of their medical problems. Struggle or conflict with the patient over control of medical care should be avoided. Reality distortions, including excessive perfectionism, idealization of logic, and avoidance of feeling, can be gently elicited, explored, and worked through with the patient.

Conclusion

Patients with personality disorders often contribute significantly to physician dissatisfaction and burnout with

medical practice. The negative effects of a personality disorder on the doctor–patient relationship are often so deleterious that many of these patients get less than optimal primary care. A unique approach to diagnostic, management, and intervention strategies is described in this chapter and summarized in Tables 45-2 and 45-3. This personality disorder schema combines DSM-5 diagnosis with cognitive-behavioral and psychodynamic viewpoints involving the patient's core beliefs and irrational thoughts, fears, defenses and coping style, behaviors, adherence to medical treatment, and use of medical services. Common physician reactions, general strategies, and specific physician interventions for 10 different personality disorders are addressed to help the family physician maintain a working physician–patient relationship that permits the delivery of needed medical care.

CHAPTER OUTLINE

Overview, 1090
Anxiety, Major Depression, and Medical Illnesses, 1092
Diagnosis and Screening of Mood and Anxiety Disorders, 1093

Assessment of the Depressed or Anxious Patient in Medical Settings, 1097
Management and Treatment of Major Depression and Anxiety Disorders, 1099

Overview

Key Points

- Depression and anxiety increase medical morbidity and mortality.
- Mood disorders comprise unipolar and bipolar disorders.
- Anxiety disorders comprise eight disorders, of which generalized anxiety disorder (GAD) and panic disorder are frequently encountered in primary care settings.
- Treatment of depression and anxiety improves overall health outcomes.
- The majority of patients with mood and anxiety disorders are treated in primary care settings.

Major depression and anxiety disorders are the two most common psychiatric illnesses in the United States and are particularly prevalent in primary care settings. Despite the relative availability of specialty psychiatric care in the United States, most patients with depression or anxiety disorder continue to receive their treatment from primary care physicians. Moreover, patients with both medical illness and comorbid mood or anxiety disorder frequently have poorer outcomes, experience more prolonged and difficult treatment, and have greater morbidity and mortality than patients without psychiatric illness (Katon, 2003). Conversely, treating underlying depressive and anxiety disorders not only improves the emotional well-being of patients but also improves overall health outcomes and lowers health care costs. Given their frequency, severity, prevalence, morbidity, and mortality, depression and anxiety disorders remain important illnesses for primary care physicians to identify and treat.

The broader categories of mood and anxiety disorders comprise a large number of specific illnesses. Describing the specific symptoms, epidemiology, assessment, and treatment of each illness is beyond the scope of this chapter; rather, we examine the illnesses that primary care physicians are most likely to encounter in clinical settings and provide the most common strategies used in assessment, diagnosis, and treatment. *Mood disorders* include major depression (also called unipolar depression), bipolar disorder (which includes bipolar I and bipolar II disorder),

cyclothymia, and dysthymia (also called pervasive depressive disorder). With the latest edition of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) (American Psychiatric Association [APA], 2013), several new mood disorder categories have been added, including disruptive mood dysregulation disorder (chronic, severe persistent irritability, along with severe temper outbursts, beginning at an early age), premenstrual dysphoric disorder, and two broad and nonspecific depressive diagnoses (other specified depressive disorder and unspecified depressive disorder). This chapter focuses on the major mood disorders of depression and bipolar disorder. The category of *anxiety disorders* in the new DSM-5 (APA, 2013) contains GAD, panic disorder, agoraphobia, specific phobia (e.g., fear of heights), and social anxiety disorder (social phobia). Obsessive-compulsive disorder (OCD) and posttraumatic stress disorder (PTSD) have been removed from the anxiety disorder category. This chapter focuses primarily on GAD and panic disorder.

EPIDEMIOLOGY

Key Points

- Major depression and anxiety disorders are the two most common psychiatric illnesses in the United States.
- The economic burden of anxiety and depressive disorders is substantial in terms of workdays lost, disability, health care expenditures, and mortality.
- Anxiety and depression are chronic illnesses that typically run a waxing and waning course.
- Prevalence rates for anxiety disorders appear to decline with advancing age, except for GAD, which may increase in geriatric populations.
- Depression is often a highly recurrent illness; each episode of depression increases the likelihood of future episodes.

Prevalence estimates of mental disorders in the United States continue to find that anxiety and mood disorders are the two most common mental disorders in the general population (Kessler et al., 2012). Lifetime prevalence for anxiety disorders is estimated at 16.6% to 28.8% (Conway et al., 2006; Kessler et al., 2005a) and for major depression

is estimated at 14.9% to 16.2% (Kessler et al., 2003). Recent 12-month prevalence rates show a similar stratification, with anxiety disorders most common (18.1%) followed by mood disorders (9.5%). Lifetime prevalence rates of panic disorder and GAD are 4.7% and 5.7%, respectively (Kessler et al., 2005a). Anxiety disorders make up approximately 2% of all office visits to physicians in the United States, but almost 50% occur in primary care settings. In comparison, approximately 40% of patients presenting with anxiety disorders are seen by psychiatrists (Harman et al., 2002).

Major depression remains a common disorder and is associated with substantial symptom severity and role impairment (Kessler et al., 2003). One-year prevalence rates for major depression are approximately 6% in the general population followed by dysthymia (1.8%) and bipolar disorders (1%-2%). Rates in primary care settings remain substantially higher, with prevalence of 10% or greater (Spitzer et al., 1994), although many of these patients have depression that is unrecognized by their primary care physician (Schultheis et al., 1999).

COSTS

Both anxiety and depressive disorders account for substantial health care costs and thus constitute a major public health and economic concern. As of 2013, the cost of depression and anxiety disorders in the United States comes from data between 1990 and 2000 and was calculated to be \$83.1 billion in 2000, of which \$26.1 billion was for direct medical costs, \$5.4 billion for suicide mortality costs, and \$51.5 billion for work-related costs (Greenberg et al., 2003). Similarly, estimates from the 1990s placed the annual economic burden of anxiety disorders at \$63.1 billion (in 1998 dollars), of which nonpsychiatric direct medical costs accounted for 54% of the total and direct psychiatric care accounted for 31% (Greenberg et al., 1999). Not surprisingly, patients with anxiety disorders are much more likely to see their primary care physicians or use emergency services. Patients with pure GAD (i.e., no comorbid medical illnesses), for example, were 1.6 times more likely to have seen a primary care physician four or more times in the past year than those without GAD or depression (Wittchen et al., 2002). Patients with panic disorder were almost twice as likely as controls to have visited an emergency department in the previous 6 months (Roy-Byrne et al., 1999).

DISEASE COURSE

Both anxiety and depressive disorders tend to run a chronic course, with waxing and waning symptomatology. Illness severity typically worsens the longer the illness remains untreated. The age of onset for anxiety disorders varies greatly, depending on the specific condition. Specific phobias and separation anxiety, for example, often begin in childhood (median age of onset, 7 years), but panic disorder (median age, 21 years) and GAD (median age, 31 years) are typically seen in early to mid-adulthood (Kessler et al., 2005b). In elderly persons (>65 years), the prevalence of all anxiety disorders appears to decline, except for GAD, which is maintained at 4% prevalence and may increase over time (Krasucki et al., 1998). GAD is often a recurring

illness in which patients may experience periods of residual symptoms and occasional interepisode remissions (Angst et al., 2009). More than one third of patients with panic disorder have full remission with treatment, but about 20% have an unremitting and chronic course despite treatment (Katschnig and Amering, 1998).

The onset of major depression can occur at any age, although the median age of onset is 30 years (Kessler et al., 2005b). Depression is a highly recurrent illness, and each episode increases the likelihood of future episodes. Whereas patients with a single episode have a 50% lifetime chance of recurrence, those with three or more episodes have an almost 100% chance of recurrence without treatment (Eaton et al., 2008). Untreated depressive episodes can last 6 months or longer (Kessler et al., 2003). The Sequenced Treatment Alternatives to Relieve Depression (STAR*D) study found that a substantial number of patients receiving first-line treatment may require 8 weeks or more of treatment to achieve response or remission (Trivedi et al., 2006b). Although most patients recover from their depressive episode and return to normal functioning with treatment, approximately 15% of patients continue to have an unremitting course, with worsening psychosocial functioning and a higher risk for suicide (Eaton et al., 2008).

NEUROBIOLOGY AND GENETICS

The neurobiology of both depressive and anxiety disorders is complex and incompletely understood. In contrast to illnesses such as Parkinson or Huntington disease, no single area of brain pathology or anatomic lesion has been implicated in the development of anxiety or depression; rather, these illnesses appear to be mediated by dysregulation of complex interactions between neural circuits (Nestler et al., 2002). In depression, most lines of investigation have involved dysregulation of the hypothalamic-pituitary axis (HPA) and hippocampus, along with investigations of neural circuitry mediating mood, reward, sleep, appetite, motivation, and cognition. In particular, hyperactivity of the HPA in some depressed patients has been found to lead to hippocampal volume reduction, likely by reduction of brain-derived neurotrophic factor (BDNF) and changes in the mechanisms that mediate BDNF expression. However, whether reduced hippocampal volume is a partial cause or merely a result of depression is currently unclear, and it is not seen in all patients diagnosed with depression. Although epidemiologic studies show that depression appears highly heritable, with some studies showing that 40% to 50% of the risk may be genetic, no one gene appears implicated, and depression likely is the phenotypic expression of multiple genetic vulnerabilities coupled with environmental stresses (physical or emotional trauma, viral illness), physical factors (e.g., preexisting or comorbid medical illnesses such as hypothyroidism or stroke), and random processes during brain development (Nestler et al., 2002).

Neurobiologic research in anxiety disorders has focused on elucidating the neural networks involved in the *fear response*, but despite advances in neuroimaging, the exact mechanism of each anxiety disorder has yet to be completely understood. Strategies to understand the neuroanatomic underpinnings of panic disorder have focused on translational research using conditioned fear in animals as

a model for panic attacks in humans. Patients with panic disorder may have an especially sensitive fear mechanism involving the central nucleus of the amygdala, hippocampus, thalamus, hypothalamus, periaqueductal gray region, locus ceruleus, and other brainstem sites (Gorman et al., 2000). Other areas of focus in anxiety disorders have involved investigations into alterations of interoceptive processing of the anterior insula (Mathew et al., 2008). Both the insula and the anterior cingulate cortex are thought to be the regions of the brain that form a representation of the visceral state of the body. A heightened sensitivity of this region may underlie the misinterpretation of bodily signals in panic disorder.

Genetic epidemiologic studies have clearly documented that anxiety disorders aggregate in families and that this familial link primarily results from genetic factors (Smoller and Faraone, 2008). First-degree relatives of probands with the major anxiety disorders (panic disorder, social anxiety disorder, specific phobias, OCD) have a four- to sixfold increased risk of the index disorders compared with relatives of unaffected probands (Hettema et al., 2001). Genetic studies of GAD suggest that a common genetic susceptibility may apply to “clusters” of anxiety disorders and other comorbid disorders (Norrholm and Ressler, 2009). An overlap of genes may play a role in the development of multiple psychiatric conditions, including anxiety and depression.

Anxiety, Major Depression, and Medical Illnesses

Key Points

- Anxiety disorders and major depression often coexist.
- The more severe the anxiety disorder, the greater the likelihood of major depression.
- Medical illnesses are associated with higher prevalences of anxiety and depression and vice versa.
- Medically ill patients with comorbid anxiety or depressive disorders adapt more poorly to physical symptoms, complicating disease management.

INTERACTION OF DEPRESSION AND ANXIETY

Major depression and anxiety are often found together, and each illness complicates the course and outcome of the other. Studies have consistently shown that anxiety disorders are the most frequently occurring comorbid disorder with major depression, with 50% to 60% of major depressed patients with both illnesses (Zimmerman et al., 2002). Whereas anxiety can lead to depression in almost 60% of patients, depression leads to anxiety in only 15% of patients (Mineka et al., 1998). Not surprisingly, the more severe anxiety disorders, OCDs, and trauma related disorders are more likely to lead to subsequent depression; that is, panic disorder, agoraphobia, OCD, PTSD and GAD more frequently lead to depression than either social phobia or simple phobia. In addition, patients with both illnesses often have an increased severity of symptoms, increased frequency of

episodes (either mood or anxiety episodes), poorer response to treatment, higher suicide rates, more chronic course, and overall poorer prognosis.

Treatment is complicated by the fewer studies on coexisting depression and anxiety, providing clinicians with a smaller evidence base for treatment decisions. Based on DSM-IV criteria, patients with comorbid major depressive disorders are half as likely subsequently to recover from panic disorder with agoraphobia or GAD, and comorbid major depression almost doubles the likelihood of recurrence of panic disorder with agoraphobia (Bruce et al., 2005). In addition, children and adolescents with anxiety disorders are at eight times the risk of additional depression (Angold et al., 1999). Practitioners must therefore be aggressive in screening for anxiety disorders in patients reporting depressive symptoms, as well as screening for depression in patients reporting anxiety symptoms.

INTERACTION OF DEPRESSION, ANXIETY, AND MEDICAL ILLNESS

A complex and reciprocal relationship exists between medical illnesses and comorbid anxiety and depressive disorders. Medical illnesses are associated with higher prevalence rates of anxiety and depression, and anxiety and depression are associated with higher rates of comorbid medical illnesses. Studies of patients with diabetes, cancer, stroke, myocardial infarction, HIV-related illness, and Parkinson disease have higher rates of depression than patients without such illnesses (Katon, 2003). Common medical disorders seen in primary care settings have high comorbidity with anxiety disorders as well. Cardiovascular disease is associated with a 1.5 times greater risk of both GAD and panic disorder (Goodwin et al., 2008). Patients with back pain or arthritis are almost twice as likely to have panic attacks or GAD (McWilliams et al., 2004), and patients with asthma (pediatric or adult) may have a 30% increased likelihood of anxiety disorders (Katon et al., 2004). The prevalence of anxiety and depression in patients with diabetes is more than double that in the general population (Collins et al., 2009). Almost 100% of patients with irritable bowel syndrome have major depression, GAD, or panic disorder (Lydiard et al., 1993).

Medical illnesses are associated with a higher risk for mood and anxiety disorders, so the presence of these disorders places patients at higher risk for multiple medical conditions. Patients with GAD or panic disorder are almost six times more likely to have a cardiac disorder, three times more likely to have a gastrointestinal (GI) disorder, twice as likely to have respiratory difficulties, and twice as likely to have migraine headaches than patients without anxiety disorders (Harter et al., 2003). Depression may be a predictor for the subsequent development of medical illness. Several studies found an association between history of major depression and subsequent development of type II diabetes (Eaton et al., 1996; Kawakami et al., 1999) and coronary artery disease (Rugulies, 2002).

Management of patients with comorbid medical illness and anxiety or depression is complex. Such patients have higher rates of unexplained symptoms than patients without these disorders even after adjusting for the severity of medical illness (Katon and Walker, 1998). An increasing

body of literature suggests that patients with medical illness and comorbid depression or anxiety adapt more poorly to chronic symptoms, such as fatigue or pain, and tend to focus on both symptoms of their physical illnesses and physical symptoms associated with other organ symptoms. Not surprisingly, patients with medical illness and comorbid depression have 50% higher medical costs than patients with medical illness alone (Katon, 2003). Comorbid patients are more functionally impaired and have more lost workdays, poorer quality of life, and higher rates of medical utilization (Simon, 2003). Disease management is also complicated by higher rates of nonadherence to treatment and self-care regimens, as well as higher rates of risk behaviors (e.g., smoking, overeating, sedentary lifestyle). Response to antidepressant treatment may be less robust, as evidenced by patients with cardiovascular disease, stroke, and diabetes (Katon, 2003).

Diagnosis and Screening of Mood and Anxiety Disorders

Key Points

- Distinguishing unipolar from bipolar depression is critical for the proper management of depressed patients. The Mood Disorder Questionnaire (MDQ) may aid practitioners in detecting bipolar disorder in primary care settings.
- The Patient Health Questionnaire 9 (PHQ-9) is a common and easy-to-use screening tool for depression.
- No standard screening instrument for anxiety disorders has currently been accepted in general practice.

DIAGNOSIS OF MOOD DISORDERS

Mood disorders are divided into depressive disorders, bipolar disorders, and disorders based on etiology (i.e., mood disorders caused by general medical conditions and substance-induced mood disorders). For primary care physicians, identification, treatment, and management of depressive disorders are essential. Bipolar disorders, which are typically more complex to identify and treat, are best referred to mental health professionals for ongoing treatment. Therefore, this chapter concentrates on identifying bipolar disorder and distinguishing between unipolar and bipolar depression, but it does not delve into the specifics of treating bipolar patients.

The essential feature of a *major depressive episode* is a period lasting at least 2 weeks during which the patient experiences depressed mood or loss of interest or pleasure in almost all activities, a distinct change in usual self, and clinically significant distress or changes in functioning. It is accompanied by a constellation of other symptoms, such as changes in sleep, eating, energy, motivation, and concentration; difficulty making decisions; and often feelings of hopelessness, worthlessness, and guilt (Table 46-1). Patients may ruminate about death, feel that life is not worth living, have thoughts about suicide, may make plans to kill themselves, or make suicide attempts. Many patients complain

of memory difficulties, become easily distracted, and describe an inability to think clearly. Patients often pace, wring their hands, or have an inability to sit still; conversely, they may become greatly slowed or immobilized. In some patients, irritable mood may predominate more than sadness, or they may have explosive, angry outbursts (Fava and Rosenbaum, 1999). Irritability is especially noted in depressed children and adolescents. In its most severe forms—major depression with psychotic features—patients may hear voices telling them to kill themselves or may develop delusional beliefs, such as having a serious illness despite numerous tests providing no evidence (APA, 2013).

The essential feature of *dysthymia*, also called persistent depressive disorder, is a chronically depressed mood that occurs most days for at least 2 years. Patients may have a variety of other symptoms, such as feelings of inadequacy; generalized loss of interest or pleasure; social withdrawal; feelings of guilt or brooding about the past; and decreased activity, productivity, or effectiveness (Table 46-2). Neurovegetative symptoms such as insomnia or hypersomnia, poor appetite or overeating, low energy, and poor concentration may be present but are less common than in major depressive episodes. These patients may state that they have been depressed for as long as they can remember and cannot recall episodes of recovery or remission of symptoms. In addition, dysthymic patients may periodically have superimposed major depressive episodes, often called “double depression” (APA, 2013).

Bipolar disorder is a chronic mood disorder characterized by the presence of mania (bipolar I disorder) or hypomania and depression (bipolar II disorder). Manic episodes are distinct periods of abnormally and persistent moods that can be euphoric, expansive, or irritable, co-occurring with persistently increased goal-directed activity or energy, lasting at least 1 week. Although manic patients are often thought to be always euphoric, only about 20% of patients experience pure euphoria; most describe a mix of severe irritability, severe emotional lability, and volatility (Goodwin and Jamison, 2007). Manic patients often have greatly inflated self-esteem, confidence, decreased need for sleep, pressured speech, racing or crowded thoughts, distractibility, increased involvement in goal-directed activities (e.g., starting many projects but being unable to finish any), hypersexuality, and excessive involvement in pleasurable activities with a high potential for painful consequences (APA, 2013). Patients can exert great levels of physical activity, appear tireless, and may become extremely physically agitated. Approximately 60% of bipolar I patients experience psychosis, which may involve delusions of grandeur (feeling omnipotent, having special powers or “gifts”), persecution, or hallucinations (more often auditory as opposed to visual) (Goodwin and Jamison, 2007). The DSM-5 recognizes that a patient can be diagnosed with bipolar disorder even when mania is thought to emerge during treatment with an antidepressant if the manic symptoms persist at a fully syndromal level beyond the physiological effects of the treatment. Despite mania being the defining characteristic of the disease, depressed moods tend to predominate, with bipolar I patients experiencing a 3:1 ratio of depression to mania over the course of the illness (Judd et al., 2003).

Primary care physicians are more likely to encounter patients with *bipolar II disorder* than bipolar I disorder.

Table 46-1 Diagnostic Criteria for Major Depressive Episode

- A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.
- Note:** Do not include symptoms that are clearly attributable to a general medical condition or mood-incongruent delusions or hallucinations.
1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
 2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
 3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)
 4. Insomnia or hypersomnia nearly every day
 5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
 6. Fatigue or loss of energy nearly every day
 7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
 8. Diminished ability to think or concentrate or indecisiveness nearly every day (either by subjective account or as observed by others)
 9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
- B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- C. The episode is not attributable to the physiological effects of a substance or to another medical condition.
- Note:** Criteria A-C represent a major depressive episode.
- Note:** Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss. In distinguishing grief from a major depressive episode (MDE), it is useful to consider that in grief the predominant affect is feelings of emptiness and loss, while in MDE it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in grief is likely to decrease in intensity over days to weeks and occurs in waves, the so-called pangs of grief. These waves tend to be associated with thoughts or reminders of the deceased. The depressed mood of MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of grief may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of MDE. The thought content associated with grief generally features a preoccupation with thoughts and memories of the deceased, rather than the self-critical or pessimistic ruminations seen in MDE. In grief, self-esteem is generally preserved, whereas in MDE feelings of worthlessness and self-loathing are common. If self-derogatory ideation is present in grief, it typically involves perceived failings vis-à-vis the deceased (e.g., not visiting frequently enough, not telling the deceased how much he or she was loved). If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly about "joining" the deceased, whereas in MDE such thoughts are focused on ending one's own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

From American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

Bipolar II disorder is characterized by hypomanic and major depressive episodes, although over the course of the illness, it is primarily a disease of depression, with depressive episodes predominating over hypomanic episodes by a 37:1 ratio (Judd et al., 2003). Symptoms of hypomanic episodes are similar to full manic episodes, but the severity of manic behaviors is attenuated, and the extreme functional, occupational, and social impairments evident in manic episodes are absent in hypomania. Current DSM-5 criteria require that distinct elevations in mood must be present for at least 4 days, must be clearly different from the patient's usual nondepressed mood, and must be accompanied by a change in the patient's usual functioning. Because patients primarily seek help during their depressive episodes and typically do not report hypomanic episodes as abnormal, undiagnosed bipolar disorder remains a major difficulty in primary care settings (Manning et al., 1999). Moreover, bipolar disorder may be more common in primary care settings than in general populations. Of 649 patients being treated for depression in a primary care clinic, 21% screened positive for bipolar disorder (Hirschfeld et al., 2005), but 10% of patients screened positive for bipolar disorder in a general medical clinic, although 80% of these patients had been diagnosed with unipolar depression (Das et al., 2005).

The DSM-5 introduced several important conceptual changes in the subclassification of mood disorders and their

accompanying symptoms. Because mood disorders are now thought to exist along a continuum, ranging from bipolar mania to unipolar depression, DSM-5 has recognized that patients with either diagnosis can have "mixed" symptoms of the opposite pole. That is, manic patients may also have accompanying depressive symptoms (e.g., depressed mood, suicidal thinking) and depressed patients may have some co-occurring symptoms of mania (e.g., racing thoughts, decreased need for sleep). Patients with either diagnosis (bipolar disorder or unipolar depression) may also have anxious distress, psychosis, or seasonal variation of mood. Clinicians should therefore recognize that patients with either unipolar depression or bipolar disorder may have a variety of accompanying symptoms associated with the opposite pole that ultimately may have an impact on prognosis or treatment. However, the clinical significance of these co-occurring symptoms and their implications for treatment are still being evaluated.

Unipolar Depression versus Bipolar Depression

Distinguishing unipolar from bipolar depression remains a critical distinction and poses one of the greatest clinical challenges for professionals who treat patients with mood disorders. Misdiagnosis of bipolar disorder can lead to mistreatment (typically with antidepressants alone), worsening of mood, switches into mania or mixed states

Table 46-2 Diagnostic Criteria for Dysthymic Disorder

Depressed mood for most of the day for more days than not as indicated either by subjective account or observation by others for at least 2 years.

Note: In children and adolescents, mood can be irritable and duration must last for at least 1 year.

- A. Presence, while depressed, of two (or more) of the following:
1. Poor appetite or overeating
 2. Insomnia or hypersomnia
 3. Low energy or fatigue
 4. Low self-esteem
 5. Poor concentration or difficulty making decisions
 6. Feelings of hopelessness
- B. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in Criteria A and B for more than 2 months at a time.
- C. No major depressive episode (see Table 46-1) has been present during the first 2 years of the disturbance (1 year for children and adolescents); that is, the disturbance is not better accounted for by chronic major depressive disorder or major depressive disorder in partial remission.
- D. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder.
- E. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder.
- F. The symptoms are not caused by the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- G. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

From American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

(i.e., presence of both manic and depressive symptoms), rapid mood swings, worsening psychosocial impairment, more suicide attempts, and higher mortality (Goldberg and Ernst, 2002; Goldberg and Truman, 2003; Schneck et al., 2008). Treatment of patients with bipolar depression is rarely straightforward and often requires multiple medications and medication trials. Antidepressants do not appear to be especially helpful in the treatment of bipolar disorder, and antidepressants have not yet been shown to improve outcome compared with mood stabilizers alone (Sachs et al., 2007). Although no symptom is pathognomonic for bipolar depression, certain features of depression may suggest that a patient's depression is a manifestation of bipolar illness. Bipolar depression can present similar to unipolar depression, but some depression features may help distinguish the two (Ghaemi et al., 2004; Perlis et al., 2006) (Table 46-3). If a primary care physician makes a diagnosis of bipolar disorder, the patient is best served by referral to a mental health provider, preferably with expertise in treating mood disorders.

Screening Tools for Depression

Numerous screening measures have been specifically designed to detect depression, and many are sensitive to change over time when used repeatedly at follow-up visits. The integration of such tools into clinical practice, referred to as *measurement-based care*, may enhance care and improve clinical outcome. Measurement tools in the public domain and sensitive to change over time are most practical for

Table 46-3 Features Suggesting Bipolar Depression

Feature	Bipolar	Unipolar
Substance abuse	Very high	Moderate
Family history	Almost uniform	Sometimes
Seasonality	Common	Occasional
First episode before age 25 years	Very common	Sometimes
Postpartum illness	Very common	Sometimes
Psychotic features before age 35	Highly predictive	Uncommon
Atypical features	Common	Occasional
Rapid on/off pattern	Typical	Unusual
Recurrent major depressive episodes (>3)	Common	Unusual
Antidepressant-induced mania or hypomania	Predictive	Uncommon
Brief episodes (<3 mo)	Suggestive	Unusual (duration usually >3 mo)
Antidepressant tolerance	Suggestive	Uncommon
Mixed depression (presence of hypomanic features within depressive episode)	Predictive	Rare
Tension, edginess, fearfulness	More common	Less common
Somatic symptoms (muscular, respiratory, genitourinary)	Less common	More common

Modified from Kaye NS. Is your depressed patient bipolar? *J Am Board Fam Pract*. 2005;18:271-281; and Perlis RH, Brown E, Baker RW, Nierenberg AA. Clinical features of bipolar depression versus major depressive disorder in large multicenter trials. *Am J Psychiatry*. 2006;163:225-231.

primary care physicians because they are a cost-effective way to manage depressed patients over time (Trivedi et al., 2006b). Self-report measures obviate the need for trained office personnel to administer tests. Depression screening measures do not diagnose depression but do provide critical information regarding symptom severity within a given period. Almost all measures have a statistically predetermined cutoff score at which depression symptoms are considered significant. When a depression screening result is positive, an interview is necessary because screening will not include many confounding diagnostic variables (e.g., substance abuse, hypothyroidism, bereavement), and physician judgment is required. Screening measures do not address important clinical features of psychiatric illnesses (e.g., total duration of symptoms, degree of impairment) from other comorbid psychiatric conditions.

Patient Health Questionnaire 9. The PHQ-9 is often used in primary care settings because of its ease of use, sensitivity to change over time, reliability, and validity (Kroenke et al., 2001). It uses only the nine depression items from the original self-report version of the Primary Care Evaluation of Mental Disorders Patient Health Questionnaire (PRIME-MD PHQ) (Spitzer et al., 1999). Major depression is diagnosed if five or more of the depressive symptoms have been present at least "more than half the days" in the past 2 weeks and if one of the symptoms is depressed mood or anhedonia. Other depressive syndromes (e.g., minor depression) are diagnosed if two, three, or four

depressive symptoms have been present at least “more than half the days” in the past 2 weeks and if one symptom is depressed mood or anhedonia. One of the nine test items (“thoughts that you would be better off dead or by hurting yourself in some way”) counts if present at all, regardless of duration. Using cutoff scores from 9 to 15, sensitivity ranges from 68% to 95%, with specificity from 84% to 95%. Using the cutoff score of 9, sensitivity is 95% and specificity 84%.

Quick Inventory of Depressive Symptomatology—Self Report.

The 16-item Quick Inventory of Depressive Symptomatology Self Report (QIDS-SR₁₆) is an instrument designed to screen for depression and to follow the changes in severity of depression over time (Rush et al., 2006a). The QIDS-SR₁₆ is a shortened version of the original 30-item Inventory of Depressive Symptomatology (IDS). Whereas the IDS includes criterion symptoms and symptoms typically associated with depression, such as anxiety and irritability, the QIDS assesses only the nine symptom domains used to characterize depressive episodes (sad mood, concentration, self-criticism, suicidal ideation, interest, energy or fatigue, sleep disturbance, changes in appetite or weight, presence of psychomotor agitation or retardation). The total score on QIDS ranges from 0 to 27 (0-5, no severity; 6-10, mild; 11-15, moderate; 16-20, severe; 21-27, very severe). The QIDS was effective in assisting management of depression in the STAR*D study, the largest depression trial conducted thus far in the United States (Trivedi et al., 2006b).

Screening for Bipolar Disorder

Although no laboratory or imaging tests currently exist to distinguish unipolar depression from bipolar depression, screening questionnaires, as well as certain features of a patient’s history and symptomatology, may prove helpful. The MDQ is a tool that combines DSM-IV criteria and clinical experience to screen for bipolar disorder in primary care settings (Hirschfeld et al., 2000). It is a brief, one-page self-report questionnaire with 13 yes-or-no items and two additional questions regarding functioning and timing of mood symptoms and typically can be completed in 5 minutes or less. Seven or more positive responses to questions about manic symptoms, plus positive responses to the severity of impairment (moderate or severe) and coincident timing of symptoms, yields a positive screen. The specificity and sensitivity of the MDQ vary widely by clinical setting, having the best combination of the two when given to patients with suspected mood symptoms (93% specificity; 58% sensitivity) but performs more poorly in general community samples (97% specificity; 28% sensitivity) (Hirschfeld et al., 2003, 2005). Other screening tools for bipolar disorder do not offer the ease of use and higher reliability and validity of the MDQ.

DIAGNOSIS OF ANXIETY DISORDERS

The essential feature of GAD is excessive anxiety and worry about a number of events or activities, occurring most days over 6 months. Patients have difficulty controlling the worry, report subjective distress, and may experience difficulties in social or occupational functioning. The intensity,

Table 46-4 Diagnostic Criteria for Generalized Anxiety Disorder

- A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities
- B. The person finds it difficult to control the worry.
- C. The anxiety and worry are associated with three (or more) of the following six symptoms:
 1. Restlessness and feeling keyed up or on edge
 2. Being easily fatigued
 3. Difficulty concentrating or mind going blank
 4. Irritability
 5. Muscle tension
 6. Sleep disturbance
- D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- E. The disturbance is not caused by the direct physiological effects of a substance or a general medical condition.
- F. The disturbance is not better explained by another mental disorder.

From American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

Table 46-5 Diagnostic Criteria for Panic Attack

- An abrupt surge of intense fear or intense discomfort that reaches a peak within minutes and during which time four (or more) of the following symptoms occur:
1. Palpitations, pounding heart, or accelerated heart rate
 2. Sweating
 3. Trembling or shaking
 4. Sensations of shortness of breath or smothering
 5. Feeling of choking
 6. Chest pain or discomfort
 7. Nausea or abdominal distress
 8. Feeling dizzy, unsteady, lightheaded, or faint
 9. Chills or heat sensations
 10. Paresthesias (numbness or tingling sensations)
 11. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
 12. Fear of losing control or “going crazy”
 13. Fear of dying

From American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

duration, or frequency of the worry is out of proportion to the actual likelihood or impact of the feared event. Patients must have at least three associated physical symptoms, including restlessness, irritability, muscle tension, disturbed sleep, fatigability, and difficulty concentrating. The list of associated symptoms can be thought of as symptoms of inner tension (restlessness or edginess, irritability, muscle tension) and symptoms associated with the fatiguing effects of chronic anxiety (fatigue, concentration difficulties, sleep disturbance) (Table 46-4).

Panic attacks, a collection of distressing physical, cognitive, and emotional symptoms, may occur in a variety of mental health disorders and are not limited to anxiety disorders. Panic attacks are discrete periods of intense fear in the absence of real danger accompanied by at least 4 of 13 cognitive and physical symptoms (Table 46-5). The attacks have a sudden onset; build to a peak quickly; and are often accompanied by feelings of doom, imminent danger, and a

Table 46-6 Diagnostic Criteria for Panic Disorder

- A. Recurrent and unexpected panic attacks
- B. At least one of the attacks has been followed by 1 month (or more) of one or both of the following:
 1. Persistent concern about having additional panic attacks or their consequences
 2. A significant maladaptive change in behavior related to the attacks
- C. The disturbance is not attributable to the physiological effects of a substance or a general medical condition.
- D. The disturbance is not better explained by another mental disorder.

From American Psychiatric Association. *Diagnostic and statistical manual of mental disorders*. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

need to escape. Symptoms of panic attacks can include somatic complaints (e.g., sweating, chills), cardiovascular symptoms (pounding heart, accelerated heart rate, chest pain), neurologic symptoms (trembling, unsteadiness, lightheadedness, paresthesias), GI symptoms (choking sensations, nausea), and pulmonary symptoms (shortness of breath). In addition, patients with panic attacks may worry they are dying or “going crazy” or have the sensation of being detached from reality. Panic attacks can be listed as a specifier to all DSM-5 disorders and is not considered a stand-alone diagnosis.

Patients with *panic disorder* experience recurrent, unexpected panic attacks followed by at least 1 month of persistent worry that they will have another panic attack. Patients with panic disorder may begin to avoid places where a prior attack occurred or where help may not be available (Table 46-6). The DSM-5 has separated panic disorder and agoraphobia into two unique and distinct diagnoses.

Screening Tools for Anxiety Disorders

At present, screening tools for anxiety disorders have been developed to recognize anxiety as a broad syndrome, examining somatic symptoms (racing heart, lightheadedness) or cognitive symptoms (tendency to worry, intensity of worry). Other tools have been used to screen for single, distinct disorders, such as phobias or panic disorder. To date, no clear screening tool or symptom-severity measure has emerged for use in primary care settings, although newer instruments may be useful for primary care physicians. The Generalized Anxiety Disorder 7 (GAD-7) scale was developed and validated in primary care clinics and is a brief, seven-item self-report screening tool for GAD (Spitzer et al., 2006). The GAD-7 helps identify probable cases of GAD and measure symptom severity. A score of 10 or greater represents a reasonable cutoff point for identifying patients with GAD, and cutoffs of 5, 10, and 15 correlate to mild, moderate, and severe levels of anxiety, respectively. An extended version of the PHQ includes five questions for panic disorder (Spitzer et al., 1999), but its utility as a stand-alone tool is currently unclear. The Overall Anxiety Severity and Impairment Scale (OASIS) is a five-item continuous measure that can be used across anxiety disorders, with multiple anxiety disorders, and with subthreshold anxiety symptoms. OASIS can be used to measure the severity of anxiety symptoms, but it was not developed as a diagnostic tool for any specific disorder (Norman et al., 2006).

Assessment of the Depressed or Anxious Patient in Medical Settings

Key Points

- Patients with anxiety and depressive disorders often present with somatic complaints.
- Risk assessment includes identifying modifiable risk factors and developing a corresponding treatment plan.
- “Contracts for safety” have no empiric data to support their effectiveness in risk management.
- Worsening symptoms or suicidal ideation may require psychiatric hospitalization.

Diagnosing anxiety and depressive disorders may prove especially challenging in medical settings. The majority of patients with such illnesses more frequently present with somatic complaints; only a minority present with purely psychological symptoms and concerns (Bridges and Goldberg, 1985). Difficulties in diagnosis may be secondary to a patient’s inability to articulate psychological problems, reticence to speak of emotional difficulties, the short time allowed for patient visits, or a primary care physician’s relative lack of training in assessing and treating mental health disorders. Many presenting complaints may be consistent with symptoms of coexisting medical illnesses, further complicating assessment and likely requiring additional etiologic investigation. Of new patients presenting to an urban clinic, for example, only 17% presented with purely psychological symptoms. Of the remaining patients, 32% presented with pure somatization, 27% presented with symptoms for a coexisting medical illness, and 24% presented with an initial physical complaint that they were later able to relate to a psychological problem (Bridges and Goldberg, 1985). However, clinical clues in patients with physical complaints may identify a subgroup of patients who warrant further evaluation for an anxiety or depressive disorder. This includes patients who present with multiple physical symptoms (six or more), have higher ratings of symptom severity and lower ratings of overall health, and have an encounter that the physician perceives as “difficult” (Kroenke et al., 1997).

Assessment of anxious or depressed patients requires establishing specific psychiatric diagnosis (or diagnoses), providing a thorough risk assessment (i.e., suicidality, homicidality, ability or inability to care for self), assessing the severity of the illness, identifying specific target symptoms to track over time, assessing factors that are likely complicating or exacerbating the illness (e.g. medical disorders, substance abuse), and gathering collateral information whenever possible from family, friends, or other providers (Table 46-7). Distinguishing bipolar from unipolar depression, as discussed previously, is one of the most important distinctions when establishing a diagnosis. In addition, clinicians should look for the presence of comorbid anxiety disorders because patients with such disorders often require lower initial antidepressant dosing and may have their anxiety symptoms paradoxically worsen as treatment is initiated unless lower doses are used (Table 46-8). Education on the medical nature of depression and anxiety

Table 46-7 Initial Assessment of Anxious or Depressed Patients

1. Establish diagnosis.
2. Perform risk assessment:
 - Suicide risk
 - Risks to others
3. Establish severity of illness:
 - Ability to care for self
 - Functioning and functional impairment
4. Identify specific target symptoms:
 - Neurovegetative symptoms (e.g., sleep, appetite, concentration)
 - Use of measurement scales (e.g., Quick Inventory of Depressive Symptomatology [QIDS])
5. Assess factors complicating illness:
 - Alcohol or drug use
 - Comorbid or contributing medical conditions
6. Gather input from family and friends if possible.

Table 46-8 Dosing for Common Antidepressant and Antianxiety Agents

Medication	Usual Daily Starting Dose (mg)		
	Anxiety	Depression	Daily Dose Range
SELECTIVE SEROTONIN REUPTAKE INHIBITORS			
Citalopram	10	20	10-60
Escitalopram	5	10	5-30
Fluoxetine	10	20	20-80
Fluvoxamine	25	50	100-300
Paroxetine	10	20	20-60
Sertraline	25	50	50-200
SEROTONIN-NOREPINEPHRINE REUPTAKE INHIBITORS			
Desvenlafaxine	50	50	50-100
Duloxetine	30	30	30-120
Venlafaxine	37.5	75	150-300
TRICYCLIC ANTIDEPRESSANTS			
Amitriptyline	25	50	100-300
Imipramine	25	50	100-300
Nortriptyline	10	25	50-200
Desipramine	25	50	100-300
NOREPINEPHRINE-DOPAMINE REUPTAKE INHIBITORS			
Bupropion	—	150	300-450
NOREPINEPHRINE-SEROTONIN MODULATORS			
Mirtazapine	15	30	30-60

may prove extremely helpful because both patients and their families often believe that psychiatric illness is evidence of “weakness” or indicative of some other personal failing. Information on prognosis and the expected treatment course may lessen pressure and expectations for rapid improvement and let the patient know when to expect medication benefit.

Physicians should assess the severity of illness and develop a list of target symptoms to track and measure over time to better evaluate treatment response. Tracking specific symptoms particular to an individual patient's depression improves objective assessment of change. Often, patients' neurovegetative symptoms improve before the subjective experience of their mood improves. Assessing sleep, appetite, energy level, anxiety, and concentration allows the physician to select a more appropriate antidepressant or anxiolytic by targeting specific symptoms. This may include using a sedating antidepressant such as

mirtazapine for patients with insomnia or a more activating antidepressant such as bupropion for patients with lethargy or somnolence. Measurement tools that are symptom specific and sensitive to change over time (e.g., PHQ-9, QIDS-SR) may help the physician track such changes. In addition, assessing overall functionality (ability to shower, pay bills, shop, prepare meals) is equally important in establishing the degree of impairment caused by the patient's mood disorder.

DIFFERENTIAL DIAGNOSIS

Many medical conditions may cause or mimic depression. Physical disorders that have been associated with depression include Addison disease, acquired immunodeficiency syndrome (AIDS), coronary artery disease (especially in those with myocardial infarction), cancer, multiple sclerosis, Parkinson disease, anemia, diabetes, acute infection, temporal arteritis, hypothyroidism, and especially dementias. It is imperative that the physician complete a neurologic evaluation to rule out an underlying disorder as the cause of the patient's depression. In addition, many medications may worsen depression, especially cardiovascular drugs, hormones, typical antipsychotic agents, antiinflammatory agents, and anticonvulsants.

Anxiety disorders may be caused or exacerbated by medical conditions, medications taken for other psychiatric or medical disorders, and other substances with stimulant properties. For example, hyperthyroidism can mimic or exacerbate anxiety disorders, and therefore thyroid function should be carefully evaluated when patients present with anxiety symptoms. In addition, lifetime risk of thyroid dysfunction appears higher in patients with panic disorder or GAD (Simon et al., 2002). Physicians should also assess the patient's use of other medications, especially stimulants (whether prescribed or obtained from other sources), nicotine, illicit drugs, and caffeine.

SUICIDE SCREENING AND ASSESSMENT

Identifying patients at risk for suicide is a complex and difficult task, particularly in the setting of a busy medical practice. Suicide is currently the 10th leading cause of death for all ages and the third leading cause of death among the 15- to 24-year age group (Centers for Disease Control and Prevention, 2012). Older men (75 years and older) have the highest suicide rate, at 37.4 per 100,000. Men continue to take their lives at approximately four times the rate of women and account for almost 80% of all U.S. suicides. Women in their 40s and 50s have the highest rates of suicide among women (8 per 100,000), and women continue to make suicide attempts two to three times more often than men (Krug et al., 2002). Approximately 60% of all suicides are associated with patients with mood disorders (Isometsa et al., 1995a), and approximately 50% of patients who completed suicide had contact with professional help in the month before their death (Isometsa et al., 1995b).

Despite no definitive suicide assessment tool being available, risk factors have been defined that can help identify patients at risk for suicide. Suicide screening should include assessing current level of depression, severity of symptoms, feelings of hopelessness, current suicidal thoughts and

behaviors (as well as past attempts), use of drugs or alcohol (which can increase levels of impulsivity and worsen dysphoria), current levels of anxiety and agitation, access to lethal means (especially firearms), presence of psychosis (command hallucinations, poor reality testing), recent acute stressors, and presence (or absence) of a psychosocial support system (APA, 2003). When possible, additional information from family or friends can be helpful in assessing statements or behaviors that may indicate a patient's intentions of committing suicide.

Physicians should be alert to suicide risk factors that can be modified. Although numerous historical and biologic risk factors cannot be modified (e.g., history of suicide attempts, family history of suicide, male gender, history of childhood trauma), other risk factors are amenable to intervention. Patients with mood, anxiety, and psychotic symptoms can be successfully treated with medications. Substance abuse referral may help a patient actively struggling with substance abuse or dependence or for relapse prevention. Encouraging the patient to mobilize psychosocial resources, such as contacting family members for support, can provide a measure of safety while the patient is recovering from depression. Removing access to firearms can be especially helpful in preventing rapid access to lethal means during episodes of acute distress and high levels of impulsivity. Physicians should be aware that "contracts for safety" have not been shown to be effective in preventing suicide and may provide a false sense of patient safety (Rudd et al., 2006). Continued assessment of mood, hopelessness, and suicidal ideation is required throughout the course of treatment. Worsening symptoms, along with plans or active preparations for suicide, may require increased observation or hospitalization.

Management and Treatment of Major Depression and Anxiety Disorders

The key objective in treating patients with depressive and anxiety disorders is remission of all symptoms. Studies in the treatment of major depression have consistently shown that a lack of remission is associated with higher relapse rates, more severe subsequent depressions, shorter durations between episodes, continued impairment in work settings and social relationships, increased all-cause mortality, and increased risk of suicide (Judd et al., 2000). Initiation of treatment should include education about the expected temporal course of improvement; importance of regular eating, activity, social interaction, and sleep; medication selection; follow-up schedule; and safety management if symptoms worsen or suicidal ideation is evident (Table 46-9).

DEPRESSION

Pharmacotherapy remains the mainstay treatment of depression. Treatment should be considered for the majority of depressed patients, especially those who are suicidal, functionally impaired from their depression, experiencing a recurrent episode, or who have comorbid medical or

Table 46-9 Initiation of Treatment for Major Depression and Anxiety Disorders

1. Educate the patient:
 - Details of illness
 - Treatment course, prognosis, goal of treatment (remission of symptoms)
 - Importance of general health: exercise, sleep hygiene, nutrition
 - Inclusion of family when possible
 - Coordination with other providers
 - Resource lists for support groups and therapy referrals
2. Select medication from reasonable choices:
 - Patient history of antidepressant use and response
 - Family history of antidepressant response
 - Typical time course to antidepressant response
3. Administer starting dose and initiate dose titration:
 - Common side effects of medications
4. Establish monitoring with measurement-based care (e.g., Quick Inventory of Depressive Symptomatology [QIDS]).
5. Schedule follow-up in 2 to 4 weeks.

psychiatric conditions likely to worsen unless their depression is treated (e.g., panic, GAD, chronic pain). Treatment of depression has clearly been shown to prevent relapse, shorten current episodes, decrease psychosocial impairment, decrease risk of suicide, and improve quality of life. Mild depression may be treated with symptomatic intervention alone (e.g., mild sedative for insomnia), although continuing depressive symptoms or inadequate response to purely symptomatic interventions warrants more aggressive treatment of the underlying depression. Patients with psychotic depression typically require treatment with both antidepressant and antipsychotic agents, or they may require electroconvulsive therapy (ECT). Often, psychotically depressed patients require hospitalization. Patients with psychotic depression should be referred to a psychiatrist, given the severity of illness and complexity of treatment.

Again, the aim of treatment is remission of all depressive symptoms and a return to the patient's previous baseline functioning. Pharmacotherapy combined with psychotherapy has been shown to be superior to either modality alone (de Maat et al., 2008; Thase, 1997); thus, referral to a psychotherapist may be helpful, especially for patients with moderate to severe depression. Some patients may choose psychotherapy alone to treat depression; psychodynamic therapy, cognitive-behavioral therapy (CBT), interpersonal therapy, and behavioral activation may prove as effective as medication alone.

Selection of Medication

The effectiveness of antidepressants is generally comparable across classes; therefore, selection of an antidepressant depends mainly on patient preference, side effect profile, drug interactions, previous response to a specific medication, treatment overlap with other psychiatric conditions, and cost (Tables 46-10 and 46-11). Minimal data support the increased efficacy or speed of onset for any particular agent, with response rates across clinical trials generally 50% to 75% for patients receiving active treatment. The onset of improvement typically takes 3 to 6 weeks, although the STAR*D study indicates that patients may require up to 12 to 14 weeks to achieve remission of symptoms. In fact, 40% of patients in the multiyear, multisite STAR*D study who eventually achieved remission in the first level of

Table 46-11 Common Side Effects of Antidepressant Medications

Class or Drug	Side Effects	Comments
Selective serotonin reuptake inhibitor (SSRI)	GI side effects (nausea, diarrhea, heartburn); sexual dysfunction (decreased libido, delayed orgasm); headache; insomnia or somnolence	Likely little difference between SSRIs in rates of sexual side effects; SSRIs have been used to treat premature ejaculation
Serotonin-norepinephrine reuptake inhibitor (SNRI)	Hypertension, sweating, nausea, constipation, dizziness, sexual dysfunction	Risk of increased blood pressure escalates as dose is increased; abrupt withdrawal of venlafaxine may cause discontinuation syndrome
Tricyclic antidepressant (TCA)	Dry mouth, constipation, blurry vision, orthostatic hypotension, weight gain, somnolence, headache, sweating, sexual dysfunction	Use with caution in patients with cardiac conduction delays
Bupropion	Insomnia, dry mouth, tremor, headache, nausea, constipation, dizziness	Contraindicated in patients with seizure disorders or eating disorders; patients generally free of sexual side effects
Mirtazapine	Somnolence, increased appetite, weight gain, dry mouth	Sedation may be more pronounced at lower doses
Trazodone	Sedation, orthostatic hypotension, priapism	Usually used as a sedative-hypnotic
Benzodiazepines	Sedation, fatigue, ataxia, slurred speech, memory impairment, weakness	Risk of dependence or abuse, especially with shorter acting benzodiazepines

GI, Gastrointestinal.

treatment with citalopram did not show a response (i.e., 50% improvement in symptoms) until week 8 of treatment (Trivedi et al., 2006b).

For most patients, initial treatment with a selective serotonin reuptake inhibitor (SSRI), serotonin-norepinephrine reuptake inhibitor (SNRI), bupropion, or mirtazapine is reasonable. Tricyclic antidepressants (TCAs) are more often used as second-line agents in the treatment of depression because of their potential toxicity in overdose, greater side effect burden (largely from anticholinergic, antihistaminic, and antiadrenergic properties), and potential cardiac complications (conduction delays). Monoamine oxidase (MAO) inhibitors are complex drugs to use given their potentially fatal drug and dietary interactions and probably should not be prescribed in family practice settings. Most

antidepressant studies have been conducted in specialty settings, but a number of studies in primary care settings have also shown the superiority of antidepressants over placebo (Arroll et al., 2009). Thus, given the comparable speed and efficacy of antidepressants across classes and within classes, selection of an antidepressant agent may be primarily guided by side effect profile, possible secondary uses of antidepressants (e.g., treating pain or insomnia), and contraindications to particular agents (e.g., bupropion in seizure disorder patients). Table 46-8 gives the usual starting doses for treatment of major depression.

Serotonin reuptake inhibitors are safe, effective medications that can treat patients with a variety of psychiatric conditions. All SSRIs operate by the same mechanism of action and are considered equally effective in the treatment of

depression. However, failure of one SSRI does not necessarily imply failure of all SSRIs; patients may respond preferentially to one SSRI over another (Rush et al., 2006b). The SSRIs differ substantially by their potential to inhibit particular hepatic cytochrome P-450 metabolic pathways and by half-life, potency, and presence or absence of active metabolites. Clinicians should check for drug interactions in patients receiving complex polypharmacy regimens because drug–drug interactions are constantly being updated and changing. For example, fluoxetine is a potent 2D6 inhibitor that can triple TCA and phenytoin levels or increase the anticoagulation associated with warfarin. Fluoxetine also has the longest half-life of any SSRI; its active metabolite norfluoxetine has a half-life of 10 days. The SSRIs have sexual side effects (decreased libido, delayed orgasm or anorgasmia) and GI side effects (nausea, diarrhea) (see Table 46-11). GI side effects likely will remit over time, but sexual effects typically do not attenuate and may require treatment with other agents, such as a phosphodiesterase inhibitor (e.g., sildenafil) or choosing an antidepressant less likely to cause sexual side effects.

The SNRIs (venlafaxine, duloxetine, desvenlafaxine, and levomilnacipran) are similar in efficacy to the SSRIs, although a few studies have suggested a mild advantage of SNRIs over SSRIs (Thase et al., 2001). Although the SNRIs by definition inhibit the reuptake of both serotonin and norepinephrine, dual-neurotransmitter reuptake inhibition does not occur with venlafaxine until doses reach approximately 150 mg/day; below this dose, it acts primarily as an SSRI. Venlafaxine is available in immediate-release and extended-release (XR) formulations, although most patients and clinicians favor use of the XR preparation, given its once-daily dosing and lower likelihood of provoking a withdrawal syndrome on discontinuation of the drug, more frequently observed with the immediate-release formulation. Desvenlafaxine, the active metabolite of venlafaxine, is more potent than its parent compound, but any advantages over venlafaxine are currently unclear. Unlike venlafaxine, duloxetine provides dual-neurotransmitter reuptake inhibition at any dose, although this does not appear to confer any advantage over other SNRIs in terms of efficacy or side effect profile. Duloxetine currently is indicated for treatment of chronic pain as well as depression, but this is likely a class effect of SNRIs and not unique to duloxetine. Levomilnacipran is an active enantiomer of the racemic drug milnacipran (approved by the U.S. Food and Drug Administration for the treatment of fibromyalgia). It is the most noradrenergically active of the SNRIs, but whether this will translate to unique clinical characteristics has yet to be determined. Side effects of SNRIs are similar to SSRIs (see Table 46-11), with the additional side effects with SNRIs likely caused by increased noradrenergic activity, including dose-related hypertension, excessive sweating, and dry mouth (Thase, 2008a; Thase et al., 2005).

Mirtazapine is a serotonin-norepinephrine modulator that also blocks postsynaptic hydroxytryptamine (HT) receptors, including those in the 5-HT-3 (serotonin) class. Mirtazapine is sedating and can increase appetite and therefore may be favored when patients have insomnia or decreased appetite and weight loss. Because of a dose-dependent ratio of neurotransmitter blockade involving

histamine receptors, mirtazapine is generally more sedating at lower doses than higher. Although currently indicated only for depression, mirtazapine is reported to have general anxiolytic effects and may be beneficial for patients with mild to moderate anxiety. With its 5-HT-3 blockade, mirtazapine may be helpful when patients complain of nausea or other GI symptoms or side effects from SSRIs. Mirtazapine also has fewer sexual side effects than the SSRIs and SNRIs and has been tried as an antidote to SSRI-induced sexual side effects. Common side effects from mirtazapine include weight gain and daytime somnolence (see Table 46-11).

Bupropion is pharmacologically unique among antidepressants and is manufactured in immediate-release, slow-release (SR), and XR formulations. Although its primary mechanism of action is unclear, the drug has weak norepinephrine and dopamine reuptake inhibition. Bupropion is an activating drug, making it better suited for patients with poor energy or who believe they cannot tolerate a sedating medication. It is also virtually free from sexual side effects and has been used with limited success as an antidote for patients with SSRI-induced sexual side effects (Clayton et al., 2004). Bupropion rarely causes weight gain and is therefore a good choice for patients who are obese or who believe they cannot tolerate weight gain. Unlike the SSRIs, SNRIs, and TCAs, bupropion does not treat anxiety disorders and may even worsen anxiety in patients because of its activating properties. Bupropion carries a black box warning against its use in patients with a history of seizures or eating disorders; the latter group was shown to have a higher incidence of seizures in clinical trials. Given its greater propensity for seizures, bupropion dosing should not be pushed above the FDA-recommended dosing limits. Bupropion has also been approved for treatment of smoking cessation and therefore may have particular utility for depressed patients who also want to quit smoking.

Vortioxetine is the most recently FDA-approved drug for the treatment of major depression (FDA, 2013). Although it has unique pharmacologic characteristics, acting as an SSRI, a 5HT1A agonist, a partial agonist at 5-HT1B receptors, and an antagonist at 5-HT3, 5-HT1D, and 5-HT7 receptors, it is currently unclear to what extent these characteristics contribute to its antidepressant efficacy.

The TCAs are effective medications for treating depression and anxiety, with evidence of being more effective than the SSRIs for severe depression, but the TCAs confer a greater side effect burden than the newer antidepressants and can be fatal in overdose. TCAs are divided into tertiary and secondary amines. Tertiary amines, such as amitriptyline and imipramine, have greater anticholinergic, antihistaminic, and α -adrenergic blockade side effects than secondary amines, such as their respective metabolites nortriptyline and desipramine. The TCAs offer an advantage over other antidepressants in that blood levels can readily be checked and dosing individualized. Reasonable evidence suggests that the TCAs may be more effective in severely depressed patients (Gelenberg et al., 2010). In addition, nortriptyline has a therapeutic window, with superior antidepressant efficacy if levels are maintained at 50 to 150 ng/mL. Because of cardiac conduction side effects, however, the TCAs must be used with caution in patients with conduction delays or who are taking class I antiarrhythmic agents, and electrocardiograms should be checked and

monitored in patients older than 50 years and in those with suspected cardiac disease. The TCAs also may cause tachycardia and orthostatic hypotension and thus should be used with caution in patients at risk for tachyarrhythmias or falls. The greatest single disadvantage to TCAs is their potential lethality in overdose; a typical 10-day supply can be lethal, and therefore TCAs should be prescribed cautiously in patients at high risk for suicide. The TCAs are also used in a variety of headache and pain syndromes and thus may be useful in patients with such comorbidities.

Trazodone is structurally distinct from the SSRIs, TCAs, tetracyclics, and MAO inhibitors, but it still inhibits neuronal uptake of serotonin. Although the FDA has approved it as an antidepressant, trazodone is most often used as a sedative-hypnotic. Whereas dosing as an antidepressant is usually 300 to 450 mg, sedative-hypnotic dosing is usually 50 to 150 mg. The risks and side effects of trazodone include sedation, priapism, and myocardial irritability; the latter effect includes the potential of inducing torsades de pointes.

KEY TREATMENT

- All antidepressants are generally equally effective; selection is most often based on side effect profile, previous response, comorbid conditions, drug interactions, and cost (Arroll et al., 2009; Trivedi et al., 2006b) (SOR: A).
- The SSRIs, the SNRIs, mirtazapine, and bupropion are first-line treatments for depression (Rush et al., 2006b) (SOR: A).
- Antidepressant doses should be increased every 2 to 4 weeks until remission of depressive symptoms is achieved or side effects become intolerable (Gelenberg et al., 2010) (SOR: A).
- Treatment of depressive episodes ranges from 6 to 9 months to years, depending on the number of prior episodes, severity of episodes, and risk of relapse (AHCPR, 1999; Geddes et al., 2003) (SOR:A).
- Psychotherapy has proved effective in treating depression, either as monotherapy or combined with pharmacotherapy (de Maat et al., 2008; Thase, 1997) (SOR: A).

Initiation of Treatment

After a patient has been initiated on an antidepressant, dosing should be optimized to treat depressive symptoms to remission while minimizing side effects (Table 46-12). Patients should be monitored for improvement in their mood and their specific array of depressive symptoms. Continued use of measurement-based care tools, such as

Table 46-12 Assessing Antidepressant Treatment

Monitor the effectiveness of treatment.
Continue assessment of specific symptoms.
Assess need for further titration of medication.
Continue to use measurement-based care.
Assess any worsening of mood, increased irritability, or worsening suicidal ideation.
Assess adherence to medication regimen.
Assess for medication side effects.
Continue to emphasize nutrition, physical activity, and caring for self.
Minimize complexity of medication dosing (e.g., once daily or nightly, when possible).

the PHQ-9 or QIDS, can aid in the objective assessment of improvement. Patients should be followed more frequently on initiation of treatment, increasing the time between appointments as the patient improves. Monitoring for side effects, particularly those that patients may be reluctant to bring up spontaneously, such as sexual side effects, can improve adherence and the therapeutic alliance. Patients should also be monitored for any worsening of mood, increased irritability, impulsivity, insomnia, sudden switches into euphoria, or suicidal ideation. Such symptoms may suggest *bipolar diathesis*, in which case discontinuing the antidepressant and changing to mood stabilizing agents may be indicated. Antidepressant doses should be increased every 2 to 4 weeks until the patient shows a response, maximum dose is reached, or side effects limit further dose changes. Antidepressant doses should continue to be pushed until remission is achieved or the patient has undergone an adequate antidepressant trial (i.e., continuation of a therapeutic dose for at least 4 to 8 weeks) (Nierenberg et al., 2000).

Continuation of Treatment

As noted, physicians are encouraged to push treatment until symptoms remit, maximum doses are achieved, or side effects become intolerable. After symptoms remit, medications should continue for 6 to 9 months because risk of relapse is greater if patients discontinue medications prematurely (AHCPR, 1999; Geddes et al., 2003). Patients who have had multiple episodes of depression should continue pharmacotherapy because lifetime relapse rates for such patients are 50% to 85% (Eaton et al., 2008), and the risk of recurrence increases by 16% with each successive episode (Solomon et al., 2000). Ongoing treatment should also be considered for patients who experienced severe functional impairment, severe suicidal ideation, or serious suicide attempts.

Discontinuation of Treatment

For patients who have achieved ongoing remission and want to discontinue their medications, withdrawal of treatment should be gradual and carefully monitored (Table 46-13). Timing of discontinuation often depends on a patient's current life stressors and the potential consequences of depressive relapse (e.g., loss of new job, stress on recently repaired relationship). Antidepressants should be gradually withdrawn to minimize potential withdrawal syndromes and allow for rapid upward titration if depressive symptoms recur. Physicians should discuss the early warning signs of relapse (insomnia, early-morning awakening, loss of interest in activities) and instruct patients to contact their physicians if such symptoms recur. The risk of relapse is greatest in the first few months of discontinuing antidepressants, and thus a scheduled appointment in this period is often needed to monitor for relapse. Patients who relapse after cessation of antidepressants should be

Table 46-13 Discontinuation of Antidepressant Treatment

Remission of symptoms for 6-12 mo
Tapering of medications rather than abrupt cessation
Discussion of relapse risks and early warning signs of recurrence

restarted on their previous medication and again titrated to remission of symptoms.

ANTIDEPRESSANT FAILURE

Patients who fail antidepressants should be carefully reevaluated, with reconsideration of medication adherence, adequacy of dosing and treatment duration, diagnosis, comorbid psychiatric illnesses, increased stressors, and unaddressed medical or substance comorbidities. Initial antidepressant failure may be relatively common; only one third of patients achieved remission after 12 to 14 weeks of treatment with citalopram in the STAR*D study (Trivedi et al., 2006b). If a patient fails an adequate antidepressant trial, the next strategy is (1) switching to a different antidepressant within the same class or across classes, (2) augmenting the existing antidepressant with a secondary agent, or (3) adding a second antidepressant to the first. The choice of strategy depends on patient preference, assessment of benefit from current antidepressant, current side effects, and psychiatric and medical comorbidities.

Switching antidepressants is generally considered when the patient has had little to no response to the first agent or is having intolerable side effects. Across-class switches are most often considered as an initial strategy (e.g., SSRI to SNRI), although within-class switches may also prove useful (e.g., fluoxetine to sertraline). Across-class or intra-class switching may yield response rates of 20% to 50% (Thase, 2008b). In the STAR*D study, switching from citalopram to either bupropion SR, venlafaxine, or sertraline yielded remission rates of 18% to 25% (Rush et al., 2006b). No clear guidelines exist as how best to cross-taper medications, although it is generally unwise to stop antidepressants abruptly because withdrawal syndromes may ensue. Medications with short half-lives, such as venlafaxine (immediate release) or paroxetine, have most often been associated with withdrawal syndromes. Typically, patients complain of flulike symptoms, electric-like shocks in the back of their heads, or dizziness (Taylor et al., 2006). Consideration of half-life and slow cross-tapers often yields the most tolerable switch.

Augmentation strategies involve adding a second agent with no intrinsic antidepressant properties to the existing antidepressant. These are often considered when a patient has had a partial response to an antidepressant but has not reached remission, and switching to an alternate antidepressant may risk loss of existing response. The two best studied augmentation strategies to date are adding lithium and triiodothyronine (T_3). Although many lithium augmentation studies are limited by methodologic considerations, response has been seen as quickly as 48 hours or as long as 2 to 4 weeks. Standard lithium levels of 0.5 to 1.0 mmol/L have most often been used. T_3 augmentation has yielded similar results, if often better tolerated than lithium, usually with doses of 25 to 50 μ g/day. Overall remission rates in patients unable to achieve antidepressant-alone remission range from 15% to 50% (Nierenberg et al., 2006). Atypical antipsychotic drugs have also been used as augmenting agents in nonpsychotic major depression, with beneficial results. Aripiprazole currently has an indication as an augmenting agent, at 2 to 15 mg/day. To date, no other atypical antipsychotic has an FDA indication as an

augmenting agent, although a meta-analysis of atypical antipsychotics as augmenting agents found their efficacy superior to placebo, with a number needed to treat (NNT) of nine for both response and remission (Nelson and Papakostas, 2009). Buspirone has also been used as an augmenting agent because its 5-HT-1A receptor agonism may enhance SSRI response. In the STAR*D study, 30% of patients who failed to achieve remission taking citalopram went on to remit with the addition of buspirone, up to 60 mg/day (Trivedi et al., 2006a).

Combining two antidepressants to treat refractory depression is based on the theory that targeting a greater number of neurotransmitters will lead to improved antidepressant response. Common strategies include combining mirtazapine and venlafaxine, bupropion and SSRIs, or bupropion and SNRIs. Combining drugs of similar class (e.g., SSRI + SSRI or SNRI + SNRI) currently has few data to support its use. Venlafaxine combined with mirtazapine and citalopram plus bupropion SR were effective in the STAR*D study when patients failed to achieve remission on their current regimen. Adding bupropion to citalopram achieved a remission rate of approximately 30% in patients whose symptoms failed to remit after 12 weeks of citalopram therapy. The combination of venlafaxine plus mirtazapine was used in a highly treatment-refractory group (failed three previous medication trials) and achieved remission of symptoms in approximately 14% of patients (McGrath et al., 2006).

KEY TREATMENT

- Patients who fail antidepressants should be carefully reevaluated for medication adherence, adequacy of dosing and therapy duration, diagnosis, comorbid psychiatric illnesses, increased stressors, and unaddressed comorbidities (Trivedi et al., 2006a) (SOR: A).
- Common strategies used when patients fail an initial antidepressant treatment are switching antidepressants (either within class or across classes) (Rush et al., 2006b; Thase, 2008b), augmenting with other agents (lithium, T_3 , atypical antipsychotics) (Nierenberg et al., 2006; Trivedi et al., 2006a), or combining different antidepressants (McGrath et al., 2006) (SOR: A).

ANXIETY

There is significant pharmacologic overlap between the treatment of depression and anxiety disorders. Most antidepressants are also effective anti-anxiety agents, or anxiolytics (see Table 46-10), thus simplifying treatment strategies when patients have both disorders. In addition, significant overlap also exists between medications that effectively treat GAD and panic disorder. Treatment recommendations for both GAD and panic will be explored separately to highlight some of the treatment differences between the two disorders.

Generalized Anxiety Disorder

Antidepressants are generally considered first-line agents for treatment of GAD because of their efficacy and safety, effectiveness in treating comorbid major depression, and

absence of addictive or abuse potential, as seen with benzodiazepines. As a general rule, starting antidepressant doses for patients with GAD should be approximately half the lowest starting dose for treatment of depression; many experience a paradoxical worsening of their symptoms on antidepressant initiation if doses are high (see [Table 46-8](#)). Patients with anxiety disorders are typically more sensitive to antidepressant side effects (see [Table 46-11](#)), and thus starting at lower doses and titrating slowly will likely yield better results.

The SSRIs and SNRIs are considered first-line treatments, with numerous studies demonstrating both efficacy and effectiveness ([Hoffman and Mathew, 2008](#)). A Cochrane review of antidepressant treatment of GAD that included paroxetine, sertraline, venlafaxine, and imipramine found a very large effect size, with an NNT of only five patients for one patient to receive benefit, with no clear evidence of one antidepressant superior to another ([Kapczinski et al., 2003](#)). At present, the SSRIs escitalopram and paroxetine and the SNRIs venlafaxine and duloxetine are the only antidepressants with an FDA indication for GAD (see [Table 46-10](#)). No randomized controlled trials (RCTs) have yet supported the efficacy of fluoxetine or citalopram in the treatment of GAD, although their clinical use is based on the assumption that SSRIs exert a class effect and are likely equally effective. The SNRI desvenlafaxine may be effective but currently is indicated only for major depression.

The TCAs, also effective agents for treating GAD, have been relegated to second-line treatment because of side effects (e.g., anticholinergic, sedative, orthostatic) and potential lethality in overdose. Imipramine has the strongest data to support its use in GAD ([Kapczinski et al., 2003](#)). Although used effectively in the treatment of anxiety disorders, MAO inhibitors have significant side effects (risk for hypertensive crisis, potential lethal interactions with other medications) and likely do not have a role in primary care and should be reserved for psychiatric practice. Mirtazapine has shown some efficacy in open-label trials ([Gambi et al., 2005](#)) but needs further study in RCTs to be considered a first-line agent in GAD. Bupropion has a less clear role in the treatment of anxiety disorders and may worsen rather than alleviate anxiety symptoms. However, a recent pilot study showed that bupropion XL had comparable anxiolytic efficacy with escitalopram in a 12-week, double-blind RCT and was well tolerated ([Bystritsky et al., 2008](#)). Bupropion may have a role in GAD treatment in the future but currently may be considered a second- or third-line agent.

Benzodiazepines are also extremely effective for treatment of GAD and offer the advantage of rapid effect. Their onset of action is typically within hours versus weeks with antidepressants. All benzodiazepines are theoretically equally effective in GAD, and thus selection of individual agents often involves comparing half-lives, metabolic pathways, the presence or absence of active metabolites (particularly in patients with liver disease), and the speed of onset of action. Benzodiazepines with shorter half-lives result in the inconvenience of multiple daily dosing, the risk of rebound anxiety, and the common need to use as-needed (PRN) doses as a “rescue” medication when symptoms are inadequately controlled. Medications such as clonazepam, with long half-lives, or alprazolam XR, with a slower and more prolonged onset of action, may be more effective than drugs

with shorter half-lives, such as immediate-release alprazolam or lorazepam. Scheduled dosing of a benzodiazepine provides for a more consistent medication blood level and may also be a more effective approach than PRN dosing. The duration of therapeutic effect for benzodiazepines is determined by the rate and extent of drug distribution (lipophilicity) and not necessarily by the rate of elimination. Benzodiazepines such as diazepam have a longer half-life than lorazepam, but because diazepam is more lipophilic, it has a faster onset of action and shorter duration of effect after a single dose ([Schatzberg and Nemeroff, 2009](#)). Drug elimination occurs in the liver through microsomal oxidation or glucuronide conjugation. Oxidation is sensitive to liver disease and certain medical conditions and medications (e.g., cimetidine); therefore, benzodiazepines metabolized through hepatic oxidation are more likely to show unpredictability than those metabolized via conjugation. Benzodiazepines such as temazepam, lorazepam, and oxazepam are cleared through hepatic conjugation and are safer and better tolerated when oxidative elimination has been altered.

Even though the benzodiazepines offer the advantage of rapid onset and effectiveness, other disadvantages have relegated them to second-line agents. Benzodiazepines pose a significant risk of dependency and withdrawal, are potentially lethal in overdose if mixed with other sedating agents (especially alcohol), and are ineffective in treating comorbid depression. The benzodiazepines also can impair attention and vigilance and cause dose-dependent anterograde amnesia, with limited effect on psychic symptoms, including worry ([Hoehn-Saric et al., 1988](#)). Benzodiazepines should generally be considered second- to third-line agents as monotherapy in GAD, although they are often used as adjunctive agents when initiating antidepressant treatment to provide immediate relief of anxiety symptoms until antidepressant effects begin. Symptom severity and patient preference should be considered when deciding whether to use an antidepressant as monotherapy or to start a benzodiazepine with an antidepressant. A subset of patients may benefit from long-term treatment with both an antidepressant and a benzodiazepine.

Nonbenzodiazepine and nonantidepressant treatment may also be effective in the treatment of GAD, especially for patients with mild to moderate symptom severity. *Buspirone*, an azapirone that exerts 5-HT_{1A} receptor agonism, carries an FDA indication for GAD. Buspirone appears useful in the treatment of GAD, particularly for patients who have not yet received a benzodiazepine ([Chessick et al., 2006](#)). In clinical practice, buspirone can be used as monotherapy in patients with mild to moderate symptoms, and it is often considered an alternative to benzodiazepines as an augmenting agent to antidepressants. *Hydroxyzine*, an antihistaminic agent, also carries an FDA indication for GAD and has shown efficacy in RCTs ([Llorca et al., 2002](#)). Its sedative properties and lack of efficacy in comorbid disorders have relegated hydroxyzine to a second-line agent. Interestingly, a meta-analysis of effect sizes in pharmacotherapy of GAD recently showed that hydroxyzine had a larger effect size (0.45) than the SSRIs (0.36) ([Hidalgo et al., 2007](#)). At present, hydroxyzine may be considered an alternative to benzodiazepines when no comorbid illnesses are present as monotherapy. Recent studies of *pregabalin* have also shown

efficacy in the treatment of GAD. In the meta-analysis cited, pregabalin was found to have the largest effect size (0.5) of all agents (SSRIs, SNRIs, benzodiazepines, azapirones, antihistamines, complementary or alternative agents). The effect size of pregabalin was determined from two large RCTs. In addition, pregabalin was found to be effective in relapse prevention compared to placebo over a 6-month trial (Feltner et al., 2008). β -Blockers such as propranolol and pindolol have also been used in the treatment of GAD. Although these can block the physiologic effects of anxiety, such as sweating and increased heart rate, β -blockers appear ineffective in treating the underlying emotional component of anxiety, and little empiric evidence supports their use in GAD at present. In a recent Cochrane review, *quetiapine* is the only atypical antipsychotic to show effectiveness as a monotherapy in GAD (Depping et al., 2010), but the FDA denied approval for this indication because of the side effect burden outweighing the benefit of the medication.

KEY TREATMENT

- The SSRIs and SNRIs are considered first-line treatments for GAD, with the starting dose typically half that used in patients with depression (Hoffman and Mathew, 2008) (SOR: A).
- The TCAs are effective in treatment of GAD (SOR: A), but their side effect profile and potential lethality have relegated them to second-line agents (Kapczinski, et al., 2003).
- The benzodiazepines offer the advantage of rapid effect and proven efficacy (Chessick et al., 2006; Schatzberg and Nemeroff, 2009) (SOR: A), but they carry risk of abuse and dependence.
- Other agents for the treatment of GAD include hydroxyzine (Llorca et al., 2002) (SOR: A), buspirone (Chessick et al., 2006) (SOR: B), and pregabalin (Feltner et al., 2008) (SOR: B).
- Maintenance treatment of GAD reduces the likelihood of relapse (Thuile et al., 2009) (SOR: B).

PANIC DISORDER

Similar to the treatment of GAD, SSRIs, SNRIs, TCAs, and benzodiazepines have all been found to be effective for the treatment of panic disorder. The effectiveness of these agents appears relatively equal, and thus selection of a particular agent is most often based on tolerability, cost, ability to treat comorbid disorders, potential for abuse and tolerance, and patient preference. First-line agents to treat panic are most often SSRIs and SNRIs. Fluoxetine, paroxetine, sertraline, and venlafaxine all have FDA indications for panic disorder (see Table 46-10), although all the SSRIs have data to support their use (Otto et al., 2001). The SNRIs duloxetine and desvenlafaxine do not currently have large RCT evidence to support their use in panic disorder but may have efficacy based on class effect. The TCAs are also as effective in treating panic as SSRIs but are less well tolerated because of their anticholinergic and antihistaminic side effects (Bakker et al., 2002). Both imipramine and clomipramine have the most data to support their use in panic disorder

(APA, 2009). Because of tolerability and toxicity in overdose, TCAs are second-line agents for panic.

The benzodiazepines offer several advantages over antidepressants in the treatment of panic, including rapid onset, PRN dosing schedules, and relief of insomnia and somatic symptoms (Bruce et al., 2003). Similar to use in GAD, selection of a particular benzodiazepine is based on half-life, speed of onset of action, presence or absence of active metabolites, and metabolic pathways (particularly in patients with liver disease). All benzodiazepines are likely equally effective in treating panic, although in clinical practice, higher potency benzodiazepines (e.g., alprazolam, clonazepam, lorazepam) are used more often than lower potency drugs (e.g., oxazepam). Clonazepam and alprazolam both are FDA approved for panic disorder, and some clinicians prefer clonazepam to alprazolam because of clonazepam's longer half-life, less frequent dosing, and slower onset of action. Lorazepam and diazepam do not have an FDA indication for panic but seem to be effective agents in RCTs and clinical practice (Mitte et al., 2005). The benzodiazepines may be considered as first-line monotherapy when no comorbid conditions exist with panic disorder. Agents with rapid onset (alprazolam, lorazepam) may be preferred if taken on a PRN basis or used as a rescue medication. However, shorter-acting agents can introduce problems with interdose rebound anxiety or more difficulty with adherence to multidose regimens. Agents with longer half-lives, such as clonazepam and alprazolam XR, may be scheduled once or twice daily to provide more even coverage throughout the day but do not provide immediate relief if taken on a PRN basis.

Although the benzodiazepines can bring quick relief from panic symptoms, their side effect profile and risk of dependency, abuse, and withdrawal must be considered when deciding on their use. Common side effects include sedation, fatigue, ataxia, slurred speech, memory impairment, and weakness. Geriatric patients taking benzodiazepines may be at higher risk for falls and fractures (Stone et al., 2008). Patients with a substance abuse history may need to be monitored closely for signs and symptoms of abuse; patients actively abusing substances should probably not be prescribed benzodiazepines. For many of these patients, discussing clear expectations that prescriptions will not be rewritten or refilled before a set date can limit later conflicts and improve treatment adherence.

Evidence for the use of β -blockers in panic disorder is sparse. β -Blockers have been used to reduce the somatic symptoms of panic attacks, such as palpitations, but do not seem to be effective in overall treatment of panic disorder.

KEY TREATMENT

- The SSRIs, SNRIs, TCAs, and benzodiazepines have all been found to be effective in the treatment of panic disorder (Otto et al., 2001) (SOR: A).
- The first-line agents for panic disorder are SSRIs and SNRIs, with starting doses typically half that for depression (APA, 2009) (SOR: A).
- Benzodiazepines can be used as first-line agents when no comorbid psychiatric issues are present, including issues of substance abuse and dependence (Mitte et al., 2005) (SOR: A).

- Maintenance treatment of panic disorder has been shown to reduce the likelihood of relapse (Thuile et al., 2009) (SOR: B).

CONTINUATION OF TREATMENT IN ANXIETY DISORDERS

Treatment for anxiety disorders should be continued for 6 months to 1 year; a more definitive time frame is not yet clear. Results from long-term RCTs of antidepressants in anxiety disorders indicate that maintenance treatment significantly reduces the risk of relapse, whatever the disorder (Thuile et al., 2009). Decisions on length of treatment are generally made on a case-by-case basis, taking into account the risk-to-benefit ratio of treatment versus no treatment. If the decision is to discontinue treatment, the medication should be tapered at a rate that takes into account its pharmacokinetics and whether the patient experiences withdrawal symptoms (see Table 46-13).

OTHER CONSIDERATIONS

Antidepressants and Suicidal Ideation

In 2004, the FDA added a black box warning to all antidepressants indicating that the use of antidepressants in children, adolescents, and adults younger than 25 years of age increased the risk of suicidal thinking and behavior. The warning on antidepressants was based on an analysis of 372 clinical trials involving 11 antidepressant medications noting an increase in the number of patients who experienced an increase in suicidal ideation and behavior, although no increase in actual suicides was observed. Further analysis of the FDA data revealed a strong age-dependent relationship, such that the greatest risk was in patients younger than 25 years old. In clinical terms, 4 additional patients in 1000, age 18 to 24 years, would be expected to experience suicidal ideation or behavior as a result of taking antidepressants, and an additional 14 patients in 1000 younger than age 18 years would be expected to experience worsening. Patients older than 30 years showed a reduction in suicidal ideation as a result of taking antidepressants, with a reduction of 6 patients of 1000 in adults older than 65 years. The net effect of antidepressant use in patients age 25 to 64 years seems moderately protective against suicidal ideation and more strongly protective for adults age 65 years and older (Levenson and Holland, 2006). Antidepressants should be used cautiously in patients younger than age 25 years, with close monitoring for worsening of mood or thoughts of suicide, particularly in the days and weeks after the drug is initiated. For the majority of depressed patients, the beneficial effects of antidepressants greatly outweigh the risks (Libby et al., 2007).

Nontraditional Therapy

Interest in complementary and alternative medicine (CAM) for health disorders has been growing steadily in the past several decades. As a result, a greater number of alternative or complementary agents are being tested in more methodologically rigorous ways, allowing greater scientific assessment of such treatments. Survey evidence suggests that as

many as 40% to 60% of patients may be taking CAM therapies, although patients often do not disclose such use to their physicians (Elkins et al., 2005). In addition, because production of alternative agents is unregulated, variability in product strength, dosing, and purity is common, which in turn likely affects the predictability of their outcomes. Given the widespread use of CAM agents and patients' apparent reluctance to spontaneously disclose such use to their providers, it is incumbent on physicians to inquire about such use.

The majority of CAM treatments have been used to treat depression, including St John's wort (*Hypericum perforatum*), S-adenosyl-L-methionine (SAM-e), and omega-3 fatty acids. In a Cochrane review of St John's wort for treatment of major depression, great heterogeneity was found among the 29 analyzed trials (Linde et al., 2005). St John's wort was found to be superior to placebo and similarly effective as standard antidepressants, but findings were more favorable to St John's wort studies from German-speaking countries, where use of the extract has a long tradition. The more positive results may be caused by physician expertise with the medication, patient selection, or flawed methodologies in some research. The larger, placebo-controlled studies have yielded mixed results, although compared with antidepressants, St John's wort has generally been better tolerated (Shelton, 2009).

SAM-E, a dietary supplement, has been used to treat a variety of illnesses, ranging from major depression to osteoarthritis to liver disease. Clinical trials have shown SAM-e to be superior to placebo and equivalent to TCAs in treating patients with depression, although the most robust findings have been shown with parenteral administration of the drug. Studies using the oral form have yielded more variable results. In adjunctive use with antidepressants, only one open-label study has been published to date. SAM-e has been shown to be safe and well tolerated thus far (Papakostas, 2009).

Omega-3 fatty acids have a variety of health benefits and may be helpful as augmenting agents in the treatment of major depression. The best studied agents are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Findings in depression are limited by variability in study design and small sample sizes, although the majority of evidence favors a positive effect in the treatment of mood disorders (Freeman, 2009).

At present, little robust evidence supports the efficacy of CAM agents in the treatment of anxiety disorders. Kava (*Piper methysticum*) has preliminary evidence of efficacy in GAD, but further testing is needed to determine its side effects and potential for hepatotoxicity (Sarris and Kavanagh, 2009). A meta-analysis found no statistically significant difference between kava and placebo (Hidalgo et al., 2007). Given the paucity of current evidence, caution should be used when considering kava as a therapeutic agent.

OTHER TREATMENTS

Electroconvulsive Therapy

Electroconvulsive therapy involves a brief electrical stimulation of the brain while the patient is anesthetized, inducing a seizure. ECT remains the most effective treatment for

depression (UK ECT Group, 2003), although the stigma surrounding the treatment, misinformation about its practice, side effects, and cost have often made it a treatment of last resort. Although occasionally used as first-line therapy for severe depression, ECT is often used for multitrans-refractory patients, those with psychotic depression, suicidal patients (imminent), and depressed patients with compromised oral intake. A typical course is 6 to 20 treatments, with patients receiving ECT three times a week during the acute phase, gradually increasing the time between treatments as improvement becomes apparent. After acute treatment, patients are often returned to antidepressant therapy, although medication efficacy after ECT does not appear to be enhanced (Kellner et al., 2006). Physicians should be aware that ECT is safe, well tolerated, humane, and effective.

Vagus Nerve Stimulation and Transcranial Magnetic Stimulation

Vagal nerve stimulation (VNS) involves the surgical implantation of a nerve stimulator for the left vagus nerve at the cervical level and has been approved for treatment of refractory depression. VNS is not an acute treatment but has shown some long-term benefit for depressed patients (George et al., 2005). Transcranial magnetic stimulation (TMS) involves the introduction of repetitive magnetic impulses to the right prefrontal cortex in a series of treatments over several weeks. TMS is approved for the treatment of unipolar depression for patients who have failed one trial of antidepressants or for those patients who have exhibited marked intolerance to antidepressants (O'Reardon et al., 2007).

Psychotherapy

In addition to pharmacologic interventions for depression, panic disorder, and GAD, psychotherapy continues to be an effective tool used by psychiatrists and psychotherapists for treating mood and anxiety disorders. Although primary care physicians will not administer such treatments, it is important to be aware of general psychotherapeutic concepts and strategies. Several types of therapy have strong evidence supporting their efficacy in treating both depression and anxiety disorders, including CBT, interpersonal therapy, psychodynamic psychotherapy, problem-solving therapy, and supportive therapy (Cuijpers et al., 2008). Some patients may prefer to begin treatment with medications alone, but others may prefer only psychotherapy or a combination. Combined pharmacologic and psychotherapeutic interventions have generally been shown to be superior to either approach alone in trials for both anxiety disorders and depression (Furukawa et al., 2007; Pampallona et al., 2004).

Referral to Mental Health Providers

Which patients should be referred to mental health providers? Referrals may be made because of patient preference or severity of illness or because of the complexity of comorbid illnesses. Patients who experience refractory depression or

psychotic depression are best treated by specialty providers. Patients with bipolar disorder should be referred as well, especially those with bipolar depressions, because they are often especially difficult to treat, usually require complex polypharmacy, and worsen with inappropriate treatment. Patients requesting or needing psychotherapy or behavioral therapy may be referred to a mental health provider.

Summary

For the majority of depressed patients, the beneficial effects of antidepressants greatly outweigh the risks. CAM treatments for depression may be beneficial for some patients, but study methodology limits their generalizability. ECT is still considered the most effective treatment for severe depression. VNS and TMS are emerging therapies for the treatment of depression.

KEY TREATMENT

- Psychotherapy is an important and effective treatment strategy for both depression and anxiety. Psychotherapy combined with pharmacotherapy often yields results superior to either treatment alone (Furukawa et al., 2007; Pampallona et al., 2004) (SOR: A).

CHAPTER OUTLINE

Delirium, 1108
Dementia, 1112

Delirium

Key Points

- Delirium is often called altered mental status or acute confusional state.
- There are two main subtypes of delirium: the hypervigilant and hypoactive types.
- Hypoactive delirium is underdiagnosed because patients appear quiet, somnolent, or fatigued.
- Delirium is never a normal occurrence.
- Underlying cognitive impairment should be suspected in those with delirium.

Delirium is an abrupt change in brain function causing confusion that occurs from either physical or mental causes. Other terms used for delirium include *altered mental status*, *acute confusional state*, and *acute brain syndrome*. Making the diagnosis can often be difficult because most patients with delirium have comorbid physical and mental conditions. Delirium occurs in 31% to 66% of elderly adults either before or during a hospitalization (Flaherty, 2011). It is important to gain an understanding of this condition because it is often misdiagnosed. Mimickers may include dementia, depression, and acute psychosis. Delirium is often associated with poor outcomes. This includes prolonged hospitalizations, longer stays in skilled care facilities, and higher mortality rate (up to a 10-fold increase) (Inouye, 2006). It often leads to a functional decline that may not be reversible.

CLINICAL FEATURES

Delirium is often underrecognized and underdiagnosed. Even though it may be the most frequent type of acute-onset cognitive change, it is often misdiagnosed as depression, anxiety, psychosis, or other psychiatric disorders. Because it is frequently unrecognized, it has been called the “great imitator” (Caplan and Rabinowitz, 2010; Marcantonio, 2011). Delirium develops acutely and may be first recognized at night. The course of delirium typically shows diurnal fluctuations in symptoms. Many times there

are rapid swings in mood and affect in the affected individual. Lucid intervals may occur intermittently in a 24-hour period. Alertness is the key clinical feature that should be carefully assessed. It may fluctuate between hypoactivity and hypervigilance. Individuals with hypoactive delirium may be mistaken as having depression, are harder to identify, and sometimes have worse outcomes than those with the hyperactive type (Table 47-1) (Caplan and Rabinowitz, 2010; Kiely et al., 2007). These individuals can be more sedated and do not bother the inpatient nursing staff, which results in difficulty in recognition. Another key clinical feature is change in attention. Attention span is always altered in delirium and fluctuates. Patients may show difficulty focusing, following commands, or carrying on conversations (Caplan and Rabinowitz, 2010; Inouye, 2006). Recent memory is usually impaired. An individual with delirium shows changes in thinking. Thinking is often disorganized and fragmented (Marcantonio, 2011). It may be slower, more hurried, or rambling in nature. Typically, there is alteration in levels of consciousness. Individuals show decreased awareness of their surroundings. Speech may be incoherent. Visual, auditory, or tactile hallucinations are often present in delirium (Flaherty, 2011). Delusional thinking is often present. For example, patients may have false interpretations such as thinking an intravenous line is a snake. They may be seen picking at the bed sheets looking for bugs or other objects that are not there (Alagiakrishnan, 2013). Emotional disturbances are often present and may manifest as depression, anxiety, anger, fear, or paranoia. Sleep-wake cycles are commonly disturbed and often reversed (Inouye, 2006).

Delirium is never a normal occurrence. Delirium usually implies an underlying cognitive impairment and may be the first sign of a deficit in the brain. Although in general, delirium develops acutely, there are reported prodromal phases lasting for days before it develops or becomes evident. During this prodromal phase, there may be sleep problems, vivid dreams, and heightened anxiety levels (Cole et al., 2003). Some patients with acute confusion may not meet the diagnostic criteria for delirium. This condition is termed *subsyndromal delirium*. It can have comparable outcomes to delirium and is treated similarly (Levkoff et al., 1992; Marcantonio, 2011; Quimet et al., 2007). Delirium in general lasts for days to weeks. However, it can be persistent, with symptoms lasting months to years (Levkoff et al., 1992; McCusker et al., 2003).

Table 47-1 Differentiating Delirium, Dementia, and Depression

Characteristic	Delirium	Dementia	Depression
Onset	Acute	Insidious	Acute or insidious depending on life situation
Duration	Generally hours to weeks; can be longer	Months to years	Weeks to years
Trajectory	Fluctuating and may be worse at night	Progressively worsening impairment later affecting function	Diurnal; worse in the morning; can have situational changes
Attention	Impaired and fluctuates	Normal; impaired in late stages	Minimal impairment; lack of motivation
Alertness	Hypoactive or hypervigilant; can fluctuate	Normal	Normal but may be impaired periodically
Consciousness	Fluctuates	Normal; can be impaired in late stages	Normal
Memory	Short-term memory usually impaired	Initially short-term memory impairment, which progresses to both short- and long-term memory impairment	Recent memory may be impaired; frequent "I don't know" answers; long-term memory intact
Hallucinations	Frequent visual, auditory, or tactile hallucinations	In later stages except in DLB, in which visual hallucinations occur early	Only in depression with psychosis

DLB, Dementia with Lewy bodies.

ETIOLOGY

Key Points

- Normal brains do not get delirium.
- Functional impairment and sensory deficits can predispose to delirium in elderly adults.
- Asymptomatic bacteriuria is commonly misdiagnosed as a cause of delirium.

Delirium often has multifactorial causations. A number of predisposing factors are seen with delirium, including age older than 65 years and more commonly occurring in men. Abnormal cognition, whether from dementia or depression, often underlies delirium. A good clinical pearl to remember is that normal brains do not get delirious. Alterations in functional status may predispose to delirium. These patients more commonly have history of falls and immobility.

Older individuals with diminished vision or hearing are more likely to develop delirium. A clinical pearl is always to remember to keep an older patient's glasses or hearing aids readily available and nearby while in the hospital. Older individuals physiologically have diminished thirst, and resulting dehydration can lead to the development of delirium.

Many coexisting medical conditions can predispose to acute confusion (Alagiakrishnan, 2013; Caplan and Rabinowitz, 2010; DesForges, 1989; Flaherty, 2011; Inouye et al., 2006; Marcantonio, 2011). These include but are not limited to hypoxia, hypothermia, hyperthermia, and alcohol withdrawal. Infection is another very common cause of delirium. Urinary tract and respiratory tract infections are the most common infections resulting in delirium. However, asymptomatic bacteriuria should not be attributed as a cause for delirium in elderly patients. Elderly adults many times present atypically and may have subtle findings such as silent cholecystitis, diverticulitis, or intraabdominal abscesses. Other infectious causes include encephalitis meningitis, human immunodeficiency virus

(HIV), and bacteremia. Severe medical conditions such as myocardial infarctions, congestive heart failure, chronic hepatic disease, and chronic kidney failure can precipitate delirium. Asterixis may be a useful clinical sign in identifying chronic hepatic and chronic kidney disease as an etiology of delirium.

Metabolic abnormalities that should be considered include hyponatremia, hypernatremia, hypocalcemia, hypercalcemia, hypoglycemia, hypothyroidism, and hyperthyroidism. Selective serotonin reuptake inhibitors (SSRIs) used in the treatment of depression and anxiety should not be overlooked as a cause for hyponatremia. Malignancy, acute or chronic pain, and the postoperative period are also risk factors for development of delirium.

Falls resulting in fractures, especially hip fractures and subdural hematomas, cause delirium. Patients with subdural hematomas may initially have no focal neurologic signs. There should be a low threshold for doing a head computed tomography (CT) in elderly patients with delirium after a fall to evaluate for subdural hematomas.

Toxins and medications, including general anesthesia, illicit drugs, and withdrawal from alcohol, benzodiazepines, and opioids, should not be overlooked as potential causes for delirium. Anticholinergic medications predispose elderly patients to delirium. These may be prescribed drugs for urinary incontinence or may be found over the counter in many sleep aids. Tricyclic antidepressants should not be used in elderly adults for depression because of high anticholinergic side effects. Similarly, paroxetine, an SSRI, should not be used to treat depression in elderly adults because of anticholinergic side effects. Patients with a history of stroke and other neurologic diseases are also at risk. Individuals who are terminally ill are also more likely to develop delirium up to 83% of the time (Breitbart and Strout, 2000; Casarett and Inouye, 2001). Iatrogenic factors that may predispose to delirium include use of physical restraints, indwelling urinary catheters, and polypharmacy. Often overlooked causes may be fecal impaction or urinary retention and should be ruled out in the setting of delirium (Blackburn and Dunn, 1990). There should be a

high suspicion for underlying dementia in patients with delirium.

DIAGNOSTIC PROCESS

Key Points

- The Confusion Assessment Method (CAM) is a commonly used tool to evaluate for delirium.
- Cognitive testing should also be used to evaluate for underlying deficits.
- Neuroimaging, lumbar puncture, and electroencephalography (EEG) are not routinely required to evaluate for delirium unless focal findings are present.

Besides a thorough history and physical examination, diagnosis is made by short bedside evaluation exercises (Wong et al., 2010). The Mini-Mental Status Exam (MMSE) and Mini-Cog test cognitive function, including attention and visual spatial reasoning (Borson, 2000; Folstein et al., 1975). Other tests to measure attention include having the patient recite days of the week and serial numbers from 100 backward (Marcantonio, 2011). Neuroimaging, lumbar puncture, and EEG are not routinely needed unless focal neurologic findings are present. When EEG is done, findings supportive of a delirium diagnosis are generalized slowing in the theta-delta range and resolution with treatment (Caplan and Rabinowitz, 2010; Engel and Romano, 1959). The CAM developed by Inouye and colleagues is one of the most commonly used instruments in making a diagnosis of delirium (Inouye et al., 1990). It has a sensitivity of 94% to 100% and a specificity of 90% to 95% (Inouye et al., 1990; Marcantonio, 2011). The CAM can be administered in any setting within about 5 minutes (Table 47-2). Although it identifies the presence or absence of delirium, it is not reliable in assessing the severity. The CAM is a diagnostic tool and not one that should be used for following the patient for improvement or worsening of his or her delirium. There is also a CAM-ICU tool that uses nonverbal responses in the assessment of delirium (Ely et al., 2001). Clinical history and examination still remain of utmost importance in follow-up.

The *Diagnostic Statistical Manual of Mental Disorders*, fifth edition (DSM-5) diagnostic criteria for delirium include (A) disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment); (B) the disturbance develops over a short period (usually hours to a few days), represents a change from baseline attention and awareness,

Table 47-2 Diagnosis of Delirium by the Confusion Assessment Method*

- I. An acute and fluctuating course
- II. Inattention
- III. Disorganized thinking or
- IV. Alteration in level of consciousness

*Diagnosis requires I and II and either III or IV.

and tends to fluctuate in severity during the course of a day; (C) an additional disturbance in cognition (e.g., memory deficit, disorientation, language, visuospatial ability, or perception); (D) the disturbances in criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as coma; and (E) there is evidence from history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication, or withdrawal (i.e., caused by a drug of abuse or a medication) or exposure to a toxin or is from multiple causes. A substance intoxication delirium is further subclassified (American Psychiatric Association, 2013).

PREVENTION OF DELIRIUM

Key Points

- Multicomponent approaches targeting multiple etiologies and risk factors of delirium work best.
- Proactive geriatric consultation may be helpful in preventing postoperative delirium.

Because delirium is generally multifactorial in etiology, a multicomponent management approach is most helpful in preventing it. One example of such an approach is the Yale Delirium Prevention Trial, which showed that targeting risk factors can be effective in helping prevent delirium. In their trial, intervention protocols were targeted toward six risk factors: (1) orientation and therapeutic activities for cognitive impairment, (2) early mobilization to help prevent immobility and falls, (3) nonpharmacologic approaches to lessen the use of psychoactive type medications and to reduce sleep deprivation, (4) communication strategies and adaptive equipment for hearing, (5) communication strategies and adaptive equipment for vision impairment, and (6) early intervention to prevent volume depletion.

In the Yale Delirium Prevention Trial, 852 patients 70 years and older were enrolled (Inouye et al., 1999). Half of these received usual hospital care for delirium, and half received the HELP (Hospital Elder Life Program) interventions as noted. These interventions resulted in a significant reduction in development of delirium (9% vs. 15%), total days of delirium, total number of episodes of delirium, and functional decline. HELP sites have subsequently been started in other hospitals across the United States showing similar results (Inouye, 2006).

Another approach that has been shown to be of benefit in preventing delirium includes using proactive geriatric consultation in older patients. One study using this approach showed a 36% reduction in the incidence of delirium for postoperative hip fracture patients. (Marcantonio, 2011; Marcantonio et al., 2011). Another study showed that using low-dose haloperidol, 0.5 mg three times per day for 3 days, started before the onset of delirium in elderly patients undergoing high-risk hip surgery reduced the severity and duration of postoperative delirium (Flaherty, 2011; Kalisvaar et al., 2005).

TREATMENT OF DELIRIUM

Key Points

- Treatment of delirium starts with identifying and correcting the underlying cause.
- Nonpharmacologic management should always precede management with medications, and different subtypes of delirium may require a different approach.
- No medications have been approved by the Food and Drug Administration (FDA) to treat delirium, although several drugs (mainly antipsychotics and benzodiazepines) have been used with some success depending on the cause of delirium.
- Medications should be used only when the risk of injury to self or others is significant and the behavior interferes with medical management.

Treatment of patients with delirium should always start with correcting potential causes: discontinuation of the offending medication, treatment of infection, correction of electrolyte imbalance, and treatment of pain. Correcting sensory deficits is very important (Khan et al., 2012). Family members or friends of patients with delirium should be encouraged to stay at the bedside and provide frequent orientation. Patients should be encouraged to maintain previous functional levels and independence in performing ADLs. Providing a room with adequately lighting, an accurate calendar, and a dry erase board for communication can be beneficial. Placing patients next to noisy areas and placing two delirious patients in the same room should be avoided. Lighting should be adequate during the day, and bright lights should be avoided at night to maintain circadian rhythm (Chong et al., 2013). External stimuli should be minimized at night (i.e., frequent awakenings should be avoided unless they are essential in guiding medical therapies). If possible, staff assignment should be consistent to maintain familiarity. Urinary catheters and restraints should be avoided if possible (Campbell et al., 2009). Using familiar objects brought from home, aroma therapy, and pleasant music might also be helpful. Environmental strategies are underused and should be used as first-line treatments because of a lack of adverse effects (Meagher, 2001).

It is important to note that there are no FDA-approved medications to treat delirium. However, with certain behavioral circumstances, such as hallucinations, delusions, and safety issues, or situations that hinder medical care, antipsychotics may need to be used. There are very limited data to support their use, but no good alternatives exist (Flaherty et al., 2011). Low doses of haloperidol (0.5-1 mg orally or intramuscularly) are usually used as a first-line treatment modality. Elderly patients can be very sensitive to these medications and may require lower doses. If intravenous haloperidol is used, there must be monitoring for development of QT prolongation and life-threatening arrhythmias (Huffman and Stern, 2003). Haloperidol should not be used in patients with parkinsonism, and consideration should be given to use of atypical antipsychotics (especially those with low extrapyramidal activity such as quetiapine). Hypo-

tension and sedation can occur as a result of use of antipsychotics, further complicating and prolonging the hospital stay. Use of antipsychotics can increase the risk of stroke and death; thus, short-term use is recommended only if absolutely needed. Metabolic abnormalities such as hyperglycemia and hyperlipidemia are also attributed to long-term antipsychotic use. It should be noted that patients with dementia with Lewy bodies (DLB) are extremely sensitive to antipsychotics and can have acute worsening of parkinsonism when these medications are used. Benzodiazepines are generally overused (but sometimes have to be used) in the management of delirium and have a shorter onset of action. Benzodiazepines with shorter half-lives (e.g., lorazepam) are preferred because these medications can cause significant sedation, confusion, and risk of falls in elderly adults. These medications are used primarily in alcohol and drug withdrawal-induced delirium as well as in situations when antipsychotics are contraindicated. Acetylcholinesterase inhibitors (AChEIs) generally do not have a role in treatment or prevention of delirium (van Eijk et al., 2010). In patients who present with nutritional deficiencies, thiamine should be supplemented because it is free of side effects, is cost effective, and is efficacious in terms of patients with delirium caused by alcoholism or thiamine deficiency.

KEY TREATMENT

- Low-dose antipsychotics (e.g., haloperidol) are used as first-line medical treatments (Huffman and Stern, 2003) (SOR: B).
- Benzodiazepines should be avoided in most situations (SOR: B) except in alcohol withdrawal (Lonergan et al., 2009) (SOR: A).
- Low-dose haloperidol used preemptively can be effective in reducing the severity and duration of delirium postoperatively (Kalisvaar et al., 2005) (SOR: B).

NATURAL HISTORY OF DELIRIUM

Delirium usually manifests as an acute (as opposed to gradual, as in dementia) change in mental status with a fluctuating course and variable duration. It can occur across all continuums of care: home, outpatient, long-term care, emergency department, intensive care unit, and hospice units. About one third of the hospitalized older patients in one study had symptoms of delirium at discharge, and longer initial episodes usually led to worse prognoses and worse clinical outcomes (McCusker et al., 2003). Patients with a protracted course of delirium can meet criteria for dementia (Fong et al., 2009). The frequency of delirium can be as high as 89% in hospitalized patients with dementia (Fick et al., 2013). Nursing home residents are three times as likely to develop delirium if they carry a diagnosis of dementia (Boorsma et al., 2011). Although delirium is a potentially reversible condition, it usually is a bad prognosticator for underlying or future dementia, worsening frailty, and increased short- and long-term mortality rates in elderly adults (Cole and Primeau, 1993).

Dementia

Key Points

- The prevalence of dementia is increasing as the elderly population increases.
- Cognitive evaluation involves the assessment of different domains (e.g., executive function, language).
- Age-associated memory impairment (AAMI), mild cognitive impairment (MCI), and depression can mimic dementia.

Dementia is a clinical syndrome with persistent intellectual decline that is severe enough to interfere with social or occupational functioning in an alert individual. The term *dementia* is taken from Latin, meaning “without mind.” Subjective memory concerns typically bring patients to seek medical attention. A variety of different domains of cognition are important to recognize and are specified by the DSM-5 to include complex attention, executive function, learning and memory, language, perceptual-motor, and social cognition. When confronted with a patient with subjective memory concerns, clinicians must differentiate many conditions, including AAMI, MCI, depression, delirium, and dementia (Caplan and Rabinowitz, 2010). The workup helps to differentiate these and other conditions and ultimately identifies a specific etiology (e.g., Alzheimer disease [AD], vascular dementia [VD]).

CLINICAL FEATURES

The prevalence of dementia increases with age. About 5% to 10% of people older than the age of 65 years have dementia. This increases to about 30% to 50% of those older than the age of 85 years (Evans, 1996). A record number of people are getting older in the United States; some have termed this phenomenon “the silver tsunami” (Bartels and Naslund, 2013). Older people have more subjective cognitive concerns and a higher prevalence of dementia (Liffie and Pealing, 2010). A survey by the MetLife

Foundation (2011) found that AD is the second most feared disease among American adults, behind only cancer. Dementia has an increasing overall impact, including a societal, economic, health care-related, and emotional impact.

According to the DSM-5, the preferred term for dementia is *neurocognitive disorder*, which is defined as significant cognitive impairment and interference with independence not caused by delirium and not caused by other mental disorders. Cognitive impairment is quantified based on psychometric definitions in terms of standard deviations from the mean in testing. Whereas 1 to 2 standard deviations below the mean represent mild impairment, 2 to 3 standard deviations below the mean represent major impairment (Reisberg, 2006). In evaluating dementia, important consideration should also be given to function, behavior, and focal neurologic changes because these can be important clues as to the etiology as well as the prognosis. Both neuropsychiatric symptoms (wandering, agitation, changes in mood) and neurologic symptoms (gait imbalance, focal signs, seizures) may be present in individuals with dementia.

Frequently, elderly patients present with subjective cognitive concerns such as difficulty remembering names, slowing of processing speed, impaired recall, and forgetting and misplacing things such as keys. It is important to distinguish these subjective cognitive concerns related to normal aging (AAMI) from more serious conditions such as MCI that affect higher-level activities such as medication and financial management (impaired IADLs). Distinguishing MCI from AAMI can be very challenging (Table 47-3). Neuropsychological testing is used to distinguish these conditions after workup is done to rule out reversible medical conditions that can impact cognition (Pokorski, 2002). MCI has a significant risk to progress to dementia and is thus important to identify early.

Depression can also mimic dementia and must be ruled out. Known as “pseudo dementia,” depression can affect cognition. Careful history taking as well as a thorough workup, including targeted evaluation of mood symptoms, can help differentiate these conditions. Those with untreated depression have an independent long-term increased risk of dementia.

Table 47-3 Distinguishing Mild Cognitive Impairment from Age-Associated Memory Impairment

Cognitive Concern	Age-Associated Memory Impairment	Mild Cognitive Impairment	Dementia
Complaints of memory concerns	Remembers details around memory concerns	May have delay but able to recall concerns	Problems remembering details; often lost
Short-term memory	Normal	Impaired in amnesic MCI subtypes	Impaired at first and later more profound
Cognitive evaluation	Normal	Mildly impaired	Impaired
Interpersonal and social skills	Normal	Usually normal	Impaired, especially in FTD
ADLs	Normal	Normal	Usually impaired
IADLs	Normal	Usually impaired	Impaired

ADLs, Activities of daily living; FTD, frontotemporal dementia; IADLs, instrumental activities of daily living.

Adapted from Patel BB, Holland NW. Mild cognitive impairment: hope for stability, plan for progression. *Cleve Clin J Med*. 2012;79:857-864.

DIAGNOSTIC PROCESS

Key Points

- Dementia evaluation should be prompted by a warning signs approach rather than screening.
- Many different cognitive evaluation tools are helpful in evaluating cognitive deficits and support a diagnosis of dementia.
- Functional assessment is an important aspect of evaluation of dementia.
- Depression is the most common reversible etiology of dementia.

Detecting dementia in a busy clinical practice is a challenge. Often, patients with dementia do not present with memory loss complaints; instead, spouses or family members bring up concerns to the physician to be further evaluated. Importantly, cognitive concerns are incorrectly attributed to normal aging in some cases by patients and family members, as well as physicians. The U.S. Preventive Services Task Force has concluded that there is insufficient evidence to recommend for or against routine screening for dementia for any age group (Lin et al., 2013). Evaluation should be prompted by a warning signs approach. The Alzheimer's Association (2014) uses the "10 warning signs" that should prompt evaluation. Patient, caregiver, or clinician concerns regarding cognitive abilities should prompt further evaluation. Multiple different office cognitive evaluation tools are available that are beneficial in terms of quick assessment and identification of deficiencies affecting different domains of cognition. Among these are the Mini-Cog, MMSE, Montreal Cognitive Assessment (MOCA), St. Louis University Mental Status (SLUMS), and many others. Each of these tools has its pros and cons in terms of time needed to administer, cognitive domains evaluated, alternative versions available, and so on. The Mini-Cog is a good office screening tool for a busy practice. It involves a clock draw and three-item recall. The ease of scoring, brevity, and use in diverse ethnic populations make the Mini-Cog a useful tool (Borson et al., 2006). The SLUMS and the MOCA are more time-consuming tests and are more useful in evaluating MCI and early cognitive concerns. Both of these tests evaluate multiple cognitive domains. These brief office tests can be used to quantify deficiencies in cognition and to document change in cognition over time objectively (Patel and Holland 2012). They can be used to discuss the degree of cognitive impairment and thus reflect the stage of dementia when discussing this condition with care partners and family members. These tests should not be used in isolation to make the diagnosis of dementia and should be used in conjunction with functional assessment.

Functional assessment is also of vital importance when evaluating cognition. It is important to know if the patient is able to independently perform ADLs (bathing, dressing, feeding, toileting, transferring, grooming) and IADLs (shopping, cleaning, laundry, transportation, finances, medication management, using the telephone). With early cognitive impairment, there is trouble with IADLs, and patients who were previously independently able to do all of their higher-level activities now require assistance (especially with financial and medication management). Later, as

dementia progresses, ADLs become affected, which increases the care needs the individual has and increases the risk of placement. The short form of the Geriatric Depression Scale (GDS) can be used in the office setting to assess for depression (Sheikh and Yesavage, 1986). Evaluation focuses on trying to rule out reversible causes for dementia. A meta-analysis of 39 articles describing 5620 individuals with dementia-like symptoms reported that only 9% had potentially reversible dementia. These potentially reversible causes of dementia include delirium, depression, medications, thyroid problems, certain vitamin deficiencies, and excessive use of alcohol (Clarfield, 2003). A key clinical pearl is that the most common reversible cause of dementia is depression. Older patients are at a higher risk for depression and should be carefully evaluated for it.

HISTORY AND PHYSICAL EXAMINATION

Because chronicity of symptoms is of pivotal importance in terms of making the correct diagnosis, an accurate history of this must be obtained. Because dementia is of insidious onset, it is very difficult to clarify when deficits actually began. A cognitively impaired patient is often an unreliable source of information, and thus one must turn to caregivers, spouses, and friends to get further clarification and pinpoint the specific deficits.

The onset, clinical trajectory, and specific nature of symptoms are useful in making a determination of the etiology of the cognitive impairment. Further history of medications, both prescription and over the counter with emphasis on anticholinergic and psychoactive medications, should be an important aspect of assessment. Vascular disease such as diabetes, hypertension, stroke, coronary artery disease, and peripheral vascular disease should also be noted. A history of substance abuse, mental illness, head trauma, sleep concerns, seizure disorder, previous surgery, previous central nervous system infections, educational background with focus on deficiencies, occupational history, and family history of dementia are all important aspects of evaluation. Functional status as determined by ADLs and IADLs is a necessary component of the assessment. A general physical examination is a good starting point with further focused evaluations of the cardiovascular system looking for the presence of vascular disease as well as neurologic examination looking for focal deficits. Impairments in overall function raise safety and support concerns that often warrant additional evaluation (e.g., driving concerns, ability to live alone, medication management challenges, financial concerns) (McCarten, 2013).

LABORATORY AND IMAGING STUDIES

The usual laboratory workup for dementia includes a complete blood count, comprehensive metabolic profile, urinalysis, thyroid-stimulating hormone level, and vitamin B₁₂ level. In appropriate high-risk populations, one may consider syphilis and HIV serology (Kelley and Minagar, 2009). All of these tests are done to determine the contribution of comorbidities to cognition and to look for reversible causes of dementia. Apolipoprotein E-e4 (ApoE-e4), located on chromosome 19, is linked to the greatest risk of development of AD. Those not expressing the ApoE-e4 allele have

the least risk, followed by heterozygous patients with intermediate risk and then homozygous patients with greatest risk. Genetic testing for ApoE-e4 is controversial and should only be undertaken after considerable discussion of risks and benefits. After a decision is made to do this testing, a discussion with a genetic counselor may be beneficial (Ertekin-Taner, 2007). Cerebrospinal fluid (CSF) studies and structural imaging (structural magnetic resonance imaging [MRI] or CT and fluorodeoxyglucose positron emission tomography [FDG-PET]) have made great strides in terms of published research but have yet to become mainstream clinically (Mueller et al., 2012; Zetterberg and Blennow, 2013). These biomarkers hold promise for the future in terms of correctly diagnosing dementia of Alzheimer type. Imaging studies can be beneficial in the evaluation of focal neurologic deficits and should be used when suspicion is high for treatable cerebrovascular conditions such as brain tumors, normal-pressure hydrocephalus (NPH), traumatic brain injury, and so on. Thus, it is not necessary to do brain imaging in all patients being worked up for dementia. If an imaging study is warranted, it is recommended that CT or MRI be the imaging modalities of choice. Neuropsychological testing is very useful in the evaluation of cognitive deficits. It usually involves several hours of testing and completion of mentally challenging activities that the patient must be an appropriate candidate to complete, usually in one sitting. Severe visual or hearing deficits pose a challenge and make neuropsychological testing very difficult to complete. Furthermore, the patient must be willing to put forth his or her best effort in doing the testing to obtain results that can then be scored to determine deficits in different domains of cognition. Not all patients require neuropsychological testing, and only patients with challenging presentations who are not easy to diagnose should be referred. Generally, younger patients, those with very mild deficits, and those who rapidly develop dementia are good candidates for neuropsychological testing. This testing can also be useful as a baseline with which to compare for subsequent evaluations of cognitive abilities (Kulas and Naugle, 2003).

COMMON TYPES OF DEMENTIA

Alzheimer disease is the most common type of dementia, accounting for about 60% to 80% of cases with dementia, followed by DLB, which accounts for 10% to 22%. VD accounts for about 10% to 20% of all dementias, followed by more uncommon dementias. Autopsy studies done on patients with dementia usually show a mix in pathology between Alzheimer-type pathology and vascular changes (Nowrangi et al., 2011).

Alzheimer Disease

Key Points

- AD is the most common type of dementia.
- Early memory impairment is the key clinical finding in AD.
- AD is a slowly progressive dementia with an average life expectancy of 8 to 10 years from the time of diagnosis.

- Physical and mental activity is recommended to patients at risk for dementia.
- Caregiver stress and burnout should be evaluated and addressed to avoid long-term care placement.
- Feeding tubes are not indicated in late stage dementia.

Alzheimer disease is a degenerative disease diagnosed clinically, with definitive diagnosis made only through postmortem examination of the brain. Described first by Dr. Alois Alzheimer in 1906, AD has been extensively studied only in the past 30 years. The cause of AD is not well understood, but a great deal is known about the changes in the brain that occur in those with it. The classic neuropathological features in the brain include senile plaques and neurofibrillary tangles. The changes that occur in the brains of patients with AD start as many as 20 years before the first clinical manifestations of disease. The earliest clinically detectable point of deficits is known as MCI caused by AD. There is an accumulation of the β -amyloid protein outside neurons in the brain (β -amyloid plaques) and the accumulation of an abnormal form of the tau protein inside neurons (tau tangles). Gradually, information transfer at the level of synapses begins to fail, the number of synapses declines, and neurons ultimately die. β -Amyloid accumulation interferes with the interneuronal communication at synapses, leading to cell death. Tau tangles block the passage of nutrients and other necessary molecules in the neuron and contribute to cell death. These tangles are found in the hippocampus, medial temporal lobes, and amygdala. The rate of hippocampal atrophy correlates with change in clinical status. Notable brain shrinkage is evident on autopsies of brains of people with advanced AD from cell loss and debris from neuronal injury. The neuropathology of AD also involves neurotransmitters. With the loss of cholinergic neurons, there are decreased acetylcholine levels, and a decrease in the acetylcholine-synthesizing enzyme choline acetyltransferase levels in the brain. The loss of cholinergic neurons is most noted in the hippocampus and the nucleus basalis of Meynert. This alteration in levels of neurotransmitters contributes to the psychiatric symptoms in individuals with AD such as depression, anxiety, and agitation (Clark and Karlawaish, 2003; Jack et al., 2000).

The strongest risk factors for AD include advancing age and family history with a first-degree relative with early-onset type AD. The prevalence of AD doubles every 5 years, and it occurs more in women, likely because of their greater life expectancy. Additional risk factors include history of head trauma, vascular disease, presence of apoE-e4 gene, and low levels of education. Regular physical activity is the most protective factor. The course of AD is typically gradual in onset accompanied by continuing cognitive decline over many years. Behavioral concerns are also typical and include depression, anxiety, sleep disturbances, hallucinations, delusions, and agitation. The average duration of progression from onset to death is 8 to 10 years. AD is the sixth leading cause of death, which usually results from infection, cardiovascular disease, cachexia, or dehydration. Currently, about 5.2 million Americans have AD (Lindsay et al., 2002).

Memory impairment is the cornerstone of disease presentation from the start. It becomes more dramatic as the

disease progresses, eventually leading to functional impairment (first IADLs and then ADLs become impaired). Early on in the disease, patients complain of difficulty remembering names and recent events (short-term memory). Depression and apathy can also complicate things and usually worsen prognosis. As the disease progresses, additional symptoms arise, including disorientation, confusion, impaired judgment, and behavior changes. Finally, during the late stages of AD, individuals have difficulty speaking, swallowing, recognizing loved ones, and worsening impairment in completing ADLs, and eventually the patient becomes bedridden, requiring total care. Individuals with AD progress from mild to moderate to severe stages at variable rates (Kelley and Petersen, 2007).

Pharmacotherapy. At the present time, there are no disease-modifying treatments for AD that slow or stop death or neuron damage in the brain. Managing AD is complex and must involve appropriate use of available treatment options; appropriate management of comorbid conditions; keeping the patient active mentally as much as possible; care coordination between caregivers and the health care team; and use of support groups, caregiver training, and supportive services to ease caregiver stress and burden. The goals of pharmacotherapy include improvement in memory and cognition, improving behavioral problems, easing caregiver stress and burden, and ultimately delaying long-term care placement. Many agents with the promise of being disease-modifying agents are being studied worldwide. Currently, the mainstay of treatment includes the AChEIs. Early detection is important so appropriate management strategies can be applied. Tacrine was the first AChEI developed, but it fell out of favor given that it has associated liver toxicity and frequent dosing and required monitoring. The other three AChEIs are donepezil, galantamine, and rivastigmine. Donepezil has been on the market since the mid-1990s and is a once-daily formulation. As a class, these medications have been well studied and show modest efficacy in managing the cognitive symptoms of AD. The most common side effects of the AChEIs include nausea, vomiting, and diarrhea. However, there are many other lesser known side effects of these medications, including rhinitis, nightmares, syncope, bradyarrhythmia, urinary incontinence, and weight loss (Patel and Holland, 2011). Side effects such as nightmares can respond to administration of the medication in the morning. Often, medication side effects lead to a prescription cascade whereby another medication is used to combat the side effect of one medication. The AChEIs are started at a lower dose and are then titrated slowly to avoid side effects. The length of response has been documented at 52 weeks, and benefit beyond that period is uncertain. It is worthwhile considering the risk versus benefits of these medications when used in patients with AD given that some of these patients may already have cachexia and poor appetite.

Another class of medications, the *N*-methyl-D-aspartate (NMDA) receptor agonists, are used in AD treatment as well. Memantine is currently the only NMDA agonist available and is indicated for moderate to severe AD. Some data show modest improvement in cognitive symptoms as well as quality of life. Generally, memantine has a better side effect profile than the AChEIs. Multiple different

formulations of AChEIs exist, including transdermal patch, orally disintegrating pills, and liquid, thus improving compliance in patients with AD. All of these medications appear to be equally efficacious, and there is little evidence to recommend one over the other. They provide modest cognitive function enhancements but do not impact the underlying pathophysiological changes of AD. The decision to start therapy is very individual and should be made after full consideration of prognosis, comorbidities, side effects, and compliance, as well as caregiver education regarding risks and benefits in view of limited efficacy (Kelley and Petersen, 2007).

KEY TREATMENT

- AChEIs and NMDA agonists are only modestly effective and can be associated with significant side effects (Kelley and Petersen, 2007; Patel and Holland, 2011) (SOR: B).

Prevention. Many different studies have looked at the issue of prevention, and the data on AD prevention come primarily from observational studies. Prospective and randomized studies have shown no benefit from treatments such as vitamin E, nonsteroidal antiinflammatory drugs (NSAIDs), estrogen replacement, or AChEIs. The use of antioxidants in AD is an area of active research. A large clinical trial of patients with moderate AD found that vitamin E at a dosage of 1000 IU twice daily was effective at slowing the progression of moderate AD. This treatment modality fell out of favor after the well-known cardiovascular literature demonstrated an increased risk of death (from cardiovascular causes) with vitamin E dosages greater than 400 IU/day. Although observational studies also found NSAIDs to be modestly protective in dementia, their cardiovascular risk and long-term use risk preclude their use in AD. Ginkgo biloba, a popular nutraceutical, has also been studied in AD and has not shown to be of benefit. Additionally, it carries a risk of bleeding. Physical activity and exercise are well proven in terms of their health benefits, and evidence indicates that they benefit cognition as well. Cognitive leisure activities (e.g., playing cards, doing crossword puzzles) and social activities should also be recommended to those at risk of AD. Optimizing vascular risk factors (controlling blood pressure and diabetes) is also of great importance (Scarmeas et al., 2009).

Caregiver Education and Support. Health care teams must connect with and educate AD caregivers. Caregivers are of vital importance in keeping the patient with AD safe, compliant with treatment recommendations, and active. Caregiver education has been shown to reduce caregiver stress and burnout. It has been shown to reduce long-term care placement as well. Social work referral and referral to community programs and resources, such as the Alzheimer's Association, adult day health care, respite care, home health care, and hospice programs, are beneficial to caregivers and patients. Knowing about and inquiring about the health and personal challenges of AD caregivers is important. There are many tools and questionnaires available to assess caregiver burden and stress that can be used as well (Dang et al., 2008).

End-of-Life Care. Very commonly, family physicians lose focus in terms of viewing AD as a terminal illness. They wait until the later stages of the disease to discuss end-of-life issues and decision making, resulting in undue stress and expectations. Caregivers must be made aware of the prognosis of AD and the typical trajectory of it so that end-of-life decisions can be made earlier and can be planned for. Advanced care planning is much more than a living will and a power of attorney; it includes many decisions in terms of things such as hospitalization, comfort care, artificial nutrition, and placement. The insidious course of AD makes it more difficult for patients and families to accept that it is a terminal illness. Involvement of hospice services available through Medicare are reserved for very late AD patients. However, a palliative approach can be started much earlier. Loss of ADL function, loss of communication and understanding, loss of language, and being bedridden are some of the characteristics of a patient with AD who would qualify to receive the Medicare hospice benefit. Frequently, clinical dilemmas such as feeding an AD patient who cannot swallow, aspirates, and has weight loss are difficult to deal with without previous consideration. Feeding tubes should not be used in AD patients in the later stages of the disease. A palliative medicine team or specialist can be of benefit in consultation if these challenging situations arise.

Dementia with Lewy Bodies

Key Points

- Parkinsonian features and early visual hallucinations are common characteristics of DLB.
- Patients with DLB have heightened neuroleptic sensitivity.

Dementia with Lewy bodies was first described in the 1960s as dementia with other important clinical features, including visual hallucinations, dysautonomia, parkinsonism, neuroleptic sensitivity, sleep disorders (e.g., parasomnias), and fluctuating cognition. Men are more commonly affected than women. Age is a risk factor for this disease as well. These patients are very sensitive to psychotropic medications, which can result in worsening parkinsonism and dysautonomia. The mainstays of treatment include cholinesterase inhibitors because the neurochemistry of DLB is similar to that of AD. Carbidopa–levodopa is used to treat the motor symptoms. It can be extremely challenging to manage patients with DLB, and caregiver education and training are very important to keep these patients functioning actively in the community as long as possible (Knopman et al., 2003).

Vascular Dementia

Key Points

- The course of VD is typically “stepwise” or associated with occurrence of strokes.
- Optimizing vascular risk factors is the cornerstone of treatment.

There is a great deal of overlap between vascular and Alzheimer dementia in terms of comorbidities, risk factors, and pathogenesis. Cognitive deficits that occur in conjunction with a clinically obvious ischemic or hemorrhagic stroke or subclinical “silent” stroke represent the spectrum of VD. Usually memory impairment is mild early in the course of VD as opposed to AD, and executive dysfunction is present. The typical presentation of cognitive concerns occurs suddenly after a stroke or follows a “stepwise” course. Focal neurologic signs are frequently present such as hemianopsia, hemiparesis, and so on. The site and extent of the lesions determine the clinical presentation of disease. Chronic small vessel white matter ischemic disease is a common finding in elderly adults on brain imaging and may lead to mild cognitive deficits. Risk factors include hypertension, diabetes, hyperlipidemia, and atrial fibrillation. The mainstay of treatment includes control and optimization of vascular risk factors and AChEIs because patients with VD also have a deficiency in acetylcholine in the brain (De Leeuw and Gijn, 2003).

Less Common Causes of Dementia

Frontotemporal Dementia

Key Points

- Early mood and behavioral symptoms with disinhibition are characteristics of FTD.
- There are no effective drug treatments for FTD.

Previously known as “Pick disease,” FTD is an early-onset dementia with a mean age of onset of 58 years. About 20% to 40% of cases of FTD are familial. On neuroimaging, there is a gross degeneration of the frontal and temporal lobes, leading to clinical symptoms affecting personality and behavior. Cognitive impairment appears later and usually affects judgment and executive function. Social disinhibition and mood symptoms are prominent early on and help to distinguish this dementia from the others. Neuropsychological testing can be helpful in making the diagnosis. Currently, there are no effective treatments approved for FTD, but these patients are often treated with AChEIs because of the overlap of symptoms with other dementias (Snowden et al., 2002).

Normal-Pressure Hydrocephalus

Key Point

- The clinical triad of magnetic gait, dementia, and urinary incontinence is characteristics of NPH.

Normal-pressure hydrocephalus is an entity made up of up of the clinical triad of dementia, urinary incontinence, and gait abnormalities (magnetic gait). Neuroimaging shows ventriculomegaly out of proportion to cerebral atrophy. These patients usually require neurology and neurosurgery referral to determine optimal treatment options. A large-volume CSF lumbar puncture in association with vestibular testing is done to determine if any of the symptoms are

reversible. If so, the patient is referred to get a ventricular shunt procedure.

Creutzfeldt-Jakob Disease

Key Point

- Myoclonus and rapid progressive dementia over weeks are most characteristic of CJD.

Creutzfeldt-Jakob disease (CJD) is a rare neurodegenerative disorder resulting from prion infection of the brain. Cognitive decline in CJD occurs very rapidly (within weeks). Visual symptoms, ataxia, rigid posture, and myoclonus are associated symptoms. The diagnosis is usually made by the history characteristic of this disease, EEG, CSF analysis, and imaging. A brain biopsy provides a definitive diagnosis. Sporadic CJD accounts for 85% of the cases. Infectious CJD is rare and results from external sources of prions (medical procedures, transplanted organs, or infected animal products) (Knopman et al., 2003).

BEHAVIORAL AND PSYCHIATRIC SYMPTOMS OF DEMENTIA

Key Points

- Nonpharmacologic interventions should be attempted before the use of medications to control behavior.
- Depression can coexist with dementia and should be treated to improve behavior.

In the dementia trajectory, most patients experience changes in mood, personality, thoughts, and perceptions, leading to behavioral changes, including wandering, repetitive questioning, paranoia, delusions, hallucinations, agitation, aggression, euphoria, apathy, disinhibition, irritability, resistance to care, and changes in circadian rhythm leading to sleepiness during the day and behavior disturbances at night (Fuh et al., 2005).

These symptoms usually manifest during moderate to severe stages of dementia and frequently cause significant distress to the patient, increase caregiver burden, and can result in long-term care placement. Early recognition and treatment of these symptoms is beneficial and can improve quality of life while decreasing caregiver burden. Caregivers should be educated on creating a structured environment and identifying and addressing the needs of the patient (including providing a comfortable room temperature, avoidance of noisy environment, minimizing background distraction, and being sure the patient gets adequate rest). Behavioral symptoms can result from new structural changes in the brain, environmental changes (moving to unfamiliar surroundings and having unfamiliar caregivers), and worsening comorbidities. These comorbidities may include fatigue; sleep disruption; physical discomfort such as fever, infection, pain, or constipation; adverse side effects of medications; and impaired vision or hearing. Evaluation and optimizing the comorbidities is important in

improving the behavioral symptoms (Cerejeira et al., 2012). Depression can frequently coexist with dementia and when present leads to worsening of behavioral symptoms.

Many nonpharmacologic interventions have been evaluated and include cognitive-oriented interventions (e.g., reminiscence therapy), sensory stimulation interventions (e.g., acupuncture, aromatherapy, light therapy), behavior management techniques (e.g., cognitive-behavioral therapy, communication training, and individualized behavioral reinforcement strategies), and other psychosocial interventions (e.g., animal-assisted therapy, exercise). Overall, there is not sufficient strong evidence that shows positive effect of any of these nonpharmacologic modalities. However, some observational evidence suggests that light therapy, hand massage and touch, and exercise therapy could be helpful in reducing behavioral and psychiatric symptoms associated with dementia (O'Neil et al., 2011).

When nonpharmacologic therapies are ineffective and the patient's behavior is significantly problematic, drug therapies must be considered. Although many different classes of medications are used (antiepileptics, benzodiazepines, antidepressants, and antipsychotics), there is currently no FDA-approved drug treatment for the behavioral and psychiatric symptoms of dementia. Furthermore, there is significant evidence showing increased mortality risks with antipsychotics from cardiovascular and infectious causes. Antipsychotic medications are associated with short- and long-term risks and should be used sparingly. Certain behaviors, such as wandering, do not respond to antipsychotic treatment. When these medications are used, there should be a discussion with the caregiver about the risks and benefits, and the lowest effective dose should be used. When used for the long term, attempts to slowly wean these medications should be actively made.

CARE SETTINGS OF PATIENTS WITH DEMENTIA

Key Point

- Dementia is a terminal illness, and getting palliative care involved early on is important for advanced care planning.

Along the dementia trajectory, care settings can change as the dementia progresses. Patients with early stages of dementia are usually best managed in the outpatient setting. Ideally, a patient-centered, team-based approach to care should be used in the management of these patients. The role of the physician is to provide education, discuss the goals of care, discuss treatment options, explain the prognosis and the trajectory, and evaluate for optimal support in keeping the patient functioning in the community. Early completion of advanced directives, including a living will and especially the durable power of attorney for health care, will help identify the goals of care and guide future treatments. Palliative care should be introduced early to the patients and their caregivers, and discussion of resuscitation, tube feelings, laboratory testing, hospitalizations, intravenous therapies, and other aggressive interventions should start early to avoid unnecessary and inappropriate interventions over the course of disease progression.

Progression of the disease, especially functional and cognitive decline, often necessitates placement of the patient into long-term care facilities (assisted living facilities, personal care homes, and nursing homes). End-of-life care is ideally provided by hospice, which can take place in various settings from in-home services to long-term care facilities. Hospice provides valuable benefits for the patients with advanced dementia by educating and providing social support to families and caregivers as well as symptom management (e.g., pain, dehydration, constipation, depression, infection, and terminal delirium).

Alcohol Use Disorders

KEVIN SHERIN, STACY SEIKEL, and STEVEN HALE

CHAPTER OUTLINE

Overview, 1119
Screening and Assessment, 1120
Management, 1122

Treatment of Alcoholism, 1127
Special Populations, 1130
Prevention, 1132

Overview

Key Points

- Annual alcoholism-identified health costs are \$223 billion.
- Alcoholic persons are heavy users of health care.
- Primary care screening is inadequate for patients with alcoholism.

Alcoholism is a chronic and pervasive medical disorder that adds enormous cost to the U.S. health care system. Alcohol use disorder (AUD) is among the top three preventable causes of death. The Centers for Disease Control and Prevention (CDC, 2004) estimates that for every alcohol-attributable death, 30 years of potential life is lost, accounting for 2.3 million years of potential life lost and 75,000 preventable deaths per year from identified cases. The total economic costs (2006 data) attributed to AUD are \$223 billion, with 72% estimated from lost productivity, 11% from health care costs, 9.4% from criminal justice costs, and 7.5% from other effects. The economic cost of excessive alcohol consumption in this country is \$746 per person, the majority from binge drinking (Bouchery et al., 2011).

Patients with alcoholism use health care resources disproportionately compared with other populations. The report from the 2006 data analysis above included 360,785 alcohol-attributable hospitalizations at community hospitals, 1.27 million emergency department (ED) visits, and 2.78 million physician office visits (Bouchery et al., 2011). Estimates of the extent of alcohol involvement in trauma include 39% of motor vehicle collision (MVC) fatalities (National Highway Traffic Safety Administration, 2006), 47% of homicides, 29% of suicides (Smith et al., 1999), 20% to 40% of fatal recreational injuries (Mayhew et al., 1986), and 10% to 25% of home injuries (CDC, 1983; Fell and Nash, 1989). Alcohol is involved in a substantial percentage of injuries caused by falls, drowning, and burns (Hingson and Howland, 1987, 1988). More than 5% of all hospital discharges other than childbirth include at least one alcohol-related diagnosis (Chen et al., 2005).

Cirrhosis of the liver continues to be largely attributable to alcohol use, with estimates of 60% to 90% of cirrhosis deaths being attributable to alcohol (Johannes et al., 1987).

Comorbidity with hepatitis C is frequently a factor in many of these alcoholic cirrhosis-related deaths. Hospitalizations for acute pancreatitis are frequently associated with AUD. Psychiatric comorbidity is common in the alcoholic population, especially depression and suicide. These sequelae have major implications for managed care organizations and federal and local payers alike. However, screening for alcoholism in primary care and emergency settings is not universal.

PREVALENCE

Key Points

- AUD is more common than diabetes mellitus (DM).
- Heavy alcohol use is more common in men.
- More screening and brief interventions (SBIs) are needed in primary care settings, which results in decreased drinking.
- Screening in hospitals, EDs, and trauma settings can be valuable, but brief interventions in these settings have produced inconclusive results.

In the United States, an estimated 140 million persons use alcohol, making it the most popular psychoactive substance (Baldwin et al., 1993). About 61% of the U.S. population drinks alcohol (CDC, 2003). A recent U.S. study using *Diagnostic Statistical Manual of Mental Disorders*, fifth edition (DSM-5) criteria and based on data from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC, Wave 2) placed the overall rate of past-year AUD at 10.8% (Agrawal et al., 2011). Ethnic variation is minimal in whites (6.4%), Hispanics (7.3%), and African Americans (4.8%) (Office of Applied Studies, 1995). The prevalence of binge drinking—that is, drinking five or more drinks at least once in the preceding month—is 14.2% (Winick, 1996). Heavy use is found more frequently in men (10.3%) than women (2.5%). Data also indicate that the greatest risk for AUDs occurs during young adulthood (Grant et al., 2008).

Compared with other chronic medical conditions in family medicine, AUDs appear to be of significant importance for early recognition and intervention. Hypertension is estimated to affect at least 50 million Americans, and DM type 2 affects more than 2% of the U.S. population, or 5.4 million adults. AUDs rank almost as high as hypertension

and much higher than DM in terms of prevalence. The key for family physicians is to increase the screening, diagnosis, and treatment of AUD in the clinical setting to the level of importance attached to hypertension or DM. Screening in hospitals, EDs, and trauma care settings can add value (American College of Surgeons, 2008; Gentilello et al., 1999; Smothers et al., 2004). However, brief interventions for alcohol use in patients with acute injuries in the ED and in hospital admissions have been inconclusive (Dappen et al., 2007; Emmen et al., 2004). A meta-analysis of SBI was found effective in reducing alcohol consumption at 6 and 12 months among non-treatment-seeking primary care patients, regardless of gender (Fleming, 2002). Some evidence suggests that SBI for prevention is also effective in pregnancy care settings (Floyd, 2007).

CAUSATIVE FACTORS FOR ALCOHOL USE DISORDERS

See eAppendix 48-1 online.

DSM-5 CHANGES IN SUBSTANCE-RELATED AND ADDICTED DISORDERS

The DSM-5 was published by the American Psychiatric Association in 2013. The previous diagnoses of alcohol abuse and alcohol dependence were consolidated into a single disorder called *alcohol use disorder*. The “legal consequences” criteria previously used in DSM-IV was removed. An additional criterion, “craving or strong desire, or urge to use,” was added to the DSM-5.

In DSM-5, there are 11 criteria, similar to DSM-IV (Table 48-1). Coding is based on *current* severity of symptoms:

- Mild: two or three symptoms
- Moderate: four or five symptoms
- Severe: six or more symptoms

For differences between DSM-IV and DSM-5, see <http://pubs.niaaa.nih.gov/publications/dsmfactsheet/dsmfact.pdf>.

Screening and Assessment

Key Points

- Apply CAGE screening to all patients older than 18 years of age.
- Be aware of a “negative” drinking history.
- Closely follow up positive responses.
- The AUDIT-C is a standard for quantifying AUDs in medical settings.

There is good evidence to support screening for AUD when using standard screening tools in practice. For a family physician, the diagnosis of alcoholism often depends on clues from the history and physical examination (Table 48-2). Possible clues may include a history of driving under the influence (DUI) or a MVC; history of repetitive trauma; new-onset hypertension, gastritis, or pancreatitis; otherwise

Table 48-1 DSM-5 Diagnostic Criteria for Alcohol Use Disorder*

- A. A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
 1. Alcohol is often taken in larger amounts or over a longer period than was intended.
 2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
 3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
 4. Craving or strong desire, or urge to use alcohol.
 5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
 6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
 7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
 8. Recurrent alcohol use in situations in which it is physically hazardous.
 9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
 10. Tolerance, as defined by either of the following:
 - a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect
 - b. A markedly diminished effect with continued use of the same amount of alcohol
 11. Withdrawal, as manifested by either of the following:
 - a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal).
 - b. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

*Review of data from the National Epidemiologic Survey on Alcohol and Related Conditions has shown that the similarities of the profiles from DSM-IV and DSM-V alcohol use disorder (AUD) far outweighed the differences and that the difference was mostly found at the lower end of the AUD severity spectrum (Dawson et al., 2013).

Table 48-2 Screening Clues for Alcoholism

“Driving under the influence” arrest
 Domestic violence
 Unexplained trauma
 Family stress
 New hypertension
 Gastritis
 Pancreatitis
 Tremor

unexplained liver disease (aspartate transaminase [AST] > alanine transaminase [ALT]); presence of depression; recent loss of employment or separation from family; unexplained tremor; upper gastrointestinal (GI) bleeding; recent falls or accidents; and a history of family or marital violence.

The four CAGE questions (cut down, annoyed, guilty, and eye opener) are adequate for screening purposes (Table 48-3), derived from the longer Michigan Alcoholism Screening Test (MAST) questions (see eTable 48-1 online) (Hays and Spickard, 1987; Powers and Spickard, 1984).

Causative Factors for Alcohol Use Disorders

Key Points

- As with biologic sons, adopted sons of parents with alcoholism also have a fourfold increased risk of developing alcoholism.
- “Hot spots” for alcohol dependency are found on chromosomes 1, 2, and 7.
- γ -Aminobutyric acid (GABA) and opiate receptors are implicated as alcohol reward pathways.

The causes of alcohol use disorders (AUDs) are supported by biologic data. Although no single causative factor can be ascribed to alcoholism, genetic markers clearly play a significant role and have been studied in family, twin, and adoption studies (Anthenelli and Schukitt, 1998). Biologic sons of alcoholic parents have a fourfold risk of alcoholism (Goodwin, 1979). Identical twins have a 60% risk of alcoholism, versus 39% for fraternal twins (Kaij, 1960). Final expression of AUD is ultimately influenced by the environment, genetics, personality, and social circumstances of each person. Adopted and nonadopted sons of alcoholic parents have similar rates of alcoholism; that is, being reared by an alcoholic parent does not increase the risk of alcoholism. What is actually inherited is not completely known; possibilities include differences in metabolism of alcohol, psychological and physiologic reactions to drinking alcohol, temperament, differential memories of drinking episodes, and taste preferences (Anthenelli and Schukitt, 1998).

An earlier classic adoption study by Clonninger and associates (1981) led to the differentiation of *type 1* alcoholism, a mild to moderate type with later onset that has some genetic influence but is clearly affected by environmental factors, from *type 2* alcoholism, which has powerful genetic factors, is less influenced by the environment, has an onset before age 25 years, and is associated with a predisposition to criminal behavior. Further gene mapping of twin adolescents and their parents supports a more unified or integrative approach for studying the relationship of genetics and psychosocial milieu to the causes of alcoholism and other addictions (Jacob et al., 2001). The Collaborative Project on the Genetics of Alcoholism involved six centers, with

hundreds of probands and families interviewed and a computerized pedigree of genetic relationships elaborated (Gordis, 2003). Chromosome “hot spots” for alcoholics have been located at chromosomes 1, 2, and 7 for alcohol dependency, with evidence for a link between alcoholism and depression on chromosome 1 (Nurnberger et al., 2001). A possible relationship to alcohol dependency has a locus at chromosome 4 (Reich et al., 1998).

Human and animal genetic research on alcoholism can provide better treatments and more focused prevention efforts for those at risk. For example, alcohol affects the brain through certain gene proteins and secondary messengers and their expression (Hyman and Nestler, 1993; Nestler and Greengard, 1994). If brain chemistry can be modified at the level of gene proteins or second messengers, new treatment and prevention avenues may become available. The brain chemistry of individuals with alcoholism may be intrinsically different or may be altered by repeated consumption and often leads to the addiction, craving, and relapse potential. Current research indicates that AUDs are highly mediated by many neurotransmitter pathways. Future treatment of AUD may include designer drugs targeted to specific brain abnormalities. Two newer pharmacotherapeutic agents derived from this brain-based model are naltrexone and acamprosate.

The U.S. Public Health Service (USPHS) again reviewed the pharmacology of alcohol and demonstrated how alcohol interacts with the large family of ligand-gated and voltage-gated ion channels affecting electrical transmission in the brain (USPHS, 2000; Woodward, 2003, 2009). GABA and opiate receptor pathways are implicated as reward pathways in human studies. GABA, acetylcholine, and serotonin represent primary targets of alcohol’s action (Woodward, 2009). 3,4-Methylenedioxymethamphetamine (MDMA) and 5-hydroxytryptamine (5-HT; serotonin) receptors also appear to be involved as reward pathways. The action of ethanol facilitates GABA_A receptor function and inhibits NMDA glutamate receptor function through ligand-gated channels, which are receptor-signaling mechanisms (Nestler, 2009). Neuronal circuits attempt to adapt to the periodic presence of alcohol. Chronic use of alcohol may usurp these mechanisms and result in near-permanent altered neurophysiologic state that results in continued alcohol consumption (Woodward, 2009).

eTable 48-1 Michigan Alcoholism Screening Test (MAST)

The MAST is a simple, self-scoring test that helps assess if you have a drinking problem. Please circle the answers to the following Yes or No questions:

1. Do you feel you are a normal drinker? ("normal": drink as much or less than most other people)
Circle Answer: Yes No
2. Have you ever awakened the morning after some drinking the night before and found that you could not remember a part of the evening?
Circle Answer: Yes No
3. Does any near relative or close friend ever worry or complain about your drinking?
Circle Answer: Yes No
4. Can you stop drinking without difficulty after one or two drinks?
Circle Answer: Yes No
5. Do you ever feel guilty about your drinking?
Circle Answer: Yes No
6. Have you ever attended a meeting of Alcoholics Anonymous (AA)?
Circle Answer: Yes No
7. Have you ever gotten into physical fights when drinking?
Circle Answer: Yes No
8. Has drinking ever created problems between you and a near relative or close friend?
Circle Answer: Yes No
9. Has any family member or close friend gone to anyone for help about your drinking?
Circle Answer: Yes No
10. Have you ever lost friends because of your drinking?
Circle Answer: Yes No
11. Have you ever gotten into trouble at work because of drinking?
Circle Answer: Yes No
12. Have you ever lost a job because of drinking?
Circle Answer: Yes No
13. Have you ever neglected your obligations, your family, or your work for two or more days in a row because you were drinking?
Circle Answer: Yes No
14. Do you drink before noon fairly often?
Circle Answer: Yes No
15. Have you ever been told you have liver trouble such as cirrhosis?
Circle Answer: Yes No
16. After heavy drinking have you ever had delirium tremens, severe shaking, or visual or auditory (hearing) hallucinations?
Circle Answer: Yes No
17. Have you ever gone to anyone for help about your drinking?
Circle Answer: Yes No
18. Have you ever been hospitalized because of drinking?
Circle Answer: Yes No
19. Has your drinking ever resulted in your being hospitalized in a psychiatric ward?
Circle Answer: Yes No
20. Have you ever gone to any doctor, social worker, clergyman, or mental health clinic for help with any emotional problem in which drinking was part of the problem?
Circle Answer: Yes No
21. Have you been arrested more than once for driving under the influence of alcohol?
Circle Answer: Yes No
22. Have you ever been arrested, even for a few hours, because of other behavior while drinking? (If Yes, how many times _____)
Circle Answer: Yes No

Scoring for the MAST Test: Please score one point if you answered the following:

1. No
2. Yes
3. Yes
4. No
5. Yes
6. Yes
- 7 through 22: Yes

Add up the scores and compare to the following score card:

- 0 to 2: No apparent problem
- 3 to 5: Early or middle problem drinker
- 6 or more: Problem drinker

Adapted from National Council on Alcoholism and Drug Dependence of the San Fernando Valley (NCADD).

Table 48-3 Brief Screening Questions for Alcohol Use

CAGE*	<ol style="list-style-type: none"> 1. Have you ever felt you should cut down on your drinking? 2. Have people annoyed you by criticizing your drinking? 3. Have you ever felt bad or guilty about your drinking? 4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)? <p>Scoring: Item responses on the CAGE are scored 0 for “no” and 1 for “yes” answers, with a higher score an indication of alcohol problems. A total score of 2 or greater is considered clinically significant.</p> <p>The normal cutoff for the CAGE is two positive answers; however, the Consensus Panel recommends that primary care clinicians lower the threshold to one positive answer to cast a wider net and identify more patients who may have substance use disorders. A number of other screening tools are available.</p>
CAGE Questions Adapted to Include Drugs (CAGE-AID) [†]	<ol style="list-style-type: none"> 1. Have you ever felt you ought to cut down on your drinking or drug use? 2. Have people annoyed you by criticizing your drinking or drug use? 3. Have you felt bad or guilty about your drinking or drug use? 4. Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?

*Ewing JA. Detecting alcoholism: the CAGE questionnaire. *JAMA*. 1984;252:1905-1907.

[†]Brown RL, Rounds LA. Conjoint screening questionnaires for alcohol and drug abuse. *Wisc Med J*. 1995;94:135-140.

Two positive responses are considered a positive screen and indicate that further assessment is warranted. An important point is that family physicians should not assume that someone does not have an AUD when that person answers negatively to questions about drinking. If such patients do not use alcohol at all, it may indicate that they had to quit because they had problems with alcohol. Given the prevalence of AUDs, it is recommended that the CAGE questions be applied to all patients older than 18 years. Another brief set of screening questions is the TWEAK questionnaire: tolerance, worries, eye openers, amnesia, and cut down (Table 48-4).

Longer screening questionnaires include the MAST and the Alcohol Use Disorders Test (AUDIT; see eTable 48-2 online) (Saunders et al., 1993). Both are considered higher in predictive value but more difficult to administer. Age-specific and population-specific survey tools are also available, including the Geriatric Alcoholism Screen and an adolescent alcoholism inventory. The 10-item core questionnaire includes three questions on alcohol consumption (the AUDIT-C) and seven on the impact of alcohol use. The AUDIT has been shown to have good sensitivity and specificity in medical and general populations and has recently been useful for screening patients with major psychiatric disorders and as an assessment instrument for patients seeking treatment for AUDs (Cassidy et al., 2008; Donovan et al., 2006). The AUDIT-C provides an efficient standardized method for assessing the quantity and frequency of alcohol use and accounts for much of the test's

Table 48-4 TWEAK Screening for Alcohol Use

TWEAK is a five-item scale developed originally to screen for risk drinking during pregnancy.	
Points	<p>(1-2) <i>Tolerance</i>: How many drinks can you hold? or How many drinks do you need to feel high?</p> <p>(1-2) <i>Worried</i>: Have close friends or relatives worried or complained about your drinking in the past year?</p> <p>(1) <i>Eye openers</i>: Do you sometimes take a drink in the morning when you first get up?</p> <p>(1) <i>Amnesia</i> (blackouts): Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?</p> <p>(1) <i>Cut down</i>: Do you sometimes feel the need to cut down on your drinking?</p>
Administering and scoring	<p>Before administering TWEAK, drinkers are identified by a positive response to the question, “Do you consume or have you ever consumed beer, wine, wine coolers, or drinks containing liquor (i.e., whiskey, rum, or vodka)?”</p> <p>To score the test, a 7-point scale is used. The “tolerance-hold” question scores 2 points if the respondent is able to hold six or more drinks.</p> <p>The “tolerance-high” question scores 2 points if three or more drinks are needed to feel high.</p> <p>A total score of 2 or more indicates that obstetric patients are likely to be risk drinkers. However, preliminary studies suggest that cutoff points of 3 or 4 are better than 2 for identifying harmful drinking or alcoholism.</p>

discriminative power in medical populations (Rodriguez-Marros and Santamarina, 2007).

BIOLOGIC MARKERS

Key Points

- The mean corpuscular volume is higher than 100 fL.
- The AST level is higher than the ALT level.
- There is an elevated saturation (>1.7%) of *carbohydrate-deficient transferrin* (CDT) level.
- Five drinks daily for 2 weeks elevates γ -glutamyltransferase (GGT) in most people.
- Using GGT and CDT in combination increases sensitivity over either marker alone by 20% without compromising specificity.

Diagnostic clues from the laboratory include a complete blood count (CBC) with an elevated mean cell volume, elevated GGT, AST level higher than ALT, unexplained leukopenia or thrombocytopenia, and positive response to the CDT level (Borg et al., 1992). It is estimated that 5 drinks per day for 2 weeks will yield an elevated GGT in most people (U.S. Department of Health and Human Services, Substance Abuse and Mental Health Services Administration, 2006). Using CDT and GGT together increases sensitivity by 20% over either marker alone without compromising specificity (Hitela et al., 2006).

eTable 48-2 Alcohol Use Disorders Identification Test (AUDIT): Interview Version

Read questions as written. Record answers carefully. Begin the AUDIT by saying, "Now I am going to ask you some questions about your use of alcoholic beverages during this past year." Explain what is meant by "alcoholic beverages" by using local examples of beer, wine, vodka, and so on. Code answers in terms of "standard drinks." Note the correct answer number.

1. How often do you have a drink containing alcohol?
 - (0) Never [Skip to questions 9-10]
 - (1) Monthly or less
 - (2) 2 to 4 times a month
 - (3) 2 to 3 times a week
 - (4) 4 or more times a week
 2. How many drinks containing alcohol do you have on a typical day when you are drinking?
 - (0) 1 or 2
 - (1) 3 or 4
 - (2) 5 or 6
 - (3) 7, 8, or 9
 - (4) 10 or more
 3. How often do you have six or more drinks on one occasion?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
- Skip to questions 9 and 10 if total score for questions 2 and 3 = 0*
4. How often during the past year have you found that you were not able to stop drinking after you had started?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 5. How often during the past year have you failed to do what was normally expected from you because of drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 6. How often during the past year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 7. How often during the past year have you had a feeling of guilt or remorse after drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 8. How often during the past year have you been unable to remember what happened the night before because you had been drinking?
 - (0) Never
 - (1) Less than monthly
 - (2) Monthly
 - (3) Weekly
 - (4) Daily or almost daily
 9. Have you or someone else been injured as a result of your drinking?
 - (0) No
 - (2) Yes, but not in the past year
 - (4) Yes, during the past year
 10. Has a relative or friend or a doctor or another health worker been concerned about your drinking or suggested you cut down?
 - (0) No
 - (2) Yes, but not in the past year
 - (4) Yes, during the past year

Record total of specific items here:

On the basis of experience gained from the use of the AUDIT in this and other research, it is suggested that the following interpretation be given to AUDIT scores:

1. Scores between 8 and 15 are most appropriate for simple advice focused on the reduction of hazardous drinking.
2. Scores between 16 and 19 suggest brief counseling and continued monitoring.
3. Scores of 20 or higher clearly warrant further diagnostic evaluation for alcohol dependence.

Dose-response relationships are not well established, making it difficult to use these tests as a direct quantifier for alcohol consumption (SAMSHA, 2014).

INTERVIEW QUESTIONS

Guidelines for interviewing adolescents about alcohol have been reviewed (Speraw and Rogers, 1998). An atmosphere of trust and privacy must be conveyed (parents should be excluded). The questioning should be gradually moved from nonthreatening areas about general lifestyle to more specific questions about medications to questions about alcohol use. Standard interview questions for alcohol use include quantity of consumption, frequency of consumption, preference of alcoholic beverages, age at onset of drinking, attempts to cut down or quit, time of most recent drink, adverse sequelae related to drinking (or stopping drinking), and pattern of drinking (continuous, daily drinking, binge pattern). Quantity questions can classify binge drinking as never, less than one, one to three, three to five, and more than five per month. Vague or evasive answers, as well as rationalizations, should be “red flags.” Patients can also be asked how much alcohol they purchase and how often. It is important to elicit specific, concrete information and not become derailed by certain responses.

A family history of alcohol problems must be detailed because it is a major predictive variable. When a clinician receives the answer that the patient does not drink at all, the line of questioning should still be pursued to determine whether cessation was problem based. After it has been established that the person has a history of binge drinking or continuous daily drinking, follow-up questions are in order. These questions may include role impairment, family concerns, amnesia, self-concern, and hangovers to determine the patient’s sentiments about alcohol consumption.

DETAILED ASSESSMENT

After it has been established that the patient has problems with alcohol, more detailed assessment is in order. The history should then be focused on the known harmful consequences of alcohol use as related to the patient’s history. (For a list of complications, see Woodard, 2003.) Major disorders include Wernicke encephalopathy, withdrawal seizures, cerebellar disease, peripheral neuropathy, cardiomyopathy, cirrhosis, pancreatitis, gastritis, bone marrow suppression, and aseptic necrosis of the hip. A careful history should include an assessment of tolerance and withdrawal symptoms, including shakes, hallucinosis, seizures, and delirium tremens (DTs). The time of the last drink and quantification of daily drinking are prerequisites. Alcohol withdrawal often includes anxiety, nausea, vomiting, diarrhea, tremors, and elevated pulse and blood pressure (BP). A history of blackout or amnesic episodes while drinking must also be elicited. A history of family, social, legal, and occupational complications should be obtained as part of the diagnosis of alcoholism.

A psychiatric evaluation is key in the assessment for AUD. Screening tools such as the Beck Depression Inventory can help identify underlying depression. Assessment of suicidal ideation must be documented because people with alcoholism are at much greater risk for suicide-related deaths. The

Mini–Mental Status Examination (MMSE) can be useful for assessing possible dementia or delirium and pointing to the need for more extensive neuropsychiatric testing (see Chapter 42). Cognitive damage may be a factor in denial, a trait that characterizes many patients with known AUD. A sexual history should be included, with attention to multiple partners and human immunodeficiency virus (HIV) risk assessment. A history of comorbid polysubstance abuse and intravenous drug use should also be sought. Cough, hemoptysis, night sweats, fever, and weight loss suggest the need to investigate for tuberculosis.

PHYSICAL ASSESSMENT

The physical examination should pay close attention to vital signs. Elevated BP, pulse, or respiration can be a clue to the severity of alcohol withdrawal. The smell of ethanol on the breath will point to acute intoxication; the comorbid “dry mouth” may then be a local effect and not related to dehydration. Skin changes can be seen in people with alcoholism and may include rhinophyma, red swollen facies, and porphyria cutanea tarda. A thorough neurologic examination is in order, including cranial nerves, extraocular movements, gait, and cerebellar signs, as well as a sensory assessment of the lower extremities. Ataxia and nystagmus can be clues to possible intoxication or Wernicke encephalopathy. Percussion and palpation of the liver are important in alcoholism. Examination of the extremities can include visualization of Dupuytren contractures and palmar erythema. An irregular heart rhythm suggests atrial fibrillation, or “holiday heart.”

In women, a diagnosis of pregnancy should also be excluded (see AUD in Women). Alcoholism in pregnancy has severe perinatal effects. Cardiovascular, liver, GI, neurologic, and other sequelae of alcohol and other drugs of abuse have been reviewed (Gordis, 2003). AUD is frequently associated with hypertension.

KEY TREATMENT

- Evidence on the effectiveness of counseling to reduce alcohol consumption during pregnancy is limited; however, studies in the general adult population show that behavioral counseling interventions are effective among women of childbearing age. The benefits of behavioral counseling interventions to reduce alcohol misuse by adults outweigh any potential harm (United States Preventive Services Task Force [USPSTF], USDHHS, 2006) (SOR: B).

Management

ALCOHOL INTOXICATION

Key Points

- Naive alcohol users are impaired at lower levels.
- Always give thiamine to patients with alcoholism.
- Urine toxicology is frequently helpful for concomitant drug use.

Alcohol intoxication is frequently seen as a component of trauma, domestic violence, or suicide attempts (McGinnis and Foege, 1993). The degree of intoxication is determined by the amount of alcohol ingested, the duration of the ingestion, and the patient's tolerance, if any, for the alcohol. Subtle effects occur at levels of 20 mg/dL and include mild euphoria, mild impairment of coordination, and mood alterations. At 80 to 100 mg/dL, delayed reaction times and slurred speech may be noted. This 80-mg/dL level is generally accepted as an unsafe level for motor vehicle operation. Between 100 and 200 mg/dL, ataxia, grossly slurred speech, and incoordination occur. As the level climbs to 300 mg/dL, the ataxia becomes more marked, and drowsiness, lethargy, and vomiting may occur. In naive drinkers, levels above 400 mg/dL are associated with coma, respiratory depression, hypothermia, and death from central nervous system (CNS) depression, loss of airway integrity, or pulmonary aspiration. Patients with chronic alcoholism have different tolerance responses than those just listed and may be in severe withdrawal at substantial levels.

Alcohol-induced coma can be managed by protecting the airway and performing basic resuscitation, if necessary. The patient should be placed in a warm protective environment, with careful monitoring of vital signs. Gastric emptying is rarely helpful because of the rapid absorption of alcohol, but it may be considered if the ingestion has occurred within 60 minutes. Alcohol is eliminated mostly by hepatic metabolism, which follows zero-order kinetics. The rate does not change with changes in the alcohol blood level. Fructose can enhance elimination but is not typically used. In extreme cases, hemodialysis may be effective in reducing the level quickly. Activated charcoal does not efficiently absorb ethanol but may be given if other toxins have been ingested (Mayo-Smith, 2009).

Thiamine and glucose should always be administered because chronic alcoholism is associated with hypoglycemia and thiamine deficient states such as Wernicke encephalopathy (mental confusion, cranial nerve palsies, ataxia). Thiamine should be given immediately before or with glucose to prevent hypoglycemia because glucose is metabolized with the enzyme thiamine pyrophosphorylase. The physician should look for additional drug use in all patients because the effects of other drugs may be obscured by the obvious alcohol intoxication (Mayo-Smith, 2009). The result of a urine toxicology screen may be positive for concomitant intoxicants.

OVERVIEW OF ALCOHOLISM TREATMENT

Alcoholics who are actively drinking are among the highest cost users of medical services in the United States. Several studies have documented that alcohol treatment has beneficial effects on health care expenditures, primarily as a result of decreased health care use by people with alcoholism and their families. A Harvard Study compared 587 lifesaving interventions and ranked all substance abuse interventions, including treatment of alcoholism, in the top 10% (Tengs et al., 1995).

Physicians interface with the medical or behavioral effects of alcoholism when patients deteriorate to the point

of trauma, end-organ damage, or behavioral impairment. As with other chronic disorders, alcoholism is slow but progressive. As the disorder progresses, the ability to control drinking diminishes, which distinguishes an alcoholic from a nonalcoholic. Many physicians view detoxification as the treatment for this disorder, which is similar to giving patients with DM one injection of insulin to control their diabetes. It treats the immediate problem but does little to address the chronic disorder in 1 week or 1 month. Although the goal for a patient with alcoholism is complete abstinence from alcohol, the norm is alcohol consumption in increasing amounts. The family physician can view intermittent periods of abstinence or reductions in alcohol consumption as progress in treatment of the disorder and encourage further efforts. Relapse must be evaluated carefully, and keys to change can open the door to further reductions or ongoing abstinence.

The American Society of Addiction Medicine (ASAM) has developed patient placement criteria (PPC) to better guide treatment of alcoholism (Mee-Lee et al., 2001). The PPC can help to assign the appropriate level of care for detoxification and subsequent rehabilitation of those with AUDs. The ASAM criteria reflect a consensus of expert opinion for adolescents and adults in treatment. Levels of care are differentiated by three criteria: (1) degree of direct medical management provided; (2) degree of structure, safety, and security provided; and (3) degree of treatment intensity provided. Special populations that need consideration include pregnant and nursing women; adolescents; older adults; HIV-positive patients; patients with neurologic, cardiovascular, hepatic, or renal disorders; patients with psychiatric comorbidities; and persons in criminal justice settings (Wright et al., 2009).

DETOXIFICATION

The *alcohol withdrawal syndrome* is a somewhat predictable series of events that have a temporal relationship to the use, decrease in intake, or cessation of alcohol consumption. Alcohol withdrawal may occur in a patient who has a reduction in alcohol intake from a previously significant level or an absolute absence of alcohol. The pharmacology of alcohol and its subsequent metabolism is well known and follows zero-order kinetics, primarily through the liver and cytochrome pathways (Mayo-Smith, 2009).

Patients with mild to moderate alcohol withdrawal symptoms and no serious psychiatric or medical comorbidities can be safely treated in the outpatient setting (Asplund et al., 2004). The severity of these symptoms varies greatly among individuals, but in a majority, they are mild and transient, passing within 1 or 2 days (Driessen et al., 2005; Mayo-Smith, 2009).

The signs and symptoms of alcohol withdrawal vary individually but tend to be repetitive in the same person. Most people with alcoholism who withdraw from alcohol experience minimal symptoms, such as sleep disturbance or anxiety. A small number may have tremulousness, agitation, diaphoresis, and cognitive impairment. The tremors or shakes typically begin 12 to 14 hours after a period of heavy drinking and are usually noted in the early morning. Tremulousness may be accompanied by *alcoholic hallucinosis*, a misperception of objects in the

Table 48-5 Alcohol Withdrawal Seizures

Peak seizure risk is 24 to 48 hours after cessation; may occur up to 2 weeks later.
 Seizures are brief or occur in a “flurry.”
 Dilantin is ineffective.
 Use caution with medications that lower seizure threshold (e.g., tricyclics, phenothiazines).

patient’s sensory arena. Other symptoms of withdrawal include nausea, vomiting, poor oral intake, sweats, and anxiety. Seizures during alcohol withdrawal tend to occur as one isolated seizure or a brief cluster of seizures. Seizures are frequently preceded by tremors and tend to recur in a similar pattern in the same patient. Seizures may be the initial manifestation of alcohol withdrawal. Seizure activity is most common 24 to 48 hours after alcohol cessation, although seizures can occur as early as 24 hours or as late as 2 weeks after cessation of alcohol (Victor, 1983) (Table 48-5). Seizures may occur even later with concomitant benzodiazepine use. Withdrawal seizures are typically generalized, grand mal, and self-limited. Rarely, seizures may progress to status epilepticus (<3%). Physical signs include an elevated pulse and BP along with signs of autonomic hyperactivity.

The Clinical Institute Withdrawal Assessment for Alcohol scale, revised (CIWA-Ar) is a validated 10-item assessment tool used to quantify the severity of alcohol withdrawal syndrome and to monitor and medicate patients going through withdrawal (Bayard et al., 2004) (Table 48-6). Patients with moderate withdrawal should receive pharmacotherapy to treat their symptoms and reduce the risk of seizures and DTs during outpatient detoxification. Benzodiazepines are the treatment of choice for alcohol withdrawal, according to U.S. and Scottish guidelines (Scottish Intercollegiate Guidelines Network [SIGN], 2003). In healthy people with mild to moderate alcohol withdrawal, carbamazepine has many advantages, making it a first-line treatment for properly selected patients (Asplund et al., 2004).

Major alcohol withdrawal, also known as *delirium tremens*, occurs in fewer than 5% of patients with alcoholism in withdrawal. Delirium tremens is usually preceded by minor withdrawal symptoms, although they may appear frankly in a patient with minimal symptomatology. The delirium often begins 3 to 4 days after the last drink and is characterized by a marked change in sensorium with agitation, frank hallucinations, and severe disorientation (Table 48-7). Severe and potentially life-threatening autonomic hyperactivity leads to tachycardia, hypertension, and diaphoresis, frequently with low-grade fever. The severe disorientation may lead to self-injury or harm. Typically, the patient’s actions may be appropriate to the context of the state of disorientation and hallucinosis. The patient’s sleep activity is usually disturbed, along with excessive motor activity. Risk factors for DTs are a high blood alcohol level at the initial evaluation, an alcohol withdrawal seizure early in the withdrawal syndrome, and a previous history

of delirium (Victor, 1983). Concomitant infections or additional medical disorders may also predispose to severe alcohol withdrawal. Fever over 101°F (38.3°C) should be evaluated further. Before the treatment of alcohol withdrawal, a complete physical examination should be performed to assess the patient, including analysis for GI blood loss.

KEY TREATMENT

- Physicians should always use thiamine supplementation (Mayo-Smith, 2009) (SOR: A).
- Giving benzodiazepines is the treatment of choice of alcohol withdrawal and is supported by the latest systematic reviews (Ntais et al., 2005) (SOR: A).
- Carbamazepine is a first-line treatment for properly selected patients (Asplund et al., 2004) (SOR: C).
- Phenytoin (Dilantin) is ineffective in withdrawal seizures (Rathlev et al., 1994).

WITHDRAWAL TREATMENT

Treatment of alcohol withdrawal consists of supportive and pharmacologic interventions. Supportive interventions include fostering the patient’s desire for abstinence during the withdrawal process. A calm, quiet environment and reassuring and reorienting the patient if confused decreases the risk of injury or relapse.

The preferred CNS agents for detoxification are the benzodiazepines, according to U.S. and Scottish guidelines (Asplund et al., 2004; SIGN, 2003) and Cochrane review (Ntais et al., 2005). They provide the best side effect profile and have a better risk-to-benefit profile than other agents. Benzodiazepines are not likely to be fatal in overdose unless mixed with another central depressant (check the urine toxicology screen). Chlordiazepoxide and diazepam are both effective agents. If liver disease is present, or to treat withdrawal in an older patient, oxazepam or lorazepam may be a safer choice because of shorter half-life. Additionally, β -blockers such as atenolol, 50 to 100 mg/day, may decrease tremulousness and sympathomimetic symptoms if there are no contraindications (Table 48-8). A scheduled regimen of chlordiazepoxide, 100 to 300 mg on day 1 followed by daily 50% dose reductions for 3 to 5 days, rather than “as needed” or on a symptom schedule, provides for a smooth withdrawal. Doses must be held for oversedation or somnolence. Monitoring for oversedation is necessary before each dosing (Sullivan et al., 1989). Aggressive regimens support patient comfort, help maintain compliance, and reduce the risk of seizures and major withdrawal. Outpatient detoxification can be performed; without supervision, however, some risk is present (e.g., seizures, self-injury, overdose), and relapse is likely if further alcohol is available.

Anticonvulsants such as phenytoin have not been demonstrated to reduce withdrawal seizures better than benzodiazepines. Anticonvulsants used for detoxification with a history of seizures received a level B of evidence in the Scottish guidelines (SIGN, 2003). Carbamazepine is superior to other anticonvulsants and results in less

Table 48-6 Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)*

Patient: _____ Date: _____ Time: _____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for 1 minute: _____ Blood pressure: _____

Nausea and VomitingAsk, "Do you feel sick to your stomach? Have you vomited?"
Observation.

- 0 No nausea and no vomiting
- 1 Mild nausea with no vomiting
- 2
- 3
- 4 Intermittent nausea with dry heaves
- 5
- 6
- 7 Constant nausea, frequent dry heaves, and vomiting

Tremor

Arms extended and fingers spread apart. Observation.

- 0 No tremor
- 1 Not visible but can be felt fingertip to fingertip
- 2
- 3
- 4 Moderate, with patient's arms extended
- 5
- 6
- 7 Severe, even with arms not extended

Paroxysmal Sweats

Observation.

- 0 No sweat visible
- 1 Barely perceptible sweating, palms moist
- 2
- 3
- 4 Beads of sweat obvious on forehead
- 5
- 6
- 7 Drenching sweats

Anxiety

Ask, "Do you feel nervous?" Observation.

- 0 No anxiety, at ease
- 1 Mildly anxious
- 2
- 3
- 4 Moderately anxious, or guarded, so anxiety is inferred
- 5
- 6
- 7 Equivalent to acute panic states, as seen in severe delirium or acute schizophrenic reactions

Agitation

Observation.

- 0 Normal activity
- 1 Somewhat more than normal activity
- 2
- 3
- 4 Moderately fidgety and restless
- 5
- 6
- 7 Paces back and forth during most of the interview, or constantly thrashes about

Total CIWA-Ar Score _____

Rater's Initials _____

Tactile Disturbances

Ask, "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.

- 0 None
- 1 Very mild itching, pins and needles, burning, or numbness
- 2 Mild itching, pins and needles, burning, or numbness
- 3 Moderate itching, pins and needles, burning, or numbness
- 4 Moderately severe hallucinations
- 5 Severe hallucinations
- 6 Extremely severe hallucinations
- 7 Continuous hallucinations

Auditory Disturbances

Ask, "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.

- 0 Not present
- 1 Very mild harshness or ability to frighten
- 2 Mild harshness or ability to frighten
- 3 Moderate harshness or ability to frighten
- 4 Moderately severe hallucinations
- 5 Severe hallucinations
- 6 Extremely severe hallucinations
- 7 Continuous hallucinations

Visual Disturbances

Ask, "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.

- 0 Not present
- 1 Very mild sensitivity
- 2 Mild sensitivity
- 3 Moderate sensitivity
- 4 Moderately severe hallucinations
- 5 Severe hallucinations
- 6 Extremely severe hallucinations
- 7 Continuous hallucinations

Headache, Fullness in Head

Ask, "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.

- 0 Not present
- 1 Very mild
- 2 Mild
- 3 Moderate
- 4 Moderately severe
- 5 Severe
- 6 Very severe
- 7 Extremely severe

Orientation and Clouding of Sensorium

Ask, "What day is this? Where are you? Who am I?"

- 0 Oriented and can do serial additions
- 1 Cannot do serial additions or is uncertain about date
- 2 Disoriented for date by no more than 2 calendar days
- 3 Disoriented for date by more than 2 calendar days
- 4 Disoriented for place or person

*The CIWA-Ar is not copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal. From Sullivan JT, Sykora K, Schneiderman J, et al. Assessment of alcohol withdrawal: the revised Clinical Institute Withdrawal Assessment for Alcohol scale (CIWA-Ar). *Br J Addict.* 1989;84:1353-1357.

Table 48-7 Delirium Tremens

Usually preceded by tremor or seizures
 Usually begin 3 to 4 days after alcohol cessation
 Delirium with severe disorientation
 Autonomic hyperactivity
 Disturbed sleep
 Worsened by concomitant disorders (e.g., pancreatitis, pneumonia, gastrointestinal bleed)

Table 48-8 Alcohol Withdrawal: Stages and Treatment Summary

Stage	Intervention	Pharmacology
I. Mild	Be supportive Contact Alcoholics Anonymous Provide close follow-up	Thiamine, 100 mg/day Chlordiazepoxide, 25 mg three times daily if necessary, 3 days only
II. Moderate	Allow brief inpatient visit Make observations Check laboratory test results (e.g., magnesium, phosphate, electrolyte, glucose levels)	As above, <i>plus</i> chlordiazepoxide, 100-300 mg/day, 3 days only Atenolol, 50-100 mg/day, 3 days only
III. Severe	Hospitalize in ICU Delirium tremens, intermediate care Laboratory tests as above Monitor fluid status May need restraint Monitor for infection Prevent self-harm	As above, <i>plus</i> chlordiazepoxide, 100 mg hourly until asleep or subdued; then taper Antipsychotics: haloperidol, 2-10 mg/day Lorazepam, 1-2 mg intravenously prn if unable to take orally

ICU, Intensive care unit.

psychiatric distress, a faster return to work, fewer rebound symptoms, and reduced posttreatment drinking (Malcolm et al., 2001). Anticonvulsants are not generally indicated unless a concomitant seizure disorder is present.

Antipsychotic medications such as risperidone, olanzapine, and haloperidol have benefits in patients with hallucinosis and DTs but may reduce the seizure threshold (SIGN, 2003). Ear acupuncture has not shown efficacy in alcohol withdrawal in clinical trials. However, massage therapy has reduced withdrawal scores (Kunz et al., 2007; Reader et al., 2005).

INTERVENTIONS IN ALCOHOL USE DISORDER

Interventions by family physicians have the goal of changing the natural course or outcome of the alcohol use disorder (AUD) process. A family physician typically performs many interventions on patients with chronic disorders over time. Interventions generally follow an assessment and consist of advice about how to manage the disorder, may include a pharmacologic agent, and usually require some type of follow-up or ongoing monitoring.

Table 48-9 Components of Effective Brief Intervention

Feedback of physician's assessment
 Emphasis on patient responsibility
 Clear, direct advice to change
 Nonconfrontational physician approach
 Menu of options provided

From Bien TH, Miller WR, Tonigan JS. Brief interventions for alcohol problems: a review. *Addiction*. 1993;8:315-335.

Brief Interventions

Brief interventions can be very successful in primary care (SIGN, 2003) (Table 48-9). The father of the concept of *stages of change*, Prochaska (2009), reviews motivation to change in alcohol addiction. Family physicians can apply motivational interviewing in helping patients to move to the next level in stages of change (see Chapter 8). Part of any substance abuse intervention is the physician's assessment of the patient's readiness to change. First described by Prochaska and DiClemente (1983) while studying smokers, assessing the state of change assists the family physician in targeting the interventional approach to the patient. Change consists of the following six states:

1. *Precontemplation*. The physician can plant the seed of how alcohol is harming the patient (think of creative ways to list reasons) physically or emotionally. Written information is helpful, and support to the family and others involved must be offered. Further biologic or historical data should be collected, with follow-up at reasonable intervals and availability to help the patient when ready. A nonjudgmental approach is best.
2. *Contemplation*. The patient is aware that harm is occurring but is not yet ready for action. The physician tries to motivate the patient to the action phase by listing more reasons for urgency, such as bleeding, ulcers, pancreatitis, and family violence. The physician offers referral advice if the patient is interested, collects more data, performs follow-up at a short interval, and is ready to help the patient when ready to start.
3. *Preparation*. The physician assists the patient in preparing for reduction or cessation of use.
4. *Action*. The patient is ready for referral, has "hit bottom," or is otherwise ready for change. The physician arranges inpatient or outpatient detoxification and involvement in a treatment program and completes a history and physical examination, with laboratory studies as appropriate.
5. *Maintenance*. The physician performs follow-up on the patient; reviews participation in the self-help program and use of the 12 steps as well as the frequency of Alcoholics Anonymous (AA) attendance; monitors target organ issues; performs mental status and depression screening; counsels regarding relapse prevention; monitors laboratory values (e.g., GGT, CDT); prescribes vitamins, naltrexone, acamprosate, antidepressants, or disulfiram (Antabuse) as needed; monitors urine ethylglucuronide (ETG) to determine alcohol use in the previous 72 hours; monitors and schedules and performs follow-up regularly, as with any chronic disease.

6. *Relapse.* The physician anticipates relapse with any addictive disorder, is ready to help the patient again with entry into a recovery program, and offers nonjudgmental support.

Brief interventions can be carried out in the context of a routine office visit (Edwards and Rollnick, 1997; Fleming et al., 1999). Interventions can follow assessment of the patient. When the physician sees sufficient evidence to conclude or strongly suspect that an AUD is present, the brief intervention can be targeted to the patient's stage of change. An encounter with a precontemplative patient would include presentation of the physician's analysis of the problem in a supportive and nonconfrontational manner, with the goal of moving the patient to another state of change. For example:

Mr. Smith, your recent accident, alcohol use pattern, liver enlargement on physical examination, and abnormal laboratory test results lead me to conclude that your use of alcohol is a problem. As your family physician, I am concerned about your ongoing health risks. What can we do to deal with this problem?

Alternatively, a patient who is in the contemplation phase of change would be asked a different set of questions, such as:

Mr. Smith, I am glad that you are able to realize the impact that your alcohol drinking is having on your health, but we need to move forward and discuss treatment options.

An effective brief intervention should include *feedback* summarizing the physician's assessment; patient responsibility should also be emphasized, followed by clear, direct advice to change given in a nonconfrontational manner. The patient is given a menu of options from which to choose (Bien et al., 1993). Authoritative approaches are generally less effective than an empathetic approach. This type of approach will take practice and refinement for busy family physicians but can be integrated into the office practice without substantial time or expense. These techniques are more generally known as *motivational interviewing*. Motivational interviewing is effective in helping family physicians to engage patients in a variety of behavioral changes, including alcohol or tobacco use. Motivational interviewing has been a successful technique when used with brief interventions (Vasilaki et al., 2006).

Classic Intervention

When a brief intervention is not effective or if the circumstances demand more expeditious change, a classic intervention can be planned. The interventional goal is to break through the alcoholic denial system by providing an overwhelming amount of evidence and feedback to the patient with alcoholism. Classic interventions need to be carefully orchestrated by professionals trained in addiction treatment. Unless actively involved in alcoholism treatment, most family physicians will consult one of their referral treatment programs for assistance in developing a classic intervention. The family physician may be an appropriate member of the intervention group.

Treatment of Alcoholism

Key Points

- Try the least restrictive treatment first for the patient with alcoholism.
- Long-term treatment is favored for alcoholism. Regular attendance to AA meetings is helpful.
- The presence of other disorders increases acuity needs in patients with alcoholism.

The treatment options for alcoholism are extensive (Fuller et al., 2003; Kranzler et al., 2009). The medications most widely studied for AUDs are disulfiram, naltrexone, and acamprosate. Results from the Combining Medications and Behavioral Intervention for Alcoholism (COMBINE) study and trials of injectable naltrexone formulations and oral topiramate have provided important information on the use of these medications in alcohol rehabilitation. Long-acting formulations of naltrexone have been shown to reduce the adverse event profile compared with oral treatment and significantly decrease heavy drinking in men with AUD (Bankole, 2007).

A family physician is faced with several decisions when evaluating a patient for treatment of alcoholism after successful detoxification or if medically supervised detoxification is not needed. Should the patient go through a hospital or a nonhospital (residential) inpatient program, a day treatment program, or any outpatient program? Should the patient receive counseling, attend AA, or be involved in a cognitive program? Inpatient programs offer isolation from the drinking environment, intensive treatment, family involvement, in-depth assessment, and convenience for further medical or psychiatric assessment. However, they carry significant expense, typically occur after detoxification, remove the patient from the real-world environment, and have not been consistently shown to improve long-term outcomes. Patients who are suicidal or who have serious concomitant mental disorders that may impair recovery, as well as those unable to maintain abstinence in a less restrictive environment, should be considered for these facilities. Advantages of day treatment and outpatient treatment include reduced expense, ability to maintain work in some cases, and usually a longer period of treatment in a less restrictive environment. In general, as long as it is safe to try outpatient treatment initially, it is the least restrictive and most cost-effective method.

Access to relapse prevention treatments of established efficacy should be facilitated for alcohol-dependent patients. These therapies include outpatient programs, residential and "halfway house" milieu therapies, and partial hospitalization programs (SIGN, 2003).

ALCOHOL USE DISORDER AND PSYCHIATRIC COMORBIDITIES: DUAL DIAGNOSIS

Dual diagnosis is defined as AUD with one or more other psychiatric comorbidities. Frequently, people with alcoholism abuse other substances, such as crack cocaine,

nicotine, and even opiates (Tallia et al., 2005). Comorbidity estimates among people with alcoholism, gender preferences for addictive substances, and patterns of progression vary widely (Crum, 2009). Assessment of long-term outcomes highlights the impact of comorbidities on level of functioning, educational achievement, occupation, and social relationships (Crawford et al., 2008).

Patients with alcohol problems and anxiety or depression should have their alcohol problem treated first. If depressive symptoms persist for more than 2 weeks after treatment for alcohol dependence, the physician should consider use of a selective serotonin reuptake inhibitor (SSRI) or tricyclic antidepressant (TCA) or referral for supportive psychotherapy and cognitive-behavioral therapy (CBT) along with relapse prevention (SIGN, 2003). CBT has been shown to be efficacious (Longabaugh and Morgenstern, 1999; Project MATCH Research Group, 1997).

Patients with psychotic disorder and alcohol dependence should be encouraged to address their alcohol use and may benefit from motivational, CBT, family, and nonconfrontational approaches. Structured settings may offer some advantage for patients with psychotic comorbidities. Another challenge with treating people with alcoholism with comorbid conditions is *impulse control disorders* (ICDs). Also known as “behavioral addictions,” ICDs include pathologic gambling (PG) and many other conditions (Yip and Potenza, 2009). Of interest in the treatment of those with alcoholism is evidence that patients with PG can benefit from treatment with naltrexone (Kim et al., 2001).

ALCOHOLICS ANONYMOUS

Most physicians have heard of AA, and many may have suggested that patients with alcohol-related problems attend meetings. However, few physicians know much about AA. To prepare patients for their first AA meetings, it is important to be familiar with this organization (Table 48-10).

DRUG TREATMENT SPECIFIC TO ALCOHOL USE DISORDER AND RECOVERY

Key Points

- Disulfiram can be regarded as an aversive agent.
- Naltrexone produces a surmountable opiate blockage and diminishes the reinforcing effect of alcohol.
- Injectable naltrexone has greater efficacy than oral naltrexone in AUDs.
- Acamprosate reduces the urge to drink in some patients.

Treatment of AUD with medications has long been a challenging and controversial topic. Drug treatment of AUD can be divided into drugs used for detoxification (see earlier discussion) and those used to reduce or eliminate alcohol consumption after detoxification and for relapse prevention. Pharmacologic interventions for alcoholism have been reviewed (Fuller et al., 2003). The U.S. Food and Drug Administration (FDA) now approves three drugs for

Table 48-10 Information on Alcoholics Anonymous (AA)

- AA pamphlets to give to patients may be ordered from the AA’s website at www.aa.org. Look for the AA Literature menu.
- AA meetings in your area may also be found on the AA’s website.
- There are several formats of AA meetings. Open meetings may be attended by anyone interested in AA. Physicians are encouraged to attend at least one open AA meeting. The local area meeting lists designate whether a specific meeting is open or closed.
- Closed meetings may only be attended by alcoholics or those who have a “desire not to drink alcohol.”
- Other types of meetings include those for women only, men only, meetings for the gay and lesbian population, and meetings in Spanish. Other types of meeting include step study, open discussion, and speaker meetings, as well as online meetings.
- Most patients will object to attending AA meetings for a variety of reasons. Some common objections to AA:
 - “It’s too religious.” AA is not a religious program but a spiritual fellowship. It refers to a “Higher Power” and “God as we understand Him,” but no belief in God is necessary.
 - “I don’t want to stand up and bare my soul in front of a lot of other people.” Only those who wish to do so speak at AA meetings.
 - “I don’t want to meet with a lot of losers. It’s too depressing.” AA more accurately represents a cross-section of “winners” in the sense that they have survived the disease. Those who go to enough meetings are sure to find people with whom they can identify.
 - “I can’t go there. All those people are sober, and I’m not. I’d be too ashamed.” The only requirement for membership is a desire to stop drinking. Members who are still drinking are encouraged to “keep coming back.”
 - “I don’t want everyone to know about my drinking.” Anonymity is and always has been the basis of the AA program. Traditionally, AA members never disclose their association with the movement.

Common objections reprinted from Alcoholics Anonymous. *AA as a resource for the health care professional*. Alcoholics Anonymous World Services, Inc. 5-8. http://www.aa.org/assets/en_US/information-for-professionals/p-23-aa-as-a-resource-for-the-health-care-professional.

alcohol treatment to reduce or eliminate consumption—disulfiram (Antabuse), acamprosate (Campral), and naltrexone (ReVia)—as well as long-acting naltrexone (Vivitrol).

Disulfiram

Disulfiram has been available for the treatment of AUD since the late 1940s. Given as a single daily dose, disulfiram inhibits aldehyde dehydrogenase, the second alcohol degradation enzyme. This inhibition causes acetaldehyde to increase five to 10 times the usual level found after alcohol consumption. Symptoms that occur in patients acquiring alcohol from any source include flushing, palpitations, respiratory difficulty, nausea, vomiting, weakness, and general uneasiness. If alcohol consumption continues or a large volume is ingested, hypotension, syncope, loss of consciousness, and death may follow. Minor reactions may occur with inadvertent exposure from nonbeverage alcohol sources such as colognes, over-the-counter (OTC) medications, or foods with uncooked alcohol. Also used in attempted and completed suicides, disulfiram can be thought of as an “incomplete poison” that will become a “complete poison” if alcohol is added.

Disulfiram works on the patient's understanding and expectation of an adverse experience if alcohol is consumed. It can be given in dosages of 125 to 500 mg/day and can be safely started 24 to 48 hours after alcohol cessation. Avoidance or extreme caution should be used in patients with known or suspected coronary artery disease, those at risk for suicide or with serious mental illness, and those unable or unlikely to comply with a complete treatment plan that includes additional forms of treatment. Disulfiram should not be used as the only treatment for AUD; it is better considered as an adjunct for carefully selected patients. An often-quoted blinded placebo-controlled study of Veterans Administration patients found that doses of 250 mg, 1 mg, and no disulfiram produced no significant differences in total abstinence (Fuller et al., 1986). Higher doses were associated with fewer drinking days than in other groups. Adverse reactions include peripheral neuropathy; optic neuritis; drowsiness; fatigue; metallic aftertaste; and infrequent hepatotoxicity, probably resulting from hypersensitivity. Evaluation of liver enzyme levels before therapy and periodically is recommended.

Supervised treatment or directly observed therapy with oral disulfiram may be used to prevent relapse. However, patients must be informed that this treatment requires complete abstinence, and they should clearly understand the risks of disulfiram therapy.

Naltrexone

The euphoric effect of alcohol is mediated through the endogenous opioid system, with activation of the prefrontal cortex (Tuhonen et al., 1994). Naltrexone, an opioid antagonist, has documented beneficial effect in reducing relapse and craving in patients with alcoholism (O'Malley et al., 1992; Swift et al., 1994; Volpicelli et al., 1992). Alcoholics taking naltrexone report a less pleasurable effect or high from alcohol consumption and do not escalate their drinking as rapidly as control groups (Volpicelli et al., 1995). A decreased craving for alcohol has not been universally reported. Naltrexone is given as a daily 50-mg tablet or a 380-mg IM injection monthly. This dosage provides a surmountable opioid blockage that will render other opioids ineffective unless given in greatly increased doses. Naltrexone is not an aversive agent. Many patients with alcoholism report a less-than-expected pleasurable experience with alcohol consumption, but others report some mild aversive symptoms.

Naltrexone undergoes first-pass hepatic metabolism and is hepatotoxic in excessive doses. It should not be given to patients currently addicted to opiates because it will precipitate acute opiate withdrawal (Croop et al., 1997). The most common side effects at the usual dosage include nausea, headache, dizziness, anxiety, and somnolence. Good candidates for naltrexone are those likely to be compliant with therapy, those concomitantly addicted to opiates who have been detoxified and have not received opiate replacement therapy, and those with heavy alcohol cravings at entry to therapy (Volpicelli et al., 1997). Naltrexone should *not* be used as a single treatment agent but rather in conjunction with other behavioral or motivational treatment modalities. Questions remain about the duration of treatment with naltrexone in AUDs. Generally, prolonged

abstinence rates improve after 12 months of continuous abstinence.

Poor compliance with oral naltrexone reduces its potential benefits (Volpicelli et al., 1997). In a pilot study, alcohol-dependent patients treated with a subcutaneous long-acting formulation of naltrexone had detectable plasma concentrations of the medication for more than 3 days after injection and had reduced frequency of heavy drinking compared with the placebo group (Kranzler et al., 1998). A randomized clinical trial with injectable naltrexone monthly did not demonstrate reduced incidence of heavy drinking, although it did demonstrate significantly delayed onset of drinking, increased number of abstinent days, and increased abstinence (Kranzler et al., 2004). The FDA-approved long-acting naltrexone (Vivitrol), 380 mg each month intramuscularly in the buttock, for AUD in 2006. Patients should be abstinent when they are started on naltrexone.

According to the Agency for Health Care Policy and Research (AHCPR), there is good (level B) evidence to support the use of naltrexone to reduce craving and relapse (AHCPR, 1999). An alternative opioid antagonist with some success in patients with AUD, but not as well studied, is nalmefene (Kranzler et al., 2009).

Acamprosate

Acamprosate is one of the newest drugs to be added to the formulary for the treatment of AUD. The FDA has approved acamprosate for maintenance of abstinence from alcohol in patients with AUD who are abstinent at treatment initiation. This provision includes that patients also participate in a comprehensive alcohol treatment program. Acamprosate is reasonably well tolerated and without serious adverse effects (AHCPR, 1999). European trials of acamprosate showed efficacy in alcohol dependence; acamprosate enhanced abstinence and reduced drinking days in alcohol-dependent subjects.

Acamprosate is recommended in newly detoxified dependent patients as an adjunct to psychosocial interventions. Acamprosate is approved for use in alcohol-dependent and alcohol-abusing patients. Its mechanism of action is not well known, although there is fair evidence of its benefit. Acamprosate is an analog of homotaurine, a GABA-ergic agonist. The GABA-ergic system appears to affect the action of alcohol-induced behavior. Acamprosate also appears to have effects on glutamate and N-methyl-D-aspartate (NMDA) receptors. Chronic alcohol exposure is thought to alter the normal balance between neuronal excitation and inhibition, and acamprosate may help restore some of this balance. Several controlled clinical trials have demonstrated the effectiveness of acamprosate as an adjunct to psychosocial therapy for people with alcoholism who have undergone inpatient detoxification. In these studies, acamprosate was demonstrated to be superior to placebo. Acamprosate does not appear to be effective in the treatment of polysubstance abuse (Bouza et al., 2004; Mann et al., 2004). Evaluation of renal function for those at risk, including elderly patients, is indicated before initiating treatment with acamprosate.

Two U.S. multicenter trials, including the COMBINE study, failed to show an advantage of acamprosate over placebo on an "intent-to-treat" basis (Anton et al., 2006;

Mason et al., 2006). Discrepancies may be caused by differences in European studies, which included heavier drinkers with longer periods of abstinence before induction in trials (Kranzler et al., 2009).

KEY TREATMENT

Pharmacotherapy for AUDs with strength of recommendation (SOR) is as follows:

- Naltrexone (SOR: A)
- Long-acting naltrexone (Vivitrol) (SOR: A)
- Acamprosate (SOR: A)
- Disulfiram (SOR: B)

OTHER MEDICATIONS USED IN ALCOHOL TREATMENT

Anticonvulsants (Topiramate)

Anticonvulsants likely exert beneficial effects on GABA receptors. Placebo-controlled studies included carbamazepine (Mueller et al., 1997), divalproex (Brady et al., 2002), and topiramate (Johnson et al., 2003), with a multicenter study confirming the efficacy of topiramate and anticonvulsants for treatment of AUDs (Johnson et al., 2007). Topiramate was shown to decrease (1) drinks per day, (2) drinks per drinking day, (3) drinking days, (4) heavy-drinking days, and (5) GGT levels (Johnson et al., 2007). Side effects of anticonvulsants include numbness and tingling; metabolic acidosis; fatigue; dizziness; loss of appetite; nausea; diarrhea; weight loss; and difficulty concentrating, with memory, and in word finding. Suicidal thoughts or actions are infrequently reported, as are renal calculi and acute secondary glaucoma (Kranzler et al., 2009).

Baclofen

A GABA-B receptor agonist, baclofen has long been used as an antispasmodic. Only more recently has baclofen been investigated as a treatment for AUD. In a modest controlled trial of 1 month, baclofen was efficacious in achievement of total abstinent days compared with placebo (Addolorato et al., 2002). A follow-up study demonstrated efficacy in 84 patients with cirrhosis of the liver in maintaining abstinence (71% baclofen vs. 29% placebo) (Addolorato et al., 2007). There is potential for abuse of baclofen and withdrawal reactions, including delirium, which underscores the need for further research (Kranzler et al., 2009).

Serotonergic Agents

Most episodes of postwithdrawal depression will remit without specific treatment if abstinence from alcohol is maintained for days or weeks (Brown and Schukit, 1988; Schuckit, 1983). Patients with comorbid depression often require pharmacotherapy, and although the SSRIs have a low side effect profile, they can exacerbate the tremor, anxiety, and insomnia in early-recovering people with alcoholism. Recovering people with alcoholism with comorbid depression may actually do better with TCAs (Nunes and Levin, 2004).

Table 48-11 Characteristics of Women with Alcoholism

Lower rates of use than men
More hidden drinking than men
TWEAK screening better than CAGE
Less alcohol consumption than men may cause a significant disease progression
Treatment in all-women program is preferred

CAGE, Cut down, annoyed, guilty, and eye opener; TWEAK, tolerance, worries, eye openers, amnesia, and cut down.

Special Populations

ALCOHOL USE DISORDER IN WOMEN

Women have lower rates of AUD than their male counterparts, 1.5% overall and 1.5% in older adult women (Mouton and Espino, 1999) (Table 48-11). Women generally enter treatment later than men and have more psychiatric symptoms. Women seem to develop many pathologic effects of alcohol more rapidly than men (Blume and Zilberman, 2005), including fatty liver, hypertension, anemia, malnutrition, GI hemorrhage, and peptic ulcer requiring surgery (Zweben, 2009). For women, five to seven drinks daily is sufficient to cause significant disease progression.

Nonmedical use of prescription drugs in general and opioids in particular has been identified as a significant problem since the late 1990s. Women also have higher associated rates with first use of illicit drugs after age 24 years, serious mental illness, and cigarette smoking (Tetrault et al., 2008). Comorbid conditions for women include drug addiction, sexual abuse, intimate partner violence, borderline personality disorder, eating disorders, mood and anxiety disorders, and HIV infection. Women who drink alcohol may be more sensitive to the behavioral effects of concomitant cocaine use (Zweben, 2009).

Family physicians generally detect AUDs in women later than in men with alcoholism. Screening tests (e.g., CAGE) have less sensitivity in women and need to be interpreted differently, usually with lower cutoff points. This difference may result from the lower volume of alcohol consumed and the social stigmatization of these women (Bradley et al., 1998). Screening tests such as the TWEAK have performed better than the CAGE in women. It is important for physicians to educate women, even highly educated patients, about their greater risk (Green et al., 2007). Incarcerated women often begin using drugs and alcohol at very young ages and frequently require significant educational and job-training support to make successful transitions to recovery (Zweben, 2009). Women may have better treatment outcomes if referred to all-women programs or programs specializing in women's addictions (Hodgkins et al., 1997).

Alcohol Use Disorder and Pregnancy

The Institute of Medicine recognizes alcohol-related birth defects (ARBDs) and alcohol-related neurodevelopmental disorder (ARND) in addition to fetal alcohol syndrome (FAS) as potential effects of alcohol use in pregnancy and the periconception period (Muchowski and Paladine, 2004; Warren and Foudin 2001). A diagnosis of FAS requires characteristic facial anomalies, growth retardation, and

neurodevelopmental abnormalities. In *partial* FAS, affected children have some of these characteristics, with no other explanation. ARBD includes a confirmed history of maternal alcohol use plus one or more congenital defects, most often cardiac, renal, vision, hearing, or skeletal. ARNDs require a confirmed history of maternal alcohol use and the neurodevelopment abnormalities or cognitive-behavioral abnormalities found in partial FAS.

The prevalence of FAS in the U.S. population is estimated at 0.5 to 2 per 1000 births, with up to 10 in 1000 newborns having some effect from alcohol exposure. The rate of FAS is more than 20 times higher in the United States compared with other countries, including European countries, partially because of differences in diagnosis (Muchowski and Paladine, 2004). Whether a safe threshold of alcohol consumption exists before or during pregnancy is controversial. Many U.S. authorities recommend against any alcohol intake before or during pregnancy. The effects of alcohol on a fetus depend on the amount of alcohol consumed at one time, timing of alcohol consumption in gestation, and duration of alcohol use in pregnancy. This is complicated by studies using various definitions of “light” and “heavy” alcohol use, with categories that often overlap among different studies. *Binge drinking*, defined as more than five drinks in a single day, even when episodic, is more dangerous to fetal brain development than non-binge drinking (Muchowski and Paladine, 2004).

Less severe problems can occur, although a high level of alcohol use in pregnancy is associated with more severely affected offspring. A 1984 study of 31,000 pregnancies showed a higher risk of growth retardation if a mother had even one drink a day. A 2001 study of more than 600 urban African American children showed continued behavioral effects of alcohol at age 6 to 7 years with low levels (one drink daily) of maternal alcohol consumption (Muchowski and Paladine, 2004).

Some intervention attempts show promise. A review of trials in which physicians briefly counseled nonpregnant women who were problem drinkers found no consistent decrease in drinking. Trials of personalized advice to pregnant women have also been found to be no more effective than written information alone. A written self-help manual, however, did improve cessation rates in women at a prenatal clinic. The CDC sponsored a pilot project to encourage alcohol cessation and effective contraception in women at risk for alcohol-exposed pregnancy (Muchowski and Paladine, 2004). Although not a controlled trial, this more extensive intervention showed promise. Of the 143 women enrolled, 68.5% had stopped their alcohol consumption or were using effective contraception by the 6-month follow-up. Women should not be discouraged from breastfeeding if they are not using illicit drugs and do not have specific contraindications such as HIV infection (McCarthy and Posey, 2000).

Applying the Evidence. Written information about the risks of alcohol use in pregnancy should be provided to pregnant women who consume alcohol (Floyd et al., 1999; Muchowski and Paladine, 2004). Data are insufficient to recommend physician counseling for alcohol cessation before or during pregnancy. More comprehensive interventions may be more effective but have yet to be fully studied.

No studies have evaluated neonatal outcomes with women counseled on alcohol cessation in the periconception period.

Emergency Contraception. The importance of making information and resources available for emergency contraception deserves more attention for women with addictions. Emergency contraception techniques are widely available and as OTC medications in some states. However, these are underused by women at risk for unintended pregnancy. An emergency hotline is available nationally for emergency contraception access for women: 888-NOT-2-LATE (888-668-2528) (<http://not-2-late.com>).

ADOLESCENTS

Family physicians should develop expertise for recognizing alcohol use in adolescents. According to the American Academy of Family Physicians Graham Center, 38% of ambulatory adolescent health visits in the United States are made to family physicians (American Academy of Family Physicians [AAFP], 2001). Specific screening tools are available for adolescents (Comerci, 2002). AUD in the family system can create several levels of dysfunction, including the use of alcohol or other drugs by adolescents. Approximately 3% of adolescents are addicted to alcohol or other drugs (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 1997). Drinking is frequently a family matter, with 82% of drinking families raising children who drink and 72% of families who abstain raising children to abstain (Johnson and Leff, 1999). Environmental, physiologic, and genetic factors combine to place certain adolescents at risk.

Detection of AUD requires reliable information from the adolescent. An atmosphere of trust must be established, and more than one visit is often necessary. Urine drug screening can be effective but is controversial. The American Academy of Pediatrics (AAP) recommends involuntary testing only in limited emergency circumstances, such as altered mental status, inability to give consent (seizures, coma), acute medical problems putting the adolescent at serious risk, a preadolescent or very young adolescent, and court-ordered monitoring (AAP, 1998; Comerci, 2002). Family physician interventions for adolescents abusing alcohol or other substance must be tailored to the adolescent’s specific needs. Appropriate treatment programs should have strong family involvement, total abstinence goals, and professionals experienced in adolescent care.

College student drinking is a major concern on U.S. campuses. An estimated 1700 unintentional college student deaths per year involve alcohol (Hingson et al., 2005). The NIAAA Task Force on College Drinking categorized college student drinking consequences as damage to self, others, or the institution as well as the overlapping categories of drinking and driving, high-risk sexual behavior, and physical and sexual aggression (NIAAA, 2002). College prevention strategies include cognitive-behavioral skills-based interventions, brief motivation interventions, feedback-only interventions, and environmental interventions. Underage drinking statutes, including penalties for servers, and comprehensive campus-community approaches that involve students, all campus stakeholders, and community leaders have proved beneficial (Larimer et al., 2009).

TREATMENT OF OLDER ADULTS

Alcohol use disorders and prescription drug abuse are prevalent in older adults (Blow et al., 2002). Specific “geriatric AUD” screening tests can be used by family physicians, including the SMAST-G, MAST-G, AUDIT, and CAGE (Blow et al., 2009). Older adults are often categorized as “binge drinkers.” The NIAAA and the Centers for Substance Abuse Treatment (CSAT) have published alcohol use guidelines for older adults (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2008). Often, comorbid affective disorders are present in older adults. Premorbid AUDs predict a more severe course of affective disorders (Cook et al., 1991). Concomitant AUDs and depression increase late-life suicide risk, as does at-risk and problem drinking among elderly persons (Blow et al., 2004). Older persons with AUDs may respond well to brief interventions and increased socialization. The Guiding Older Adult Lifestyles (GOAL) study and Health Profile Project found brief interventions in older adults to be efficacious (Blow and Barry, 2000, 2009; NIAAA, 2008).

PHYSICIANS WITH ALCOHOL USE DISORDERS

See eAppendix 48-2 online.

Prevention

Primary prevention is the education of at-risk populations to avoid problems. Family physicians have the power to identify families with alcoholism and provide education to the children and adolescents who are at risk. Primary prevention includes the community; a Chinese proverb says the physician who also cares for the community is the “best physician.” Family physicians can offer universal screening for alcoholism and AUD; this is an example of the secondary level of prevention in their practice. The evidence for effectiveness of “designated driver” and school-based drinking and driving prevention programs has been insufficient (Ditter et al., 2005). School prevention programs noted as effective include the Michigan Model for Comprehensive School Health Education (Shope et al., 1996).

PUBLIC POLICY RECOMMENDATIONS

Family physicians can affect public policy advocacy on issues of AUD through professional organizations such as the AAFP and state academies. The CDC (2004) recommends that states and local jurisdictions consider adoption

of effective strategies aimed at reducing excessive drinking. Family physicians can advocate policies that include (but are not limited to) increasing alcohol excise taxes, reducing DUI limits to the 0.04 blood alcohol level, toughening DUI penalties, restricting advertising along highways or in ethnic minority communities, zoning restrictions on placement of points of sale, and increasing opportunities for screening in various settings (e.g., courts, jails, EDs).

Public policy interventions can be categorized as (1) measures to reduce the availability of alcohol, such as control of hours and days of sales, outlet-density restrictions, monopoly regulatory systems, and minimum-age drinking laws or as (2) penalties, such as increased DUI enforcement, server-liability laws, and altering the server environment through training. “Ecologic research” on environmental changes and prevention of AUD includes the Communities Mobilizing for Change on Alcohol Project, Community Trials Project, and Sacramento Neighborhood Alcohol Prevention Project (Treno et al., 2009). This emerging body of evidence should help communities in the future as they strive to create environments that reduce the frequency of AUDs.

48-2 *Physicians with Alcohol Use Disorders*

The prevalence of alcohol use disorders (AUDs) among physicians is comparable with the national lifetime prevalence of 13.5% (Reiger et al., 1990). Family physicians, along with anesthesiologists, were overrepresented in a study of 1000 physicians with substance use disorders (Talbot et al., 1987).

Male physicians outnumber female physicians in studies of substance use disorders. Risk factors used in other patient groups apply to physicians as well (see online discussion of causative factors). The pattern of physician use of alcohol differs from that in the general population by the increased use of alcohol, benzodiazepines, and prescription opiates (Hughes et al., 1992). Much of the prescription drug use is self-prescribed. Impairment is generally noted first in the alcohol-abusing physician's family and social life. Marital discord, relationship problems, and heavy drinking at social events can progress to work dysfunction and impairment (Talbot et al., 1987). The physician's thinking initially becomes impaired in spatial and constructive skills, along with negative effects on memory. Verbal skills are maintained, although cognition is affected as drinking continues. A physician with alcoholism will frequently turn to benzodiazepines for relief of anxiety or stress symptoms. Further impairment leads to avoidance of responsibility, such as not returning pages while on duty, showing up late, or arriving for patient care responsibilities with alcohol on the breath.

Several studies have shown that alcohol use patterns are established early in the physician's career (Birch et al., 1998; Clark et al., 1997). In 2001, The Joint Commission (formerly the Joint Commission on the Accreditation of Healthcare Organizations) pressured hospital organizations to address the wellness of their medical staff (The Joint Commission, 2008). State medical societies and licensing bodies have been active in establishing physician health programs and guidelines to assist the physician in returning to a productive career (Federation of State Physician Health Programs, 2005). Treatment outcomes for physicians in these structured programs are excellent, with sustained recovery rates of 70% to 80% or better (Paris and Cannavan, 1999). A cohort study of 100 physicians with AUDs found similar trends and an average sustained abstinence of 17.6 years (Lloyd, 2002).

As with the treatment of any chronic illness, early identification and intervention improve recovery rates of physicians with AUDs. Posttreatment behavioral and biologic (urine) monitoring, as well as attendance at physician support groups and AA meetings, are important in the recovery process (Galanter et al., 1990). The American Academy of Family Physicians (1998) recognizes physician treatment and recovery from alcoholism or other forms of substance abuse and supports physicians who successfully complete treatment programs acceptable to the physician health program of the individual state.

CHAPTER OUTLINE**Overview, 1133****Health Risks Associated with Smoking, 1134****Other Diseases and Conditions, 1140****Smoking and Mental Health, 1145****Social and Legal Action, 1145****Smoking Cessation, 1145****Current Developments, 1150**

Overview

Key Points

- Tobacco use is the leading cause of death in the United States.
- Toxins from cigarette smoke cause disease in most organs of the body.
- Smokers die an average of 13 or 14 years earlier than nonsmokers, and 50% of continuing smokers will die of a tobacco-related disease.
- Smoking is responsible for 40% of all deaths from cancer and 21% of deaths from cardiovascular disease.
- Almost 10% of deaths attributable to smoking occur in nonsmokers exposed to secondhand smoke.

The power of nicotine addiction became clear when I saw malnourished and hungry people trading food rations for cigarettes.

—WILLIAM FOEGE (1989), COMMENTING ON REFUGEE CAMPS DURING THE NIGERIAN CIVIL WAR

Tobacco smoking leads to a dependence on nicotine that is indistinguishable from other forms of drug dependence. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, (DSM-5) classifies “tobacco abuse disorder” in the Substance Abuse Disorder category (APA, 2013). In such a dependency, the drug is needed to maintain an optimal state of well-being. *Nicotine*, the addictive constituent of tobacco, meets these criteria because a typical withdrawal syndrome occurs after smoking cessation; tolerance to its use develops; and most important, use persists after developing symptoms attributable to the substance and in the face of its known harm. Some believe that nicotine is more addicting than cocaine or alcohol (Kandel et al., 1997; Krasnegor, 1979; Lee and D’Alonzo, 1993).

Nicotine acts on specific $\alpha 4\beta 2$ nicotinic acetylcholine receptors in the mesocorticolimbic system through neural pathways that are now seen as a common pathway for addictive drugs. Nicotine modulates the release of dopamine in the brain’s reward centers in the ventral tegmental area and the nucleus accumbens, decreasing the normal

rate of degradation of dopamine as well. High concentrations of nicotine are delivered to the central nervous system (CNS) within seconds of a puff. Complete saturation of nicotinic receptors occurs with as few as three cigarettes and lasts as long as 3 hours (Brody et al., 2006).

It may take only one cigarette to hook an adolescent. About one fourth of young people experience a *first-inhalation relaxation experience* (FIRE) with their first cigarette, a large percentage of whom become addicted (DiFranza et al., 2007).

For tobacco-dependent persons, craving and withdrawal symptoms result when nicotine occupancy on receptors declines over time (e.g., during sleep at night). Relief from these symptoms requires that the smoker replenish the nicotine within the receptor as completely as possible, which is why the first cigarette of the morning is often the most “satisfying” to addicted smokers. Because the cigarette is the most efficient rapid-delivery device for nicotine and the concurrent relief of craving and withdrawal symptoms, physicians and patients need to understand that medicinal nicotine replacement products are quite inefficient, by comparison, delivering lower concentrations of nicotine and incompletely resolving cravings and nicotine withdrawal.

The sheer number of nicotine doses is also highly reinforcing. A typical one-pack-daily smoker receives about 100,000 reinforcing hits a year, much more than with cocaine or heroin (Brunton, 1999).

Smoking affects nearly every organ of the body. Active smoking is now causally associated with age-related macular degeneration, diabetes, colorectal cancer, liver cancer, adverse health outcomes in cancer patients and survivors, tuberculosis, erectile dysfunction, orofacial clefts in infants, ectopic pregnancy, rheumatoid arthritis, inflammation, and impaired immune function. In addition, exposure to secondhand smoke has now been causally associated with an increased risk for stroke (U.S. Department of Health and Human Services [USDHHS], 2014). Tobacco contributes to about 488,000 deaths annually in the United States (USDHHS, 2014) and has rightly been dubbed the “leading cause of death in the United States” (McGinnis and Foege, 1993; Mokdad et al., 2004). One third of these smoking-related deaths are from cardiovascular disease and cerebrovascular accident (CVA, stroke), 29% from lung cancer, 20% from chronic respiratory disease, and at least 8% from cancers other than lung (Figure 49-1). There are now 13 different cancers associated with smoking. The new report

*Average annual number of deaths, 2000-2004.

Figure 49-1 Deaths attributable to smoking each year. (From Centers for Disease Control and Prevention Office on Smoking and Health. http://www.cdc.gov/tobacco/data_statistics/tables/index.htm.)

adds liver and colorectal cancer to that list. It also adds diabetes, rheumatoid arthritis, erectile dysfunction, impaired immune function, and cleft palate in infants (USDHHS, 2014). Just over 10% of deaths attributable to smoking occur in nonsmokers exposed to secondhand smoke, most from cardiovascular causes (Centers for Disease Control and Prevention [CDC], 2008). Each year, smoking is responsible for 18% of the total deaths in the United States—seven times more Americans than were killed in the Vietnam War. More than 10 times as many U.S. citizens have died prematurely from cigarette smoking than have died in all the wars fought by the United States during its history (USDHHS, 2014). Furthermore, cigarettes kill more Americans than alcohol, car accidents, suicide, AIDS, homicide, and illegal drugs combined (American Cancer Society [ACS], 2005).

As shown by the grim, disease-specific facts, most smokers do not understand the implications for longevity involved in continued tobacco use. On the average, male smokers in the United States die 13.2 years earlier and female smokers 14.5 years earlier than nonsmokers (Manson et al., 2000). Half of all continuing adult smokers will die of a cigarette-related illness (Doll et al., 2004). This relative lack of knowledge about tobacco harm may be in part because of the lack of publicity given to celebrities who die from smoking-related diseases (see eTable 49-1), although the death of news anchor Peter Jennings from lung cancer in 2005 received considerable attention and spurred increased interest in cessation.

The CDC (2012) estimated that in 2011, 19% of American adults smoked cigarettes (21.6% of men and 16.5% of women). Smoking prevalence is lowest among

Asians (9.9%) and Hispanics (12.9%) and highest among American Indians and Alaska Natives (31.5%). Smoking prevalence is also higher among adults living below the poverty level (29%). Higher educational status confers additional protection against smoking, with persons holding a graduate degree smoking the least (5%). Thus, cigarette-related disease is increasingly becoming a set of afflictions suffered by the poor and undereducated, persons who understand the least about their risks and who have the poorest access to medical care resources (CDC, 2008).

Recent data show good news about teen smoking. The National Youth Tobacco Survey showed a drop in overall middle and high school youth tobacco use from 33.6% in 2000 to 20.4% in 2011; male use fell from 37.5% to 25.3%, and female use from 29.6% to 15.4%. Among non-Hispanic white youth, the drop went from 37.1% to 21.9%. Among black youth, tobacco use fell from 25.4% to 19.8%. About half of the current tobacco users consumed more than one form of tobacco (Arrazola et al., 2014). The tobacco industry spends more than \$8 billion annually on marketing (>\$24 million/day) (Campaign for Tobacco-Free Kids, 2013).

Although few people start smoking as adults, each day 4000 children and adolescents try smoking for the first time, and 3000 of them become regular users of tobacco. Half of high school seniors who smoke started by age 14 years. Most smokers start smoking before 18 years, and only 5% start after age 20 years. Each year, 70% of those who smoke say that they would like to stop, and about 50% attempt to quit, but fewer than 5% succeed (Fiore et al., 2008). The likelihood of success in smoking cessation increases with the number of attempts, and those with a college education are twice as likely to succeed as less educated smokers. Family physicians must view tobacco addiction as a chronic disease that requires frequent intervention.

Health Risks Associated with Smoking

Toxins from cigarette smoke go everywhere the blood goes and cause disease in almost every organ of the body.

CANCER

Key Points

- A dose-response relationship exists between the number of cigarettes smoked and the risk of cancer. For example, those smoking more than 1 pack a day have 20 times the lung cancer risk of nonsmokers.
- Smoking formerly labeled “low-tar” and “low-nicotine” cigarettes provides no benefit over smoking regular cigarettes.
- Fewer than half of all smoking deaths are from cancer; the rest are from heart disease, chronic lung disease, and stroke.
- Tobacco use increases the risk of cancer in most organs.

eTable 49-1 Celebrities Who Died of Cancer or Other Smoking-Related Diseases*

Patrick Swayze (57), pancreas
Nat King Cole (45), lung
Lon Chaney (47), lung
Steve McQueen (50), lung
Eroll Flynn (50), heart disease
Roger Maris (51), lung
Babe Ruth (53), throat
Jimmy Dorsey (53), lung
Michael Landon (54), pancreas
Betty Grable (57), lung
Edward R. Murrow (57), lung
Humphrey Bogart (57), throat
Clark Gable (59), heart disease
Gary Cooper (60), lung
Chet Huntley (62), lung
Sammy Davis Jr (64), throat
Walt Disney (65), lung
Yul Brynner (65), lung
Spencer Tracy (66), lung
Giacamo Puccini (66), throat
Peter Jennings (67), lung
John Wayne (72), lung
Ed Sullivan (72), lung
Leonard Bernstein (72), lung
Duke Ellington (75), lung
Johnny Carson (79), emphysema
<i>Also:</i>
The Marlboro Man (Wayne McLaren) (51), lung
R.J. Reynolds I, II, and III (all died of emphysema)
Jack Benny, Arthur Godfrey, Bette Davis, Lucille Ball, and Desi Arnaz

*Age of death is in parentheses.

Table 49-1 Evidence-Based Relationship Between Smoking and Disease

The evidence is sufficient to infer a causal relationship between smoking and:	Cancer of the bladder, cervix, esophagus, kidney, larynx, lung, oral cavity, pharynx, pancreas, stomach Acute myeloid leukemia Abdominal aortic aneurysm Subclinical atherosclerosis Stroke (CVA) Coronary heart disease COPD Acute respiratory infections, including pneumonia Reduced lung function in infants Impaired lung growth during childhood and adolescence Respiratory symptoms in children and adolescents, including cough, phlegm, wheezing, and dyspnea Asthma-related symptoms (e.g., wheezing) in childhood and adolescence Premature onset of age-related decline in lung function All respiratory symptoms among adults, including coughing, phlegm, wheezing, and dyspnea Poor asthma control SIDS Reduced fertility in women Fetal growth restriction and low birth weight Premature rupture of membranes, placenta previa, and placental abruption Preterm delivery and shortened gestation Cataracts Increased absenteeism from work Adverse surgical outcomes related to wound healing and respiratory complications Hip fractures Low bone density in postmenopausal women Peptic ulcer disease
The evidence is suggestive of a causal relationship between smoking and:	Colorectal cancer Liver cancer Increased prostate cancer mortality Acute respiratory infections in persons with COPD Increased lower respiratory tract illnesses during infancy Impaired lung function in childhood and adulthood (with maternal smoking) Poorer prognosis for children and adolescents with asthma Increased nonspecific bronchial hyperresponsiveness Ectopic pregnancy Spontaneous abortion Cleft palate Low bone density in older men Dental caries Erectile dysfunction Macular degeneration Graves disease

COPD, Chronic obstructive pulmonary disease; CVA, cerebrovascular accident; SIDS, sudden infant death syndrome.

From U.S. Surgeon General. *The health consequences of smoking: a report of the Surgeon General, 2004*. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service, Office of the Surgeon General; 2004.

About 30% of all cancer deaths are attributable to cigarette smoking. **Table 49-1** lists diseases, including many cancers, for which the evidence is sufficient to *infer* a causal relationship, as well as those for which the evidence is sufficient only to *suggest* a causal relationship. Reviewing tobacco's

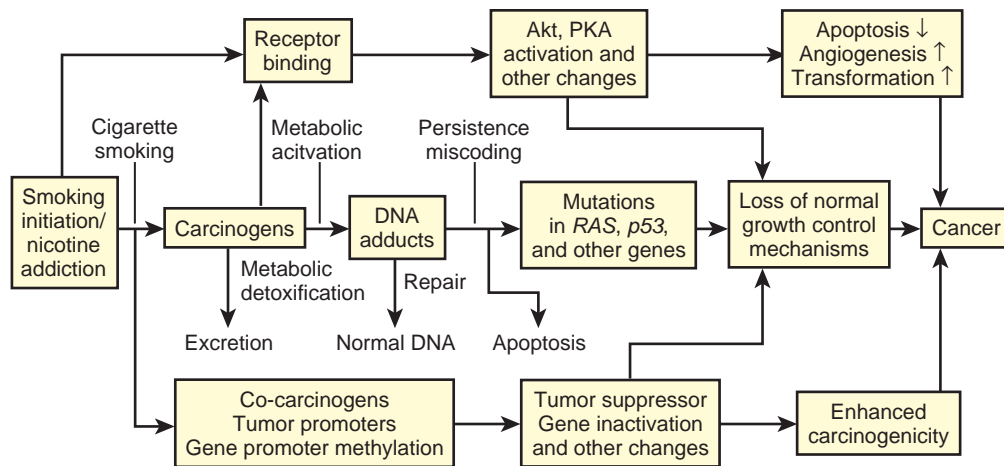

role in carcinogenesis, **Hecht (2008)** discusses several mechanisms that contribute to cancer, including metabolic changes in DNA and formation of DNA-carcinogen adducts, leading to mutation, and inhibition of genes such as *p53*, a tumor suppressor; and mutations in the *K-RAS* oncogene (**eFigure 49-1** online).

Lung

A clear dose-response relationship exists between lung cancer risk and daily cigarette consumption. From 1950 to 1990, the U.S. mortality rate for lung cancer increased fourfold for men and sevenfold for women. Although the mortality rates in men have been declining since 1990, lung cancer is still the principal cause of cancer death (28% of all cancer deaths) for both genders. In 1988, lung cancer passed breast cancer as the leading cause of death from cancer in women (**Figures 49-2** and **49-3**). For the first time ever, women are as likely as men to die from smoking-related diseases and they have about the same risk of death from lung cancer (**USDHHS, 2014**). Although the incidence rates have declined for most cancer sites, they are increasing for both men and women for melanoma and cancers of the liver and thyroid (see **Figures 49-2** and **49-3**). Although the incidence of squamous cell carcinoma of the lung declined as smoking rates dropped between 2000 and 2010, the incidence of adenocarcinoma of the lung increased dramatically. It is suggested that changes in the composition and design of the cigarette itself may have had some impact on the relative risk (RR) of lung cancer, as well as on the shift in the types of lung cancer occurring (**Thun et al., 2013**).

The 5-year survival rate for lung cancer is only 15% and has improved only slightly since the early 1960s (**ACS, 2005**). Almost 60% of lung cancer patients die from it within 1 year and 85% within 5 years. By the time the diagnosis is made, three of four patients already have metastases. However, the risk of death from lung cancer is substantially reduced when smoking is discontinued. Reducing smoking from an average of 20 cigarettes a day to less than 10 per day reduces the lung cancer risk by 25% (**Godtfredsen et al., 2005**). A diminished risk for lung cancer is experienced in former smokers after 5 years of cessation; however, the risk remains higher than that of nonsmokers for as long as 15 to 20 years (**U.S. Surgeon General, 2004**).

The U.S. Preventive Services Task Force (USPSTF) published draft recommendations (grade B) in August 2013 for early detection of lung cancer with annual low-dose computed tomography scans among high-risk smokers ages 55 to 79 years with a 30 pack-year history of smoking cigarettes, and less than 15 years since stopping smoking. The USPSTF's recommendations are based on evidence from clinical trials and modeling studies, finding that the benefit of early detection in this population of heavy smokers outweighs the risk of false positive findings and unnecessary further testing as well as radiation concerns. The USPSTF analysis shows a possible benefit as high as a 14% reduction in lung cancer mortality. Other groups, including the ACS, the American Thoracic Society, and the American College of Chest Physicians, have recently made similar recommendations (<http://www.uspreventiveservicestaskforce.org/Page/Topic/recommendation-summary/lung-cancer-screening>).

eFigure 49-1 Mechanisms that contribute to tobacco-caused cancer. (From American Chemical Society, for Stephen S. Hecht. *Progress and Challenges in Selected Areas of Tobacco Carcinogenesis*.)

Figure 49-2 **A**, Trends in death rates among men for selected cancers, United States, 1930 to 2009. **B**, Trends in death rates among women for selected cancers, United States, 1930 to 2009. (Rates are age adjusted to the 2000 U.S. standard population.) *Asterisk* indicates that the uterus includes the uterine cervix and uterine corpus. Because of changes in International Classification of Diseases (ICD) coding, numerator information has changed over time. Rates for cancers of the uterus, ovary, lung and bronchus, and colon and rectum are affected by these changes. (From Siegel R, Naishadham MA, Jemal A. *Cancer statistics, 2013*. *CA Cancer J Clin*. 2013;63:11-30.)

			Men	Women			
Lung and bronchus	87,260	28%		Lung and bronchus	72,220	26%	
Prostate	29,720	10%		Breast	39,620	14%	
Colorectum	26,300	9%		Colorectum	24,530	9%	
Pancreas	19,480	6%		Pancreas	18,980	7%	
Liver and intrahepatic bile duct	14,890	5%		Ovary	14,030	5%	
Leukemia	13,660	4%		Leukemia	10,060	4%	
Esophagus	12,220	4%		Non-Hodgkin lymphoma	8430	3%	
Urinary bladder	10,820	4%		Uterine corpus	8190	3%	
Non-Hodgkin lymphoma	10,590	3%		Liver and intrahepatic bile duct	6780	2%	
Kidney and renal pelvis	8780	3%		Brain and other nervous system	6150	2%	
All sites	306,920	100%		All sites	273,430	100%	

Figure 49-3 Ten leading cancer types for the estimated deaths by sex, United States, 2013. (Estimates are rounded to the nearest 10 and exclude basal cell and squamous cell skin cancers and in situ carcinoma except urinary bladder.) Although the amount of tar in cigarettes has declined in recent years, the risk of lung cancer has not changed. Smoking formerly labeled “low-tar” and “low-nicotine” cigarettes provides no benefit over smoking regular cigarettes, and the uptake of carcinogens is no different in “regular,” “light,” and “ultralight” smokers (Hecht et al., 2005), as previously marketed. However, surveys show that most people believed “light” cigarettes to be less dangerous than regular cigarettes and regular cigarettes much more likely to cause illness. The recent federal legislation banning the use of words such as “light” from tobacco advertising is beginning to dispel this myth.

Increasing data regarding the genetic predisposition to lung cancer are emerging (see Smoking and Genetics, later in this chapter). Family aggregation related to lung cancer is likely multifactorial, including exposure to secondhand smoke, major genetic factors (e.g., chromosome 6p locus, *CYP1A1* gene), other genes that modify risk of lung cancer, and genes that may enhance nicotine addiction or modify nicotine metabolism (D’Amico, 2008; U.S. Surgeon General, 2004).

Larynx

The risk for laryngeal cancer is 20 to 30 times greater in smokers. About 70% of oral and 85% of laryngeal cancer deaths are directly attributable to smoking. The risks of cancer of the oral cavity, pharynx, and larynx drop sharply during the first 10 years after smoking cessation. There appears to be a synergistic, multiplicative effect between smoking and drinking, such that the risk for development of cancer of the larynx is as much as 75% higher in people who use tobacco and alcohol versus those exposed to either substance alone (U.S. Surgeon General, 1990, 2004).

Esophagus

Cigarette smoking is a casual factor in both squamous cell carcinoma and adenocarcinoma of the esophagus. Heavy smokers (>1 pack per day) have 10 times the mortality rate from esophageal cancer as do nonsmokers. Alcohol use is synergistic, with the combination of both heavy smoking and drinking greatly raising the risk of esophageal squa-

mous cell carcinoma. This combination effect is stronger among men (Morita et al., 2010).

Head and Neck

Cancers of the head and neck account for about 5% of all cancers diagnosed and 3% of cancer deaths each year. Tobacco use, whether smoking or chewing, is a key causal factor, with excess risks ranging from five to 25 times that of persons not using tobacco. Smoking accounts for 45% to 75% of all head and neck cancers (Freedman et al., 2007). The risks are dose dependent, and concurrent alcohol use multiplies the risks of developing head and neck cancer.

Pancreas

An equally dismal picture occurs with cancer of the pancreas, for which the 5-year survival rate is only 2%. Because of the nonspecific nature of the initial symptoms and the difficulty in making a diagnosis, the mean survival time after diagnosis of pancreatic cancer is less than 6 months. Smokers have two to three times the risk of pancreatic cancer as nonsmokers, and the risk is proportional to the amount smoked. Increased risk persists at least 10 years after quitting. About one fourth of pancreatic cancer cases (20%-25%) are attributable to cigarette smoking (Maisonneuve and Lowenfels, 2010; U.S. Surgeon General, 2004).

Cervix, Uterus, and Ovary

Women who smoke cigarettes have four times the risk of cervical cancer as nonsmokers. Even women who smoke only 100 cigarettes during their lifetime more than double their risk of cervical cancer. The risk from smoking is greater in women younger than 30 years than in those older than 30 years (Slattery et al., 1989). Constituents from cigarette smoke, including mutagens and the carcinogen 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), have been detected in the cervical mucus of smokers at levels 40 to 50 times those in serum. Smoking is a risk factor for cervical intraepithelial neoplasia (CIN) and cervical cancer among women who test positive as well as negative for human papillomavirus (HPV). The RRs for CIN and

cervical cancer are two to four times greater for current and former smokers compared with never-smokers (U.S. Surgeon General, 2004). Although the risk of mucinous ovarian cancer has been shown to be as much as three times greater in women who smoke cigarettes (Qian et al., 1989; Tworoger et al., 2008), the evidence is inadequate to confer a causal relationship (U.S. Surgeon General, 2004).

Bladder and Kidney

Forty percent of bladder cancers are smoking related, and higher rates of kidney cancers are also noted in smokers. Smokers have two to four times the risk of bladder cancer as those who never smoked. The risk for kidney cancer is strongly dose dependent. Even one to nine cigarettes per day creates a 60% excess risk of renal cell cancer in men, and the risk doubles for men smoking more than one pack a day. Overall, the RR for women smokers is about 1.38 and 1.54 for men (Hunt et al., 2005). Smoking accounts for most cancers of the renal pelvis and ureter in the United States (McLaughlin et al., 1996; U.S. Surgeon General, 2004). The kidneys and bladder are the final common pathways for the concentration of toxic products of tobacco smoke and provide the longest direct exposure to carcinogens and radioactive substances, such as polonium 210, in tobacco smoke (Winters and DiFranza, 1982).

Colon and Rectum

A strong relationship has been noted between smoking and colorectal cancer, but the induction period is about 35 years. This lengthy induction would explain why it is just beginning to show up in women and indicates that efforts to prevent smoking among young people should be intensified (Giovannucci et al., 1994). The increased risk is about 20% higher for current smokers and appears to be stronger for rectal cancer. As with many other tobacco-related cancers, the risks are related to both intensity and duration of smoking, and decrease with early cessation. Although the evidence is suggestive but not conclusive, a causal relationship would mean that about 12% of the colorectal cancer burden would be attributable to smoking (Hannan et al., 2009; Tsoi et al., 2009; U.S. Surgeon General, 2004).

Liver

Although the 2004 Surgeon General's Report concludes that the relationship between smoking and liver cancer is suggestive but not causal, a meta-analysis from the World Health Organization International Agency for Research on Cancer found an RR of 1.55 among current smokers and 1.2 among former smokers for development of liver cancer (Lee et al., 2009). A recent European nested case-control study found that smoking had an increased risk for hepatocellular cancer (odds ratio [OR], 4.55 for current and 1.98 for former smokers) but a very high attributable risk (50%) as a contributing factor given the high smoking rates in the study population (Trichopoulos et al., 2011).

Leukemia

Overall, smoking cigarettes increases a person's risk for leukemia by 30%. The mortality rate from leukemia is increased 50% in cigarette smokers (RR, 1.53), the response is dose related, and the prognosis worsens for those with continued smoking after diagnosis and treatment. The risk is greatest

for myeloid leukemia. The potent carcinogen *benzene*, a constituent of cigarette smoke, seems to be the major toxin responsible for leukemia among smokers. Approximately 14% of all cases of leukemia in the United States may be caused by cigarette smoking (Brownson et al., 1993).

Breast

Although smoking was not initially thought to be a risk factor for breast cancer, the evidence has grown over time and now suggests a causal relationship, particularly among women who start smoking early in life, are heavy smokers, and smoke for a long time. Both active and passive smoking have been implicated in breast cancer. This is still controversial, however, because some studies show the association to be quite small. The California Environmental Protection Agency and Canadian Task Force convened to study the problem both found significant relationships with both active and passive smoking, and the U.S. Surgeon General's report on passive smoking (USDHHS, 2006) found that mechanism to be suggestive (Reynolds, 2013).

Second Primary or Recurrent Cancers

Continued smoking interferes with both radiotherapy and chemotherapy used for cancer treatment. An increase in second primary tumors among continuing smokers is seen in lung (Lin et al., 2005) and head and neck cancer (Chuang et al., 2008). The emergence of contralateral breast cancer has also been linked to continued smoking among women (Li et al., 2009).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Key Points

- Chronic obstructive pulmonary disease (COPD) is the leading cause of disability in the United States, and cigarette smoking is its main cause.
- The risk of COPD is directly proportional to the number of cigarettes smoked, but lung function improves with cessation of smoking, even after age 60 years.

Cigarette smoking is the main cause of COPD, which includes emphysema and chronic bronchitis. COPD is the fourth leading cause of death and the leading cause of disability in the United States. Female smokers are 13 times more likely to die from COPD, and male smokers have about a 12-fold increased risk (U.S. Surgeon General, 2004). During their lifetimes, smokers have about a 40% chance of developing chronic bronchitis. There may also be important racial differences, with African Americans, particularly women, having a higher risk than white smokers (Dransfield et al., 2006; Pelkonen, 2008). COPD among women is rising more quickly than among men, and since 2000, more women than men have died each year from COPD (CDC, 2008). Patients who smoke and present with COPD are also at substantially higher risk for tobacco-related cancers.

Changes in bronchi and the lung parenchyma are proportional to the duration and intensity of smoking. Cigarette smoke inhibits ciliary activity of the bronchial epithelium

and phagocytic activity of macrophages in the alveoli, resulting in decreased clearance of foreign material and bacteria from the lung, which leads to increased infection and tissue destruction. Smoking also releases inflammatory mediators, including oxidases and proteases, and inhibits pulmonary repair mechanisms. Even after age 60 years, smokers who quit have better pulmonary function than those who continue smoking. Lung function is inversely related to the number of cigarettes smoked over a lifetime. The rate of decline in pulmonary function is arrested by smoking cessation, the earlier the better.

CARDIOVASCULAR DISEASE

Key Points

- The risk of myocardial infarction (MI) is proportional to the number of cigarettes smoked.
- More than half of deaths from coronary artery disease are sudden, but the risk of sudden death is reduced immediately on cessation of smoking.
- Filter cigarettes and those with “low tar” or “low nicotine” do not reduce the risk of MI.

Coronary Heart Disease

Heart disease is the leading cause of death in the United States, and tobacco use is a major risk factor. Up to 30% of all deaths from heart disease are caused by smoking, with a strong dose-dependent relationship. In general, smokers have two to four times the risk of coronary heart disease as nonsmokers. For women smokers, the risk may be even higher. Women who smoke only one to five cigarettes a day have 2.5 times the risk of developing coronary heart disease as nonsmokers, rising to 75 times the risk in those who smoke 40 or more cigarettes a day. Three fourths of MIs in women younger than 50 years have been attributed to smoking (Dunn et al., 1999; Slone et al., 1978). Women who smoke and use oral contraceptives (OCs) have up to 10 times greater risk of heart attack than women who do neither, depending on which generation of OC is used.

Smoking acutely raises systolic blood pressure, heart rate, and cardiac output and causes vasoconstriction. It increases inflammation, promotes thrombosis and platelet aggregation, increases atherogenesis and plaque destabilization, and promotes oxidation of low-density lipoproteins (LDLs). Both active and secondhand smoke exposure cause endothelial dysfunction, a key element in early atherogenesis. Increased levels of C-reactive protein (CRP) are found in smokers, and the low-grade inflammatory response associated with smoking also results in increased leukocyte counts. Increased blood viscosity and lower oxygen-carrying capacity from carbon monoxide (CO) in cigarette smoke further decrease the coronary reserve. CO has an affinity for hemoglobin (forming carboxyhemoglobin) that is 245 times stronger than that of oxygen. Thus, CO reduces oxygen delivery to the myocardium and has a decidedly negative inotropic effect. Carboxyhemoglobin also lowers the threshold for ventricular fibrillation and could help explain the higher incidence of sudden death in those who smoke.

More than half of all deaths from coronary heart disease are sudden deaths caused by cardiac arrhythmia. Nicotine is arrhythmogenic because it increases serum catecholamine concentration. Those who quit smoking reduce their risk of sudden death immediately; the decline is not time dependent (Goldenberg et al., 2003). The risk of sudden cardiac death from smoking applies to both men and women.

The risk of MI is proportional to the number of cigarettes smoked, but as few as one to four cigarettes a day raises the risk of dying from ischemic heart disease by 2.7 times in men and 2.9 times in women (Bjartveit and Tverdal, 2005). The risk of MI increases progressively to as much as 20-fold in persons smoking 35 or more cigarettes per day. Persons who smoke cigarettes containing “low” amounts of nicotine have the same degree of MI risk as those who smoke cigarettes containing larger amounts. Smokers of these “low-dose” cigarettes still have three times the MI risk as nonsmokers (Kaufman et al., 1983).

It has been observed that smoking seems to confer a protective effect on mortality after the first nonfatal heart attack, the so-called “smoker’s paradox.” This phenomenon may be explained by differentials in age (first MI 12-14 years earlier among smokers) and fewer other comorbid factors such as diabetes and hypertension. On the other hand, continued smoking in this group is associated with more frequent recurrence of cardiac events and lower long-term survival.

Continued smoking after coronary stent placement is an independent risk factor for restenosis, as well as for repeat thrombosis after coronary artery bypass graft surgery.

Within a few years of stopping, the risk of MI in men decreases to a level similar to that in men who have never smoked, even in heavy smokers who have a positive family history of coronary heart disease (Rosenberg et al., 1985). The risk of coronary heart disease is reduced by about half after the first year of cessation, falling to that of never-smokers after 15 years of abstinence (U.S. Surgeon General, 1990). Those who have coronary heart disease and stop smoking have a reduction of about 36% in both all-cause mortality and nonfatal MI (Crichley and Capewell, 2004). Women who follow lifestyle guidelines involving diet, exercise, and not smoking have a very low risk of coronary heart disease (Stampfer et al., 2000).

“Silent” ischemia probably accounts for most cardiac ischemic events. Patients with coronary heart disease who smoke have three times as many episodes of silent ischemia as nonsmokers, and the duration of each is 12 times longer (Barry et al., 1989). Frequent episodes of myocardial ischemia, even though asymptomatic, must damage the heart. Because smoking also increases platelet adhesiveness, increases levels of triglycerides and LDL cholesterol, and lowers high-density lipoprotein cholesterol, a higher incidence of MI would be expected (Chelland et al., 2008).

Benefits from stopping smoking can be demonstrated at all ages. No decrease in benefit is seen with age, so it is still worthwhile for someone older than 65 years of age to break the addiction. Men who continue smoking in their 70s are 50% more likely to die from cancer, cardiovascular disease, and respiratory disease compared with those who never smoked. (Hermanson et al., 1988; LaCroix et al., 1991).

Stroke (Cerebrovascular Accident)

Key Points

- Risk of stroke is six times greater in smokers (>1 pack/day).
- Smokers who are also hypertensive have a 20 times greater stroke risk.
- The risk of CVA declines rapidly after smoking cessation and at 5 years is the same as for a nonsmoker.
- Exposure to secondhand smoke increases the risk for stroke by an estimated 20% to 30% (USDHHS, 2014).

Stroke (CVA) is the third most common cause of death in the United States. Although hypertension is the greatest risk factor for stroke, cigarette smoking is also significant. The incidence of stroke in smokers is two to four times higher than in nonsmokers. Among those screened in the Multiple Risk Factor Intervention Trial (MRFIT), smokers had twice the risk of a nonhemorrhagic stroke, and smoking was strongly associated with all forms of stroke (Neaton et al., 1993). A more recent systematic review and meta-analysis published in 2013 also concluded that smoking about doubles the lifetime risk of stroke and that the risk for ischemic stroke is similar among men and women. For hemorrhagic stroke however, the risk among women was 17% higher than men who smoked (Peters et al., 2013).

The risk of stroke increases in proportion to the amount of smoking. Those who smoke more than 40 cigarettes a day have twice the stroke risk of those who smoke fewer than 10 cigarettes a day. Compared with women who have never smoked, the risk of stroke increases 2.2-fold in women smoking 1 to 14 cigarettes a day and 3.7-fold in women smoking 25 or more cigarettes a day (Colditz et al., 1988). Noting a clear dose-response relationship, Bonita and associates (1986) found a threefold increase in the risk of stroke in smokers versus nonsmokers (see eFigure 49-2 online). The risk is 5.6 times higher in persons smoking more than one pack daily. Cigarette smokers who are also hypertensive have a 20-fold increased risk of stroke (U.S. Surgeon General, 2004).

Sclerosis of the carotid arteries is directly proportional to the amount of smoke exposure. Smoking increases the risk of ischemic heart disease and cerebrovascular disease regardless of the level of serum cholesterol. A low cholesterol level did not protect against smoking-related arteriosclerotic cardiovascular disease in patients in South Korea, where the prevalence of smoking is among the highest in the world (72% of men) (Jee et al., 1999). Smoking may increase the likelihood of thrombosis by increasing serum fibrinogen, enhancing platelet aggregation, and increasing blood viscosity.

The risk of stroke declines rapidly after cessation of smoking. Older adults who stop smoking have significantly higher cerebral perfusion levels than those who continue to smoke. Even those who have smoked for 30 to 40 years have improved cerebral circulation within a relatively short time after stopping smoking (Rogers et al., 1985).

After 5 years, risk of CVA is at the level of nonsmokers, which emphasizes that “it is never too late to quit,” no matter how long the patient has been smoking.

Subarachnoid Hemorrhage

A recent systematic review of the risk factors for subarachnoid hemorrhage (SAH) shows that smoking doubles the risk for SAH (Feigin et al., 2005). About one third of all SAH was found to be attributable to smoking in a smaller case-control study, and although the risk dropped within a few years after quitting, it may remain increased for up to 15 years in the heaviest female smokers (Anderson et al., 2004). For SAH associated with cerebral aneurism, smoking increases the risk of bleeding three to six times.

Older studies involving high-dose estrogen OCs showed a significant interaction with smoking, increasing the risk for stroke and SAH among women who both smoked and used OCs. Studies of women who use second- and third-generation OCs find no increased risk of stroke, even among smokers (Yang et al., 2009). However, the American College of Obstetricians and Gynecologists (2006) states that “practitioners should prescribe combination hormonal contraceptives with caution, if at all, to women older than 35 years who smoke.” The overall mortality RR among OC users who smoke 15 or more cigarettes a day was 2.25 in a large cohort study (Vessey et al., 2010).

PERIPHERAL VASCULAR DISEASE

Smoking is strongly associated with other forms of cardiovascular disease, including abdominal aortic aneurysm (AAA) and peripheral vascular disease, in both men and women. Smoking causes as much as half of all peripheral artery disease and significantly increases the failure rates after lower-limb bypass surgery. As with coronary artery disease, secondhand smoke exposure is also associated with intermittent claudication. The risk of AAA rises in proportion to the duration and intensity of smoking and is up to sevenfold greater at 20 pack-years (U.S. Surgeon General, 2004). The USPSTF has recommended one-time screening for AAA by ultrasonography in men age 65 to 75 years who have ever smoked, including men who only smoked pipes or cigars. Consideration should also be given for screening women older than age 65 years with a history of smoking (Derubertis et al., 2007) because about 40% of the annual deaths from AAA occur among women, in whom the disease is more deadly than men. Smoking is also an independent risk factor for erectile dysfunction, an additional fact that may help motivate men to stop smoking.

Other Diseases and Conditions

Alzheimer Disease

Studies show conflicting evidence linking smoking with Alzheimer dementia and other causes of cognitive decline. However, a meta-analysis found that compared with never-smokers, current smokers had RRs of 1.79 for Alzheimer disease (AD) and 1.78 for vascular dementia. Smokers in this study also had greater yearly declines in Mini-Mental State Examination (Anstey et al., 2007). Another systematic review and meta-analysis also found significant risk for AD among smokers (RR, 1.59), as well as elevated risk for developing vascular dementia (1.35) and cognitive decline (1.20) compared with never-smokers (Peters et al., 2008).

eFigure 49-2 Cigarette smoking and risk of stroke, adjusted for age and gender. *Bars indicate 95% confidence limits.* (From Bonita R, Scragg R, Stewart A. Cigarette smoking and risk of premature stroke in men and women. *BMJ*. 1986;293:6.)

Indeed, the risk of cognitive decline may begin among smokers as early as age 35 years, joining diabetes and age as variables in the Framingham Risk Score that impact cognitive function as well as heart disease (Jooseten et al., 2013).

Graves Disease

Smoking appears to be one of the many factors causing Graves disease, particularly among women, and includes a higher risk of Graves ophthalmopathy as well (Vestergaard, 2002).

Diabetes Mellitus

Diabetes is a rapidly growing worldwide pandemic, and cigarette smoking is responsible for about 10% of the incidence of type 2 diabetes. The risk of developing type 2 diabetes is 30% to 40% higher for active smokers than nonsmokers, and the risk is proportional to the number of cigarettes smoked. Smoking promotes central obesity, which is a well-established risk factor for insulin resistance and diabetes (USDHHS, 2014). People who smoke more than one pack a day have about double the risk for type 2 diabetes as nonsmokers, and the risk is still 1.5 times greater for those who smoke only 1 to 14 cigarettes a day (Manson et al., 2000; Willi et al., 2007). A recent meta-analysis examined the risk of secondhand smoke exposure and development of type 2 diabetes, finding a 28% increased risk for exposed individuals (Wang et al., 2013).

Smoking increases the risk for development of the metabolic syndrome and its attendant cardiovascular consequences (Chiolero et al., 2008).

Patients with diabetes who smoke are at increased risk for both micro- and macrovascular complications. Cigarette smoking increases the risk for diabetic nephropathy, retinopathy, and neuropathy. This association is strongest in patients requiring insulin for control. Stopping smoking reduces the risk of developing diabetes and is essential for preventing diabetic complications.

Depression

Smokers are more likely to experience major depression than nonsmokers, and the incidence increases steadily with the number of cigarettes smoked. This increased risk may result from genes that predispose to both conditions (Kendler et al., 1993). Smoking may predispose to depression and, conversely, may be an antecedent to smoking in the adolescent population (Brook et al., 2004; Goodman and Capitman, 2000).

Wrinkles

We are not very effective in getting the message about tobacco's hazards across to adolescents. By talking about disease, we may not be speaking their language. The fact that smoking causes wrinkles, bad breath, and yellow teeth may be a more effective message than evidence that smoking kills. Premature wrinkling (crow's feet) increases with the number of cigarettes smoked; heavy smokers are five times more likely to have wrinkles than nonsmokers (Kadunce et al., 1991).

Macular Degeneration and Cataract

Macular degeneration is the leading cause of blindness after age 65 years, and nothing prevents or delays its progression. Smoking 20 or more cigarettes a day increases the

risk of macular degeneration two- to threefold. As with other smoking-related disorders, macular degeneration also appears to be dose related, with the incidence increasing with the number of pack-years (Christen et al., 1996; Thornton et al., 2005). Smoking is also a cause of nuclear cataract, with smokers having two to three times the risk of never-smokers.

Other

Smoking is a cause of rheumatoid arthritis, and it interferes with the effectiveness of certain treatments. Smoking increases the risk for tuberculosis and for dying from tuberculosis (USDHHS, 2014).

THE MYTH OF FILTERED CIGARETTES

There is a mistaken popular belief that filtered brands of cigarettes, which now account for more than 97% of those sold in the United States, are safer than nonfiltered cigarettes and that formerly labeled "light" cigarettes convey a degree of health protection. "Low-tar" and "low-nicotine" filtered cigarettes are now the most commonly purchased products. Because the addiction is to nicotine, people who smoke low-nicotine cigarettes undergo "compensatory smoking," in which they inhale more frequently and more deeply to maintain their blood nicotine levels. As a result, tar intake increases, so the cigarette changes from the low-tar to the high-tar category. Smokers who take 14 puffs per cigarette inhale 58% more tar than those taking the standard 8.7 puffs per cigarette. Most manufacturers create tiny perforations in the filter to dilute the smoke with air, thus creating their "light" and "ultralight" cigarettes. Many smokers, however, block the holes with their lips or their fingers to obtain undiluted smoke with a higher concentration of nicotine (Kozlowski et al., 1980).

Cigarettes with reduced yields of nicotine and CO are not safer. The fourfold increased risk of MI does not vary according to the nicotine content. The degree of risk is proportional to the number of cigarettes smoked (Palmer et al., 1989). Similar myths about "natural" and "organic" cigarettes should be dispelled because there is absolutely no evidence that these tobacco products confer any health protection compared with other brands.

CIGARS

Key Points

- Cigars are not a safe alternative to cigarettes and cause both cancer and heart disease.
- Cigar-related health risks are related to number smoked and depth of inhalation.
- The risk of tobacco-related disease is increased when smoking is combined with alcohol consumption.

In 2012, the CDC estimated that about 9.1% of men and 2.0% of women, and 12.6% of students in grades 9-12 were current cigar smokers (CDC, 2013). The mortality patterns from cigar smoking relate in part to the degree of inhalation by the smoker. Primary cigar smokers, or those who have never or rarely smoked cigarettes, inhale much less than secondary cigar smokers—those who have

switched from or are concurrent cigarette smokers. The main reason for the difference is the pH of the smoke, which in cigars is higher than in cigarettes, allowing nicotine to be absorbed across the oral mucosa. Secondary cigar smokers, however, have learned to inhale smoke, increasing their risk of cancer and heart disease.

Cigar smokers have a risk of oral and pharyngeal cancer that is similar to cigarette smokers; their risk of esophageal cancer is several times that of never-smokers. As with cigarette smoking, the use of alcohol multiplies the risk of these cancers, accounting for about 75% of cases in developed nations (Pelucci et al., 2008).

Lung cancer risk varies with depth of inhalation and number of cigars per day. Primary cigar smokers with no or slight inhalation have about a 1.8 mortality ratio of lung cancer; moderate-deep inhalers increase this to 4.9, with an overall mortality ratio of 2.11 compared with nonsmokers. Secondary cigar smokers have a mortality ratio of 5.4; moderate-deep inhalers in this group increase the risk to 9.77. Combined cigarette–cigar smokers have an overall lung cancer mortality ratio of 11.20 (National Cancer Institute (NCI), 1998).

Cigar smokers are also at higher risk for both COPD (RR, 1.45) and coronary artery disease (RR, 1.27) compared with nonsmokers (Iribarren et al., 1999). As with the cancer risk, the level of inhalation increases risk; for example, secondary cigar smokers with moderate-deep inhalation patterns have a fivefold increased risk for COPD (NCI, 1998).

ELECTRONIC CIGARETTES

Electronic cigarettes (e-cigarettes), first developed in China in 2003, consist of a metal tube resembling a normal cigarette; a battery; an atomizer; and a replaceable cartridge containing liquid nicotine, propylene glycol, and flavoring. Examples of flavorings are chocolate, cherry, and bubblegum, all of which can be enticing to children. When a user puffs on the e-cigarette (called vaping), an indicator light at the tip glows, and the heating element vaporizes the solution from the cartridge containing nicotine and other substances. A mist is produced that is similar to cigarette smoke and contains the propylene glycol, a known pulmonary irritant used in antifreeze. Although a few other compounds, including acetaldehyde, benzene, cadmium, formaldehyde, lead, and contaminants such as metallic particles, have been found in the vapor, they are at much lower concentrations than in conventional cigarettes. Toxicology studies, however, are not yet available, and the health effects of long-term use are unknown.

Sales of these devices have grown rapidly, both through the Internet and increasingly at convenience stores and gas stations in the United States, with projections of \$1 billion or more in sales by 2014. All of the major traditional cigarette companies have now entered the e-cigarette market and see this as a growing slice of the nicotine business through which to market new products. Television is again seeing ads for these new nicotine delivery devices. Youth uptake of e-cigarettes, although less than for conventional cigarettes, is increasing. Data from the 2012 National Youth Tobacco Survey show that the percentage of high school students who reported ever using an e-cigarette rose

from 4.7% in 2011 to 10.0% in 2012. In the same time period, high school students using e-cigarettes within the past 30 days rose from 1.5% to 2.8%. Use also doubled among middle school students. Altogether, in 2012 more than 1.78 million middle and high school students nationwide had tried e-cigarettes.

Many questions remain unanswered about e-cigarettes, including whether they will help current smokers quit or lead to “dual use” and perpetuate nicotine dependence. Early studies have not shown them to be very effective for cessation. Adolescents who use e-cigarettes have an increased likelihood of smoking conventional cigarettes and are also more likely to smoke heavily.

Many states do not restrict the sale of e-cigarettes to minors. There has been a surge in the number of calls to poison control centers. More than half of the calls involve children five years of age and younger, with the most common symptoms being nausea and vomiting. The nicotine-containing liquid can be purchased in bulk (up to a gallon) and can cause vomiting and seizures when ingested or absorbed through the skin. A single teaspoon of the highly concentrated form can kill a small child.

SMOKELESS TOBACCO

Key Points

- Snuff users have a 50-fold increased risk of cancer of the cheek and gum.
- The carcinogens in smokeless tobacco have a greater concentration than in cigarette tobacco; the level of nitrosamines is more than 14,000 times that allowed in bacon and beer.

Smokeless tobacco comes in two types: *snuff*, which is dry or moist, and *chewing* (spitting) tobacco, which comes as a loose leaf, plug, or twist. Smokeless tobacco contains many of the same carcinogens as cigarette tobacco, but some are present in much greater concentrations. *Nitrosamines*, which are powerful chemical carcinogens, are present at levels up to 14,000 times higher than the federal government allows in bacon and beer (Connolly et al., 1986).

A variation on smokeless tobacco is called *snus*, which contains powdered, flavored tobacco in small satchets placed under the lip, releasing nicotine through the buccal mucosa. Because of differences in manufacturing, snus has comparatively small levels of the carcinogenic compounds found in traditional smokeless products. No spitting is required. Snus marketing campaigns emphasize its use when smoking is not allowed, and most U.S. snus users also smoke cigarettes. In Sweden, snus use has eclipsed smoking, and many smokers have used snus to quit smoking but have continued using snus, and many appear to be dependent. Again, in the United States, this has sparked a fierce debate about the use of snus and similar products as agents for “harm reduction,” and whether smokers should be advised to switch as a means of smoking cessation because exclusive smokeless tobacco use avoids many of the dangers of combustible tobacco.

Treatment of smokeless tobacco use is difficult because none of the standard medications used for smoking

cessation have shown effectiveness for smokeless tobacco users, although behavioral counseling has a modest effect (Fiore et al., 2008). The nicotine patch and lozenge have been suggested, and clinical trials of combination therapy are ongoing. Behavioral interventions such as mailings, oral or dental screenings, group discussions, workplace interventions, and telephone support showed the best evidence for smokeless tobacco cessation (SOR: B). There was no benefit from the use of bupropion sustained release (SR) or nicotine patches or gum (Cayley, 2009; SOR: A).

Use of smokeless tobacco increases the frequency of oropharyngeal cancer and causes gum recession and tooth loss. Overall, the RR for oral cancer among snuff users is 2.6; for esophageal and pancreatic cancer, it is 1.6 (Boffetta et al., 2008). Leukoplakia is found in 18% to 64% of users (Connolly et al., 1986). Snus has been associated with a higher risk of oropharyngeal cancer in some studies (Roosar et al., 2008) but not others (Luo et al., 2007) and has a small risk of pancreatic cancer. A systematic review and meta-analysis of the risk for MI and stroke among current smokeless tobacco users found small increases in RR for these conditions (Boffetta and Straif, 2009).

Although educational programs have been launched by the National Cancer Institute and Major League Baseball, smokeless tobacco use has trended upward in adolescents. College athletes often believe that male peers, coaches, and professional athletes are indifferent to the use of spitting tobacco (Hilton et al., 1994). An estimated 8.6% of high school students use smokeless tobacco, and its use is more common among high school boys (14%) than girls (2.2%). As with college students, many high school spit tobacco users participate in organized sports. Enlisting the support of coaches to help with tobacco use prevention is an untapped resource that should be explored.

INVOLUNTARY (PASSIVE) SMOKING

Key Points

- Secondhand smoke contains 7000 different chemicals, of which more than 70 are carcinogenic.
- About one third of lung cancers occur in nonsmokers who live with a smoker or work in a smoky environment.
- Passive smoking is the third leading preventable cause of death, after alcohol and smoking itself.
- Passive smoking increases the risk of sudden infant death syndrome (SIDS) in infants and otitis media, cancer, and respiratory disease in older children, in direct proportion to smoke exposure.

Secondhand smoke, also called *environmental tobacco smoke* (ETS), is the combination of smoke emitted from the burning end of a cigarette, cigar, or pipe and the smoke exhaled by a smoker. Two thirds of the smoke from a burning cigarette never reaches a smoker's lungs but instead goes directly into the air. *Sidestream smoke* is emitted into the air from a smoldering cigarette or cigar between puffs, and *mainstream smoke* is what the smoker inhales directly; the exhaled smoke also contributes to ETS. Although diluted by air before being inhaled, sidestream smoke contains greater

concentrations of toxic substances than mainstream smoke because of a lower combustion temperature and lack of filtration through the cigarette.

The 2006 Report of the Surgeon General, *The Health Consequences of Involuntary Exposure to Tobacco Smoke* (USDHHS, 2006), concludes the following:

1. Secondhand smoke causes premature death and disease in children and adults who do not smoke.
2. Children exposed to secondhand smoke are at increased risk for SIDS, acute respiratory infections, ear problems, and more severe asthma. Smoking by parents causes respiratory symptoms and slows lung growth in their children.
3. Exposure of adults to secondhand smoke has immediate adverse effects on the cardiovascular system and causes coronary heart disease and lung cancer.
4. The scientific evidence indicates that there is no risk-free level of exposure to secondhand smoke.
5. Eliminating smoking in indoor spaces fully protects nonsmokers from exposure to secondhand smoke. Separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot eliminate exposures of nonsmokers to secondhand smoke.

Tobacco smoke contains more than 7000 different chemicals, at least 70 of which are known carcinogens. Nonsmokers exposed to secondhand smoke at home or at work increase their risk of lung cancer by 20% to 30% (USDHHS, 2014). The U.S. Environmental Protection Agency, (EPA) National Toxicology Program, U.S. Surgeon General, and International Agency for Research on Cancer have determined that environmental tobacco smoke is a class A (known) human carcinogen, in the same class as asbestos, mustard gas, arsenic, and benzene. In addition to the 3000 lung cancer deaths a year in nonsmokers, almost 40,000 heart disease deaths each year are linked to secondhand smoke. Secondhand smoke exposure also causes chronic otitis media, cough, and lower respiratory illnesses in children (e.g., asthma, bronchitis, pneumonia). It is estimated that tobacco smoke in the home and workplace could be responsible for the deaths of about 50,000 nonsmokers annually in the United States, making passive smoking the third leading preventable cause of death, after those from direct smoking and alcohol (Air Resources Board, 2005).

In a classic study, Hirayama (1981) was among the first scientists to demonstrate an increased risk of lung cancer in nonsmoking housewives exposed to the secondhand cigarette smoke of their husbands (see eFigure 49-3 online). Since then, many studies have shown an association between being married to a smoker and having an increased risk of lung cancer. The overall risk of lung cancer increases 20% to 30% in nonsmokers exposed to ETS in the home; combined home and work exposure further increases the risk (USDHHS, 2006).

A report from the California EPA's Air Resources Board is another well-researched review of the health effects of passive smoking. Their meta-analyses of the breast cancer risk indicate that the RR for breast cancer, particularly among premenopausal women, is between 1.68 and 2.20 (Air Resources Board, 2005; Miller et al., 2006). A 2009 Canadian task force report found a causal link between passive smoke exposure and breast cancer, especially in

eFigure 49-3 Lung cancer mortality in women according to the presence or absence of direct and familial indirect smoking. (From Hirayama T. Nonsmoking wives of heavy smokers have a higher risk of lung cancer: a study from Japan. *BMJ*. 1981; 282:183.)

younger, premenopausal women, and a causal relationship between active smoking and breast cancer at all ages (Johnson et al., 2011). A meta-analysis of case-control studies found a significant relationship between passive smoke exposure and cervical cancer, with a 73% increased risk among exposed nonsmoking women (Zeng et al., 2012). It is estimated that the risk of MI is up to 70% greater for a woman whose husband smokes (Wells, 1994). RR estimates from meta-analysis indicate a 25% to 30% increase in the risk for coronary heart disease in exposed nonsmokers; as with lung cancer, multiple sites of exposure increase the risk (USDHHS, 2006). The cardiovascular effects of even brief exposure to secondhand smoke are often nearly as great as those of direct smoking, with platelet aggregation and arterial endothelial damage occurring within 30 minutes of exposure; furthermore, secondhand smoke induces oxidative stress and promotes vascular inflammation (Barnoya and Glantz, 2005). Exposure to secondhand smoke is associated with increased levels of inflammatory markers related to the development of atherosclerosis. People exposed have higher white blood cell counts and elevated CRP levels, oxidized LDL cholesterol, homocysteine, and fibrinogen. Even occasional exposure results in elevated levels. These increases are similar to those seen in active smokers.

Reports show that the health benefits of banning smoking in public places and the workplace include a reduction in heart attacks. Examination of community MI rates after implementation of strong smoke-free legislation found a pooled random-effects estimate of the rate of acute MI hospitalization 12 months later to be 0.83 (95% confidence interval, 0.80-0.87), with growth of this benefit expected over time (Lightwood and Glantz, 2009). With similar findings, systematic review and meta-analysis of 10 locations with smoke-free legislation concluded that the acute MI risk decreased by 17% overall, with the greatest effect in younger individuals and nonsmokers (Meyers et al., 2009).

Secondhand Smoke: Effects on Children

More than 50% of children younger than 5 years of age live in homes with at least one adult smoker. Children of smoking parents have more bronchitis and pneumonia during their first year of life and more otitis media when older. They have increased incidence of cough, bronchitis, and pneumonia proportional to the number of cigarettes smoked by the parents, particularly the mother. In fact, children of parents who smoke at least a half-pack a day have almost twice the risk of hospitalization for a respiratory illness. Secondhand smoke causes new-onset asthma in exposed children, and young persons with asthma have more asthma episodes (Charlton, 1994; Rantakallio, 1978; USHHS, 2006).

Passive smoking also increases the risk of sudden infant death syndrome. Infants exposed to secondhand smoke have twice the risk of SIDS, and infants whose mothers smoke before and after birth are three to four times more likely to die from SIDS (USDHHS, 2014).

Small children are victimized more by passive smoking than adults. Because of their more rapid breathing, children inhale larger amounts of harmful substances. Children exposed to their parents' cigarette smoke have six times the average number of respiratory infections. They also have

deficits in growth and in intellectual and emotional development, as well as more behavior disorders, such as hyperactivity.

Physicians and health care providers who care for children should advise parents to quit smoking to limit their children's exposure to secondhand smoke and should advocate for smoke-free indoor air both at home and in cars when children are passengers because these two locations account for the majority of childhood exposure to secondhand smoke.

Thirdhand Smoke

Thirdhand smoke occurs when cigarette smoke reacts with nitrous acid on surfaces to form *tobacco-specific nitrosamines* (TSNAs). Nitrous acid is a common indoor pollutant and, when combined with cigarette smoke, forms a carcinogen that becomes more potent over time. Thus, nicotine is converted to a dangerous carcinogen after it is absorbed on indoor surfaces in automobiles and furniture. This can be especially hazardous to infants and children who live close to the floor because the TSNAs are especially concentrated in dust and carpeting. Smokers may believe that smoking only when others are not present (e.g., in car or home) creates no risk to nonsmokers who arrive later. In fact, the smoke clings to upholstery, cotton, and carpeting and actually builds up over time, exposing nonsmokers to potent carcinogens. This thirdhand smoke can be especially dangerous because TSNAs cannot be simply inactivated by dry cleaning or washing with soap and water. Most soaps are alkaline, and cleansers that dissolve nicotine must be acidic. Thus, it is almost impossible to remove TSNAs from carpeting, which will continuously uptake nicotine. Even washing smooth stone and metal with an alkaline soap will not remove nicotine residue (Dreyfuss, 2010; Sleiman et al., 2010).

PREGNANCY

See eAppendix 49-1 online.

Key Points

- The more a pregnant woman smokes, the greater the risk of premature delivery and low-birth-weight infants unless she stops smoking by the fourth month of gestation.
- Smoking during pregnancy increases the risk of congenital abnormalities, mental retardation, learning problems, and attention-deficit hyperactivity disorder (ADHD).
- The risk is increased for spontaneous abortion, placenta previa, and premature rupture of membranes.
- Reduced fertility is proportional to the number of cigarettes smoked.

KEY TREATMENT

- Because of the serious risks of smoking to the pregnant smoker and the fetus, whenever possible, pregnant smokers should be offered person-to-person psychosocial interventions that exceed minimal advice to quit (Fiore et al., 2008) (SOR: A).

Health Risks with Smoking: Pregnancy

As in other areas, a dose-response relationship exists between cigarette smoking during pregnancy and resulting harm. The more a pregnant woman smokes, the lower the infant's birth weight is likely to be. On average, babies born to women who smoke during pregnancy weigh 200 g less than those born to comparable nonsmokers. Heavy smokers have a 130% increased incidence of their newborn weighing less than 2500 g. However, a woman who gives up smoking by her fourth month of gestation has the same risk as a nonsmoker. Women who stopped smoking in the first trimester had 26% fewer preterm deliveries and 18% fewer low-birth-weight infants than those who continued smoking (Mainous and Hueston, 1994a). Pregnant women who do not smoke but who have high passive smoke exposure are twice as likely as those with low exposure to have a low-birth-weight infant (Mainous and Hueston, 1994b). The risk of spontaneous abortion in heavy smokers is twice that in nonsmokers. Smoking during pregnancy doubles the incidence of placenta previa and causes abruptio placentae, bleeding during pregnancy, and premature rupture of membranes. Smoking also increases the incidence of premature births and perinatal deaths, with about 5600 deaths from perinatal conditions annually (Centers for Disease Control and Prevention, 2005).

Transplacental exposure to carcinogenic substances absorbed from the mother's smoking during pregnancy had been thought to predispose infants to cancer later in life (Sandler et al., 1985). However, large-scale studies have not borne out the early reports on cancer among these infants, and the data are inconclusive. The interplay between toxic exposure and genetics continues to be investigated and is likely to be one of the main reasons for inconsistency among studies linking prenatal smoking and cancer or congenital disorders. However, strong experimental evidence indicates that maternal smoking causes fetal hypoxia, which could explain the increased incidence in some studies of congenital abnormalities noted in babies of smokers. The offspring of mothers who smoke during the 3 months before or after conception were twice as likely to have a cleft palate as the offspring of nonsmokers (Khoury et al., 1989). However, subsequent studies of smoking and cleft lip or palate have shown smaller odds ratios for these problems, about 1.3 (Wyszynski et al., 1997). In the case-control National Birth Defects Prevention Study, infants whose mothers smoked during pregnancy had up to twice the risk of septal heart defects for the heaviest exposure, with a dose-response reduction in risk for lighter smokers (Malik et al., 2008). The evidence for associations with other congenital abnormalities is inconclusive (U.S. Surgeon General, 2004). Children of women who smoke during pregnancy have almost three times the risk of being born with a

hyperkinetic or attention-deficit hyperactivity disorder (ADHD) (Linnet et al., 2005). A review of the neurodevelopmental issues among these children found consistent evidence of both prenatal and postnatal exposure being associated with later behavioral problems, irritability, oppositional defiant behavior, conduct disorders, and ADHD (Herrmann et al., 2008).

Reduced fertility is also a problem in women who smoke cigarettes (U.S. Surgeon General, 2004). Smokers are three to four times more likely to take longer than 1 year to conceive, and heavy smokers have more difficulty than light smokers. Interestingly, decreased fertility rates are found in both natural and in vitro attempts at conception. Spermatozoa from smokers also show more morphologic abnormalities and less motility than spermatozoa from nonsmokers.

Clinician counseling improves smoking cessation rates by up to 80% when used during pregnancy. Pregnancy is an opportune time for the family physician to encourage women to discontinue smoking (Fiore et al., 2008). Most "quit lines" have developed tailored approaches for pregnant patients. Cessation any time during pregnancy is beneficial to mother and fetus, but the earlier she stops, the better. About 25% of women who smoke at the beginning of their pregnancy will stop on their own at some time during the 9 months, but more than half of them resume smoking within 6 months after delivery. Unfortunately, efforts at relapse prevention among these women have little success (Hajek et al., 2008).

Pharmacotherapy during pregnancy has been widely debated. All of the NRT products are pregnancy category D except for the lozenge, which was introduced as an OTC product and does not have a pregnancy classification (Fiore et al., 2008). The risk-to-benefit ratio for using NRT seems favorable because one chemical at a low dose appears much less harmful than 4000 toxins from cigarettes; therefore, it may be preferred to continued smoking for those who do not respond to counseling (Osadchy et al., 2009; Rore et al., 2008). Some advocate the use of intermittent-dose products, such as the gum, lozenge, or nasal spray, instead of the continuous dose delivered by the patch. Others advise caution, however, noting the neurodevelopmental problems of fetal exposure to nicotine and the need for more research on its safety during pregnancy (Pauly and Slotkin, 2008). Little research has been done on bupropion and none with varenicline during pregnancy.

None of the pharmacotherapeutic agents used for cessation has been found to increase abstinence among pregnant patients, and counseling remains the first choice of the PHS guidelines (Fiore et al., 2008).

- Although abstinence early in pregnancy will produce the greatest benefits to the fetus and expectant mother, quitting at any point in pregnancy can yield benefits. Therefore, physicians should offer effective tobacco-dependence interventions to pregnant smokers at the first prenatal visit and throughout pregnancy (Fiore et al., 2008) (SOR: B).

Smoking and Mental Health

Mental illness with substance abuse puts patients at particular risk for dying of tobacco-related illness because they are more likely to smoke and to smoke more heavily than others in the population. Patients with psychiatric illness consume up to 70% of the cigarettes smoked in the United States, with two to four times the general prevalence of smoking (Grant et al., 2004; Kalman et al., 2005). Among mentally ill and substance-abusing patients, as many as 200,000 die each year from tobacco-related causes—almost half the total U.S. tobacco-related mortality (Williams et al., 2004). Individuals in this special population of smokers do express strong interest in quitting smoking, however. Counseling and pharmacology that is useful with other smokers is effective in mentally ill and substance-abusing patients who smoke (Ranney et al., 2006), and just as with other smokers, this part of their health care must not be neglected.

Social and Legal Action

See eAppendix 49-2 online.

Smoking Cessation

Key Points

- Patients who smoke should receive advice and encouragement to stop at every visit.
- Take advantage of the teachable moment, when a patient who smokes is being treated for any medical condition.
- Multiple strategies and persistence are usually needed for successful cessation because tobacco dependence is a chronic disease.
- Brief counseling, usually lasting less than 3 minutes, is an effective way to begin intervention.
- In the United States, there are now more former smokers than current smokers. More than half of previous smokers have quit smoking (USDHHS, 2014).

Family physicians are in a unique position to assist their patients in smoking cessation. Because 7 of every 10 smokers visit their physicians at least once a year, this is a golden opportunity that should not be missed. Among smokers, 70% want to quit, and about 40% make an attempt each year, but fewer than 5% succeed. Even brief physician advice can double the quit rate (Fiore et al., 2008). Of those

who try to quit on their own and do not use recommended cessation methods, most relapse within 8 days (CDC, 2008).

A survey by the Association of American Medical Colleges (2007) about physician behavior related to smoking cessation is summarized as follows:

Most physicians consistently ask patients who smoke about their smoking status and advise them to stop (86%), but only 13% say they usually refer smokers to others for appropriate treatment and only 17% say they usually arrange for follow-up visits to address smoking. Only 31% “usually” advised use of nicotine replacement therapy, and 25% “usually” prescribed other medication for cessation. Only 7% regularly referred patients to a quit line.

Patients should be asked about tobacco use at every visit because repeated screening increases rates of clinical intervention. Tobacco users should be advised to quit at every visit (SOR: A) because there is a dose-response relationship between the number of contacts and abstinence. Tobacco use screening coupled with brief advice is one of the top three clinical prevention measures and is cost-effective as well (Maciosek et al., 2006). Tobacco cessation treatment may include a variety of components: counseling for behavior change in both individual and group settings, such as motivational interviewing and problem solving or skills training, use of evidence-based pharmacotherapy, and proactive telephone quit line counseling (Fiore et al., 2008; USPSTF, 2009). Patients should receive at least minimal advice and encouragement at every visit based on the five A's approach (Table 49-2). The American Academy of Family Physicians (AAFP, 2005) has a campaign to encourage its members to engage themselves in smoking cessation interventions. Using two A's, ask and act, the AAFP program emphasizes brief counseling and effective follow-up. The AAFP emphasizes a team approach to tobacco use cessation in the office setting. It has many resources that can assist in developing effective approaches for the practice team. These materials can be accessed on the AAFP website.

As part of taking the history from a patient who smokes, clinicians should ask the following three questions to assess the patient's degree of nicotine addiction:

1. How much do you smoke? (How many cigarettes or cans of “dip” per day, for how many years?)
2. When do you smoke the first cigarette of the day?
3. How long is the period between cigarettes before craving another smoke?

Patients who smoke more than 20 cigarettes a day, who light their first cigarette within 30 minutes of waking, and who have cravings within 1 hour of the most recent cigarette are likely to have significant physiologic addiction to nicotine. Smoking fewer than 10 cigarettes a day suggests less addictive behavior, and a few patients report that they

Table 49-2 Five A's for Tobacco Users Willing to Quit

Ask about tobacco use at every visit.
Advise to quit through clear, personalized messages.
Assess about willingness to quit.
Assist efforts to quit.
Arrange follow-up and support.

49-2 *Social and Legal Action*

Key Points

- A variety of health policy initiatives are effective in reducing tobacco use and should be widely implemented.
- Tobacco-related income (excise taxes and the Master Settlement funds) are not generally being used for tobacco prevention and control, a tragic missed opportunity for public health.

The U.S. Task Force on Community Preventive Services (2005) reported strong evidence for decreasing smoking using the following policy initiatives:

- Legislation on clean indoor air
- Efforts to increase tobacco excise taxes
- Mass media campaigns for counter advertising and education about tobacco and health
- Smoking cessation telephone services (quit lines)
- Reducing patient costs for smoking cessation services
- Office system changes for physicians, including chart reminder systems

- Community efforts to reduce sales and availability of tobacco products to youth

The 1998 Master Settlement Agreement between the tobacco companies and attorneys general across the United States for \$246 billion ended state litigation to recover smoking-related health care costs over the decades. Although the settlement held promise for a vigorous primary prevention effort to reduce demand for smoking in adolescents, little of this funding has been allocated to tobacco control, and most state agencies charged with this responsibility have lacked creativity and forcefulness, although there are notable exceptions. After receiving these billions from the industry for dropping lawsuits, the states spent almost all the money in ways unrelated to antismoking programs. From 1998 to 2008, the states collectively spent only 3.2% of their tobacco-related revenue (excise taxes and Settlement funds) on tobacco prevention, education, and cessation issues. In fiscal year 2009, no state spent the amount the Centers for Disease Control and Prevention (CDC) recommended for tobacco control; only nine states budgeted even half that level. In fiscal year 2014, the states will collect \$25 billion in tobacco-related revenues and would need to spend only 15% of those funds to meet CDC targets for tobacco prevention expenditures (Campaign for Tobacco-Free Kids, 2014).

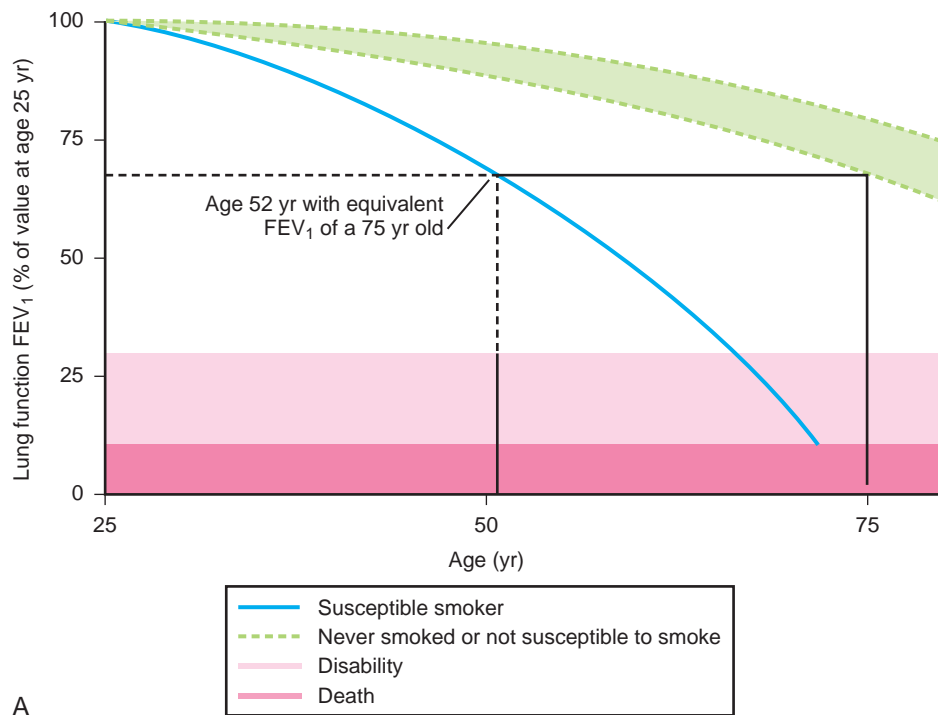

Figure 49-4 A, Explaining lung age to participants. **B,** Graph of lung function against age showing how smoking accelerates age-related decline in lung function. FEV₁, Forced expiratory volume in 1 second. (From Parkes G, Greenhaigh T, Griffin M, Dent R. Effect on smoking quit rate of telling patients their lung age: the Step2quit randomized controlled trial. *BMJ*. 2008;336:598-600.)

smoke only during social situations and only 5 to 10 cigarettes a week. Determining the patient's pattern of smoking will provide clues into the level of addiction.

Office spirometry to obtain a forced expiratory volume in 1 second (FEV₁) can also be useful in motivating smokers to

quit. Comparing the smoker's "lung age" with the age of a healthy individual who has the same FEV₁ and then showing the smoker a graphic display (Figure 49-4, A) more than doubled the rate of quitting smoking after 12 months (13.6% vs. 6.4%) in one study (Parkes et al., 2008). For

example, a 52-year-old smoker with a 20-pack-year history (1 pack/day for 20 years) may have the lung age of a 75-year-old. Probable age at disability and death if the person continues smoking or stops smoking can be shown (Figure 49-4, B). Such a visual presentation is often effective in achieving cessation even if smokers have a normal lung age because he or she may think it is not too late to quit.

STAGES OF CHANGE

Patients who begin any major behavioral or lifestyle change go through successive stages in the process, as follows:

- **Precontemplation:** The patient is not interested in quitting smoking in the near future (within 6 months).
- **Contemplation:** The patient is thinking about quitting within the next few months but has taken no action.
- **Preparation:** The patient is planning to quit in the next 30 days.
- **Action:** The patient is in the process of quitting or has quit during the past 6 months.
- **Maintenance:** The patient has abstained for more than 3 months.

Family physicians should emphasize progression through the process of change to facilitate the patient's efforts to stop smoking. When a patient reaches the preparation stage, the physician can play a major role in motivating the patient, including counseling and routine use of pharmacotherapy. However, recent research indicates that many smokers do not go through sequential stages and are often successful in quitting during spontaneous, unplanned attempts, perhaps sparked by an illness or by policy changes such as price increases or clean indoor air laws. Physicians' continued support and encouragement may help increase the frequency and success of these efforts (Ferguson et al., 2009).

HELPING TO CHANGE BEHAVIOR

In addition to the support for smoking cessation activity described by the U.S. Public Health Service (PHS) (Fiore et al., 2008), *motivational interviewing* is a patient-focused approach to discussing patients' ambivalence about changing their tobacco use behavior. Motivational interviewing uses empathy and a nonjudgmental style to open a dialogue that can show the importance of change and build a patient's self-motivation. Patients can build on prior success (even brief) and become more active partners in the path to abstinence (Mallin, 2002; Miller and Rollnick, 2002). A clear relationship exists between the intensity of counseling and its effectiveness. Although even brief counseling (≤ 3 minutes) doubles the spontaneous quit rate, intensive therapy can be more effective and should be used whenever possible (Fiore et al., 2008).

Both physicians and their patients who smoke should think of nicotine dependence as a chronic disease, usually characterized by many episodes of remission and relapse. A number of strategies are often needed, and expectations must be realistic because smokers usually do not succeed on their first or even second attempt. Clearly, however, the

chances of success increase with each attempt, and relapse should not be considered a sign of failure.

Intensive counseling is associated with a 22% smoking cessation success rate, and even minimal counseling (< 3 minutes) has a 13% quit rate (Schroeder, 2005). Physicians should take advantage of the teachable moment, such as when a smoker is being seen for a respiratory or cardiovascular problem, an asthma attack in a smoke-exposed child, or the smoking-related death of a loved one (Miller and Wood, 2003). One of the most productive times for cessation advice to be received and effective is during prenatal care or after a nonfatal cardiac event. When intensive counseling and follow-up are provided to patients recovering from coronary bypass graft surgery or a heart attack, more than 60% stop smoking and stay off cigarettes, almost twice the rate of those who receive less definitive advice (Smith and Burgess, 2009; SOR: A). A Cochrane review of cessation interventions among hospitalized patients shows that intensive interventions that begin in the hospital and have at least one supportive contact after discharge increase the odds of successful tobacco abstinence (Rigotti et al., 2007).

PHARMACOTHERAPY

The updated clinical practice guideline, Treating Tobacco Use and Dependence (Fiore et al., 2008), discusses the use of the different forms of nicotine replacement therapy and the other two FDA-approved prescription medications used for tobacco cessation, bupropion and varenicline (Table 49-3). Effective second-line agents include clonidine, delivered transdermally or orally, and nortriptyline (Fiore et al., 2008), but neither is FDA approved for this indication. All of these medications in randomized clinical trials have two to four times the odds ratio for success compared with placebo for smoking cessation. Medication and treatments to avoid include antidepressants such as selective serotonin reuptake inhibitors, benzodiazepines, mecamylamine, hypnosis, acupuncture, laser therapy, and β -adrenergic blocking agents, none of which has been found to have a beneficial effect (Fiore et al., 2008).

KEY TREATMENT

- Tobacco users attempting to quit should be prescribed one or more effective first-line pharmacotherapies for tobacco use cessation, including five nicotine replacement therapies (NRTs) (transdermal patch, gum, nasal spray, lozenges, or vapor inhaler) and non-nicotine replacement (bupropion SR or varenicline) (Eisenberg et al., 2008; Fiore et al., 2008) (SOR: A).
- Brief counseling (≤ 3 minutes) doubles the spontaneous quit rate; intensive therapy can be even more effective and should be used whenever possible (Fiore et al., 2008) (SOR: A).

Nicotine Patch

The nicotine patch is a mainstay of treatment, often combined with other short-acting forms of nicotine replacement therapy and counseling. The main advantages of the

Table 49-3 Clinical Guidelines for Nicotine Withdrawal

		Dosage
Nicotine patch	Patches should be applied as soon as patients waken on their quit day. At the start of each day, the patient should place a new patch on a relatively hairless location between the neck and waist. There should be no activity restrictions while using the patch. Treatment for 8 wk or less is as effective as longer treatment periods. New research indicates that starting the patch 2 wk before quit day increases success.	<i>Nicoderm, Habitrol</i> : 21 mg/24 hr for 4 wk; then 14 mg/24 hr for 2 wk; then 7 mg/24 hr for 2 wk. <i>Nicotrol</i> : 15 mg/16 hr for 4 wk; then 10 mg/16 hr for 2 wk; then 5 mg/16 hr for 2 wk. <i>ProStep</i> : 22 mg/24 hr for 4 wk; then 11 mg/24 hr for 4 wk.
Nicotine gum	Gum should be chewed slowly until a peppery taste emerges and then parked between the cheek and gum to facilitate nicotine absorption through the oral mucosa. The gum should be slowly and intermittently chewed and parked for about 30 minutes. Acidic beverages (e.g., coffee, juices, soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 5 minutes before and during chewing. Instructing patients to chew the gum on a fixed schedule may be more beneficial than ad lib use. Patients often do not use enough gum to obtain the maximum benefit.	<i>Nicorette</i> : Available as 2 mg and 4 mg per piece. Smokers of more than 1 pack a day, those who smoke within 30 minutes of awakening, and those with a history of severe withdrawal symptoms should use 4 mg; light smokers should use 2 mg. Chew one piece every 1-2 hr (at least 9/day) for 6 wk; then one piece every 2-4 hr for 3 wk; then one piece every 4-8 hr for 3 wk; then discontinue. For the 2-mg dose, do not exceed 30 pieces/day; for the 4-mg dose, 20 pieces/day.
Nicotine lozenge	Each lozenge is one 2- or 4-mg dose and should be dissolved in the mouth when the urge to smoke starts; lasts 20-30 minutes. Start with 4 mg if first cigarette is within 30 minutes of waking; others start with 2 mg. Use 9-20/day for up to 12 wk. No eating or drinking during use or 15 minutes before use. Side effects include sore teeth or gums, indigestion, throat irritation, and other symptoms similar to those with nicotine gum.	<i>Commit lozenge</i> : 2 mg and 4 mg per piece. Smokers of more than 1 pack a day who smoke within 30 minutes of waking and those with prior history of severe withdrawal should use the 4-mg form. Light smokers should start with the 2-mg strength. Do not swallow, bite, or chew the lozenge.
Nicotine inhaler	Local irritation in the mouth and throat occurs in 40% of patients. Coughing and rhinitis are also common. The severity and frequency of these symptoms decline with continued use. In cold weather, the inhaler and cartridges should be kept in an inside pocket or warm area because nicotine delivery declines significantly at temperatures below 40°F (4.4°C).	<i>Nicotrol inhaler</i> : 10 mg/cartridge (4 mg delivered and 2 mg absorbed). Each cartridge lasts about 20 minutes with frequent puffing and is equivalent to about two cigarettes. Use 6-16 cartridges/day for the first 12 wk; then reduce gradually over 12 wk.
Nicotine nasal spray	Moderate nasal irritation for first 3 wk or longer. Nasal congestion and transient changes in sense of smell and taste may also occur. Should not be used in patients with severe reactive airway disease. Do not sniff, swallow, or inhale through nose while administering doses. Deliver with head tilted slightly back.	<i>Nicotrol NS</i> : One spray (0.5 mg) to each nostril (1.0 mg total). Use 1-2 doses/hr and 8-40 doses/day (maximum, 5 doses/hr). Each bottle contains 100 doses. Usual maximum, 12 wk.
Bupropion SR	Contraindicated in patients with a history of significant head trauma, seizure disorder, or eating disorder and in those who have used a MAO inhibitor in the past 14 days. Side effects are insomnia and dry mouth. If insomnia is present, take the evening dose in the afternoon but at least 8 hours after the first dose.	150-mg tablets; one every morning for 3 days and then twice daily. Start 2 wk before the target quit date and continue for 12 wk.
Varenicline	Start 1 wk before quit date. Side effects are nausea (30% of patients), abnormal dreams, insomnia, headache, taste aversion, and flatulence. FDA warning addresses behavior changes and suicidal ideation.	<i>Chantix</i> : 0.5 mg (white tablet) once daily for 3 days; then twice daily for 4 days; then 1.0 mg (blue tablet) twice daily for a total of 12 wk.

FDA, Food and Drug Administration; MAO, monoamine oxidase.

*Some patients may prefer the nasal spray or inhaler because the more rapid delivery of nicotine better simulates smoking. Others may prefer bupropion because it is non-nicotine therapy. Bupropion should be considered especially in those with a history of depression.

Modified from U.S. Department of Health and Human Services. *Treating tobacco use and dependence: clinical practice update*. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service; 2008.

patch are consistent delivery, easy use, and concealment. The major disadvantage is insomnia, which can be avoided by not wearing the patch at night.

In a study by [Cornish and Gariti \(2002\)](#), by the second day of patch use, nicotine levels are about half or greater than those achieved by smoking. Quit rates at 4 to 8 weeks (depending on the study) are about double the rate of success for placebo—that is, up to 70% for the nicotine patch versus up to 40% for placebo. After 1 year, the abstinence rates are about 25% for the gum and patch compared with 12% for placebo. The combination of a short-acting

form of NRT (gum, lozenge, nasal spray) added to the patch increases the odds of success because it helps control cravings and gives the smoker the ability to titrate the dose. Combination therapy is becoming the standard approach for most patients using NRT. Recent evidence also indicates that smokers who begin the patch 2 weeks before the quit date may double the rate of abstinence ([Rose et al., 2009](#)). When dosing the patch, it is common to use 1-mg replacement per cigarette smoked in a day. For heavy smokers, that might mean “double patching” for 2 packs a day. High-dose patch therapy is not universally accepted, however, and

there is less robust evidence for its routine use (Dale et al., 2000; Fiore et al., 2008).

Nicotine Gum

To obtain maximal results, the gum must be chewed slowly and then parked between cheek and gum to allow for buccal absorption. Although 2-mg and 4-mg strengths are available, the 4-mg strength is recommended for patients who smoke more than one pack a day. Absorption is decreased if the mouth is acidic, so the patient should avoid beverages such as coffee, tea, soda, and fruit juice. Abstinence rates at 4 to 6 weeks are 73% for nicotine gum compared with 49% for placebo gum. The duration of treatment, as with other NRT, should be at least 6 weeks, although a Cochrane review did not find evidence of enhanced success for the patch beyond 8 weeks (Stead et al., 2007). The gum is most useful when used in combination with the patch.

Nicotine Inhaler and Nasal Spray

The nicotine inhaler resembles a cigarette and mimics the act of smoking, thus permitting perpetuation of a behavioral ritual, but the nicotine is absorbed through the buccal mucosa rather than the lungs. Its efficacy is similar to that of the patch. The nicotine nasal spray is more rapidly absorbed than the other forms of NRT and should be a first-line treatment for heavier smokers. As monotherapy, the nasal spray has a higher odds ratio for success than the other NRTs used alone (Fiore et al., 2008).

Nicotine Lozenges

Nicotine lozenges deliver slightly more available nicotine than nicotine gum, are easier to use, and have fewer gastric side effects. The lozenge comes in several flavors and should be sucked like candy, slowly, until the flavor becomes intense. It is then held between the cheek and gums, similar to nicotine gum, and sucked again after the flavor has diminished. It should not be chewed or swallowed. The 4-mg strength lozenge should be used for those whose first cigarette is within 30 minutes of waking, with the 2-mg strength used for lighter smokers. Smokers should use seven or eight lozenges or more per day, up to 20. Although slightly more effective than gum as monotherapy, lozenges are most effective in combination with the patch.

Bupropion

Bupropion is a monocyclic antidepressant, thought to inhibit the reuptake of both dopamine and norepinephrine. It may exert multiple mechanisms, producing craving relief from dopaminergic activity, and antagonism of nicotinic acetylcholine receptors. The U.S. PHS guidelines and other analyses show that bupropion doubles long-term abstinence compared with placebo (Eisenberg et al., 2008; Fiore et al., 2008). Dosing begins 1 week before the quit date: 150 mg for 3 days and then 150 mg twice daily for the remainder of the week until quit day, with long-term maintenance at that dose. Bupropion may also be effective in relapse prevention, although a Cochrane review questions that conclusion (Hajek et al., 2008). Bupropion carries a small risk of seizures, as with other antidepressants, and is contraindicated in patients with a significant history of head trauma, eating disorders, or seizure disorders. Bupropion is effective in delaying weight gain

Table 49-4 Recommended Dosages for Nicotine Replacement Therapy

associated with smoking cessation. The FDA has issued a black box warning for both bupropion and varenicline, highlighting the risk of serious mental health events, including changes in behavior, depressed mood, hostility, agitation, suicidal thoughts, and attempted suicide.

Combination Therapy. Just as long-acting and short-acting NRT can be combined to augment cessation success, bupropion can be used with the patch or other forms of NRT. Combination therapy appears to be a promising approach. A 9-week study combining bupropion SR with transdermal nicotine found much greater efficacy than with either medication alone (Jorenby et al., 1999), and subsequent review in the PHS guidelines confirms the utility of combination therapy (Fiore et al., 2008). One might think of bupropion or the patch as the “controller” medication and the short-acting NRT as the “rescue” drug, much as dual therapy is used in asthma control. A trial of “triple therapy” using the patch, bupropion, and the nicotine vapor inhaler for up to 6 months showed a 2.57 odds ratio for abstinence compared with the patch alone (Steinberg et al., 2009).

Clinicians at the Mayo Clinic Nicotine Dependence Center have routinely used combination therapy and base initial NRT patch dosing on venous cotinine levels. If that is not available, the intensity of smoking or spit tobacco use can be a useful guide (Table 49-4) (Dale et al., 2000).

Varenicline

Varenicline is a partial agonist and antagonist that is selectively bound to the $\alpha 4\beta 2$ nicotinic receptors, thus blocking nicotine from these brain cells, as well as stimulating them to release dopamine at lower levels than does nicotine itself. This leads to reduced cravings and fewer symptoms of nicotine withdrawal. A Cochrane review of its effectiveness concludes that it increases the odds of successful cessation two to three times more than attempts not using pharmacotherapy, with a pooled RR at 1 year compared with bupropion of 1.52 (Cahill et al., 2008). Varenicline is titrated over 1 week, mainly to help overcome its major side effect of nausea, ameliorated by taking varenicline with meals. Begin with 0.5 mg daily for 3 days, then 0.5 mg twice daily, and then 1 mg twice daily on day 8, which is quit day for the patient. Treatment should continue for at least 12 weeks; an additional 12 weeks may be useful in patients who are insecure in their attempts and are at high risk for relapse. The longer dosing schedule was shown to increase success in clinical trials.

Concern has been raised about varenicline and its potential to cause behavior changes and suicidal thoughts. In July 2009, the FDA issued a black box warning for both

varenicline and bupropion, saying that patients taking either of these drugs should be observed for symptoms of behavior change, including hostility, aggression, depressed mood, and suicidal ideation or attempts. Patients should stop taking varenicline and contact their physicians if these or other unusual neuropsychiatric symptoms occur. In addition, patients should take precautions when driving or operating machinery until they know whether varenicline might adversely affect them. Pilots, air traffic controllers, and persons with commercial motor vehicle licenses cannot use varenicline, according to federal rules issued in 2008. A cohort study of more than 80,000 persons using different medications for smoking cessation, however, found no clear evidence that varenicline caused suicide or depression (Gunnell et al., 2009). The most recent study of varenicline and depression was a multicenter, double-blind, randomized trial of 525 persons with stable, treated depression or a history of depression. Varenicline had a significant cessation effect vs placebo (35.9% vs 15.6% continuous abstinence; OR, 3.35) with no differences between groups of suicidal symptoms or exacerbation of depression (Anthenelli et al., 2013).

Early evidence shows that using varenicline in combination with the nicotine patch and with bupropion appears to be safe and well tolerated; however, more investigation is needed before these combinations become a mainstay of smoking-cessation therapy (Ebbert et al., 2009a, 2009b).

Second-Line Medications

Clonidine and nortriptyline are listed in the PHS guidelines as second-line drugs, and both have been shown to have significant effects on cessation compared with placebo (Fiore et al., 2008). Nortriptyline is generally titrated up to 75 to 100 mg/day and used for 8 to 12 weeks. It has the advantage of being quite inexpensive, but drug levels may be needed to avoid toxicity. Clonidine patches, 0.2 mg/day, are recommended for up to 10 weeks and should be started 1 week before the quit date. Clonidine's side effects of drowsiness may limit its usefulness in many patients. Neither is FDA approved for smoking cessation.

Quit Lines

One of the least used methods, yet one of the most effective, is telephone quit lines. Surveys have shown that 70% to 85% of smokers prefer to use a quit line to seeing a clinician, perhaps because of the convenience, anonymity, and ability to obtain counseling in their native language. The toll-free number, 800-QUIT-NOW (800-784-8669), is a single access point to the National Network of Tobacco Cessation Quit Lines. Callers are automatically routed to a state-run quit line, if one exists in their area. If there is no state-run line, callers are routed to the NCI's quit line, where they may receive cessation services and other information. Quit lines are available in almost every state (Schroeder, 2005). There is also a California Smoker's Helpline at 800-662-8887, which links people nationwide to counselors who will give one-to-one support. Quit lines are even more effective when combined with NRT (Bush et al., 2008).

Relapse Prevention

Perhaps the most poorly understood element in smoking cessation is preventing relapse. Follow-up and ongoing

contact with patients is essential, especially in the first few weeks of a cessation attempt. The first 2 weeks are the most crucial period, when smoking even one cigarette is a strong predictor of a return to regular smoking within 1 year. A return visit, proactive telephone call, or regular sessions with a quit line counselor in the early stages of cessation should be integrated into the patient's treatment. To be truly successful, family physicians should integrate tobacco dependence treatment into their practice (Solberg, 2000). The AAFP has created a toolkit that can be downloaded for this aim, called "Office Champions" (see Web Resources). A Cochrane review on relapse prevention found that although no definitive evidence yet exists for specific interventions to sustain abstinence, efforts to help smokers identify and deal with "tempting situations" show promise (Hajek et al., 2008). However, an excellent series of materials for patients is available from the NCI's website and may be very useful in helping patients with discussions of relapse issues ("Forever Free" at <http://www.smokefree.gov/resources.aspx>).

Current Developments

SMOKING AND GENETICS

Genetics plays a key role in a variety of issues related to tobacco dependence. Recent research has included the molecular basis for nicotine dependence, genetic influences on the family of nicotine receptors, genetic influences on tobacco-related cancer and heart disease, and treatment issues.

Genetic testing may be able to indicate persons most susceptible to becoming addicted to nicotine. Addictive individuals who have a particular gene and are trying to quit may be more responsive to nicotine patches than non-nicotine measures such as bupropion (Zyban). Multiple genes are involved, however, and considerable research will be needed to create practical applications for these discoveries.

Much work is currently underway regarding genes and gene mutations that predispose cigarette smokers to lung cancer. *Gene methylation* is a chemical modification that may be a marker for the early detection of lung cancer. The gene *GPC5* has an important tumor suppressor-like function that, if insufficient, can promote lung cancer development. A variant of this gene has been found in one third of nonsmokers who develop lung cancer (Yafei, 2010).

Scope of the Problem

Key Points

- Approximately 9.2% of the U.S. population age 12 years or older, or an estimated 23.9 million Americans, reported being current users of illicit drugs in 2012.
- The prevalence of current illicit drug use is greatest in those 18 to 20 years of age, with a rate of 23.9%.
- Marijuana is the most frequently used illicit drug in the United States, and its use is increasing.
- Medical emergencies related to nonmedical use of pharmaceuticals have increased 132% between 2004 and 2011.
- In 2013, the diagnoses of substance use disorder (SUD), mild, moderate, or severe in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5) replaced the diagnoses of substance abuse and dependence from the DSM IV.

According to the [2012 Substance Abuse and Mental Health Services Administration \(SAMHSA\) National Survey on Drug Use and Health \(SAMHSA, 2012\)](#), an estimated 23.9 million Americans age 12 years or older, or 9.2% of the population, were current users of illicit drugs or reported having used an illicit substance 1 month before the survey. This rate is slightly higher than reported rates of illicit substance use of 7.9% to 8.3% between the survey years of 2002 and 2008. With an estimated 18.9 million current users, or 7.2% of the population age 12 years and older, marijuana was the most frequently used illicit drug and increased from 5.8% in 2007. Among people who used illicit drugs, marijuana was used by an estimated 79.0%, with many reporting daily or almost daily use. Following marijuana was nonmedical use of prescription psychotherapeutic drugs such as narcotic pain relievers or sedatives (6.8 million), cocaine (1.6 million), hallucinogens (1.1 million), methamphetamine (440,000), and heroin (335,000).

Individuals age 18 to 20 years, or 23.9%, have the highest rate of illicit drug use. The next highest rate, of 19.7%, was seen in individuals between 21 and 25 years of age. Rates of illicit drug use among youths age 12 to 17 years was approximately 9.5% in 2012.

The rate of substance use for boys and men age 12 years and older was almost twice as high as that for girls and women (11.6% vs. 6.9%). In general, men are much more likely to be current users of marijuana (9.6% vs. 5.0%), cocaine (1.0% vs. 0.3%), and hallucinogens (0.6% vs. 0.3%) compared with women. However, men and women have similar rates of nonmedical use of psychotherapeutic drugs, pain relievers, stimulants, and sedatives (2.8% vs. 2.4%).

The prevalence of illicit drug use varies by race and ethnicity. The rate of illicit substance use has been found to be highest among people reporting two or more races, at 14.8%. An estimated 12.7% of American Indians or Alaska Natives, 11.3% of blacks, 9.2% of whites, 8.3% of Hispanics, 7.8% of Native Hawaiians or other Pacific Islanders, and 3.7% of Asians were current illicit drug users in 2012. Illicit drug use also varies by education level. Among adults age 18 years or older, the prevalence of current illicit drug use was greatest among adults who did not complete high school, at a rate of 11.1%. The rate dropped to 6.6% in college graduates.

In 2012, an estimated 7900 people used an illicit substance for the first time each day. Most initiates were female and younger than 18. Of the estimated 2.9 million people age 12 years or older who used illicit drugs for the first time in 2012, approximately 65.6% of these individuals first used marijuana. Another 26% initiate illicit drug use by taking prescription drugs such as pain relievers in a non-medical manner. The most recent Drug Abuse Warning Network (DAWN) 2011 national estimates of drug-related emergency department (ED) visits reveal that there were more than 2.5 million ED visits related to drug misuse or abuse, or an approximate rate of 790 ED visits per 100,000 people (DAWN, 2011). The most frequent reasons for ED visits related to drug misuse or abuse involved cocaine intoxication, marijuana intoxication, and nonmedical use of pharmaceuticals such as narcotic pain relievers.

Approximately 18.1% of unemployed individuals age 18 years and older were current illicit drug users. This was significantly higher than the prevalence of current drug use among individuals employed full time (8.9%) and part time (12.5%).

The prevalence of substance abuse was also significantly higher among individuals with serious mental illness. The most recent available analysis comparing prevalence of illicit substance use among individuals with comorbid

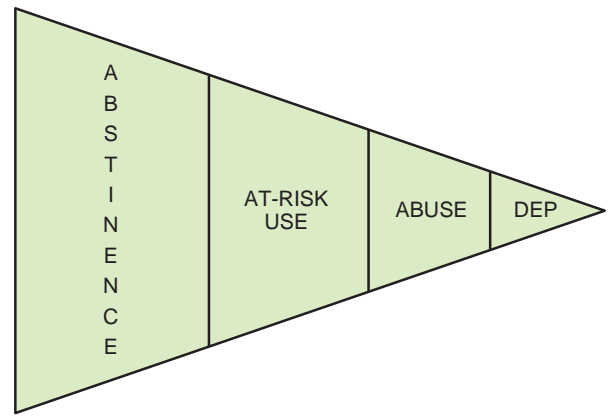

Figure 50-1 Continuum of drug use in patients with substance use disorders. *DEP*, Dependence. (Modified from Brown, RL Module III: Screening and Assessment, Project MAINSTREAM Syllabus Interdisciplinary Faculty Development Program in Substance Abuse Education, October 2005, last accessed from <http://www.amersa.org/mainstream.asp> 11/19/2014.)

serious mental illness comes from the 2011 National Survey on Drug Use and Health, which showed the rate of illicit drug use in the past year among adults age 18 years or older with serious mental illness was 25.2%, compared with a rate of 11.8% among same-age adults without serious mental illness.

TERMINOLOGY

The term *substance use disorder* implies a continuum of use, from abstinence to at-risk use to abuse and dependence (Figure 50-1). The majority of the general population, as well as family medicine patients, are “abstainers.” The majority of users of illicit substances do not meet criteria for the diagnosis of an SUD. This model of substance use is important for family medicine physicians to keep in mind as they talk with their patients about substance use issues. It highlights the key role played by screening for substance use and early intervention at the at-risk use level before specialized treatment services are more likely needed.

The updated terminology of SUD diagnoses and criteria in the DSM-5 reflects this continuum as well. Table 50-1 lists the DSM-5 diagnostic criteria for SUDs, mild, moderate, and severe. Table 50-2 lists the older DSM-IV diagnostic criteria for substance abuse and dependence for reference because these terms are still frequently used in patient care settings and the medical literature. Other key changes with the DSM-5 are the inclusion of cravings in the diagnostic criteria, elimination of legal problems as a criterion, and the addition of a cannabis withdrawal diagnosis. DSM-IV abuse and dependence and DSM-5 SUD moderate and severe diagnoses for several substances have shown good correlation (Compton et al., 2013). The clinical significance in terms of appropriateness of current treatments developed for DSM-IV abuse and dependence diagnoses for DSM-5 mild SUDs remains as yet unclear.

Table 50-3 shows some common drug street names. Comprehensive lists can be found on the Office of National Drug Control Policy’s website (<http://www.whitehousedrugpolicy.gov>). Street names vary by region

Table 50-1 DSM-5 Diagnostic Criteria for Substance Use Disorders

Substances	Cannabis, hallucinogens (PCP or similarly acting arylcyclohexylamines), other hallucinogens such as LSD, inhalants, opioids, sedatives, hypnotics, anxiolytics, stimulants (including amphetamine-type substances, cocaine, and other stimulants), and other or unknown substances
Criteria	Mild if two or three of the following for at least 1 year, moderate if four or five, and severe if six or more <ol style="list-style-type: none"> 1. Taking the substance in larger amounts or for longer than you meant to 2. Wanting to cut down or stop using the substance but not managing to 3. Spending a lot of time getting, using, or recovering from use of the substance 4. Cravings and urges to use the substance 5. Not managing to do what you should at work, home, or school because of substance use 6. Continuing to use even when it causes problems in relationships 7. Giving up important social, occupational, or recreational activities because of substance use 8. Using substances again and again even when it puts you in danger 9. Continuing to use even when you know you have a physical or psychological problem that could have been caused or made worse by the substance 10. Needing more of the substance to get the effect you want (tolerance) 11. Development of withdrawal symptoms, which can be relieved by taking more of the substance
Modifiers	<ol style="list-style-type: none"> 1. “In early remission”: no criteria except craving for 3 to 12 months 2. “In sustained remission”: no criteria except craving for at least 12 months 3. “On maintenance therapy”: e.g., with methadone or buprenorphine containing medications 4. “in a controlled environment”: e.g., incarcerated, in residential-based treatment

DSM-5, Diagnostic and Statistical Manual of Mental Disorders, 5th edition; LSD, lysergic acid diethylamide; PCP, phencyclidine. Adapted from American Psychiatric Association. Diagnostic and statistical manual of mental disorders. 5th ed. Arlington, VA: American Psychiatric Association; 2013.

Table 50-2 Diagnostic Criteria for Substance Abuse and Dependence (DSM-IV)

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by:

Abuse	One or more of the following, occurring in a 12-month period, and these symptoms have never met the criteria for substance dependence: <ol style="list-style-type: none"> 1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home 2. Recurrent substance use in situations in which it is physically hazardous 3. Recurrent substance-related legal problems 4. Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
Dependence	Three or more of the following, occurring in the same 12-month period: <ol style="list-style-type: none"> 1. <i>Tolerance</i>, as defined by either of the following: a need for markedly increased amounts of the substance to achieve intoxication or desired effect or markedly diminished effect with continued use of the same amount of substance. 2. <i>Withdrawal</i>, as manifested by either of the following: the characteristic withdrawal syndrome for the substance or the same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms. 3. The substance is often taken in larger amounts or longer than intended. 4. There is a persistent desire or unsuccessful efforts to cut down or control substance use. 5. A great deal of time is spent in activities to obtain the substance, use the substance, or recover from its effects. 6. Important social, occupational, or recreational activities are given up or reduced because of substance use. 7. The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.

and user group. The most useful information is obtained on the local level simply by asking patients what they call the drug they are using.

Screening

Key Point

- A single-question screen for drug use, comparable in sensitivity and specificity to the four-question CAGE-Adjusted to Include Drugs (CAGE-AID), has been validated for primary care: "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" An answer of one or more is a positive screen.

Table 50-3 Common Drug Street Names

Substance	Street Names (NIDA website)	
Benzodiazepines	Candy, downers, sleeping pills, sticks, handlebars	
Cocaine	Blow, bump, C, candy, coke, crack, flake, rock, snow	
Codeine	Captain Cody, school boy, pancakes and syrup	
Dextromethorphan	Robotripping, Robo, Triple C	
Flunitrazepam (Rohypnol)	Roofies, rope, rophies, forget-me pill, Mexican Valium	
GHB	Liquid ecstasy, Georgia home boy, grievous bodily harm	
Heroin	Brown sugar, dope, H, horse, junk, skag, skunk, smack	
Ketamine	K, special K, vitamin K, cat Valiums	
LSD	Acid, blotter, boomers, cubes, microdot	
Marijuana	Blunt, dope, ganja, grass, herb, joints, pot, reefer, weed	
MDMA	Adam, clarity, ecstasy, Eve, lover's speed, Molly, peace, X	
Methamphetamine	Chalk, rank, crystal, fire, glass, go fast, ice, meth, speed	
Methylphenidate	Skippy, vitamin R, the smart drug, R-ball	
Oxycodone (OxyContin), hydrocodone (Vicodin)	Oxy, OC, killer, vike	
PCP	Angel dust, boat, hog, love boat, peace pill	

GHB, γ -Hydroxybutyrate; LSD, lysergic acid diethylamide; MDMA, methylenedioxymethamphetamine; NIDA, National Institute on Drug Abuse; PCP, phencyclidine.

Screening, brief intervention, and referral to treatment (SBIRT) for alcohol use disorders in primary care has been well studied and is recommended for incorporation into routine primary care by the U.S. Preventive Services Task Force (USPSTE, 2008; SOR B). However, SBIRT in primary care for drug use has been less studied to date, and the USPSTF states that there is currently insufficient evidence to recommend for or against routine screening for drug use in primary care.

With the recent increase in prescription drug misuse, interest in drug use SBIRT incorporation into primary care has broadened and is being studied for efficacy (Insight Project, 2009). Limitations on drug use SBIRT in primary care include lower prevalence of drug use in primary care patients compared with alcohol use as well as concerns about the practicality of use and positive predictive value (PPV) of available screening instruments in the primary care setting. The American Academy of Pediatrics, Bright Future Initiative, and American Medical Association Guidelines for Adolescent Preventative Services all recommend at least annual screening of adolescents for drug use. The American College of Obstetricians and Gynecologists advocates regular, periodic screening for all patients, regardless of pregnancy status, although no specific screening instrument is recommended and, to date, no screening instrument has been validated for pregnant women (Lanier and Ko, 2008). Common validated screening instruments for drug use are briefly discussed later.

The CRAFFT is the only screening instrument validated for adolescents and has shown an 83% PPV (Table 50-4). It screens for alcohol as well as drug use (Knight et al., 2002).

The ASSIST, CAGE-AID, and Drug Abuse Screening Test (DAST) have been validated in nonpregnant adults. PPVs for the Alcohol, Smoking and Substance Involvement Screening Test (ASSIST) are not currently available (Newcombe et al., 2005). It screens for tobacco and alcohol in addition to drugs. The ASSIST is available at no cost from the World Health Organization.

Table 50-4 CRAFFT Screening Tool for Adolescents

CRAFFT	Question
Car	Have you ever ridden in a <i>car</i> driven by someone (including yourself) who was “high” or had been using alcohol or drugs?
Relax	Do you ever use alcohol or drugs to <i>relax</i> , feel better about yourself, or fit in?
Alone	Do you ever use alcohol or drugs while you are by yourself, or <i>alone</i> ?
Forget	Do you ever <i>forget</i> things you did while using alcohol or drugs?
Friends	Do family members or <i>friends</i> ever tell you that you should cut down on your drinking or drug use?
Trouble	Have you ever gotten into <i>trouble</i> while you were using alcohol or drugs?

Scoring:

A “no” response = 0 points; a “yes” response = 1 point.

0-1 point = negative screen.

2-6 points = positive screen; consider a safety contract for “yes” response to “car” question regardless of total score.

The CAGE-AID has shown 12% to 78% PPV, with PPV increasing with increasing prevalence of drug use in the study population (Brown and Rounds, 1995). It screens for both alcohol and drug use (see eTable 50-1 online).

The DAST has similarly shown a wide PPV range of 23% to 75% and is also in the public domain. It screens for drug use only (Staley and El-Guebaly, 1990).

The ASSIST and DAST are more lengthy screens than the CAGE-AID and CRAFFT and consequently have not been reproduced here. The SAMHSA SBIRT initiative recommends both the ASSIST and the DAST for drug screening (Lanier and Ko, 2008). SBIRT models vary but typically involve a brief screen of several questions regarding tobacco, alcohol, or drug use conducted by frontline staff. A single-question screen for drug use has been validated for primary care: “How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?” An answer of one or more is a positive screening response (Smith et al., 2010). With sensitivity of 100% and specificity of 73.5%, this single-question screen is comparable to the four-question CAGE-AID.

Patients screening positive receive more in-depth screening with a self-administered or provider-administered screening instrument, such as the DAST or ASSIST, which both allow for stratification of each patient along the SUD continuum. The physician then scores the formal screen and reviews the results with the patient. Patients screening negative are given brief feedback about the results of their screen, and their healthy choices regarding substance use are reinforced by the physician. Patients screening positive for at-risk use but who do not meet criteria for an SUD receive a brief intervention, often using the FRAMES model (Table 50-5) or the “five A’s” model (Table 50-6). Both are useful for patients receptive to change. Motivational interviewing techniques may be more useful than the FRAMES or five A’s for patients who are more ambivalent about change (Searight, 2009).

Patients screening positive and meeting criteria for an SUD are offered referral to onsite or, more typically, community drug treatment programs. Referral to treatment can be time consuming and therefore is often done by ancillary staff with knowledge of local treatment resources or by referring the patient to a community-based agency that provides treatment-matching services.

Table 50-5 FRAMES Intervention Technique

Feedback about personal risk
 Responsibility of the patient for change
 Advice to change
 Menu of strategies
 Empathy: express empathy
 Self-efficacy: elicit and support patient’s self-efficacy for change

Table 50-6 Five “A’s” Intervention Technique

Assess the risk of the behavior for the patient.
 Advise the patient on his or her risk and how to modify it.
 Agree: come to an agreement with the patient on treatment.
 Assist the patient with the treatment plan.
 Arrange follow-up or referral to treatment.

eTable 50-1 CAGE-AID Screening Tool for Adults

CAGE	Question
Cut down	Have you felt you ought to <i>cut down</i> on your drinking or drug use?
Annoyed	Have people <i>annoyed</i> you by criticizing your drinking or drug use?
Guilty	Have you felt bad or <i>guilty</i> about your drinking or drug use?
Eye opener	Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (<i>eye opener</i>)?

Scoring:

A “no” response = 0 points; a “yes” response = 1 point.

0-1 point = negative screen.

2-4 points = positive screen.

Laboratory Testing

Key Points

Any drug testing method involves several important considerations:

- Samples can be adulterated to mask true results; creatinine, pH, specific gravity, and temperature are often used to detect urine sample adulteration.
- A single test result is a marker of use at one point in time and does not itself make a diagnosis of an SUD; laboratory detection of drug use is one tool that may be used during screening, diagnosis, treatment, and relapse prevention of SUDs.
- Rates of false positives and false negatives depend on the drug ingested, quantity ingested, duration of use, and specific laboratory cutoffs used; it is important to know the cutoff values of the laboratory used and to obtain a comprehensive history of drug ingestion quantity and frequency over time.

Laboratory testing is frequently used in SUD screening, treatment, and monitoring for relapse. The most common testing method is the *urine drug test*. Other options include blood, sweat, hair, and oral fluid testing. [Table 50-7](#) lists

the advantages and disadvantages of each method ([Ries et al., 2009](#)).

[Table 50-8](#) details typical detection times and causes of false-positive results for drugs that can be detected by readily available urine drug testing. Most urine drug tests use immunoassays because these are inexpensive, fast, and easily automated. Gas chromatography with mass spectroscopy is typically reserved for confirmation of a positive result. Methadone is not a part of most urine drug screen panels and does not show as a positive opiate test result. Separate testing for methadone is available. Separate testing is also needed for most “club drugs,” including 3,4-methylenedioxymethamphetamine (MDMA), ketamine, and γ -hydroxybutyrate (GHB). Benzodiazepines have a wide range of potencies, half-lives, and metabolites, which makes urine drug screen results less reliable ([Ries et al., 2009](#)).

Pharmacology

COCAINE

Cocaine is a powerful and highly addictive stimulant derived from the leaf extract of the *Erythroxylon coca* bush. In 2012, there were an estimated 1.6 million current users of cocaine, or 0.6% of the U.S. population. Cocaine use is highest among individuals 18 to 25 years of age.

Table 50-7 Drug-Testing Methods: Advantages and Disadvantages

Test	Advantages	Disadvantages
Blood	Difficult to adulterate; detects very recent ingestion	Invasive; drugs clear blood more quickly after ingestion than urine
Hair	Noninvasive; difficult to adulterate; detects patterns of use over time; frequently used in forensics and research	Not useful for recent ingestion; more difficult to process than other methods
Oral fluids	Noninvasive; direct observation easy and makes adulteration more difficult; detects recent ingestion; rapid results	Unintentional contamination from recently ingested substances; drugs clear quickly after ingestion (see “Urine”)
Sweat	Noninvasive; uses patch for collection; monitors for use over extended period	Quantification of drug levels difficult
Urine	Noninvasive; rapid results; relatively inexpensive vs. other methods	Easy to adulterate sample, even when observed collection method used

Table 50-8 Urine Drug Testing: Detection Times and Drugs Causing False Positives

Drug	Detection Time	False-Positive Result
Amphetamines, methamphetamine	1-3 days	Bupropion, chloroquine, chlorpromazine, ephedrine, labetalol, phenylpropanolamine, propranolol, pseudoephedrine, ranitidine, selegiline, trazodone, tyramine, Vick’s inhaler
Barbiturates	Short acting: 1-4 days Long acting: several weeks	Phenytoin
Benzodiazepines	Highly variable	Oxaprozin, sertraline
Cocaine	3 days	None
LSD	2-5 days	Amitriptyline, chlorpromazine, doxepin, fluoxetine, haloperidol, metoclopramide, risperidone, sertraline, thioridazine, verapamil
Marijuana (THC)	Single joint: 2 days Heavy use: 27 days	Efavirenz, pantoprazole
Methadone	2-3 days	Quetiapine
Opiates	1-2 days	Gatifloxacin, levofloxacin, ofloxacin, papaverine, rifampicin, poppy seeds
PCP	7 days	Dextromethorphan, diphenylhydramine, thioridazine, venlafaxine
Propoxyphene	6 hours to 2 days	Cyclobenzaprine, diphenylhydramine, doxylamine, imipramine, methadone

LSD, Lysergic acid diethylamide; PCP, phencyclidine; THC, delta-9-tetrahydrocannabinol.

Cocaine causes a brief, intense feeling of euphoria by blocking the reuptake of dopamine, a neurotransmitter that is associated with pleasure and movement. This blockade accordingly increases the level of dopamine in the central nervous system (CNS). The more rapidly cocaine is absorbed into the bloodstream and delivered to the CNS, the more intense the “high” experienced by the user. Cocaine can be inhaled, injected, or smoked. Injecting or smoking cocaine produces an intense, 5- or 10-minute high that is much stronger than the sensation produced by snorting powder cocaine. The euphoria induced by snorting powder cocaine typically lasts 15 to 30 minutes but is slower in onset than injecting or smoking cocaine. Small amounts of cocaine give users feelings of euphoria, increased mental alertness, and energy.

Symptoms of cocaine intoxication include euphoria, agitation, impaired judgment, bizarre behavior, paranoia, tachycardia, elevated blood pressure, dilated pupils, and diaphoresis. Increased doses of cocaine cause some cocaine users to experience auditory hallucinations, tactile hallucinations, delusions, and aggressive behavior. Sudden cardiac arrest, seizures, and respiratory arrest are examples of fatal complications from cocaine overdose. Tolerance to cocaine causes addicts to binge on cocaine or take more cocaine at increasingly frequent intervals. Withdrawal from cocaine begins with a “crash,” or excessive sleep. After 1 to 2 days, the user may feel anxious, irritated, fatigued, and depressed from the absence of cocaine and decreased dopamine levels, which can also cause intense cravings, depression, and suicidal ideation.

Although cocaine has legitimate medical uses, such as local anesthesia in eye, ear, and throat surgery, nonmedical use and importation were banned by the Harrison Act in December 1914.

MARIJUANA

Derived from a mix of flowers, stems, seeds, and leaves of the plant *Cannabis sativa*, marijuana is the most commonly abused illicit drug in the United States. Marijuana is classified as an illicit drug under federal law, and thus in national drug surveys; however, 20 states and the District of Columbia have passed legislation legalizing at least some form of marijuana use for medicinal purposes. In 2013, two states, Colorado and Washington, legalized recreational use of marijuana as well.

Nerve cells in the brain have receptors for THC (delta-9-tetrahydrocannabinol), the main active chemical in marijuana. After the drug enters the brain, THC causes the release of dopamine and produces feelings of euphoria. Smoking marijuana can produce a high that lasts 1 to 3 hours. Ingesting marijuana that has been mixed with food or brewed with tea can cause a longer high that lasts up to 4 hours. While high on marijuana, users may experience pleasant feelings, a feeling that time passes more slowly, and perceptions of heightened sensation with color and sound stimuli. Marijuana users may also have sudden hunger, thirst, and feelings of paranoia and anxiety. As the euphoria passes, marijuana users may feel depressed or sleepy. Long-term marijuana use can cause damage to short-term memory by altering the manner in which information is processed in the hippocampus.

Marijuana use can also cause respiratory problems such as chronic cough, recurrent lung infections, and lung cancer. The DSM-5 has added a diagnosis of cannabis withdrawal, defined as marijuana cessation in heavy, long-term users resulting in clinically significant distress or social, occupational, or other important functional impairment due to at least three withdrawal symptoms. There is currently no medication approved by the U.S. Food and Drug Administration (FDA) for the treatment of cannabis withdrawal, although studies are ongoing for several promising candidates, including gabapentin (Mason, et al., 2012).

METHAMPHETAMINE

Methamphetamine is a highly addictive stimulant that can cause increased alertness and increased physical activity with small doses by causing the release of high levels of the neurotransmitter dopamine in the brain. Abusers of methamphetamine experience a brief “rush” by smoking or injecting methamphetamine. Oral ingestion or snorting methamphetamine can produce a high that can last approximately half a day. Because of tolerance, chronic users of methamphetamine may take higher doses of the drug or binge for several days. Long-term use of methamphetamine can cause functional and molecular changes to the brain. Chronic methamphetamine users may exhibit anxiety, violent behavior, and symptoms of psychosis (e.g., hallucinations, paranoia, delusions). Fortunately, the use of methamphetamine in the United States has been decreasing. In 2012, there were approximately 440,000 users of methamphetamine.

HALLUCINOGENS

Hallucinogens alter mood and perception. Commonly abused hallucinogens include lysergic acid diethylamide (LSD), phencyclidine (PCP), MDMA, and hallucinogenic mushrooms. In 2012, there were 1.1 million current users of hallucinogens in the United States; use increased among youths age 12 to 17 years. LSD is sold as tablets, capsules, or liquids. It is often added to absorbent paper and dosed in small, decorated squares. Users of LSD experience unpredictable sensations of sound, color, hallucinations, and delusions. Long-term consequences of LSD usage include flashbacks, depression, and long-lasting psychosis. Users of PCP may smoke, ingest, inject, or snort it to experience hallucinations. PCP use may cause violent behavior, anxiety, and paranoia.

“CLUB DRUGS”

Ketamine, MDMA, GHB, and flunitrazepam (Rohypnol) are substances used in nightclubs, “raves,” and dance parties to enhance feelings of intimacy and sensory stimulation. “Ecstasy,” or MDMA, produces distorted perceptions of time, enhanced enjoyment of tactile sensations, and feelings of increased energy by increasing the release of serotonin, dopamine, and norepinephrine. MDMA is usually taken as a tablet or a capsule. The pure crystalline powder form of MDMA is often referred to as “Molly.” The sympathetic overload caused by MDMA can produce

hypertension, tachycardia, tremor, diaphoresis, and arrhythmias. MDMA intoxication is also associated with a potentially fatal serotonin syndrome that causes hyperthermia, autonomic instability, and myoclonus. Users of MDMA will typically experience severe depression 2 days after its ingestion.

Ketamine is a dissociative anesthetic derived from PCP. Usually stolen from veterinarian and physician offices, illicit supplies of ketamine are dried in powder form and smoked in nightclubs with tobacco and marijuana or inhaled. “Special K” can produce sensations of floating outside one’s body, visual hallucinations, and dreamlike states that last for 30 to 45 minutes after ingestion.

Gamma-hydroxybutyrate can cause euphoria at lower doses and drowsiness, dizziness, visual disturbances, hypotonia, and amnesia at higher doses. Overdoses of GHB can cause seizures, severe respiratory depression, coma, and death. Because of its sedative and amnesic effect, GHB has been used as a “date rape” drug.

Flunitrazepam (Rohypnol) is a powerful benzodiazepine with 10 times the strength of diazepam that is capable of reducing anxiety, muscle tension, and inhibition. Higher doses of flunitrazepam can produce lack of muscle control, loss of consciousness, and anterograde amnesia. As with GHB, flunitrazepam has been used as a “date rape” drug (Gahlinger, 2004).

Bath salts are synthetic cathinone derivatives. These derivatives have psychoactive properties similar to cocaine and MDMA. These white or brown powder drugs are usually sold at convenience stores, smoke shops, and online. Bath salts can be taken orally, inhaled via smoking or vaporization, or injected intravenously. Users can experience euphoric feelings, increased sex drive, along with paranoia, agitation, hallucinations, and violent behavior. In 2011, intoxication with bath salts either alone or in combination with other drugs accounted for 22,904 ED visits.

BENZODIAZEPINES

Benzodiazepines are a family of depressants used therapeutically to produce sedation, relieve anxiety, induce sleep, control seizures, and alleviate muscle spasms. Abusers of benzodiazepines experience reduced inhibition and impaired judgment. Users of cocaine and amphetamines may take benzodiazepines to counter the stimulant effects. Concurrent use of benzodiazepines with alcohol and other depressants can be life threatening. Abrupt cessation of benzodiazepine use can cause seizures and a withdrawal syndrome similar to delirium tremens.

OPIATES (NONMEDICAL USE OF PRESCRIPTION DRUGS)

Hydrocodone (Vicodin) is the most frequently prescribed opioid in the United States. Oxycodone (OxyContin) and hydrocodone are prescribed in the treatment of acute and chronic pain. Abusers of hydrocodone and oxycodone experience euphoria, relaxation, and sedation. Long-term use can result in tolerance. Abusers may overdose as they take increasing doses of the medication while pursuing euphoric sensations that they previously experienced. Overdoses may result in severe respiratory depression, hypotension, coma,

and death. Recently, methadone, primarily diverted from prescriptions for chronic pain and not methadone maintenance treatment, has been linked to increased opiate overdoses as well. Its relatively long onset of action and long half-life make methadone-naïve individuals more prone to overdose as they seek a stronger high with escalating doses, which accumulate, causing overdose. In 2011, there were 488,004 ED visits related to nonmedical use of prescription opioids.

HEROIN

Heroin, or diacetylmorphine, is a synthetic opiate, first created by Bayer in the late 1800s and marketed for pain relief and treatment of morphine addicts. It has a high abuse potential because of its rapid onset of action and short half-life. Heroin is therefore a Schedule I substance (i.e., not available for therapeutic use in the United States). The number of people that have used heroin in the past year has been increasing. In the 2012 SAMHSA National Survey on Drug Use and Health, an estimated 669,000 people used heroin within the last year. This increased use may be a consequence of the prescription drug epidemic as prescription drug users switch to heroin when tolerance to prescription opiates develops or when they are unable to gain access to prescription opiates. Heroin can be injected intravenously or subcutaneously (“skin popping”), snorted intranasally, as well as smoked in freebase form. Use of the intranasal route has greatly increased, along with the purity of street heroin and awareness of human immunodeficiency virus (HIV) infection risk associated with injecting. Heroin itself is an inactive prodrug with two active metabolites, one of which is morphine, and both of which are active at the μ -opioid receptor. After intravenous (IV) injection, users describe an intense rush within 1 to 2 minutes followed by a period of euphoric sedation lasting about 1 hour. In dependent users, withdrawal symptoms can begin within 4 to 6 hours (Ries et al., 2009).

Intoxication and Withdrawal

Signs and symptoms of intoxication and withdrawal and treatments are based on drug class. Generally, withdrawal symptoms are characterized by the opposite of intoxication, with their intensity inversely proportional to the duration of action of the drug and proportional to chronicity of use. Symptom onset is proportional to the half-life of the drug.

Treatment of intoxication for most substances is supportive and symptomatic and typically occurs in inpatient settings. Receptor antagonists are available for both opiate and benzodiazepine intoxication, with use reserved primarily for the overdose state. Treatment of withdrawal usually follows one of two principles: (1) substituting a longer-acting, less reinforcing equivalent and then tapering or (2) symptom control. Withdrawal treatment may occur in the inpatient or outpatient setting depending on the severity of the withdrawal anticipated, the underlying mental and physical health issues of the patient, and the level of support available to the patient in the outpatient setting.

OPIATES

Intoxication with opiates causes miotic pupils, euphoria, altered level of consciousness, constipation, and respiratory depression. Treatment of opiate overdose involves providing respiratory support and administering naloxone, a pure opiate antagonist. Naloxone is typically administered IV but may also be administered subcutaneously, intramuscularly, via endotracheal tube, or intranasally until IV access is established (Barton et al., 2005). The initial dose is typically 0.4 to 0.8 mg, with a 2-minute onset of action when given IV. Doses are repeated and escalated as needed to reverse the overdose. After reversal, patients need to be monitored for 1 to 3 hours for repeated dosing and sometimes longer if longer-acting opiates such as methadone have been used in the overdose. Naloxone treatment can initiate a rapid and intense withdrawal syndrome (Ries et al., 2009).

Opiate withdrawal is rarely fatal but is extremely uncomfortable and typically is accompanied by strong cravings. Withdrawal signs and symptoms include vomiting, diarrhea, body aches, rhinorrhea, thermoregulation, insomnia, anxiety, dysphoria, gooseflesh, yawning, and pupil dilation. Treatment can be symptomatic, as with the α_2 -adrenergic agonist clonidine, or can involve receptor agonist or antagonist activity. Methadone can be used with short- or long-taper protocols. Buprenorphine, a partial opiate agonist, can similarly be used. The antagonist naltrexone in combination with clonidine has been used effectively in both inpatient and outpatient settings (Ries et al., 2009).

SEDATIVE–HYPNOTICS (INCLUDING BENZODIAZEPINES)

Intoxication with the sedative–hypnotic drug class causes slurred speech, ataxia, respiratory depression, stupor, coma, and death (mostly with mixed overdose). Treatment of overdose involves providing respiratory support and gastrointestinal (GI) tract evacuation. Activated charcoal is particularly helpful for barbiturate overdose, as is urine alkalization for phenobarbital overdose. Flumazenil, a benzodiazepine receptor antagonist, can be used in benzodiazepine overdose but with caution because it can dramatically increase the risk of seizures and cardiac arrhythmias, especially in mixed overdoses and in patients physiologically dependent on benzodiazepines (Ries et al., 2009).

Withdrawal signs and symptoms from sedative–hypnotics include tachycardia, hypertension, fever, agitation, anxiety, hallucinations, insomnia, irritability, nightmares, sensory disturbances, tremor, tinnitus, anorexia, diarrhea, nausea, seizures, delirium, and death. Most sedative–hypnotic withdrawal is managed by either simple, slow, fixed-dose taper or substitution and taper. A *simple taper* involves decreasing the dose by no more than 10% every 1 to 2 weeks until the starting dose has been 75% decreased and then by 5% every 2 to 4 weeks for the last 25% until the taper is completed. *Substitution and taper* involves substituting a long-acting benzodiazepine (e.g., clonazepam) or phenobarbital for a shorter-acting drug and tapering as above. Conversion tables are available to calculate an approximate equivalent dose, and the dose is titrated over several days to a week to achieve good relief of withdrawal symptoms before tapering is begun of the substitute, as with the simple taper

method. Other adjunctive medications that have shown positive effects include carbamazepine, sodium valproate, propranolol, and trazodone. Because many patients dependent on benzodiazepines in particular have underlying anxiety and other psychiatric comorbidities and because withdrawal protocols are typically prolonged, anticipation and treatment of reemergence of these symptoms must be anticipated, or relapse is more likely (Ries et al., 2009).

OTHER DRUGS

eTable 50-2 online lists the signs and symptoms of intoxication and withdrawal of other drugs. There are no specific antidotes or reversal agents for the remaining drug classes. Care of overdose patients is largely supportive and aimed at treating the medical effects of the particular overdose, such as treatment of myocardial ischemia resulting from cocaine overdose. Currently, no FDA-approved medications are available for stimulant (including cocaine and methamphetamine), marijuana, hallucinogen (e.g., LSD, PCP), or club drug (e.g., MDMA) withdrawal. Behavioral therapies are the mainstay of treatment.

KEY TREATMENT

- Naloxone at 0.4 to 0.8 mg initial dose and repeated as needed is effective for opiate-intoxicated patients with inadequate spontaneous ventilation (Ries et al., 2009) (SOR: A).
- Sedative–hypnotic withdrawal is managed by simple taper or substitution to phenobarbital or longer-acting benzodiazepine and taper (SOR: C).

MEDICAL MANAGEMENT (BEYOND WITHDRAWAL)

Medical management of SUD after the acute withdrawal period for opiate dependence has a relatively long history, with various opioids being tried as maintenance therapies from the late 1800s until passage of the Harrison Act of 1914, which effectively outlawed prescribing opiates for treating addiction for nearly half a century. Currently, three pharmacologic interventions predominate: methadone, buprenorphine, and naltrexone. Of these three therapies, methadone is the most studied and the standard of care for patients with chronic relapsing opiate dependence. However, methadone is also the most stigmatized and has many regulatory barriers to access.

Naltrexone works as a competitive opiate receptor antagonist to block the effects of opiate agonists. It has been shown to be most useful in patients with a strong external motivator for treatment adherence, such as professionals with ongoing licensing board monitoring. In more generalized patient populations, retention in treatment with naltrexone is only 20% to 30% at 6 months. The usual dose of naltrexone is 50 mg/day or 350 mg weekly divided into three doses (100, 100, and 150 mg). A reduced starting dose of 25 mg on day 1 is used to minimize GI side effects such as nausea and vomiting, which occur in 10% of patients. Liver enzymes are monitored because liver toxicity is a rare but more serious side effect, shown to resolve after stopping

eTable 50-2 Signs and Symptoms of Intoxication and Withdrawal for Other Drugs

Drug	Intoxication	Withdrawal
Stimulants, including cocaine	Pupil dilation, headache, hyperventilation, dyspnea, cough, chest pain, wheezing, hemoptysis, bronchospasm, pulmonary edema, psychosis, tremor, hyperreflexia, tics, myoclonus, seizures, cerebral hemorrhage or infarct, cerebral edema, nausea, vomiting, bowel infarction or perforation, diuresis, myoglobinuria, acute renal failure, fever, malignant hyperthermia, rhabdomyolysis	Depression, anxiety, fatigue, anhedonia, increased appetite, hypersomnolence, increased dreaming, increased drug craving
Marijuana	Pupil constriction, conjunctival injection, headache, tachypnea, tachycardia, orthostatic hypotension, tremor, ataxia, increased appetite, urinary retention	Irritability, insomnia, anxiety, depression, restlessness, anorexia, vivid dreams, chills, nausea, diaphoresis
PCP	Horizontal nystagmus, increased tear and saliva production, lost corneal reflex, eyes open coma, pupil dilation, absent laryngeal/pharyngeal reflexes, diaphoresis, flushing, apnea, pulmonary edema, tachypnea, tachycardia, hypertension, high output cardiac failure, stupor, hyperreflexia, nausea, vomiting, acute renal failure, malignant hyperthermia, rhabdomyolysis	Depression, anxiety, irritability, hypersomnolence, diaphoresis, tremor, dysphoria, craving
MDMA	Bruxism, headache, dry mouth, diaphoresis, flushing, tachycardia, hypertension, tremor, increased muscle tone, nausea, anorexia, acute renal failure, malignant hyperthermia, rhabdomyolysis	Depression, anxiety, fatigue, difficulty concentrating, muscle pain
LSD	Pupil dilation, piloerection, diaphoresis, hypertension, tachycardia, hyperreflexia, tremors, seizures, nausea, vomiting, urinary retention, thermodyregulation	Fatigue, irritability, anhedonia

LSD, Lysergic acid diethylamide; PCP, phencyclidine; MDMA, 3,4-methylenedioxymethamphetamine.

naltrexone (Reis et al., 2009). A monthly depot injectable form of naltrexone was approved by the FDA for treating opiate-dependent patients in 2010. Studies of longer-acting naltrexone implants are ongoing for FDA approval.

Methadone is a long-acting opiate receptor agonist with strong affinity for its receptor and can be dosed once daily for most opiate-dependent patients. Currently, methadone may be used for treating opiate dependence in hospitalized patients (i.e., for withdrawal) or in licensed methadone treatment facilities. Take-home doses are regulated and depend on length of time in treatment and treatment response, including good attendance, adherence to program rules, lack of diverting behaviors, and abstinence, as verified by drug test results. Generally one take-home dose a week is allowed from the outset (many programs are closed on Sundays). Progression to increased take-home doses is determined by state and federal regulations, with the more restrictive statute taking precedent. For family physicians with patients in methadone maintenance, knowing a patient's take-home schedule can provide insight into how well they are doing in treatment. Recent increases in overdose deaths involving methadone have been explored and are more likely caused by an increase in misuse or diversion of methadone prescribed to treat chronic pain and less likely from an increase in opiate agonist treatment facility diversion (Center for Substance Abuse Treatment, 2004).

Buprenorphine is a partial opiate agonist that causes a 50% activation of the opiate receptors. This is typically enough to alleviate withdrawal symptoms and prolonged abstinence symptoms but not enough to induce euphoria for patients with opiate dependence. It binds more tightly than any of the opiate agonists and has a long half-life, making it a good candidate for blockade therapy. Buprenorphine is given as a sublingual tablet or film, most often compounded with naloxone (Suboxone), to discourage IV use because the naloxone, a potent opiate antagonist, has little effect unless injected. Buprenorphine comes in 2-mg, 4-mg, 8-mg, and 12-mg strengths. Unlike methadone, the Drug Abuse Treatment Act of 2000 allows physicians to prescribe buprenorphine outside a methadone treatment facility, with the goal of bringing the treatment of opiate dependence into primary care, greatly expanding treatment availability. To prescribe buprenorphine for opiate dependence, a physician needs to take an 8-hour course, now available online, and submit his or her application for an additional "X" number from the [U.S. Drug Enforcement Administration \(DEA\)](#). Physicians also need to have a way to refer or provide behavioral health-based addiction treatment for their patients. The number of patients proscribed by statute to 30 the first year and up to 100 patients at any given time past the first year if an additional waiver is submitted. Typical doses of buprenorphine range from 8 to 16 mg/day.

Many pharmacologic interventions have been studied for stimulant dependence, but to date, none have been FDA approved. Several anticonvulsants, baclofen, disulfiram, and antidepressants have shown promise in select patient populations, have shown little effect, or are still in clinical trials. Topiramate has recently been shown to decrease cocaine use compared with placebo, but FDA approval for this indication is still pending (Bankole et al., 2013). Research in treating stimulant dependence also includes

maintenance therapy, with sustained-released preparations of slow-onset stimulants such as modafinil (Ries et al., 2009). Vaccine therapy is also currently being studied and involves stimulating the patient's immune system to produce antibodies; for example, when bound to cocaine, antibodies prevent the drug from crossing the blood-brain barrier (Martell et al., 2009).

There is even less evidence for use of medications in the long-term management of other substances of abuse, such as hallucinogens, marijuana, and club drugs. Currently, behavioral therapies are the mainstay of treatment (Ries et al., 2009).

KEY TREATMENT

- Methadone maintenance is the most studied and effective medical treatment for opiate dependence ([National Consensus, 1998](#)) (SOR: A).
- Buprenorphine maintenance therapy, an alternative to methadone for treating opiate dependence, can be prescribed by appropriately trained and certified primary care physicians but is somewhat less effective than methadone prescribed at adequate doses ([Mattick et al., 2008](#)) (SOR: A).
- Oral naltrexone is typically reserved for use in patients with strong external motivators for treatment adherence, such as licensed professionals, because treatment retention is otherwise poor, and relapse is common ([Minozzi et al., 2006](#)) (SOR: B).

Behavioral Therapies for Substance Use Disorders

Behavioral therapies are a mainstay of SUD treatment. Common modalities include cognitive-behavioral therapy, contingency management, motivational enhancement therapy (MET), "therapeutic communities," and 12-step facilitation. Except for MET, these have not been adapted for use by family medicine physicians in routine office practice but are usually available as community-based referrals.

COGNITIVE-BEHAVIORAL THERAPY

Cognitive-behavioral therapy (CBT) is based on the assumption that the learning processes used by patients to initiate and continue their drug use behaviors can also be used to reduce or stop their drug use. CBT has been extensively studied, especially with cocaine users, and has shown good results. CBT is primarily used in the outpatient setting, usually with weekly individual sessions over several months. Sessions focus on patients learning to recognize the situations in which they are most likely to use drugs, learning to avoid those situations, and learning to cope with their problems without resorting to drug use. These lessons are accomplished through functional analysis and skills training. In functional analysis, each episode of drug use is analyzed in terms of what the patient was feeling, thinking, or doing before and after the use. This helps identify high-risk situations and coping issues. Skills training involves working

on ways to avoid these situations and learn new (or reconnect with past) coping mechanisms for handling high-risk situations and other life stressors without using drugs (Carroll, 1998).

CONTINGENCY MANAGEMENT

Contingency management (CM) is based on operant conditioning and involves a structured and consistently administered system of consequences that are used to reinforce behaviors consistent with treatment goals. Basic principles include close temporal proximity of consequence to targeted behavior, performance of targeted behavior easy to verify and verified often, positive consequence given and escalated for continuous positive behavior change, and positive consequence removed when targeted behavior is not performed. CM has been shown to be more effective when a single targeted behavior is addressed at a time and when resumption of continuous positive change is reinforced after a brief slip. Barriers include funding sources to cover the cost of rewards and determining appropriate length of treatment for this method. Advantages of CM include the breadth of behavioral changes that can be targeted and its demonstrated success in patients with severe and complex SUDs (Petry et al., 2001).

MOTIVATIONAL ENHANCEMENT THERAPY

Motivational enhancement therapy engages patients in increasing their internal motivations for making healthy changes in their drug use and building on a patient's strengths and resources in making prior behavioral changes. Goals are set by the patient, although the counselor may advise specific goals when appropriate. This approach is nonconfrontational. The counselor elicits change talk—that is, positive statements about making a change—from the patient in a way that highlights discrepancies between the patient's life goals or beliefs and current drug use behaviors (Miller and Rollnick, 2013). Awareness of these discrepancies increases the patient's internal desire for change or discomfort with the status quo. A patient's stage of readiness to change, whether precontemplative, contemplative, preparation, action, maintenance, or relapse, may also be used to guide the session. In addition, assessment of a patient's self-efficacy for change can facilitate the patient discussing prior successful behavioral changes, and any optimism for change is reflected and highlighted (Prochaska et al., 1992). MET has been used in both inpatient and outpatient settings, from one session (brief intervention) to several months of weekly sessions.

THERAPEUTIC COMMUNITIES

Therapeutic communities (TCs) are traditionally residential facilities in which the community structure and function are agents of change, and 12-step–based self-help programs guide individual recovery. Average lengths of stay are about 12 months (6–24 months). Community members progress through varying roles and responsibilities in their recovery and collectively ensure day-to-day functioning of the community. Days are highly structured and involve group and individual sessions, as well as time for community and

personal chores and self-development, such as exercise, vocational time, and educational time. TCs have been successfully adapted to serve special needs populations, such as adolescents, patients with concomitant mental health disorders, patients with HIV infection, and women with children. Successful completion of a TC program has been shown to lead to a significant decrease in SUD behaviors. Day treatment or nonresidential TCs are also available and may be more cost effective for patients with less severe social problems to address (National Institute on Drug Abuse, 2002).

TWELVE-STEP FACILITATION

Twelve-step facilitation (TSF) is a modality that seeks to increase the SUD patient's attendance and active involvement in 12-step self-help groups such as Cocaine Anonymous (CA) and Narcotics Anonymous (NA). TSF is used in residential treatment programs as well as outpatient settings. Sessions are highly structured, often workbook guided, and cast the counselor in the role of facilitator of change, with patient involvement the true agent of change. The underlying 12-step principles are the same: the patient's lack of control must be accepted, willpower is insufficient to stop use, and abstinence is desired. Research has shown that the more 12-step self-help group involvement, both in terms of number of meetings attended and, more robustly, the degree of active participation, the greater the success of achieving abstinence and recovery (McIntosh, 2009a).

Formal TSF counseling is outside the scope of most family medicine practices. However, physicians making a 12-step self-help group referral can increase the likelihood the patient will engage by (1) contracting with the patient to attend a certain number of meetings weekly, (2) having the patient call the local CA or NA hotline during the visit to set up his or her first meeting, and (3) encouraging attendance at several different meetings to ensure a “good fit.” Checking in with patients previously referred or in long-term recovery on meeting attendance and 12-step involvement, such as sponsorship and step work, is supportive of recovery and easily integrated into the primary care visit.

KEY TREATMENT

- CBT and CM decrease cocaine use and increase treatment retention (Knapp et al., 2007) (SOR: B).
- Twelve-step involvement positively correlates with achieving abstinence and recovery (McIntosh, 2009b) (SOR: C).

PRIMARY CARE OF PATIENTS WITH SUBSTANCE USE DISORDERS

The primary care of SUD patients must take into account the systemic effects of the drug(s) ingested, route of administration, methods of drug procurement, illicit drug–prescription drug interactions, and typically higher rates of nonadherence to follow-up and prescribed regimens (Ries et al., 2009). Infectious diseases (e.g., HIV, hepatitis B and C, tuberculosis) and sexually transmitted infections (e.g.,

gonorrhoea, Chlamydia, herpes, syphilis, human papillomavirus) are more common in SUD patients than in the general population, and patients should be screened routinely. Other infections common in IV drug users include skin abscesses, cellulitis, infectious endocarditis, and pneumonia.

Cocaine and other stimulants can cause myocardial infarction and stroke, raise blood pressure, and make essential hypertension resistant to treatment. Crack cocaine use, inhaled methamphetamines, and marijuana can lead to lung injury, chronic obstructive pulmonary disease, fibrosis, and pulmonary hypertension. Seizures can stem from stimulant use, benzodiazepine withdrawal, and “ecstasy” and other “club drug” intoxication (Ries et al., 2009).

Treatment for asthma, hypertension, chronic pain, and diabetes is complicated by the concomitant SUD. Patient adherence to treatment regimens is often compromised by the SUD, with “getting high” and minimizing withdrawal symptoms becoming the focus of their activities. Regular and nutritious meals may be difficult to access or may not be a priority for SUD patients, along with hygienic activities. Sleep disorders are common and can exacerbate health problems and their management. SUD patients’ ability to store their medications safely and securely can be compromised by homelessness, diversion, and an unsafe living environment.

Ongoing SUDs can mask symptoms, leading to late presentation of diseases such as cancer. This masking often is compounded by lack of access or use of primary care and preventive services by SUD patients.

Special Populations

ADOLESCENTS

In 2012, approximately 9.5% of youths age 12 to 17 years were current users of illicit drugs. This continued a trend of decreased illicit substance use among adolescents. Compared with 2002 data, the prevalence of illicit drug use had decreased for several drugs, including marijuana (8.2%-7.2%) and nonmedical use of prescription drugs (4.0%-2.8%). Concern about performance-enhancing agents and steroid use among high school and junior high school students has led to surveillance of steroid use among teenagers since 1989. Compared with previous years, the overall use of anabolic steroids has decreased. Although predominantly found among young men, the proportion of anabolic steroid use attributable to young women has increased.

Most youths reported that drugs are readily available. For example, approximately 47.8% of teenagers 12 to 17 years old reported that it would be “fairly easy” to obtain marijuana, 16.0% reported they could obtain cocaine, and 11.5% reported that they could obtain LSD. In 2012, 13.2% of adolescents reported that they had been approached by someone selling drugs within the past month.

Because peer pressure is a significant factor for adolescents, their perceptions of risk associated with substance abuse and peer disapproval have also been surveyed. A majority of teenagers have strongly disapproved or somewhat disapproved of illicit drug use by their peers. However,

the perceived risk of using marijuana, cocaine, hallucinogens, and other drugs has been lower in recent years. Teenagers may possess less knowledge about adverse drug effects than their predecessors and may display some “generational forgetting” (Johnston et al., 2008).

RACIAL AND ETHNIC MINORITIES

In 2012, the rate of current illicit drug use varied significantly among people of seven different major racial categories. Current drug use was highest among people who reported having two or more races (14.8%). An estimated 12.7% of American Indians or Alaska Natives, 11.3% of blacks, 9.2% of whites, 8.3% of Hispanics, 7.8% of Native Hawaiians or other Pacific Islanders, and 3.7% of Asians were current illicit drug users in 2012.

PREGNANT WOMEN

Approximately 5.9% of pregnant women age 15 to 44 years were current users of illicit substances in 2012. Compared with nonpregnant women, the rate of drug use is significantly lower for all age groups. Use of cocaine, heroin, methamphetamines, marijuana, MDMA, inhalants, and nicotine during pregnancy has been associated with adverse outcomes such as intrauterine growth retardation, delayed cognitive development, and difficulty with attention and learning. Effects vary by substance ingested, quantity and frequency of ingested drug or drugs, and stage of fetal development when ingestion occurs. Currently, methadone maintenance is the treatment of choice for opiate dependence during pregnancy, although buprenorphine has been used when methadone is not available. Newborns are monitored for signs of withdrawal and treated if symptoms are noted.

MENTAL HEALTH AND SUBSTANCE ABUSE

The prevalence of illicit substance abuse or dependence among patients with serious mental illness was 31.3% in 2011. Similarly, adults age 18 years and older with an episode of major depression within the past year had higher rates of illicit drug use than adults without a major depressive episode (28.5% vs. 13.4%). Having a major depressive episode within the past year was also associated with higher prevalence of dependence on illicit drugs.

Smarter search. Faster answers.

Smarter, Faster Search for Better Patient Care

Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:

1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

Start searching with ClinicalKey today!

Visit ClinicalKey.com for more information and subscription options.
